Program Nr: 310 from the 1999 ASHG Annual Meeting

Evidence for a paternal effect on chromosome 7 in autistic disorder. *A. Ashley-Koch[1], C.M. Wolpert[1], M.M. Menold[1], L. Zaeem[1], S. Basu[1], S.L. Donnelly[1], S.A. Ravan[2], C.M. Powell[3], M.B. Qumsiyeh[1], A.S. Alysworth[3], J.M. Vance[1], J.G. Gilbert[1], H.H. Wright[2], R.K. Abramson[2], G.R. DeLong[1], M.L. Cuccaro[2], M.A. Pericak-Vance[1].* 1) Dept of Medicine, Duke Univ Med Ctr, Durham, NC; 2) W.S. Hall Psychiatric Inst, Univ of South Carolina, Columbia, SC; 3) Dept of Pediatrics, Univ of North Carolina, Chapel Hill, NC.

Autistic Disorder (AD) is a complex neuro-developmental genetic disorder with an estimated 2-10 loci underlying its genetic etiology. Several genome screens have been performed and have suggested at least one putative AD locus is located on 7q. We have previously reported a multiplex AD family in which three siblings and their mother are segregating a paracentric inversion on 7q (inv(7)(q22q31.2)). The two male siblings have AD; the female sibling exhibits expressive language disorder; the mother does not have AD. Haplotype data on the family suggests the inversion was inherited from the maternal grandfather. Based on these cummulative suggestive data, we performed a comprehensive analysis of our AD data set by genotyping 76 families for markers spanning a 30 cM region (D7S2527-D7S530-D7S640-D7S495-D7S684-D7S1824). Two-point analysis yielded a maximum parametric lod score of 1.12 at D7S1824, maximum heterogeneity lod score of 2.10 at D7S495, and maximum MLS of 0.97 at D7S2527 and D7S640. Multi-point MLS and NPL analysis resulted in peak scores of 1.55 at D7S2527 and 2.15 at D7S640, respectively. This linkage region overlaps the distal inversion breakpoint in our multiplex family. Examination of affected sibpairs revealed significant paternal (p=0.007), but not maternal IBD sharing (p=0.64) at D7S640. Using multiplex and singleton families, significant linkage disequilibrium was detected with paternal (p=0.02), but not maternal transmissions (p=0.15) at D7S1824. We also observed increased recombination in the region (D7S2527 to D7S1824) among AD families compared with non-AD families (p=0.01, sex-averaged and p<0.0001, sex-specific), suggesting this region exhibits increased instability in AD families. In summary, these results provide further evidence for the presence of a 7q AD locus, and suggest this locus may be paternally expressed.

Program Nr: 311 from the 1999 ASHG Annual Meeting

Evaluation of linkage disequilibrium between SNPs in a large outbred population. *S.H. Shaw[1], D.C. Hutchison[1], R. Saiz[1], L.E. Delisi[2], R. Sherrington[1]*. 1) Axys Pharmaceuticals, La Jolla, CA; 2) Department of Psychiatry, SUNY-Stony Brook, NY.

We have evaluated the extent of linkage disequilibrium in a large, outbred population by measuring linkage disequilibrium between marker alleles in a series of high density single nucleotide polymorphisms (SNPs) in an approximate 1Mb region of human chromosome 22q11. Nineteen SNPs were tested across this region with an average spacing of 57 kb (range=1.4-289 kb). These 19 SNPs were genotyped in a population consisting of 453 unrelated pedigrees that were largely collected in the U.S. and U.K. Haplotypes for all pedigrees were constructed using Genehunter and approximately 1400 unambiguous haplotypes from unrelated individuals in this population were evaluated for linkage disequilibrium between marker alleles. Every marker pair combination was tested (171 tests) and 2X2 contingency tables were constructed. Chi-square and corresponding p-values were computed for each pairwise test. In addition, several measures of linkage disequilibrium were calculated and compared to see how well they predicted distance. When comparing distance versus linkage disequilibrium (as measured by p-value), 14/16 (88%) of marker pairs less than 50 kb apart had p-values $< 5X10^{-8}$ (genome-wide significance for association studies), and all 16 marker pairs had p-values < 0.05. 9/18 (50%) of the marker pairs in the 50-100 kb range and 4/7 (57%) of the marker pairs in the 101-150 kb range also had p-values $< 5X10^{-8}$. It was noted that linkage disequilibrium was less robust between marker pairs with relatively large differences in allele frequencies. In addition, a region with no detectable linkage disequilibrium was observed between 2 SNPs (g04 and g05) which are only 60 kb apart. Interestingly, no SNP on either side of g04 and g05 were in linkage disequilibrium with markers across this interval, therefore creating a gap of detectable linkage disequilibrium in this region of chromosome 22. This finding most likely indicates a region of increased recombination located between these 2 markers. This data supports the use of high density SNP maps for disease linkage disequilibrium studies in outbred populations.

Program Nr: 312 from the 1999 ASHG Annual Meeting

Fast multipoint linkage calculation with Allegro. *D.F. Gudbjartsson[1,2], K. Jonasson[1], C.A. Kong[1,3].* 1) Decode Genetics Inc., Reykjavik, Iceland; 2) Institute of Statistics and Decision Sciences, Duke University, Durham, NC; 3) Department of Human Genetics, University of Chicago, Chicago, IL.

A new method for multipoint linkage calculation has been developed. The method achieves considerable speedup over previous methods, and allows larger families to be analysed. The method has been turned into a computer program, Allegro. Allegro has the same basic functionality as the well known Genehunter program, includes the features of Genehunter plus, and contains many improvements. Among the supported features are parametric and nonparametric LOD scores, nonparametric NPL scores, information, exact p-values, expected crossover rate, haplotyping and simulation. The program is simple to use and accepts the same data file format as Genehunter. It has been used extensively at Decode Genetics and typical speedup compared to Genehunter is 30-fold. On a computer with one Gb of memory the program can handle pedigrees with upto about 25 bits (for instance a family with 20 descendants and 15 founders), the corresponding maximum for Genehunter being about 20 bits.

Calculation of LOD scores involves three steps. Firstly, the determination of single point probabilities of individual inheritance vectors, secondly multipoint calculation, where the proximity of markers on the chromosome is taken into account, and thirdly the score calculation (which for parametric LOD scores involves peeling). The bulk of the calculation of Genehunter involves steps 1 and 3 and it is here that the improvements are largest. The key idea is to make use of tree traversal to avoid repeated calculation for similar inheritance vectors. This idea is utilized in the single point calculations, in the peeling, and in the calculation of nonparametric score statistics (for instance pairs score). Thus the time required for a typical Allegro run is governed by step 2, but even here there is significant speed-up. Genehunter employs so-called founder reduction to shorten inheritance vectors and speed calculation. Further bit reduction, founder couple reduction, has been developed in the new method, thereby gaining more speed.

Program Nr: 313 from the 1999 ASHG Annual Meeting

Lod score approach to direct identical-by-descent mapping based on genomic mismatch scanning. *R.S. Spielman*[1], *V.G. Cheung*[2], *W.J. Ewens*[3]. 1) Dept Genetics, Univ of Pennsylvania School of Medicine, Philadelphia, PA. 19104-6145; 2) Dept Pediatrics,Univ Pennsylvania School of Medicine, Philadelphia, PA; 3) Dept Biology, Univ Pennsylvania, Philadelphia, PA.

Direct identical-by-descent (IBD) mapping is a form of genetic analysis that combines two procedures: genomic mismatch scanning (GMS) to enrich for regions that are identical by descent (IBD) between two subjects affected with the same disease, and mapping on microarrays. A region that contains a disease-predisposing gene inherited from a common ancestor of some or all of the affected individuals is expected to show IBD that is increased over background IBD in subject pairs. We describe a method of statistical analysis to assess the strength of the evidence for increased IBD at each site tested in an ordered array representing positions along the chromosome(s).

In this analysis, we calculate a likelihood ratio for the data at each point in the microarray, representing sites along the chromosome. For each subject pair, the numerator is the likelihood of the observation (IBD or not) at that site, assuming that the probability of IBD is the observed proportion of IBD in the sample at that site. The denominator for each subject pair is the likelihood of the same observation, but given that the probability of IBD at the site is the proportion of IBD observed in that pair, over all sites tested. (This denominator corresponds to the background level of IBD.) We take the logarithm of the ratio and sum over all subject pairs to give a kind of lod score. In our examples, we illustrate the analysis with data from one chromosome, but the analysis can easily be extended to the entire genome.

The method is illustrated by re-analysis of the data of Cheung et al (Nat Genet 18:225, 1998) and with data for an artificial example of direct IBD mapping.

Program Nr: 314 from the 1999 ASHG Annual Meeting

Predictors of survival in neurofibromatosis 2. *M.E. Baser[1], J.M. Friedman[2], D.G.R. Evans[3].* 1) Los Angeles, USA; 2) Department of Medical Genetics, University of British Columbia, Vancouver, CAN; 3) Department of Medical Genetics, St. Mary's Hospital, Manchester, UK.

Preliminary data indicate that neurofibromatosis 2 (NF2) patients with severe phenotypes have increased mortality, but the natural history of the disease is poorly characterized. In cross-sectional studies, germ-line *NF2* mutation type is associated with age at onset of symptoms and number of intracranial meningiomas. We used the Cox proportional hazards model to assess clinical and molecular predictors of survival in the United Kingdom NF2 patients series (336 patients, 78 deceased, from 214 families). The patients were aged 4-86 yrs (median, 34 yrs), were diagnosed from 1945-1998 (median, 1990), and were followed for a median of 9 yrs after onset of symptoms. Of 144 patients from 77 families with identified germ-line *NF2* mutations, 71 had frameshift or nonsense mutations, 27 had splice-site mutations, 22 had missense mutations, 22 had large deletions, and 2 had in-frame deletions. The clinical variables considered were presence of vestibular schwannomas (VSs), non-VS cranial nerve tumors, spinal tumors, peripheral nerve tumors, lens opacities, and various symptoms associated with CNS tumors; number of intracranial meningiomas; ages at onset of symptoms and at diagnosis; calendar year of diagnosis; and proband status. Four clinical variables were independent predictors of survival. The relative risk of death decreased 3.61-fold per decade increase in age at diagnosis ($p < .001$) and 1.79-fold per decade increase in calendar year of diagnosis ($p < .001$); increased 1.76-fold per intracranial meningioma ($p = .002$); and was 2.23-fold higher in probands ($p = .007$). There was a possible interaction between age at diagnosis and number of meningiomas ($p = .055$). Germ-line *NF2* mutation type did not predict survival in these data. These results indicate that readily-characterized clinical variables are associated with survival in NF2.

Program Nr: 315 from the 1999 ASHG Annual Meeting

Lifetime breast cancer risk associated with BRCA 1 and BRCA 2 mutations among patients of Ashkenazi Jewish origin. *C.B Begg[1], J.M Satagopan[1], M. Robson[2], K. Offit[2].* 1) Epidemiology and Biostatistics, Mem Sloan-Kettering Canc Ctr, New York, NY; 2) Clinical Genetics Service, Mem Sloan-Kettering Canc Ctr, New York, NY 10021.

BACKGROUND: A very high lifetime penetrance for breast cancer in carriers of BRCA 1 and BRCA 2 mutations is provided by several family-based studies. These studies evaluate multiple affected family members. Penetrance estimate can also be obtained directly by using a consecutive series of incident breast cancer cases seen in one large hospital, or from several institutions. A large population-based control series can be used to provide age-specific prevalence of the mutation, relative risk estimates, and the lifetime penetrance. METHODS: We evaluated 298 women self-identified as being Jewish who were treated for early stage breast cancer at Memorial Sloan-Kettering Cancer Center between 1980 and 1990. Fodor et. al. (1998) published cancer risk in a similar hospital based case-selection of 268 breast cancer patients treated between 1986 and 1995 at Mount Sinai Medical Center, New York. These data were combined to give an aggregated case series of 566 patients. Control data were obtained from a large population series of 3440 Jewish women from the Washington D.C area evaluated by Struewing et. al. (1997). Cases and controls were genotyped for the following founder mutations: 185delAG, 5382insC, and 617delT. RESULTS: We estimated the relative risk of breast cancer to be 10.8 in women under age 40, 5.5 for women in the age group 40-49, and 4.4 in women above age 50. Mutation prevalence are reported in Struewing et. al. (1997). Assuming that the population incidence of breast cancer in Jewish women are similar to the population rates in American women (as in the SEER database), and based on the above age-specific relative risk estimates and the published prevalence estimates, the penetrance of breast cancer at age 70 among founder mutation carriers is 29%. CONCLUSION: The lifetime risk of breast cancer among mutation carriers derived using a population-based approach as above is substantially lower than the risk reported by high-risk family studies.

Program Nr: 316 from the 1999 ASHG Annual Meeting

Tissue microarray FISH and digital imaging: Towards automated analysis of thousands of tumors with thousands of probes. *L. Bubendorf[1], J. Kononen[1], M. Barlund[1], A. Kallioniemi[1], A. Grigorian[2], G. Sauter[3], E.R. Dougherty[2], O.P. Kallioniemi[1]*. 1) Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Texas A&M University; 3) University of Basel, Switzerland.

Using our recently developed tissue microarray technology (Kononen et al., Nat. Med. 4:844-7, 1998), up to 1000 tissue specimens can be analyzed by fluorescence in situ hybridization (FISH) in a single experiment. Furthermore, it is also possible to produce tens of thousands of replicate tissue microarray sections from the same clinical material, providing templates for either genome-scale search for genetic alterations, or focussed high-resolution surveys of specific chromosomal sites. As an example of the latter approach, we studied 17q23 amplicons in breast cancer by hybridizing BAC probes from a 3 Mb genomic contig on a breast cancer tissue microarray (n=668). Almost 5000 FISH results were generated, resulting in a rapid definition of the critical region of this novel amplification, present in 8.8% of primary breast cancers, with a significant association with poor prognosis (p=0.002). To further explore the potential of tissue microarray FISH and to develop automated image analysis, we applied a new confocal digital imaging system (CARV, Atto Instuments, Rockville, MD) to acquire images of the arrayed tissue specimens (X-Y scanning) at different focal planes (Z-axis scanning). Relative copy numbers of test vs. reference probes were calculated over a defined field of view in each specimen at different focal planes (along the Z-axis) with a new 3D spot counting algorithm. Taken together, tissue microarray FISH, and automated digital imaging will enable genome-scale analysis of genetic alterations in thousands of clinical specimens.

Program Nr: 317 from the 1999 ASHG Annual Meeting

Association of the I1307K APC mutation with hereditary and sporadic breast/ovarian cancer. *E. Dagan[1,2], R. Gershoni-Baruch[1,2], Y. Patael[3], R. Bruchim-Bar-Sade[3], E. Friedman[3].* 1) Human Genetics, Rambam Medical Ctr, Haifa, Israel; 2) Bruce Rappoport Faculty of Medicine, Technion-Institute of Technology, Haifa, Israel; 3) Susanne Levy Gertner Oncogenetics Unit, Chaim Sheba Medical Ctr, TLV, Israel.

Females with BRCA mutations have a 40-60% lifetime risk of developing breast and/or ovarian cancer. The incomplete penetrance of BRCA genes mutations, suggests that other factors determine the phenotypic expression of mutant BRCA alleles. In Ashkenazi Jews three predominant founder mutations in BRCA1/2 (185delAG, 5382insC and 6174delT) were described. Lately, it has been suggested that the I1307K APC polymorphism associated with increased colon cancer risk, occurs in 6-7% of the Ashkenazi population and may act as a low penetrance gene/modifier in sporadic or hereditary breast cancer. To test this notion, BRCA carriers with either breast and/or ovarian cancer (n=143); or are asymptomatic (n=53), were tested with respect to being co-carriers of the I1307K mutation. Similarly, the prevalence of I1307K mutation was determined in non BRCA carrier, Ashkenazi breast/ovarian cancer patients (n=382) and in ethnically matched healthy controls (n=418). Twenty three of the controls (5.5%) and 17 of sporadic breast/ovarian cancer patients (4.6%) carried the I1307K mutation (p=ns). Of 196 BRCA mutation carriers, 17 carried the I1307K mutation, a rate (8.7%) although higher, not significantly different than in controls. The APC mutation was equally prevalent in symptomatic BRCA carriers (10/143; 7%), sporadic breast/ovarian cancer patients (17/382; 4.6%) and asymptomatic BRCA carriers (7/53; 13.2%). The co-mutation carrier status is similar in women diagnosed with breast cancer before (4/55; 7.3%) and after (5/59; 8.5%) 42 years. The I1307K mutation was equally prevalent among patients with inherited (9/114; 7.9%) sporadic (16/357; 4.9%) breast cancer, and controls (23/418; 5.5%). Co-carriers of the Jewish mutations in BRCA and APC, are not at higher risk for breast/ovarian cancer. The notion that the I1307K polymorphism may act as a low penetrance gene/modifier or is rather associated with increased breast cancer risk is weakened.

Program Nr: 318 from the 1999 ASHG Annual Meeting

Mutations in sporadic tumors in the BRCA1-interacting protein CtIP and the evaluation of its association with the ubiquituous co-repressor CtBP in mammalian cells. *F. Du[1], B. Weber[2], R. Baer[3], A. Bowcock[1]*. 1) Div.Hum.Genet.,Dept.Genet., Washington Univ. Med. Ctr., St. Louis, MO; 2) Dept. Genet. and Med., Univ.Pennsylvania, Phila,PA; 3) Dept.Micro., UT SW Med Ctr., Dallas,TX.

The protein encoded by CtIP interacts in vivo with the BRCT domains of BRCA1.This interaction is abolished by tumor-associated mis-sense mutations in this region. CtIP was originally identified on the basis of its association with the CtBP transcriptional co-repressor. To further investigate the role of CtIP in sporadic and hereditary cancer, we first determined its genomic structure by direct sequencing of bacterial artificial chromosome DNA and determine that CtIP is encoded by 18 exons spanning ~ 100kb. We then used DHPLC to screen for genetic alternations in coding sequence in a panel of genomic DNAs/cDNAs from patients/tumors with sporadic breast/ovarian/uterine cancer. One endometrial adenocarcinoma harbored a serine deletion at codon 439, but also retained the wt allele. The BT474 cell line harbored a Glu(510)Gln alteration and one high risk breast cancer patient harbored an Asp(540)His change. CtIP also harbors a polymorphism (Arg589His). The His allele is seen in 2% Caucasians. In order to confirm the interaction between CtIP and CtBP in-vivo, we performed a mammalian two-hybrid assay. A Gal4p-responsive reporter (luciferase) gene was transfected into mammalian cells along with an expression plasmid encoding either full-length CtIP fused to the transactivation domain of VP16 or full-length CtBP fused to the DNA-binding domain of GAL4p. Although neither fusion protein activated the reporter construct on its own, we observed a significant increase in luciferase activity when cells were co-transfected with both expression plasmids. This confirms that CtIP interacts in-vivo with the ubiquituous co-repressor, CtBP. The interaction is mediated by the "PLDLS" motif within exon 10. Further mammalian two-hybrid assays indicate that exon 10 of CtIP alone is insufficient for efficient interaction between the two proteins. BRCA1 has recently been implicated in a variety of cellular processes including DNA repair, transcription and replication. The CtIP/CtBP complex may mediate some of these.

Program Nr: 319 from the 1999 ASHG Annual Meeting

Loss of function mutations in the gene encoding peroxisome proliferator-activated receptor gamma (PPARgamma) in colorectal carcinomas. *C. Eng[1], P. Sarraf[2], W.M. Smith[1], E. Mueller[2], J.B. Kum[1,2], H.M. Wright[2], L.A. Aaltonen[3], A. de la Chapelle[1], B.M. Spiegelman[2].* 1) Human Cancer Genetics Program, Ohio State Univ Comp Cancer Ctr, Columbus, OH; 2) Cancer Biology, Dana-Farber Cancer Inst, Boston, MA; 3) Medical Genetics, University of Helsinki, Helsinki, Finland.

The lifetime risk of developing colorectal carcinoma is approximately 5%, of which the majority are sporadic. Stepwise accumulation of somatic genetic alterations contributes to the development from normal colonic mucosa to adenomatous polyp with subsequent progression to dysplastic polyp and invasive carcinoma. Human colon cancers express PPARgamma, a member of the nuclear receptor superfamily involved in fat cell differentiation and glucose homeostasis. Ligand activation of this receptor causes most, but not all, colon cancer lines to undergo a differentiative response and to reverse the malignant phenotype. Paradoxically, however, ligand activation in min mice, the murine model of human familial adenomatous polyposis, caused increased polyposis. Since 1.6 million patients take the anti-diabetic drugs that function as PPARgamma ligands, determination of the role of this receptor in human colorectal tumor biology is critical. Among 55 sporadic colorectal carcinomas, 12 (22%) somatic mutations were found. Of the 35 cancers that were microsatellite stable (MSI-), 2 (6%) were found to have somatic mutations, Q286P and K319X, both within the ligand binding domain. Of the 20 MSI+ tumors, 10 (50%) carried somatic mutations, 472delA, R288H and IVS2+7-+15delA (N=8). The IVS2+7-+15delA mutation is of unclear significance. 472delA results in deletion of the entire ligand binding domain and hence, is presumed to be inactive. Q286P and K319X retain a total or partial ligand binding domain, but lose their ability to activate transcription through failure to bind to ligands. R288H showed a normal response to synthetic ligands but greatly decreased transcription and binding when exposed to natural ligands, Prostaglandin J2, 9(S)-HODE or 15(S)-HETE. These data in humans indicate that colon cancer in humans is associated with loss of function mutations in the gene encoding PPARgamma.

Program Nr: 320 from the 1999 ASHG Annual Meeting

Functional analyses of *PPP2R1B* mutations in small-cell lung carcinoma. *E.D. Esplin, J.L. Li, S.W. Long, P.M. Ramos, D. Stickens, S.D. Thomas, S.S. Wang, G.A. Evans.* McDermott Center, UT Southwestern Medical Center, Dallas, TX.

PP2A is a serine/threonine protein phosphatase involved in the control of cellular growth including down-regulation of the mitogen-activated protein kinase (MAPK) cascade. It plays a critical role in oncogenesis as a target for chemical tumor promoters, SV40 small t antigen, and the HOX11 oncogene. PP2A is composed of a catalytic C subunit, regulatory B subunit, and structural/regulatory A subunit. Several isoforms of each subunit exist, leading to a variety of structural forms of the PP2A holoenzyme. We recently identified mutations in the *PPP2R1B* gene, encoding the b isoform of the A subunit of PP2A, in lung tumors, colon tumors and lung tumor-derived cell lines. To characterize the affects of these mutations on protein function and tumorigenesis, we examined protein-protein interactions between the normal and mutated subunits of the holoenzyme. Both alleles of *PPP2R1B* in small-cell lung carcinoma (SCLC) cell line H1450 carry mutations in the C-terminus. Each of these mutations results in A subunits with decreased affinity for the C subunit. To test whether these mutations affect enzyme activity, we analyzed the total phosphatase activity of H1450 cell lysates using phosphorylated myelin basic protein. We found a decrease in total H1450 phosphatase activity, suggesting PP2A activity is decreased toward some substrates as a result of *PPP2R1B* mutations. Known substrates of PP2A include MAP/ERK kinase (MEK), a key component of the MAPK cell growth and differentiation pathway. We examined the phosphorylation state of MEK 1 and MEK 2 in cells carrying *PPP2R1B* mutations. Two of these cell lines showed the presence of hyperphosphorylated protein. These results suggest mutations in the *PPP2R1B* gene cripple the ability of PP2A to control cell growth through the MAPK cascade. To further assess the tumor suppressor activity of PP2A, we developed a model of lung tumorigenesis using nude mice and the SCLC cell line H1450. The expression of *PPP2R1B* by transfection into H1450 cells provides a useful assay for *in vivo* tumorigenesis mediated by mutations in *PPP2R1B.*

Program Nr: 321 from the 1999 ASHG Annual Meeting

Molecular genetic testing of a population based sample of women with breast cancer aged 30 years or less. *G. Evans[1], F. Lalloo[1], E. Redmond[1], C-L. Wu[1], B. Bulman[3], A. Moran[2], L. O'Dair[1], J. Varley[3], C. Mathew[4].* 1) University Department of Medical Genetics and Regional Genetics Service, St Mary's Hospital, Manchester, UK; 2) Department of Epidemiology, Christie NHS Trust, Manchester, UK; 3) Paterson Institute of Cancer Research, Christie NHS Trust, Manchester, UK; 4) Department of Molecular Genetics, Guys Hospital, London,UK.

Women diagnosed as having breast cancer at age 30 years or under on the Manchester Cancer Registry since 1980 have been contacted to obtain details of their family history and a blood sample. These have been obtained on 72 women and screening of the BRCA1 and BRCA2 genes have been undertaken. In addition families fulfilling criteria for Li Fraumeni Syndrome (LFS) or Li Fraumeni Like (LFL) have been analysed for mutations in TP53. Forty-four women had an isolated case of breast cancer without no first or second degree relative with breast or ovarian cancer under 60 and only one of these had a previously unreported missense mutation in BRCA1. Two women had an aggregation of tumours consistent with LFS and in one a mutation was identified in TP53. Of 2 further women fulfilling LFL criteria, one had a mutation in TP53. The TP53 negative woman also screened negative for mutations in BRCA1 and BRCA2. This left 24 women with a further history of breast or ovarian cancer in first or second degree relatives diagnosed under the age of 60. To date, 10 of these women have had a mutation identified in BRCA1 and one in BRCA2. TP53 testing of all women without mutations in BRCA1/2 will also be completed. These results show that breast cancer diagnosed at the age of 30 or younger in the context of a further family history is a strong predictor for the presence of inherited mutations in BRCA1, BRCA2, or TP53. Of the 12 families with mutations in BRCA1/2, there were 19 breast cancers (mean age 42) in first and second degree relatives and 7 ovarian cancers. The pattern of cancers in these families suggest that the mutations found are associated with a high lifetime risk of developing breast and/or ovarian cancer contrary to the reports of other population studies.

Program Nr: 322 from the 1999 ASHG Annual Meeting

Germline BRCA mutation is an adverse prognostic factor in Ashkenazi Jewish women with breast cancer: Survival disadvantage depends on nodal status. *W.D. Foulkes[1], N. Wong[1], J-S. Brunet[3], M. Trudel[1], A-J. Paradis[1], G. Kuperstein[3], P.O. Chappuis[1], L. Kapusta[2], J. Slingerland[2], S.A Narod[3], L.R Bégin[1].* 1) Depts Medicine, Pathology, Surgery and CPRU, Montreal General and Jewish General Hospitals, McGill University, Montreal, QC, Canada; 2) TSRCC, University of Toronto, Toronto, ON, Canada; 3) Women's College Hospital, Toronto, ON, Canada.

Germline mutations in BRCA genes account for >10% of breast cancer (BC)diagnosed under 65 yrs of age in Ashkenazi Jewish (AJ) women. The clinicopathologic features of these cancers are known but the prognosis remains uncertain. We used a historical cohort approach to answer this question. 204 AJ women diagnosed with invasive BC diagnosed <65 yrs 1986-1995 were studied. Pathology blocks were reviewed and immunohistochemical studies were undertaken. Follow-up was determined from chart review. DNA extracted from the blocks was analysed for the 3 common founder AJ mutations (185delAG, 5382insC and 6174delT). There were 32 BRCA mutation carriers (15.7%), 24 in BRCA1 and 8 in BRCA2. The median follow up was 76 months. At five years, there were 30 breast cancer deaths (14.7%) and 37 deaths from any cause. Tumor size (P=0.008), grade (<0.0001), ER (<0.0001) age (0.001), P53 status (0.018), HER2 status (0.056) and P27 status (0.009) were all associated in the expected ways with a worse prognosis. Women with BRCA mutations fared much worse: 5 year BC-specific mortality = 42.4% vs. 13.5% for non-carriers (P=0.0058). The difference in all-cause mortality was more striking: 38.9% vs. 15.7% (P=0.0006). BRCA1 and 2 did not differ in effect. In a univariate Cox model, the RR for dying of BC within 5 years of diagnosis in association with a BRCA mutation was 2.9 (1.3-6.3, P=0.008), but multivariately, BRCA status was not a significant factor (RR=1.2, P=0.66). However, removing grade (which is highly correlated with BRCA status) from the multivariate model resulted in a RR of 2.9, P=0.009. Importantly, studying node negative (NN=119) and node positive (NP=71) women separately, the multivariate RR was 2.5, P=0.15 for NN, BRCA+ women and 0.6, P=0.53 for NP, BRCA+ women; indicating that NN and NP women should be considered separately in survival analyses.

Program Nr: 323 from the 1999 ASHG Annual Meeting

Detection of heterozygote deletions within the hMLH1 gene using multiplex PCR of short fluorescent fragments.
T. Frebourg, F. Charbonnier. INSERM EPI 9906, Faculté de Médecine et de Pharmacie, IFRMP, Rouen, France.

Detection of heterozygote deletions involving one or several exons represents a technical problem in autosomal dominant disorders, limiting the efficiency of mutations screening, and requires Southern blot analysis which is DNA and time consuming. We and others have identified in the hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, large genomic Alu-mediated deletions within the hMLH1 gene. To facilitate the detection of such heterozygote deletions, we developed a simple semi-quantitative procedure based on the multiplex PCR of short fluorescent fragments. Short exonic fragments (92 to 296 pb) of the 19 hMLH1 exons, were PCR-amplified from genomic DNA using dye labelled primers. Exons 1 to 10 and 11 to 19 were PCR-amplified in two separate tubes. PCR products were loaded on a 4.25% denaturing polyacrylamide gel,electrophoresis was performed for 3 h on an Applied Biosystems model 377 automated sequencer, and data were analyzed using the Gene scanner Model 672 Fluorescent Fragment Analyser (Applied Biosystems, Perkin-Elmer). The concentration of genomic DNA and of the primers, the annealing temperature, the number of cycles, were optimized in order to obtain a very reproducible pattern between each sample. Reduction of the fluorescent intensity of the corresponding peaks allowed us to detect easily a deletion of exon 2 and a deletion of exon 13 to 16 in two French HNPCC families. This simple procedure can be applied to genes which inactivation might be mediated by exonic deletions.

Program Nr: 324 from the 1999 ASHG Annual Meeting

The rate of the founder Jewish mutations in BRCA1 and BRCA2 in prostate cancer patients in Israel. *E. Friedman[1], A. Vazina[1,2], A. Shtriker[1,2], Y. Yaacobi[1,2], T. Tischler[2].* 1) Oncogenetics Unit, Inst Gen, Chaim Sheba Medical Ctr, Tel Hashomer, Israel; 2) Departments of Urology and Oncology, Rabin, Wolfson and Sheba Medical centers, Israel.

Inherited predisposition occurs in 5-10% of all prostate cancer (CaP) patients, but the genes involved in conferring genetic susceptibility remain largely unknown. Several lines of evidence indicate that germline mutations in BRCA1 and BRCA2 might be associated with an increased risk for CaP. Three mutations in these two genes (185delAG and 5382InsC (BRCA1) and 6174delT (BRCA2)) occur in about 2.5% in the general Ashkenazi population, and the 185delAG BRCA1 mutation, in up to 1% of non-Ashkenazi Jews. In order to assess the contribution of these germline mutations to prostate cancer in Jewish Israeli patients, we tested 174 unselected prostate cancer patients (95 of Ashkenazi origin) for these mutations by PCR amplification and modified restriction enzyme digests. Patients age range was 45-81 years (median 66), and in 24 (14.4%) the disease was diagnosed before 55 years of age. Nineteen (11%) and 12 (6.9%) patients had first or second degree relative with CaP or breast cancer, respectively. Overall, 5 mutation carriers were detected: 2/152 (1.3%) 185delAG, 2/104 (2%) 5382InsC, and 1/158 (0.6%) 6174delT. In all carriers, the disease was diagnosed after the age of 55, and only one of them had a family history of breast and CaP. In addition, no allelic losses at the BRCA1 locus were demonstrated in 17 patients with a family history of CaP, using 7 microsatellite markers. We conclude that the rate of the predominant Jewish BRCA1 and BRCA2 mutations in CaP patients does not significantly differ from that of the general population, and that mutational inactivation of the BRCA1 is rare in familial CaP. Thus, germline BRCA1 and BRCA2 mutations probably contribute little to CaP occurrence, to inherited predisposition, and to early onset disease in Jewish individuals.

Program Nr: 325 from the 1999 ASHG Annual Meeting

Retinoblastoma treatment in premature infants diagnosed prenatally by ultrasound and molecular analysis. *B.L. Gallie[1,2], J.A. Gardiner[1], A. Toi[2], E. Héon[1,2], H. Chan[1], J. Sutherland[1], L. MacKeen[1], J. Anderson[1], L. Han[1], A. Budning[1], M. Sermer[2]*. 1) Ophthal/Ped, Div Immunol CA, Hosp Sick Children, Toronto, ON, Canada; 2) University Health Network, University of Toronto, Toronto, Canada.

The long-term visual outcome of two infants with familial retinoblastoma (RB) has been improved by prenatal diagnosis and treatment of vision-threatening tumors before expected birth-dates. One infant was diagnosed by prenatal ultrasound and one by molecular identification of germline RB gene mutation. Both were prematurely delivered at 36 weeks gestation for prompt treatment of their macular tumors. The infant with a large macular tumor observed to grow rapidly over one week, and a smaller macular tumor in the other eye, was treated with chemotherapy and laser. She will have a central scotoma in the eye with the large macular tumor, and normal central vision in the eye with the smaller macular tumor. The other infant had a tiny paramacular tumor at birth, and subsequently developed five tiny tumors, all of which are treated successfully with laser. She will have normal central vision in both eyes. If allowed to deliver at term, both infants would have had much larger macular tumors with significant loss of central vision despite more intensive therapy.

Program Nr: 326 from the 1999 ASHG Annual Meeting

Association of the C677T polymorphism in the MTHFR gene with breast and/or ovarian cancer risk in Jewish women. *R. Gershoni-Baruch[1,2], E. Dagan[1, 2], D. Israeli[3], E. Friedman[3].* 1) Dept Human Genetics, Rambam Medical Ctr, Haifa, Israel; 2) Bruce Rappoport Faculty of Medicine, Technion Institute of Technology, Haifa, Israel; 3) Susanne Levy Gertner Oncogenetics Unit, Chaim Sheba Medical Center, Tel-Aviv, Israel.

Methylenetetrahydrofolate reductase (MTHFR) catalyzes the reduction of 5,10-methylenetetrahydrofolate to 5 methyltetrahydrofolate the primary circulatory form of folate and carbon donor for the re-methylation of homocysteine to methionine. A common missense mutation (C677T) in the MTHFR gene is associated with reduced enzyme activity, hyperhomocysteinemia and increased risk for atherosclerosis. Recently, a marginal association of the C677T polymorphism with endometrial and colorectal cancer was observed. To delineate the putative role of the C677T polymorphism in breast/ovarian tumorogenesis we determined the frequency of this polymorphism in 491 Jewish women with either sporadic (n = 355), hereditary (n = 136) breast and/or ovarian cancer who were all previously genotyped for the three predominant Jewish founder mutations in BRCA: 185delAG, 5382insC and 6174delT. Sixty nine asymptomatic BRCA mutation carriers were similarly analyzed. We found that C677T homozygotes were equally distributed among women with either sporadic (71/355; 20%) or hereditary breast/ovarian cancer (43/ 205; 21%); among women diagnosed with breast cancer prior to age 42 (22/122; 18%) and after that age (42/243; 17.3%); and among BRCA mutation carriers either asymptomatic (11/69; 15.9%) or manifesting cancer (32/136; 23.5%). Among women with bilateral breast cancer and those with both breast and ovarian carcinomas the rate of C677T homozygotes (24/72; 33.3%) was significantly higher (p = 0.0026). This observation, namely, that C677T homozygotes are at greater risk of acquiring a second primary tumor, if further corroborated has important clinical implications.

Program Nr: 327 from the 1999 ASHG Annual Meeting

A large genomic deletion of *hMLH1* in a family with Muir-Torre syndrome. *J.J.P. Gille[1], M.H.P. Strunk[1], R.J. van Schooten[1], L. Jaspars[2], M.H. Vermeer[3], G. Pals[1], F.H. Menko[1].* 1) Dept. of Clinical Genetics and Human Genetics; 2) Dept. of Pathology; 3) Dept. of Dermatology, University Hospital Vrije Universiteit, Amsterdam, The Netherlands.

Muir-Torre syndrome (MTS) is an autosomal dominant condition characterized by sebaceous gland tumors and visceral malignancies. In kindreds diagnosed with HNPCC (hereditary nonpolyposis colorectal cancer) sebaceous gland tumors and other MTS-associated skin tumors have been recognized. HNPCC is often due to germline mutations in one of five DNA-mismatch repair (MMR) genes (*hMSH2*, *hMLH1*, *hPMS1*, *hPMS2*, and *hMSH6*). Among MTS kindreds 14 *hMSH2* and 2 *hMLH* have been reported in the literature. Evidently, MTS and HNPCC are overlapping syndromes.

We studied a family (C149) in which the index patient (II-1) had two primary colorectal cancers at the age of 32 years. His father (I-1) had recurrent skin lesions diagnosed as sebaceous adenomas, sebaceous epitheliomas, keratoacanthomas with sebaceous differentiation and squamous cell carcinoma. At the age of 58 years this latter patient developed colonic cancer. No other close relatives were diagnosed with large bowel cancer or skin tumors. MSI studies of the colonic tumors of both patients revealed the MSI-H (high) phenotype. Germline mutation analysis of *hMLH1* and *hMSH2* by single strand conformation analysis and direct sequencing revealed that I-1 was apparently homozygote for two frequently occurring *hMLH1* polymorphisms located in exon 8 (696A>G) and intron 14 (IVS14-19A>G), respectively. Surprisingly, II-1 was not a carrier of any of these two polymorphisms, indicating that both patients were in fact hemizygote and carriers of a (partial) deletion of the *hMLH1* gene. Hemizygosity was confirmed by analysis of CA-repeat markers intragenic (D3S1611) and closely linked to *hMLH1* (D3S2623). No transmittance of alleles from I-1 to II-1 was observed. Our results indicate that both affected relatives are carriers of a genomic deletion of *hMLH1* that encompasses at least exons 8-14. The family presented here is the first MTS family with a large genomic deletion of *hMLH1*.

Program Nr: 328 from the 1999 ASHG Annual Meeting

Mutational analysis of the RET proto-oncogene in 200 French MEN 2 families: a genotype-phenotype correlation. *S. GIRAUD[1], P. PIGNY[2], P. NICCOLI-SIRE[3], P. NIZARD[1], A. MURAT[4], M. BILLAUD[5], G.M. LENOIR[1], GETC[3]*. 1) Lab. de Genetique,Hospital E. Herriot,LYON,FRANCE; 2) Hospital Huriez,LILLE; 3) Hospital La Timone,MARSEILLE; 4) Hotel-Dieu,NANTES; 5) CNRS,UMR 5641,LYON.

Germline mutations of the RET proto-oncogene are associated with three inherited related disorders: multiple endocrine neoplasia type 2A (MEN 2A), type 2B (MEN 2B) and familial medullary thyroid carcinoma (FMTC). We have screened exons 8, 10, 11, 13, 14, 15 and 16 of RET in the germline DNA of 200 MEN 2 families. RET mutations have been identified in 99% of MEN 2A (101/102), 100% of MEN 2B patients (27/27). Mutations of RET were found in 91% of FMTC families (66/72) but in all FMTC families with at least three cases of MTC.The majority of MEN2A mutations identified in our series were missense changes located in the region coding for the extracellular cysteine-rich domain of RET: 86% of the mutations affected codon 634 in exon 11 and 10% involved either codons 609, 611, 618 or 620 in exon 10. Also, two single nucleotide substitutions were found in exons 13 and 14 (Y791F and V804M) in two MEN 2A cases. A unique mutation in exon 16 (M918T) within the RET tyrosine kinase has been identified in all cases. With regard to FMTC, mutations in exons 10 et 11 were found in 54%; of the cases. However, as previously described, the distribution of mutations was dissimilar to MEN 2A since cysteine codons of exons 10 and 11 were affected in 39% and 15%, respectively. Furthermore, a new RET mutation that consists in a nine base pair duplication in exon 8 which creates an additional cysteine codon was characterized in one FMTC kindred. Finally, point mutations at codons that specify residues within the tyrosine kinase domain were found in 35% of the cases: 8% at codon 768 or 790 in exon 13; 20% at codon 804 in exon 14 and 7% at codon 891 in exon 15. Notably, carriers of RET mutations in exons 13 to 15 were characterized by a later age of onset and a variable penetrance of medullar thyroid cancer.Finally, based on the results of our functional analyses we will propose a possible biochemical explanation for the correlation between genotype and phenotype.

Program Nr: 329 from the 1999 ASHG Annual Meeting

Renal Neoplasms in a Familial Multisystem Syndrome with Fibrofolliculomas as a Cutaneous Marker. *G.M. Glenn[1], M.M. Walther[1], J.R. Toro[1], S. Hewitt[1], P. Duray[1], P.L. Choyke[2], G. Weirich[3], M. Turner[1], W.M. Linehan[1], B. Zbar[3].* 1) Genetic Epidemiology Branch, Urologic Oncology Branch, Dermatology Branch, and Laboratory of Pathology, National Cancer Institute, Bethesda, MD; 2) Diagnostic Radiology Department, National Institutes of Health, Bethesda, MD; 3) Laboratory of Immunobiology, Frederick Cancer Research and Development Center, Frederick, MD.

In our studies of familial kidney neoplasms, we recognized a subset of families with renal tumors who were also affected by lung cysts, pneumothorax, and multiple cutaneous papules. In some family members, skin examinations, biopsies and dermatopathologic diagnoses were consistent with Birt-Hogg-Dube syndrome (BHD), a dominantly inherited predisposition to developing fibrofolliculomas, trichodiscomas, and acrochordons, but previously not known to be associated with internal neoplasms. We found renal neoplasms and BHD segregated together in an autosomal dominant pattern. To identify internal tumors, we performed CT scans of abdomen and pelvis with contrast, high resolution chest CTs, renal sonograms, and now have added colonoscopies to improve ascertainment of cases in families for linkage analysis. With referrals from dermatologists nationwide and abroad, we are studying 23 families with 79 individuals affected with BHD, of which 20 have renal epithelial neoplasms, 19 have spontaneous pneumothorax histories, and 12 have had colon polyps and/or colon carcinoma, and a colon tubulovillus adenoma has been seen. Distribution of renal tumor (RT) number in individuals from BHD families is: 1 RT in each of 6 individuals; 2-3 RTs in 4 individuals; and greater than 2-3 RTs in 10 individuals. Renal histopathologies included: Renal oncocytoma in 10 patients; papillary renal carcinoma in 4 patients; clear cell renal carcinoma in 4 patients; and chromophobe renal carcinoma in 2 patients. It is important to recognize the risk for benign and malignant internal tumors, and pneumothorax in individuals when there is a dermatologic diagnosis of BHD. The number and size of families we are studying should allow demonstration of the phenotypic spectrum and identification of the genetic basis of this genodermatosis associated multisystem and neoplastic syndrome.

Program Nr: 330 from the 1999 ASHG Annual Meeting

Association of oral contraceptives with breast cancer risk in a population-based sample of 426 breast cancer families. *D.M. Grabrick, J.R. Cerhan, F.J. Couch, R.A. Vierkant, T.M. Therneau, C.M. Vachon, J.E. Olson, V.S. Pankratz, L.C. Hartmann, T.A. Sellers.* Mayo Clinic, Rochester, MN.

Oral contraceptives (OCs) are weakly associated with an increased risk of breast cancer (BC) in the general population, but some data suggest a higher risk among BRCA1 and BRCA2 mutation carriers. This is clinically important as women in breast-ovarian cancer families may consider OC use to reduce their ovarian cancer risk. We analyzed data from the Minnesota Breast Cancer Family Study, a historical cohort study of relatives of 426 BC cases identified between 1944 and 1952, and followed through 1996. Ninety-eight percent of eligible families were recruited, and 93% of members participated. OC use and cancer incidence in sisters, daughters, granddaughters, nieces, and marry-ins were determined through telephone interviews. Through 1996, a total of 239 incident BCs were identified in the cohort of 6,150 women at risk. The lifetime prevalence of ever having used OCs was 51% overall and was similar for blood relatives and marry-ins (p=0.99). We used proportional hazards regression, accounting for birth cohort and correlated family data, to model the association between a time-dependent definition of OC use and age at onset of BC. The association of OC use with BC was examined within strata defined by degree of relationship to the proband, with never users as the reference category within each stratum. Among sisters and daughters, women who used OCs for 1 to 4 years were at 4.2-fold greater risk (95% C.I.: 2.1-8.6); for duration of use greater than 4 years the risk estimate was 2.2 (95% C.I.: 0.8-6.4). The corresponding risk estimates for granddaughters and nieces were 1.3 and 1.2, and for marry-ins 1.1 and 1.3, all nonsignificant. When analyses were repeated among the subset of families with 3+ breast or ovarian cancers, risks associated with OC use were further elevated among first-degree relatives: 5.5 (2.4-12.5) and 3.3 (1.0-11.0) for 1 to 4 and greater than 4 years, respectively. These data suggest that use of oral contraceptives may significantly increase risk of breast cancer among women with a family history of breast cancer, especially those with a strong family history.

Program Nr: 331 from the 1999 ASHG Annual Meeting

Constitutional chromosomal instability and predisposition to childhood solid tumors; a new syndrome? *B. Hirsch[1], S. Berry[1], B. Bostrom[1,2], S. Sencer[2]*. 1) Univ Minnesota Medical School, Minneapolis, MN; 2) Children's Hospitals and Clinics, Minneapolis,MN.

The association between chromosomal instability (CI) and predisposition to malignancy is well documented in a number of genetic disorders. However, there are currently only a few well defined syndromes in which CI data are integrated into diagnostic testing or therapy planning.

We here report four children, from three unrelated families, who may represent a novel genetic syndrome. Clinical findings include IUGR, microcephaly, skin pigmentation anomalies, and/or anal abnormalities. Three children (CIA1, CIB1,CIC2)developed Wilms tumors within the first 2 yrs.of life,and one child (CIC1, the older sibling of CIC2),a high grade astrocytoma at 2.5 yrs. After surgical resection, chemotherapy was given to all but CIC2. Two children succumbed to therapy-associated AML within one yr., one died from therapy associated pancytopenia and sepsis. CIC2, who was not given chemotherapy because of concern for hypersensitivity, is alive 5 months post surgery. The three who succumbed all received topoisomerase II inhibitors.

G-banded metaphase analysis from blood lymphocytes and/or skin fibroblasts revealed markedly elevated rates of chromosomal breaks and rearrangements, 50 fold or greater relative to laboratory norms. No recurring abnormality or breakpoint was detected between children; however "clonal" rearrangements were found within individual studies. The pattern and rates of CI were not characteristic of a known disorder. SCE rates were normal, i.e. not indicative of Bloom syndrome.

The etiology of this syndrome is unknown. No mutation of the NF1 gene in patient CIAC2 was found. Although there was no prior significant cancer history in these families, analyses of mismatch repair genes are planned. Constitutional CI is clearly a hallmark of this disorder. Recently, a sibling to CIB1 was born with IUGR,microcephaly and displaced anus. Cytogenetic analysis revealed marked CI, as a result of which this patient is being carefully monitored for tumor development.

Program Nr: 332 from the 1999 ASHG Annual Meeting

The "few-hits-and-run" concept: a new model of carcinogenesis providing a meaningful etiologic and pathogenic interpretation of all the curious features of Lynch syndrome. *N. Janin.* Département de Génétique, Hôpital Necker-Enfants Malades, Paris, France.

The genotype-phenotype relationship of Lynch syndrome displays many curious features which cannot be explained by the prevailing concepts of carcinogenesis and genetic predisposition to cancer. In order to explain these anomalies, we propose a model of replication error (RER)-associated carcinogenesis based on the simple idea that the RER mutator phenotype has only a short term viability in normal cells because the enormous mutation load sustained by RER+ cells spontaneously leads to their elimination through apoptosis or senescence. The proposed model states that RER+ carcinogenesis is divided into two clearly distinct evolutive phases: 1 a preliminary phase starting with the counter-selective loss of mismatch repair function, in which most clones with the RER mutator phenotype are eliminated through apoptosis or an accelerated aging process; 2 an explosive phase that is initiated only if mutations blocking apoptosis and senescence, rapidly acquired during the short lifespan of the non-transformed RER+ clones, eventually rescue one RER+ cell that gives rise to the malignant clone. The classical concepts of initiation and promotion are irrelevant to this model as we consider RER+ carcinogenesis to progress irreversibly and very rapidly once initiated. The "run-initiation" is the unorthodox several-step initiation process of the model that entails all the rate-limiting steps of carcinogenesis. We shall show how the few-hits-and-run model simply explains the tissue specificity and penetrance of Lynch syndrome by taking into account the physiological variations of two key parameters which modulate the probability of completing the run-initiation process once a stem cell has acquired mismatch repair deficiency. These parameters are X and N, the number of self-maintenance mitoses tolerated by RER+ stem cells and the number of mitoses in the proliferating compartment of the tissue, respectively. X defines the life span of the RER+ clone and N modulates the number of viable and potentially transformable daughter cells generated before the extinction of the non-malignant RER+ clone.

Program Nr: 333 from the 1999 ASHG Annual Meeting

Association of glutathione-S transferases m **and** q **null polymorphisms and malignant melanoma.** *P.A. Kanetsky[1,2], R. Holmes[2], A. Walker[1], D. Najarian[1], A. Halpern[3], D. Guerry[2], T.R. Rebbeck[1,2]*. 1) Department of Biostatistics & Epidemiology and; 2) Cancer Center, University of Pennsylvania, Philadelphia, PA; 3) Department of Dermatology, Memorial Sloan-Kettering Cancer Center, New York, NY.

Polymorphisms in glutathione-S transferases m (*GSTM1*) and q (*GSTT1*) are candidate cancer susceptibility genes because of their role in carcinogen metabolism. GST's are active in skin and may impact upon the development of malignant melanoma by reducing cellular oxidative stress. To test for an association between *GSTM1* and *GSTT1* null polymorphisms (*GSTM1*0* and *GSTT1*0*, respectively) and melanoma, patients with incident melanoma (n=249) were accrued through the University of Pennsylvania Pigmented Lesion Clinic. Melanoma cases were compared to a group consisting of clinic patients with dysplastic nevi (DN) alone (n=98) and cancer-free controls (n=117) referred by clinic patients. Each participant completed a questionnaire that elicited information on demographics and cutaneous phenotype, and received a skin examination by a research nurse. DNA isolated from buccal swabs was amplified for *GSTM1* and *GSTT1* using polymerase chain reaction. After adjusting for age and presence of any DN, we found no association between melanoma and *GSTM1*0, GSTT1*0,* either *GSTM1*0* or *GSTT1*0,* or both *GSTM1*0* and *GSTT1*0*. However, among a subset of participants with blond or red hair, melanoma cases (n=56) were over 8-fold more likely [OR=8.9, 95% CI (1.1, 76)] to carry the null genotype for both *GSTM1* and *GSTT1* compared to the referent group (n=43). No associations between GST genotype and melanoma were noted after stratification on eye color, proclivity to burn in strong sun, ability to tan after repeated sun exposure, or freckling. These data suggest that among persons already at increased risk for melanoma, i.e. those with blond or red hair, GST m and q may act synergistically to further elevate cancer risk.

Program Nr: 334 from the 1999 ASHG Annual Meeting

Identification of a YAC carrying cell senescence gene for breast cancer. *G.P. Kaur[1], D.E. Reddy[1], C.L. Keck[2], N. Popescu[2], R.S. Athwal[1]*. 1) Fels Institute for Cancer Research and Molecular Biology, Temple Univ.Sch.Med., Philadelphia, PA 19140; 2) Laboratory of Experimental Carcinogenesis, NCI, Bethesda, MD 20892.

Loss of heterozygosity at chromosome 16q24 is frequently observed in breast cancer, suggesting the presence of tumor suppressor genes in this region. Previously, we have localized a cellular senescence gene at 16q24.3, within a genetic interval of 3-7 cM. A partial YAC contig of this genomic region was accessed. YACs, carrying chromosome 16 specific markers from senescence gene region, were modified to introduce neo selectable marker. Retrofitted YACs were first transferred into mouse A9 fibrosarcoma cell lines. Resulting A9-YAC hybrids were used as microcell donors to transfer YAC sequences into two immortal cell lines derived from human and rat mammary tumors. One YAC derivative, der792t2, restored senescence in both immortal cell lines, while an unrelated YAC from chromosome 6q, had no senescence activity. Human DNA present in A9-der792t2 hybrid, localized to chromosome 16q24.3 and 11q13 by fluorescent in situ hybridization. Since chromosome 11 does not induce senescence in any of recipient cell lines, we conclude that senescence activity is localized to 16q24.3 fragment in der792t2. Thus, using a functional approach, we have narrowed the senescence gene localization to a 360 kb of der792t2.

Program Nr: 335 from the 1999 ASHG Annual Meeting

BRCA1 germline mutations in women with uterine serous papillary carcinoma. *O. Lavie[1], G. Hornreich[1], A. Ben Arie[4], B. Kaufman[2], R. Catane[2], U. Beller[1], P. Renbaum[3], E. Levy-Lahad[3].* 1) Gynecologic Oncology; 2) Institute of Oncology; 3) Medical Genetics Unit, Shaare Zedek Medical Center, Jerusalem; 4) Dept. of Obstetrics and Gynecology, Kaplan Medical Center, Rehovot, Israel.

Uterine serous papillary carcinoma (USPC) is a distinct type of endometrial cancer which accounts for 3-4% of uterine malignancies. USPC histology resembles that of ovarian papillary serous adenocarcinoma, and is associated with a similarly adverse prognosis. In the Ashkenazi Jewish (AJ) population there is a high frequency (~30%) of founder BRCA1/2 mutations in women with ovarian cancer. In order to assess the role of BRCA1/2 mutations in USPC we studied 12 women consecutively diagnosed with USPC at two institutions. Nine were AJ, and 3 were Iraqi Jewish. Five patients (42%) had a personal history of breast cancer (brca) preceding the diagnosis of USPC, and 3 (25%, 2 AJ and one Iraqi Jewish) had a family history suggestive of familial breast-ovarian cancer. Genomic DNA samples from all patients were tested for the founder mutations (BRCA1 - 185delAG and 5382insC, BRCA2 - 6174delT). Two of nine (22%) AJ patients with USPC were found to be BRCA1 carriers (one 185delAG and one 5382insC). Both had a positive family history, and one was previously diagnosed with brca. DNA samples were obtained from the uterine tumors of both carriers and tested for loss of heterozygosity (LOH) at D17S855, an intragenic BRCA1 marker. LOH was observed in both tumors, suggesting USPC in these cases was causally related to the germline BRCA1 mutation. This preliminary study suggests that USPC can be a BRCA1-related malignancy. If substantiated in larger series, it may have implications for the prophylactic surgery offered to carriers, in that hysterectomy may need to be considered in conjunction with oophorectomy.

Program Nr: 336 from the 1999 ASHG Annual Meeting

PTCH Mutations in Squamous Cell Carcinoma. *P.K. Lee, X.L. Ping, H. Zhang, X.L. Wu, F.F. Chen, M.J. Zhang, D.N. Silvers, D. Ratner, M. Peacocke, H.C. Tsou.* Dermatology, Columbia University, New York, NY.

Squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) are classified as non-melanoma skin cancer (NMSC). Ultraviolet (UV) light exposure is the major risk factor for the development of SCC in Caucasians. Other risk factors include immunodeficiency, arsenic exposure and aging. Mutations in the tumor suppressor gene, p53, have been identified in SCC and BCC samples studied. Most of these mutations were UV specific C->T and CC->TT nucleotide changes, resulting in amino acid substitutions in the coding sequences of the p53 gene. PTCH, the human homologue of Drosophila patched gene, has also been shown to be mutated in sporadic BCCs. The role of the PTCH gene in SCC is unknown.

In this study, we screened a total of 20 SCC samples for mutations in the PTCH gene. We used PCR-SSCP as an initial screening method. Seven SSCP variants were detected in six SCC samples. Sequence analysis of these seven variants identified one nonsense mutation, three missense mutations and three silent mutations. In one SCC sample, we identified a tandem GG->AA transitional change at nucleotide 3152 in exon 18 of the PTCH gene, which resulted in a premature stop codon at codon 1051. In two other SCC samples, we identified UV specific C->T nucleotide changes in coding sequences of the PTCH gene. Sequence analysis of the p53 gene in these six SSC samples identified two CC->TT and four C->T UV specific nucleotide changes.

Our study provides the first evidence that PTCH is mutated in SCC and that mutations in both p53 and PTCH genes are found in the same SCC. The identification of the UV specific nucleotide changes in both tumor suppressor genes supports the notion that UV exposure plays an important role in the development of SCC.

Program Nr: 337 from the 1999 ASHG Annual Meeting

A Direct Interaction Between the EXT Tumor Suppressors and Glycosyltransferases. *M. Lovett[1], A. Simmons[2], C. Lopes[2], L. Hwang[2], Y. Yang[2], M. Musy[2].* 1) Washington University Medical Center, St.Louis, MO; 2) UT Southwestern Medical Center, Dallas, TX.

Hereditary multiple exostoses (HME) is an autosomal dominant disease in which bony outgrowths occur from the juxtaepiphyseal regions of the long bones. In a few percent of cases these exostoses undergo malignant transformation to chondrosarcomas. HME results from mutations in one of two homologous genes, EXT1 and EXT2 and loss of the wild type alleles of these genes appears to result in malignant transformation in a manner typical of tumor suppressors. EXT1 and 2 are members of a new gene family that is conserved from C. elegans to higher vertebrates. In humans this family comprises five genes of which only EXT1 and EXT2 are known to be involved in HME. The EXT genes are most conserved at their C-termini, but they do not contain any discernible motifs and their function(s) are unclear. Indirect evidence suggests that EXT proteins are involved in glycosaminoglycan (GAG) synthesis, and affect hedgehog signaling. There is also a report that these proteins co-purify with glycosyltransferase (GalNAc-T) activity and it has been postulated that they are themselves GalNAC-Ts. We performed two-hybrid screens with a fragment of EXT2 from the region that is most conserved in the gene family and identified two interacting proteins: the tumor necrosis factor type 1 receptor associated protein (TRAP1) and a novel glycosyltransferase, GalNAc-T5. TRAP1 is a distantly related member of the Hsp90 family of chaperonins that was previously reported to interact with the RB1 gene product and with the TNF1 receptor. TRAP1 interacted with both EXT1 and EXT2, but failed to interact with the related EXTL1 or EXTL3 proteins. By contrast, GalNAc-T5 interacted in vivo only with EXT2, but could also bind EXT1 protein in vivo. Significantly, both sets of interactions were abrogated by a disease-causing EXT mutation, indicating that they are important in HME. The EXT2:GalNAc-T5 interaction provides the first direct physical link between EXT proteins and glycosaminoglycan synthesis, suggests that EXTs are not themselves GalNAc-Ts and points to a potentially novel pathway of tumor suppression.

Program Nr: 338 from the 1999 ASHG Annual Meeting

Allelic loss at the four critical lung cancer tumour suppressor gene regions on human chromosome 3p including homozygous deletions at 3p12-13. *D.P. Macartney[1], A. Chauhan[2], S. Hosoe[3], E.R. Maher[1], F. Latif[1]*. 1) Division of Medical Genetics, Department of Paediatrics and Child Health, Birmingham University, Birmingham, UK, B15 2TT; 2) Cytogenetics and DNA Laboratory, Birmingham Womens Hospital, Birmingham, UK, B15 2TG; 3) Department of Internal Medicine, National Kinki-Chou Hospital, 1180, Nagasonecho, Sakai, Osaka, 591, Japan.

Cytogenetic and allelotyping analyses have revealed that human chromosome 3p is the most frequent site of allele loss in lung cancer and that this loss is observed in the earliest stages of the disease. Four distinct regions of loss at 3p12-13, 3p14.2, 3p21.3 and 3p25 have been identified which are potential sites for tumour suppressor genes involved in lung cancer. We have analysed these four regions using 12 microsatellite markers in 36 SCLC (small cell lung cancer) and 51 NSCLC (non-small cell lung cancer) normal/tumour pairs. We confirmed that 3p allele loss is more frequent in SCLC than NSCLC. Loss of heterozygosity was observed in all four regions for SCLC and NSCLC with no relationship seen between tumour type and a specific critical region. To date homozygous deletions have been reported in SCLC cell lines and NSCLC tumours with squamous histology at 3p21, in cell lines at 3p14.2 and in one SCLC cell line and one SCLC tumour at 3p12. Our results, based on the determination of homozygous deletion by the apparent retention of one microsatellite marker flanked by two markers showing clear loss (Cairns *et al.* 1995; Reed *et al.* 1996), strongly suggest the identification of two homozygous deletions, one of 1cM or less in a SCLC tumour at 3p12 and one of 30cM or less in a NSCLC tumour at 3p12-13. Quantitative PCR is being used to confirm the data and to fine map the deletions which may allow the 3p12 critical region to be narrowed further. In addition, when confirmed this will be the first report of a homozygous deletion in a NSCLC tumour at 3p12-13 further establishing the potential importance of this region in the pathogenesis of both SCLC and NSCLC.

Program Nr: 339 from the 1999 ASHG Annual Meeting

BRCA1/BRCA2 mutations in relation to tumor characteristics and prognosis. *E.A. Ostrander, K.E. Malone, P.L. Porter, D. Doody, M.G. Lin, N. Suter, J.R. Daling.* Fred Hutchinson Cancer Research Center, Seattle, WA.

The possibility that inherited susceptibility may influence tumor characteristics and/or prognosis has important implications for treatment choices and for understanding the natural history and progression of breast cancer. Using a population-based series of breast cancer cases diagnosed before age 45 in Washington State who are the focus of partially overlapping studies of both the genetic-epidemiology of the disease and prognostic factors, we assessed the relation of germline mutations in BRCA1 and BRCA2 to prognosis and tumor characteristics. 386 cases deemed to be at increased risk of carrying mutations, 203 diagnosed before age 35 unselected for family history, and 225 diagnosed before age 45 who had a first degree family history, were tested for mutations. Among the 387 cases, we found that BRCA1 positive cases (n=23) had a 50% reduction in the risk of dying (10 year survival) compared to BRCA1-/BRCA2- cases. BRCA2 positive cases (n=15) had an increased risk of dying (RR=2.5). As part of a study of prognostic factors for invasive breast cancer, we have obtained tumors from 217 of the 387 cases genotyped for BRCA1/2. Compared to BRCA1-/BRCA2- cases and compared to all cases in the prognosis study, the 13 BRCA1 positive tumors studied had adverse characteristics (92.3% ER-, 100% PR-, 73.3% high grade, etc.). BRCA2 positive tumors had similar tumor profiles to BRCA1-/BRCA2- cases and to the distribution in all invasive breast cancer cases. Finally, as reported in some other studies, we find that BRCA1, but not BRCA2 mutations are disproportionately related to a higher percentage of medullary breast cancers. These data suggest a need for larger, more extended analyses to better understand the relationship between inherited predisposition and natural history of disease.

Program Nr: 340 from the 1999 ASHG Annual Meeting

hMSH6 Alterations in Patients with MSI-L Colorectal Cancer. *Y.R Parc, K.C Halling, L. Wang, E.R Christensen, J.M Cunningham, L.J Burgart, T.L Price-Troska, S.N Thibodeau.* Departement of Laboratory Medecine and Pathology, Mayo Clinic, Rochester, MN.

Most hereditary nonpolyposis colorectal cancer (HNPCC) patients have germline mutations of one of the DNA mismatch repair genes, most frequently hMSH2 or hMLH1. It has been reported that some HNPCC families with low level MSI (MSI-L, MSI at 1-30% of the loci examined) have germline mutations of the hMSH6 gene. However, the role of hMSH6 in unselected MSI-L colon carcinoma is unknown. The aim of this study was to determine the frequency of hMSH6 mutations in patients with unselected CRC with MSI-L. Tumors from 46 patients with MSI-L colorectal cancer, derived from 404 unselected colon cancer, were screened for hMSH6 mutations using conformation sensitive gel electrophoresis (CSGE) and for an absence of hMSH6 protein expression by immunohistochemistry. Alterations found with CSGE were confirmed by DNA sequencing on normal and tumor tissue. One somatic (Asp389Asn) and 16 germline changes were found. Of the 16 germline changes, 9 were intronic (none involving the splice junction), and 7 were exonic (3 missense: Gly39Glu; Leu395Val; Ser503Cys and 4 silent alterations). One intronic alteration, an 18 bp deletion within the branch site of intron 7 (34 bp upstream from exon 8), was found in eight patients. However, these patients demonstrated a normal RNA expression by northern blot. None of the three patients with germline missense mutations had a family history consistent with or suggestive of HNPCC. Allele frequencies of these three alterations were 1%, 2% and 1%, respectively. The codon 39 alteration has already been reported as a polymorphism (Genomics 1996;31:395), the codon 395 alteration was found in 2 of 50 normal control patients, but the codon 503 alteration was not found in any of the 50 normal controls. The patient that met the Amsterdam criteria demonstrated the 18 bp deletion in intron 7 and a silent mutation in exon 3. Immunohistochemical staining for hMSH6 revealed no evidence of loss of hMSH6 expression in any of the 46 tumors. Our results suggest that hMSH6 mutations are minimally involved in the development of sporadic colorectal cancer with an MSI-L phenotype.

Program Nr: 341 from the 1999 ASHG Annual Meeting

Somatic Mutations in the SRD5A2 Gene Encoding Prostatic Steroid 5alpha-Reductase During Prostate Cancer Progression. *J.V. Reichardt, A. Akalu.* Biochem, Inst Genetic Medicine, Univ Southern CA Sch Medicine, Los Angeles, CA.

Prostate cancer will strike about 180,000 men in this country this year alone and almost 40,000 will die of the disease. Prostate cancer is an androgen-dependent disease which often progresses from androgen-dependent to androgen-independent growth. We have investigated the SRD5A2 gene encoding the prostatic (or type II) steroid 5alpha-reducatase which is centrally involved in androgen-activation in the prostate. We had previously shown that this gene undergoes frequent LOH (loss of heterozygosity) and genomic instability events during tumor progression. We report here our systematic analyses of the SRD5A2 gene in 30 matched tumor and constitutional DNA samples from men with prostate cancer. We identified at least two hot spots for somatic mutations: 1) the A49T (alanine at codon 49 to threonine) mutation which was found to occur de novo in 7 of 30 tumors and 2) the V63M substitution (valine-63 to methionine) which we identified as a de novo somatic mutation in 3 out of 30 tumor specimen. These two mutational hot spots, therefore, are found in one third of prostate tumors examined. Our data supports the notion that somatic mutations of the SRD5A2 gene may play an important role in prostate cancer progression. These data have important implications for the management of prostate cancer and its chemoprevention.

Program Nr: 342 from the 1999 ASHG Annual Meeting

Biochemical characterization of genetic variants identified during BRCA1 and BRCA2 clinical mutation screening for effects on RNA splicing. *T. Scholl, M. Pyne, D. Pruss, B. Ward.* Product Development, Myriad Genetic Laboratories, Salt Lake City, UT.

Certain variants detected in BRCA1/2 clinical testing could be predicted to interfere with RNA splicing based on location or sequence context. Their clinical significance was determined by using coding region polymorphisms to assess the chromosomal contribution to normal and aberrant RNA splicing products. Sixteen genetic variants occurring near intron-exon junctions within BRCA1/2 were evaluated. Nine represent mutations since the chromosome carrying the variant did not produce detectable levels of normal mRNA or produced only aberrantly spliced transcript(s): B1IVS4-1G->T, B1IVS8+2T->A, B1IVS16+6T->C, B1IVS18-13A->G, B1IVS19-2A->G, B1IVS22+2delT, B2R2336P, B2IVS7+2T->G, B2IVS17-1G->C; seven are polymorphisms since both chromosomes produced the legitimate message: B1C(TGC)197C(TGT), B1IVS8-57insT, B1IVS17ins1, B1IVS20+48ins12, B1IVS22+8T->C, B2IVS25-12T->G, B2IVS26-19G->A. SNP haplotype analysis was used to confirm conclusions based on biochemical data and also supported a reinterpretation of results for the polymorphism, B1IVS20+48ins12, which had previously been reported as a potential mutation. This combined approach to variant characterization produces very informative data since the contribution by either chromosome to every RNA species can be determined. Therefore, complications arising from the assessment of alternative versus aberrant splicing products are eliminated. The biochemical data is augmented with a haplotype analysis that resolves the relationship between genetic variants and aberrant transcripts produced by one chromosome. This method offers the potential to determine the clinical significance of variants that impact splicing using a sample from only a single patient and thereby obviate the requirement for an extensive familial or genetic study. The application of this approach has improved the clinical utility of the results presented to over 100 individual patients and permitted the unequivocal diagnosis of the presence of a deleterious mutation in thirty of these patients.

Program Nr: 343 from the 1999 ASHG Annual Meeting

Sex-specific expression of gastrin-releasing peptide receptor is related to smoking history and risk for lung cancer. *S.P. Shriver[1,2], H.A. Bourdeau[1], C.T. Gubish[1], D.L. Tirpak[1], A.L. Gaither Davis[1], J.M. Siegfried[1]*. 1) Department of Pharmacology, Lung Cancer Program, University of Pittsburgh Cancer Institute, University of Pittsburgh, Pittsburgh, PA 15261, USA; 2) Department of Biology, The Pennsylvania State University, 208 Mueller Lab, University Park, PA 16802.

Increasing evidence demonstrates that women are more susceptible to tobacco carcinogenesis than men. Activation of the gastrin-releasing peptide receptor (GRPR) in the human airway has been associated with long-term tobacco use, and with proliferative response of bronchial cells to gastrin-releasing peptide. The GRPR gene is located on the X chromosome and escapes X-inactivation. We hypothesized that expression of GRPR in the airway may be associated with susceptibility of women to the effects of tobacco carcinogens. GRPR mRNA expression was analyzed in lung tissues and cultured airway cells from 78 individuals, and in lung fibroblasts exposed to nicotine. Labeled nicotine and nicotine antagonists were used to assay airway cells for nicotinic acetylcholine receptors. A polymorphism located in exon 2 of the GRPR gene was used to detect allele-specific GRPR mRNA expression. GRPR mRNA is expressed in airway cells and tissues from female nonsmokers and short-term smokers at a significantly higher frequency than in males (£25 PY (pack-years); p=0.01); and female smokers exhibit expression of GRPR at a significantly lower mean pack-year exposure than males (56.3 PY for males vs. 37.4 PY for females, p=0.037). Elevated GRPR mRNA expression in lung fibroblasts was observed following exposure to nicotine, and lung fibroblasts and bronchial epithelial cells exhibited high-affinity, saturable nicotinic acetylcholine binding sites. Polymorphism analysis demonstrates that GRPR expression in women is the result of transcription from both copies of the gene. Our results suggest the GRPR gene is expressed more frequently in women in the absence of smoking, and/or that expression is activated earlier in response to tobacco exposure compared to men. This effect may be mediated by nicotine. The second expressed copy of the GRPR gene in females may be a factor in the increased susceptibility of women to tobacco-induced lung cancer.

Program Nr: 344 from the 1999 ASHG Annual Meeting

BRCA1 and _BRCA2_ germline mutations in a population-based series of early onset breast cancer patients in France. *O.M. Sinilnikova[1,2], V. Bonadona[3], S. Chopin[1], A. Brémond[3], H. Mignotte[3], P. Mathevet[2], A. Martin[4], C. Zinzindohoue[2], D. Raudrant[2], R-C. Rudigoz[2], C. Palayer[5], P. Romestaing[2], C. Montvernay[2], G. Lenoir[1,2], C. Lasset[3]*. 1) International Agency for Research on Cancer, Lyon; 2) Hospices Civils de Lyon, Lyon; 3) Centre Léon Bérard, Lyon; 4) Clinique Jeanne d'Arc, Lyon; 5) Clinique Eugène André, Lyon, France.

To study the contribution of germinal *BRCA1* and *BRCA2* mutations in breast cancer in the general population we have analyzed for mutations in these genes a population-based series of early-onset breast cancer patients from France of the Rhône administrative region. 457 women diagnosed with breast cancer before the age 45 in the Rhône region through the years 1995-1997 have been identified through a population-based cancer registry and 265 (60%) have already agreed to participate in the study and were interviewed, providing information on personal and familial cancer risk factors. The participation rate was slightly higher in the youngest age at diagnosis groups : 79%, 67% and 59% in the before 36, 36-40 and 41-45 age groups, respectively. 225 patients have already donated their blood. Here we report the results of the *BRCA1* and *BRCA2* mutation screen in 76 patients diagnosed with breast cancer before 40 years of age. The entire coding sequences and splice junctions of *BRCA1* and *BRCA2* have been analyzed by heteroduplex mutation detection technique. Eleven *BRCA1* and seven *BRCA2* mutations have been identified : ten mutations resulting in generation of a premature Stop codon, four missense variants, one in-frame deletion and three intronic variants expected to result in aberrant splicing. Our results indicate that a substantial proportion of young breast cancers (£40 years) drawn from the general population is attributable to mutations in the *BRCA1* and *BRCA2* genes (24% (18/76); truncating mutations only 13% (10/76)). 11% (5/46) of patients revealing no family history of breast or ovarian cancer were found to be *BRCA1* or *BRCA2* mutation carriers. Our data argue for utility of *BRCA1* and *BRCA2* mutation test in early-onset breast cancer patients unselected for family history of cancer.

Program Nr: 345 from the 1999 ASHG Annual Meeting

Polymorphisms in the methylenetetrahydrofolate reductase gene and susceptibility to leukemia. *C.F. Skibola[1], M.T. Smith[1], E. Kane[2], E. Roman[2], S. Rollinson[3], R. Cartwright[2], G. Morgan[2].* 1) School of Public Health, U.C. Berkeley, Berkeley, CA; 2) Leukaemia Research Fund Centre for Clinical Epidemiology, Leeds, UK; 3) Department of Haematology, University of Leeds, Leeds, UK.

Leukemias most likely arise through adverse gene-environment interactions with susceptibility being related to polymorphisms in multiple genes. We investigated the possible association between polymorphisms in the folate metabolizing enzyme, 5,10-methylenetetrahydrofolate reductase (MTHFR), and leukemogenesis. MTHFR catalyzes the reduction of 5,10-methylenetetrahydrofolate (methyleneTHF), a methyl donor for DNA synthesis, to 5-methyltetrahydrofolate (methylTHF), the primary methyl donor for methionine synthesis. A common 677 C®T polymorphism in the MTHFR gene results in thermolability of the enzyme that decreases the pool of methylTHF and increases the pool of methyleneTHF in homozygous mutants (677TT). Recently, another common 1298 A®C polymorphism has been identified in the MTHFR gene that results in diminished enzyme activity. We tested whether carriers of these variant alleles are protected from adult acute leukemia. We analyzed DNA from a case-control study in the United Kingdom of 308 adult acute leukemia patients and 491 age and sex matched controls. MTHFR variant alleles were determined by a PCR-RFLP assay. The MTHFR 677TT genotype was lower among 71 acute lymphocytic leukemia (ALL) cases compared to 114 controls, conferring a 4.3-fold decrease in risk of ALL (OR= 0.23; 95% CI= 0.06-0.81). We observed a 2.8-fold reduction in risk of ALL in individuals with the MTHFR 1298AC polymorphism (OR=0.33; 95% CI = 0.15-0.73), and a 14-fold decreased risk of ALL in those with the MTHFR 1298CC variant allele (OR=0.07; 95% CI= 0.00-1.77). In acute myeloid leukemia (AML), no significant difference in MTHFR 677 and 1298 genotype frequencies was observed between 237 cases and 377 controls. Individuals with the MTHFR 677TT, 1298AC and 1298CC genotypes have a decreased risk of adult ALL, but not AML, which suggests that folate metabolism plays a key role in the development of ALL.

Program Nr: 346 from the 1999 ASHG Annual Meeting

BRCA1 mutation screening using morphoclinical features of breast cancers. *H.H. Sobol[1], F. Eisinger[1], C. Nogues[2], M. Champeme[2], I. Bieche[2], D. Birnbaum[1], C. Pallud[2], J. Jacquemier[1], R. Lidereau[2]*. 1) Department of Genetic Oncology, Inserm E9939, Paoli Calmettes Inst, Marseille, France; 2) Genetic Oncology Unit, Rene Huguenin Centre, Saint-Cloud, France.

BRCA1-breast cancers display a specific morphoclinical pattern. The three most discriminant parameters are young age at onset, oestrogen receptor negativity (ER-) and poor differentiation (TD3) of the tumor. We tested the interest of these parameters in BRCA1 mutation search in a series of 65 consecutive invasive breast cancers with onset by the age of 35 years. A high BRCA1 mutation rate of 28.5 percent was found in tumors both ER- and TD3, versus only 3.9 percent in tumours with another profile (p=0.017; OR=9.8. When using early onset only the mutation rate was 9.2 percent. The family history of cases ER- and TD3 with a BRCA1 mutation was then investigated and none of them harbored an extensive family history of breast/ovarian cancer. Such a strategy would allow to identify gene carriers who would have been overlooked using current criteria such as family history of breast/ovarian cancer.

Program Nr: 347 from the 1999 ASHG Annual Meeting

C-abl, a downstream target of ATM signaling, localizes with ATM to synaptonemal complexes in meiotic spermatocytes. *W. Wang, M.S. Meyn.* Department of Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada.

ATM mutations cause ataxia-telangiectasia (A-T), an autosomal recessive disease marked by neurodegeration, immunodeficiency, genetic instability, infertility, radiosensitivity and cancer. In the presence of double-strand DNA breaks (DSBs), ATM is thought to activate multiple cellular functions via kinase cascades. E.g., following irradiation, the proto-oncogene c-abl is phosphorylated in an ATM-dependent manner. C-abl in turn, can phosphorylate Rad51, a protein that plays a central role in genetic recombination. We previously demonstrated that ATM localizes to the synaptonemal complexes (SCs) of homologous chromosomes during meiosis I, a time when DSBs occur. *Atm -/-* and *C-abl-/-* mice are infertile, suggesting that both Atm and c-abl play critical roles in meiosis. Using immunohistochemical techniques, we have examined testes from normal and *Atm -/-* mice for the expression of c-abl, SCP3, ATM and rad51.

We confirm previous observations that c-abl protein is expressed in testes and now report that expression is highest in zygotene/pachytene spermatocytes. Beginning in mid-zygotene, discrete foci of c-abl are seen along the paired axes of SCs. These foci persist through early pachytene and colocalize with ATM and Rad51 at early recombination nodules. Pairing of meiotic chromosomes is grossly abnormal in *Atm -/-* mice, with meiosis I ending in fragmentation of SCs and apoptosis. Despite these abnormalities, formation of c-abl foci appears to be normal in *Atm -/-* spermatocytes. Unlike Rad51, no off-axis c-abl foci are observed in the degenerating pachytene *Atm -/-* nuclei.

Our studies indicate that c-abl forms foci along the SCs of paired chromosomes and suggest that c-abl is a component of early recombination nodules. In addition, functional Atm does not appear to be required for c-abl focus formation. These results, together with the demonstration of abnormal Rad51 foci in *Atm -/-* spermatocytes, suggests that the ATM/c-abl/Rad51 signaling pathway plays a critical role in regulating genetic recombination in both mitotic and meiotic cells.

.

Program Nr: 348 from the 1999 ASHG Annual Meeting

Subtelomeric rearrangements detected by FISH in patients with idiopatic mental retardation. *B. Anderlid[1], G. Annerén[2], E. Blennow[1], M. Nordenskjold[1]*. 1) Dept of Clinical Genetics, Karolinska Institute, Stockholm, Stockholm, Sweden; 2) Dept of Clinical Genetics, Akademiska Hospital, Uppsala.

Introduction: Mental retardation (MR) affects 1-3% of the population. One important cause is chromosomal rearrangements altering the gene dosage. Although thoroughly investigated, many cases do not get an etiological diagnosis. The subtelomeric regions are gene rich and have a high degree of involvement in chromosomal rearrangements. Recent investigations showed submicroscopic subtelomeric rearrangements in 5-10% of cases with idiopatic MR. Material: 44 patients (23 male and 21 female), aged 1-30 years (median 7.9 years) with idiopatic MR were analysed. Severe MR was found in 27, 31 had dysmorphic features or malformations and 14 had heredity for MR. Standard chromosome analysis was normal in all. Methods: The subtelomeric regions were screened with fluorescent in situ hybridization (FISH). The Chromoprobe Multiprobe T System was used. It contains probes from all subtelomeric regions on a device making it possible to analyse all chromosomes on one slide. Probes from p-arms are labelled with digoxigenin and q-arms with biotin. The signals are amplified using antibodies (antidigoxigenin-FITC and antibiotin-Cy3)in several steps. Results: Subtelomeric rearrangements were found in 6 patients: Del 9q - a woman born 1977 with MR and autism. Del 21q,dupl 9q - a boy born 1984 with severe MR, short stature, VOC, CNS malformation and heredity for MR. Del 2q - a girl born 1988 with mild MR, dysmorphic features and a sister with MR. Del 22q - a woman born 1966 with MR, autism, epilepsy and dysmorphic features. Del 6q - a boy born 1995 with severe MR, microcephaly, hyperactivity, skeletal malformations and a brother with MR. Del 4p - a girl born 1996 with severe MR, reduction of white matter, epilepsy and dysmorphic features. A high number of cross hybridizations were detected. The most common were 11p-17p, 12p-6p and 12p-20q. Conclusion: Six out of 44 patients with idiopatic MR were found to have subtelomeric rearrangements not detected by routine chromosome analysis. This supports the hypothesis that subtelomeric rearrangements are an important etiological factor in idiopatic MR.

Program Nr: 349 from the 1999 ASHG Annual Meeting

MITF mutations in Waardenburg syndrome. *J. Augé[1], T. Attié-Bitach[1], B. Gilbert[2], M. Le Merrer[1], S. Lyonnet[1], A. Munnich[1], M. Vekemans[1]*. 1) Dept de Génétique & INSERM U-393, Hopital Necker, Paris, FRANCE; 2) Hopital Dupuytren, Limoges, FRANCE.

Waardenburg syndrome (WS) is a genetically heterogeneous disease associating congenital sensorineural deafness with skin irides and hair pigmentary disorders. WS has been classified in 3 types according to the presence (WS1) or absence (WS2) of dystopia canthorum. WS3 is more severe associating muscular limb defects to a WS1 phenotype. Mutations of the PAX3 gene are responsible for WS1 and WS3, while genetic heterogeneity is observed in WS2, where less than 20% MITF mutations are found. So far, ten different MITF mutations have been reported in 13 patients, 11 in WS2 cases and 1 in a family with a Tietz albinism-deafness syndrome (2 mutations identified twice). Here we report on the mutational spectrum in 31 WS families (20 WS1, 8 WS2 and 3 unclassified) analysed for PAX3 and/or MITF genes by single strand conformation polymorphism. We identified 8 PAX3 (4 novel mutations) and 4 MITF mutations. One MITF mutation has been identified in a WS2 patient with deafness, blue eyes, and grey hair. Her daughter is also affected with deafness and heterochromia of the irides. They carried a nonsense mutation (R214X) in exon 7 that has already been reported in two other patients with WS2. The 3 other mutations are novel MITF mutations. A missense mutation in exon 6 was identified in a patient with deafness, blue eyes, and a patchy hypopigmentated skin. His father has early greying and blue eyes but no DNA was available for studies. The causal nature of this missense mutation in uncertain, although lying in the basic domain and absent in 50 controls chromosome. An intron 7 MITF splice mutation was found in a large pedigree segregating for neurosensorial deafness, premature hair greying and irides heterochromia. Finally, an exon 8 2bp deletion was identified in a boy with deafness and heterochromia of the irides. The mutation was inherited from his mother who presented irides heterochromia, but was no deaf. In conclusion, this study reports 3 novel MITF mutations out of 13 mutations described so far and confirms the strong association of MITF mutations and WS2.

Program Nr: 350 from the 1999 ASHG Annual Meeting

Congenital Heart Disease in Monosomy 21: Definition of two distinct loci. *G.M. Barlow[1], X-N. Chen[1], G. Calabrese[2], G. Palka[2], P. Caldwell[3], C. Booth[4], L. Linck[5], J.R. Korenberg[1].* 1) Medical Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) University of Chieti, Italy; 3) Kaiser Permanente Punawai Clinic, Waipahu, Hawaii; 4) Lutheran General Medical Group, Chicago, IL; 5) Oregon Health Sciences University, Portland, OR.

Monosomy for chromsome 21 is usually associated with death in utero. However, individuals with partial deletions of chromosome 21 and congenital heart disease (CHD) provide the opportunity to identify genes contributing to cardiovascular development. To do this, we have defined the molecular structure and cardiac features of 16 subjects with partial deletions of chromosome 21. Thirty-eight markers spanning chromosome 21 were analysed using fluorescence in situ hybridisation with bacterial artifical chromosomes (BACs) or quantitative Southern blot dosage analysis. Of the sixteen individuals with partial monosomy 21, six (38%) have CHD. These are: case 1, who is deleted from APP-ITSN (intersectin) and has a VSD; case 2, who is deleted from SOD1-D21S17 and has a secundum ASD; case 3, who is deleted from KCNE-ter and has an ASD; case 4, who is deleted from ITSN-ter and has an ASD; case 5, who is deleted from CBR-ter and has complex CHD including a severe coarctation of the aorta, pulmonic stenosis, patent foramen ovale and hypoplastic left ventricle; and case 6, who is deleted from D21S121-DSCAM and also has complex CHD including a membranous VSD, an ASD secundum, anteriorly placed aorta, and patent ductus arteriosus. Combining the molecular results reveals that two deletions do not overlap (cases 1 and 5). Position effects notwithstanding, this suggests that deletions of two distinct regions of chromosome 21 can lead to CHD. Further, the region between CBR and the telomere that is associated with complex CHD overlaps the candidate region for congenital heart disease in trisomy 21 (Down Syndrome). We therefore propose that these regions contain dosage-sensitive gene(s) that are important for normal development of the heart and great vessels, and whose perturbation in aneuploidy 21 results in CHD.

Program Nr: 351 from the 1999 ASHG Annual Meeting

BOR syndrome. Report of seven family groups. *C. Bellini[1], D. Massocco[1], F. Scopesi[1], G. Piaggio[2], E. Verrina[2], F. Perfumo[2], F. Campone[1], W. Bonacci[1], G. Serra[1].* 1) Servizio di Patologia Neonatale, Universita di Genova, Istituto Gaslini, Genova, Italia; 2) Divisione di Nefrologia, Istituto Gaslini, Genova, Italia.

We review seven new families with branchio-oto-renal (BOR) syndrome (MIM 113650). BOR syndrome is an autosomal disorder with an incidence, probably understimated, of 1/40.000 cases. It consists of conductive, sensorineural, or mixed hearing loss; preauricular pits; structural defects of the outer, middle or inner ear; renal anomalies; lateral cervical fistulas, cysts or sinuses; nasolacrimal duct stenosis or fistulae; characteristic facial appearance. Facial paralysis has also been occasionally described. The minimal diagnostic criteria of BOR syndrome are unknown. In our study, all first diagnosed patients in each familial group were recognized on the basis of severe renal impairment, spanning from complete bilateral agenesis to bilateral or unilateral renal dysplasia. When evidentiated, kidneys were usually reduced in size. Severe renal insufficiency was demonstrated in all first diagnosed patients. On the basis of diagnosis of BOR syndrome, many family members of each family were evaluated. Parents of two patients were healthy without any marker of BOR syndrome. Pedigrees of the five other families showed presence of preauricular pits, branchial fistulae and hearing impairment at various degree. Severe renal impairment leading to death was recognized in one member among these families. Our study demostrated that BOR syndrome is an underdiagnosed disorder, usually recognized in the presence of severe renal failure, but often not diagnosed in the presence of mild clinical signs, such as mild branchial anomalies. We enphatize a meticolous search for renal anomalies and/or hearning loss in all subjects showing minimal signs of branchial defects; on the other hand, one BOR syndrome is diagnosed in a patient, it is necessary to examine all family members for the presence of the syndrome; and, this is true even if there are minimal stigmate of the disease in the family members.

Program Nr: 352 from the 1999 ASHG Annual Meeting

Clinical variability and genetic heterogeneity in multiple epiphyseal dysplasia. *M.D. Briggs[1], W. Newman[1], I.D. Young[2], G.R. Mortier[3].* 1) Wellcome Trust Centre for Cell Matrix Research, School of Biological Sciences, Univ. of Manchester; 2) Clinical Genetics Service, City Hospital, Nottingham, England; 3) Dept. Medical Genetics, Univ. Hospital of Gent, Gent, Belgium.

Multiple epiphyseal dysplasia (MED) is characterised by early-onset degenerative joint disease and in severe cases short stature. The mild 'Ribbing' and severe 'Fairbank' forms have been used to define the phenotypic spectrum within this autosomal dominant disease. MED can result from mutations in the genes encoding cartilage oligomeric matrix protein (COMP) and type IX collagen (COL9A2 and COL9A3). We are performing genetic linkage and mutational analysis in families with various MED phenotypes and comparing molecular findings to clinical and radiographic presentation. In a family with severe MED we identified a COMP mutation (D473N) that has also been shown to cause pseudoachondroplasia. In 2 families with mild MED, different mutations have been identified in the exon 3 splice-donor site of COL9A2, one of which results in the degradation of mRNA from the mutant allele. In another family in which COL9A2 is implicated, affected individuals are of normal stature, but osteochondritis dissecans has contributed significantly to early onset degenerative joint disease. Electron microscopy of cartilage from an affected family member shows normal extracellular matrix and chondrocyte morphology. Finally, we have ascertained a four generation family with MED in which preliminary genetic analysis has excluded linkage to the COMP or type IX collagen genes. Affected individuals have a normal birth length and an adult height around the third percentile (150-165 cm). Most have complained during childhood of knee and hip pain after exercise and some underwent hip replacements or knee surgery because of early-onset osteoarthritis. Current studies are focused on identifying the disease gene in this family and the genetic defect of MED in 5 other families. Our data suggest that mutations in at least five genes are likely to result in phenotypes within the MED disease spectrum, which helps to explain the clinical variability within this osteochondrodysplasia. (This work is funded by the Arthritis Research Campaign).

Program Nr: 353 from the 1999 ASHG Annual Meeting

Atypical microdeletion in 15q11-q13 re-establishing the regions for Angelman and Prader-Willi syndromes. *J.J. Burger, V. Wiebe, D. Horn, H. Tonnies, K. Sperling, A. Reis.* Human Genetics; Charite, Humboldt University, Berlin, Germany.

The genetic basis of Angelman syndrome (AS) is complex. AS appears to be caused by the loss of maternal UBE3A gene activity. Most AS patients have a 4 Mb de-novo deletion on their maternal chromosome 15q11-q13. If this deletion is of paternal origin, affected individuals develop Prader-Willi syndrome (PWS). We report an uncommon deletion of the UBE3A gene. It spans approximately 700 kb, encompasses the entire UBE3A gene, is flanked by microsatellites PAR/SN and D15S986, and is of maternal origin. The methylation pattern at the SNRPN locus is normal in Southern-Blot analyses. We confirmed the deletion with FISH using several BAC probes from the deleted region. We identified one clone spanning the distal breakpoint. We found the deletion also in the maternal grandfather and his sister, who has two children with disturbances compatible with AS. Our results suggest that the deletion occurred in the great-grandfather and that it causes AS when it is transmitted through a female germline. These findings support the hypothesis that the functional loss of the maternal UBE3A gene is sufficient to cause AS. Moreover, our results indicate that the deleted region does not contain any genes or other factors involved in PWS.

Program Nr: 354 from the 1999 ASHG Annual Meeting

A immunological method to detect mutations in the XNP gene, involved in several X-linked mental retardation syndromes. *C. CARDOSO[1], L. VILLARD[1], C. MIGNON[1], A.M. LOSSI[1], Y. LUTZ[2], J.L. MANDEL[2], M.G. MATTEI[1], C.E. SCHWARTZ[3], L. COLLEAUX[1], M. FONTES[1]*. 1) INSERM U 491, Faculté de Medecine de la Timone, 27 Bd J.Moulin, 13385 MARSEILLE cedex 05, FRANCE; 2) INSERM U 184, IGCBM, Parc d'innovation , BP 163 67404 Illkich cedex, FRANCE; 3) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC 29646, USA.

Mutations in the XNP gene, located in Xq13.3, cause several X-linked mental retardation syndromes : the a-thalassemia with mental retardation syndrome (ATR-X), Juberg-Marsidi syndrome, Carpenter Waziri syndrome, Holmes-Gang syndrome, Smith-Fineman-Myers syndrome, mental retardation with spastic paraplegia and mental retardation without a-thalassemia. Sixty-percent of mutations in XNP have been found within the zinc finger domain of the protein (encoded by exons 7,8 and beginning of exon 9) while 40% of the mutations were found in the helicase domain extending over 3 Kb at the C-terminus of the protein. All male patients reported so far have had severe mental retardation and dysmorphic features. In addition, patients may be affected with genital anomalies, Hb H inclusions, spastic paraplegia, club foot and optic anomalies. Thus, we anticipate that the presence of mental retardation and facial dysmorphy in a male will be the major criteria to consider a mutation in XNP as the causative factor. To study the function of the XNP gene product in normal and pathological conditions, we produced monoclonal antibodies against the XNP protein and performed immunocytochemical and western blot analyses on cells from various patients. Our results indicated that XNP expression was altered or absent in some cases. Based on these findings, we propose to use monoclonal antibodies directed against XNP to diagnose patients with mental retardation and mutations in this gene.

Program Nr: 355 from the 1999 ASHG Annual Meeting

Clinical features of the major form of childhood deafness, DFNB1, caused by a connexin26 gene defect. *F. Denoyelle[1,2], S. Marlin[1,2], D. Weil[2], E.N. Garabédian[1], C. Petit[2].* 1) Service d'ORL pédiatrique, Hôpital Armand-Trousseau, Paris, France; 2) Unité de Génétique des Déficits Sensoriels, Institut Pasteur, Paris, France.

DFNB1, an autosomal recessive form of deafness due to connexin26 gene (*CX26*) mutations, has been recently shown to be one of the most frequent hereditary defects in humans. To date, no clinical characterisation of the DFNB1 inner ear defects has been reported, which prevents the providing of prognostic information and proper genetic counseling. We searched for mutations in the non coding exon and in the coding region of *CX26* in 112 children (92 families) affected by sensorineural deafness with various degrees of hearing loss. The children either belonged to a family affected by autosomal recessive deafness (DFNB family) or represented sporadic cases. Audiometric, radiological and vestibular features were investigated and compared in deaf children with and without *CX26* mutations. Among the prelingually affected families, *CX26* mutations were present in 56.7% of DFNB families and 33.3% of the sporadic cases, versus none of the families with post lingual DFNB forms (p=0.01). The inner ear defects of 42 children carrying bi-allelic *CX26* mutations were compared with that of 50 prelingually deaf children without *CX26* mutations. DFNB1 deafness was mild to profound without genotype/phenotype correlation, associated to sloping or flat audiometric curves, radiologically normal inner ear and normal vestibular tests. The hearing loss was very rarely progressive. Frequent variations in the deafness severity between sibs were observed. The here described audiometric, vestibular and radiological characteristic features of DFNB1 would or should be the reference used to guide the order of *CX26* molecular diagnostic tests for deaf children with a compatible phenotype. A prognostic information can now be given to families: the hearing loss of the DFNB1 form of deafness is rarely progressive during childhood. A major element for the genetic counselling emerges: the severity of the hearing loss due to DFNB1 is extremely variable and cannot be predicted, even within families.

Program Nr: 356 from the 1999 ASHG Annual Meeting

A novel form of autosomal dominant movement disorder: familial dyskinesia and facial myokymia. *M. Fernandez[1], W. Raskind[1], J. Wolff[1,3], M. Matsushita[1], H. Lipe[3], T. Bird[1,2,3].* 1) Medicine and; 2) Neurology, Univ of Washington; 3) Veterans Affairs Puget Sound Health Care System, Seattle, WA.

Familial dyskinesia and facial myokymia (FDFM) is a novel autosomal dominant disorder characterized by adventitious movements that sometimes appear choreiform and that are associated with perioral and periorbital myokymia. The disorder has an early childhood or adolescent onset. The involuntary movements are paroxysmal at early ages, worsen, and may become constant in the twenties. Thereafter, there is no further deterioration and there may even be improvement in old age. The adventitious movements are worsened by anxiety, but not by voluntary movement, startle, caffeine or alcohol. The disease is socially disabling, but there is no intellectual impairment or decrease in lifespan. We report a four-generation family with 13 affected members, including 7 males and 6 females. We obtained samples from 9 affected and 3 unaffected members from three generations of this family. A simulation study suggested that the material available could provide a maximum lod score of 2.7. For this reason, a candidate gene approach was taken. We have focused on regions known to contain genes associated with chorea or myokymia. Using primers for polymorphic loci closely flanking or within genes of interest we excluded linkage to five regions: 1. The Huntington disease gene on chromosome 4p; 2. The paroxysmal dystonic choreoathetosis gene at 2q34; 3. The DRPLA gene at 12p13; 4. The choreoathetosis/spasticity disease locus on 1p that lies in a region containing a cluster of potassium (K^+) channel genes; 5. The episodic ataxia type 1 (EA1) locus on 12p that contains the KCNA1 gene and two other voltage-gated K^+ channel genes, KCNA5 and KCNA6. This latter area is of special interest not only because EA1 is caused by a K^+ channel gene mutation, but because the disease is also associated with myokymia. We are currently evaluating additional regions associated with chorea: 9q21 (chorea-acanthocytosis) and 20p (huntington-like disorder). Our results provide further evidence of genetic heterogeneity in autosomal dominant movement disorders and suggest a novel gene underlies this new condition.

Program Nr: 357 from the 1999 ASHG Annual Meeting

Age-related features of genetic mutations producing cognitive impairment: the Fragile X mutation, NF1, and Williams Syndrome. *G.S. Fisch[1], P.N. Howard-Peebles[2], N. Carpenter[3], J. Tarleton[4], R. Simensen[5], J.J.A. Holden[5]*. 1) Epidemiology & Public Health, Yale Univ School of Medicine, New Haven, Connecticut; 2) GIVF, Fairfax, and the Medical College of Viriginia, Richmond, Virginia; 3) Chapman Institute of Medical Genetics, Tulsa, Oklahoma; 4) Fullerton Genetics Center, Asheville, North Carolina; 5) Greenwood Genetics Center, Greenwood, South Carolina; Ongwanada Resource Centre, and Queens University, Kingston, Ontario.

Neurogenetic disorders of known etiology are valuable in that they provide a unique opportunity to study genotype-phenotype as well as brain-behavior relationships. Recently, our multicenter consortium investigated children and adolescents with the fragile X [fra(X)] mutation, noting longitudinal declines in composite IQ scores and adaptive behavior scores (DQ) in nearly all males with the full mutation and, to lesser extent, most fully mutated females. We were interested as to whether other genetic mutations of known etiology produced comparable age-related outcomes; or, whether the course of cognitive ability and/or adaptive behavior followed different temporal patterns. We obtained IQ and DQ scores, as well as maladaptive behavior scores, from children and adolescents diagnosed with the fra(X) mutation, Williams syndrome (WS), or Neurofibromatosis type 1 (NF1). Participants with NF1 (N=14) or WS (N=16) were age-matched with males diagnosed with the fra(X) mutation. IQ for all subjects was assessed with the Stanford-Binet 4th Edition; adaptive behavior (DQ) was evaluated using the Vineland Adaptive Behavior Scales. Our findings show strong and significant negative correlations between chronological age (CA) and either IQ or DQ among individuals with the fra(X) mutation and WS. Correlation between age and IQ in fra(X) was $r=-.74$ ($p<.005$); in WS, $r=-.73$; ($p<.005$). Correlation between age and DQ in fra(X) was $r=-.53$ ($p<.05$); in WS $r=-.86$ ($p<.001$). Unlike these individuals, children and adolescents with NF1 show modest positive correlations between age and IQ. All three etiological groups display significant age-related decreases in adaptive behavior scores. Additional analyses will be presented and discussed.

Program Nr: 358 from the 1999 ASHG Annual Meeting

A nonsense mutation of the *ATRX* gene causing mild, moderate and profound mental retardation in members of a single family. *R.J. Gibbons[1], R. Guerrini[2], J.L. Shanahan[1], R. Carrozzo[3], P. Bonanni[2], D.R. Higgs[4]*. 1) Nuffield Department of Clinical Biochemistry and Cellular Science, University of Oxford, John Radcliffe Hospital, Headington, Oxford, OX3 9DU, UK; 2) Institute of Child Neurology and Psychiatry, University of Pisa, and Institute for Clinical Research Stella Maris Foundation, Pisa, Italy; 3) Servizio di Genetica Medica e Laboratorio di Citogenetica, Ospedale San Raffaele, Milano, Italy; 4) MRC Molecular Haematology Unit, Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK.

Mutations in the X-encoded gene *ATRX* are known to give rise to severe syndromal mental retardation. Here we describe a pedigree including 4 affected members aged 17 to 45 years. Two patients with the typical facial features of ATR-X syndrome have moderate (IQ41) and profound mental retardation (IQ unmeasurable on the Weschler scale) respectively. The other two presented with mild mental retardation (IQ56 and IQ58) and epilepsy but without the characteristic facial dysmorphism. While the two more severely affected boys had the characteristic facial features of ATR-X syndrome, there was no correlation between the degree of mental retardation and the severity of any other clinical or hematological features.

Mutation analysis identified a previously unreported 324C>T nonsense mutation in exon 2 of the *ATRX* gene in all four patients. No alternative splicing that might lead to the skipping of exon 2 could be detected in any of the affected individuals or normal controls. The explanation for the marked phenotypic variability between the affected individuals is as yet unexplained.

In the past, mutations in the *ATRX* gene have only been found in individuals with severe mental retardation and a variety of major developmental abnormalities. The striking phenotypical variability observed in this pedigree has important implications for counselling affected families and suggests that mutations in this gene should be considered as a cause of mild MR in male patients lacking specific diagnostic features.

Program Nr: 359 from the 1999 ASHG Annual Meeting

Madelung deformity in childhood is the result of SHOX haploinsufficiency. *I.A. Glass[1], S. Flanagan[1], M. Berry[2], D. Vickers[3], J.A. Batch[1], G. Rappold[4], V. Hyland[5]*. 1) Queensland Genetics Service and Department of Paediatrics, University of Queensland, Herston Hospitals Campus,Brisbane, Australia; 2) Mater Hospital Laboratory Services, Brisbane; 3) Department of Orthopaedics,Royal Childrens Hospital, Brisbane; 4) Institute of Human Genetics,University of Heidelberg, Germany; 5) Molecular Genetics, Department of Pathology, Royal Brisbane Hospital.

The madelung deformity is an abnormality of the forearm characterised by shortening and bowing of the radius with subluxation of the distal ulna. The exact proportion of madelung attributable to Leri-Weill syndrome(LWS),a sex-linked mesomelic skeletal dysplasia with disproportionate short stature, has historically been a contentious issue. Haploinsufficiency of the homeobox gene SHOX which maps to PAR1, appears to be the molecular basis of LWS. We have undertaken SHOX molecular analysis of 11 probands (10F,1M)who presented for orthopaedic surgery for correction of their madelung deformity. FISH analysis was carried out on metaphase spreads of peripheral lymphocytes. Cosmid LLNOYCO31M134F5 containing SHOX exons 1(part) to 5b was labelled with biotin, hybridised to the metaphases and detected by incubation with mouse monoclonal anti-biotin antibody,followed by goat anti-mouse-Oregon Green 488 antibody.We detected absence of SHOX signal in 6/11 probands,indicating large scale SHOX deletions were present. Further investigation of the 5 portion of SHOX exon 1 was performed using a 5intragenic SHOX dinucleotide repeat,but no further deletions were detected by this approach. Sequencing of theSHOX exons in the remainder of this cohort identified a patient harboring a heterozygous C to T transition(R195X). In one family, where the proband manifested a SHOX deletion, the demonstration of normal SHOX signals in a sibling, with equivocal radiological signs of early madelung deformity enabled this individuals status as a gene carrier to be clarified. We conclude that a substantial proportion of madelung deformity is due to LWS/SHOX haploinsufficiency and that molecular analysis of such cases may be useful for genetic counselling purposes.

Program Nr: 360 from the 1999 ASHG Annual Meeting

Expression of cholesterol biosynthetic enzymes is upregulated in Smith Magenis syndrome fibroblasts. *O. Goker-Alpan[1], J. Blancato[3], A.C.M. Smith[2,3], W.A. Gahl[1]*. 1) HDB, NICHD/NIH, Bethesda, MD; 2) NHGRI/NIH, Bethesda, MD; 3) Georgetown Univ., Washington DC.

Smith-Magenis syndrome (SMS), due to interstitial deletion of 17p11.2, is associated with distinctive phenotypic features and mental retardation. Most patients are deleted for the interval between the markers D17S58 and cCI17-498. This interval includes the locus for the human sterol regulatory element binding protein-1 (SREBP-1) gene, which produces isoforms a and c by alternative splicing. The SREBP family of transcription factors transduces intracellular signals activated by cholesterol into the nucleus to induce expression of several genes responsible for the synthesis of cholesterol and LDL-receptors. Past clinical studies have documented hypercholesterolemia, mainly due to an increased LDL fraction, in some children with SMS (Smith et al., 1998, AJHG 63(4) Suppl. A19). To investigate the effects of haploinsufficiency of SREBP-1a and -1c in humans, we performed molecular and cytogenetic studies on fibroblasts from children with documented hypercholesterolemia who were deleted for the SMS critical region.

FISH, performed using purified BAC clones containing nucleotides 368-660 of SREBP-1 cDNA as a probe, demonstrated deletion of SREBP-1 in 10 of 10 children with SMS. On Northern blot analysis, fibroblasts from 3 SMS patients manifested elevated levels of mRNA for HMGCoA reductase, farnesyl diphosphate synthetase and squalene synthetase, enzymes involved in cholesterol synthesis. There was also upregulation of SREBP-2 mRNA.

Several transgenic mouse models exist to study the regulation of cholesterol biosynthesis by SREBPs. In mice homozygously deleted for SREBP-1a and -1c, the levels of SREBP-2 were increased along with increased transcription of genes encoding cholesterol biosynthetic enzymes; heterozygotes appeared normal (Shimano et al., 1997, JCI 100(8): 2115-2124). Nevertheless, we are considering whether haploinsufficiency of SREBP-1 in human fibroblasts might produce effects comparable to those in mice homozygously disrupted for SREBP-1.

Program Nr: 361 from the 1999 ASHG Annual Meeting

Creating a mouse model for DiGeorge(DGS)/Velocardiofacial Syndromes. *P.C. Hsieh[1,2], W. Kimber[3], A. Chen[2], S. Hirotsuni[2], R. Paylor[4], A. Wynshaw-Boris[2,5]*. 1) HHMI Research Scholars Program, HHMI-NIH, Bethesda, MD; 2) Genetic Diseases Research Branch, National Human Genome Research Institute, National Institute of Health, Bethesda, MD; 3) Department of Physiology, School of Medicine, Johns Hopkins University, Baltimore, MD; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Department of Pediatrics, School of Medicine, University of California, San Diego, CA.

DiGeorge syndrome is a clinical disorder caused by failure of third and fourth branchial derivatives to develop properly during embryogenesis. DiGeorge patients typically have impaired cellular immunity, hypocalcemia, congenital heart defects, and facial dysmorphism. Genetic analyses have shown that over 90% of DiGeorge patients have hemizygous interstitial deletions of ~2Mb in human 22q11. Over 85% of Velocardiofacial patients and more than 25% of Conotruncal Face Anomaly patients have similar hemizygous deletions. Therefore, these syndromes are a group of related disorders resulting from haploinsufficiency of gene(s) located in 22q11. Comparative mappings between the human and mouse genomes have shown that syntenic region of 22q11 is conserved on mouse chromosome 16, despite differences in gene order. Using a conventional gene targeting, the DiGeorge Minimal Critical Region (DGMCR) was deleted in ES cells. The ~150kb deletion was confirmed by Pulse-Field Electrophoresis and FISH. Chimeras were generated with this DiGeorge Direct Deletion ES clone, and they were healthy and viable. DiGeorge Direct Deletion (DGDD) mouse lines were generated from these chimeras. Analyses of DGDD mice have shown a marked reduction in fertility in the 129 inbred DGDD heterozygotes compared to wild-type mice. Behavior studies have shown an increase in pre-pulse inhibition in DGDD heterozygous mice. Homozygous DGDD in both backgrounds are early embryonic lethal, indicating gene(s) within DGMCR are essential for embryonic development.

Program Nr: 362 from the 1999 ASHG Annual Meeting

Gastroesophageal reflux and irritable bowel syndrome in classical and hypermobile Ehlers Danlos syndrome (EDS). *H.P. Levy[1], W. Mayoral[2], K. Collier[2], T.L. Tio[2], C.A. Francomano[1]*. 1) NHGRI, NIH, Bethesda, MD; 2) Georgetown University Medical Center, Washington, DC.

Rupture of the GI tract is a known manifestation of vascular EDS (type IV), and diverticuli and hiatal hernia have been reported without specification of EDS subtype. However, the spectrum and frequency of GI complications in classical (types I and II) and hypermobile (type III) EDS have not been established.

We reviewed the charts of 51 EDS patients for GI findings. 38 patients had classical, and 13 had hypermobile EDS. Age range was 8 to 78 years. Sex ratio was biased, with F:M=41:10 (30:8 classical and 11:2 hypermobile). Gastroesophageal reflux (GERD) was suspected clinically in 26 of 45 patients [58%] for whom data was available (17 of 32 classical [53%] and 9 of 13 hypermobile [69%]). Irritable bowel syndrome (IBS), defined as chronic intermittent diarrhea and/or constipation, with or without abdominal cramps, was reported by 24 of 43 patients (56%) for whom data was available (18 of 30 classical [60%] and 6 of 13 hypermobile [46%]. Also, 4 patients (2 classical, 2 hypermobile) had endoscopic diagnoses of non-specific inflammatory bowel disease (IBD); thus 28 of 47 informative patients [60%] had IBS or IBD. Overall, 34 of 47 patients [72%] had any combination of GERD, IBS & IBD. If all missing data was considered negative, the overall prevalence would be 26 of 51 [51%] for GERD and 28 of 51 [55%] for IBS/IBD.

EDS patients may have chronic pain, leading to NSAID-induced gastritis mimicking GERD or narcotic-induced symptoms mimicking IBS. Alternatively, EDS may cause reduced lower esophageal sphincter tone, increased distensibility, and/or decreased GI motility, resulting in GERD and/or IBS. Autonomic dysfunction could cause both GERD and IBS. 10 patients had suspected or confirmed cardiovascular autonomic dysfunction; 9 also had GI complications.

We conclude that GERD and IBS are common complications of classical and hypermobile EDS, and should be sought and treated in these patients.

Program Nr: 363 from the 1999 ASHG Annual Meeting

Clinical features of familial thoracic aortic aneurysms/dissections. *D.M. Milewicz[1], M. Jewell[1], M. Willing[2], D. Guo[1]*. 1) Dept Internal Medicine, Univ Texas Medical Sch, Houston, TX; 2) Univ of Iowa, Iowa City, Iowa.

Autosomal dominant inheritance of thoracic aortic aneurysms and dissections (TAA) occurs in individuals with Marfan syndrome (MFS) and is due to FBN1 mutations. TAAs can also be inherited in an autosomal dominant manner in the absence of skeletal and ocular features of MFS. Ten families with multiple members with TAAs in the absence of ocular and skeletal complications of MFS have been identified and medical records and autopsy reports of affected members reviewed. Individuals at risk for developing TAAs underwent echocardiograms to evaluate the proximal aorta. DNA was collected for linkage analysis. The pattern of inheritance of TAAs was autosomal dominant in these families but the age of onset of aortic disease was highly variable (ranging between 26 and 80 years of age in one family) and there was decreased penetrance of the disorder. The majority of affected individuals presented with asymptomatic aortic root dilatation or acute type I dissections; 1 individual presented with an aneurysm involving the descending thoracic aorta. Histopathology of the aorta showed fragmentation and loss of elastic fibers in the media. The majority of affected males had inguinal hernias. Four of the families had an individual with a cerebral aneurysm who did not have an aortic aortic aneurysm. The phenotype was not linked markers within FBN1 in these families. Described here are the clinical features of autosomal dominant TAA syndrome with decreased penetrance and variable expression that is not due to FBN1 mutations. Cerebral aneurysms and inguinal hernias may be other phenotypic manifestations of the syndrome.

Program Nr: 364 from the 1999 ASHG Annual Meeting

Deletion length correlates with IQ in Williams Syndrome. *C.A. Morris[1], C.B. Mervis[2], B.F. Robinson[2], N. DeSilva[3], P.A. Spallone[4], A.D. Stock[4], X. Lu[5], X. Meng[5], M.T. Keating[5].* 1) Pediatrics, Genetics Division, Univ. Nevada Schl. of Medicine, Las Vegas, NV; 2) Psychology, Univ. of Louisville, Louisville, KY; 3) Univ. Kentucky Schl. of Medicine, Lexington, KY; 4) Pathology, Univ. Nevada Schl. of Medicine, Reno, NV; 5) Howard Hughes Institute, Univ of Utah, Salt Lake City, UT.

Williams Syndrome(WS) is a multisystem disorder that includes dysmorphic facial features, supravalvar aortic stenosis(SVAS), an unusual personality, and unique cognitive profile(WSCP) characterized by strengths in auditory rote memory and language and weakness in visuospatial constructive cognition. WS is caused by a 1.5Mb deletion of chromosome 7q11.23, defined by the interval between markers D7S1778 and D7S489A. We have previously described SVAS kindreds with normal IQ but demonstrating the WSCP, associated with smaller deletions within the region ranging from 83-500kb. We have also shown that individuals with classic WS who have deletions greater than 1.5Mb have lower IQ scores than the WS mean. To determine if smaller deletion size is correlated with better cognitive ability in WS, we studied deletion lengths in 200 individuals with the classic phenotype; only one had a shorter deletion (1Mb), bounded on the telomeric end by genomic clone B270D13. That man had a K-BIT IQ of 95, as compared to the WS mean of 66.27(SD 14.73); he also fit the WSCP. Of the remaining individuals, 12 had IQs between 86 and 97. These data suggest that although a short deletion may contribute to a high level of functioning in a small number of individuals with WS, factors other than deletion size must also be involved.

Program Nr: 365 from the 1999 ASHG Annual Meeting

Extreme anticipation and unusual multisystem phenotype in a family with Spinocerebellar Ataxia Type 7 (SCA7). *S.E. Palmer[1], P. Gunaratne[2], C.S. Richards[2], R.A. Saldivar[3], K.S. Kagan-Hallet[1]*. 1) Depts. Pediatrics or Pathology, Univ Texas Health Sci Ctr, San Antonio, TX; 2) Dept. Molec. & Human Genetics, Baylor College of Medicine, Houston, TX; 3) Dept. Pathology, Santa Rosa Childrens' Hosp., San Antonio, TX.

A 14-month-old child presented in the terminal phase of a progressive encephalopathy. Additional features included chronic hepatomegaly, coarse facies, pigmented retinopathy, and episodic mild metabolic acidosis. Neurodegeneration began in mid-infancy. Mitochondrial, metabolic, and hepatic evaluations were negative except for Fanconi pattern in urine. Muscle histology was nonspecific, possibly due to disuse; CNS scans showed atrophy. Paternal family history revealed recent onset of "cone dystrophy" in the father (age 23), and 10-year history of macular degeneration and ataxia in an aunt (age 20s) without diagnosis; the asymptomatic grandfather (age 60) has a brother who became "crippled and blind" (age 50s) whose daughter has "multiple sclerosis" (age 30s). SCA7 mutation analysis of the proband by PCR assay showed an extremely large expansion (size indeterminate, molecular characterization pending). The father was found to carry an expanded SCA7 allele with 52 repeats. Prenatal diagnosis of two sibling pregnancies showed large expansions similar in size to that of the proband. Autopsy of the proband showed two unusual non-CNS findings: 1) papillary fibroelastosis and ventriculomegaly suggestive of hypertrophic cardiomyopathy; and 2) striking renal tubulopathy with dilated tortuous tubules. Cerebellar histology showed pancellular loss and expected intranuclear inclusions. This family displays the striking anticipation with infancy onset known to occur with paternally-transmitted SCA7 alleles. The additional systemic features in the proband, suggestive of mitochondrial or metabolic disorder, are highly likely to be related to the very large expansion since exhaustive clinical workups were otherwise negative. The presence of heart and kidney disease in this young child, apparently due to a greatly expanded SCA7 allele, may provide futher insight about the molecular pathophysiology of this trinucleotide repeat expansion.

Program Nr: 366 from the 1999 ASHG Annual Meeting

The Neonatal Progeroid (Wiedemann-Rautenstrauch) Syndrome. Report of five new cases and review of the literature. *E.K. Pivnick[1], B. Angle[2], R.A. Kaufman[1], B.D. Hall[3], P. Pitukcheewanont[1], J.H. Hersh[2], J.L. Fowlkes[3], L.P. Sanders[4], J.M. O'Brien[4], G.S. Carroll[1], W.M. Gunther[1], H.G. Morrow[5], G.A. Burghen[1], J.C. Ward[1]*. 1) University of Tennessee, Memphis, TN; 2) University of Loisville, Louisville, KY; 3) University of Kentucky, Lexington, KY; 4) Central Baptist Hospital and Maternal-Fetal Medicine, Lexington, KY; 5) South Memphis Clinic, Memphis, TN.

The Neonatal Progeriod Syndrome (NPS) which is also known as the Wiedemann-Rautenstrauch syndrome is a rare autosomal recessive disorder characterized by generalized lipoatrophy except for fat pads in the suprabuttock areas, hypotrichosis of the scalp hair, eyebrows, and eyelashes, relative macrocephaly, triangular face, natal teeth, and micrognathia. We report 5 new patients who demonstrate phenotypic heterogeneity and who represent the single largest series of NPS reported to date. Two of the patients are from an African-American kindred, which have not been reported previously. The fact that there are 2 pairs of siblings among the 5 patients further establishes that NPS is an autosomal recessive condition. This report also includes a complete review of the previously reported 16 patients and compares them to the 5 new patients. Abnormalities in endocrine and lipid metabolism were found in 3 of our 5 patients. Skeletal findings in 2 of our patients demonstrated some new findings as well as the typical radiological abnormalities previously noted in NPS. It is apparent, based on the 21 cases, that mild to moderate mental retardation is common in NPS. Long term follow-up of patients with NPS should provide more information relative to their ultimate psychomotor development. NPS is usually lethal by 7 months, however, on rare occasions, patients have survived past infancy or the teens. Our three surviving patients range in age from 16-23 months. Variability in the phenotype of NPS is clear from the 16 literature cases and the 5 additional cases reported herein. However, the phenotype remains distinct enough to allow a secure diagnosis.

Program Nr: 367 from the 1999 ASHG Annual Meeting

Distinct neurological profile in Williams syndrome. *B.R. Pober, A.M. Szekely.* Dept Genetics, Yale Univ Sch Medicine, New Haven, CT.

Williams syndrome (WS) is due to a chromosome microdeletion involving multiple genes, several of them demonstrating brain-specific expression. However, neurological problems in WS have received little attention in the medical literature. We performed a full neurological evaluation on 51 WS subjects (32 females and 19 males) ages ranging from 6-49yrs (mean=22yrs). The authors, one of whom is a trained neurologist, conducted a neurological review of systems and systematic examination lasting 45 minutes.

The most striking findings included a variety of abnormalities involving cerebellar dysfunction. More than 50% of subjects had impaired control of eye movements (ocular dysmetria, abnormal saccades and jerky pursuit) while >70% had dysmetria, dyssynergia, dysdiadochokinesis and ataxia. Intriguingly, many subjects who had pronounced difficulty in performing rapid alternating movements demonstrated preserved rhythm tapping skills. Another common neurological abnormality included marked hyperreflexia along with pathological reflexes (70% of cases). Several neurological signs were most prevalent in teenagers and young adults, particularly cerebellar dysfunction and reflex abnormalities. Others, like postural instability, resting tremor and frontal release signs, appeared most frequently in older adults.

Among 5 subjects with MRI documented Chiari malformation I (CM I), 3/5 had symptoms (headache, visual complaints) and/or neurological manifestations (i.e. weakness, atrophy, sensory loss, diminished tendon reflexes of the upper extremities) characteristic of CM I. Close to 20% of the remaining subjects had symptoms and at least one sign indicating that they should be screened for CM I.

Our data suggest that persons with WS show a specific pattern of neurological abnormalities including prominent cerebellar dysfunction and distinct age-related changes. These findings can aid clinical management as well as provide insight into abnormal neurological processes that may result from disturbed function of CNS-specific genes in the WS critical region.

Program Nr: 368 from the 1999 ASHG Annual Meeting

Magnetic Transfer Imaging in Smith-Lemli-Opitz Syndrome. *F.D. Porter[1], N. Richert[2], J. Frank[2], N. Nwokoro[1].* 1) HDB/NICHD, NIH, Bethesda, MD; 2) LDRR/CC, NIH, Bethesda, MD.

The Smith-Lemli-Opitz Syndrome (SLOS) is due to an inborn error of cholesterol biosynthesis. Individuals with SLOS have mutations in the 7-DHC reductase gene. Consequently, they have elevated serum levels of 7-DHC and reduced serum cholesterol levels. Currently treatment of SLOS includes dietary cholesterol supplementation. Although marked improvements in behavior have been noted, it is not clear what the long term effect, if any, dietary cholesterol supplementation will have on the central nervous system. The purpose of this study is to determine whether Magnetic Transfer Imaging (MTI) can provide a quantitative measure of abnormal myelin in SLOS patients. MTI imaging measures the exchange between bound (macromolecular) water and free water in tissues after selective saturation of the bound water fraction with an off resonance radiofrequency pulse. The amount of magnetic transfer, calculated as the MT ratio (MTR) is determined by the equation: MTR=M0-Ms/M0x100 where M0 and Ms represent the signal intensities of images obtained with (Ms) and without (M0) the saturation pulse. MTI exams were performed on 10 SLOS patients (4M:6F; age 0.6-12 yr), 3 healthy pediatric patients (mean age 1.4 yr.) and 4 healthy adults (mean age 37 yr.) using 1.5 T unit. Images were obtained using a T1-weighted pulse sequence with and without a MT saturation pulse. MT images were co-registered to each other, and MTR was determined on a voxel by voxel basis. In SLOS patients, an age-dependent increase in the MTR histogram peak (Hp) and histogram mean (Hm) was observed. The Hp increased from 0.26 (at age 0.6yrs) to 0.34 (at age 10 years); and the Hm increased from 0.24 to 0.33 in the same age group. Linear regression analysis demonstrates a relatively strong correlation (r=0.721) between MTR and age in SLOS group. This is in contrast to normal pediatric patients where maximum MTR values in grey and white matter are observed by 20 months of age. Although no longitudinal serial data is yet available, these results suggest that there are ongoing changes in the myelin structure in SLOS patient and this technique may provide a tool for monitoring therapeutic interventions.

Program Nr: 369 from the 1999 ASHG Annual Meeting

Smith-Magenis syndrome: A genomic disorder with a common molecular mechanism and variable clinical phenotype. *L. Potocki[1,3], K.-S. Chen[1], D.E. Osterholm[1], L.G. Shaffer[1], J.R. Lupski[1,2,3]*. 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies mental retardation syndrome associated with a deletion of chromosome 17p11.2. We have previously described the clinical phenotype of SMS in 27 patients (Greenberg et al. 1996). We have extensively characterized the clinical phenotype in an additional 29 SMS patients under the SMS clinical research protocol through the General Clinical Research Center at Texas Children's Hospital. The multidisciplinary study includes developmental and speech and language assessments, ophthalmologic, audiologic, and otolaryngologic evaluation, echocardiogram and EKG, sleep study with EEG, renal ultrasound, scoliosis survey, urinalysis, thyroid function studies, immunoglobulin levels, lipid profile, complete blood count, and levels of blood urea nitrogen and creatinine. Common findings include ophthalmologic anomalies, hearing impairment, cardiac anomalies, hypercholesterolemia, and sleep disturbance. While common phenotypic features can be defined, a wide range of clinical variability exists between patients. It had been postulated that this phenotypic variation among SMS patients could be due to variations in the size of the deletion, although a common deletion region was assigned by polymorphic marker analysis. We have shown that the SMS microdeletion occurs by unequal crossing over due to homologous recombination between flanking repeat gene clusters (SMS-REPs). Herein we present clinical data on 56 SMS patients, and the data of pulsed-field gel analyses on the majority of SMS patients subjected to the multidisciplinary clinical evaluations. A patient-specific junction fragment was identified in more than 90% of SMS patients with the common deletion (as defined by G-band and FISH analyses). Interestingly, although the majority of SMS patients have the same sized deletion, the clinical spectrum is variable. These data suggest that other factors, such as the unmasking of recessive alleles, or modifier loci may cause variability in the phenotype of SMS.

Program Nr: 370 from the 1999 ASHG Annual Meeting

VACTERL-H features associated with a deletion of *ZIC3* in Xq26.2. *S.M. Purandare[1], D. Chitayat[2], G.B. Ferrero[3], C.D. Kashork[4], B. Marino[3], L.G. Shaffer[4], B. Casey[1]*. 1) Pathology, Baylor College of Medicine, Houston, TX; 2) Hospital for Sick Children, University of Toronto, Ontario, Canada; 3) Pediatrics, University of Turin, Turin, Italy; 4) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Loss of appropriate left-right positional information during development results in situs abnormalities. These comprise complete reversal (situs inversus) or indeterminate sidedness (situs ambiguus) of organs in the chest and abdomen. Previously we identified coding-region mutations in an X-linked transcription factor, *ZIC3*, among cases of familial and sporadic situs abnormalities. We now describe a 1.3 Mb deletion encompassing *ZIC3* that segregates through a family with at least four affected males with situs abnormalities and one male with features of VACTERL-H association. Fetal ultrasound and post-mortem analysis of the proband showed situs ambiguus (complex heart malformation, asplenia, right sided stomach and pancreas, bilateral trilobed lungs), renal hyperplasia, imperforate anus, and digit anomalies. His maternal uncle, however, manifested features of VACTERL-H, including dysraphic lumbar spine, imperforate anus, heart malformations, horseshoe kidney, limb anomalies, and aqueductal stenosis with hydrocephalus; no features diagnostic of left-right axis anomalies were present. Sequence-tagged site (STS) analysis of the proband by PCR failed to amplify seven markers between sWXD1184 and DXS1062 inclusively, which span aproximately 1.3 Mb in Xq26.2. FISH analysis using a cosmid probe from the deleted region detected 6 female carriers across 4 generations. A number of VACTERL-H families consistent with X-linked inheritance have been described. Our results raise the possibility that mutations in *ZIC3* and/or closely-linked genes in Xq26.2 may be responsible for some of these cases.

Program Nr: 371 from the 1999 ASHG Annual Meeting

Brachydactyly with fibular hypoplasia is associated with a dominant mutation in CDMP1. *N.H. Robin[1], D.B. Everman[1], J. Hecht[2], S.M. Morrison[3], M.L. Warman[1].* 1) Dept Genetics, Case Western Reserve Univ School of Medicine, Cleveland, OH; 2) University of Texas Medical School, Houston; 3) Dept Radiology, Case Western Reserve Univ School of Medicine, Cleveland, OH.

Brachydactyly (BD) refers to the underdevelopment of skeletal elements within hands and feet. Isolated heritable brachydactylies can be classified into subtypes BDA through BDE based upon the pattern of digital involvement. We have previously shown that one autosomal dominant brachydactyly, BDC, is caused by functional haplo-insufficiency for Cartilage Derived Morphogenetic Protein-1 (CDMP1) on human chromosome 20. Homozygous mutations in this gene also cause two severe skeletal phenotypes, Hunter-Thompson acromesomelic dysplasia (HT) and Grebe syndrome (GS). Each, in addition to hand involvement, has severe reduction defects of the arms and legs; as expected, brachydactyly was observed in obligate heterozygotes in Grebe syndrome families. To determine whether there may exist mutations within CDMP1 which cause phenotypes intermediate between BDC and GS/HT, we evaluated two unrelated probands who manifest brachydactyly and fibular hypoplasia. Fibular hypoplasia has not been observed in BDC patients with previously identified functional haploinsufficiency mutations in CDMP1. Both probands were found to have an identical C-T transition within CDMP1 that changes and Arginine to Tryptophan within the consensus RXXR polypeptide cleavage site. This change was not observed in 100 control alleles. The RXXR cleavage site is necessary for normal processing of CDMP1 protein dimers. One of our two probands has an identically affected sister who also has this mutation, as does her father. However, he manifests only brachydactyly. Our other proband's mother and maternal aunt are reported to have small hands and clubfeet. In addition, this proband's fetus has fibular hypoplasia detected by prenatal ultrasound. DNA and radiographic studies are pending for the mother, aunt, and fetus. Our results suggest that mutations which affect the RXXR cleavage site cause a dominant negative effect leading to a phenotype which is intermediate between BDC and GS/HT.

Program Nr: 372 from the 1999 ASHG Annual Meeting

Frequency and type of mutations within the human JAG1 gene in Alagille Syndrome. *A. Roepke, A. Kujat, M. Graeber, I. Hansmann, I. Giannakudis.* Humangenetik, Martin-Luther-Universitt, Halle/S., Sachsen-Anhalt, Germany.

Alagille syndrome (AGS, MIM# 118450, McKusick, 1998) is an autosomal dominant disorder characterized by liver disease with heart, skeletal, ocular and facial abnormalities. The gene JAG1 on chromosom 20p12 has been identified as responsible for AGS. JAG1 encodes a ligand in the Notch signaling pathway, that plays an important role in cell fate determination. JAG1 spans 36 kb, comprises 26 exons and encodes a 1218 amino acid protein with several domains and high interspecies conservations. We screened 74 AGS patients by SSCP and sequencing to evaluate frequency and type of mutation in the JAG1 gene. Of the 74 patients, 50 (68%) have mutations within JAG1: we found 13 (18%) small deletions, 6 (8%) small insertions, 10 (14%) nonsense mutations, 9 (12%) missense mutations and 12 (16%) splice site mutations. Most of the mutations (88%) are, by computational analysis, expected to result in a truncated protein thus leading to loss of functional domains that are responsible for the interaction with the Notch receptor. This observation is consistent with haploinsufficiency of JAG1 as well as with a dominant negative effect. One mutation was found in exon 26 within the transmembrane domain. This mutation should reduce the hydrophobicity of this region. 8 of 9 missense mutations occur in exons 4-6 and show an exchange of amino acids which are highly conserved from Drosophila to human. These regions may be important for the ligand-receptor interactions. Yet, the mutations are distributed over the entire gene evidence is provided for a mutational bias in exon 5 and 17. To date no mutations were found in exon 8. In 25 out of 41 cases (61%) a de novo mutation was found. In 16 families (39%) the mutation could be determined as maternal (n=10) or paternal (n=6). According to our analysis which includes deletion screening by microsatellites as well, up to 10% of the cases are due to genetic mosaicism. Mosaicism was also detected in clinically normal patients with AGS, which has to be taken into account in genetic counselling. This work was supported by the DFG.

Program Nr: 373 from the 1999 ASHG Annual Meeting

The Neurodevelopmental Profile of Young Children with Sex Chromosome Variations (SCV)Prenatally Diagnosed. *C.A. Samango-Sprouse*[1,2]. 1) Pediatrics, Children's Natl Medical Ctr, Washington, DC; 2) George Washington University Washington, D.C. 20020.

Few studies have investigated the neurocognitive profile of young children with SCV who are prenatally diagnosed. A large prospective study of 43 subjects with SCV was undertaken.The Bayley Scales of Infant Development(BSID-II), the Gesell Developmental Schedules and the Preschool Language Scale(PLS-3) were used for the neurodevelopmental assessments. Socioeconomic status was determined using the Hollingshead Social Class Index. Muscle tonus was evaluated using the Bobath neurodevelopmental approach. Data was compared to population norms since family studies were not possible because many probands were often first children. The mean age of the study subjects was 16 months (range 2-60 mos). There were 35 XXY, 3 XXX and 4 XYY. 36 patients were Caucasian, 2 were African-American and 3 were of Hispanic origin.The social class was class 3 or middle income or higher.The mean MDI was 99.70 (sd=20.5)with several children testing in the superior range of intelligence. The mean PDI ws 100.3(sd=18.5),the mean fine-motor score(FMDI) was 102.58, the mean receptive language score (RL)was 98.76(sd=18.9),and the mean expressive language score(El)was 89.5 (sd=16.5). Findings from the BSID indicate high risk factors in attention and emotional regulation. 20 percent of children had torticollis and significant delays in unilateral balance reactions. Truncal hypotonia was present in 68 percent and 40 percent had appendicular hypotonia. There was a significant discrepancy between expressive and receptive language skills that was evident by 18 months of age. 33 percent of all children received early intervention services. Preliminary findings of this study demonstrate an increased prevalence of developmental disruption in children with SCV evident during preschool years. Further studies are necessary to determine the natural history of brain and behavior relationships associated with SCV. Families should be counseled that these children may require therapeutic services during preschool years to optimize their neurocognitive development and school achievement.

Program Nr: 374 from the 1999 ASHG Annual Meeting

Recognition of Congenital Heart Disease as a component of a distinct Prader-Willi Syndrome infant phenotype due to a combination of Mosaic Trisomy 15 with Maternal Uniparental Disomy 15. *L.R. Shapiro[1,3], M. Gewitz[2,3], P. Woolf[2,3], B. Fish[2,3], S. Ingram[1], B.F. Golden[1], R. Marion[4].* 1) Pediatrics/Medical Genetics, New York Medical Col, Valhalla, NY; 2) Pediatrics/Cardiology, New York Medical Col, Valhalla, NY; 3) Westchester Medical Ctr, Valhalla, NY; 4) Albert Einstein Col of Medicine, Bronx, NY.

The usual infant phenotype of Prader-Willi Syndrome (PWS) includes hypotonia and craniofacial features but *not* congenital heart disease (CHD). The major pathogenic mechanisms are a deletion of a paternal chromosome 15(q11-q13) or maternal uniparental disomy (UPD) of chromosome 15 resulting from maternal meiotic non-disjunction, subsequent trisomy 15 and *rescue* by loss of the paternal chromosome 15 in some cells (trisomy 15 mosaic) or all cells.

While trisomy 15 mosaicism has been reported in amniocytes and CVS, only 4 liveborn infants have been reported and had severe CHD, facial dysmorphism and skeletal abnormalities. The *combination* of trisomy 15 mosaicism *with* maternal UPD 15 has been reported in only 4 liveborns who had hypotonia (4/4), dysmorphic facies (3/4) and CHD (2/4); however, the diagnosis of PWS was not considered in any of these infants. When trisomy 15 mosaicism *combined* with maternal UPD 15 was detected prenatally, it could be confirmed postnatally in fibroblasts but not lymphocytes.

Two*additional* liveborn infants are hereby reported who were diagnosed with PWS (hypotonia and facial features) *and* severe CHD and found to have the combination of low level trisomy 15 mosaicism *with* maternal UPD 15. With recognition and approriate diagnostic testing, it is possible that more infants with severe CHD will be found to have the *combination* of low level trisomy 15 mosaicism with maternal UPD 15.

In conclusion, severe CHD in an infant with hypotonia and facial dysmorphism may be due to this distinct form of PWS which may represent a more common cause of severe CHD in early infancy than previously appreciated.

Program Nr: 375 from the 1999 ASHG Annual Meeting

Loss of chromosome 13 and tetraploidy in human vascular endothelial cells in culture. *H.M. Aviv[1], L. Zhang[2], S. Patel[1], A. Bardeguez[3], K. Okuda[2], M. Kimura[2], A. Aviv[2].* 1) Center for Human and Molec. Genetics; 2) Hypetension Res. Center; 3) Dept. of OB/GYN, UMDNJ, Newark, NJ.

Previously, we found that *in vivo* the frequency of aneuploidy, mainly tetrasomy, of vascular endothelial cells (VECs) of the human abdominal aorta increased with the donor's age, reaching a prevalence of 30% of VECs in older persons. In this study, we monitored aneuploidy in serially passed VECs from the umbilical veins of 8 healthy newborns until replicative senescence. The cells were cultured in enriched growth medium containing a number of growth factors. Chromosome analysis was performed approximately every 7 population doublings (PD), continuing up to a few PDs before senescence. Chromosome analysis was also performed in 3 fibroblast cell strains from circumcision skin specimens of newborns.

Initially, all cultures of VECs had normal karyotypes. However, a consistent pattern of aneuploidy emerged in later passages. Seven of the 8 cell strains lost chromosome 13 in 100% of metaphase cells in mid-passage (PD 28-56) and 5 of the 8 cell strains gained chromosome 11, although usually not in all metaphase cells. Only cell strain #2, the cell strain that did not exhibit loss of chromosome 13, gained chromosome 11 in 100% of cells by PD 28. Five of the 7 cell strains that lost chromosome 13 in 100% of cells became hypotetraploid by the next chromosome analysis. The fibroblast cell strains, grown until senescence in enriched and regular growth medium did not exhibit consistent aneuploidy. Thus, it appears that loss of chromosome 13 is a constant feature of human VECs. Interestingly, this chromosome harbors the Rb and the endothelin-B receptor genes. The former is a mitotic checkpoint gene while the latter is a specific growth regulator of VECs. Moreover, the loss of chromosome 13 triggers the development of tetraploidy of VECs *in vitro*. Our findings are in line with the concept that the genetic make-up of VECs changes both *in vitro* (as a function of cell replication) and *in vivo* (as a function of the donor's age). These results have broad implications to the development of complex genetic traits, which may be triggered by altered gene expression as human beings age.

Program Nr: 376 from the 1999 ASHG Annual Meeting

Cell cycle-dependent expression and subcellular localization of human barren-1 (HCAP-H). *O.A. Cabello[1], E. Eliseeva[3], I. Ouspenski[1], I. Coldwell[4], F. Herbert[1], S. Thang[1], C.A. Austin[4], B.R. Brinkley[1], S. Plon[3,2], J.W. Belmont[2,3].*
1) Dept Cell Biol, Baylor Col Med, Houston, TX; 2) Dept Mol & Human Gen, Baylor Col Med, Houston, TX; 3) Dept Pediatrics, Baylor Col Med, Houston, TX; 4) Dept Biochem & Genetics, U. New Castle Upon Tyne, U.K.

Drosophila *barren* is required for chromatid arm separation. Its homolog in Xenopus, XCAP-H, is a subunit of the conserved heteropentamer 13S condensin and is required for mitotic chromosome condensation. HCAP-H fully complements the growth arrest phenotype of yeast mutant *brn1* and of a temperature-sensitive *brn1* allele, indicating that *BRN1* and HCAP-H are functional orthologs. However, in contrast to previous reports, HCAP-H does not interact with topoisomerase II a or b, as indicated by GST pull-down, co-immunoprecipitation, and yeast two-hybrid interaction assays, nor does recombinant HCAP-H modify the decatenation activity of topoisomerase II a in vitro. We have previously mapped the human brrn-1/HCAP-H locus to 2q11.2. Northern blot analyses of PHA-stimulated lymphocytes and Molt-4 elutriated cells, indicated that HCAP-H is transcribed during G2. Although the HCAP-H mRNA level is cell cycle-dependent, Western blots with two affinity-purified antibodies indicate that HCAP-H protein levels remain stable throughout the cell cycle in HeLa cells. These results suggest that the mitotic function of HCAP-H may require newly synthesized protein and that HCAP-H might fulfill a second function during interphase. Immunofluorescence microscopy of HeLa cells demonstrated that the subcellular localization of HCAP-H is cell cycle regulated: during mitosis it associates with discrete regions along condensed chromosomes; during interphase, it exhibits a distinct punctate nucleolar distribution. The staining pattern is specific, as demonstrated by epitope competition. These results are consistent with a role of HCAP-H in mitotic chromosome condensation. Moreover, we propose that HCAP-H may fulfill a second role in interphase nucleoli, possibly modulating the conformation and function of rDNA.

Program Nr: 377 from the 1999 ASHG Annual Meeting

The concept of chromosome condensation and de-condensation during mitosis has to be replaced by the concept of chromosome region specific protein swelling. *U. Claussen[1], J. Lemke[1], S. Michel[1], I. Chudoba[1], P. Muehlig[2], M. Westermann[3], J. Claussen[1], N. Rubtsov[4], U.W. Grummt[5]*. 1) Inst Human Gen & Anthropology, Jena, Germany; 2) Molecular Biotechnology, Jena, Germany; 3) Ultrastructural Research, Jena, Germany; 4) Cytology and Genetics, Novosibirsk, Russia; 5) Physical Chemistry, Jena, Germany.

The concept of chromosome condensation and de-condensation during mitosis has been investigated. The morphological changes of mitotic cells and chromosomes were analyzed during treatment with solutions needed for chromosome preparation such as fixative, acetic acid, and mixtures of water and acetic acid. Furthermore, chromosome stretching experiments were performed to analyze the splitting process of Giemsa bands into their sub-bands. Surprisingly, chromosome spreading is composed of a dramatic water-induced swelling of mitosis prior to evaporation of the fixative and subsequent flattening. Even singel chromosomes swell which leads to an elongation up to two times the original length. Chromosome swelling preferentially takes place in Giemsa light bands. Prophase, prometaphase and metaphase chromosomes are therefore preparation induced reproducible artifacts. The biology behind the chromosome region-specific swelling is not well understood. The mitotic and chromosome swelling process is a gel-like one and is a prerequisite for metaphase spreading, for the formation of the G-banding pattern, and for the production of cytogenetically analyzable chromosomes. Consequently, the concept of chromosome condensation and de-condensation during mitosis should be replaced by the concept of chromosome region specific protein swelling. Chromosome 5 specific high resolution multicolor-banding (MCB) experiments confirm that at the DNA level chromosomes in interphase nuclei show the same banding pattern as those in late metaphase and therefore are not de-condensed. The DNA specific chromosome banding pattern in interphase has even been used for the detection of single chromosome band deletions which opens up new fields in molecular cytogenetics.

Program Nr: 378 from the 1999 ASHG Annual Meeting

Systematic mapping of balanced chromosome rearrangements in association with Russell-Silver syndrome (RSS). *S. Doerr[1], M.L. Ayala-Madrigal[1,2], A.T. Midro[3], I. Giannakudis[1], I. Hansmann[1].* 1) Inst. f. Humangenetik, Halle, Germany; 2) UdeG and CIBO, IMSS Guad., Mexico; 3) Dept. of Clin. Genetics, Bialystok, Poland.

Russell-Silver syndrome is a heterogeneous disorder mainly characterized by pre- and postnatal growth retardation and some morphological abnormalities. Most cases are sporadic although in a minority familial inheritance has been described. About 10 % of patients show maternal uniparental disomy of chromosome 7. This is in good agreement with the data of our own survey identifying 3 cases of maternal UPD7 in a group of 31 probands. Furthermore, two autosomal translocations involving band 17q25 were reported in association with RSS (Ramirez-Dueñas et. al., 1992; Midro et. al., 1993). Molecular analysis of the breakpoints on chromosome 17 enables us to refine the localization of the breakpoint of the de novo translocation previously described as t(1;17)(q31;q25) to 17q23-24, whereas the breakpoint of the translocation described as t(17;20)(q25;q13) is localized in 17q25. Since the cytogenetic and molecular analysis of disease-associated balanced chromosome rearrangements is an efficient strategy to map and clone disease genes we cloned the breakpoints of the 1;17 translocation, and cloning of the 17;20 translocation is in progress. In order to identify a gene for RSS in the region 17q23-24 a YAC/PAC/cosmid contig (~ 5 Mb) for the RSS critical region around the breakpoint was constructed. This contig comprises loci for 30 STSs and 13 genes/ESTs. By searching for expressed sequences within the breakpoint area we identified a gene of a multigene family in close proximity to the breakpoint. Interestingly another member of this family is located in 17q25 close to the breakpoint segment of the second translocation. As a prerequisition for mutation screening in 31 probands with RSS, we determined the genomic structure of the gene within 17q23-24. Searching for mutations is in progress by direct sequencing of the identified 11 exons. Ongoing analysis led to the identification of 6 intragenic polymorphisms representing 4 common haplotypes in controls, but only 2 haplotypes exist in probands. Whether these observations contribute to the etiology of the disease is under investigation.

Program Nr: 379 from the 1999 ASHG Annual Meeting

Chromosomal Study of 300 Children born after Intracytoplasmic Sperm Injection(ICSI). *E.S. Elsobky[1], M.A. Aboulghar[2], R.T. Mansour[2], G.I. Serour[2].* 1) Human Genetics Ctr, Heliopolis, Cairo, Egypt; 2) Egyptian IVF-ET Ctr, Cairo,Egypt.

Conventional in-vitro fertilization (IVF) may be inadequate to allow fertilization in cases of male factor infertility, Intracytoplasmic sperm injection into the egg(ICSI;Palermo et al, 1992)have remarkably changed the opportunity to achieve pregnancy in such cases, yet it is an invasive procedure using in many cases a critically poor sperm quality bypassing natural selective mechanisms against the disomic gametes with potential cytogenetic risk. To study the cytogenetic impact of ICSI on its outcome we performed blood chromosomes for 300 children born after ICSI.Chromosomal abnormalities were identified in 13 cases(4.3%)including:Sex chromosome abnormalities in 7 cases(2.3%),Autosomal aneuploidy(Trisomies)in 3 cases(1%),Structural abnormalities(reciprocal translation)in 3 cases(1%)and rare case with three associated abnormalities(sex chromosome aneuploidy,autosomal inversion and reciprocal translocation).These results reflect the high incidence of chromosome abnormalities among children born after ICSI(almost 7 times the population incidence),this could be attributed to two possible major roots;increased incidence of sex chromosome abnormalities due to meiotic errors in subfertile males with high frequency of disomic sperms, and direct transmission of paternal structural chromosomal abnormalities which is also high among infertile men treated rather than ICSI procedure.

Program Nr: 380 from the 1999 ASHG Annual Meeting

Higher frequencies of X-Y aneuploid sperm in fathers of boys with Klinefelter syndrome when the extra X-chromosome was of paternal origin. *B. Eskenazi[1], X. Lowe[2], S. Kidd[1], K. Weisiger[1], D. Moore II[2], Y-J. Chuu[2], M. Aylstock[3], A. Wyrobek[2]*. 1) School of Public Health, University of California, Berkeley, CA; 2) Biology and Biotechnology Research Program, Lawrence Livermore National Laboratory, Livermore, CA; 3) Klinefelter Syndrome and Associates, Roseville, CA.

The objective of this research was to determine whether men with elevated frequencies of disomic sperm are at greater risk of fathering trisomic children. In 36 families who had a boy with Klinefelter syndrome (KS; 47,XXY; <6yrs old), inheritance of the extra X-chromosome was paternal in 10 and maternal in 26 families, based on 4 polymorphic microsatellite markers. Frequencies of sperm with aneuploidies involving chromosomes X, Y, or 21 were examined for all fathers by four-color sperm FISH (10,000 sperm per man), to determine whether fathers of the paternally-inherited KS group produced higher frequencies of aneuploid sperm than did the fathers of the maternally-inherited KS group. Specific classes of sperm aneuploidy were evaluated: X-Y sperm (which might produce KS upon fertilization), 21-21 (for Down syndrome), as well as X-X or Y-Y (Meiosis II errors). Fathers of the paternal KS group showed higher frequencies of X-Y sperm (median, 13.5 vs. 8.0 per 10K; p=0.01, crude; p=0.16, adjusted for age) and total hyperhaploidy (sum of hyperhaploidy for X, Y and 21) (median, 36.5 vs. 23.5; p=0.03, crude; p=.15, adjusted for age). Men who were older (at least 40 years) and had a boy with paternally-inherited KS had the highest rates of X-Y aneuploidy. Frequencies of X-Y and 21-21 sperm were correlated among men (Pearson's r=0.42, p=0.01), suggesting that trans-chromosomal mechanisms may be involved. However, frequencies of sperm with X-X, Y-Y, and 21-21 disomies did not differ between the KS groups (p>0.2). These findings support the hypothesis that men with higher rates of aneuploidy in their sperm are more likely to father children with trisomy.[Supported by NIEHS Superfund grant P4ZES04705 to UCB with subcontact to LLNL; partially performed under the auspices of the U.S. DOE by LLNL under contract W-7405-ENG-48.].

Program Nr: 381 from the 1999 ASHG Annual Meeting

Sex chromosome mosaicism originating at the myeloid/lymphoid cell lineage. *W.L. Flejter[1], E. Jackle[1], S. Aufox[1], K. Geisinger[2], M.J. Pettenati[1]*. 1) Pediatrics/Medical Genetics; 2) Pathology, Wake Forest Univ Sch Med, Winston-Salem, NC.

A peripheral blood sample was received for Fragile X testing. DNA analysis was negative, although the results suggested the presence of two X chromosomes. FISH analysis of the unstimulated blood, using X and Y chromosome probes, revealed four cell lines; XY/XXY/ XYY/ XXYY. A second blood sample was obtained for further studies. Conventional chromosome analysis of PHA-stimulated blood showed only 48,XXYY cells. Interphase FISH studies on the second sample, after PHA stimulation for 48, 72 and 96 hrs, again showed multiple sex chromosome cell lines. Interestingly, the frequency of XXYY cells increased over time in culture while the frequency of the other cell lines decreased. Subsequently, a buccal smear was obtained to see if mosaicism was present in a different cell type. FISH results showed XY, XXY and XXYY cell lines. To determine if discordance between the chromosome and FISH analyses could be explained on the basis of cell lineage, cytological staining of the slide preparations was performed. FISH results clearly showed that lymphoid cells had only an XXYY chromosome constitution while the myeloid cells showed all four cell lines.

Discordant karyotypes have been described as a relatively frequent finding in different tissue types from the same patient. However, discordant results in stimulated vs. unstimulated cultures have not been well documented. One hypothesis for the discrepancy is that normal cells are at a growth advantage over abnormal cells in culture. However, our results, as well as other published studies, suggest that metaphase cells found at direct analysis represent a different population of cells than those present after PHA-stimulation. These findings raise important questions regarding accurate karyotype results particularly in cases of prenatal diagnosis after abnormal ultrasound, a normal karyotype in a dysmorphic child, suspected mosaicism in individuals who don't fit the characteristic phenotype of a distinct genetic syndrome, and in patients with recurring pregnancy loss or infertility.

Program Nr: 382 from the 1999 ASHG Annual Meeting

Delayed DNA replication leads to chromosomal instability at FRA7H, a common fragile site on human chromosom 7. *A. Hellman[1], A. Rahat[1], S.W. Scherer[2], L.C. Kerem[2], B.[1].* 1) Department of Genetics, The life sciences Institute, The hebrew University, Jerusalem, Israel; 2) Department of Genetics, The hospital for sick Children, Ontario, Canada.

Common fragile sites are specific unstable chromosomal loci characterised by constrictions, gaps or breaks on chromosomes from cells exposed to inhibition of DNA replication. In contrast to the rare fragile sites, no expanded repeats have been found in the common fragile sites, and the molecular basis for their fragility is currently unknown. Here we studied the replication pattern of FRA7H, a common fragile site on human chromosome 7. Using a FISH based method we found that ~30% of S-phase nuclei from nonsynchronyzed cell culture showed two unreplicated alleles (SS signals), indicating that the replication of FRA7H is initiated relatively early in the S phase. However, a high fraction, 35%, of the S-phase nuclei showed one replicated and one unreplicated allele (SD signals), indicating that a considerable fraction of FRA7H alleles accomplished its replication only during late-S phase. This allelic asynchrony is not due to allele specific replication time as found in the analysis of a chromosome 7 isodysomic and a marked chromosome 7 cell lines. The cytogenetic expression of FRA7H occurs over a region of ~160 kb. Upon aphidicolin treatment (the FRA7H inducer and an inhibitor of DNA synthesis), large difference appeared between the replication time of the FRA7H central region (D=44%) and both of its sides (D=19%). Two-colour FISH analysis using pairs of adjacent clones from the FRA7H region revealed that in a large fraction (15-25%) of the S-phase nuclei the central FRA7H region accomplished its replication while the adjacent sequences from both sides did not. All these results led us to propose that the fragility of FRA7H is a consequence of a low rate of DNA synthesis, along a single replicon comprising this fragile region. This low rate might result from random formation of non-B DNA structures, which interfere with the replication elongation. Upon aphidicolin treatment, some FRA7H alleles may fail to overcome this interference, resulting in the fragile site expression.

Program Nr: 383 from the 1999 ASHG Annual Meeting

Microdeletion at 12q24.1 within the NS critical interval in two unrelated patients presenting with Noonan syndrome. *A.M. Ion, A. Brady, A. Crosby, K. Marks, S. Jeffery, M.A. Patton.* Medical Genetics, St George's Hospital, London, UK.

Noonan Syndrome (NS) is a genetic condition characterised by a typical facial appearance, "Turner-like" phenotype and congenital heart defects, particularly pulmonary valve stenosis and hypertrophic cardiomyopathy. This disorder has been previously mapped at the chromosomal band 12q24.1 to a 10 Mb interval between markers D12S84 and D12S79. As part of our strategy for cloning and characterising genes involved in this condition we screened several patients presenting with typical Noonan syndrome and learning disability for submicroscopic chromosomal abnormalities. FISH probes included several cosmids that result from the subcloning of two YACs spanning part of the NS critical interval. We report here two patients presenting with typical NS and abnormal hybridisation pattern for one or several of the cosmids mentioned above. FISH performed on metaphase spreads from these patients identified four cosmids that were partially or completely deleted in the two patients. The four cosmids were subcloned from the same YAC that spans an interval of approximately 1.4 Mb of the NS critical rgion. Results were confirmed in both patients by several successive FISH techniques (over 50 metaphase spreads). Molecular analysis in the first patient showed a missing allele for one polymorphic marker within the 1.4 Mb interval. However, the same marker was not informative for the second patient. Both patients were heterozygous for all other informative markers in the region. This findings suggest a microdeletion present in both patients that may be associated to the Noonan syndrome phenotype.

Program Nr: 384 from the 1999 ASHG Annual Meeting

Development and validation of exon-specific FISH probes for DMD carrier detection. *M. Jaju[1], A.H. Ligon[2], C.S. Richards[1], C.D. Kashork[1], L.G. Shaffer[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Departments of Obstetrics /Gynecology & Pathology, Brigham & Women's Hospital/Harvard Medical School, Boston, MA.

Duchenne Muscular Dystrophy (DMD) is an X-linked disorder affecting about 1/3500 liveborn males. Approximately 65% of mutations in the dystrophin gene are deletions. Current molecular methods of carrier detection in females depend on dosage assessment. We report the use of FISH as an alternative method for deletion detection. To date, we have identified 13 exon-specific cosmids that have been used for FISH. The current probe set includes exons 3-6, 8, 12, 13, 17, 19, 43-45, 48, 50, 51, and 60. The validity of these probes for providing direct detection of dystrophin exon deletions and establishing carrier status was demonstrated by comparing FISH results with standard molecular diagnosis in three groups of families: (1) Xp21 contiguous gene deletion (CGD) probands and their female relatives (n=8); (2) mothers/female relatives and corresponding DMD-affected males (n=6); and (3) mothers/female relatives for whom no corresponding affected male was available for study (n=14). Results of FISH and molecular analyses were available for 11 of 14 affected males studied. In every case, the expected deletion was confirmed using FISH. In three CGD probands for whom molecular analysis was unavailable, deletions were demonstrated using multiple FISH probes. For these 14 families, 7 of 15 female relatives studied were identified as deletion carriers using the family-specific FISH probes. These FISH results were 100% concordant with available molecular results. In the 14 families for whom affected males were unavailable, deletions were detected in 5 of 16 females tested. Of these, molecular diagnosis had been performed in 14 cases and the FISH results were concordant in every case. Our study demonstrates that FISH is an accurate and reliable approach to identifying carriers of DMD deletions.

Program Nr: 385 from the 1999 ASHG Annual Meeting

Terminal deletions may not be terminal: FISHing for mechanisms of chromosomal 1p36 deletions using telomere region-specific probes. *C.D. Kashork, B.C. Ballif, S.K. Shapira, L.G. Shaffer.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Chromosome integrity is dependent upon the presence of telomeric sequences. Thus, cytogenetically defined terminal deletions must have telomeres to be structurally stable. Three possibilities for apparent, terminal deletions exist: true terminal deletions that stabilize through a process of telomere replacement or acquisition, interstitial deletions that retain the original telomere, and derivative chromosomes which obtain a different telomere through cytogenetic rearrangement. We report the use of telomere region-specific probes to characterize apparent, cytogenetic terminal deletions in patients with 1p36 monosomy. The probes consist of sub-telomeric DNA sequences unique to each chromosome arm (Cytocell). Simultaneous FISH for 41 telomeric regions was performed on 32 patients with 1p36 deletions. All patients were previously studied using cytogenetic and molecular methods, and were found to have varying sized deletions. Results using the telomere region-specific probes showed 5 patients had *de novo* telomeric rearrangements, including 3 cases of derivative chromosomes 1p with 1q sequences identified, one case with 2p telomeric sequences on 1p, and one case with Xp sequences replacing the 1p. An additional case was previously known to have a satellited 1p, not detectable by this assay. 21 patients had apparent terminal deletions of 1p with no other telomeric rearrangement detected, and 5 patients showed no deletion of the 1p probe, indicating interstitial deletions. Of the 5 patients with interstitial deletions, 2 were previously not known, but uncovered with the use of the 1p probe. For 6 cases, regions of homology near the 1p telomere may have allowed for recombination to occur with non-homologous segments, leading to derivative chromosomes. Of the 21 terminal deletions, the chromosomes must have been stabilized through the addition of $(TTAGGG)_n$ sequences. The mechanism of how these deletions acquired the necessary terminal cap is under investigation. Our findings may help delineate mechanisms for other terminal deletions, in addition to those involved in monosomy 1p36.

Program Nr: 386 from the 1999 ASHG Annual Meeting

The variant smaller DGS/VCFS deletions occur at two distinct blocks of duplicated sequence within the 3 Mb common deletion. *H. Kurahashi, T. Shaikh, S. Saitta, B. Emanuel.* The Childrens Hospital of Philadelphia, Phila.,PA.

The 22q11.2 deletions associated with DGS/VCFS occur with a high frequency. It has been suggested that they result from recombination involving duplicated sequence blocks (duplicons) interspersed in 22q11.2. The deletion interval contains four duplicons which are repeated at several other locations on 22q. The deletion endpoints (DEPs) appear to occur within the duplicons in regions we have designated A, B, C, and D. The A-D 3 Mb deletion occurs most frequently. Further, we and others have previously described several patients with atypical deletions (A-B, A-C, C-D). To determine the organization of the duplicons and their role in deletion formation, we have constructed a contig across the four DEP regions using BAC, PAC and cosmids. The size of each duplicon is greater than 100 kb. Whereas A and D contain at least two copies of the duplicon, B and C appear to contain a single copy. By sequence analysis the duplicons share greater than 95% identity and each of them contains common elements. To further examine the role of the duplicons in deletion formation, we have performed pulsed field gel electrophoresis of genomic DNA from A-B and A-C deletions. Southern hybridization with probes flanking the deleted region have identified novel rearrangement fragments. For A-B deletions we used a probe immediately distal to duplicon B (ZNF74) which identifies a normal 200kb NotI fragment and a rearranged 650kb fragment. A probe proximal to duplicon A detects the same rearrangement fragment, confirming that the DEPs are located within A and B. Isolation of the 650kb region of the gel from an A-B deletion and PCR analysis demonstrates co-migration of markers which flank the deletion proximal to A and distal to B, confirming that the novel band contains the DEPs. Similar studies for the A-C deletions with a probe distal to duplicon C and for the C-D deletion with a probe proximal to the C duplicon demonstrate rearrangement fragments by pulsed field gel electrophoresis analysis. These studies provide the first definitive evidence for two distinct duplicons and several recurring variant deletion endpoints within the 3 Mb 22q11.2 deletion region.

Program Nr: 387 from the 1999 ASHG Annual Meeting

Automated FISH spot counting by laser scanning cytometry detects homologous pairing of imprinted chromosomal domains. *J.M. LaSalle, C.P. Lagdamen.* Medical Microbiol & Immunology, Univ California Davis Sch Med, Davis, CA.

Interphase chromosome dynamics are important in the epigenetic regulation of gene expression. Homologous pairing of chromosome 15q11-13 regions occurs exclusively in the late S phase of the cell cycle and is deficient in cells from patients with the imprinting disorders Angelman (AS) and Prader-Willi's (PWS) syndromes. However, further investigations have been limited by the laborious method for detecting chromosome pairing by cell sorting and confocal microscopy. A novel technology for the automated detection and quantitation of fluorescent in situ hybridization (FISH) signals is the laser scanning cytometer (LSC), a microscope-based cytometer capable of rapid multiparameter analyses. We have developed a method to simultaneously determine cell cycle stage and FISH spot pairing by LSC. Normal human lymphocytes were hybridized with direct-labeled probes for either chromosome 15 or 12 and analyzed by LSC for FISH and DNA content. Due to its two-dimensional low resolution scanning, the LSC analysis undercounted the number of FISH spots by about 10%. Therefore, one-spot nuclei that contained one rather than two overlapping FISH signals were gated out of the analysis by using the area and fluorescent integral of the FISH signals from two-spot nuclei as a standard. Gates were set separately for each cell cycle stage, as the intensity of each signal doubled following replication. Using this approach, homologous pairing of D15Z1 was detected in more than 30% of the nuclei in late S phase, while other cell cycle stages showed less than 15% pairing. For the D12Z3 negative control, pairing was less than 15% in all cell cycle stages. These results are comparable to those achieved by the previous method but can be performed in approximately 10-fold less time. In future studies, the LSC-based detection of homologous pairing will be used to examine additional AS and PWS patients, to perform a genome-wide search for homologous pairing on other chromosomes, and to test homologous pairing in other tissues and species. This research should also have widespread applications in prenatal and cancer cytogenetics for automated multiparameter analyses on limited cell samples.

Program Nr: 388 from the 1999 ASHG Annual Meeting

Comparative genomic hybridization (CGH) in combination with flow cytometry improves the accuracy of cytogenetic analysis of spontaneous abortions (SAs). *B.L. Lomax[1], S.S. Tang[1], E. Separovic[1], T. Thomson[2], D.K. Kalousek[1]*. 1) Dept.of Path., Univ.of B.C., Canada; 2) Dept.of Lab.Med., B.C.Cancer Agency, Canada.

Chromosomal abnormalities account for approximately 60% of early pregnancy losses. Conventional cytogenetic analysis of SAs is dependent on tissue culture and subject to tissue culture failure and overgrowth of maternal cells. CGH represents an alternative cytogenetic technique capable of detecting chromosomal imbalances. CGH overcomes technical problems associated with tissue culture and in combination with flow cytometry can theoretically detect all numerical and unbalanced structural chromosomal abnormalities associated with SAs.

Routine cytogenetic and CGH analysis was performed on tissues samples from 175 SAs. All samples shown to be chromosomally balanced by CGH were analyzed by flow cytometry to determine ploidy. By conventional cytogenetic analysis, 56 (32%) demonstrated diploidy, 97 (55.4%) demonstrated aneuploidy and 22 (12.6%) failed. By CGH/flow analysis, 57 (32.6%) demonstrated diploidy, 111 (63.4%) demonstrated aneuploidy and 7 (4%) failed. Of the 149 cases successfully analyzed by both methods, there was a 93.2% correlation of the results. Discrepancies between the cytogenetic and CGH/flow results occurred in 10 cases. Six cases produced a 46,XX karyotype by cytogenetic analysis while CGH/flow demonstrated aneuploidy/polyploidy thereby indicating maternal contamination of the tissue cultures. In 2 cases, where tetraploidy was demonstrated by cytogenetics and diploidy by flow cytometry, tissue culture artifact is implied. In 2 unexplained discrepant cases, where the findings by CGH and cytogenetics differed, mislabeling of the samples is suspected and follow-up is in progress.

Our results demonstrate that CGH in combination with flow cytometry can readily identify aneuploidies associated with SAs, including trisomy, monosomy, gains and losses of partial chromosomes, triploidy and tetraploidy. CGH has a lower failure rate than conventional cytogenetic analysis and together with flow cytometry provides more accurate results by avoiding maternal contamination and tissue culture artifacts.

Program Nr: 389 from the 1999 ASHG Annual Meeting

Assessment of the relationship between size of deletion and level of developmental delay in cri-du-chat syndrome using a novel set of 5p FISH probes. *R.C. Marinescu[1], E.M. Dykens[2], R.M. Hodapp[3], D. Grady[4], X.-N. Chen[5], J. Overhauser[1]*. 1) Dept. of Biochem/Mol Pharm, Thomas Jefferson Univ, Philadelphia, PA; 2) Neuropsychiatric Inst, UCLA, Los Angeles, CA; 3) Graduate School of Education and Information Studies, UCLA, Los Angeles, CA; 4) Dept. of Biol Chem, UCI, Irvine, CA; 5) Med Genetics Birth Defects Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Cri-du-chat syndrome is a segmental aneusomy syndrome that is associated with a deletion of the short arm of chromosome 5. A set of minimally overlapping YAC clones that span 5p as well as a 5p-telomeric BAC clone were developed to assess 110 cri-du-chat syndrome individuals with previously determined de novo terminal deletions of 5p. Of the 110 samples, 103 had terminal deletions, 4 had interstitial deletions, one had had an unbalanced translocation and no deletion could be detected in two samples. Developmental assessment was performed on 50 of these individuals with FISH-confirmed terminal deletions using the Vineland Adaptive Behavior Scales test. Composite Vineland Scores ranged from 20 - 75. In general, the communication score was higher than the composite score. Comparison of the size of the deletion with the composite Vineland score, as well as the Vineland Communication score, demonstrated that there was no correlation between the size of the deletion and the level of developmental delay. Many of the individuals scored at the basal level of 20. Of the individuals with scores higher than 50, most were between the ages of 1 and 10. Therefore, the age at the time of testing does appear to play a role in the level of delay that is observed.

Program Nr: 390 from the 1999 ASHG Annual Meeting

A Resource of Mapped BAC Clones for Cancer Chromosome Aberrations Identification. *N.J. Nowak[1], J.M. Conroy[1], G.P. Caldwell[1], J.J. Catanese[1], G. Schuler[2], B. Trask[3], D.R. Bentley[4], G. Shen[5], P.J. de Jong[1].* 1) Dept Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 2) NLM, NIH, Bethesda, MD; 3) University of Washington, Seattle, WA; 4) The Sanger Centre, Hinxton, Cambridge, UK; 5) DCB, NCI, Bethesda, MD.

Cancer is a heterogeneous disorder, encompassing more than 100 diseases, the progression of which is thought to result from an accumulation of genetic alterations at numerous loci controlling growth and proliferation. As part of NCI's initiative (RFA: CA-98-005) and joint effort with Caltech and the University of Washington, we are generating a high density, genome-wide resource of mapped BAC clones. These clones are selected from the RPCI-11 human BAC library for their application as tools for FISH analysis of chromosomal rearrangements in human cancer. The short-term goal would provide cytogeneticists with an evenly spaced set of clones, mapped at high resolution to analyze tumor rearrangements using FISH on metaphase chromosomes. The long-term goal would provide cytogeneticists with a genome wide clone array as a CGH target for high-resolution analyses of tumor DNA. A genome wide BAC clone array is being assembled through screening of the human BAC library, RPCI-11, with 4,000 markers mapped on the G3 and GB4 radiation hybrid panels. Markers (STS/EST) are judiciously chosen at a spacing of less than 1 Mb, and "overgos" are designed and arrayed into probe pools for hybridization based screening covering 6 fold redundancy of the library. Thus far, we have recovered BAC clones for over 1500 markers on chromosomes 1-3, 5, 6, 10, 11, 18-22 and X (http://bacpac.med.buffalo.edu/human/overview.html). We have recovered an average of 1 BAC/1-2 Mb for these chromosomes. One BAC clone per marker is characterized by in situ hybridization experiments to establish its usefulness as a FISH probe and to provide additional independent confirmation of the map location. Application of these resources will build a database of chromosome aberrations with diagnostic and prognostic potential providing clinicians with new tools for improving the current classification system of tumors.

Program Nr: 391 from the 1999 ASHG Annual Meeting

X chromosome inactivation studies in mosaic trisomies. *M.S. Penaherrera[1], I.J. Barrett[2], C.J. Brown[1], D.K. Kalousek[2], W.P. Robinson[1]*. 1) Dept. Medical Genetics; 2) Dept. of Pathology, Univ British Columbia, Vancouver, BC, Canada.

Skewed X-chromosome inactivation (XCI) is frequently found in fetal tissues of individuals with mosaic trisomy when the trisomy has arisen by a meiotic event and is predominantly confined to the placenta. Our model to explain both the elimination of the trisomy from most fetal tissues and the increased rate of skewing is that, the majority of the ~20 cells comprising the embryonic pool at the time of XCI are trisomic and that these trisomic cells are subsequently eliminated from fetal tissues by selection. Under this model, we would expect that the fewer diploid cells present at the time of XCI, the more likely extreme skewing is to occur. Furthermore, the greater the proportion of trisomic cells in the original embryonic pool the more difficult it would be to completely eliminate them from all fetal tissues. We therefore hypothesize that extreme skewing may be more often associated with a poor outcome, due to the presence of low level fetal mosaicism. In this study, XCI status was evaluated in 16 cases of prenatally detected meiotic trisomy mosaicism, involving chromosomes 2, 4, 7,16 or 22 and predominantly confined to the placenta. Using a PCR based methylation test at the androgen receptor locus, 10/16 cases showed extreme XCI skewing (>90% inactivation of one allele) in blood or other diploid fetal tissues, as compared to 6/111 in the control population ($p<0.001$). Of the 6 cases without extreme skewing, 4 had a normal outcome, while a low birth-weight (<5%ile) was the only abnormality in the remaining two cases. In contrast, of the 10 cases with extreme skewing, a normal outcome was found in only 2 cases. In the remainder, outcome ranged from severe IUGR to fetal malformations and intrauterine or neonatal death. It is possible that fetal mosaicism was present in those cases with a poor outcome even if amniotic fluid results were negative for the trisomy. Further investigations are required to determine the if XCI status adds useful information to the prediction of pregnancy outcome in prenatally detected mosaic trisomy.

Program Nr: 392 from the 1999 ASHG Annual Meeting

The first case of a microdeletion on chromosome 10p13 gives further evidence for a contiguous gene syndrome in the DiGeorge syndrome 2 region. *A.M. Rauch[1], P. Lichtner[2], M. Zenker[3], S. Schuffenhauer[2], M. Hofbeck[3], U. Trautmann[1]*. 1) Inst. for Human Genetics, FAU Erlangen, Germany; 2) Abt. Medizinische Genetik, LMU Muenchen, Germany; 3) Children's Hospital, FAU Erlangen, Germany.

DiGeorge syndrome (DGS) is a developmental field defect characterized by hypoplastic thymus and parathyroid, conotruncal heart defects and facial anomalies. About 90% of patients have a 3 Mbp microdeletion in 22q11.2, which in turn shows an immense clinical variability. Due to several patients with cytogenetical visible deletions of chromosome 10p, a second DGS locus was postulated. Recently Schuffenhauer et al performed deletion mapping in patients with deletion 10p and defined a critical DGS2 region in 10p13 of about 1cM containing D10S547 and D10S585. However, a microdeletion involving this DGS2 region was not yet quoted. We report here the first observation of a microdeletion 10p in a patient with growth and mental retardation and minor facial anomalies resembling published patients with larger deletions of 10p. Despite muscular hypotonia, shortness of stature, microcepahly and marked delay in developmental milestones he had no medical problems. Especially there was no abnormality of heart, kidneys, hearing, vision, T-cells, immunoglobulins, parathormone, x-ray of skull and EEG. There was no aberration detectable with GTG-banding at a 850 band level or with FISH for loci D22S75, cHKAD26 and D22S425 in 22q11.2. FISH with two Pacs containing WI-2389 and D10S585, respectively, demonstrated a de novo deletion of the DGS2 critical region in 10p13. As adjoining Pacs from a contig (P. Lichtner, unpublished) were not deleted, the size of this novel microdeletion is estimated to be about 400 kb. STRP analysis of loci D10S547 and D10S585 was not informative. Based on the clinical symptoms of this patient and those reported in other patients with larger deletions of 10p13 a tentative map of phenocritical segments can be constructed. Our findings indicate that a microdeletion of the recently proposed DGS2 critical region is not sufficient to produce the complete DGS phenotype. We therefore conclude that the DiGeorge syndrome 2 is a contiguous gene syndrome.

Program Nr: 393 from the 1999 ASHG Annual Meeting

A common neocentromeric region identified in two “acentric” chromosomes derived from 9p in unrelated individuals. *D.L. Satinover[1], G.H. Vance[2], D.L. Van Dyke[3], S. Schwartz[1]*. 1) CWRU and University Hospitals of Cleveland,OH; 2) Indiana Univ. School of Med., Indianapolis, IN; 3) Henry Ford Hospital, Detroit, MI.

Over the past few years, several cases of “neocentric” marker formation have been reported in accessory chromosomes without detectable levels of alpha-satellite sequences. Neocentromere activation has occurred in a variety of different markers originating from both autosomal and sex chromosomes. However, little is still known about the mechanism leading to the activation of a neocentromere. To attempt to answer the critical question whether neocentromere activation occurs at random or at preferential genomic sequences, we have further characterized two neocentromeres derived from the short arm of chromosome 9. Although these are mirror image duplications with different breakpoints (9p21.1 and 9p12), the neocentromeric region is not at the axis of symmetry and only a single neocentromeric region is formed. Our study was designed to develop a BAC contig across the neocentromeric region and utilize both FISH with the BACs as well as immunofluorescence with CENP-C to define our neocentromeric regions. We localized both neocentromeres to 9p23. Utilizing a series of BACs within 9p23, the neocentromeric region has been delineated between D9S269 and D92028 and BACs 246A3 and 420J5 respectively. The CENP signal is sandwiched between BAC 246A3 and 420J5. Radiation hybrid mapping reveals a distance of 1.35 Mb between these markers. To date, our BAC contig has added an additional 15 STS and 13 new BACs within this region of 9p23. Additional BAC clones and STSs are currently being localized to our map to further refine the neocentromeric sequences present in each marker.

Our current studies of these two markers indicate that: (1) The neocentromere region can be sized to smaller than 1.35 Mb by radiation hybrid mapping; (2) A complete BAC contig of this region is currently under construction; and most importantly (3) We have shown that neocentromeres found in two acentric chromosomes derived from 9p share a similar putative neocentromeric region in 9p23. These are very engaging findings suggesting that specific regions will preferentially gain neocentromeric activity.

Program Nr: 394 from the 1999 ASHG Annual Meeting

Deficient histone H4 acetylation in Roberts Syndrome. *R.A. Schultz[1,2], L.C. Probst[1], L.D. McDaniel[1,2].* 1) McDermott Ctr, Rm NB 10.120, Univ TX Southwestern Med Ctr, Dallas, TX; 2) Department of Pathology, Univ TX Southwestern Med Ctr, Dallas, TX.

Roberts syndrome (RBS) is a developmental disorder characterized clinically by tetraphocomelia (symmetrical limb reduction), cleft lip and palate, prenatal and postnatal growth retardation, mental retardation, craniofacial malformations, and cardiac and renal defects. RBS cells exhibit in vitro phenotypes that include aberrant splaying or repulsion of the heterochromatic regions of metaphase chromosomes (HR), faulty chromosome segregation, and modest sensitivity to a spectrum of chemical and physical agents, particularly those which damage DNA. Previous results from our lab and from others suggest that the HR phenotype is a consequence of altered chromatin structure, possibly related to a defect in histone acetylation/deacetylation. It is noteworthy that the developmental disorder Rubinstein-Taybi Syndrome also involves a defect in a protein associated with histone acetylation. We have been characterizing RBS cells to gain further insights into associations between chromatin structure and development and to identify the RBS genetic defect. Data will be presented demonstrating that RBS cells are hypersensitive to the histone deacetylase inhibitor tricostatin A (TSA), a result consistent with a potential defect in deacetylation. However, using antibodies against specific acetylated forms of histone H4, we have identified a defect in lys16 acetylation in RBS cells as detected by reduced intensity of immunofluorescence staining. Quantitative evaluation of the results indicated that this was only a partial defect, as some histone H4(Ac16) acetylation was detected in RBS cells. The defect was documented in all three RBS cell lines examined, was specific for H4(Ac16), and could be observed at all stages of the cell cycle. The results suggest a relationship between TSA hypersensitivity and defective histone H4 acetylation.

Program Nr: 395 from the 1999 ASHG Annual Meeting

Late replication and histone deacetylation spreading in a human X;1 translocation. *S.S. Thomas[1], L. Hudgins[2], E.A. Keitges[3], C.M. Disteche[1]*. 1) Dept. of Pathology, Univ. of Washinton, Seattle, WA; 2) Div. of Medical Genetics, Univ. of Washington and Children's Hospital, Seattle, WA; 3) Dynacare, Seattle, WA.

An unbalanced translocation between the X chromosome and chromosome 1 was found in a child with multiple congenital abnormalities, including ventricular septal defects, hydrocephalus, seizures, growth retardation of prenatal onset and significant development delay. Breakpoints of the translocation were located at bands Xq21 and 1q21. By FISH analysis the XIST (X-inactive specific transcript) gene was found to be present on the derivative X close to the breakpoint. Late replication studies using BrdU-labeling late in S phase and Giemsa or BrdU antibody stainings revealed extensive but incomplete spreading of late replication. This is consistent with inactivation of the derivative chromosome including a large portion of the attached chromosome 1, which would explain survival of this child, who otherwise would be trisomic for most of the long arm of chromosome 1. Lack of acetylated histone H4 was previously shown to characterize the inactive X chromosome but there was no evidence of its spreading in human X/autosome translocations. Antibody to acetylayed histone H4 was applied to chromosome preparations from a lymphoblastoid cell line from the patient. Lack of staining was most prominent in the X portion of the derivative chromosome but was also observed in the chromosome 1 portion, in a pattern corresponding to the late replication pattern. The concordance between histone deacetylation and late replication in the derivative chromosome indicates that histone deacetylation can spread into autosomal material attached to the inactive X chromosome in a human X/autosome translocation..

Program Nr: 396 from the 1999 ASHG Annual Meeting

Spectral karyotyping (SKY) in combination with locus-specific FISH, a technique to simultaneously define genes and chromosomes involved in chromosomal translocations. *G. Tonon, A. Roschke, W.M. Kuehl, I.R. Kirsch.* Dept Genetics, Medicine Branch, National Cancer Institute, Bethesda, MD.

Genes critical for the origin and development of cancer have often been found proximate to chromosomal breakpoints. Identifying the genes that flank chromosomal reconfigurations is thus essential to the study of cancer cytogenetics. To simplify and expedite this identification, we have developed an approach, based on simultaneous spectral karyotyping (SKY) and fluorescence in situ hybridization (FISH) analyses. In SKY, each chromosome is defined by a single color, and rearranged chromosomes present two or more colors, corresponding to the different chromosomes participating in the rearrangement. The signal specific for the queried genes (FISH probe) was easily detectable in the metaphase spread, together with the signals from the painted chromosomes (SKY probes). This technique is rapid and simple. The concentration and size of the FISH probes for successful analysis covered a wide range. We have been able to identify the FISH signal with a 12.5 Kb probe at 10 mg/ml concentration, using only 0.1 mg of total probe. Two FISH probes can be used, therefore more than one gene can be tested in the same metaphase for its involvement in breakpoints. As a test of this method the myeloma cell line Karpas 620 was studied. This cell line has a complex karyotype, characterized by numerous chromosomal rearrangements. Using as a probe the constant region of the immunoglobulin heavy chain, we found six copies of this gene, all of them located coincident with translocations. Surprisingly, two of these copies were not located in chromosome 14 derivatives, where this gene normally resides, but at the breakpoint between chromosome 8 and 11, demonstrating an insertion of this gene and therefore a previously undetected chromosomal aberration. In summary, we demonstrate a technique that in a single step can localize specific genes and define their involvement in chromosomal breakpoints. This approach will be particularly useful for the analysis of complex karyotypes and for testing hypotheses arising from the flow of information derived from cancer gene expression studies.

Program Nr: 397 from the 1999 ASHG Annual Meeting

Clinical Outcome of Common Trisomies 13, 18, 20, and 21 Diagnosed through Amniocytes: A Collaborative Karyotype-Genotype Study. *R. Wallerstein[1,3], M-T. Yu[2,3], L.Y.F. Hsu[1,2,3], 23 North American Cytogenetic Laboratories[3]*. 1) Human Genetics Program, New York University, New York, NY; 2) Prenatal Diagnosis Laboratory of New York, New York, NY; 3) Collaborative Amniocentesis Mosaicism Project.

Karyotype-phenotype correlations of common trisomy mosaicism prenatally diagnosed via amniocentesis was reviewed in 305 new cases from a collaboration of North American cytogenetic laboratories. Abnormal outcome was noted in 10/25 (40%) cases of 47,+13/46, 17/31 (54%) cases of 47,+18/46, 10/152 (6.5%) cases of 47,+20/46, and in 49/97 (50%) cases of 47,+21/46. Risk of abnormal outcome in pregnancies with less than 50% trisomic cells and greater than 50% trisomic cells were: 26% (4/15) vs. 60% (6/10) for 47,+13/46, 52% (11/21) vs. 75% (6/8) for 47,+18/46, 4.5% (6/132) vs. 20% (4/20) 47,+20/46, and 45% (27/60) vs. 59% (22/37) for 47,+21/46. Phenotypically normal liveborns were observed with mean trisomic cell lines of 9.3% for 47,+13/46, 8.6% for 47,+18/46, 27% for 47,+20/46, and 17% for 47,+21/46. Concordance of confirmation study with original amniocentesis was observed in 6 out of 13 (46%) studies performed on pregnancies with 47,+13/46 mosaicism, 8/12 (66%) of 47,+18/46, 10/97 (10%) of 47,+20/46, and 24/54 (44%) of 47,+21/46. There were higher confirmation rates in pregnancies with abnormal vs. normal outcome: 47,+13/46 (50% vs. 44%), 47,+18/46 (100% vs. 33%), 47,+20/46 (66% vs. 7%), and 47,+21/46 (55% vs. 40%). Repeat amniocentesis is not helpful in differentiating clinical outcome due to very similar confirmation rates in both normal and abnormal cases. Fetal blood sampling may have a role in mosaic trisomy 13, 18, and 21 as the risk for abnormal outcome increases with positive confirmation: 1/5 (20%) normal cases vs. 5/8 (62%) abnormal cases. High resolution ultrasound examination(s) is recommended for clinical correlation and to facilitate genetic counseling.

Program Nr: 398 from the 1999 ASHG Annual Meeting

Short stature and premature ovarian failure loci in proximal Xp. *A.R. Zinn[1], R.L. Prueitt[1], P.R. Papenhausen[2], V.L. Roberts[3], J.L. Ross[4].* 1) McDermott Center & Dept. of Internal Medicine, UT Southwestern Medical School, Dallas, TX; 2) LabCorp of America, Research Triangle Park, NC; 3) Endocrine Associates of Florida, Longwood, FL; 4) Dept. of Pediatrics, Thomas Jefferson University, Philadelphia, PA.

Turner syndrome, the phenotype of human monosomy X, is thought to be due in large part to haploinsufficiency of genes that escape X-inactivation. Recently we identified a critical region at Xp11.2-p22.1 for short stature, premature ovarian failure (POF), high arched palate, and autoimmune thyroid disease by genotype/phenotype correlation of 28 girls and women with partial deletions of Xp (Zinn et al. AJHG 1998 63:1757). We now report a 31 year old woman with short stature, secondary amenorrhea, and a *de novo* interstitial deletion of Xp11 partly overlapping the previously defined critical region. The patient's height was 143.5 cm, 3.3 SD below the population mean and 1.7 SD below her midparental target height. Molecular cytogenetic studies of peripheral blood leukocytes showed no evidence of mosaicism and confirmed that the deletion is interstitial, with proximal breakpoint between *ZXDB* (Xp11.21) and *DXS423E* (Xp11.22) and distal breakpoint between *SYP* (Xp11.23) and *SYN1* (Xp11.3). The deletion spans 5-10 Mb and is to our knowledge one of the smallest interstitial deletions associated with characteristic Turner syndrome features. Both copies of the Xp pseudoautosomal short stature gene *SHOX* are present, supporting our previous suggestion that haploinsufficiency of the pseudoautosomal *SHOX* gene does not account for the entire growth deficit in Turner syndrome. The deletion in our patient extends proximal to a previously reported interstitial deletion (Xp11.23-p22.11) in a mother and two daughters with isolated short stature reported by Herva et al. (AJMG 1979 3:43). Our data are consistent with these authors' hypothesis that there are distinct stature and POF loci situated in proximal Xp. Additional studies will refine the interval most likely to contain the responsible gene(s).

Program Nr: 399 from the 1999 ASHG Annual Meeting

The Necker Human Embryos Collection. *T. Attié-Bitach[1], F. Encha-Razavi[1], I. Kirillova[2], A-L. Delezoide[1], C. Esculpavit[1], D. Esnault[1], M. Vekemans[1]*. 1) Dept de Génétique & INSERM U-393, Hopital Necker, Paris, FRANCE; 2) Institute for Hereditary Diseases, Minsk, BELARUS.

After many years of descriptive embryology, our knowledge of human development remains very limited because human embryo research is restricted by both practical and ethical considerations. The mouse is a good model that can teach us an enormous amount about human development. But there are now good arguments to suggest that future developmental research should include also studies in human embryos. Collection of human embryos was obtained from 546 RU486 induced abortions between January 1996 and December 1998. The embryos have been collected according to the French law and the French Ethical Committee recommendations. Whole gestational sacs were placed either in 4% paraformeldehyde (PFA) or saline solution for transport to the laboratory for stereomicroscope assessment of Carnegie stage and dissection where required. Photography and image capture records were made at the same time. Three hundred and nineteen embryos (60%) were obtained of which 6 were lost during inclusion, 38 were damaged, 11 judged abnormal, 41 were frozen, 64 were used for electronic microscopy studies and 160 were paraffin embedded. The embryos spanned Carnegie stages 9-21 which correspond to a wide window of human organogenesis A potential concern is the uncertainty as to when embryonic demise actually occurs as autolysis may reduce mRNA retention, producing suboptimal expression studies. Our experience is that mRNA is retained and in situ hybridization experiments for several genes (RET, GDNF, SOX10, PAX2, SHH, JAGGED1...) are successful. Chromosome analysis of 37 embryos was obtained using FISH analysis with chromosomes 16, X and Y probes. No abnormal result has been noted to date. In conclusion, we believe that there is a need for future research on human embryos. The collection of intact embryos from medical termination is possible. It provides embryos spanning a wide window of human development. Our experience shows that molecular and tissue in situ hybridization studies are possible on this material. We are making material from our collection available for collaborative gene expression studies.

Program Nr: 400 from the 1999 ASHG Annual Meeting

Physical mapping of the MKS2 locus in Meckel syndrome. *L. Benedetti-Clech[1], J. Roume[2], M. Le Merrer[1], V. Cormier-Daire[1], J. Augé[1], A. Munnich[1], F. Encha-Razavi[1], N. Dagonneau[1], M. Vekemans[1], T. Attié-Bitach[1].* 1) Dept de Génétique & INSERM U-393, Hopital Necker, Paris, FRANCE; 2) Service de Foeotopathologie, Hopital St Antoine, Paris, FRANCE.

Meckel syndrome (MKS) is a rare, lethal autosomal recessive disorder characterized by occipital meningoencephalocele, multicystic dysplasia of the kidney, fibrotic changes of the liver and postaxial polydactyly. MKS1 has been mapped to chromosome 17q21-q24 in Finnish pedigrees. However, genetic heterogeneity at this locus has been shown in several Western European and North African families. More recently, based on homozygosity mapping in seven inbred families from North Africa and the Middle East, a second locus, MKS2, has been mapped to chromosome 11q13 between markers D11S916 and D11S937. Interestingly, in this form of the disease, fetuses show a distinctive CNS malformation pattern, including a prosencephalic dysgenesis, an occipital exencephalocele and a rhombic roof dysgenesis with absent tectum of the brain and agenesis/ dysgenesis of the cerebellar vermix. In order to refine the mapping of the MKS2 locus, we constructed a physical map using 14 overlapping yeast artificial chromosome (YAC) clones. Microsatellite markers of the YAC contig were subsequently studied in the families. This allowed us to restrict the homozygous region to a 0 cM genetic interval between markers D11S4079 and D11S937. The critical region is included in two overlapping YACs (1 Mb). We are currently constructing a bacterial artificial chromosome (BAC) contig by screening the RPCI-11 BAC library with the markers closely linked to the MKS2 locus. In addition, using a complementary strategy to identify candidate genes, four expressed sequence tags were excluded (including the ARIX gene). Another candidate gene located on the contig, possibly in the homozygous region, is being sequenced in MKS2 patients. In conclusion, at least two mutant genes are associated with the MKS phenotype. The identification of these genes should contribute importantly to our understanding of brain, kidney and limb human embryonic development.

Program Nr: 401 from the 1999 ASHG Annual Meeting

Prenatal diagnosis and carrier detection of albinism. *A. Blumenfeld[1], I. Bejarano-Achache[1], A. Rosenmann[2].* 1) Molecular Biol Unit, Hadassah Univ Hosp; 2) Michaelson Inst for Prevention of Blindness, Hadassah Med Org, Jerusalem, Israel.

Oculocutaneus Albinism Type I (OCA I) is an autosomal recessive disease that comprises several phenotypes of hypopigmentation and low vision up to legal blindness. OCA I is caused by lack of tyrosinase activity, and in most cases mutations were found in the tyrosinase gene (TYR). Due to the severe visual handicap, affected families seek genetic counseling and prenatal diagnosis.

Prenatal diagnosis of OCA I was performed at Hadassah since 1989 by light and electron microscopic examination of melanogenesis in fetal scalp biopsies. Thirty one prenatal tests were performed, and five affected fetuses were diagnosed. Since 1997 we offer molecular genetic tests for carrier detection, and prenatal diagnosis of OCA I. Five molecular prenatal tests were performed, and two affected fetuses were diagnosed. In three families mutations in the two copies of the TYR gene were detected in the propositus; one is a compound heterozygote, and two were homozygote. Each of the normally pigmented parents was found to carry one mutation, and the fetuses were tested by direct screening for the mutation(s). In the two other families, only one mutation was detected in the propositus. Three polymorphisms within the TYR gene were used to determine haplotypes of the albino child and both parents. The prenatal test was based on a combination of mutation detection and haplotype analysis.

We have screened 115 unrelated Israeli albinos and their families with twelve mutations previously described in our population, or in non-Israeli Caucasians. In certain ethnic groups we found at least one mutation in all, and two mutations in over 90 percent of albinos. In these groups we offer mutation detection to normally pigmented unrelated spouses of albinos and of diagnosed carriers pertaining to OCA I families.

Based on our findings, prenatal and carrier molecular diagnosis of OCA I becomes possible in an increasing number of Israeli albino families.

Program Nr: 402 from the 1999 ASHG Annual Meeting

Chromosome 21 deletion and cortical dysgenesis: Intersectin (ITSN) is expressed in subsets of post-mitotic neurons in the developing brain. *X-N. Chen[1], D.P. Huynh[2], Y. Huo[1], Z-Y. Shi[1], M. Hattori[3], Y. Sakaki[3], S.M. Pulst[2], J.R. Korenberg[1]*. 1) Med Genet, Cedars-Sinai Med Ctr, UCLA, CA; 2) Dept Medicine, Cedars-Sinai Med Ctr, UCLA, CA; 3) Human Genome Research Group, RIKEN GSC, Japan.

To study the mechanisms responsible for Down Syndrome (DS) and aneuploidy of chromosome 21, we have characterized genes in the candidate region for cortical dysgenesis (CD) and deletion 21. The gene encoding intersectin (ITSN) spans more than 300 kb of the 5 Mb candidate region, includes transcripts specific to the brain, and domains (EH, SH3, GEF, PH), and is involved in clathrin-mediated endocytosis. As first step, we studied its expression and deletion in 16 individuals using FISH. In the fetal and adult human, we used multiple-tissue Northern blots with 20 exon and domain-specific cDNA fragments and in the developing and adult mouse, domain-specific immunocytochemistry. For human expression, novel patterns of fetal- and brain-specific transcripts were found. These include a 4.5 kb moiety specific to the fetus, that includes all domains of ITSNs with high expression in liver and possibly significant for hematopoesis. A 2.0 kb form is also largely specific to fetus and appears to begin with the 5UTR encoded by exon 1 but excludes the EH domains and includes alternatively spliced forms of the SH3 domains. Exon1 is particularly highly expressed in fetal brain and alpha helix in fetal liver, kidney, brain and lung, suggesting further alternative splicing for isoforms involved in early development. For mouse, antibodies to SH3 (Src homology 3) domains were generated and used to study the brain in the developing and adult mouse. ITSN immunoreactivity was found beginning on E11 in subsets of post-mitotic neurons of the cortex, in axonal bundles and in the myocardium; on E14-16, in cellular subsets of the dermis. In the adult mouse brain, staining was also found in a subsets of neurons in the cortex, hippocampus, thalamus and the axonal bundles but not in cerebellum or in dendritic processes. These findings suggest a role for ITSN in the early development of the brain, a possible contribution to CD in deletion for 21, to the mental retardation found in DS.

Program Nr: 403 from the 1999 ASHG Annual Meeting

Mapping gene expression domains and neuronal cell differentiation during human embryonic forebrain development. *D.M. Hagan[1], S. Lisgo[1], T. Strachan[1], D. Davidson[2], R. Baldock[2], M. Stark[2], E. Boncinelli[5], M. Clement-Jones[1], D. Wilson[1], S.C. Robson[3], G. Clowry[4], S. Lindsay[1]*. 1) Human Genetics, Univ. of Newcastle Upon Tyne, Newcastle, UK; 2) MRC Human Genetics Unit,Edinburgh,UK; 3) Dept. of Fetal Medicine. Univ. of Newcastle upon Tyne,UK; 4) Dept. of Child Health, Univ. of Newcastle upon Tyne, UK; 5) Lab. of Molecular Biology of Development, Milan, Italy.

The human forebrain is crucially important to higher order functions and is affected by many significant and disabling genetic or congenital disorders. From a very early stage of development the human forebrain is unmistakably different from that of other mammalian species suggesting that we need to study forebrain development directly in human. Fundamental to normal brain development is the differentiation of progenitor cells along either neuronal or glial pathways, processes which are under genetic control. Relatively little however is known about the molecular mechanisms controlling development and differentiation of the embryonic forebrain.

We examined the expression of a range of genes in embryonic forebrain at human CS18 (44 post-ovulatory days). The genes investigated are either implicated in mammalian forebrain development and/or are causative genes for disorders with abnormal brain pathology and include *PAX6, PAX3, SHH,EMX1,EMX2,OTX1* and *OTX2*. We have also investigated neuronal and glial cell differentiation immunohistochemically. All of the genes investigated were abundantly expressed at CS18. Specific domains of expression were identified within the developing forebrain. Expression boundaries did not necessarily conform to any one underlying morphological feature concurring with the concept of gene expressing subregions or compartments within the developing forebrain neuroepithelium. To aid visualisation and interpretation of the gene expression and immunohistochemical patterns, computer-based 3 dimensional reconstructions of the data are being prepared. This study should provide a better understanding of the complex organisation and gene interactions of the developing human forebrain.

Program Nr: 404 from the 1999 ASHG Annual Meeting

Improved Growth and Cultured Neuron Viability In Partial Interferon-Alpha/Beta and -Gamma Receptor Knockout Trisomy 16 Mouse Fetuses. *D.M. Hallam, T.N. Heffernan, L.E. Maroun.* Department Of Medical Microbiology And Immunology, Southern Illinois University School Of Medicine, Springfield, IL.

The trisomy 16 mouse fetus is a well studied model for Down syndrome (Trisomy 21), the leading genetic cause of mental retardation in the newborn population. Human chromosome 21 and mouse chromosome 16 each carry a large cluster of genes that code for components of the interferon (IFN) -alpha/beta and -gamma receptors, and Down syndrome cells display significantly increased sensitivity to IFN action. We have previously reported that in utero anti-IFN IgG treatment of mice pregnant with trisomy 16 fetuses results in a significant improvement in trisomy 16 fetus growth and morphology [Teratology 51 (1995) 329-335] and that anti-IFN-gamma immunoglobin treatment can prevent the premature death of trisomy 16 fetal mouse cortical neurons in culture [Neurosc. Lett. 252 (1998) 17-20]. As a measure of growth, trisomy fetus crown-to-rump length was measured relative to euploid littermates. To evaluate neuron viability, cortical neurons were cultured in serum-free media for six days and quantitated by photographic analysis. Apoptosis was assessed using the annexin-V apoptosis assay and analyzed by flow cytometry. We have now used interferon receptor subunit knockout mice to produce mouse fetuses that carry three #16 chromosomes and one copy each of disabled IFN-gamma receptor and IFN-alpha/beta receptor component genes. We observed that this partial interferon receptor knockout trisomy mouse fetus has significantly improved growth, and yields cortical neurons whose viability and frequency of apoptosis is the equivalent of that seen in their euploid counterparts.

Program Nr: 405 from the 1999 ASHG Annual Meeting

The Prenatal Diagnosis of the Skeletal Dysplasias. *D. Krakow[1], M. Priore[1], L. Rimoin[1], D. Carlson[1], R. Lachman[2], D. Rimoin[1]*. 1) Division of Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Department of Radiology, Harbor-UCLA Medical Ctr, Torrance, CA.

The osteochondrodysplasias, including the dysostoses, are a genetically heterogeneous group of disorders characterized by abnormalities in the patterning, development, growth and maintenance of cartilage and bone. While it is difficult to determine the precise incidence of these disorders, the overall birth incidence for this group of conditions approaches 1/10,000. With the increasing use of ultrasound many prenatal-onset skeletal dysplasias are now being recognized, but a precise diagnosis determined by ultrasound findings can be challenging. Through the International Skeletal Dysplasia Registry (ISDR) we undertook two studies. First we retrospectively analyzed over 750 cases which were ascertained in the prenatal period by either ultrasound or radiographs. In 70 % of the cases the referring diagnosis was incorrect, and the diagnosis correct in approximately 30%. The most common final diagnoses made by the ISDR were osteogenesis imperfecta type II (20%), thanatophoric dysplasia (11%), and achondrogenesis II (8.2%). When compared to the referring diagnosis, these three relatively common diagnoses were made correctly less than half the time. We have prospectively ascertained ultrasounds in over 80 cases referred to us for a precise diagnosis. We have determined lethal versus non-lethal in 100% of the cases, and overall, we have generated the correct diagnosis based on ultrasound findings in almost 80% of cases. The criteria that we employ for diagnosis are based on those used for radiographic diagnosis. For example, these include the size and shape of the long bones, the location of the bony abnormality, mineralization and associated congenital anomalies. Our ultrasound referred cases are then analyzed by radiographs, histomorphology and molecular diagnosis when applicable. This is of critical importance since the most accurate diagnosis must be made for the further counseling of the families. We believe that with careful review and an understanding of the radiographic findings in these disorders, an accurate diagnosis can be obtained in the prenatal period.

Program Nr: 406 from the 1999 ASHG Annual Meeting

Mammalian orthologs of invertebrate sex differentiation genes are androgen-responsive in motor neurons. *A.P. Lieberman[1], D.L. Friedlich[2], K.H. Fischbeck[1]*. 1) Neurogenetics Branch, NINDS, NIH, Bethesda, MD; 2) HHMI-NIH Research Scholars Program.

The androgen receptor is a ligand-activated transcription factor that is expressed in motor neurons of the brainstem and spinal cord. Activation of the androgen receptor induces trophic effects in motor neurons in vivo. We sought to identify androgen-responsive genes in motor neurons in hopes of identifying novel pathways activated by androgens in these cells. Mouse motor neuron-neuroblastoma hybrid cells permanently transfected with the full-length normal human androgen receptor respond to stimulation with a synthetic androgen (R1881) by showing increased survival and enlarged soma size. This in vitro model thus recapitulates the trophic actions of androgens on motor neurons. Using this model and a PCR-based subtractive hybridization approach, we identified ten genes that are expressed at higher levels following androgen stimulation. Two of these genes, tra-2 alpha and fox-1, encode RNA-binding proteins that are mammalian orthologs of invertebrate sex differentiation pathway components. Tra-2 (transformer-2) is an enhancer of RNA splicing involved in Drosophila and C. elegans sex differentiation, while fox-1 (feminizing on X-1) functions upstream of tra-2 in C. elegans. Expression of both genes is increased in our model by stimulation with R1881 in a time and dose-dependent fashion. We isolated full-length cDNAs for mouse tra-2 alpha and fox-1, and found that they are widely expressed in mouse tissues. Tra-2 alpha mRNA is subject to complex, tissue-specific alternative splicing. The full-length cDNA, consisting of two RS domains and the RNA recognition motif, is the dominant form expressed in brain and is the major androgen-responsive transcript in our in vitro model. Mouse fox-1 protein is 90% identical to the human fox-1 protein, and is 75% identical to C. elegans fox-1 over an 84 amino acid stretch that encodes the RNA binding domain. Our data suggest that a pathway consisting of mammalian orthologs of invertebrate sex differentiation genes is androgen-responsive in motor neurons.

Program Nr: 407 from the 1999 ASHG Annual Meeting

Expression of the short stature homeobox gene, *SHOX*, correlates with skeletal abnormalities in Turner syndrome. *S. Lindsay[1], M. Clement-Jones[1], E. Rao[2], R.J. Blaschke[2], A. Zuniga[3], R. Zeller[3], S.C. Robson[4], T. Strachan[1], G.A. Rappold[2]*. 1) School of Biochem. & Genetics, Univ Newcastle upon Tyne, Newcastle on Tyne, England; 2) Institute of Human Genetics, Ruprecht-Karls-University, Heidelberg, Germany; 3) Dept. of Developmental Biology, Univ Utrecht, Utrecht, The Netherlands; 4) Dept. of Fetal Medicine, Univ Newcastle upon Tyne, Newcastle upon Tyne, England.

Turner syndrome is characterized by short stature and is frequently associated with a variable spectrum of somatic features: gonadal dysgenesis, heart and renal abnormalities and a range of skeletal anomalies which include Madelung deformity, a key feature of Leri-Weill syndrome. Defects of the pseudoautosomal homeobox gene SHOX were previously shown to lead to short stature and Leri-Weill syndrome (1,2), and haploinsufficiency of SHOX was suggested to cause the short stature phenotype in Turner syndrome (3,4). Despite exhaustive searches, no direct murine orthologue of SHOX is evident. SHOX is however closely related to the SHOX2 homeobox gene on 3q which has a murine counterpart, Og12x (5,6). We analysed SHOX and SHOX2 expression during human embryonic development, and referenced the expression patterns against those of Og12x. The SHOX expression pattern in the limbs and first and second pharyngeal arches not only explain SHOX related short stature phenotypes but also for the first time provide strong evidence for the causal involvement of this gene in the development of additional Turner stigmata. 1. Program Nr: 408 from the 1999 ASHG Annual Meeting

Gene Expression Profiles of Developing Forelimbs and Hindlimbs: Investigating the Genetic Pathways of Limb Identity. *E.H. Margulies*[1], *J.W. Innis*[1,2]. 1) Departments of Human Genetics and; 2) Pediatrics, University of Michigan, Ann Arbor, MI.

Dramatic morphological differences exist between the upper and lower limbs of animals. While most of the genes known to be involved in limb development are similarly expressed in both structures and conserved between animal species, some genes, such as the transcription factors *Pitx1*, *Tbx5*, and *Tbx4*, are differentially expressed and have recently been identified as important components of the genetic pathways determining limb identity. However, upstream regulators and downstream targets of these transcription factors are predominantly unknown. A comprehensive gene expression profile from the developing forelimb and hindlimb would 1) provide a novel resource for determining the genetic hierarchies regulating limb development and identity 2) allow for an evolutionary comparison of limb patterning between other animal models 3) identify candidate genes for the nearly four dozen inherited human limb malformation syndromes that affect either the upper or lower limbs and 4) identify the subset of all genes specifically expressed in the developing vertebrate limb.

To identify differentially expressed genes between developing forelimbs and hindlimbs, Serial Analysis of Gene Expression (SAGE) was used to generate a comprehensive, unbiased and quantitative gene expression profile from populations of mRNA purified from mouse E11.5 forelimbs and hindlimbs. 11,776 forelimb and 11,806 hindlimb SAGE Tags representing 10,793 different transcripts were sequenced. Using the test statistic developed by Audic and Claverie (1997), 69 transcripts, including *Pitx1*, were identified as differentially expressed ($p < 0.05$) and 30 have a greater than 5-fold difference. Whole-mount *in situ* hybridizations are being used to confirm the gene expression differences detected by SAGE and to identify other regions of expression in the embryo. This is the first comprehensive analysis of gene expression in the developing vertebrate limb and will provide a valuable framework for investigating the genetic interactions involved in limb identity and development.

Program Nr: 409 from the 1999 ASHG Annual Meeting

Novel function of *LMX1B*during kidney and limb development and pathogenesis of nail patella syndrome. *R. Morello[1,2], S.D. Dreyer[1], K. Oberg[1,3], B. Lee[1]*. 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Advanced Biotech. Center, Genoa, Italy; 3) Pathology, Loma Linda Univ., Loma Linda, CA.

Nail patella syndrome (NPS) is a dominantly inherited skeletal malformation syndrome characterized by nail, skeletal and renal abnormalities. Mutations in a LIM homeodomain protein (LIM HD) specifying dorsal limb mesenchymal cell fate, *LMX1B*, result in NPS. Interestingly, *Lmx1b-/-*mice duplicate the human condition. Here, we performed transactivation studies to determine whether a dominant negative effect might underlie the NPS phenotype in human vs. mice. In addition, we identify potential downstream targets of *Lmx1b*in joint and kidney development. Transfection of mutant *LMX1B*constructs containing homeodomain, LIM domain, and activation domain mutations each exhibited dose-related loss of transactivation of target reporters without dominant negative effect on wild type *LMX1B*action in mixing experiments. This was unaffected by cotransfection of LIM HD interacting proteins, E47 and Ldb1. We tested markers of joint development *Gdf-5*and *sFRP2*as candidate targets of *LMX1B*action. While *Gdf-5*expression is normal in the mutant mice, *sFRP2*expression appears to be symmetrically distributed in the dorsal-ventral axis of the *Lmx1b-/-*limb. This effect is likely due to the ventralized pattern of the dorsal structures in mutant limbs. In contrast to *LMX1B*function in limb development, its role in kidney development was discovered by correlation with the renal phenotype in NPS. Based on histological abnormalities in glomerular basement membranes (GBM) of NPS patients, we hypothesized that *LMX1B*might play a role in GBM development. We show that *Lmx1b*localizes to the glomeruli from E15.5 and newborn mice. Expression of *sFRP2*, also a marker of glomerular epithelium, and of a1(IV) collagen were intact. However, mutant kidneys showed marked absence of a3(IV) and a4(IV) collagen expression consistent with histologic GBM abnormalities and the clinical albuminuria observed in NPS patients. Moreover, this suggests a novel and integral role for*LMX1B*in the coordinated transcriptional switching of a1(IV) and a2(IV) to a3(IV) and a4(IV) expression during GBM morphogenesis.

Program Nr: 410 from the 1999 ASHG Annual Meeting

Detection of male and female fetal DNA in maternal plasma by multiplex fluorescent PCR amplification of short tandem repeats (STRs). *B. Pertl[1], O. Samura[2], A. Sekizawa[2], D.W. Bianchi[2]*. 1) Dept of Ob/Gyn, Univ of Graz, Graz, Austria; 2) Division of Genetics, Dept of Pediatrics,Tufts Univ Sch of Med, Boston, MA.

Background: Bi-directional cell trafficking of fetal and maternal cells occurs during pregnancy. Almost all-prior investigations have focused on complete and intact fetal cells in the maternal circulation. Recently, reports by Lo et al. have suggested that large amounts of cell-free fetal DNA are detectable in maternal serum and plasma. However, prior reports only detected Y chromosomal sequences in male fetuses. The goal of this study was to develop a fluorescent PCR assay for the detection of both male and female fetal circulating DNA in the plasma of pregnant women.

Methods: Maternal DNA was extracted from plasma samples of 12 pregnant women at term and newborn umbilical cord blood DNA was extracted to confirm fetal polymorphisms. The mother/child pairs were genotyped at 9 different polymorphic short-tandem repeat (STR) loci. Multiplex fluorescent PCR was used to detect fetus-specific alleles in the corresponding maternal plasma samples.

Results: Fetus-specific alleles were found in all maternal plasma samples studied. Using these polymorphic STRs every mother-child pair was informative in at least 4 out of 9 loci. Paternally inherited fetal alleles were detected in 80% of informative STRs.

Conclusions: Compared to other fetal DNA detection systems that use fetus-derived Y sequences to detect only male fetal DNA in maternal plasma, our technique can be applied to both male and female fetuses. This may expand the clinical applications of the use of fetal DNA in maternal plasma.

Program Nr: 411 from the 1999 ASHG Annual Meeting

Preimplantation diagnosis for translocations by karyotyping single blastomeres and second polar body. *Y. Verlinsky, S. Evsikov, J. Cieslak, V. Ivakhnenko, G. Wolf, C. Strom, A. Kuliev.* Reproductive Genetics Inst, Chicago, IL.

Preimplantation genetic diagnosis (PGD) for translocations is currently based on interphase FISH analysis of blastomeres or the first polar bodies, containing metaphase chromosomes, which, however, still have limitations for testing of some translocations and for complete karyotyping. To improve the accuracy of PGD for maternal translocations by the first polar body, sequential karyotyping of the second polar body or single biopsied blastomeres is required. Visualization of the chromosomes of single blastomeres is also needed for accurate PGD for paternally derived translocations. To obtain metaphase chromosomes from the human second polar body, we injected the polar body nucleus into the cytoplasm of an enucleated oocyte, which was followed by treatment with okadaic acid to induce premature chromosome condensation. Analyzable chromosomes were obtained in 66% of cases, and the method was applied for PGD of the following maternal translocations: t(17;18)(q32;q23); t(12;18)(p13.31;q21.32). To visualize chromosomes of single human blastomeres, we fused biopsied blastoneres with enucleated or intact mouse zygotes and fixed the resulting heterokaryons at the metaphase of the first cleavage division, or treated with okadaic acid to induce premature chromosome condensation. The method was 91% efficient and has been applied for PGD of the following paternally derived reciprocal translocations: t(6;7)(q23;q36); t(11;22)(q23.3;q11.2); t(1:8)(p13;q23); t(13;20)(q22;q11.2); t(15;16)(q13;q13). Of 49 embryos tested, karyotyping allowed pre-selection of 13 balanced or normal embryos for transfer back to patients. Both of these methods in combination with FISH analysis will allow a significant improvement in PGD of both maternally and paternally derived translocations.

Program Nr: 412 from the 1999 ASHG Annual Meeting

RNA interference of SMN, Spinal Muscular Atrophy gene, leads to embryonic lethality and to germ cell apoptosis in the nematode C.elegans. *S. Bertrandy[1], S. Lefebvre[1], Y. Kohara[2], A. Munnich[1], D. Thierry-Mieg[3]*. 1) INSERM U393, Hopital Necker Enfants Malades, Paris, France; 2) NIG, Mishima, Japan; 3) CRBM-CNRS, Montpellier, France.

Spinal muscular atrophy (SMA) is a frequent autosomal recessive neuromuscular disorder characterized by degeneration of spinal motoneurons. The disease results from alterations of the Survival Motor Neuron (SMN) gene encoding a 294 amino acid protein of unclear function. SMN protein interacts with RNA and RNA-binding proteins and is involved in spliceosomal snRNP biogenesis and pre-mRNA splicing. Recently, we have shown that SMN proteins from C.elegans and Danio rerio bind RNA in vitro. RNA interference experiments were carried out by injection of SMN ds-RNA in wild type animals that generated a progeny with various defects. Two-days post-injection, there was sudden burst of late embryonic lethality that affects 100% of late progeny, indicating SMN requirement for survival in C.elegans. Furthermore, the day after injection, many healthy adult progeny had gonads with few germ cells and signs of germ cell apoptosis. This defect was completely suppressed when injecting the ced-4 (n1162) mutant involved in the execution of the programmed cell death pathway. This epistasis result indicates that SMN has a protective effect on germ line cells. Interestingly, the ced-4 mutant did not suppress the embryonic or larval lethality. Unlike what seems to happen in the mouse, where SMN inactivation led to massive apoptosis in early embryos, here the cause for lethality is not just ced-4 dependant apoptosis. We shall present in situ RNA hybridization and immunofluorescence data in C.elegans. Preliminary results indicate that this ubiquitous gene is highly expressed in gonads and in developing embryos. In very early embryos, the protein localizes mainly to cytoplasmic granules and later in the nucleus. We would like to know if SMN controls alternative splicing of ced-4 in germ line and if it plays a role in maturation, splicing, protection or transport of specific RNAs (especially maternal). Investigations in C. elegans will help understanding the role of SMN in cellular survival.

Program Nr: 413 from the 1999 ASHG Annual Meeting

XIST expression in embryonal carcinoma cells: a model for X-chromosome inactivation in early human development. *J.C. Chow[1], C.M. Clemson[2], J.B. Lawrence[2], C.J. Brown[1]*. 1) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Dept. of Cell Biology, University of Massachusetts Medical Centre, Worcester, Mass.

X-inactivation results in a cis-limited silencing of most genes on one X in females. Xist is required for the initiation and spread of inactivation and in mouse, prior to inactivation, it is expressed as a low-level unstable transcript from both X's. Upon differentiation, only the inactive X obtains a high level of stable Xist expression--a change which may involve a promoter switch or an antisense transcript. To address whether human XIST has the same differential promoter usage and stability changes early in development, we have analyzed expression in human somatic cells and lines derived from earlier in development, including embryonal carcinoma (EC) lines. Using RT-PCR, we found a low-level stable transcript that initiates ~100bp upstream of the main transcriptional start in male and female somatic cell lines and in a male EC line, but no transcription further upstream. From its expression profile in both male and female somatic cells and its stable nature (T1/2 ~5h), this upstream transcript does not appear to be the human equivalent of the mouse upstream promoter. We also detected expression 18 kb downstream of the published 3'end of XIST and are currently characterizing the transcript to determine its orientation and start site. Using quantitative RT-PCR, XIST levels in female somatic cells were found to be ~2000 molecules/cell. In male and female EC lines, however, XIST levels were significantly lower, 1/100 and 1/10 of normal female somatic levels, respectively. This is due in part to the fact that these lines contain a mixed population of cells as seen by RNA-FISH, with some cells showing a low-level pinpoint XIST signal that colocalises with the X chromosome. We are currently determining the inactivation status of the X-chromosomes present in the EC lines and monitoring changes after induction of differentiation in order to identify cell lines representative of early stages of human development.

Program Nr: 414 from the 1999 ASHG Annual Meeting

Association of the sonic hedgehog receptor patched with caveolin-1. *M.R. Gailani, J. Bukowski, H.J. Karpen.* Dept Pediatrics, Yale Univ, New Haven, CT.

The hedgehog signalling pathway, first described in Drosophilla and conserved in vertebrates, plays an important role in early embryonic patterning and continued control of cell growth. Activation of the pathway results in cancer including basal cell carcinoma of the skin. Sonic hedgehog (verterate homologue, SHH) acts on target cells to increase transcription of several genes including its receptor patched (PTCH). PTCH, a negative regulator of the pathway, associates with a second membrane protein smoothened (SMO), inhibiting its function. When SHH binds to PTCH, SMO can transmit the SHH signal. We hypothesized that the PTCH/SMO receptor complex localizes to the cell membrane and other proteins may be involved in complex formation. To study this, PTCH and SMO cDNAs were linked to the green fluorescent protein cDNA, transfected into COS cells, and examined under confocal microscopy. The majority of PTCH was concentrated in the golgi with some of the protein moving to and from the cell membrane. A 3-D reconstruction of the cell suggested PTCH localized just under the membrane in association with caveolae; small micro-invaginations of the cell membrane. Caveolin-1, the major structural protein of caveolae, concentrates a diverse group of signalling molecules within caveolae, usually in an inactive state. We hypothesized that the SHH receptor complex is sequestered in caveolae through a direct interaction between PTCH and caveolin-1. Co-immunoprecipitation and immunocytochemistry (ICC) studies confirm that the two proteins associate with each other. Similar experiments with SMO and caveolin show no direct interaction, however all three proteins co-localize at the cell membrane. PTCH contains a putative caveolin-1 binding site which directly binds caveolin-1 in GST fusion protein binding experiments. Co-fractionation experiments confirm that caveolin-1 and PTCH are at the cell membrane. The data suggests a model by which the SHH receptor complex is held in an inactive state at a defined region in the cell membrane. Future studies will examine the effect of the SHH protein on this complex. Knowledge of protein interactions in the SHH receptor complex may suggest drug targets and therapeutic interventions aimed at susceptible tumors.

Program Nr: 415 from the 1999 ASHG Annual Meeting

Functional and expression studies of APECED protein and its mouse homologue. *M.K. Halonen[1,2], P. Bjorses[1,2], J.J. Palvimo[3], M. Pelto-Huikko[4], L. Peltonen[5,1], M. Kolmer[1], I. Ulmanen[1]*. 1) Department of Human Molecular Genetics, National Public Health, Helsinki, Finland; 2) Hospital for Children and Adolescence, Helsinki University Hospital, Finland; 3) Department of Physiology, Unversity of Helsinki, Finland; 4) Department of Anatomy, University of Tampere, Finland; 5) Gonda Neuroscience and Genetics Research Center, UCLA, Department of Human Genetics, Los Angeles, California, USA.

Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) is an autoimmune disease with autosomal recessive inheritance. We have cloned the defective gene named AIRE and shown that in transiently transfected mammalian cell lines the APECED protein is mainly located in specks in the cell nucleus. APECED protein harbors two PHD zinc fingers, four LXXLL domains, a SAND domain and an ASS domain suggesting a function in transcription regulation. By immunohistochemistry the human APECED protein appears in immunologically relevant tissues such as the thymus, spleen, lymph nodes and peripheral leukocytes. We have characterized 16 different mutations in APECED patients. Four mutations affecting different domains of the protein were further analyzed by in vitro transient expression to examine the effects of the mutations on the subcellular targeting of the APECED protein. Most of the mutant proteins were not transported to the nucleus. Using transactivation assay we examined the potential of the mutant APECED proteins to activate transcription. For most of the mutants analyzed, the stimulating effect on transcription was totally lost or significantly reduced. We have also cloned the mouse APECED cDNA. The expression pattern of the mouse Aire gene was studied in various transfected cell lines, finding the subcellular localization very similar to the human counterpart. Utilizing antisera against mouse peptides we have studied the tissue distribution of APECED protein in mouse. The mRNA distribution was characterized by in situ hybridization. The results obtained by both methods indicate that mouse APECED protein is expressed in specific thymal cells as well as in other immunological tissues. The mouse Aire gene also exhibits transactivation properties.

Program Nr: 416 from the 1999 ASHG Annual Meeting

Localization of BLM in the PML-nuclear bodies is mediated by a functional domain within its N-terminus. *P. Hu, T. Ye, S.F. Beresten, R. Stan, A.J. van Brabant, N.A. Ellis.* Department of Human Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY, 10021.

Blooms syndrome (BS) is a rare, autosomal recessive disorder characterized by short stature and a predisposition to developing cancers of all types. Cells derived from BS patients exhibit hypermutability and increased chromatid exchange including evaluated sister-chromatid exchange (SCE). BLM, the gene mutated in BS, encodes a DNA helicase that belongs to the RecQ DNA helicase family and stable transfection of BLM can bring to or toward normal the high-SCE phenotype of BS cells. By indirect immunofluorencence, we observed the BLM protein in two predominant patterns: 1) discrete nuclear dots that colocalize with the PML-nuclear bodies (PML-NBs), and 2) diffuse microspeckles. In order to understand the function of BLM in the PML-NBs, we mapped the functional domain in BLM that is required for its PML-NB localization. Ten different mutated BLM constructs were generated in fusion with GFP, including one with the helicase domain (amino acids 674-1114) deleted, four with various deletions from the N-terminus (from amino acid 1 to 568), and five N-terminal segments linked to the nuclear localization signal. Each construct was transiently transfected into HeLa cells, and the cells were immunostained with anti-PML. When normal GFP-BLM was transfected, approximately 50% of the cells exhibit GFP dots and nearly all GFP dots colocalized with the PML-NBs. By transfecting mutant GFP-BLM constructs and counting the percentage of cell with GFP dots and GFP dots in the PML-NBs, we mapped a 300 amino acid region in the N-terminus of BLM that is sufficient to mediate translocation into the PML-NBs. SCE analysis has been carried out on several key constructs after they were permanently transfected into BS cells, and preliminary evidence suggests that cells containing BLM proteins which fail to localize to the PML-NBs have SCE frequencies that are intermediate; that is between normal and vector-transfected BS cells. Helicase assays are now underway. These results will allow us to determine whether localization of BLM in the PML-NBs is required for maintenance of genomic stability.

Program Nr: 417 from the 1999 ASHG Annual Meeting

Structure of the giant *HERC2*gene and identification of multiple partial paralogs. *Y. Ji[1], N.A. Rebert[1], J.M. Joslin[2], M.J. Higgins[3], R.A. Schultz[2], R.D. Nicholls[1]*. 1) Case Western Reserve Univ., Cleveland, OH; 2) Univ. Texas Southwestern Med. Cntr., Dallas, TX; 3) Roswell Park Cancer Inst., Buffalo, NY.

Recombination between chromosomal specific low-copy repeats (duplicons) is the underlying mechanism for several microdeletion syndromes. Recently, we and others identified a chromosome 15 duplicon in the common breakpoint regions of Prader-Willi (PWS) and Angelman syndrome (AS) deletions. We identified a large 15 kb transcript, *HERC2*, as an ancestral gene in this duplicon as well as a family of ~11 *HERC2*-related genes. A rearranged *HERC2* transcript was detected in 1 of 5 PWS/AS deletion patients. Therefore, we proposed that the presence of large blocks of homologous sequence and active transcription of *HERC2*-related duplicons at 15q11 and at 15q13 facilitates recombination and leads to the PWS/AS deletions. *HERC2* encodes a giant protein of 528 kD, with motifs suggesting function as a guanine nucleotide exchange factor and E3 ubiquitin protein ligase. We report here characterization of the *HERC2* gene structure and duplicated segments, and identify a *Drosophila* homolog. A genomic contig of *HERC2* was sequenced, revealing a total of 93 exons spanning ~250 kb, and a strong CpG island promoter. A ribosomal protein L41 processed pseudogene was found in intron 2 of *HERC2*, and a putative VNTR comprised of 27 copies of a ~76-bp repeat occurs in intron 70. Multiple duplicated but rearranged copies of *HERC2* were identified by database analysis. Sequence comparison indicates that *HERC2* has undergone several deletion events to form complex duplicons in 15q11, 15q13 and 16p11. Zoo-blot analysis identified *HERC2* homologs from human to *Drosophila*. Previously, we identified a unique mouse *Herc2* gene with 96% amino acid identity to human HERC2 and showed that mutations of *Herc2* lead to a developmental syndrome, *jdf2*. A partial *Drosophila* homolog was cloned, with amino acid identity of 70% to human HERC2 over 742 residues. Using BAC clones, we are mapping the chromosomal location to establish *Drosophila* as a model organism. These studies, and ongoing protein analyses, further our understanding of the function of *HERC2* in development and putative role in protein trafficking pathways.

Program Nr: 418 from the 1999 ASHG Annual Meeting

The order of intron removal influences the outcome of splice site mutations. *C.D. Kuslich, U. Schwarze, P.H. Byers.* University of Washington, Seattle, WA.

Splice site mutations cause many genetic disorders but it is unclear why identical mutations (e.g. IVSX+1G®A) have different outcomes, i.e. exon skip, intron inclusion or use of cryptic donor sites. We postulated that preferred order of intron splicing dictates the outcome of splice site mutations. To test this hypothesis we determined the order of intron removal in selected regions of three human collagen genes (COL1A1, IVS14-19; COL1A2, IVS19-22, IVS28-31 and IVS41-44; and COL3A1, IVS18-22) and examined the consequences of splice mutations in these areas. We incubated dermal fibroblasts with ActD for 5-40 minutes, isolated nuclear RNA, made cDNA and used intron/exon primer pairs to amplify intron-containing transcripts. Intron primers were labeled with fluors or ^{32}P and the products analyzed after PCR in the linear range by separation on the ABI310™ or PAGE, respectively. In the region examined in COL1A1, intron 16 is removed last in most transcripts. In COL1A2, the introns in the 19-22 domain are removed in reverse order, in 28 - 33 IVS32 is removed early, and in 41 - 44 region IVS42 is removed first in the major and 43 is spliced first in an alternative pathway. In COL3A1 there are alternative pathways in which IVS20 is usually removed late and infrequently before IVS19. Four +1G®A donor site mutations in these genes have different outcomes. In COL1A2 IVS30+1G®A results in exon 30 skip only; IVS32+1G®A skips and uses rare AT/AC terminal dinucleotides; IVS43+1G®A results in intron inclusion (major) and exon 43 skip (minor). In COL3A1, IVS20+1G®A results in rare exon skip, use of cryptic donor sites within the exon or intron, and intron inclusion. In COL1A1, IVS16-2A®G results in exon skipping (rare) and use of a cryptic acceptor site while in COL3A1 IVS19-3T®G results in exon 20 skipping only. These outcomes are all consistent with the following model: donor or acceptor site mutations in rapidly removed introns lead to exon skipping but the same mutations in slowly removed introns lead to use of cryptic sites or whole intron inclusion. Complex outcomes are consistent with multiple splicing pathways. Consequently, knowledge of splice order is essential for correct prediction of splice mutation outcomes. (NIH AR21557).

Program Nr: 419 from the 1999 ASHG Annual Meeting

Rent1, a mammalian *trans*-effector of nonsense-mediated RNA decay, is essential for cellular viability. *S.M. Medghalchi, H.C. Dietz.* HHMI and The Institute of Genetic Medicine, Johns Hopkins Univ School of Medicine, Baltimore, MD.

The ability to detect and degrade transcripts that lack full coding potential is ubiquitous but nonessential in lower eukaryotes, leaving in question the selective pressure for complete evolutionary maintenance of this function. One hypothesis holds that nonsense-mediated RNA decay (NMD) protects the organism by preventing the translation of peptides with dominant negative or deleterious gain-of-function potential. All organisms that are competent for NMD express a structural homologue of *S. cerevisiae* Upf1p. Recent data suggest that rent1, the mammalian counterpart, is essential for NMD in cultured cells. We have now explored the consequence of loss of rent1 and NMD function in vertebrates through targeted gene disruption in murine embryonic stem cells. The targeting event is predicted to delete all functional domains from rent1. Germline transmission of the targeted Rent1 allele was observed and resulting heterozygous (+/-) offspring showed no apparent phenotypic abnormalities. Fibroblasts derived from (+/-) animals showed full efficiency of NMD despite absence of immunodetectable protein from the mutant allele, suggesting that half-normal levels of rent1 can support the pathway. Breeding of (+/-) animals resulted in the expected 1:2 ratio between (+/+) and (+/-) offspring, but (-/-) mice were never observed ($p<0.0002$) documenting that rent1 is essential for embryonic viability. Analysis of staged embryos documented that (-/-) blastocysts are viable in the preimplantation stage but resorb immediately after implantation (3.5 and 6.5 d.p.c., respectively). Isolated day 3.5 p.c. (-/-) embryos emerged from the zona pellucida but the inner cell mass progressively regressed in culture. After 4 days in culture, both the inner cell mass and trophoblasts had completely deteriorated. In contrast, cells derived from (+/+) and (+/-) embryos proliferated and differentiated in culture. These data suggest that NMD is essential for mammalian cellular viability and support a role for the pathway in the regulated expression of critical physiologic transcripts. Ongoing studies using a conditional rescue allele should help to define the role of NMD in cellular metabolism.

Program Nr: 420 from the 1999 ASHG Annual Meeting

Functional genomics of the B-box gene family reveals a possible role in subcellular compartmentalization. *G. Meroni[1], A. Reymond[1], A. Fantozzi[2], S. Cairo[1], D. Riganelli[2], G. Merla[1], E. Zanaria[1], S. Messali[1], L. Luzi[2], A. Guffanti[1], P.G. Pelicci[2], A. Ballabio[1]*. 1) Telethon Inst Genetics & Med, Milan, Italy; 2) European Inst Oncology, Milan, Italy.

The genes belonging to the B-box family have been implicated in a variety of processes. Among them, PML, RFP, and Tif1 acquire oncogenic activity when fused to RAR alpha, RET, and B-raf, respectively. Recently, two additional B-box genes involved in human diseases have been identified, the FMF gene which is mutated in Familial Mediterranean Fever, and the MID1 gene, involved in X-linked Opitz syndrome. These genes contain a RING, two B-boxes, a coiled-coil, and a frequently conserved C-terminal domain. Very little is known about the molecular mechanisms mediating the function of B-box genes and thus we decided to redefine and characterize the entire family using a systematic and comprehensive approach to efficiently move from sequence/structure information to functional knowledge. We identified novel members of the B-box family by a systematic search of the dbEST and we have collected the full-length cDNA of the 15 known and 18 novel B-box genes. To evaluate the possible involvement of the B-box genes in human diseases, we have defined their chromosomal position and analyzed their expression patterns in adult tissues and during development. In addition, we have designed functional assays which allowed us to find that many family members show a strong growth suppression potential and are able to repress transcription. Moreover, we found that most of the B-box proteins are able to homodimerize and to form large multiprotein complexes. The B-box proteins, through their ability to form multiprotein complexes, appear to play an extremely important role in defining different subcellular compartments, both in the nucleus and in the cytoplasm, suggesting a possible involvement in compartimentalizing other proteins. These data will be useful to better understand the role of this class of proteins during normal development and to assess their role in the pathogenesis of tumors and inherited diseases.

Program Nr: 421 from the 1999 ASHG Annual Meeting

Characterization of a novel maternally imprinted human gene and its mouse ortholog located in the PWS region.

F. Muscatelli[1], I. Boccaccio[1], H. Glatt-Deeley[2], F. Watrin[1], N. Rockel[1], M. Lalande[2]. 1) Unite INSERM 491, Marseille, FRANCE; 2) Department of Genetics and development biology School of Connecticut 263 Farmington Avenue FARMINGTON C.T. 06117-1231 USA.

Within the PWS critical region, six imprinted genes which are expressed from the paternal allele only, have been isolated. SNRPN and NDN{JAY97, encode for proteins, IPW is spliced and polyadenylated and has been suggested to play a functional role as a RNA, PAR1 and PAR5 are two uncharacterized transcripts. Deficient mice for Snrpn, Ipw, Zfp127 and Ndnhave been independently created and any biological role cannot be associated to one of these genes in the etiology of the PWS mouse model phenotype. We now report the characterisation of a novel gene, nM, from the PWS region. We have shown that nM is imprinted and expressed from the paternal allele in human brain and fibroblasts.We have characterized and localised its murine ortholog, nS, in the syntenic region to the human PWS region. We demonstrate that nS is also expressed only from the paternal allele in brain. The mouse and human nM orthologous genes encode putative proteins may play a role in the etiology of the PWS phenotype and its mouse model respectively.

Program Nr: 422 from the 1999 ASHG Annual Meeting

A TIGR (or MYOC,GLC1A) Gene Promoter Polymorphism Associates with Steroid-Glaucoma and Evidence for Its Tissue Specific Expression in The Human Trabecular Meshwork Cells. *T.D. Nguyen[1], H. Chen[1], L. Kapp[1], S. Shirato[3], K. Kawasi[2], Y. Kitazawa[2], J.R. Polansky[1]*. 1) Dept. Ophthalmology, Univ California, San Francisco, San Francisco, CA; 2) Dept. Ophthalmology, Gifu University, Gifu 500, Japan; 3) Dept. of Ophthalmology, Univ. of Tokyo, Tokyo 113, Japan.

Since the steroid induction of the TIGR gene is a feature potentially relates to clinical manifestation of steroid-glaucoma patients, we evaluated possible promoter mutation(s) among these patients and analyzed their influence on the promoter functions. Genomic DNAs of 26 patients and 23 normal individuals were collected based on intraocular pressure (IOP) elevation by sustained topical steroid testings for 4 weeks (Armaly MF,1963). A polymorphic sequence of the promoter, namely TIGR.mt11, was found in over 50% of the patients but not found in the normals. Subsequently, a 283 bp promoter region that covers the TIGR.mt11 or TIGR.wt (wild type) sequences was cloned into alkaline phosphatase (AP) reporter gene vectors (SEAP, Clontech, CA.) and we showed that the TIGR.mt11 has more than 5 folds of AP activities over the TIGR.wt construct by transfection studies using transformed human trabecular meshwork (TM) cells. In similar studies for Hela and COS-7 cells, we found a significantly reduced AP activity compared to the TM cells. A similar AP activity was found for the three cell lines when a 1.4 kb promoter region was used suggesting that the 283 bp region is a target of TM tissue specific binding. Results obtained from gel shift assays for glucocorticoid treated and untreated TM and Hela cells have provided evidence for such a DNA binding protein. The TIGR.mt11 sequence variant and its effects on TIGR gene expression suggest possible association of the TIGR gene and steroid-glaucoma. Future studies of the mechanism of TIGR.mt11 mutation on TIGR gene expression, and characterization of the TM tissue specific factor(s) might be relevant for understanding genetics/pathogenesis of steroid-glaucoma, and possibly other forms of glaucoma. Supported by The Glaucoma Research Foundation, That Man May See, and InSite Vision, Inc..

Program Nr: 423 from the 1999 ASHG Annual Meeting

How does an A-to-G splice donor site mutation at position +3 result in aberrant splicing? A lesson learned from a mutation in the *COLQ* gene. *K. Ohno, J.M. Brengman, A.G. Engel.* Department of Neurology, Mayo Clinic, Rochester, MN.

Congenital endplate acetylcholinesterase (AChE) deficiency, the cause of a disabling myasthenic syndrome, arises from defects in the *COLQ* gene encoding the triple helical collagenic tail subunit of AChE that anchors catalytic subunits of AChE to the synaptic basal lamina. We recently cloned human *COLQ* cDNA, determined the genomic structure of *COLQ*, and identified 6 recessive truncation mutations in 6 patients (*PNAS* 95: 9654, 1998). We here report two novel disease-associated *COLQ* mutations: an A-to-G substitution at position +3 of intron 16 (IVS16+3A®G) and R315X. Family analysis shows that the mutations are heteroallelic and recessive. Because both A and G are consensus nucleotides at the +3 position of splice donor sites, we constructed a minigene spanning *COLQ* exons 15 to 17 and harboring IVS16+3A®G, and analyzed pre-mRNA splicing in COS cells. This revealed that IVS16+3A®G causes skipping of exon 16. The mutant splice donor site of intron 16 harbors five discordant nucleotides at -3, -2, +3, +4, and +6 that do not base-pair with U1 snRNA, the molecule responsible for splice donor site recognition. Using additional constructs of the minigene harboring IVS16+3A®G, we also show that a nucleotide complementary to U1 snRNA either at +4 or +6 restores normal splicing, whereas a complementary nucleotide at -3 or -2 has no or little beneficial effect on splicing. Consistent with a role of residues +4 and +6 in splicing, analysis of 1801 human native splice donor sites reveals that presence of a G nucleotide at +3 is associated with preferential usage of nucleotides concordant to U1 snRNA at positions +4 to +6. Analysis of 11 disease-associated IVS+3A®G mutations indicates that on the average 2 of 3 nucleotides at positions +4 to +6 fail to base-pair, and that the nucleotide at +4 never base-pairs, with U1 snRNA. We conclude that with G at intron position +3, normal splicing generally depends on concordance of intronic residues at +4 to +6 with U1 snRNA, but additional *cis*-acting elements may also participate in assuring fidelity of splicing.

Program Nr: 424 from the 1999 ASHG Annual Meeting

Gene-specific versus regional control of X inactivation: status of murine X-linked genes. *K. Tsuchiya, R.A. Conlon, H.F. Willard.* Case Western Reserve Univ. Cleveland, OH.

X inactivation results in transcriptional silencing of most, but not all genes on the inactive X chromosome. The factors that are responsible for the expression of a gene from the inactive X are unknown. Control of expression of X-linked genes may occur at the level of individual genes, at the level of chromosomal domains, or both. The clustering of six genes that escape inactivation in a 370 Kb region of human Xp11.2 indicates that there is at least one coordinately regulated domain on the human inactive X. To determine if this domain is present on the mouse X chromosome, we have characterized the mouse homologues of genes mapping in and adjacent to the Xp11.2 escape domain. We have determined that the mouse Dxs1008E, Smcx, Sb1.8, Ads9, and Ib772 genes are all present on the same 600 Kb mouse YAC, in the same relative order as the human genes. While human SMCX and mouse Smcx genes are known to escape inactivation, the mouse Sb1.8 gene is subject to inactivation, in contrast to human SB1.8. To extend these previous findings, we have now characterized the murine Dxs1008, Ads9, and Ib772 genes. Polymorphisms were identified and expression was tested by restriction enzyme digestion of RT-PCR products from two non-randomly inactivated F1 females resulting from a cross between t(X;16) carrier females and M. castaneus males. All three genes were subject to inactivation. The observation that Smcx is the only mouse gene in this region so far that escapes inactivation suggests that specific sequences in or near this gene may influence its expression from the inactive X. To test this hypothesis, we have made a construct consisting of a Betageo reporter under the control of 2.7 Kb of the mouse Smcx promoter. We have targeted this construct to Hprt, a locus on the X chromosome that is subject to inactivation. Six chimeric (80-100%) male mice have been generated and are being bred for germline transmission of the construct. We will then assess the X inactivation status of the reporter gene in hemizygous females by assaying lacZ expression, to test whether the Smcx promoter can confer the ability to escape inactivation in a different location on the X chromosome.

Program Nr: 425 from the 1999 ASHG Annual Meeting

The product of *Dazl*, a *DAZ* (Deleted in AZoospermia)-like gene, is associated with actively translating polyribosomes. *S. Tsui[1], T. Dai[1], E. Salido[2], S. Warren[3], P. Yen[1]*. 1) Medical Genetics, Harbor-UCLA Medical Center, Torrance, CA; 2) Pathology, University of La Laguna, Spain; 3) Howard Hughes Medical Institute, Emory University, Atlanta, Georgia.

The human *DAZ* gene family on the Y chromosome is deleted in about 10% of infertile males with idiopathic azoospermia. *DAZ* homologues are present on the Y chromosomes of great apes and old-world monkeys only. However, there is an autosomal *DAZL* (DAZ-like) gene that is present in all mammals examined. The DAZL and DAZ proteins, which are expressed in germ-cells only, contain an RNA recognition motif and either a single copy (as in DAZL) or multiple copies (as in DAZ) of a DAZ repeat. A role for DAZ and DAZL in spermatogenesis is supported by their homology to a *Drosophila* male infertility protein Boule, and the sterility of *Dazl* knock-out mice. The biological pathway in which these proteins act is unknown. Mouse Dazl was shown by immunostaining to be present mainly in the cytoplasm. We present data demonstrating that DAZ and DAZL bind to RNA polymers, preferentially poly U and poly G, *in vitro*. We also used an anti-DAZL antibody to trace Dazl in mouse testicular extracts and subcellular fractions. The majority of Dazl was found in the post-mitochondrial supernatant (PMS). On sucrose gradients, most Dazl co-migrated with polyribosomes, similar to the fragile X mental retardation protein Fmrp. Treatment of PMS with 30 mM EDTA, which dissociates polysomes into ribosomal subunits, or with RNase A, which breaks the polysomes into monosomes, caused a significant reduction in the sedimentation rate of Dazl, further supporting its association with polysomes. Additional studies indicated that Dazl was associated with polysomes through its binding to poly(A) RNA, which was affected by RNase and NaOH but not EDTA treatment. Our results implicate Dazl in translational regulation in germ cells.

Program Nr: 426 from the 1999 ASHG Annual Meeting

The cis-preference model of L1 retrotransposition. *W. Wei[1], E. Ostertag[2], H.H. Kazazian[2], J.V. Moran[1].* 1) Human Genetics, Univ. of Michigan Med. Sch., Ann Arbor, MI; 2) Genetics, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA.

Mutagenic L1 insertions have resulted in a variety of diseases. These insertions appear to be derived from retrotransposition-competent progenitor L1s (RC-L1s), containing two intact open reading frames (ORF1 and ORF2). Thus, we proposed that the L1-encoded proteins preferentially function to both bind and retrotranspose the RNA from which they are translated. Here, we present evidence in strong support of this cis-preference model.

Previously, we developed an assay to monitor L1 retrotransposition in HeLa cells. We tagged L1s with an indicator gene (mneoI) designed to detect retrotransposition events and showed that about 30-60 RC-L1s are present in the genome. We also found that point mutations (PM-L1s) in the ORF1 or ORF2-encoded proteins abolish retrotransposition. Here, we used a transient assay to monitor L1 retrotransposition in a rapid, quantitative manner. We first found that the ORF1-encoded protein cannot function in trans to retrotranspose an RNA consisting of L1 ORF2 and mneoI. Thus, L1 retrotransposition requires that ORF1 and ORF2 are encoded by the same L1 RNA molecule.

We next found that PM-L1s containing mneoI are complemented inefficiently when co-transfected into HeLa cells with different RC-L1s (L1.3 or RP). Four ORF1 mutants are complemented at very low levels, whereas six ORF2 mutants are complemented at somewhat higher levels (about 0.01% and 1% the frequency of L1.3 retrotransposition, respectively). Moreover, L1.3 or RP rarely complements an RNA containing only L1 ORF2 and mneoI. Thus, the presence of a functional ORF1 protein in the PM-L1s is required for low level complementation. We further confirmed that the PM-L1s are not dominant negative mutations because their expression does not inhibit the retrotransposition of tagged RC-L1s. Together, our data show that the proteins encoded by RC-L1s preferentially function in cis to retrotranspose the RNA from which they are translated, but can function in trans at low levels to mobilize other L1 RNAs.

Program Nr: 427 from the 1999 ASHG Annual Meeting

Hes-1 binds to an E box within intron 1 (IVS I) of the human acid alpha-glucosidase gene and acts as a transcriptional repressor. *B. Yan[1], N. Raben[1], K. Nagaraju[1], R. Nichols[2], P. Plotz[1]*. 1) ARB, NIAMS/NIH, Bethesda, MD; 2) Department of Medicine, Dartmouth Medical School, Hanover, NH.

Glycogenosis type II, a severe, recessively-inherited myopathy and cardiomyopathy (Pompe syndrome, acid maltase deficiency), is caused by deficiency of the lysosomal enzyme acid alpha-glucosidase (GAA), leading to abnormal glycogen accumulation in lysosomes. Although the GAA gene has been cloned and sequenced, very little is known about its regulation and expression. In previous studies, we have demonstrated that IVS I(~2.7kb) contains a negative regulatory element. In this study, reporter gene constructs and transient transfection assays were employed to localize the putative regulatory element. A series of deletion fragments of IVS I were cloned in both orientations upstream of bacterial chloramphenicol acetytransferase (CAT) gene under control of the thymidine kinase (TK) gene promoter and were assayed in Hep G2 cells. The negative regulatory element was localized to a 90bp fragment within IVS I which repressed the activity of the TK promoter by ~ 50% in both orientations. Footprinting analysis revealed a protected region of 23bp containing a potential YY1 binding site and two E boxes, CATCTG and CACGCG. The latter belongs to E box class C and is a specific binding site for Hes-1, which is in the Notch signal transduction pathway. Further transfection assay confirmed the repressive effect of the protected region, and gel-shift assay revealed that two proteins specifically bind to it. Super-shift assay with antibodies confirmed that the binding proteins are transcriptional factors Hes-1 and YY1. Hes-1, a mammalian homologue of Drosophila Hairy, is a basic helix-loop-helix (bHLH) factor and functions as a developmental transcriptional repressor in both invertebrates and vertebrates. We have demonstrated here that Hes-1 plays a role in the regulation and expression of a disease- related human housekeeping gene.

Program Nr: 428 from the 1999 ASHG Annual Meeting

Jameslink: An innovative touch-screen kiosk system for tailored cancer risk assessment and notification. *J.S. Graham, T.L. Bradley, H. Hampel, J.A. Westman, F.A. Wright.* Human Cancer Genetics Program-Comprehensive Cancer Center, The Ohio State University, Columbus, OH.,USA.

It has been shown that healthcare professionals rarely ascertain and record family history data, recognize specific cancer susceptibility syndromes, and refer appropriate families for genetic counseling. In response to this need, our program has developed a model touch-screen kiosk that systematically captures personal and family cancer history data, and allows for manual evaluation of the data and communication of results to the kiosk user. Fields collected include any cancer diagnosis in the user and first- or second-degree relatives, including ages of onset, multiple primaries, and maternal and paternal ethnicity. Family histories are classified according to criteria derived from peer-reviewed literature. The ultimate goals of the project are to educate the user about the family's likely cancer pattern (sporadic, familial, or hereditary) and corresponding surveillance or risk-intervention strategies and accrue appropriate families to pertinent research trials. Users receive a risk assessment letter regarding cancer risk level (general population, increased risk, significant risk) and the ACS screening guidelines. When appropriate, enhanced guidelines are provided (increased site-specific surveillance and/or genetic counseling). Evaluations on 663 individuals have been completed. The risk data are as follows: general population, 57%; increased surveillance, 17%; hereditary, 11%. Of those surveys evaluated, 11% did not contain sufficient data to score. The remaining 3% of the sample include those surveys demonstrating an early age of onset in the absence of family history. Studies are ongoing to evaluate user preferences, data accuracy and validity, kiosk methodology, and adequacy of information with regard to risk assessment. Video recording and focus group evaluations are planned. Pilot data have demonstrated that the Jameslink system is very effective at recording data required for risk assessment, but also provides a means for translating that data into a tailored message that educates the entire family about cancer risk and intervention options.

Program Nr: 429 from the 1999 ASHG Annual Meeting

How Confident are Health Professionals in Providing Genetic Services? The Role of Genetics Education. *E.V. Lapham[1], J.O. Weiss[2], C. Kozma[1], J.L. Benkendorf[1], M.A. Wilson[2].* 1) Georgetown Univ Medical Center Washington, DC; 2) Alliance of Genetic Support Groups, Washington, DC.

With the increase in genetic information, the exponentially increasing need for genetic services, and the relatively few genetics professionals, a wide range of health professionals are providing genetic services in hospitals, clinics, geriatric facilities, schools and other places. Their services include conducting intake interviews, taking family and medical histories, providing various kinds of therapies and counseling, interpreting assessment results, participating in case conferences, providing case management, and referring clients to community based resources. This was verified in a 1998 survey of 3600 members (57% response) of six professional associations: dietitians (ADA), occupational therapists (AOTA), physical therapists (APTA), psychologists (APA), speech-language pathologists and audiologists (ASHA), and social workers (NASW). The study showed that 70% discussed the genetic component of problems with at least a few of their patients, 19% made referrals for genetic counseling, 15% referred for genetic testing and 29% provided counseling about genetic concerns. How confident are these health professionals in providing genetic services? While 67% take family histories, only 1 in 4 feel confident in eliciting genetic information. Although most social workers (87%) and psychologists (79%) provided psychosocial counseling, only 26% and 29% respectively have confidence in counseling clients making decisions about genetic testing. Less than half of the social workers (45%) and psychologists (49%) feel confident in helping patients cope with a newly diagnosed genetic disorder or test result. How much formal education in genetics have the health professionals had? Overall, 21% had one or more courses in genetics, 44% had genetic content in course work and 33% had none. High confidence is correlated to amount of genetics education, independent of overall education ($p<.05$) for most services. The need for education to incorporate genetics into the practices and teaching of these professionals is vital if they are to confidently meet the genetic needs of their patients.

Program Nr: 430 from the 1999 ASHG Annual Meeting

Cancer Genetic Counseling and Testing by Telemedicine. *T.M. Diamond, R. Sutphen.* H Lee Moffitt Lifetime CA Scr, Tampa, FL.

Telemedicine is the practice of medicine at a distance using videoconferencing. This technology is increasing in importance due to reduced equipment costs and the potential to deliver medical advice and health care to areas less well served by traditional services. Since cancer genetic counseling relies primarily on detailed analysis of family history information and medical records rather than physical findings, it would seem to be an ideal candidate for the use of telemedicine. Also, since information provided during cancer genetic counseling is often relevant to multiple family members telemedicine may offer a method for simultaneous delivery of genetic information to family members who are geographically distant. However, little published experience exists regarding genetic counseling via telemedicine, and it is possible that the sensitive nature of these sessions may make telemedicine less than optimal for the delivery of these services. We are evaluating the use of telemedicine as a method to deliver cancer genetic counseling and testing services. Individuals presenting for cancer genetic counseling are asked to participate in the telemedicine study and are randomly assigned to receive counseling in a standard face-to-face meeting or by telemedicine. Study participants who are eligible for and elect to proceed with genetic testing receive their results and post-test counseling by the opposite delivery method, i.e. participants who had pre-test counseling by telemedicine have their disclosure in a face-to-face meeting and vice versa. Questionnaire instruments are used to: 1)examine differences between indivduals who elect to participate versus those who do not, 2) evaluate the participants' pre- and post-test genetic counseling experience, and 3) evaluate the geneticist's pre- and post-test counseling experience. We present preliminary outcomes from this study.

Program Nr: 431 from the 1999 ASHG Annual Meeting

Beliefs and Risk Perceptions regarding Prostate Cancer and its Heredity. *N.H. Arar[1], M. Sarosdy[2], I. Thompson[2,3], D. Troyer[4], L. Hunt[5], R. Plaetke[1].* 1) Div of Nephrology, Univ Texas Health Sci Ctr (UTHSCSA), SA, TX; 2) Div of Urology, UTHSCSA; 3) Div of Urology, Brooke Army Medical Center, SA, TX; 4) Dep of Pathology, UTHSCSA; 5) Dep of Pediatrics, UTHSCSA.

Five to 10% of prostate cancer (CaP) cases have a family history that suggests a genetic basis of CaP. We performed a medical anthropological study based on qualitative methods to investigate CaP patients and their relatives (1)beliefs of the causes and symptoms of CaP (2)opinions concerning the hereditary aspects of CaP, and (3)attitudes towards screening of CaP. Participants were recruited from 25 families enrolled in a CaP family study (on average 4.0 CaP cases per family). Applying open-ended and ethnographic interview techniques, we performed 16 semi-structured interviews. All interviews were tape recorded and transcribed. 13 interviews have already been content-analyzed. Patients were on average 67, the spouse was 68, the son 48 and the daughter 31 years old. Eight participants were Caucasians, 4 African-Americans and 1 Mexican-American. 6/10 patients had at least college education and 7/10 had retired. All the patients and their relatives were aware that CaP runs in their family. 8/10 patients and all relatives believed that CaP in their family is caused by heredity and can progress without any obvious symptoms. However, having a family history of CaP was not perceived as an important risk factor for the male members. Consequently, neither patients (before getting the disease) nor the son had taken any preventive measures to reduce their risk. This finding suggests that awareness of the clustering of CaP in families is not sufficient to encourage (healthy) male relatives to seek early screening. Health planners and genetic counselors should pay special attention to this matter. We will present :the rationale for using a qualitative design, examples of open-ended questions and quotes regarding participants' beliefs, and a summary of the sociodemographic factors and its correlation analysis with participants' beliefs. This research was funded by NIH HG00191/ELSI and the San Antonio Area Foundation (SAAF). The Ascertainment of the CaP families was funded by grants from SAAF and NCI (CA 70183).

Program Nr: 432 from the 1999 ASHG Annual Meeting

Attitudes about hereditary breast cancer among diverse breast cancer survivors. *W.F. Cohn[1], G. Fraser[2], S.M. Jones[3], S. Miesfeldt[4].* 1) Health Evaluation Sciences; 2) Anthropology; 3) Cancer Center; 4) Hematology/Oncology, University of Virginia, Charlottesville, VA 22908.

Much is unknown about the breast cancer genetic counseling and risk assessment process. Until the factors involved in a woman's understanding of the cause and course of hereditary breast cancer (HBC) are known, the clinical utility of major basic scientific advances in this area will not be fully realized. Purpose: To examine the attitudes and beliefs of genetically endangered women from diverse backgrounds concerning the etiology, course and management of HBC. Methods: All women with breast cancer diagnosed < age 50 years and entered in the Virginia Cancer Registry (VCR) in 1995 were eligible for inclusion. Thirty-one hospitals, statewide, entering 370 eligible patients in the VCR, participated in this project. Potential participants received a family history questionnaire and an informed consent document. Responses were received from 132 women: 45 were determined to be at-risk for HBC based on their personal and family histories. Eighteen women completed an in-depth qualitative interview, based on an interview guide, which addressed attitudes and beliefs related to the cause and course of HBC. All interviews were audiotaped and transcribed. Participants included 14 European-Americans, 3 African-Americans and 1 Native-American from throughout the state. Results: Interviews were content analyzed by two investigators using an emergent category system. Analysis of the interviews revealed thirteen major emergent categories relating to the attitudes, knowledge, and beliefs of study participants regarding the cause and course of HBC. Included in these were: factors related to causation, including impact of family history and multifactorial causation; disease risk expectation for self/family; risk reduction strategies; impact of genetic susceptibility on risk management and cancer treatment decisions; information sources, needs and comprehensibility; genetic "blame". These data provide those directly involved with the care of women genetically endangered to develop breast cancer a better understanding of the fears, myths and beliefs that surround this disease.

Program Nr: 433 from the 1999 ASHG Annual Meeting

Genetics education for different audiences: strategies developed by a pharmaceutical company. *E.A. Balkite, P.K. Manasco, R.P. Sutton.* Genetics Directorate, Glaxo Wellcome Research & Dev, Res Triangle Pk, NC.

Recognizing the increasingly important role genetics is playing in drug development, basic laboratory research, and clinical trials, Glaxo Wellcome formed a Genetics Education Team (GenED) in January, 1997 to respond to its education needs. The team's responsibility is to oversee the design and delivery of a comprehensive and prioritized education and training program in genetics for over 60,000 employees worldwide with various levels of knowledge in genetics. GenED consists of an international team of trainers, scientists and communicators from across the company--including Clinical Genetics, Research, Corporate Affairs, Human Resources, Sales Training, and International Medical Education and Training. The team members developed a core genetics curriculum with additional modules in ethics, clinical trials, and SNPs. GenED also surveyed employees to determine how they wanted to learn about genetics. As a result, the program addresses the different levels of understanding needed to educate scientists and non-scientists alike, as well as the preferred way to learn. Education and learning occur via printed materials, audiotapes, videotapes, Intra and Internet web sites, and face-to-face presentations depending on the target audience. Surveys conducted in May,1999 have demonstrated increased knowledge in some areas and identified needs in others for continuing education and training in basic genetics and pharmacogenetics.

Program Nr: 434 from the 1999 ASHG Annual Meeting

Pooling for Mutation Detection. *C.I. Amos.* Dept Epidemiology, UT MD Anderson Cancer Ctr HMB, Houston, TX.

Mutation detection through end-to-end sequencing of genes predisposing for familial colon cancer or breast cancer has been an expensive proposition because, for each familial cancer, several loci, each consisting of a large number of nucleotide bases must be considered (e.g. for breast cancer, BRCA1 or BRCA2 cause similar phenotypes and so each locus must be subjected to analysis). Here, I present a statistical approach for optimally constructing small pools of samples. The optimal pooling strategy depends upon the frequency of mutations per amplified exon or other unit in a population and is constrained by the technical capacity to detect mutations. Statistical considerations show that provided the mutation frequency per exon is less than 1%, pooling of samples results in a substantial decrease in the total number of samples that need to be assayed in order to detect mutations. Optimal pool sizes and the percent of original number of tests is given below:

Mutation Frequency	1%	0.5%	0.1%	0.05%
Optimal Pool Size	4	5	7	10
Percent of Tests	41%	32%	19%	15%

Even without using an optimal pooling strategy, a significant reduction in cost can be effected by pooling. For example, if the limit of resolution for pooling is 5 samples, less than 25% of the total number of tests need to be performed if the mutation frequency per exon is less than .1%. These findings underscore the potential value of sample pooling to control the costs associated with mutation detection.

Program Nr: 435 from the 1999 ASHG Annual Meeting

TNF polymorphisms in siblings with late-onset Alzheimer disease - The NIMH Genetics Initiative AD Study Group. *J.S. Collins[1], R.T. Perry[1], B. Watson, Jr.[1], L.E. Harrell[1], R.T. Acton[1], D. Blacker[2], M.S. Albert[2], R. Tanzi[2], M.G. McInnis[3], S.S. Bassett[3], R.C.P. Go[1]*. 1) Univ Alabama at Birmingham; 2) Massachusetts General Hospital, Boston; 3) Johns Hopkins University, Baltimore, MD.

One suggestive region found during a collaborative genome wide scan for Alzheimer disease (AD) genes in 266 late-onset families, is a 20 cM area located in the HLA region at chromosome 6p21.3. Some of the most significant findings were near the location of the tumor necrosis factor (TNF) gene. TNF is a pro-inflammatory cytokine, which may also assist in limiting the extent and duration of inflammation. Inflammation could be involved in the pathogenesis of AD as plaques may upregulate pro-inflammatory cytokines. Anti-inflammatory drugs have also been shown to delay and prevent the onset of AD.

A G®A polymorphism at -308 of the TNF promoter region has been previously implicated in autoimmune and infectious diseases. This polymorphism and a second polymorphism, a G®A transition at position -238 of the TNF promoter region, were typed in 145 AD families consisting of 558 affected and unaffected siblings. The microsatellite TNFa, located 3.5 kB from the 3' end of TNF, was also typed in these families. These typings were combined to form haplotypes for this region and the haplotype 2-1-2, respectively, was found to be significantly associated with AD with a p-value of 0.003, using the sibship disequilibrim test. The TNFa2 allele, which has been previously associated with a higher secretion of TNF, was also significantly associated (p=0.04) with AD in these families.

Program Nr: 436 from the 1999 ASHG Annual Meeting

Polynesian origins: new insights from the Y-chromosome. *R. Deka[1], B. Su[2], P. Underhill[3], N. Saha[1], S.T. McGarvey[4], J. Chou[2], P. Oefner[3], M.D. Shriver[1], R. Chakraborty[2], J. Martinson[5], L. Jin[2].* 1) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH; 2) Human Genetics Center, Univ Texas Health Science Center, Houston, TX; 3) Dept Genetics, Stanford University, CA; 4) Dept Medicine, Brown University, Providence, RI; 5) Dept Biological Anthropology, Oxford University, Oxford, England.

The question surrounding the colonization of Polynesia has remained controversial. Two hypotheses, one postulating Taiwan as the putative homeland and the other assering a Melanesian origin, have received much attention. The former, dubbed as the 'express train' model, based on linguistic and archeological evidence, has received support from recent mitochondrial DNA data. In this work, we present new data based on 19 biallelic markers on the Y-chromosome in a sample of 551 individuals from 36 populations living in East Asia, Southeast Asia, Taiwan, Micronesia, Melanesia and Polynesia. Surprisingly, nearly none of the Taiwanese Y-chromosome haplotypes was found in Micronesia and Polynesia. Likewise, a Melanesian-specific haplotype was not found in Polynesia. However, all of the Polynesian, Micronesian and Taiwanese haplotypes are present in the extant Southeast Asian populations. Evidently, Y-chromosome data do not lend support to either of the prevailing hypothesis. Genetic divergence between the Taiwanese and the Micronesian/Polynesian populations is twice that between the Southeast Asians and either of these two groups of island populations. We postulate that Southeast Asia provided genetic source for two independent migrations, one toward Taiwan and the other toward Polynesia. (Supported by grants from the NIH, NSF and the Chinese National Natural Science Foundation).

Program Nr: 437 from the 1999 ASHG Annual Meeting

Genomic control for association studies. *B. Devlin[1], K. Roeder[2].* 1) Department of Psychiatry, Western Psychiatric Inst & Cli, Pittsburgh, PA; 2) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA.

A dense set of Single Nucleotide Polymorphisms (SNP) covering the genome and an efficient method to assess SNP genotypes are expected to be available in the near future. An outstanding question is how to use these technologies efficiently to identify genes affecting liability to complex disorders. To achieve this goal, we propose a statistical method that has several optimal properties: it can be used with case-control data and yet, like family-based designs, control for population heterogeneity; it is insensitive to the usual violations of model assumptions, such as cases failing to be strictly independent; and, by using Bayesian outlier methods, it circumvents the need for Bonferroni correction for multiple tests, leading to better performance in many settings while still constraining risk for false positives. A simpler, frequentist method also springs naturally from this work. The performance of our ``genomic control'' method is evaluated by simulations of an association scan (100,000 SNP) using case-contol data drawn from either essentially homogeneous or quite heterogeneous populations. The false postive rate is small for both kinds of samples, but power is reduced for the latter.

Program Nr: 438 from the 1999 ASHG Annual Meeting

SNPs, Linkage Disequilibrium, Shared Chromosomal Segments, and Genome-Wide Association Mapping. *P.J. Donnelly, C. Wiuf.* Dept Statistics, Univ Oxford, Oxford, England.

When it first arises, a particular mutation will be on a unique haplotypic background. Assuming that the mutation arose only once, chromosomes in the current population which carry it will all share a region, IBD, around the mutation. We present a theoretical analysis, based on population genetics modelling and simulation, of the likely size of this shared region and of the way in which it depends on the population frequency of the mutation, and the demographic history of the population. These results are contrasted with those for regions shared by chance in arbitrary samples from the population. We discuss consequences for patterns of linkage disequilibrium and the required density of proposed SNP maps, and for their use in the design and analysis of genome wide, association-based, studies for genes involved in common, complex, disorders. Our work exploits recent exact results on the structure of conditioned coalescents -- processes which describe the genealogical history of a sample of chromosomes under the assumption that a particular subset of the chromosomes carry a mutation assumed to have arisen uniquely.

Program Nr: 439 from the 1999 ASHG Annual Meeting

Haplotype Analyses in Case-Control Populations: Factors Which Influence Accuracy of Haplotype Estimation.

D. Fallin[1], *N. Schork*[1,2,3,4]. 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Genset Corporation, La Jolla, CA; 3) Program for Population Genetics, College of Public Health, Harvard University, Boston, MA; 4) Jackson Laboratory, Bar Harbor, ME.

Linkage disequilibrium and haplotype analyses have been shown to be effective tools in fine-mapping and candidate gene analyses. However, these methods require determination of phase, which is often not feasible due to unavailability of family members, ancestral information, or cost of laboratory analyses. Accurate estimation of haplotype frequencies within case and control populations, and/or designation of particular haplotypes in ambiguous heterozygote individuals would enable a broader use of linkage disequilibrium analyses in diploid populations, specifically in the commonly used case-control design. We have modified haplotype frequency estimation via the EM algorithm to improve the computational efficiency for analysis of SNPs. We present simulation results demonstrating the overall high level of accuracy of our program, showing that for over 90% of all scenarios simulated, the frequency estimates are within 1% of the generating values. We provide suggestions for programming options including minimum number of restarts, maximum iterations, and maximum convergence criteria that allow for minimal estimation bias. We also show the relative magnitude and direction of influence on accuracy for several factors, including sample size, proportion of ambiguous individuals/heterozygous loci, presence of HWE, underlying haplotype and allele frequencies, number of loci in haplotype, and level of linkage disequilibrium in the area. We also note that most the factors exhibiting even modest influence on accuracy can be assessed directly from the data set of interest.

Program Nr: 440 from the 1999 ASHG Annual Meeting

Evidence for a second major gene for APO-A1 beyond the AI-CIII-AIV gene cluster: The NHLBI Family Heart Study (FHS). *M. Feitosa[1], I. Borecki[1], S. Hunt[2], H. Coon[2], C. Ellison[3], D. Arnett[4], G. Heiss[5], J. Eckfeldt[4], M. Province[1]*. 1) Washington Univ., St. Louis, MO; 2) Univ. Utah, Salt Lake City, UT; 3) Boston Univ., Boston, MA; 4) Univ. Minnesota, Minneapolis, MN; 5) Univ. North Carolina, Chapel Hill, NC USA.

Previous studies have shown that elevated plasma levels of apolipoprotein B (APO-B) and depressed plasma levels of apolipoprotein A1 (APO-A1) are associated with increased risk of cardiovascular disease and premature atherosclerosis. While familial resemblance for APO-A1 and APO-B has been reported, the results on the inheritance pattern are conflicting. Some studies have shown an effect of the apo AI-CIII-AIV gene cluster on these apolipoproteins. With the aim of addressing these issues, complex segregation analysis was applied to a sample of 697 individuals belonging to 436 nuclear families from the FHS. The phenotypes were adjusted for the effects of age, BMI, waist to hip ratio, waist circumference, subscapular to triceps ratio, smoking, alcohol consumption, caloric intake, physical activity and energy expenditure, and apo AI-CIII-AIV genotypes. For APO-B, there was no suggestion of a major gene. The Mendelian hypothesis was rejected (p=0.02) and there was no transmission of the major effect (p=0.45). For APO-A1, without adjusting for AI-CIII-AIV genotype, Mendelian transmission fit the data (p = 0.80), however the no-transmission model also was not rejected, yielding an inconclusive result. However, after adjusting for apo AI-CIII-AIV ($p < 0.001$), there was strong evidence for a major gene while the no transmission model was rejected (p= 0.00009). The gene accounted for 41% of the variance, with an allele frequency of 0.51, with an additional multifactorial component accounting for 25% of the variance. This suggests that there may be a second major gene aside from the apo AI-CIII-AIV locus which influences APO-A1 plasma levels.

Program Nr: 441 from the 1999 ASHG Annual Meeting

Complete sequence analysis of the human apolipoprotein E locus reveals previously undetected heterogeneity among e2, e3 and e4 alleles. *S.M. Fullerton[1], A.G. Clark[1], K.M. Weiss[1], S.L. Taylor[2], D.A. Nickerson[2], J. Stengård[3], E. Boerwinkle[4], C.F. Sing[5]*. 1) Departments of Anthropology and Biology, Pennsylvania State University, University Park, PA; 2) Department of Molecular Biotechnology, University of Washington, Seattle, WA; 3) National Public Health Institute, Department of Epidemiology and Health Promotion, Helsinki, Finland; 4) Human Genetics Center, University of Texas Health Science Center, Houston, TX; 5) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

As part of our ongoing study of genetic contributions to CVD risk, we have analyzed DNA sequence variation at the apolipoprotein E locus (*APOE*) in 96 individuals from four populations (African-Americans from Jackson, MS, non-Hispanic whites from Rochester, MN, Finns from North Karelia, Finland, and Mayans from Campeche, Mexico). Within the 5.5 kb region surveyed we identified 23 variable sites (22 SNPs and 1 indel), including two nonsynonymous SNPs that define the classic e2, e3, and e4 protein alleles. The observed sites segregate as 25 distinct haplotypes and comprise an e2 clade, an e4 clade, and a pair of divergent e3 clades. The root haplotype, identified via human-chimpanzee sequence comparison, falls in the e4 clade, suggesting that the e4 allele is ancestral to the other major alleles at this locus. Interestingly, this allele (which makes up only 13.5% of the chromosomes surveyed here) is now known to be associated with elevated lipid levels and Alzheimer's Disease risk. The most common allelic class, e3 (79.7%), is derived from the e4 clade and is split into two major lineages, from one of which the e2 alleles (6.8%) are derived. Heterogeneity within the three main allelic classes is only partially explained by within-lineage mutational divergence. Instead, substantial recurrent mutation and/or interallelic recombination, often involving sites in the 5' regulatory region of the gene, generate extensive site homoplasy and haplotype diversity.

Supported by NHLBI grants HL39107, HL58238, HL58239, and HL58240.

Program Nr: 442 from the 1999 ASHG Annual Meeting

Familial aggregation of QT interval variability in a general population: results from the NHLBI Family Heart Study. *Y. Hong[1], P.M. Rautaharju[2], P.N. Hopkins[3], D.K. Arnett[4], L. Djoussé[5], J.S. Pankow[5], D.C. Rao[1], M.A. Province[1]*. 1) Div Biostatistics, Washington Univ Sch Medicine, St Louis, MO; 2) Wake Forest Univ., Winston-Salem, NC; 3) Univ. of Utah, Salt Lake City, UT; 4) Univ. of Minnesota, Minneapolis, MN; 5) Boston Univ., Boston, MA; Univ. of North Carolina, Chapel Hill, NC.

Background: ECG findings of QT-interval prolongation are associated with increased risk of coronary heart disease and of cardiac death. Although information on genetics of the congenital long QT syndrome is mounting, little is known about the genetics of QT interval in the general population. **Methods:** Heart rate adjusted QT interval (Bazett's QTc, and QT index (QTI)) was assessed by ECG in 2399 members (1270 female) aged 25-91 years in 468 randomly selected families participating in the NHLBI Family Heart Study. Familial correlation and segregation analyses were applied to evaluate whether familial/genetic factors and/or a major gene play a role in the variability of QTc and QTI in this population. **Results:** The parent-offspring (0.14±0.03) and sibling (0.18±0.03) correlations for age and sex-adjusted QTc were moderate and significant, while the spouse correlation was not different from (0.09±0.05). This suggests that there are familial/genetic influences on QT interval variability. Segregation analysis results suggest that there is a major effect in addition to heritable multifactorial effects ($h^2 = 0.34$). The major effect accounted for 11% of the QTc variation, but it did not follow Mendelian inheritance. Hence a major gene effect for QTc can not be supported. Further adjustments of QTc for serum cholesterol, blood pressure levels, current smoking, alcohol consumption, vigorous physical activity, BMI, and anti-arrhythmic medications did not significantly change the results of familial correlation or segregation analyses. Similar results were found for QTI. **Conclusion:** The QT-interval variation in the general population is influenced by moderate heritable multifactorial effects, while a major gene effect is not directly supported. Interestingly, these heritable effects appear to be independent of other major cardiovascular risk factors.

Program Nr: 443 from the 1999 ASHG Annual Meeting

Family-based association tests for markers on the X-chromosome despite of incomplete parental information. *S. Horvath[1,2], MP. Baur[1], NM. Laird[2], M. Knapp[1]*. 1) Inst. for Medical Statistics, University of Bonn, Bonn Germany; 2) Harvard School of Public Health Boston.

Family-based association methods have recently been introduced that allow testing for linkage and/or linkage disequilibrium between a marker and a disease even if there is only incomplete parental marker information (e.g. S-TDT by Spielman and Ewens 1998, Am J Hum Genet 62:450-458, SDT by Horvath and Laird 1998, Am J Hum Genet 63:1886-1897 and RC-TDT by Knapp 1999, Am J Hum Genet 64:861-870). All of these tests have been designed with autosomal markers in mind. Here we introduce the X-linked RC-TDT which like the (autosomal) RC-TDT is a non-parametric test that makes no assumption about the mode of inheritance of the disease and can thus be applied to complex X-linked diseases. Further it makes no assumption about the ascertainment of the sample and like most family-based association tests does not detect spurious association due to population stratification. The X-linked RC-TDT follows the same logic as the RC-TDT: First, one reconstructs the missing parental genotypes from offspring genotypes where possible. Second, similar to the TDT one counts the number of times a heterozygous mother transmits the interesting allele to the affected offspring. Third, one corrects for the bias introduced in the reconstruction step by conditioning on reconstructiblity. Even if only sons are affected (which could happen for an X-linked recessive disease) (unaffected) daughters are still very informative for reconstructing parental genotype information. We also discuss alternatives to the X-linked RC-TDT and apply the tests to real data.

Program Nr: 444 from the 1999 ASHG Annual Meeting

Breast cancer penetrance estimates for *BRCA1/2* from a segregation analysis of the pedigrees of mutation positive probands. *D.J. Kaufman[1], T.H. Beaty[2], J.E. Bailey-Wilson[3], J.P. Struewing[1]*. 1) Laboratory of Population Genetics, National Cancer Institute, Bethesda, MD; 2) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 3) Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD.

Estimates of the risk of breast cancer for female carriers of germline *BRCA1/2* mutations have ranged from 27% to over 85% by age 70. A community-based study, the Washington Ashkenazi Study (WAS), collected personal and family histories of cancer and a blood sample on 5318 Jewish individuals. There were 114 unrelated *BRCA1/2* founder mutation carriers in this study. Using the "kin-cohort" method, the breast cancer penetrance was previously estimated to be 56% by age 70. There were 58 reported breast cancers among the 322 first-degree female relatives of the mutation carrier volunteers from WAS. Using data on these subjects, the REGTL module of the S.A.G.E. software modeled age-of-onset of breast cancer as the phenotype. Each of the 114 volunteer carriers was replaced in the data set by a woman affected at age 30, so the software would correctly identify her as a mutation carrier. Likelihoods were conditioned on the artificial carriers' phenotypes to avoid influencing the risk estimates. Estimated penetrance of breast cancer at age 70 is 61% under a dominant major gene model; across ages, penetrance estimates correspond closely to the age-specific risks calculated using the kin-cohort method. In non-carriers, segregation analysis predicted lower rates of breast cancer than did the kin-cohort method (6% versus 13% by age 70). This occurred because the estimated allele frequency was very high (0.22), so most cases were attributed to *BRCA1/2*. The model-based estimates of penetrance from the segregation analysis are very close to those obtained from the non-parametric kin-cohort method. A similar segregation analysis of ovarian cancer penetrance in *BRCA1/2* carriers is currently being performed.

Program Nr: 445 from the 1999 ASHG Annual Meeting

Single Nucleotide Polymorphisms: Mathematical modeling of the ascertainment bias and a comparison with sample distributions. *M. Kimmel*[1], *R. Chakraborty*[2], *L. Jin*[2], *R. Deka*[3]. 1) Dept Statistics, Rice University, Houston, TX; 2) Human Genetics Ctr, Univ Texas, Houston, TX; 3) Dept Environmental Health, Univ Cincinnati, Cincinnati, OH.

Single-nucleotide polymorphisms (SNPs) are considered an important new tool in the study of molecular evolution and gene mapping. One of the reasons is their frequent occurrence in the genome, estimated to be equal to 1 SNP per every kb of DNA. However, the SNP loci typed are subject to a serious ascertainment bias. The reason is that they are routinely discovered by reviewing sequences from a small number of individuals from a specific population. Therefore, more asymmetrically distributed polymorphisms will be frequently missed. We developed a mathematical model, based on a modification of the infinite sites model, which allows numerical predictions of the impact of ascertainment bias on the frequency distributions of SNPs, based on several scenarios of ascertainment. As an illustration, we provide a comparison with the distributions of nearly 400 SNP loci, each of which were originally screened in Caucasians, but studied now in six diverse populations. (Research supported by NIH grants GM 41399, GM 53545 and GM 45861, and by the Keck's Center for Computational Biology at Rice University).

Program Nr: 446 from the 1999 ASHG Annual Meeting

Effects of Stratification in the Analysis of Affected Sib-Pair Data: Benefits and Costs. *S.M. Leal, J. Ott.* Laboratory of Statistical Genetics, Rockefeller University, New York, NY.

The benefits and costs of stratifying affected sib-pair (ASP) data are examined in three situations where. 1.) There is no difference in identity-by-descent (IBD) allele sharing between stratified and unstratified ASP data sets. 2.) There is an increase in IBD allele sharing in one of the stratified groups. 3.) The data is stratified based upon IBD allele sharing status at one locus, and the stratified ASPs are then analyzed for linkage at a second locus.

Where there is no difference in IBD sharing between strata, a penalty is always paid for stratifying the data. The loss of power to detect linkage in the stratified ASP data sets is due to multiple testing and the smaller sample size within individual strata.

In the case where etiologic heterogeneity (i.e. severity of phenotype, age of onset, different ethnic backgrounds) represents genetic heterogeneity, the power to detect linkage can be increased by stratifying ASP data. This benefit is obtained where there is sufficient IBD allele sharing and sample sizes.

Once linkage has been established for a given locus, data can be stratified based upon IBD status at this locus, and tested at a second locus for linkage. In the case where the relative risk is in the vicinity of 1, the power to detect linkage at the second locus is always greater for the unstratified ASP data set. Even for values of the relative risk which sufficiently diverge from 1, with adequate sample sizes and IBD allele sharing, the benefits of stratifying ASP data are minimal.

Although stratification can be advantageous, it should be carried out with caution in order to avoid a potential loss in power to detect linkage.

Program Nr: 447 from the 1999 ASHG Annual Meeting

Haplotype-relative-risk-based evolutionary analysis of the tyrosine hydroxylase promoter region in manic depressive illness. *E.A. Lobos, R.D. Todd.* Dept Psychiatry, Washington Univ Sch Medicine, St Louis, MO.

Genetic association studies of the tyrosine hydroxylase (TH) gene and manic depressive illness (MD) have given conflicting results. Our earlier cladistics-based association analysis (CBAA) of TH haplotypes suggested that the locus was involved with MD susceptibility (Lobos and Todd, AJMG 74, 1997). CBAA has advantages over traditional association analysis because it models the evolution of the polymorphisms (PMs) at a genetic locus, but, when used in a case-control study, it does not control for genetic stratification. Thus, we re-tested the involvement of TH with MD using a sample of affected families. Haplotypes not transmitted to 72 affected offspring were used as a control sample to compare to transmitted haplotypes. A replication sample of 61 affected siblings was also analyzed. Seven PMs (including two from our prior report) were found within 600 bp of DNA sequence at the 5' end of TH. Nine haplotypes were found in our sample by PCR amplification and double digestion with restriction enzymes (ambiguous haplotypes were estimated). A cladogram (haplotype tree) was constructed to relate the nine haplotypes by 10 single-mutational steps. Our prior study of TH showed possible recombination within the region analyzed, resulting in an ambiguous cladogram. The smaller region studied here led to a simpler structure for analysis. A nested design for statistical testing was imposed on the cladogram. It created 5 one-step 'clades' (grouped closely-related haplotypes) and 2 two-step clades for frequency testing at higher levels of the hierarchy. We found no evidence for significant differences in frequency between the TH promoter haplotypes transmitted to affected offspring and those not transmitted. Testing higher-level clades also detected no significant frequency differences. Most studies using haplotype relative risk or transmission disequilibrium tests to explicitly control for genetic population stratification have ignored evolutionary information. In this study, we have combined CBAA with affected-family-based controls to make maximum use of haplotype information while controlling for both undetected population stratification and evolutionary process.

Program Nr: 448 from the 1999 ASHG Annual Meeting

Demographic, genealogical and genetic characterization of an isolated Sardinian micropopulation suitable for the study of complex traits. *P.M. Melis, L. Morelli, A. Angius, G. Casu, N. Ombra, S. Casula, G.B. Maestrale, D. Piras, S. Cabras, M. Pirastu.* Ist. Genetica Molecolare, C.N.R., Alghero, Sassari, Italy.

We have identified a very ancient (founded more than 1000 years ago) isolated village in a geographically isolated area of Sardinia to be used as an ideal model population for the identification of the genetic factors of complex disorders using an identity-by-descent (IBD) approach and linkage disequilibrium (LD) mapping. Blood samples were collected from 80% of the villagers. The original population size of about 200 has doubled between 1640 and 1870 and has reached 1200 inhabitants in 1990. A database was created using archival records (Quinque Libri) from the 17th century to 1990 in order to reconstruct the genealogy of the entire village. Village endogamy was about 95% with 35% consanguineous marriages for these centuries. Through the archives we reconstructed maternal and paternal lineages of all individuals and we complemented these data through Y chromosome haplotyping and mitochondrial DNA sequencing. We found that biological lineages were fewer than the one obtained through historical records: 75% of the actual population descends from 8 paternal and 10 maternal lines antedating the 17th century. In particular, 2 paternal and 4 maternal lineages include 50% of the population. We analyzed 50 unrelated males using six unevenly spaced genetic markers spanning a 12.5 Mb region on Chr Xq13. We identified 35 different haplotypes. Significant LD was observed between markers at 5 Mbp average distance. By overlapping the LD regions shared by different haplotypes we constructed LD contigs belonging to the village founders Chr X. We identified 5 ancestral X chromosomes shared by 80% of today inhabitants. We are studying some common diseases particularly frequent in the village (hypertension and nephrolithiasis). We correlated all the affected individuals and calculated all the meiotic steps separating them. This information in addition to the knowledge of the population structure are currently used to increase the efficiency of a multistep genome wide search for these complex disorders.

Program Nr: 449 from the 1999 ASHG Annual Meeting

Extensions of transmission/disequilibrium tests for correlated data or how to use your entire dataset for a test of linkage and association. *S.A. Monks*[1], *N.L. Kaplan*[2]. 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Biostatistics, National Institute of Environmental Health Sciences, RTP, NC.

The transmission/disequilibrium test (TDT) on family data consisting of diseased child/parent trios has become widely used as a test of linkage and association. When genetic information from more than one diseased child per family is available, the TDT is no longer a valid test of linkage and association. Martin et al. (1997) noted that, by treating the transmissions from a heterozygous parent to their diseased children as a single unit, the TDT could be extended to utilize all diseased children while maintaining validity as a test of linkage and association. Much attention has been placed on extensions of the TDT for disease susceptibility loci, and extensions have also been proposed for quantitative trait loci. In particular, Rabinowitz (1997) proposed a method that is a valid test of linkage and association for data consisting of child/parent trios. Monks and Kaplan extended this test to allow for the use of data from additional children. Here, we demonstrate that each of these extensions can be obtained through the use of within cluster resampling (Hoffman 1999), a general method for analyzing correlated data. We then show that the TDT and Rabinowitz's method can be extended to tests of linkage and association for data consisting of pedigrees or a mixture of nuclear families and extended pedigrees, and that the resulting test statistic takes on a common and widely used form.

Program Nr: 450 from the 1999 ASHG Annual Meeting

Improved power of sib-pair linkage analysis using measures of complex trait dynamics. *J.H. Moore.* Program in Human Genetics, Vanderbilt University, Nashville, TN, USA.

There is a growing concern that methods of linkage analysis for complex traits have insufficient power to detect underlying loci. We investigated whether the power of sib-pair linkage analysis can be improved by measuring complex trait dynamics. We simulated complex traits using a deterministic nonlinear dynamic one-locus gene expression system with epistasis arising from feedback regulation and estimated the power of sib-pair linkage analysis for identifying the underlying QTL.

A total of 500 nuclear families consisting of two parents and two sibs were simulated for each of 1000 experiments. Markers with two alleles of equal frequency were simulated at 5 cM positions along one 100 cM chromosome. The marker at the 50 cM position was used as the QTL. The complex traits were simulated by iterating a deterministic nonlinear difference equation using initial values and parameter values drawn from genotype-specific normal distributions. The first trait was defined as the last value obtained from iterating the dynamic system 150 times and the second trait as the autocorrelation of adjacent values from the last 100 observations. The first trait represents sampling from a complex dynamic system at one point in time while the second trait represents measuring the dynamics from sampling at multiple time points. For each of the 1000 simulations we carried out a sib-pair linkage analysis of the two traits using the multipoint Haseman-Elston method and the nonparametric Wilcoxon rank-sum test approach. A single-test P-value £ 0.05 was considered statistically significant evidence for detecting linkage.

The power for identifying the QTL for the first trait was less than 10% while the power for identifying the QTL for the second trait was 100%. The difference in power reflects the difference between sampling a complex dynamic system at one time point and at multiple time points. It is anticipated that measuring traits from complex dynamic systems at multiple time points will improve the success of a proposed linkage study.

Program Nr: 451 from the 1999 ASHG Annual Meeting

Familial Aggregation of Stroke and its Relationship to Hypertension. *M.S. Nicolaou, A.L. DeStefano, I. Gavras, L.A. Cupples, A.J. Manolis, C.T. Baldwin, H. Gavras, L.A. Farrer.* Boston University School of Medicine, Boston, MA.

We evaluated patterns of familial aggregation of hypertension and stroke to test the hypothesis that inherited susceptibility to these disorders may be determined by a common set of factors. Genealogical and medical history information was obtained for a cohort of 354 hypertensive probands ascertained in a clinic-based setting, their 1427 first-degree relatives and 239 of their spouses. The risk of hypertension was higher for the parents and siblings of the probands than that for spouses (OR=2.4; 95% CI, 1.8-3.4; OR=2.2; 95% CI, 1.6-3.0 respectively). Using the spouses as a reference group the risk of stroke for parents of the hypertensive probands was 7.3 times higher (OR=7.3; 95% CI, 3.6-14.8) while a non-significant but slightly increased risk for siblings (OR=1.6; 95% CI, 0.8-3.3) was observed. Controlling for hypertension, obesity, smoking, coronary heart disease, diabetes and cholesterol resulted in decreased estimates of the risk of stroke for parents (OR=5.4; 95% CI, 2.6-11.2) and siblings (OR=1.2; 95% CI, 0.6-2.5). The risk of stroke was significantly higher for hypertensive parents and siblings than non-hypertensive parents (OR=5.2; 95% CI, 2.8-9.7) and siblings (OR=5.8; 95% CI, 2.1-15.9) while a history of hypertension was not associated with an increased risk for stroke in spouses (OR=0.7; 95% CI, 0.2-3.1). The risk of stroke in hypertensive relatives of probands with stroke was higher than that of the normotensive relatives (OR=13.4). A less elevated risk ratio was observed in the relatives of probands who did not have a stroke (OR=4.0). Our data showing a higher occurrence of hypertension and stroke in biological first-degree relatives of hypertensive probands than in spouses suggest that some of the genetic factors predisposing to these conditions may be the same. Elucidation of these factors through family studies of stroke may be difficult because of secular trends toward improved treatment for hypertension. Although a history of hypertension increases the risk of stroke among parents and sibs, multivariate analyses revealed a familial component to stroke independent of hypertension.

Program Nr: 452 from the 1999 ASHG Annual Meeting

An examination of association based tests for localizing genes. *D.M. Nielsen[1,2], B.S. Weir[1]*. 1) Program in Statistical Genetics, NC State Univ, Raleigh, NC; 2) Bioinformatics, Glaxo Wellcome, Research Triangle Park, NC.

It is generally accepted that the degree to which a disease susceptibility locus affects phenotype influences the power to detect and localize that locus. What is equally important is the manner in which these loci act. Since most association based measures examine alleles individually rather than as genotypes, it is reasonable to assume that tests based on these measures are effective at detecting genes with large additive effects. Loci which may have a substantial biological effect on the disease of interest, but which may not have a large additive component, might not be readily detected using these approaches. By applying insights from classical quantitative genetics, it is possible to formalize the relationships between markers, trait loci and phenotypes in a manner which allows us to determine which genetic properties association based tests have power to detect. We find the expected values of the statistics involved in these tests are sensitive only to the additive effects of the marker loci, while the variances are sensitive to both additive effects and dominance deviations. In a randomly mating population, the additive effects of a marker locus are a simple funtion of the additive effects at the trait locus and the linkage disequilibria between loci. Therefore, these factors have the largest effect on the power of an association based test to detect a trait locus. They are, however, confounded in the summary measures captured at the marker locus, and may cancel out when combined, so that large additive effects at the trait locus and strong disequilibria between loci are not sufficient to provide high power for detecting the trait locus.

In general, power to detect a trait locus using association based tests will depend on the way in which the trait locus affects phenotype and the manner in which the marker is associated with that trait locus. Because of this, some trait loci will not be readily detected by these methods. Additionally, care must be taken when comparing results across markers.

Program Nr: 453 from the 1999 ASHG Annual Meeting

HPCX (Xq27-28) linkage is common among Finnish prostate cancer families: Strong association with late onset disease. *J. Schleutker[1], M. Matikainen[2], A. Baffoe-Bonnie[1,5], J. Xu[3], P. Koivisto[2], T. Tammela[2], J. Smith[1], D. Stephan[1], W.B. Isaacs[4], J.M. Trent[1], J. Bailey-Wilson[1,5], O-P. Kallioniemi[1]*. 1) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Laboratory of Cancer Genetics, IMT, TAUH, University of Tampere, Finland; 3) Center for Genetics of Asthma and Complex Diseases, University of Maryland, Baltimore, MD; 4) Department of Urology and Oncology, Johns Hopkins Medical Institutions, Baltimore, MD; 5) Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD.

In order to explore the genetic basis of prostate cancer susceptibility, we performed a nation-wide genetic epidemiological study in Finland, taking advantage of the genetically homogeneous population and cancer registry information. Fifty-seven informative families were studied by linkage analysis using microsatellite markers for the HPC1 region at 1q24-q25 (39 markers) and the HPCX region at Xq27-q28 (22 markers). Two point lod scores for all HPC1 markers were strongly negative, even in families with four or more affecteds and early age of onset. In contrast, lod scores for most markers at the HPCX region were mildly positive (max 2.05 at theta 0.14, marker DXS1205). Subgroup analyses suggested that most of the positive lod scores came from families with no male to male transmission (NMM) of disease (alpha 0.50 in this group), as could be expected for an X-linked disease. Maximum lod score in this group was 2.11 (theta 0.08, DXS1205). Sibpair analyses gave a lod score of 3.35 with DXS1205 ($p<0.00009$), implying that the generic model of disease transmission (Xu et al., 1998) used in the parametric analysis may be incorrect. Indeed, further stratified analyses indicated that virtually all late age of onset (average age at diagnosis >65 years) NMM families were linked (lod score 3.03 at theta 0, DXS1205), whereas those with early-age of onset were not. This suggests that HPCX linked families, which appear to be particularly common in Finland, may have a distinct phenotype, characterized by late age of onset.

Program Nr: 454 from the 1999 ASHG Annual Meeting

The Future of Genetic Case-Control Studies. *N.J. Schork[1,2,3,4], D. Fallin[1], X. Xu[3], M. Blumenfeld[2], D. Cohen[2]*. 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Genset Corp, La Jolla, CA & Paris, France; 3) Program for Population Genetics, Harvard School of Public Health, Boston, MA; 4) The Jackson Laboratory, Bar Harbor, ME.

The power and simplicity of the case/control study design makes it an appealing strategy for testing the relationship between particular genetic polymorphisms (or haplotypes) and traits or diseases. Despite this fact, there are a number of problems that plague the use and interpretation of genetic case/control studies. We describe methods that should allow researchers to evaluate and in many instances overcome many of these problems. These methods rely on the use of multiple genetic markers and can be used to investigate and control for the following problems: 1. genetic stratification; 2. allelic and locus heterogeneity; 3. indirect association and linkage disequilibrium; 4. sample heterogeneity; 5. the assessment of statistical significance; 6. the evaluation of the power and likely yield of a case/control study; and 7. The assessment and use of admixture. We showcase these methods with actual data and argue that because of its simplicity, the case/control design may become a design of choice rather than a design by default for future genetic epidemiology studies.

Program Nr: 455 from the 1999 ASHG Annual Meeting

Genetic epidemiology of Syndrome X disorders on Kosrae. *D. Shmulewitz[1], S.C. Heath[1], S.B. Auerbach[2], M.L. Blundell[1], J.D. Winick[1], S. Signorini[1], J.L. Breslow[1], J. Ott[1], T. Lehner[1], M. Stoffel[1], J.M. Friedman[1].* 1) Starr Center for Human Genetics, The Rockefeller University, New York, NY; 2) Health Resources and Services Administration, Department of Health and Human Services, New York, NY.

Syndrome X, a term used for the observed clustering of metabolic disorders, includes obesity, type II diabetes, hypertension, and dyslipidemia/heart disease. These disorders have been shown to have underlying complex genetic inheritance. We studied the prevalence and genetic epidemiology of these disorders on the Pacific island of Kosrae. This population based study included 2188 individuals (>90% of the adults on the island), of whom 1709 have been placed on a single pedigree. Participants in the study answered questions on their health status, family relationships, demographics and socioeconomic status. Subjects also underwent a clinical evaluation that included: anthropometric measures(weight, height, waist, hip), serum chemistries (leptin, fasting blood sugar [FBS], insulin, total cholesterol [TC], triglycerides [TG], apolipoproteins A1 [ApoA1] and B [ApoB]) and blood pressure (BP) measurements. Statistical analyses were carried out with the SAS package, and heritability and segregation analyses were performed using MORGAN and LOKI. The population on Kosrae showed, relative to the US, an increased prevalence of obesity (BMI>=35, 24%), diabetes (FBS>=126, 12%), hypertension (systolic BP>=140 or diastolic BP>=90, 17%), and dyslipidemia (TC>=240 or TG>=200 or ApoA1£88 or ApoB>=120, 20%). After adjusting for the covariates, sex, age, smoking, village of residence, and parity, heritabilities for the traits were calculated. They ranged from 0.20-0.64, indicating a significant genetic component for all. Segregation analyses showed significant evidence for multiple quantitative trait loci (QTL) for all the variables. Examples of major gene effects include BMI (25% of variance), FBS (51%), TC (41%), and BP (38%). This population is uniquely suited for further gene-mapping experiments, to find genes that are involved in the development of obesity, diabetes, hypertension, dyslipidemia, and their clustering in Syndrome X.

Program Nr: 456 from the 1999 ASHG Annual Meeting

Estimation of relative hazard for AIDS based on distributions of three HIV-1 resistant polymorphisms (SDF1-3'A, CCR2-641, CCR5-D32) in global populations. *G. Sun[1], B. Su[2], J. Xiao[3], F. Hu[3], D. Lu[3], R. Chakraborty[2], R. Deka[1], L. Jin[2,3]*. 1) Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Human Genetics Center, University of Texas Health Science Center, Houston, TX; 3) Institute of Genetics, Fudan University, Shanghai, China.

Chemokine receptors (CCR5, CXCR4 and CCR2) have been shown to be important coreceptors for HIV infection. Mutations at CCR5 (CCR5-D32), CCR2 (CCR2-641), and stromal-derived factor SDF1 (SDF1-3'A), a primary ligand for CXCR4, are known to have protective effects against HIV-1 infection. We studied the three-locus genotype frequency distributions in 70 worldwide populations from a sample of 2,341 individuals without any known history of the HIV-1 infection and AIDS symptoms. From these data, we estimated the AIDS onset risk (relative hazard, RH) of each population. The survey shows that the substantial frequency differences of each of these mutations translate into an extensive variation in RH for AIDS in worldwide populations. The estimated RH values are highly correlated (Spearman's r = 0.639, $P = 0.006$) with prevalence of AIDS. However, no evidence of natural selection against the mutant gene-carriers is detected. Finally, the combined three-locus genotype data predicts the highest RH in Southeast Asia and Africa, where AIDS is known to be more prevalent. (Supported by grants from the NIH and NSF).

Program Nr: 457 from the 1999 ASHG Annual Meeting

Evaluation of replication : The HLA-DR region in Rheumatoid Arthritis (RA) as an example. *F. Tores[1], M. Martinez[1], F. Cornélis[2], European Consortium on Rheumatoid Arthritis (ECRAF)[3].* 1) INSERM U358, Paris, France; 2) Université Paris 7-Denis Diderot; 3) EEC-BIOMED2.

Interpreting genome-wide scan linkage results has raised considerable debate. Guidelines have been proposed along with the use of genome-wide significance criteria for claiming significant or suggestive linkages. Linkage results must also be replicated. Replication studies do not face the multi-test problem of genome-wide screens. It has been shown, however, that initial positive results tend to overestimate genetic effects whereas subsequent studies will regress to the true value (Lander and Kruglyak, 1995; Suarez et al.,1994). Failure to replicate does not necessarily disprove the initial finding. However, it can also result from genetic heterogeneity. The replication dataset may not constitute a representative sample of the screen dataset, even though both samples are collected by the same investigators, using similar ascertainment and diagnostic criteria, as it is often done in a two-stage based genome-wide scan study. To investigate for genetic heterogeneity between two samples, we propose a bootstrap-based approach of the combined dataset. The goal is to quantify the probability of observing conflicting results when assuming both datasets are random samples of the same population. We illustrate this investigation in the ECRAF genome-wide scan data of RA. The HLA-DR region was tested within a 5cM region using three markers (D6S276, Tnfa, HLA-DR). The screen dataset (set1) is composed of 90 families (total of 105 ASPs). The replication dataset (set2) has similar sample size (96 families; 110 ASPs). Yet, significance for linkage, under pairwise or multipoint ASP analyses, is more than 10 times higher in set1 than in set2 (MLS=4.34 and 2.73, respectively). Simulations showed a poor empirical power of the linkage test power in set2. Bootstrap results did not reveal significant heterogeneity between the two datasets: variability between samples was not larger than that within samples, especially in set1. These results pointed out the sensibility of linkage test to the contribution of a small number of families, even in relatively large samples.

Program Nr: 458 from the 1999 ASHG Annual Meeting

Admixture Linkage Disequilibrium Mapping of Quantitative Trai Loci. *M. Xiong, L. Jin.* Human Gen Ctr/Houston HSC, Univ Texas, Houston, TX.

The linkage disequilibrium (LD) based methods are increasingly being used as tools for both initial localization and fine-scale mapping of human disease genes. However, the rapid attenuation of LD with the age of the mutation at the trait locus and the recombination fractions between the marker and trait locus makes it difficult to use LD-based methods in mapping genes involved in the complex traits in general populations. It has been recognized that the disequilibrium may result from recent admixture of populations in which the frequencies of the marker alleles and trait alleles are different. This principle has been sucessfully applied to the mapping of qualitative diseases, but less is known about its utility in mapping of quantitative trait loci (QTL). In this report, we propose a regression method based on LD for mapping QTL . Like TDT, the test statistic of this method is valid in the presence of population substructure. We investigated its power under three admixture population models: immediate population admixture model, general gene flow model, and island model and demonstrated that this method has high statistical power for any recently admixed population. The performance of this method is compared with transmission/disequilibrium test (TDT) designed for quantitative traits. The statistical power of the method for the selected sample using admixed populations is also evaluated.

Program Nr: 459 from the 1999 ASHG Annual Meeting

Direct observation of family history-taking in primary care practice. *L.S. Acheson, G.L. Wiesner, M. Goodwin, S.J. Zyzanski, K.C. Stange.* Case Western Reserve University, University Hospitals, Cleveland, OH.

Context: Primary care physicians are in a central position to identify families at risk for genetic abnormalities who may benefit from genetic consultation. Family history is the main clinical tool to screen for familial patterns of disease, but there are few data on family history-taking in primary care.

Objective: To describe the rate of family history-taking in community family practice and to identify characteristics of physicians, patients, and visits associated with obtaining family history information.

Design: Cross-sectional observational study in 84 community family practices in Northeast Ohio. Research nurses directly observed 4454 consecutive patient visits during 2 separate days in the offices of 138 family physicians.

Main outcome measures: Directly observed family-history-taking during an office visit and family history recorded in the office medical record.

Results: Family history was discussed during 51% of visits by new patients and 22% of visits by established patients. Younger physicians were more likely to obtain a family history; the rate varied from 0 to 81% of patient visits. Patients who were younger or middle-aged, married, female, and in better health were more likely to discuss family history during an office visit. Visits involving family history-taking were 3 minutes longer and more likely to be for well care rather than for acute or chronic medical problems. Discussions of family history averaged 2 minutes in length. Many patients who had no discussion of family history at the observed visit did have family history information in their medical records.

Conclusions: Family history-taking is highly variable from physician to physician. The amount of time used for family history-taking during any given visit to a family physician is small, but such information may be accumulated over multiple contacts, especially initial and well care visits. These findings may be used to design interventions to increase the rate and completeness of family history ascertainment.

Program Nr: 460 from the 1999 ASHG Annual Meeting

Cancer genetic clinics for hereditary breast/ovarian cancer (HBOC):differences between consultation content in Canada, France and United Kingdom. *L. Bouchard[1,5], F. Eisenger[2], G. Evans[3], W.D. Foulkes[4], B. Kerr[3], I. Blancquaert[1], H. Sobol[2], C. Julian-Reynier[5]*. 1) Universite du Quebec a Montreal and Council of Health Technology Ass., Montreal,Canada; 2) Inst.Paoli-Calmettes and E9901, Marseilles, France; 3) Dept.Medical Genetics, St-Mary Hospital, Manchester, UK; 4) Dept.Medicine, McGill University, Montreal, Canada; 5) INSERM U379, Marseilles, France.

The knowledge that BRCA1/BRCA2 are linked to HBOC plays a prominent role in clinical practice.Recommendations about clinical management seem influenced by cultural values.The objective of this study was to compare the content of cancer genetic consultations in 3countries.Method: Between 1996 and 1998,3cancer genetics clinics were surveyed:in Manchester(UK),Marseilles(F)and Montreal(Ca).Physicians completed a questionnaire on their patients'medical data and on their recommendations regarding prevention for 355 women attending the genetics clinic for the first time.Results:The women were 44 years old on average(16-76)and 33%had been diagnosed with cancer.In Marseilles(N=141)and Montreal(N=84), 78%of consultees were referred by a specialist compared to 32%in Manchester(N=130)($p<0.001$).Molecular analysis was offered more frequently in Marseilles(69%)and Montreal(59%)than in Manchester (48%)($p<0.005$).The topics discussed during consultation differed significantly according to the country.Environmental risk factors(diet, alcohol,tobacco)were more often recommended in Manchester(55%)than in Montreal(19%)and Marseilles(10%)($p<0.001$).In contrast,chemoprevention was mentioned more often in Montreal(42%)than in Manchester(24%)or Marseilles(14%)($p<0.001$).In Montreal and Marseilles, prophylactic mastectomy was discussed in 38% and 21% of cases respectively ($p=0.018$)and prophylactic oophorectomy in 44% and 14% of cases($p<0.001$).Manchester scored in between. These differences were more pronounced for women without cancer.Conclusion:These results seem to confirm the existence of a cultural dimension in clinical practice that might well be based on different traditions and beliefs regarding screening,treatment efficacy and the value of body integrity and fertility issues.

Program Nr: 461 from the 1999 ASHG Annual Meeting

Community-Based Recruitment Problems Encountered with a Colon Cancer Risk-Assessment Study. *M. Cappelli[1], H. Stern[3, 4], K. O'Rourke[3, 4], S. Viertelhausen[3, 4], L. Van Houten[1], A. Hunter[2]*. 1) Psychology, Children's Hospital of Eastern Ontario; 2) Genetics, Children's Hospital of Eastern Ontario; 3) Surgery,University of Ottawa; 4) Loeb Research Institute.

It has been postulated that Ashkenazi Jews have a higher risk of colorectal cancer than the general population. A study assessing the risk of colon cancer in the Ashkenazi Jewish population in the Ottawa-Carleton region was conducted recently. A community-based recruitment approach was used to target close to all the adult Ashkenazi Jews in the community. Of the 3548 households in which packages were mailed to, only 1595 responded, leaving 1953 households who did not respond. The main objectives of the present study are to assess the effectiveness of using a community-based approach for recruiting at-risk families and to examine the factors that determined participation and response rates in the risk-assessment study. Six hundred individuals from three different groups are currently being recruited to participate in a standardized telephone interview. The three groups include: those who particiapted in the risk-assessment study, those who responded and refused, and those who did not respond. We anticipate that factors related to individuals' attitudes and perceptions of colon cancer, physicians' input, past health prevention behaviour, recruitment methods, and personal and family history of cancer will be associated with participation and response rates in the risk assessment study. We expect to find that those with increased knowledge about colon cancer and its prevention, those whose physicians have recommended colon screening and those who practice greater health prevention behaviours will have been more likely to participate in the colon cancer risk assessment study. We also expect to find that the advertisements at synagogues and the Jewish Community Centre will have been less effective methods of recruitment than perhaps the mail-out, which is a more active form of recruitment. From these finfings we hope to develop effective strategies which may improve participation and response rates in similar future studies geared towards disease prevention.

Program Nr: 462 from the 1999 ASHG Annual Meeting

Dissent as a Mechanism to Provide Choice in Population-Based Public Health Studies: Implementation and Preliminary Analysis. *A.M. Comeau[1], R.B. Parad[1,2], R. Eaton[1].* 1) New England Newborn Screening Program, U Mass Medical School, Boston, MA; 2) Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

What are the criteria by which disorders are added to the list of mandatory newborn screens? And given those criteria, which, if any disorders should be added to the list in Massachusetts? Advances in technology, recognition that early detection and intervention involve a spectrum of outcomes, and evolving definitions of "mandatory" and "pilot" programs in keeping with ethical, legal and social mores point to the need for a systematic review of options. After an independent advisory board affirmed the rationale for the 9 mandated screens in MA, it added a 10th (MCAD) and recommended that screening for 19 other metabolic disorders detectable by MS/MS and screening for cystic fibrosis be offered to the MA birthing population in the form of two pilot studies. Human subjects review required informed consent for the pilot studies, and approved an alternate form of informed consent, verbal 'consent or dissent'. Implementation included development of written materials for parents and providers, in-service and grand rounds trainings of providers, distribution of materials and QA/QC monitoring. As of April 30, parents of 17,992 newborns have been offered the opportunity to participate in either or both of the studies. A total of 401 (2.2%) declined participation in either study, with smaller numbers declining one or the other study. A substantial overall increase in awareness and understanding of newborn screening is reported. Other analyses will be presented.

Program Nr: 463 from the 1999 ASHG Annual Meeting

Genetic testing for Cystic Fibrosis : Evaluation of three European Quality Assessment trials. *E.M.C. Dequeker, J.J. Cassiman.* Center for Human Genetics, KULeuven, Leuven, Brabant, Belgium.

Within the framework of the European concerted action on cystic fibrosis (CF) yearly quality assessment trials have been set up since 1996 in order to evaluate the quality of the genetic testing for CF performed in diagnostic laboratories. The large majority of European laboratories providing genetic services for CF participated (1996: n=136, 1997: n=145, 1998: n=159). Successive quality control trials resulted in a gradual reduction of the percentage of laboratories making one or more mistakes on a total of 12 alleles to be examined (1996: 35%, 1997: 24%, 1998: 21%), although the error rate remains unacceptably high. The types of error made ranged from administrative errors, erroneous technical results to misinterpretation of the (technical correct) data. The annually organised QA schemes also provide a nice tool to evaluate the evolution in testing strategies. There is a tendency in molecular diagnostic laboratories over the past few years to shift to the use of commercially available kits. Almost 50% of the participants used a commercially available kit as primary testing tool for screening of DNA samples for mutations in the CFTR gene. The results of the QA scheme of 1998, however, showed that the use of a commercial kit alone does not necessarily ensures a high accuracy of mutation analysis. We conclude that external control trials contribute to an overall improvement of the quality of genetic testing. However, continued efforts will be needed to further improve the genetic services provided to the community.

Program Nr: 464 from the 1999 ASHG Annual Meeting

Consumer interest in genetic testing for breast cancer susceptibility: Variation with test and gene characteristics.

E.L. Harris[1], B. Stewart[2], B. Valanis[1], N. Vuckovic[1]. 1) Kaiser Permanente (KP) Center for Health Research, Portland, OR; 2) Oregon Health Sciences University, Portland OR.

Genetic testing for breast cancer risk will soon extend beyond rare, high-risk genes, such as deleterious mutations in BRCA1/BRCA2. Also, there is evidence that risks associated with such mutations may be lower than estimated from high-risk families. Anticipating new knowledge about genetic susceptibility to breast cancer, we assessed consumer opinions about genetic testing for breast cancer risk from a broad perspective (rare, high-risk genes; more common, moderate-risk genes). A survey (Genetic Testing and Breast Cancer: Your Opinions) was mailed to: 1) adult female KP Northwest health plan members unselected for personal or family cancer history; 2) women with only a family history of breast cancer; and 3) women with breast cancer and a family history of breast cancer. Respondents were predominantly white non-Hispanic (77%; 10% black; 2% Asian/Pacific Islander; 1% white Hispanic; 1% Native American/Alaskan; 8% mixed race/other); median age was 59 years. 21% appeared to have difficulty interpreting numerical risks.

Results indicate that interest in genetic testing increases with a higher prior probability of carrying a deleterious mutation and with higher penetrance (breast cancer risk associated with a mutation), but does not vary with positive or negative predictive values of a genetic test. 31% would definitely want testing if they had a 1 in 10 prior probability, 19% for 1 in 100, and 14% for 1 in 1,000. 55% would definitely want testing if penetrance were 95%, 49% if it were 75%, 36% if it were 50%, and 24% if it were 25%. This pattern of results was similar for the three mailing groups described above, as well as by age, numeracy, and previous information about breast cancer and genetics. In conclusion, gene characteristics may affect individuals' decisions about genetic testing. Consumer preferences should be considered by policymakers when recommending strategies for genetic testing.

Supported by NCI P01 CA72085 and PHS T32 HS00069.

Program Nr: 465 from the 1999 ASHG Annual Meeting

Ten Years of Minimum Data Collection - New York State's/GENES' Experience. *K.B. Harris, K.A. Pass.*
Wadsworth Ctr,Lab Newborn/Gen, New York State Dept Health, Albany, NY.

In 1987, the NYS Genetic Services Program began collecting individual patient contact forms from clinical genetic service units in response to the development of the CORN Minimum Data Set. All funded providers were and are required to submit information on each patient receiving face-to-face genetic services. Many programs not receiving funding also provide information. Data collected include a unique patient identifier, service date, provider zip code and county of residence, age, sex, race, ethnicity, payer (insurer), reason for visit, cognitive and clinical services provided, diagnostic tests ordered and diagnosis.

Uniform data collection of services as difficult to define as those provided by clinical genetic programs is problematic, as demonstrated by criticisms of the CORN Minimum Data Sets of 1987-1994. Some of the limitations of the NYS/GENES database will be discussed, including full reporting, clerical mistakes, validation of data, and maintaining committment of the non-funded providers.

Given those caveats, however, the data set, which includes individual patient information on 350,000 visits by 285,000 patients at 47 clinical genetics service units in NYS offers valuable insight into the evolution of public health genetics, clinical genetic services and the medical and lay communities' perception of the worth of these services. Maps of NYS and New York City demonstrate access to services geographically; graphs show trends of access by those of different ethnicities and financial status. Programmatic knowledge of federal SPRANS priorities, availbility of health insurance, state funding levels for genetics services and institutional commitment to genetic services illustrate the impact of policy changes on accessibility of genetics to populations throughout NYS.

Program Nr: 466 from the 1999 ASHG Annual Meeting

Identification of family members at risk for hereditary breast and ovarian cancer and up-take rates for predicitive testing: A report from a 3 year multi-disciplinary clinical study. *I. Nippert[1], B. Dworniczak[1], B. Ziese[1], C. Jackisch[2], S. Preisler-Adams[1], J. Horst[1]*. 1) Department of Human Genetics, Westfaelische Wilhelms-University (WWU), Muenster, Germany; 2) Women`s Hospital, WWU, Muenster, Germany.

Introduction: In January 1997 a multidisciplinary BRCA1/BRCA2 predictive testing program was implemented at the Westfaelische Wilhelms-University Muenster, Medical School. The test is offered - free of charge - to individuals and families who meet defined high risk criteria. Individuals and families follow a thorough pre- and post-test counseling protocol in order to ensure informed consent and client autonomy. **Methods:** In order to assess uptake rates of individuals at risk for hereditary breast and ovarian cancer their decision making process is recorded. **Results:** Since January 1997 to May 31th, 1999, 314 families have been seen for pre-test counseling. Of these families 206 (65.6%) met the inclusion criteria and were offered the test. 52 (25.0%) declined the offer, 23 (11.2%) could not be tested because the index patient refused to be tested or could not be reached, 22 (10.7%) are still considering the offer and 109 (52.2%) took up the test. So far a mutation has been found in 14 (12.8%) families, none was found in 23 (21.1%) and in 72 the test is still running. In the 14 affected families, 61 first grade relatives at risk were identified. It is up to the counsellees to inform their relatives about the risk. 9 relatives (14.7%) took up the test, 5 (8.2%) declined the offer, 4 (6.6%) are still undecided and of 43 (66.1%) it is unknown whether or not they have been informed by their affected relative. Of the 9 persons tested, 6 had a positive test result, of these 6 persons 4 chose to be informed, 1 decided not to know the test result and 1 person's decision is still pending. **Conclusion:** In genetics the true patient is a family with a shared genetic heritage. But in modern society families seem to be fragmented rather than unified and in most families identified to carry a mutation, affected members seem to be willing to disclose the findings only to a chosen set of relatives.

Program Nr: 467 from the 1999 ASHG Annual Meeting

Genetic testing in children: the "Rule of Earliest Onset" falls short of the mark. *M.Z. Pelias.* Dept Biometry & Genetics, Louisiana State Univ Med Ctr, New Orleans, LA.

Questions about genetic testing in children have been the subject of concern for almost one decade. Professionals in cancer genetics have recently suggested that minors be tested according to the "Rule of Earliest Onset," which mandates testing minors no earlier than the age of first possible onset of disease. Justifications for this rule include potential stigmatization and discrimination, maximizing the minor's participation in deciding to proceed with testing, and allowing medical benefits to accrue to the child. While this approach is logical for early onset cancers, it fails to acknowledge other interests of parents and other benefits that their children could enjoy. Interests of parents derive from their right and duty to make decisions for their minor children. Genetics professionals who presume that parents will not make decisions that are in the "best interests of the child" usurp the parental prerogative and improperly insert themselves into the privacy of family and parents. Rather, professionals should provide thorough counseling, with a presumption of deference to parents who are trying to do their best for their families. Among benefits for children is the primary concern for their health. In addition to medical benefits, however, are numerous other benefits for children, including resolution of uncertainty and anxiety, increased communication and candor within the family, opportunities for emotional and financial adjustment to the family's genetic situation, understanding and compassionate assessment of life prospects, and even acceleration of the maturation of the child toward his or her own nascent autonomy. While these and other benefits can be viewed from the perspective of their concomitant risks, the risks are perhaps best appreciated when they are acknowledged and thoroughly considered during the counseling process prior to testing. Parents who are struggling to do their best for their families need all the help they can get, and they do not need artificial or arbitrary obstacles to thwart their efforts.

Program Nr: 468 from the 1999 ASHG Annual Meeting

Services for the prevention and management of genetic disorders and birth defects in developing countries. *V.B. Penchaszadeh[1], A. Christianson[2], R. Giugliani[3]*. 1) Div Medical Genetics, Beth Israel Medical Center, New York, NY, USA; 2) Dept Human Genetics, University of Pretoria, Pretoria, South Africa; 3) Dept Medical Genetics, University Hospital,UFRGS, Porto Alegre, Brazil.

While genetic services have had an explosive development in the industrialized world, they are lagging in developing countries. An Advisory Group constituted mostly by geneticists from 13 developing countries was convened on January 5-7, 1999 by the World Health Organization and the World Alliance of Organizations for the Prevention of Birth Defects, to assess and make recommendations on genetic services in the developing world. As rapporteurs of the meeting, we present its main conclusions and recommendations. Genetic diseases and birth defects occur in developing countries at equal or higher frequencies than in the industralized world and their impact on health and quality of life is greater because of deficient services and the load of infections and malnutrition. The role of genetic factors in disease, however, is not sufficiently aknowledged. Recommendations of the Group included: need that health professionals and public health officials recognize the burden imposed by birth defects and genetic disorders; need for political will and commitment for their prevention and management; improve knowledge on the epidemiology of birth defects and genetic disorders; define goals of genetic services in terms of individual and family wellbeing as well as of public health; improve reproductive health, prenatal and newborn care, including attention to maternal age, nutrition, vitamin supplementation and avoidance of teratogens; organize genetic services in a comprehensive manner, integrated with other relevant health services, rooted in the primary care level, with proper referral channels to existing genetic centers; prioritize prevention programs and service targets according to prevalence, severity and the predicted outcomes of measures; respect ethical principles and cultural diversity; train health professionals in genetics; educate the public in genetics; encourage the formation of and support parent/patient organizations. Advocacy for these recommendations is taking place internationally.

Program Nr: 469 from the 1999 ASHG Annual Meeting

How do U.S. Laboratories do Huntington Disease testing for at-risk individuals? *W.K. Seltzer[1], N. McIntosh[2], R.H. Myers[3], The US Huntington's Disease Genetic Testing Group[1,2,3]*. 1) Athena Diagnostics, Worcester, MA; 2) DIANON Systems, Inc., Stratford, CT; 3) Massachusetts General Hospital, Boston, MA.

The clinical, psychosocial and ethical implications of molecular diagnostic testing for Huntington disease (HD) in at-risk individuals are profound. Practice guidelines were established in 1994 by the American Academy of Neurology and the Huntington Disease Society of America (Neurology 1994; 44:1533-1536) to aid clinicians and laboratories in providing maximum benefits to their patients while minimizing the potential risks.

A survey was faxed to 33 US labs listed as offering HD testing in the Genetests™ directory. The survey was devised to assess (1) information that is minimally required by labs to process a specimen for at-risk HD testing; (2) how closely labs are adhering to the guidelines; and (3) current attitudes towards the lab's role as 'gatekeeper' in assuring compliance with the guidelines. Nineteen labs (60%) returned completed surveys.

Most labs reviewed requisitions (18/19), noted the age of the patient (17/19) and documented receipt of consent forms (16/19), prior to processing a patient's specimen. Information most often required included a patient identifier (13/19) and date of birth (15/19); declaration of the patient's clinical status (15/19); documentation of counseling (14/19), and testing being requested by a medical professional (15/19).

Most labs (15/19) stated that they generally followed the guidelines, but exceptions had been made in unusual cases. When asked if a lab would be in favor of shifting the responsibility of complying with the guidelines to the requesting physician, no consensus was reached.

Results from this survey suggest that labs are requiring or requesting much the same information before processing at-risk HD specimens, and are generally adhering to the guidelines. Labs, however, are divided when it comes to relinquishing the responsibility of 'gatekeeper' to comply with them.

Program Nr: 470 from the 1999 ASHG Annual Meeting

Genetic counseling for retinoblastoma (RB) in the new millenium: The implications of identifying RB gene mutations. *J. Sutherland[1], R. Panton[1], J. Anderson[1], L. Han[1], B. Gallie[1,2].* 1) Eye Gen Team, Ophthalmology, Hosp Sick Children, University of Toronto, Toronto, ON, Canada; 2) Ontario Cancer Institute/Princess Margaret Hospital, University Health Network, Univeristy of Toronto, Toronto, Canada.

The RB gene mutation has been identified and reported by our laboratory for 225 probands and 290 of their relatives. Of the 170 isolated cases, 104 were bilaterally affected. All their tested parents were normal except for two families, suggesting that the mutations had arisen *de novo* in the majority of probands. Of the 66 unilateral isolated cases, 60 were normal for the two RB gene mutations found in the proband's tumor, implying that the chance of tumors developing in the unaffected eye and other lifetime cancer risks are reduced. Thus for 164 families, the risk for others to be affected is close to the population risk, while a <1% risk of mosacism remains. Siblings and cousins in these families are spared invasive clinical screening. The cost of molecular screening found equal to conventional screening for the immediate generation, and 5-fold less when future offspring of 64 probands were considered. Despite having no family history, 6/60 probands with unilateral tumors had germline RB gene mutations, indicating that their relatives required screening, just as familial RB relatives. We utilize a prenatal decision tree for genetic counseling discussion of options. When molecular tests indicate that the infant has the family's RB gene mutation, imposing a >90% risk to develop RB tumors, we include the option for early delivery at 36 weeks, in order to maximize visual outcome and chance for cure, and minimize treatment morbidity.

Program Nr: 471 from the 1999 ASHG Annual Meeting

Changing economic patterns in prenatal cytogenetic diagnosis. *P. Wyatt, A. Summers, A. Neidhardt, S. Olsen, E. Mak-Tam.* Dept Genetics, North York General Hospital, Toronto, ON, Canada.

Historically, the prenatal diagnosis of fetal chromosomal disease has been based on using advanced maternal age as the initial screening tool. This resulted in large volume testing of specimens with low abnormality rates. Many of the fees negotiated to pay for these cytogenetic services have been based on processing high volumes of low risk specimens. Changing pregnancy screening techniques have replaced maternal age as the primary screening tool with methods such as maternal serum screening (1st and/or 2nd trimester testing), second trimester ultrasound changes, and, recently, even first trimester ultrasound changes such as nuchal tranlucency, have been added to the techniques used to evaluate the risks of chromosomal disease in pregnancy. This will likely lead to a substantial change in the proportion of cases with abnormalities in cytogenetic laboratories. This change in abnormality rate and complexity per case processed in each laboratory may necessitate an adjustment of the fees paid for cytogenetic analysis by governments/health care organizations. Analysis of the information available from one of Canada's largest genetic centers confirms that the abnormality rate in the cytogenetic laboratory has changed from a rate of 1 autosomal aneuploid per 120 specimens in 1983 to a rate of 1 autosomal aneuploid for every 40 specimens by 1998. Initial information confirms that the use of new markers will continue to increase the abnormality rate in 1999 - anticipated to reach a rate of 1 abnormal per 20 specimens received. Objective data demonstrating the changing complexity of genetic care has remained difficult to quantitate. The area of changing complexity of prenatal cytogenetic service confirms the rapid change that is occurring in genetic care and may be of assistance to quantify the change to the various agencies involved with payment.

Program Nr: 472 from the 1999 ASHG Annual Meeting

On the use of population-based registries in the clinical validation of genetic testing for disease susceptibilities.

Q.H. Yang[1], M.J. Khoury[2], S.S. Coughlin[3], F.Z. Sun[4], W.D. Flanders[5]. 1) Division of Birth Defects and Pediatric Genetics, National Center for Environmental Health, Centers for Disease Control and Prevention (CDC), Atlanta, GA; 2) Office of Genetics and Disease Prevention, Centers for Disease Control and Prevention (CDC), Atlanta, GA; 3) Division of Cancer Prevention and Control, National Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control and Prevention (CDC), Atlanta, GA; 4) Department of Genetics, Emory University School of Medicine, Atlanta, GA; 5) Department of Epidemiology, Emory University, Atlanta, GA.

Many new genetic tests for susceptibility to adult-onset diseases are developed on the basis of selected and high-risk groups. Before such tests can be used in medical practice, however, epidemiologic studies must be conducted to evaluate their clinical sensitivity, specificity, and positive predictive value in the general population. For many common adult-onset diseases, this process may take decades of follow-up. Here, we illustrate how clinical validation of new predictive genetic tests can be done retrospectively using case-control studies that are derived from population-based registries of diseases. We use the examples of birth defects and cancer registries to illustrate a hypothetical process by which such tests can be clinically validated. We demonstrate how such epidemiologic studies can be successfully used to derive measures of a test's sensitivity, specificity, positive predictive value, negative predictive value and of the population attributable fraction of disease due to the disease-susceptibility genes. Under certain assumptions, data derived from population-based case-control studies provide adequate estimates of lifetime risks for disease (penetrance) among people with specified genotypes. With adequate protections of human subjects, studies involving population-based registries of disease will increasingly become a valuable asset in effort to validate the numerous genetic tests that will emerge from advances in human genetic research and the Human Genome Project.

Program Nr: 473 from the 1999 ASHG Annual Meeting

Simulation of gene expression patterns in cDNA microarray data. *L.R. Bailey, J.H. Moore.* Program in Human Genetics, Vanderbilt University, Nashville, TN.

The development of cDNA microarray technology has facilitated the simultaneous measurement of the relative expression levels of thousands of genes. The goal of this study was to develop a computational methodology for simulating gene expression patterns in cDNA microarray data. We required this method to be simple enough to be implemented with any statistical or spreadsheet software package and to be flexible enough to generate patterns for any number of gene expression variables and with any defined mathematical relationship among them.

To accomplish this goal we developed a simulation methodology that consists of the following five steps. First, generate random deviates from a particular statistical distribution for the number of variables to be modeled and for the total number of observations present in all biological or clinical endpoint groups. Second, define any parameters to be used and the mathematical relationship between the gene expression variables and the parameters. Third, apply the mathematical function to the parameters and variables to generate a new variable. This new quantitative dependent variable will be used to generate a dichotomous or polytomous dependent variable representing the functional biological or clinical endpoint groups. This is accomplished in step four by sorting the quantitative dependent variable in ascending or descending order and assigning group values to sequential blocks. The fifth and final step is to place the independent variables in the same observational order as the quantitative dependent variable. This final step generates a pattern specified by the mathematical function that is associated with the new dichotomous or polytomous dependent variable.

We illustrate this methodology by simulating different patterns of gene expression among multiple genes and assessing the power of linear discriminant analysis and a feed-forward neural network for detecting these simulated patterns. We expect cDNA microarray datasets simulated in this manner will be useful for developing and testing new pattern recognition methods and will be useful for assessing the power of a proposed microarray study.

Program Nr: 474 from the 1999 ASHG Annual Meeting

Comparative analysis of an evolutionary chromosomal breakpoint indicates a recent origin for the human 4q telomere. *D.J. Bolland[1,2], M. van Geel[3], L. Carim Todd[2], R.R. Frants[4], P.J. de Jong[3], J.E. Hewitt[1,2]*. 1) Institute of Genetics, University of Nottingham, Nottingham, UK; 2) School of Biological Sciences, University of Manchester, Manchester, UK; 3) Department of Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 4) MGC-Department of Human Genetics, Leiden University Medical Centre, Leiden, The Netherlands.

Comparative mapping and sequence analysis may be used to identify conserved sequences and to investigate chromosome evolution. We have been focusing on the subtelomeric region of human chromosome 4q, the candidate region for facioscapulohumeral muscular dystrophy (FSHD). The mechanism most likely to be causing FSHD is a position effect. FRG1, the most telomeric gene on 4q, was used as the starting point for development of comparative gene maps of this region. The Japanese Pufferfish, Fugu rubripes, has a similar gene complement to human in a genome estimated to be only 400Mb, making Fugu an ideal organism for cloning human disease genes. We sequenced a 40kb cosmid containing the Fugu homologue of FRG1. Adjacent to FRG1 in this cosmid are the homologues of two human chromosome 8p22 genes, acid ceramidase (AC) and pericentriolar material gene 1 (PCM1). We have shown that the mouse homologues of FRG1, AC and PCM1 are also tightly linked and map to the central region of chromosome 8. Sequencing of a 180kb mouse PAC (RPCI21-44K14) revealed both gene order and orientation to be the same in mouse and Fugu. In addition to the Fugu and mouse clones, we have sequenced a 130kb human 4q35 PAC containing FRG1 (RPCI1-226K22). The availability of 350kb of sequence containing the human AC and PCM1 genes from chromosome 8p22 will enable a detailed comparative study of the breakpoint region. Using BACs, we have demonstrated that the FRG1-AC-PCM1 gene linkage group is also conserved in pig, cow and dog but not in chimpanzee and baboon, suggesting that the disruption of this linkage group arose relatively recently in the primate lineage. These data suggest recent telomere formation in the forerunner of human chromosome 4q and fit the proposed position effect hypothesis whereby the FSHD gene was moved to a location unfavourable for normal expression.

Program Nr: 475 from the 1999 ASHG Annual Meeting

Gene isolation on human chromosome 7q: Identification of the type II citrullinemia gene and a splenic lymphoma gene. *A. Boright[1], M. Corcoran[2], D. Oscier[2], S. Mould[2], K. Kobayashi[3], T. Saheki[3], D. Sinasac[1], J. Rommens[1], L.C. Tsui[1], S. Scherer[1]*. 1) Dept Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Royal Bournemouth Hospital, UK; 3) Dept. of Biochemistry, Kagoshima University,.

As part of our effort to generate a gene map of human chromosome 7 we are analyzing genomic DNA sequence using a compendium of bioinformatic tools followed by wet-bench experimentation for full-length transcript identification. Initially, we focussed on the 7q21-q22 region since it contains the loci for many diseases including, NIDDM, myeloid leukemias and lymphoproliferative disorders. We have analyzed exhaustively a 15 Mb region for which complete genomic sequence exists and have been able to identify over 95 genes that could be annotated based on known or inferred function. Our analysis indicates the average gene is 54 kb in length, contains 12 exons and encodes a mRNA of 2.5kb. For some regions the GC content exceeds 60-70% representing H3 isochores. We have integrated into a single map for 7q21-q22, all of the DNA markers and genomic clones for disease gene studies. Using this information we have recently identified the gene that causes type II citrullinemia (Nature Genetics 22, 159-163, 1999) and another (CDK6) involved in splenic lymphoma. For the latter, the analysis of chromosomal translocations in four patients identified the site of rearrangement upstream of the CDK6 cell cycle gene leading to a marked overexpression of CDK6 . In 3 of the patients with a t(2;7)(p11;q22) karyotype, DNA sequencing of the breakpoint revealed it was located 3.8 kb 5'-of exon 1 and involved aberrant VJ recombination between the immunoglobulin light chain region on chromosome 2p and DNA sequence at 7q21 resembling the heptamer recombination signal. In a fourth patient, the breakpoint resided 66 kb upstream to exon 1 juxtaposing CDK6 to an uncharacterized transcript. The analysis of the genomic sequence surrounding CDK6 identified additional potential heptamer recombination signals and these sites are being characterized in other clinical samples with 7q21 rearrangements.

Program Nr: 476 from the 1999 ASHG Annual Meeting

SNP determination using cleavable primers and time-of-flight mass spectrometry. *D.C. Chen, S. Royer, S. Nieto, H. Lin, J.M. Butler, J.A. Monforte.* Biotechnology, GeneTrace Systems Inc., Alameda, CA.

Single nucleotide polymorphisms (SNPs) are the most frequent form of DNA sequence variation in the human genome and as such are becoming increasing popular genetic markers for genome mapping studies, medical diagnostics, and identity testing. The recent acceleration of sequencing efforts in the Human Genome Project is expected to result in more than 100,000 human SNPs for analysis within the next two or three years. Automated, high volume testing procedures will be required to score multiple samples and examine population variation across these SNP markers. To complement its target discovery process, GeneTrace Systems has developed robotic sample processing, automated time-of-flight mass spectrometry, and rapid genotyping software that is capable of analyzing thousands of samples daily. We use a primer extension assay with a novel cleavable primer that improves the capability for accurately calling heterozygote samples and extends the range for non-overlapping multiplexes. Multiplex SNP results will be illustrated from a number of marker systems including mitochondrial DNA and Y chromosome polymorphisms. In addition, SNP data from a subset of the 450 samples in the NIH DNA Polymorphism Discovery Resource will be shown across several human SNP markers.

Program Nr: 477 from the 1999 ASHG Annual Meeting

STACK_PACK and STACK (Sequence Tag Alignment and Consensus Knowledgebase): A novel, comprehensive, hierarchical EST clustering and consensus generation and analysis system providing unique insight into the human genome. *A. Christoffels, R. Miller, W. Hide.* SANBI, University Western Cape, Bellville, Wp, South Africa.

The sequence errors characteristic of ESTs together with their fragmented nature makes them unsuitable for accurate assessment of gene biology and expression. We hierarchically organise and incorporate as much EST information as possible resulting in long consensus sequences, gene expression variants, sequence quality and templates for protein translation. The STACK_PACK system employed does not rely on specific clustering algorithms, but rather approaches the problem of management viewing integration and analysis of the clustering data. We have successfully employed STACK_PACK to generate a highly processed, hierarchically organised database, STACK (http://www.sanbi.ac.za/stack/).We have performed tissue and index level organisation and have processed GenBank release 110 (151098) to reduce the ~1.3 million input ESTs to 173740 STACK sequences. These sequences are represented in 16 tissue divisions. We have also generated a 'high confidence' SANIGENE dataset comprising 95814 sequences where each consensus sequence is represented by at least 2 sequence reads. In order to improve the information content of each cluster, clusters that share clone-IDs were linked and resulted in 76155 linked sequences with an average of 1400.6 bases.. In addition to the tissue divisions, we have generated a whole body index by clustering 330000 STACK tissue consensi on a 128 CPU SGI-CRAY Origin 2000. The index comprises 141291 STACK-INDEX sequences (67000 3' unique sequences) and 23553 SANIGENE-INDEX sequences. With the addition of the index, our database can be browsed hierarchically from the EST level, through the tissue state to the index level using a Perl-object html system (http://ziggy.sanbi.ac.za/cgi-bin/showCLUSTER.pl) that clearly shows the assembly paradigm, and delivers information on alternate expression forms of genes. We are now employing the system to develop a dataset of alternately expressed cancer forms of genes.

Program Nr: 478 from the 1999 ASHG Annual Meeting

Fine mapping of an X-breakpoint from a balanced (X;3) translocation in a female patient with nonspecific mental retardation (MRX), and identification of a new MRX candidate gene. *L. Crisponi[1], M. Uda[1], M. Rocchi[2], P. Ma[3], E. Chen[3], S. MacMillan[4], D. Schlessinger[5], L. Boccone[1], A. Cao[1], G. Pilia[1].* 1) IRTAM, CNR, Cagliari, Italy; 2) Univ. di Bari, Bari, Italy; 3) Perkin-Elmer Co., Foster City, CA; 4) Washington University, S. Louis, MO; 5) National Institute of Aging, HIH, Bethesda, MD.

X-linked Mental Retardation (XLMR) can be roughly categorized as syndromic (MRXS) or nonspecific (MRX). Linkage studies in single large MRX families have identified approximately 60 loci that fall in 8-10 non-overlapping regions along the X chromosome, suggesting the involvement of at least 8-10 corresponding X-linked genes. So far four genes responsible for MRX have been cloned (FMR2, oligophrenin-1, GDI1, PAK3). For the remaining genes, linkage intervals are still too wide to permit identification of causative gene defects by positional cloning. We have studied a female patient with a balanced de novo translocation t(X;3)(q13.1;p14) associated with mental retardation. A number of MRX loci(MRX 4,5,8,13,14,20,22,26,31, 52 and 58) have been mapped to the Xq13 region, so that the X breakpoint in this patient might be associated with one of them. Yeast Artificial Chromosome (YAC) and Bacterial Artificial Chromosome (BAC) clones were used as probes in fluorescent in situ hybridization (FISH) analysis to map the breakpoint to a 150 kb interval. A 150 kb BAC spanning the breakpoint has been completely sequenced, and using Southern blotting experiments with genomic probes designed to identify all the restriction fragment of the critical region, we have been able to map the breakpoint within a 3 kb interval. GenBank comparisons found several Expressed Sequence Tags(ESTs) in the vicinity, and computational searches with GRAIL2 predicted several additional potential exons. A cDNA cognate for sequence from one of the potential exons was recovered from a human testis library. This new gene, the 5'end of which maps 10 kb from the translocation breakpoint, represents a strong candidate for MRX. Complete characterization of its structure and expression profile is underway, along with mutation analysis in MRX families with lesions mapping to Xq13.

Program Nr: 479 from the 1999 ASHG Annual Meeting

A simple method for generating target sequences for methylation-sensitive PCR. *O.A. Haas, A. Weinhäusel, R. Ebmer.* CCRI & LBICD, St. Anna Children's Hospital, Vienna, Austria (o.a.haas@magnet.at).

The analysis of differentially or abnormally methylated DNA becomes an increasingly important issue. It simplifies the diagnosis of specific constitutional disorders, such as syndromes associated with imprinting defects and uniparental disomies of particular chromosomes, and helps in the evaluation of neoplasm-associated methylation abnormalities. The most convenient and efficient laboratory method for this purpose is the methylation-sensitive polymerase chain reaction (MS-PCR). It takes advantage of the fact that chemical deamination of DNA with bisulfite converts unmethylated, but not methylated cytosine (C) to uracil which is subsequently replaced by thymidine (T). By that, unrelated DNA sequences are generated from originally homologous, but differentially methylated alleles. Since the respective PCR primers have to be designed according to the modified deaminated unmethylated and methylated DNA, the specific target sequence has to be defined unequivocally. So far, this was achieved by PCR amplification of an extended part of the deaminated sequence of interest, which thereafter had to be cloned and sequenced. Our approach is based on the assumption that in the unmethylated gene regions all CpG's are unmethylated, whereas in the methylated one all CpG's are methylated. We therefore simply deduce the sequence of the deaminated unmethylated DNA by converting all C's to T's. In the case of deaminated methylated sequence, we only change C's that are not contained in CpG's. To simplify this approach even further, we have developed a computer programme that generates the target sequence according to the above specification. With this method, we have already established and successfully applied diagnostic MS-PCR tests for the following genes: HUMARA, XIST, FMR1 (promoter and repeat), PEG1/MEST, SNRPN, BRCA1, ABL, RET and WT1.

Program Nr: 480 from the 1999 ASHG Annual Meeting

Digital Gene Localization of Bone-related ESTs. *L. Jia[1], N. Ho[1], J. Powell[2], L. Yang[2], P. Robey[3], M. Young[3], C. Francomano[1]*. 1) Medical Genetics Branch, National Human Genome Research Institute; 2) Center for Information Technology; 3) National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD. U.S.A.

Approximately 10,000 expressed sequence tags (ESTs) from 10 bone-related cDNA libraries have been analyzed against human High Throughput Genomic Sequence (HTGS) Database. This analysis, which has been termed digital gene localization (DGL), can predict the chromosomal location of the ESTs. We used the NCBI Network BLAST analysis with high stringency parameters (> 100 bp long, 98% homology) for the DGL. From this analysis, 407 ESTs from 10 human bone related cDNA libraries have assigned chromosomal locations. By radiation hybrid mapping and FISH, the chromosomal locations of 4 novel genes have been confirmed which are fully matched with the DGL results. The DGL analysis also predicted the gene structure, including intron/exon junctions, of these genes. We have calculated the bone-related gene distribution vs. whole UniGene distribution. Compared to the traditional gene localization methods, including FISH and radiation hybrid mapping, DGL is more accurate and faster, but limited to regions of the genome for which high throughput genomic sequence is available. DGL can greatly accelerate the chromosomal assignment of many genes.

Program Nr: 481 from the 1999 ASHG Annual Meeting

Complete genomic sequence of the 471 kb Familial Dysautonomia candidate region on chromosome 9q31. *M. Leyne[1], J. Mull[1], S.P. Gill[1], C.B. Liebert[1], C.M. Robbins[2], H.W. Pinkett[2], I. Makalowska[2], C. Maayan[3], A. Blumenfeld[3], F.B. Axelrod[4], M. Brownstein[2], B.P. Chadwick[1], J.F. Gusella[1], S.A. Slaugenhaupt[1]*. 1) Harvard Inst. of Human Genetics, Mass. General Hospital, Boston, MA; 2) National Institute of Health, Bethesda, MD; 3) Hadassah University Hospital, Jerusalem, Israel; 4) New York University Medical Center, New York, NY.

Familial Dysautonomia (FD) is an autosomal recessive disorder that affects the development and survival of sensory, sympathetic and some parasympathetic neurons. The gene defect is almost exclusively limited to the Ashkenazi Jewish population where the carrier frequency is 1:30. The FD gene maps to human chromosome 9q31 and recent haplotype analysis of 441 disease chromosomes has refined the candidate interval to a 471 kb region. A detailed physical map spanning this interval was constructed and consists of 3 overlapping BAC clones and 58 cosmids. We have used exon trapping and cDNA selection to identify 8 candidate genes in the FD region. In order to refine the candidate interval and isolate new FD candidate genes, we determined the genomic sequence of the 471 kb critical region by direct sequencing of the BAC clones. The genomic sequence has yielded several new polymorphisms that have narrowed the candidate region from 471 kb to 162 kb. In addition, gene prediction programs identified three new FD candidate genes. In total, 8 of the 11 candidate genes isolated to date map within the new 162 kb critical region.The genomic structure of these genes has been determined and mutational analysis of the coding sequence of these candidate genes was performed by sequencing RT-PCR products from affected and control individuals. No pathogenic mutations were identified within the coding regions of any of our candidate genes suggesting that the FD mutation may be located in an intron or in an untranslated region of one of these genes. A cosmid library from an FD patient homozygous for the FD haplotype has been constructed and we are currently constructing an FD contig of our candidate region. Direct sequence analysis of the FD contig sequence compared with the control contig sequence will allow us to identify the mutation resulting in FD.

Program Nr: 482 from the 1999 ASHG Annual Meeting

Evidence from single-nucleotide polymorphisms (SNPs) for natural selection affecting human and orangutan Xq28. *R.D. Miller, P. Taillon-Miller, P.-Y. Kwok.* Division of Dermatology, Washington Univ. Sch. Medicine, St. Louis, MO.

In the course of identifying informative SNPs on the long arm of the human X chromosome, we found and further investigated a 1.3 mb region which has fewer SNPs. This region, near the tip in Xq28, is rich in genes, among others containing those encoding the MMP1A homologue, creatinine transporter (CREAT), adrenoleukodystrophy protein (ALD), isocitrate dehydrogenase gamma (IDH), arginine-vasopressin receptor (AVPR2), renin-binding protein (RBP), host cell factor C1 (HCFC1), red cone photoreceptor (RCP), filamen A (FLN1), emerin (EMD), and glucose-6-phosphate dehydrogenase (G6PD). This region has an unusually high content of G+C (56% compared with 37% in Xq25). Conceivably, the reduced frequency of SNPs could be due to either a reduced mutation rate in this region or to one or more natural selection events. The prediction was that if there were a reduced mutation rate, a related species would have reduced divergence in this region, but if selection had occurred, the divergence in this region would be the same as in controls regions. To distinguish these alternatives, the comparative DNA sequence was determined from sequence tagged sites (STSs) from human and a female Sumatran orangutan. In the Xq28 region, more than 17,000 bp of homologous sequence from 26 STSs was obtained, and for comparison of divergence, additional homologous sequence was obtained from Xq25 and two nearby regions. In Xq28, the divergence between human and orangutan was 2.9% (standard deviation 0.95%), not significantly different from the divergence in Xq25 of 2.5% (probability = 0.25), nor from the two other regions. These results suggest that human Xq28 has been subjected to selection, reducing the frequency of informative SNPs. In this work, five heterozygous nucleotides were identified in the orangutan, none of which corresponded to human SNPs, and none were in the Xq28 region, suggesting that orangutans may also lack variability in this region.

Program Nr: 483 from the 1999 ASHG Annual Meeting

Determination of retrotransposition rates in cultured cells with a GFP-based assay. *E.M. Ostertag[1], E. Luning Prak[1], R.J. DeBerardinis[1], J.V. Moran[2], H.H. Kazazian, Jr.[1]*. 1) Dept Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Dept Human Genetics, Univ Michigan, Ann Arbor, MI.

L1 retrotransposons are autonomous retroelements of which an estimated 40-60 remain active in the human genome. These elements occasionally create *de novo* insertions and can cause genetic disease. Here we describe a new retrotransposition assay using a Green Fluorescent Protein (GFP) retrotransposition marker and Fluorescence Activated Cell Scanning (FACS) analysis that is quicker and less subjective than our previous assay using a neomycin phosphotransferase (neo) marker. The new assay is able to detect near real-time retrotransposition in a single cell and is sufficiently sensitive to distinguish retrotransposition rates between different L1 elements. Therefore, this assay could be used for several important experiments such as determining dependence of retrotransposition on cell cycle and nuclear membrane breakdown, and demonstrating retrotransposition in a mouse model. In this study, we determine the retrotransposition rate of two different L1 retrotransposons, $L1_{RP}$ and L1.3. $L1_{RP}$ is an element recently discovered as a full-length *de novo* insertion into the RP2 gene of a retinitis pigmentosa patient. To date, $L1_{RP}$ and L1.3 are the two most active elements in the neo retrotransposition assay. The $L1_{RP}$ element retrotransposed in the GFP assay at a rate of approximately 0.3% of transfected cells per day, a rate about 5-fold higher than for L1..3. We also show that retrotransposition from an episomal vector can occur at a constant rate for at least 16 days in cultured cells. In summary, we have developed a new assay which demonstrates continuous and high frequency retrotransposition in HeLa cells and which we are using to develop a mouse model of retrotransposition.

Program Nr: 484 from the 1999 ASHG Annual Meeting

Centromere repositioning. *M. Rocchi, G. Montefalcone, S. Tempesta, R. Roberto, M. Ventura, N. Archidiacono.* Istituto Di Genetica, Universita Di Bari, Bari, Italy.

Primate pericentromeric regions have been recently shown to exhibit extraordinary evolutionary plasticity. In the present paper we report an additional peculiar feature of these regions which we discovered while analysing, by FISH, the evolutionary conservation of primate phylogenetic chromosome IV, IX, and X. If the position of the centromere is not included in the analysis, a relatively small number of rearrangements must be invoked to account for interspecific differences. However, if the centromere is included, a paradox emerges: the position of the centromere seem to have undergone, in some species, an evolutionary history independent from the surrounding markers. A significant number of additional rearrangements must be proposed to reconcile the order of the markers with centromere position. Alternatively, the evolutionary emergence of neocentromeres can be postulated. These data suggest that the evolutionary history of these regions is becoming increasingly more complex.

Program Nr: 485 from the 1999 ASHG Annual Meeting

Cross-species sequencing and functional studies identify non-coding elements with biological import including a potent IL-4 and IL-13 enhancer. *E.M. Rubin[1], G. Cretu[1], W. Miller[2], K.A. Frazer[1]*. 1) LBNL, Berkeley, CA; 2) Penn State Univ, University Park, Penn.

While computational methods for recognizing coding sequences are well established, greater than 95% of the human genome is comprised of non-coding sequences and we are currently faced with the challenge of shifting through these regions to identify non-coding elements of biological import. Based on the premise that biologically functional non-coding sequences will be conserved among vertebrates and that non-functional non-coding sequences will diverge, we compared an 830 kb region on human 5q31 which codes for 19 genes, including a bio-medically important cluster of cytokines genes, with the orthologous region on mouse chromosome 11. Following the identification of all the conserved sequences in this region and exclusion of the putative coding sequences we were left with 69 highly conserved (>100 bp and > 70% identity) non-coding elements. Experimental analysis of 15 of these elements demonstrated that they are single copy in the human genome and that 10 of them, in addition to humans and mice, are highly conserved in other vertebrates. The fact that these non-coding elements are present in multiple species suggests that they have been evolutionary conserved due to biological function. We have focused on assigning biological function to the most highly conserved non-coding element identified in these studies (401 bp in length and 83% identity) which is located in the ~12 kb region between IL-4 and IL-13 in the human, mouse, baboon and dog genomes. To study the function of this element we used a 450 kb 5q31 human YAC and the Cre-Lox system to create identical lines of human YAC transgenic mice differing only in that some contained and others lacked the 401 bp element on the YAC. Comparing the expression of the human transgenes in these different lines of mice revealed that the animals lacking the 401 bp element had a 10 fold decrease in expression of IL-4 and IL-13. These studies illustrate a cross-species sequence based strategy for identifying non-transcribed elements of biological import and have lead to the discovery of a potent regulator of IL-4 and IL-13 transcription.

Program Nr: 486 from the 1999 ASHG Annual Meeting

Possible activation of a b**-tubulin pseudogene (TUB4q) could explain the FSHD molecular defect.** *M. van Geel[1], A.F. Beck[1], E.E. Eichler[3], R.R. Frants[2], P.J. de Jong[1]*. 1) Dept of Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY; 2) MGC-Dept of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 3) Dept of Genetics, Case Western Reserve School of Medicine, University Hospitals of Cleveland, Cleveland OH.

The subtelomere of chromosome 4q35 contains the gene for the autosomal dominant neuromuscular disorder facioscapulohumeral muscular dystrophy (FSHD). Deletion of integral copies of a 3.3 kb repeated unit (D4Z4) are causal to the disease, but no associated gene has been identified. A b-tubulin related sequence, TUB4q, resides in the region. Functionality of the putative gene is questionable in view of demonstrated lack of expression. Nine family members of TUB4q have been identified mainly on pericentromeric and telomeric regions of the genome and originate from large segment duplications of Chr. 4q35. Like TUB4q, members on Chr. 10, 16 and 18 maintain an open reading frame and share close sequence relationships. To unravel the TUB4q family phylogeny, orthologous (derived from speciation event) and paralogous (derived from duplication event) TUB4q sequences were isolated from the chimpanzee (Pan) and baboon primate species. Besides the Chr. 4q35 TUB4q orthologue, 11 individual family members were identified, each in Pan and baboon. Both maximum likelihood and maximum parsimony methods were used to define orthologous and paralogous relationships among the human, baboon and Pan TUB4q copies. The putative baboon protein sequence is 88.7 % identical to the human Chr. 4 TUB4q orthologue, but surprisingly 97.1 % identical to the human Chr. 10 copy. Although, baboon and human diverged approximately 25 million years ago, TUB4q protein conservation remains, suggesting a functional TUB4q gene on human Chr. 10. Phylogenetic analysis suggests recent inactivation of the human Chr.4 TUB4q gene, which has been replaced by a duplicated copy on Chr. 10. Possible activation of the normally non-functional TUB4q gene in the FSHD region could have implications for the FSHD disease mechanism.

Program Nr: 487 from the 1999 ASHG Annual Meeting

Human BAC Ends. *S. Zhao[1], J. Malek[1], G. Mahairus[3], L. Fu[1], B. Nierman[1], C. Venter[2], M. Adams[2].* 1) Dept Eukaryotic Genomics, Inst for Genomic Research, Rockville, MD; 2) Celera Genomics Corp., Rockville, Maryland; 3) Dept Molecular Biotechnology, Univ of Washington, Seattle.

End sequences from Bacterial Artificial Chromosomes (BACs) have been playing critical roles in large scale genomic sequencing projects: 1) selecting clones for sequencing, 2) validating, joining and ordering contigs, and 3) building genome assembly scaffolds. To date, we have generated >300,000 end sequences from >180,000 human BAC clones with an average read length 460 bp for a total of 140 MB covering ~4.6% of the genome. Over 60% of the clones have BAC end sequences (BESs) from both ends representing >5.5X coverage of the genome by the paired ends clones. Our quality assessments and sequence analyses indicate that BESs from human BAC libraries developed at California Institute of Technology (CalTech) and Roswell Park Cancer Institute (RPCI) have similar properties. The analyses also indicate that BESs generated by The Institute for Genomic Research (TIGR) and the University of Washington (UW) are sufficiently accurate for use in both building the minimum tiling path of sequence-ready clones across the genome and building genome assembly scaffolds. The annotation results of BESs for the contents of available genomic sequences, sequence tagged sites (STSs), expressed sequence tags (ESTs), protein encoding regions and repeats indicate that this resource will be valuable in many areas of genome research.

Program Nr: 488 from the 1999 ASHG Annual Meeting

A High Level of Negative Meiotic Recombination Interference across a Large Region of Human Chromosome 17 Detected by Analyzing Single Sperm. *Y. Zou[1,2], X. Cui[1], C. Jackson-Cook[2], H. Li[1].* 1) Coriell Institute for Medical Research, 401 Haddon Avenue, NJ 08103; 2) Department of Human Genetics, Virginia Commonwealth University, Richmond, VA. 23298.

To learn the content of uneven distribution of meiotic recombination events in the human genome, four polymorphic markers that are located in TP53, VNT (vitronectin), B-Box (IAI3B), and Col1A1 (type I collagen, alpha 1) genes and span about a half portion (~51.9 cM on GeneMap'99 but 67.0 cM determined by the present study) of the human chromosome 17 were selected. Meiotic recombination frequencies between these markers were determined by analyzing single sperm from two donors. An excess number of double crossovers with respect to all possible tri-locus combinations of the four loci were detected. The coincidence coefficients ranged from 1.57 to 2.76 when the data for the two individuals were analyzed separately and from 1.67 to 2.41 for the pooled data. Such a high degree of negative interference could be a reflection of the physical structure favoring the occurrence of double crossovers in the covered chromosomal region. If the recombination events occurring during meiosis and mitosis share similar molecular mechanisms, these results may have a significant implication on understanding the frequent occurrence of loss of heterozygosity through an "interstitial deletion-like" mechanism as detected in a number of tumors. Results from the present study also indicate no significant difference in meiotic recombination frequencies between the two selected donors for all the intervals between the selected markers. However, two of the three intervals (between VNT and B-Box, and between B-Box and Col1A1) determined in the present study were shown to be significantly larger than reported previously. These results suggest a necessity of detailed genome-scale survey for understanding the genetic structure of the human genome.

Program Nr: 489 from the 1999 ASHG Annual Meeting

The molecular basis of late onset very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency. *B.S. Andresen[1,2], S. Olpin[3], M. Pourfarzam[4], T.J. Corydon[2], H. Lund[1,2], J. Schaefer[5], L.D. Schroeder[1,2], L. Bolund[2], N. Gregersen[1]*. 1) Research Unit for Molecular Medicine, Skejby Sygehus, Aarhus, Denmark; 2) Institute of Human Genetics, Aarhus University, Denmark; 3) The Children`s Hospital, Sheffield, UK; 4) Royal Victoria Infirmary, Newcastle, UK; 5) University Hospital of Dresden, Dresden, Germany.

VLCAD deficiency (VLCADD) is a potentially fatal defect of mitochondrial fatty acid -oxidation. Patients present with three different clinical phenotypes: Two childhood forms (severe and mild) and a late onset, exclusively muscular, form. We have investigated the molecular-genetic basis for the disease in eleven unrelated families with late onset VLCADD and compared this group of patients to a group of patients with severe childhood VLCADD. Mutant proteins were examined by overexpression of recombinant protein in COS cells. Patient cells were examined by beta-oxidation activity measurements and by tandem MS. Our results show that differences in the clinical presentation of VLCADD can be explained by differences in the molecular pathology of patient mutations, and that aberrant folding, leading to decreased amounts of protein, is a major molecular defect mechanism. We speculate that variation in the factors that influence folding and degradation of mutant proteins may explain some of the clinical variation observed. Finally, we present evidence that the CMT1A duplication (17p11.2) may be involved in disease in at least one late onset VLCADD patient.

Program Nr: 490 from the 1999 ASHG Annual Meeting

Molecular, biochemical and structural analysis of ten novel lysosomal neuraminidase mutations: correlation with clinical severity in sialidosis. *E. Bonten, A. d.Azzo.* Genetics, St Jude Child Res Hosp, Memphis, TN.

Sialidosis is a severe neurodegenerative lysosomal disorder caused by structural lesions in the lysosomal neuraminidases gene. Type I sialidosis (normophormic) is a mild form of the disease usually diagnosed in the second decade of life and characterized by the cherry-red spot-myoclonus phenotype and progressive impaired vision, but absence of dismorphic features. Type II sialidosis is a severe form of the disease, which can be subdivided into three forms: (I) congenital or hydropic (in utero), (II) infantile (0-12 months), and (III) juvenile (2-20 years). All type II patients eventually develop progressive mucopolysaccharidosis-like features, including coarse facies, visceromegaly, dysostosis multiplex, vertrebal deformities and severe mental retardation. We have identified 12 mutations, 10 of which novel, in the mRNA and genomic DNA of 9 unrelated sialidosis patients and some of their parents. The majority of the mutations were base substitutions resulting in single amino acid changes. Five patients were compound heterozygotes, while the others were homozygotes. To study the biochemical properties of the individual mutant proteins we expressed their encoded cDNA's in COS-1 cells or deficient sialidosis fibroblasts. Transfected cells were analyzed for residual neuraminidase activity and subcellular localization of the mutant enzyme. Based on these biochemical studies we grouped the mutations in three distinct catagories. Five mutant proteins lacked residual neuraminidase activity and were not localized in lysosomes. Three lacked residual activity, but had weak lysosomal localization. In contrast, the remaining three had residual activity (30-60%) and clear lysosomal localization. Interestingly, only the first category carried mutations on residues that are conserved within the family of bacterial/mammalian neuraminidases. Furthermore, we could make a clear correlation between the impact of the mutation on the neuraminidase function and the disease phenotype. In future the assignment of mutations to one of the groups might be helpful for determining the clinical prognosis of sialidosis patients.

.

Program Nr: 491 from the 1999 ASHG Annual Meeting

The human rBAT promoter and promoter mutations in cystinuria. *M. Boutros, P. Ong, I. Saadi, F. Hiou-Tim, C. Vicanek, R. Rozen, P. Goodyer.* Human Genetics, McGill University, Montreal,PQ, Canada.

Cystinuria is an inherited (1:7000) disorder of the kidneys and intestine, affecting reabsorptive transport of cystine and dibasic amino acids. Affected individuals develop recurrent kidney stones due to the low solubility of cystine in acidic urine. There are 2 known cystinuria loci. The rBAT gene (2p21) encodes a transmembrane glycoprotein expressed at the apical surface of cells in the proximal renal tubule and small intestine. Over 30 distinct rBAT coding mutations have been identified in association with the fully recessive (Type I) form of cystinuria. A second gene (19q) accounts for the incompletely recessive forms (Types II and III. To study developmental regulation and to search for promoter mutations, we isolated 4kb of the 5' rBAT flanking sequence. We noted five SP-1, four AP-2, one NF-kB, 11 gamma interferon sites and a potential PAX 8 site. We screened a panel of cell lines and found that the first 800 nucleotides of the rBAT promoter are sufficient to drive tissue- specific expression at 10-fold higher levels in a proximal tubular cell line. Co-transfection of PAX 8, a proximal tubule specific transcription factor expressed during development, with this 800 bp promoter showed a 2-fold increase in activity. To determine if rBAT is developmentally regulated, we performed Northern analysis on samples of kidney from a fetus (18 weeks) and a 3-year old girl. mRNA levels were 3-5 fold higher in post-natal tissue. Immunohistochemical analysis of human kidney tissue revealed that rBAT is expressed in the early and late segments of the proximal tubule. In a group of Type I/III patients, we found 2 promoter mutations: G(-265)A located within an AP-2 site, and G(-194)C. In transfection experiments, we found that G(-265)A decreases promoter activity to 60 percent of wild type. Studies of the second mutation are in progress.

Program Nr: 492 from the 1999 ASHG Annual Meeting

Glycerol Kinase Deficiency: Patients' Missense Mutations Map to Active Site Cleft. *K.M. Dipple[1,2], Y.H. Zhang[1,2], B.L. Huang[1,2], E.R.B. McCabe[1,2].* 1) Dept Pediatrics, Div Genetics, UCLA, Los Angeles, CA; 2) Mattel Children's Hospital at UCLA, Los Angeles, CA.

Glycerol kinase deficiency (GKD) occurs as part of an Xp21 contiguous gene syndrome or as isolated GKD. The isolated form of GKD may be either symptomatic (episodic metabolic and central nervous system decompensation) or asymptomatic (only pseudo-hypertriglyceridemia). To better understand the pathogenesis of isolated GKD, and attempt to determine genotype-phenotype correlations, we mapped six missense mutations to a model based on the crystal structure of E. coli GK (Hurley et al., Science 259:673, 1993). The use of the E. coli structure is justified based on the 50% identity and 65% similarity with human GK. Mutations were analyzed by automated genomic sequencing (ABI 377). Two of the patients (N288D and Q438R) were asymptomatic while the third (M428T) was difficult to classify because he had neonatal asphyxia, which could be a presentation of GKD, but was asymptomatic after the neonatal period. Only one of the patients (R405Q) was clearly symptomatic with episodic hyperglycerolemia, glyceroluria, and hypoglycemia. In addition to the patients we identified, two patients with missense mutations were reported in the literature and were asymptomatic (D440V: Walker et al., Am. J. Hum. Genet. 58:1205, 1996; W503R: Sjarif et al., J. Med. Genet. 35:650, 1998). The structure of E. coli GK has two large domains that are separated by a deep cleft that is the active site. Mapping of the patients' missense mutations to the structure of E. coli GK using the Insight II program, showed that all but one of the patients' missense mutations map to the active site cleft. The one mutation that was not in the active site cleft mapped adjacent to it. These data suggest that, with this small sample size, patients with isolated GKD due to missense mutations have alterations that map to the active site of GK. We are unable to distinguish the impact of the mutation in the obviously symptomatic patient (R405Q) from those in the asymptomatic patients. More detailed structural and function analysis of these mutations will be required to understand their precise roles in the pathogenesis of GKD.

Program Nr: 493 from the 1999 ASHG Annual Meeting

Molecular cloning, characterization and functional expression of a second mammalian delta1-pyrroline-5-carboxylate reductase. *K. Dougherty[1], C.A. Hu[2], C. Obie[2], D. Valle[2]*. 1) Peridontics Prevention and Geriatrics, Univ of Michigan, Ann Arbor, MI; 2) Institute of Genetic Medicine and the HHMI, Johns Hopkins University School of Medicine, Baltimore.

Mammalian P5CR is an ATP- and NAD(P)H-dependent enzyme catalyzing the reduction of P5C to proline, the first committed step in the de novo biosynthesis of proline. Biochemical studies of P5CR obtained from a variety of tissues have shown tissue-specific kinetic properties and sensitivity to inhibitors. To better understand the molecular enzymology, tissue-specificity and regulation of mammalian P5CRs, we previously isolated a human gene encoding P5CR (P5CR.1) by complementation cloning in S. cerevisiae (Dougherty et al., JBC 267:871, 1992). We have now identified a second human gene encoding a putative P5CR, designated P5CR.2. The P5CR.2 ORF is 960 bp with 81% nucleotide identity to P5CR.1, and encodes a protein with 84% amino acid identity to P5CR.1. Both P5CR.1 and P5CR.2 genes are broadly expressed. To confirm the identity of the putative P5CR.2 cDNA, we expressed it in a P5CR-deficient strain of S. cerevisiae and showed that, like P5CR.1, it conferrs proline prototrophy. In a search for human diseases associated with P5CR deficiency, we noticed that there is a proline auxotrophic human leukemic lymphoblastoid cell line (REH), previously shown to be deficient in NADH-dependent P5CR activity, but with normal NADPH-dependent P5CR activity (Lorans and Phang, BBRC 101:1018, 1981). Northern blot analysis and direct sequencing of RT/PCR product showed that the REH cells expressed a normal amount of wild-type P5CR.2 transcript, but undetectable P5CR.1 transcript. In conclusion, we have cloned and characterized a second human gene encoding P5CR and identified a cell line expressing only P5CR.2. This result together with earlier biochemical studies of P5CR activities in these cells indicate P5CR.2 utilizes NADPH while P5CR.1 utlizes NADH. We speculate that various combinations of expression of P5CR.1 and P5CR.2 accounts for the tissue variations in the biochemical characteristics of P5CR activity.

Program Nr: 494 from the 1999 ASHG Annual Meeting

Screening candidate genes in patients with Hermansky-Pudlak syndrome. *M. Huizing[1], V. Shotelersuk[1], E.C. Dell'Angelica[2], J.S. Bonifacino[2], W.A. Gahl[1].* 1) HDB; 2) CBMB, NICHD, NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder characterized by oculocutaneous albinism, platelet storage pool deficiency, and ceroid lipofuscinosis. Although the basic defect in HPS is not known, it is considered to involve a vesicular membrane shared by the melanosome, dense body, and lysosome, all of which are affected in HPS. Several genes, some corresponding to mouse models manifesting both hypopigmentation and platelet storage pool deficiency, are candidates to cause HPS. The discovery of one HPS-causing gene, HPS-1, and its murine homologue ep (for pale ear), may lead us to the basic defect, but the function of the HPS1/ep protein product has not yet been determined. In addition to mutations in HPS-1, we demonstrated that mutations in the gene for the beta-3a subunit of adaptor complex-3 (AP-3) cause a variant of HPS in two brothers; AP-3 mutations also result in the HPS mouse called pearl. AP-3 is a coat protein that assists in vesicle formation from Golgi membranes. Other candidate genes for causing HPS include the genes responsible for murine models of the disease as well as genes involved in vesicular trafficking, cargo packaging, vesicle formation and docking, or membrane fusion. We used immunofluorescence microscopy followed by DNA-sequencing to screen HPS patients for defects in candidate genes. The platelets of 9 patients with mutations in HPS-1 showed dramatically decreased fluorescence when treated with anti-HPS-1 antiserum. This illustrates the utility of our HPS-1 antibody, and the feasibility of using immunofluorescence to ascertain patients with HPS-1 mutations. Similarly, fibroblasts of the beta-3a deficient patients showed decreased signal when incubated with beta-3a antiserum or with antiserum against the mu or delta subunits of the AP-3 complex. We also screened the fibroblasts of 27 patients without HPS-1 mutations for the presence of other candidate gene products, including ARF1, ARF6, rab27, and the mu subunit of AP-3. Although no abnormalities in these proteins were detected, immunocytofluorescence appears to be a reasonable technique for identifying abnormalities in protein trafficking causing HPS.

Program Nr: 495 from the 1999 ASHG Annual Meeting

Fabry Disease: Biochemical, Molecular and Subcellular Localization Studies of Eight a-**Gal A Missense Mutations with Residual Activity.** *Y.A. Ioannou, P. Ashton-Prolla, C.M. Eng, R.J. Desnick.* Human Genetics, Mount Sinai Sch Medicine, New York, NY.

Fabry disease is an inborn error of glycosphingolipid catabolism resulting from the deficient activity of the lysosomal hydrolase, a-galactosidase A (a-Gal A). PCR amplification and subsequent sequencing of genomic DNA from unrelated patients with residual a-Gal A activity (mild cardiac variants) identified eight missense mutations E59K, I91T, R112H, F113L, N215S, D244N, M296V and R356W. Of note, the D244N mutation created a new N-glycosylation consensus sequence. Each mutation was introduced by site-directed mutagenesis into the a-Gal A cDNA which was modified by addition of a FLAG octapeptide and a histidine tag. Using this transient expression system, the wild type and mutant a-Gal A cDNAs were expressed at levels 25-fold and 1.5 to 30-fold greater than endogenous COS-7 activity (0.15 mmoles/hr/mg), respectively. The expressed wild-type and mutant enzymes were characterized with respect to enzyme activity, pH stability and intracellular localization. Different disease-causing mechanisms were identified for these mutations including decreased affinity for both the natural and artificial substrates, retention in the endoplasmic reticulum, a delay in protein transport/maturation, and instability at acidic pH. In addition, when each missense mutation was expressed in COS-7 cells and incubated in the presence of 200 mM D-galactose for 36 hr, the cellular a-Gal A activities were increased by 1.3 to 5 fold greater than that of the respective mutation expressed in the absence of the substrate analogue. These results emphasized the molecular heterogeneity of the mutations causing Fabry disease and indicated that the residual activity in Fabry cardiac variants with residual activity can be increased by substrate analogues that facilitate proper enzyme folding and lysosomal transport.

Program Nr: 496 from the 1999 ASHG Annual Meeting

Metabolic consequences of targeted disruption of the 70kDa Peroxisomal Membrane Protein (PMP70). *G. Jimenez-Sanchez, K.J. Hebron, C. Obie, G. Thomas, D. Valle.* Institute of Genetic Medicine and The Howard Hughes Medical Institute, Johns Hopkins University, Baltimore, MD.

ATP-binding cassette (ABC) transporters are members of a superfamily of membrane proteins involved in the transport of a variety of molecules across biological membranes. There are 4 known human peroxisome ABC transporters: PMP70, ALDP, ALDP-related (ALDR) and PMP70-related (P70R). We targeted the murine PMP70 gene by standard methods. PMP70-/- animals lack PMP70 mRNA and protein but immunohistochemistry shows that peroxisomes are present and contain normal amounts of PTS1 and PTS2 targeted matrix proteins. Thus, PMP70 is not required in peroxisome biogenesis. Metabolic evaluation of these animals revealed dicarboxylic aciduria suggesting a defect in b-oxidation. Consistent with this, we found that PMP70-/- mice show cold intolerance with a decrease in body temperature to 12^{o}C after 90 min at 4^{o}C. Whether this impaired thermogenesis reflects impaired peroxisomal b-oxidation or a secondary defect in mitochondrial b-oxidation is currently under investigation. Immunoblots of PMP70-/- liver and kidney showed a specific massive increase (>20X) of P70R suggesting this may compensate for the absence of PMP70. Steady state levels of P70R mRNA are not different from control indicating the mechanism for P70R accumulation in PMP70-/- is post transcriptional. Preliminary pulse studies suggest that P70R is synthesized at a higher rate in the PMP70-/- mice suggesting some alteration in translational regulation accounts for P70R accumulation. PMP70 mice have a marked (10X) reduction in hepatic glycogen in the fed state. Glycogen synthase mRNA and activity levels are not different from control. The level of hepatic glycogen increases in animals on a high (69%) carbohydrate diet, confirming the ability of PMP70-/- mice to synthesize glycogen. Taken together these results suggest increased utilization of glycogen in the PMP70-/- mouse. How these metabolic abnormalities derive from deficiency of PMP70 is not clear but we favor a model in which impaired peroxisomal b-oxidation of dicarboxylic fatty acids is the primary defect.

Program Nr: 497 from the 1999 ASHG Annual Meeting

Canine model and genomic structure organization of glycogen storage disease type Ia (GSD Ia). *P. Kishnani[1], E. Faulkner[1], S. Vancamp[2], M. Jackson[2], T. Brown[2], A. Boney[1], Y.T. Chen[1]*. 1) Medical Genetics, Duke Univ Medical Center, Durham, NC; 2) North Carolina State Univ, NC.

GSD Ia was diagnosed in 6 pups from an established canine (maltease beagle) GSD Ia breeding colony. 5 pups died within 6 weeks (2 within minutes, 1 at 36 hrs, 1 each at weeks 4 and 6). 1 is alive at age 6 months. Histology of affected pups showed diffuse, marked hepatocellular vacuolation, with distended clear hepatocytes and central to marginally located rounded nuclei. Kidneys showed increased cellularity & finely granular eosinophilic expansion of mesangium in several glomelular tuffs as early as age 8 days which progressed to segmental/ diffuse increased cellularity with age. Vacuolation of proximal convoluted tubular epithelium was also noted. Biochemical analysis revealed increased liver glycogen content and isolated marked reduced glucose -6-phosphatase (G-6-Pase) enzyme activity in liver and kidney. Affected pups were homozygous for the M121I GSD Ia mutation identified in this breed. They have tremors, weakness and neurologic signs when hypoglycemic. They have retarded postnatal growth and development and progressive hepatomegaly. Chemistries include fasting hypoglycemia 20-40 (60-100mg/dl), increased blood lactate 4.2-11.5 (0.7-2.5 mg/dl), cholesterol 326-639 (102-173 mg/dl), triglycerides 33-142 (2-26 mg/dl) and uric acid 0-1.9 (0-0.3 mg/dl). Treatment includes frequent PO feeds, which provide 12-14 mg/kg/min glucose. We have characterized the canine G-6-Pase gene by screening a canine genomic library with our published canine G-6-Pase cDNA as probe. It spans ~11.8kb and consists of 6 exons (> 90% amino acid sequence homology to derived human sequence). We have sequenced the first 1.4kb of the 5' region. It contains several putative response element motifs homologous to the published human 5' region (GRE, IRS, HNF 1, HNF 5,C/EBP, CRE, AP1, and AP2 sites). Putative TATAA and CAAT promoter boxes are also present. Establishment of this GSD Ia canine colony, with affected dogs that closely resemble human disease makes it a perfect model to better study pathophysiology, long term complications and to develop novel therapeutic approaches such as drug and gene therapy.

Program Nr: 498 from the 1999 ASHG Annual Meeting

Analysis of the expression of glutaryl-CoA dehydrogenase: In vitro and In vivo studies. *D.M. Koeller, M. Woontner, J. Kwon, L.S. Crnic.* Dept Pediatrics, Univ Colorado Health Sci Ctr, Denver, CO.

Glutaric acidemia type I (GAI) is an autosomal recessively inherited organic acidemia caused by a mutation in the glutaryl-CoA dehydrogenase(GCDH)gene. Glutaryl-CoA dehydrogenase catalyses the oxidative decarboxylation of glutaryl-CoA, an intermediate in the oxidation of lysine and tryptophan. Clinically, the most characteristic feature of GAI is progressive dystonia. The pathophysiologic basis for the movement disorder seen in GAI patients is degeneration of neurons in the caudate and putamen nuclei of the striatum. In an attempt to understand the basis for the specific neuropathology in GAI, we have analyzed the expression of the GCDH gene using both in-vitro and in vivo approaches. Transfection studies in fibroblasts and hepatocytes mapped the mouse GCDH promoter within a 400 bp region of DNA 5' of the translation start site. The promoter lacks a TATA consensus sequence, but includes a potential CCAAT box, and several Sp1 sites. An 11 bp element important for promoter activity was identified in both the mouse (2 copies) and human (1 copy) GCDH promoters. Western blot analysis of mouse tissues demonstrated that the highest levels of GCDH expression are in liver and kidney, consistent with its role in amino acid oxidation. Expression in multiple regions of the brain was also detected by western blotting. Analysis of mice expressing a beta-galactosidase reporter gene under the control of the GCDH promoter demonstrated expression in the hippocampus, the cerebral cortex, and both granule and pyramidal cells in the cerebellum. Significantly, no expression of the GCDH promoter driven beta-galactosidase gene was detected in the caudate-putamen, the region of the brain most severely affected in GAI patients. Based on these results, possible models for the pathophysiology of GAI are presented.

Program Nr: 499 from the 1999 ASHG Annual Meeting

The Hermansky-Pudlak syndrome (HPS) protein is a component of a tissue-specific organellar protein trafficking complex. *J. Oh[1], Z.-X. Liu[1], G. Raposo[2], R.A. Spritz[1]*. 1) Human Medical Genetics Program, Univ Colorado Health Sci Ctr, Denver, CO; 2) Institut Curie, Paris, France.

Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder in which oculocutaneous albinism, bleeding, and ceroid-lipofuscin lysosomal storage disease are associated with defective biogenesis of multiple cytoplasmic organelles: melanosomes, platelet granules, and lysosomes. The HPS protein is a novel 700-aa protein that is unrelated to other known proteins and which contains no peptide motifs that might provide clues to its function. Furthermore, analysis of HPS patient mutations and comparison of the human, mouse, and rat HPS polypeptides fails to highlight obvious critical, conserved, or divergent segments of the protein. We present biochemical, cell biological, immunological, and microscopic data that suggest that HPS protein is a component of a tissue-specific protein complex involved in trafficking of "cargo proteins" destined for nascent organelles. Biochemical and cell fractionation studies show that the HPS protein is a non-glycosylated, non-membrane cytoplasmic protein which in non-melanotic cells is contained principally in a ~200 kDa protein complex located in the cytosol and in a small vesicle fraction. In contrast, in melanotic cells about half of the HPS protein is contained in a >400 kDa membrane-associated protein complex. Confocal and digital microscopy show that this cell-specific complex is located in the perinuclear region, and by immunoelectron microscopy this compartment appears to consist of small uncoated peri-Golgi vesicles and early-stage melanosomes. However, the HPS protein is not associated with the trans-Golgi network, and co-immunoprecipitation analyses show that HPS is not directly associated with the AP-3 adaptin-like complex, which has been implicated in both cargo protein trafficking and in HPS-like clinical features. We suggest that the function of the HPS protein may be to receive cargo proteins from AP-3 or other components of the cargo protein sorting machinery, and deliver these proteins into specific nascent organelles.

Program Nr: 500 from the 1999 ASHG Annual Meeting

Hyperimmunoglobulinemia and periodic fever syndrome due to mutations in the gene mevalonate kinase (MVK). *B.T. Poll-The[1], S.M. Houten[2], J. Frenkel[3], W. Kuis[3], M. Duran[1], T.J. de Koning[1], A. van Royen-Kerkhof[3], G.J. Romeijn[2], L. Dorland[1], G.T. Rijkers[3], H.R. Waterham[2], R.J.A. Wanders[2].* 1) Dept Metabolic Disorders, Univ Children's Hosp, Utrecht, Netherlands; 2) Clinical Chemistry and Pediatrics, Academic Medical Centre, University of Amsterdam, Netherlands; 3) Dept. of Immunology, Wilhelmina Children's Hospital, Utrecht Medical Center, Netherlands.

Hyperimmunoglobulinemia D and periodic fever syndrome (HIDS) is characterized by recurrent episodes of fever, lymphadenopathy, arthralgia, gastrointestinal symptoms and rash. During attacks of severe fever, mildly increased excretion of mevalonic acid (5.3 to 27.8 mmol per mole creat) was noticed in HIDS. Mevalonate kinase (MK) activity was 1.3 - 6.5% of the mean in control lymphocytes, and 0.8 - 6.1 % of the mean in control fibroblasts. Deficient MK-activity and increased excretion of mevalonic acid is also found in mevalonic aciduria, a severe multisystemic disorder associated with periodic fever. However, in these patients the excretion of mevalonic acid is constitutive and much higher than observed in HIDS. Sequence analysis of MVK cDNAs identified the same 1129 G -> A mutation in all 8 patients currently examined. Two patients were homozygous for this mutation, which changes the valine at position 377 of the MK sequence to isoleucine (V377I). Six patients were compound heterozygotes for the 1129 G -> A mutation and an additional missence mutation: 803 T -> C, I268T (3 patients); 59 A -> C, H20P (2 patients); 116 T -> C, L39P. None of 24 sequenced control subjects carried the V377I allele. The identification of the 1129 G -> A mutation in 8 unrelated HIDS patients suggests that this allele is responsible for the HIDS presentation. Immunoblot analysis demonstrated a deficiency of MK in patients' cells indicating a protein destabilization effect of the mutations. Our findings in patients with a dysregulation of the immune system expand the phenotypic spectrum of MK deficiency, and demonstrate an interrelation between the cholesterol biosynthetic pathway and the regulation of the immune response.

Program Nr: 501 from the 1999 ASHG Annual Meeting

Carbamyl phosphate synthetase I (CPSI) deficient patients express only mutant allele message despite genomic heterogeneity. *M. Strand[1], L. Hall[2], M. Summar[2]*. 1) Pediatrics, Vanderbilt University, Nashville, TN; 2) Pediatrics, Medical Genetics, Vanderbilt University, Nashville, TN.

In our studies of patients with CPSI deficiency (CPSID), our sequence analysis of CPSI message identified only one unique mutation for each patient (19 of 20 patients). The sequence did not show either a normal band or a different mutation elsewhere. The sequence analysis was performed on fragments derived from patient RNA isolated from liver, fibroblast, or lymphoblastoid cells. If the RNA reflects transcription from both CPSI alleles, this implies that all patients carry the same unique mutation on both chromosomes. In the case of rare metabolic diseases, a high degree of consanguinity is expected, which often explains such homozygosity. However, when we analyzed the genomic DNA for a common CPSI exonic polymorphism we found 6 of the 12 patients were heterozygous. We have subsequently analyzed 6 patients and found that in 4 cases the genomic DNA is heterozygous for their unique mutations. Southern blot analysis of these patients does not reveal a large deletion and we have not identified patients without expressed CPSI message. These results suggest that a common null mutation resulting in loss of expression for one allele does not explain this phenomenon. This observation may represent imprinting of one of the CPSI alleles rendering it silent for expression. Such a situation will impact the prenatal diagnosis of this metabolic disorder and our understanding of the tight regulation of this gene.

Program Nr: 502 from the 1999 ASHG Annual Meeting

A mouse model for the Smith-Lemli-Opitz syndrome (SLOS). *G.S. Tint[1,2], H. Waage[3], K.K. Sulik[3], F.F. Moebius[4], B.U. Fitzky[4], H. Glossmann[4], S. Shefer[2], G. Salen[1,2]*. 1) VA New Jersey Health Care System, East Orange, NJ; 2) UMDNJ-New Jersey Medical School, Newark, NJ; 3) University of North Carolina, Chapel Hill, NC; 4) Institute for Biochemical Pharmacology, Innsbruck, Austria.

SLOS is a not-uncommon severe birth defect-mental retardation syndrome caused by a defect in 7-dehydrocholesterol (7DHC) D7-reductase (DHCR7. E.C.1.3.1.21), the final enzyme in the cholesterol (CH) biosynthetic pathway. Children exhibit multiple abnormalities of face, limbs, genitalia and internal organs, develop slowly, are photosensitive, frequently exhibit destructive behaviors and have greatly reduced survival. Human DHCR7 contains 9 exons, spans 14 kb, is localized to 11q13 and codes for a 55 kDa protein. Using stem cell gene targeting we mutated this gene in the mouse to create an animal model for the syndrome. Matings of animals heterozygous for the targeted disruption have thus far resulted in 11 -/-, 20 +/-, and 7 +/+, which approximates the 1:2:1, expected ratio. The male to female ratio is also approximately as expected. The litters were of normal size, indicating that all pups survive to term. However, the homozygotes died shortly after birth (within about 14 hrs). Among the eleven -/- mice, two wide cleft palates were observed while abnormally distended bladders were also noted in 6 -/- mice predominately in males. DHCR7 activity in 8 -/- newborn mice was found to be ~ 1% of that in a control animal (26±20 vs. 2030pmol/min/mg protein). Liver 7DHC concentrations, undetectable in controls, were 0.43±0.24 mg/g in 8 -/- animals while CH levels averaged 0.69±0.50 mg/g (compared to 1.90±0.66 mg/g in 7 adult controls). In brain (n=3 -/-) the defect was far worse with mean CH and 7DHC levels of 0.41±0.03 and 1.19±0.23 mg/g, respectively, vs. 3.99 and <0.01 mg/g, respectively, in 2 +/- newborns. All of the biochemical parameters closely mirror the differences we see between the group of affected SLOS children who are in the middle range of clinical severity and age matched controls. Thus, the model appears to successfully model CH and 7DHC metabolism in about 50% of affected children.

Program Nr: 503 from the 1999 ASHG Annual Meeting

Paradoxical effect of acid b**-galactosidase gene dosage on the phenotype of twitcher mouse (genetic galactosylceramidase deficiency).** *J. Tohyama[1], M.T. Vanier[2], K. Suzuki[1], T. Ezoe[1], J. Matsuda[1], K. Suzuki[1]*. 1) University of North Carolina, Chapel Hill, NC; 2) INSERM U189, Lyon-Sud School of Med, Oullins, France.

Twitcher is a mouse model of human Krabbe disease (globoid cell leukodystrophy) due to a mutation in the galactosylceramidase gene. We recently generated a mouse model of human GM1-gangliosidosis by inactivating the acid b-galactosidase locus. These mutants have been cross-bred to evaluate the genetic and metabolic relationship between the two lysosomal b-galactosidases. Comparisons were made only among offspring of different genotypes from double-heterozygote mating. The mice doubly deficient for both b-galactosidases develop massive accumulation of lactosylceramide in all tissues, as predicted from the known overlapping substrate specificity of these enzymes. However, different acid b-galactosidase gene dosage have dramatic and counter-intuitive effects on the phenotype of twitcher mice that defy conventional wisdom concerning autosomal recessive genetic disorders. Paradoxically, twitcher mice with additional complete acid b-galactosidase deficiency have by far the mildest clinical and neuropathological phenotype with the longest life span, followed by twitcher mice with a normally active pair of acid b-galactosidase genes. Furthermore, twitcher mice with a single functional acid b-galactosidase gene have the most severe disease with the shortest life span and additional hyper-reactivity and seizures not seen in other genotypes. Consistent with the clinical seizures, these twi -/-, GM1 +/- mice develop neuronal degeneration, particularly in the CA3 region of hippocampus and superficial layers of cerebral cortex, and less prominently in basal nuclear structures. Brains of the doubly deficient mice inexplicably contain only half normal amounts of galactosylceramide throughout their development despite the relative preservation of myelin. Brain psychosine (galactosylsphingosine) levels are dramatically increased in all twi -/- mice irrespective of the acid b-galactosidase gene dosage. These findings indicate that there are hitherto unrecognized genetic and metabolic interrelationships between the two lysosomal b-galactosidases and among their substrates.

Program Nr: 504 from the 1999 ASHG Annual Meeting

A cost-effective, time-efficient scanning strategy for genome scans of recessive diseases. *J.S. Acierno Jr[1,2], J.F. Gusella[1,2], S.A. Slaugenhaupt[1,2]*. 1) Harvard Institute of Human Genetics, Harvard Medical School, Boston, MA; 2) Genomics Core Facility, Massachusetts General Hospital, Charlestown, MA.

Researchers are often faced with two obstacles when beginning a genome scan for linkage studies: (1) delay of the start of a genome scan due to the initial availability of DNA on only a single multi-affected family, with continued collection of additional families expected, and (2) the prohibitive cost of completing a scan on the large number of individuals needed to obtain linkage.

For recessive diseases with no phenocopies, an initial genome scan of a single nuclear family of parents with at least two affected children can exclude a substantial amount of the genome by identifying broad regions of chromosomes through haplotyping in which the affected offspring are not sharing both parental chromosomes. The availability of grandparents can increase the amount of exclusion by establishing phase for regions not completely informative in the parents. Unaffected siblings can also increase exclusion through identifying regions they share with their affected siblings.

We propose a novel strategy of completing an initial screen on a single two- or three-generation nuclear family with multiple affected children followed by haplotype analysis for identification of discordance. This subset of remaining markers can then be used for a linkage study once adequate families are collected. We then illustrate the practical application of this strategy through describing a disease recently linked by our institution using this method and the resulting substantial reduction in time to completion and number of genotypes performed. This strategy can reduce the total amount of genotypes performed by up to approximately 75% through genotyping as few as 4 or 5 individuals.

Program Nr: 505 from the 1999 ASHG Annual Meeting

EXPERIMENTAL DETERMINATION OF THE EFFICIENCY OF HAPLOTYPE CONSTRUCTING PROGRAMS USING 5 SNPS FROM THE NAT2 GENE. *C.J. Allan, K. CANTONE, P. Khan, P. Boyd, I. Purvis, C.-F. Xu.* Discovery Gen, Molec Gen Unit, Glaxo Wellcome, Hertfordshire, England.

Haplotype analysis has been a powerful tool in narrowing down the location of disease susceptibility genes. In addition to its use in linkage studies in pedigrees, haplotype analysis has been applied to population studies and can be used in determining the origin and migration of ancestral alleles. Several computer programs are available which can construct haplotypes from the genotypes of unrelated individuals. The present study has used polymorphisms in the NAT2 gene as a model system to evaluate the efficiency and accuracy of these programs. The genotypes of 80 individuals for each of 5 SNPs within an 850bp PCR fragment were determined by direct sequencing. Haplotypes were subsequently estimated by a program using an E-M algorithm written by Chiano and Clayton. In parallel, the PCR products from the same individuals were cloned into TA cloning vectors and the haplotypes of each individual were experimentally determined by sequencing 8-10 clones. A comparison of the 2 sets of haplotype data showed a 99.9% match between the computer generated haplotypes and those determined experimentally. Our results therefore suggest that the E-M algorithm based haplotype prediction program can provide effective estimates of haplotypes for unrelated individuals using genotype data from multiple SNPs.

Program Nr: 506 from the 1999 ASHG Annual Meeting

Missense mutations of the TLR4 gene are associated with hyporesponsiveness to lipopolysaccharide (LPS) in humans. *N.C. Arbour[1], B.C. Schutte[2], J.N. Kline[1], K.L. Frees[1], S.J. Swartz[1], N.C. Meyer[1], D.A. Schwartz[1,3].* 1) Dept of Medicine; 2) Dept of Pediatrics; 3) Veterans Affairs Medical Center, University of Iowa, Iowa City, IA.

Bacterial LPS or endotoxin causes the adverse effects of Gram negative sepsis and influences the course of acute respiratory distress syndrome, asthma, and other forms of chronic airway disease. We recently showed that healthy non-asthmatics demonstrate a reproducible airway response to inhaled LPS, with some developing airflow obstruction at low LPS concentrations and others unresponsive to high LPS levels. The Toll-like receptor TLR4 has been implicated in LPS signaling and a missense mutation identified in the mouse TLR4 gene that is associated with a hyporesponsive LPS phenotype. To test whether mutations in the TLR4 gene are associated with LPS hyporesponsiveness in humans, we developed a single stranded conformational polymorphism assay in which the coding region of the TLR4 gene was screened for mutations in 83 normal, healthy subjects challenged with incremental doses of endotoxin. Band variants were confirmed by sequencing and amplification-refractory mutation system analyses. We identified two missense mutations (Asp299 Gly and Thr399 Ile) within the fourth exon, both of which are located in the extracellular domain of the TLR4 receptor. Asp299 is highly conserved between species but Thr399 is not. The allelic frequency of the two substitutions was approximately 6.6% in our study population, 7.9% in a normal control population from Iowa, and 3.3% in CEPH parental chromosomes. 22.6% of the study subjects who were hyporesponsive to inhaled LPS had this sequence variant while only 5.8% of the LPS responsive subjects had this sequence variant (P=0.029). These results provide the first genetic link between a gene associated with LPS signaling and reduced response to LPS in humans. This finding contributes to our overall understanding of LPS signaling and may have important implications for the treatment of Gram negative sepsis as well as other diseases caused by exposure to endotoxin.

Program Nr: 507 from the 1999 ASHG Annual Meeting

Epistatic interactions and mapping of loci that modify the severity of PKD in a mouse model. *D.R. Beier, S. Kuida, O.A. Iakoubova.* Div Genetics, Brigham & Women's Hosp, Harvard Med Sch, Boston, MA.

Mouse models of human disorders are powerful tools for identifying modifying loci that influence complex genetic traits. We have previously identified modifiers that mediate the severity of PKD in the juvenile cystic kidney *(jck)* mouse using F2 progeny of a C57BL/6 x DBA/2 (B6xD2) intercross. Specifically, we found a highly significant association for the inheritance of B6 alleles on chr 1 with severe disease. This observation was unexpected, since the PKD phenotype in the B6 background is not severe. We proposed that the inheritance of both the B6 locus on chr 1 and a D2 gene elsewhere in the genome results in the severe phenotype, presumably as a consequence of an interaction.

We have now proven that the severe disease phenotype is a recessive trait, since F1 *jck/jck* mice have very mild PKD. When heterozygous mice from this cross are intercrossed, the F2 progeny recapitulate the variable phenotype seen in the previous B6xD2 intercross, supporting the model that an interaction of parental alleles causes severe PKD. Given that the chr 1 locus behaves recessively, the statistical effect of the interacting locus will be obscured in an intercross, because only 25% of the progeny are informative for the interaction. To address this, we made a D2.B6 *jck/+* congenic strain carrying the chr 1 modifier as homozygous B6 and the remainder of the genome as D2. In a cross with a B6 *jck/+* mouse, the congenic region on chr 1 is fixed as B6, while the rest of the genome is segregating as in an F2 population, and all the affected mice should be informative for the interacting D2 locus. Consistent with this hypothesis, we were readily able to localize on proximal chr 4 a D2 locus significantly associated with severe PKD. This localization is of particular interest because this is the position of a locus previously shown to modify the progression of PKD in two different mutations, *cpk* and *pcy*. This suggests this gene might influence PKD severity irrespective of its cause, and, as such, represents a potential target for therapeutic intervention in human PKD.

Program Nr: 508 from the 1999 ASHG Annual Meeting

Localization of Paroxysmal Kinesigenic Dyskinesia (PKD) to chromosome 16p11.2-q11.2. *L.B. Bennett[1], E.S. Roach[2], A.M. Bowcock[1]*. 1) Department of Genetics and Pediatrics, Washington University School of Medicine, St Louis, MO; 2) Dept Neurology, UT Southwestern Med Ctr, Dallas, TX.

Paroxysmal kinesigenic dyskinesia (PKD) is an autosomal dominant disorder characterized by episodic choreiform or dystonic movements brought on or exacerbated by voluntary movement or by the contemplation of voluntary movement. The abnormal movements usually begin between 6 and 16 years, and about half of the affected individuals have a family history. The biochemical defect responsible for the disease is not known. Neither is the genetic location of susceptibility alleles, the penetrance of disease alleles nor the extent of genetic heterogeneity. Most cases of PKD have been classified as familial although a smaller number have been described as acquired or symptomatic and have been associated with other neurological diseases such as multiple sclerosis or cerebral palsy.

We identified a large African-American kindred with the disease and performed a genome-wide scan with highly polymorphic microsatellites at 25 cM resolution. Linkage analyses localized the gene in this family to chromosome 16p11.2-q11.2. When a penetrance estimate of 80% was used a maximum two point LOD score of 3.76 at recombination fraction theta = 0.001 was obtained with D16S419. Critical meiotic-recombination events in one individual localize the disease gene in this family to a 20cM region between D16S3100 and D16S771. The non-kinesigenic form of the disease has been linked to chromosome 2q reinforcing the conjecture that the two diseases are distinct entities.

A gene for infantile convulsions with paroxysmal dyskinesia (ICCA syndrome) has also been mapped to Chr 16p12-q12 in families from France and China. The PKD and ICCA regions overlap by approximately 6cM. It is therefore tempting to speculate that these two diseases are due to different mutations in the same gene. Alternatively, chr 16p11-q11 may harbor several loci predisposing to familial convulsions.

Program Nr: 509 from the 1999 ASHG Annual Meeting

High-throughput SNP genotyping using single-base extension. *S. Bolk, J.N. Hirschhorn, N. Kalyanaraman, B.W. Langhorst, J.S. Ireland, P. Sklar, E.S. Lander.* Center for Genome Research, Whitehead Institute/MIT, Cambridge, MA.

With the identification of single nucleotide polymorphisms (SNPs) in the coding regions of hundreds of genes, there is a need for rapid, accurate and robust methods for genotyping SNPs. We are developing a spectrum of genotyping assays for use in association studies of complex diseases, mapping, and other applications. To genotype individual SNPs, we use single base extension (SBE) followed by fluorescence resonance energy transfer (FRET). In this technique, a FAM-labeled primer is extended by a single base in the presence of ROX and TAMRA-labeled ddNTPs. We have transformed this method into a high throughput platform that we have applied to ongoing large-scale association studies.

In order to develop SBE-FRET as a technique for cost-efficient, high-throughput genotyping, we have optimized the methodology as originally described by Chen et al. (PNAS 94, 1997). With the goal of optimizing genotyping quality across a large number of assays while minimizing cost, we have developed a set of optimal conditions for SBE-FRET. We evaluated a number of critical parameters including post-PCR clean-up and SBE reaction conditions. Our experience with optimized SBE-FRET genotyping has proven that this method is suitable for high-throughput SNP genotyping. SBE-FRET provides accurate, reproducible genotypes. In a pilot study of 30 loci to be used in SBE-FRET genotyping, we observed >99% reproducibility and >99% accuracy. SBE-FRET is generalizable to many polymorphisms; we have rapidly developed genotyping assays for over 180 cSNPs. Finally, SBE-FRET allows high-throughput genotyping and automated scoring of genotypes. We can now process 2,000 genotypes/day on one real-time PCR machine and have automated allele calling. We have begun association studies for bipolar disorder, coronary artery disease, and type II diabetes using SBE-FRET. To date, we have produced over 60,000 genotypes in these studies. We are also developing technologies designed to eliminate the need for locus-specific FAM-labeled primers, including the use of tagged SBE primers and a generic FAM-labeled oligonucleotide.

Program Nr: 510 from the 1999 ASHG Annual Meeting

b**-2 Adrenergic Receptor Gene Variations, Blood Pressure, and Heart Size In Normal Twins.** *A. Busjahn[1], G.-H. Li[2], H.-D. Faulhaber[1], H. Schuster[1], B. Timmermann[2], M.R. Hoehe[2], F.C. Luft[1].* 1) Franz Volhard Clinic, Berlin, Germany; 2) Max Delbrueck Center for Molecular Medicine, Berlin, Germany.

Genetic variability which influences cardiovascular phenotypes in normal persons is likely to be relevant to cardiovascular disease. We studied normal monozygotic and dizygotic twins and found strong genetic influences on blood pressure and heart size. We then relied on the dizygotic twins and their parents to apply molecular genetic techniques.

We performed a linkage analysis with markers close to the b-2 adrenergic receptor gene locus in the dizygotic twins and their parents, and found strong evidence for linkage to the quantitative traits blood pressure and heart size. We used allele-specific PCR to genotype the subjects further. We then performed a maximum likelihood association analysis based on sib pairs, and found that four functionally-relevant polymorphisms in the b-2 AR gene, namely Arg16/Gly, Gln27/Glu, Thr164/Ile, and a variant in the promoter region (-47C/T) were variably associated with blood pressure and heart size differences, but were in linkage dysequilibrium with each other. A subsequent conditional analysis suggested that the Arg16/Gly polymorphism exerted the predominant effect. Arg16 wildtype subjects had recumbent, sitting, and standing systolic blood pressures 7-8 mm Hg higher than homozygous Gly16 subjects, while heterozygous subjects were intermediate. Gly16 was also associated with a lesser cardiac septum thickness and lower norepinephrine levels. Additional interactions between the polymorphisms may be elucidated by larger studies with complex haplotype analyses.

These findings underscore the importance of the b-2 AR gene to blood pressure regulation, heart size, and probably also to the development of hypertension. We suggest that a combined linkage and association approach will elucidate the genetic variabilty influencing blood pressure and other cardiovascular phenotypes.

Program Nr: 511 from the 1999 ASHG Annual Meeting

Linkage analysis of 50 candidate genes involved in essential hypertension in 95 Chinese nuclear families with 460 affected sib-pairs. *S. Chu[1,2], M. Xiong[2], D. Zhu[1], G. Wang[1], Y. Zhan[1], W. Zhang[1], H. Zhou[1], H. Wang[1], W. Li[2], D. Shen[2], L. Jin[2,3]*. 1) Shanghai Institute of Hypertension, Ruijin Hospital, Shanghai Second Medical University, Shanghai, China; 2) Human Genetics Center, University of Texas Houston, Houston, TX; 3) National Human Genome Center at Shanghai, Shanghai, China.

Essential hypertension (EH), defined as elevated blood pressure (BP) due to unknown etiology, is a common and important risk factor for stroke, coronary heart disease, congestive heart failure, end-stage renal disease, and peripheral arterial disease. The complex nature of blood pressure determination is largely due to the fact that many genetic and environmental factors are involved and they may interact with each other in unpredictable ways. We investigated the linkage of EH, in 95 Chinese nuclear families containing 460 affected sib-pairs, at 45 chromosomal regions containing 50 candidate genes that have been implicated to the etiology of EH based on previous physiological, biochemical, and genetic studies. The distance between the candidate genes and the microsatellites selected ranges from 2 8cM. The two-locus, non-parametric linkage analysis (NPL) with GENEHUNTER indicated a positive linkage at D12S398 ($p = 0.021$). However, the application of the transmission/disequilibrium test (TDT) supports significant linkages, with small p values, at D8S261, D11S1347, D12S398, and D14S61, implicating LPL, APOA1-C3, V1AR, TGF-B3, respectively.

Program Nr: 512 from the 1999 ASHG Annual Meeting

All over the map: An integrated physical and genetic map of single nucleotide polymorphisms. *R.J. Clifford, M.N. Edmonson, T. Scherpbier, Y. Hu, C. Nguyen, A.K. Voltz, K.H. Buetow.* LPG/DCEG/NCI, NIH, Bethesda, MD.

The mission of the National Cancer Institute's Cancer Genome Anatomy Project is to provide a comprehensive description of the molecular changes underlying cancer initiation and progression. As part of the CGAP Genetic Annotation Initiative (CGAP-GAI), the Laboratory of Population Genetics is developing an extensive set of human single nucleotide polymorphisms (SNPs) as a resource for the molecular and epidemiological investigation of cancer. SNPs are predicted from publicly available EST sequences using computer algorithms, validated in the laboratory, then confirmed to segregate in a Mendelian fashion in CEPH families. Confirmed SNPs are positioned on the genetic map relative to the ABI version 1 marker panel. Our present collection of 10,243 candidate SNPs is derived from 6459 UniGene EST assemblies, 1967 of which correspond to named genes. 6485 SNPs have been placed on the genetic and/or physical maps. Information about CGAP-GAI SNPs is available online at (http://cgap.nci.nih.gov/GAI). Our website includes: i) an integrated genetic and physical map showing the locations of candidate, validated and confirmed SNPs, ii) a Java-based SNP viewer that displays polymorphisms in the context of EST assemblies, iii) a search engine that allows SNPs to be retrieved by keyword, gene symbol, or GenBank accession number, iv) genetic mapping reports for confirmed SNPs and v) access to our SNP prediction tools. Our site also contains links to the NCBI's UniGene and Genemap'98 sites.

Program Nr: 513 from the 1999 ASHG Annual Meeting

The Absent Granular Layer Histology in Ichthyosis Vulgaris is Linked to the Epidermal Differentiation Complex on Chromosome 1. *J.G. Compton[1], J.J. DiGiovanna[2], K. Johnston[3], P. Fleckman[4], S.J. Bale[1].* 1) National Institute of Arthritis, Musculoskeletal and Skin Diseases, NIH, Bethesda, MD; 2) Department of Dermatology, Brown University, Providence, RI; 3) Dermatology Service, 1st Medical Group, Langley AFB, VA; 4) Department of Medicine (Dermatology), University of Washington, Seattle, WA.

Ichthyosis vulgaris (IV) is a mild to severe scaling disorder of uncertain etiology estimated to affect as many as 1:250 in the population. Family studies have shown that in many cases IV follows an autosomal dominant inheritance pattern. To investigate the genetic basis for inherited IV, we have performed gene linkage studies in two multigeneration families with clinical IV but distinct histological features. The epidermis in this disorder characteristically displays non-specific orthohyperkeratosis. Reduced or absent granular epidermal layers and decreased filaggrin levels have been described. A subset of individuals has been characterized with the clinical findings of IV and a total absence of the granular layer. Because of the prominent role of profilaggrin in human keratohyalin comprising the granules, the absent granular layer pathology (AGL) has led to suggestions that defects in the gene for profilaggrin (FLG), its processing to filaggrin, or a gene involved in profilaggrin regulation may underlie IV. Family 1 had 7 individuals with IV, severe heat intolerance and epidermis with 1-3 granular layers (consistent with normal epidermal histology). IV in this family did not segregate with FLG or other genes in the epidermal differentiation complex. In contrast, five of the six IV patients in Family 2, all siblings, had epidermis with no granular layer. Significant evidence was obtained for linkage of the AGL phenotype, though not IV, to the epidermal differentiation complex (and FLG) assuming either a recessive (max Lod 3.4) or dominant (max Lod 3.6) inheritance model. Sequence analysis of FLG did not uncover a mutation in the amino or carboxyl terminal portions of the coding sequence adjacent to filaggrin repeats.

Program Nr: 514 from the 1999 ASHG Annual Meeting

Genetic mapping of familial hypertrophic-restrictive cardiomyopathy. *M.W. Consevage[1], S. Kasarda[1], D.W. Sabol[2], P.K. Rogan[3]*. 1) Division of Pediatric Cardiology, Penn State Univ Coll Medicine, Hershey, PA; 2) Phylogenetix Laboratories, Pittsburgh, PA; 3) Section of Medical Genetics and Molecular Medicine, The Children's Mercy Hospital and Clinics, Kansas City, MO.

Familial hypertrophic cardiomyopathy (HCM) is a genetically heterogeneous, autosomal dominant disorder that results from abnormalities of several sarcomeric force-generating proteins. Myocyte disarray and variable expressivity in the pattern and the degree of ventricular hypertrophy are characteristic of HCM. While mutations in the genes encoding these proteins account for ~50 - 60% of all HCM cases, the genetic etiology in the remaining patients has remained elusive. We have localized a previously undescribed locus for HCM in a clinically distinctive pedigree. Most affected members of this family demonstrate the usual finding of a non-obstructive HCM. However, two individuals, who initially had finding of a HCM phenotype, later progressed to restrictive cardiomyopathy (RCM). Similar RCM subtypes have been reported within FHCM families, but these genes responsible have not previously been mapped (Am J Cardiol. 80:1046-50). This familial HCM-RCM phenotype maps to a previously undescribed locus. Linkage to known HCM loci and 23 other sarcomeric loci was excluded for this family. A genome search demonstrated linkage to chromosome 5q33. Haplotype analysis has limited the disease interval to 6 cM, which includes the positional candidate gene encoding d-sarcoglycan. HCM has been reported in various muscular dystrophies (Int J Cardiol 16:205-8; Am J Med Sci 305:166-70; Am Heart J 128:1264-6), consistent with the possibility that particular mutations within these genes responsible for these disorder may also cause HCM. The Syrian cardiomyopathic hamster (BIO14.6), a widely used animal model for human HCM, results from mutations within the d-sarcoglycan gene(Hum Mol Genet 6:601-7), i.e., the same gene responsible for human limb-girdle muscular dystrophy type 2F (Nat Genet 14:195-8). These observations support the concept that an alternative set of genes related to the muscular dystrophies should be considered as candidates for HCM.

Program Nr: 515 from the 1999 ASHG Annual Meeting

HLA-DRB1*01 alleles are associated with skin test reactivity to cockroach allergens in Caucasians and African Americans. *J. Donfack[1], D. Hoki[1], R. Parry[2], L. Lester[3], C. Ober[1]*. 1) Departments of Human Genetics, University of Chicago, Chicago, IL; 2) Medicine, University of Chicago, Chicago, IL; 3) Pediatrics, University of South Dakota, Sioux Falls, SD.

A genome-wide search for loci that confer susceptibility to atopy was completed in the Hutterites, a founder population of European descent (Ober et al., 1999, *Clin Exp Immuno*, in press). Skin prick tests (SPT) to 14 common allergens were used as a measure of atopy. A positive (+) SPT results from previous exposure and a specific IgE response to the allergen. The marker locus, DQ.CAR, was significantly associated with +SPT to cockroach allergens using the TDT (P = 0.00001). DQ.CAR is located in the HLA class II region, making HLA class II loci excellent positional candidate genes for the DQ.CAR associated atopy-susceptibility locus. *HLA-DRB1*, *HLA-DQA1*, and *HLA-DQB1* genotypes were examined in 750 Hutterites with skin test phenotypes. The most significant associations were found between +SPT to cockroach allergens and *DRB1*0101* (P = 0.0006), *DQA1*0101* (P = 0.0002), and *DQB1*0501* (P = 0.0001). These alleles occur together on six haplotypes in the Hutterites, making it impossible to determine their individual effects on the allergic phenotype in this population. To replicate these findings and evaluate the individual effects of these class II loci on cockroach allergies, we studied 42 unrelated African American subjects who were +SPT to cockroach allergens and 45 African American subjects who had -SPT to cockroach allergens. The only allele that was significantly increased in cases compared with controls was the *DRB1*0102* allele (Frequency *DRB1*0102* positive cases vs controls 0.131 and 0.011, respectively; P = 0.0012). Neither *DQA1*0101* nor *DQB1*0501* was increased in the +SPT subjects (P > 0.20). *DRB1*0101* and *DRB1*0102* alleles differ only by two amino acid sites. Although HLA class II loci have previously been associated with specific IgE, these data are the first to suggest that HLA class II alleles confer susceptibility to cockroach allergens in Caucasians and African Americans. (Supported by NIH grants HL49596, HL56399, and HD21244.).

Program Nr: 516 from the 1999 ASHG Annual Meeting

AN INTEGRATED GENETIC LINKAGE MAP WITH 1140 MARKERS CONSTRUCTED FROM FIVE F2 CROSSES OF AUTOIMMUNE DISEASE -PRONE AND -RESISTANT INBRED RAT STRAINS. *S. Dracheva[1], E. Remmers[1], P. Gulko[3], Y. Kawahito[4], R. Longman[1], J. Wang[1], J. Shepard[1], L. Ge[1], B. Joe[1], G. Cannon[2], M. Griffiths[2], R. Wilder[1]*. 1) ARB, NIAMS/NIH, Bethesda, MD; 2) Research Service Veterans Affairs Medical Center and Department of Medicine/Rheumatology, University of Utah, Salt Lake City, UT; 3) Columbia University College of Physicians and Surgeons, New York, NY; 4) Koyto Prefectural University of Medicine, Kyoto 602, Japan.

The rat (Rattus norvegicus) is an important experimental model for many human diseases including arthritis, diabetes and other autoimmune and chronic inflammatory diseases. The rat genetic linkage map, however, is less well developed in comparison with those of the mouse and human. Here, we present an integrated linkage map with 1140 markers. We constructed this map by genotyping 200 F2 progeny of five crosses: F344/NHsd x LEW/NHsd (674 markers), DA/Bkl x F344/NHsd (532 markers), BN/SsN x LEW/N (715 markers), DA/Bkl x BN/SsNHsd (194 markers) and DA/Bkl x ACI/SegHsd (246 markers). These inbred rat strains vary in susceptibility/resistance to multiple autoimmune diseases and are used extensively for many types of investigation. The rat integrated map was independently constructed with two different programs: MAPMAKER and MULTIMAP. The total length of the MULTIMAP rat map at LOD score 1 was 5.5% larger than that of the MAPMAKER (1885.5 cM vs. 1787.4 cM). The order of the markers, placed in unique map positions by the MULTIMAP program was the same as on the map constructed using the MAPMAKER program. Thus, integrated maps constructed by two different methods confirmed each other. The integrated map includes 360 loci mapped in three or more of the five crosses. The map contains 196 new SSLP markers developed by our group, as well as many SSLP markers developed by other groups. Inclusion of the markers associated with 237 genes permits map comparison among species. This integrated map should allow comparison of rat genetic maps from different groups and facilitate genetic studies of rat autoimmune and related disease models.

Program Nr: 517 from the 1999 ASHG Annual Meeting

High Throughput Scanning for Variations by Mismatch Repair Detection (MRD). *M. Faham, S. Baharloo, S. Tomitaka, J. DeYoung, P. Gajiwala, N. Freimer.* Psychiatry, Univ. of Calif San Francisco, San Francisco, CA.

Various techniques have been developed for high throughput genotyping using single nucleotide polymorphisms (SNPs) with the aim of identifying disease-susceptibility alleles by linkage disequilibrium analyses. Using a static map of common SNPs identified in the general population may prove insufficient to identify alleles of common disease. Rare as well as common variants in the general or patient population may need to be tested to identify variations involved in common disease. Flexible approaches that can identify variations in different patient populations are needed. Therefore we believe that developing technologies that are capable of large scale scanning of the genome to find the disease-causing variations directly is of paramount importance. Mismatch Repair Detection (MRD) is a method that utilizes bacterial mismatch repair system in vivo to detect variations. In order to detect variations in many fragments simultaneously, we have developed MRD from its original form that was described earlier. We changed the experimental procedures to make the method more robust and eliminate the need for intermolecular ligation. More importantly, we have constructed a strain that we call Mutation Sorter (MS). When transformed with a mixture of DNA fragments, MS will sort the fragments into two pools: the variant and the nonvariant pools. The problem of DNA variation detection is then reduced to identifying which fragments are in which pool. This task can be performed by multiple methods including running an acrylamide gel or microarray hybridization. We expect that thousands of fragments can be analyzed simultaneously. Results from the MRD procedure are robust and reproducible. We will present results of scanning more than 40 fragments simultaneously.

Program Nr: 518 from the 1999 ASHG Annual Meeting

Examination of multiple loci in late onset familial Alzheimer disease (AD). *M.E. Garcia[1], L.R. Bailey[1], J.L. Hall[1], W.K. Scott[2], A.M. Saunders[5], G.W. Small[3], A.D. Roses[4], M.A. Pericak-Vance[2], J.L. Haines[1], P.M. Conneally[6].* 1) Prog in Hum Gen, Vanderbilt Univ Med Ctr, Nashville, TN; 2) Center for Hum Gen, Duke Univ., Durham, NC; 3) Dept. Psychiatry, Univ. California, Los Angeles, CA; 4) Glaxo Wellcome R&D, RTP, NC; 5) Dept. Medicine, Duke Univ., Durham, NC; 6) Dept. Med. Mol. Genet., Indiana Univ., Indianapolis, IN.

Apolipoprotein E (APOE) is the only known susceptibility gene for late-onset AD. Our previous genomic screen identified four potential locations (on chrs. 4, 6, 12, and 20) for one or more AD genes with the strongest results on chr. 12 (Pericak-Vance et al., JAMA, 1997). Further analysis indicated that the chrs. 4 and 20 results were false positives (Garcia et al., ASHG abst. 1673, 1998). The chr. 12 locus has been confirmed but does not explain all the remaining genetic effect on AD. The results on chr. 6 have remained consistently positive (lods 1-2) for many markers across multiple datasets. Lod score analysis revealed two regions of possible linkage on chr. 6 near markers D6S1019 (54 cM from ptel; lod=1.37) and D6S391 (90 cM from ptel; lod=0.85). We evaluated the independence of the chr. 6 genetic effect with both APOE and the chr. 12 locus by using a two-trait-locus ASP analysis (TWOLOC) on a dataset of 116 families with 227 ASPs, choosing the most informative and significant markers in each region. The analysis considered interactions with one of the following: 1) a locus on chr. 12 near markers D12S398 and D12S1632 or 2) the APOE locus. The two-locus models offered strong evidence of linkage (D6S1019: General MLS=12.83; D6S391: General MLS=6.97) using APOE (single locus MLS=5.42) as the second locus. Little evidence of interaction between loci was found since the differences between the general, additive, or multiplicative models were < 1 lod unit. It is not clear if the two regions on chr. 6 represent one or two loci. It is interesting to note that D6S1019 is near the MHC, a region implicated by both association and linkage studies (Small et al., Neurob Aging,1991; Kehoe et al., HMG,1999). These data suggest that a potential locus (or loci) on chr. 6 acts independently of both APOE and the susceptibility locus on chr. 12.

Program Nr: 519 from the 1999 ASHG Annual Meeting

A genetic region on chromosome 16 may predispose to the development of Crohn's disease at an early age in Ashkenazi Jews. *B. Gulwani-Akolkar[1], P.N. Akolkar[1], M. Daly[3], C. Sabatti[4], X-Y. Lin[1], S.E. Danzi[1], R. Pergolizzi[1], I. Storch[1], N. Risch[4], S. Katz[1], J. Levine[2], J. Silver[1].* 1) North Shore University Hospital/NYU Medical Center, NY; 2) Long Island Jewish/Einstein College of Medicine, NY; 3) MIT Genome Center, Cambridge, MA; 4) Stanford University, Stanford, CA.

Although the etiology of Crohn's disease (CD) is unknown there is strong evidence that genetic factors play an important role in its development. Recent genome-wide screening studies have suggested that there may be susceptibility loci on chromosomes 12 and 16; however, several groups have been unable to replicate these findings. To determine whether these loci play a role in CD in Ashkanazi Jews (AJ), 89 AJ affected-relative pairs were analyzed for linkage to the putative susceptibility loci on chr 12 and 16. In addition, 42 non-Jewish affected- relative pairs were analyzed for comparison. We observed weak linkage to the candidate region of chr 16 in the Ashkenazi population (NPL 1.53, p=0.06) and no linkage in the non-Jewish population. However, when the AJ population was subdivided on the basis of age-of-onset of CD there was a striking increase in linkage in the group where both affecteds within a family had an age-of-onset <21; this group displayed strong linkage to the chr 16 region (NPL 2.63, p=0.006). No similar increase in linkage was observed in the non-Jewish group where the age-of-onset was <21. When linkage to the chr 12 region was examined we observed evidence for linkage in the AJ population (NPL 2.09, p=0.02) but not in the non-Jewish population. However, in contrast to what was observed for chr 16, no increased linkage evidence was observed in the AJ group where the age-of-onset was <21. These data suggest that Ashkenazi Jews show increased linkage evidence on chromosomes 12 and 16. Furthermore, the striking increase in linkage in the <21 group suggests that the chr 16 region may predispose to the development of CD at an early age in the Ashkenazic Jewish population. This work was supported by funds from the New York Crohn's Foundation, Reach Out for Youth with Ileitis and Colitis, and a grant from the NIH.

Program Nr: 520 from the 1999 ASHG Annual Meeting

Detection of Modifier Loci Influencing the Lung Phenotype of Cystic Fibrosis Knockout Mice. *C. Haston, C. McKerkie, B. Budisin, T. Samanta, G. Kent, M. Corey, L-C. Tsui, R. Rozmahel.* Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

The majority of cystic fibrosis patients develop pulmonary disease and the severity of this complication appears to be independent of CFTR genotype. In this work mouse models of CF were used to investigate the hypothesis that CF associated lung disease is influenced, in part, by modifier genes. In order to identify the genetic factor(s) associated with predisposition of lung disease, a genome wide scan for quantitative trait loci (QTL) contributing to the observed differences in CF-associated lung disease between B6 and BALB Cftr-/- mice has been initiated. The pulmonary phenotype was assessed with three assays: a semi quantitative histological method based on the extent and severity of left lung pathology; image analysis of nucleic area per lung tissue area in a histological section, a quantitative measure of tissue cellularity; and myeloperoxidase levels in the right lung as an index of neutrophil influx. Histological results showed that B6 Cftr-/- mice had increased interstitial mononuclear cell infiltration with alveolar thickening and collagen deposition, relative to BALB Cftr-/- mice or control mice. The lung tissue cellularity of B6 Cftr-/- mice significantly exceeded that of BALB Cftr-/- mice and normal littermate controls (nuclei percent of 22.5±1.5 (SEM), 16.1±1.2, [p=0.011], and 13.5±0.9 respectively, for the three groups of animals). The right lung myeloperoxidase of BALB Cftr-/- mice exceeded that of B6 Cftr-/- mice, (141±35 units/gram of protein versus 55±21, p=0.028). Preliminary data have been obtained for 100 DNA markers, at 20 cM spacing, in 93 twelve week old F2 mice. The QTL analysis revealed one locus meeting the criterion of suggestive linkage for the alveolar thickening phenotype and a second suggestive locus was identified based on tissue cellularity. In conclusion, the distinct CF lung phenotypes in two congenic CFTR-knockout mouse strains should permit the identification of the modifier genes.

Program Nr: 521 from the 1999 ASHG Annual Meeting

Affected sibpair analysis: Exploring the efficiency of fine mapping in the presence of genotyping error. *E.R. Hauser[1], A. Ashley-Koch[1], M.A. Pericak-Vance[1], M. Boehnke[2].* 1) Dept of Medicine, Duke Univ Medical Ctr, Durham, NC; 2) Dept of Biostatistics, Univ of Michigan, Ann Arbor, MI.

We examined the impact of genotyping error on the efficiency of fine mapping data to localize a gene to a small interval. Feakes et al (1999), using empirical data from a multiple sclerosis genomic screen, suggested the limit of efficiency in fine mapping of complex disorders is a 2.5 to 5 cM map. Past that point, loss of information from map and genotype errors (including mutation) outweighed the information gained from increased marker density. We explored the problem of genotype error and map density by simulating SNP and microsatellite data for affected sibpairs. We used a chromosome of 100 cM in length, with a disease locus at 52 cM. Two or four equally frequent alleles were simulated for each SNP or microsatellite marker, respectively. We assumed markers were in correct map order and all families were linked to the disease locus. Using an additive model, we considered sibling recurrence risks (l_s) of 1.0, 1.4, 1.6 and 2.0. Genotype error rates were set at 0%, 0.1%, 0.5%, 1.5%, 3% or 5%. Marker densities of 2, 5, 10 and 20 cM were evaluated. For each analysis, 1000 replicates of 100 or 400 families were simulated. For high error rates (3-5%), useful information can be extracted by increasing map density to 2 cM if the sibling recurrence risk is relatively large ($l_s \geq 1.6$). However, if the recurrence risk is small ($l_s < 1.6$), there is little utility in increasing map density past 5-10 cM. For low error rates ($\leq$1.5%), useful information is still extracted with a 2 cM map, regardless of l_s. We also examined the effect of genotyping error on the estimate of the disease gene location. Our results suggest *random* genotyping error does not produce bias in the estimate, but does increase the variability of the estimate. We are continuing to examine effects of high error rates for individual markers and marker order misspecification. In conclusion, we agree with Feakes et al (1999) that genotyping error can decrease the efficiency of your mapping endeavor. However, with low genotyping error rates and accurate marker order, useful information can still be obtained with dense maps.

Program Nr: 522 from the 1999 ASHG Annual Meeting

Mapping a locus for lymphedema-distichiasis to chromosome 16q24.3. *S. Jeffery[1], J. Mangion[2], N. Rahman[2], S. Mansour[1], G. Brice[5], J. Rossbotham[5], A.H. Child[5], A.L. Evans[5], P. Mortimer[5], R. Barfoot[2], A. Sigurdsson[2], S. Edkins[2], M. Sarfarazi[4], K. Burnand[3], T. Nunan[3], M.R. Stratton[2], V.A. Murday[1].* 1) Medical Genetics, St. George's Medical School, London, England; 2) Institute of Cancer Research, London, England; 3) St Thomas' Hospital, UMDS, London, England; 4) Surgical Research Center, Dept of Surgery, University of Connecticut; 5) Cardiology and Dermatology, St George's Medical School, London,.

Lymphedema-distichiasis (LD) is a dominantly inherited syndrome with onset of lymphedema at or just after puberty. Most affected individuals have distichiasis, fine hairs arising inappropriately from the eyelid meibomian glands, evident from birth. We have analysed three families with this disorder, and found a locus for LD on chromosome 16q24.3, the first localisation for this form of lymphedema. Subsequent analysis of the region for recombinants places the locus between D16S422 and D16S3074, a distance of about 16cM. Possible candidate genes in this interval include the N-proteinase for type 3 collagen PCOLN3, the metalloprotease PRSM1 and the cell matrix adhesion regulator CMAR.

Program Nr: 523 from the 1999 ASHG Annual Meeting

Strategies for fine mapping of QTLs contributing to variation in peak bone density. *D.L. Koller[1], M.J. Econs[1], P.A. Morin[2], J.C. Christian[1], S.L. Hui[1], P. Parry[2], M.E. Curran[2], L.A. Rodriguez[2], P.M. Conneally[1], G. Joslyn[2], M. Peacock[1], C.C. Johnston, Jr.[1], T. Foroud[1]*. 1) Indiana Univ. School of Medicine, Indianapolis, IN; 2) Axys Pharmaceuticals Inc., La Jolla, CA.

Osteoporosis is a leading public health problem that is responsible for substantial morbidity and mortality. A major determinant of the risk for osteoporosis in later life is peak bone mineral density (BMD) attained during early adulthood, which is largely determined by genetic factors. We conducted an autosomal genome screen for loci underlying BMD variation in 429 Caucasian sister pairs, computing LOD scores for BMD at four skeletal sites using the maximum likelihood variance method in Mapmaker/SIBS. LOD scores above 1.85 were further pursued in an expanded sample of 595 sister pairs. The highest LOD score attained in the expanded sample was 3.86, at chromosome 1q21-23 with lumbar spine BMD. Chromosomes 5q33-35 (LOD=2.23), 6p11-12 (LOD=2.13) and 11q12-13 (LOD=2.16) also produced interesting linkage findings. We employed non-parametric linkage analysis in sibships, as is typical in genetic studies of complex disease, and observed several instances where particular individuals or sibships exerted a disproportionate influence on the linkage results. Siblings with extreme phenotypic values produced large differences in LOD score results when included or excluded, as did single half-sibling pairs included as full sibs prior to detection of their true relationship. Variable informativeness among nearby markers, especially in one five-sibling pedigree without genotyped parents, led to highly discrepant two-point and multipoint linkage results at the same marker position. Our study is the largest genome screen to date for genes underlying variation in peak BMD, and represents an important step toward identifying genes contributing to osteoporosis in the general population. While genome-wide linkage analyses are a necessary initial step toward this goal, detailed analysis of the contribution of individual sibships and families to linkage results will likely yield important insights necessary for successful fine-mapping and eventual localization of genes for complex disorders.

Program Nr: 524 from the 1999 ASHG Annual Meeting

Mapping of the locus for autosomal dominant renal Fanconi Syndrome. *U. Lichter-Konecki[1], K.W. Broman[1], R. Dart[2], E. Blau[2], D.S. Konecki[1].* 1) Center for Medical Genetics, Center for Medical Genetics, Marshfield Ctr Medical Genetics,Marshfield Medical Res Fndn, Marshfield, WI, USA; 2) Marshfield Clinic, Marshfield, WI, USA.

Familial renal Fanconi Syndrome is a genetic model for the study of the pathophysiology of renal tubular transport. Affected individuals are normal at birth. However, during the second decade of life they develop polyuria, and loss of proximal tubular function results in rickets. With increasing age, these individuals may develop renal failure. Therapy for renal Fanconi Syndrome consists of symptomatic supplementation therapy, dialysis, and kidney transplantation. The isolation of the affected gene should initially facilitate postnatal and prenatal diagnosis of renal Fanconi Syndrome. Long term, the isolation of this gene and its gene product will allow the study of the pathophysiology of renal Fanconi Syndrome. Such studies should lead to a better understanding and consequently a better treatment of this entity. Through knowledge about the pathophysiology of this disorder new drugs may be developed to treat renal tubular transport disorders. We were able to map the locus for autosomal dominant familial renal Fanconi Syndrome to the long arm of human chromosome 15 by genotyping a large Central Wisconsin pedigree by performing a whole genome scan with 367 highly polymorphic simple sequence repeat (SSR) markers. A maximum LOD score of 3.01 was calculated using the LINKAGE program package (version 5.03), with the analyses conducted assuming a fully penetrant autosomal dominant mode of inheritance. For the linkage analysis, younger individuals were treated as possessing unknown phenotype. The fine mapping of the locus for autosomal dominant renal Fanconi Syndrome is currently in progress, the goal of which is to sufficiently narrow the region to allow the isolation of the associated gene through a positional cloning approach.

.

Program Nr: 525 from the 1999 ASHG Annual Meeting

Mitochondrial DNA polymorphism detection and heteroplasmy quantitation using high performance liquid chromatography. *M. Marino[1], J. Devaney[1], B. Levin[2], L. Tully[2]*. 1) Transgenomic, Inc., Gaithersburg, MD; 2) National Institute of Standards and Technologies, Biotechnology Division, Gaithersburg, MD.

Sequence analysis confirms the presence or absence of single nucleotide polymorphisms along with an abundance of additional sequence information. Minimizing time, expense, and data acquisition are critical concerns of large-scale initiatives. To evaluate suspected polymorphic sites alternative technologies are desired. A new chromatographic technique, denaturing high performance liquid chromatography (DHPLC) separates the DNA fragments based on their size, sequence, and charge density. Using DHPLC to screen the samples for heteroduplex formation reduces analysis time compared to sequencing. In this study, we investigate DHPLC for determination of polymorphisms of the mtDNA genome. The control region of the mitochondrial genome contains highly polymorphic areas of DNA sequence referred to as hypervariable regions. These unique sequences are maternally inherited and exist in high copy number, which enhance their use for forensic and genealogical determinations. Optimal elution temperature (59°C) and gradient conditions (1% increase in acetonitrile/minute) for analysis of the 440 bp fragment of the HV 1 region (15970F / 16410R) were determined and applied to various polymorphic pairs. Individuals with one single nucleotide polymorphism, compared to the Anderson (i.e. reference) sequence at positions 16067 (T ® C) and 16343 (A ® G) within the PCR-amplified fragment were evaluated for heteroduplex detection. To evaluate heteroplasmy of the mitochondrial genome, a silent mutation within the coding region was used to simulate heteroplasmy at various ratios of wild type to mutant. Individuals with the wild-type (C) and mutation (T) nucleotide at position 6371 were PCR-amplified and the concentration of DNA in each PCR product was determined by DHPLC. This quantitation allowed the products to be combined in different concentrations to determine the limits of heteroplasmy detection. These heteroplasmic products will be the basis of a Standard Reference Material being developed at the National Institute of Standards and Technology.

Program Nr: 526 from the 1999 ASHG Annual Meeting

Genetics of lupus: fine mapping of the Fc g **receptor gene cluster at chromosome 1q22-23.** *K.L. Moser[1], J.C. Edberg[2], J. Kelly[1], C. Gray-McGuire[1], N. Asundi[1], H. Yu[1], Y. Zhu[2], K. Chen[2], B.R. Neas[1,3], J.E. Salmon[4], R.P. Kimberly[2], J.B. Harley[1,3,5]*. 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Univ. of Alabama at Birmingham, Birmingham, AL; 3) Univ. of Oklahoma, Okla. City, OK; 4) Hospital for Special Surgery, NY, NY; 5) VA Medical Center, Okla. City, OK.

Systemic lupus erythematosus (SLE) is a genetically complex autoimmune disease of unknown origin. Deficiency in Fcg receptor (FcgR) function was observed in SLE patients over 20 years ago. Significant associations have been found with functionally important allelic polymorphisms in several of the FcgR genes. More recently, a genome scan of 94 multiplex SLE pedigrees suggested linkage at the low affinity FcgR gene cluster at chromosome 1q22-23. We have now performed fine mapping in this region by genotyping additional microsatellites and alleles of the FcgRIIa, FcgRIIIa and FcgRIIIb candidate genes in 40 African-American (AA), 77 European-American (EA), and 9 other multiplex SLE pedigrees (total n=126). Data were analyzed using the model-based two-point lod score, sib-pair, and Transmission Disequilibrium Test (TDT) methods implemented in the ANALYZE package. Lod scores of 3.97 and 3.43 were found for the FcgRIIa and D1S2762 loci, respectively, using a recessive model with 50% penetrance. Supportive evidence for linkage was obtained from surrounding loci using both lod score (lods>1.5) and sib-pair analyses (0.05>p>0.0001). Analysis by TDT identified an effect between SLE and alleles at the FcgRIIIa locus (p = 0.0002) but not at the FcgRIIa locus (p=0.15) or the FcgRIIIb locus (p=0.50). Unlike earlier analyses of FcgRIIa that suggested significant differences in the contribution of FcgRIIa between AA and EA pedigrees, preferential transmission of the associated FcgRIIIa allele from parents to affected offspring was found in both groups (p=0.006, AA; p=0.002, EA). Analysis by TDT in each ethnic group was not significant for FcgRIIa (p=0.08, AA; p=0.5, EA) or FcgRIIIb (p=0.05, AA; p=0.5, EA). Given the known functional differences between FcgR alleles, these data indicate that FcgRIIIa is a strong candidate gene for susceptibility to SLE.

Program Nr: 527 from the 1999 ASHG Annual Meeting

Linked modifier at the Huntington's disease locus. *R.H. Myers[1], A. Novelletto[2], L.A. Cupples[3], A. DeStefano[1,3], J. Srinidhi[4], I. Kornbluth[1], J.F. Gusella[4], M.E. MacDonald[4].* 1) Boston Univ Sch Medicine, Boston, MA; 2) Universit Tor Vergata, Rome, Italy; 3) Boston Univ Sch Public Health, Boston, MA; 4) Massachusetts General Hospital, Harvard Med Sch, Boston, MA.

Huntington's disease (HD) has a mean onset age of 40years, but onset is highly variable. HD is attributable to a triplet CAG repeat on chromosome 4p16.3, which accounts for about 50% of the variation in onset age among persons with mid-life onset. In an affected sib-pair design, we sought to determine whether the size of the normal repeat at the HD locus influences disease expression and whether there is evidence for a linked modifier on the normal chromosome. Sibships with at least two affected siblings were collected from Italian (n=88 sibs) and New England (n=64 sibs) families. The Italian sample had a smaller HD repeat size (p=0.004), smaller normal repeat size (p=0.04) and later onset age (p=0.01); Italian sample: HD allele mean=43.6, normal allele mean=17.9, mean onset age=44.1 years, New England: HD allele mean=46.5, normal allele mean=19.1, mean onset afe=38.6 years. Onset age was adjusted for HD repeat size modeled as [log(onset)= a+b(CAG)]. Some analyses adjusted for HD repeat size, and an interaction of the HD and normal allele sizes. Analyses controlled for correlated observations for siblings. The normal repeat size was not associated with the age at onset in analyses unadjusted for the HD repeat, but a significant association between the normal repeat and onset age was seen in the Italian sibs (p=0.03) and in the combined data (p=0.02) after adjustment for the HD allele. A significant interaction of HD and normal allele sizes with onset age was seen in both the Italian (p=0.002) and New England samples (p=0.05), after adjustment for the HD and normal alleles. Larger normal alleles were associated with later onset age. Using sib-pair linkage strategies, significant evidence for linkage of a modifier locus on the normal chromosome, other than the normal repeat itself, was found for onset age after adjustment for the HD repeat and normal repeat sizes (p=0.003). Similar normal chromosome haplotypes in the two samples were associated with younger onset ages.

Program Nr: 528 from the 1999 ASHG Annual Meeting

Correcting for population stratification in linkage disequilibrium mapping studies. *J.K. Pritchard, M. Stephens, P.J. Donnelly.* Dept Statistics, University of Oxford, Oxford, UK.

In linkage disequilibrium mapping, the presence of population structure can lead to spurious associations between a phenotype and unlinked candidate loci. One common approach to dealing with this problem is to use certain family-based study designs such as the TDT, which are not invalidated by population structure. Here, we present an alternative approach, using genetic information to correct for the presence of population structure in the context of case-control studies. We anticipate that our approach will be of particular value in situations where it is difficult to collect family-based controls, such as for late-onset diseases. Our approach is to use multi-locus genotype data from a case-control sample to infer the details of population structure in the sample. The problem with population structure arises because allele frequencies can vary across ethnic groups. We have developed a method, using bayesian clustering, which uses this variation in allele frequencies to detect the presence of population structure, and to assign individuals (probabilistically) to the appropriate subpopulations. It is not necessary to identify subpopulations before applying the technique. A modified test of association can then be performed, taking account of the inferred population structure. We present results illustrating the performance of this method when applied to real and simulated case-control data.

Program Nr: 529 from the 1999 ASHG Annual Meeting

Schizophrenia: The Identification of Genetic Subgroups. *A.E. Pulver[1], S.E. Antonarakis[3], J.L. Blouin[3], D. Housman[4], H. Kazazian[2], V.K. Lasseter[1], J.G. Mulle[1], G. Nestadt[1], P. Wolyniec[1].* 1) Johns Hopkins Univ Baltimore, MD; 2) Univ of Penn, Phila., PA; 3) Univ of Geneva, Geneva, Switzerland; 4) Mass Inst of Tech, Cambridge, Mass.

Schizophrenia is a common, complex phenotype with strong evidence of genetic susceptibility. Although there are no symptoms that are pathognomonic, inter-rater and test- retest reliability has been established for the diagnosis. Family studies have suggested that the relatives of schizophrenic probands may be at an increased risk for several psychiatric diagnoses i.e., schizophrenia, other psychotic disorders and schizophrenia spectrum personality disorder(schizoid, schizotypal and paranoid personality disorders [SSPD]). Genetic heterogeneity is likely. Previously our group reported the results of a genome scan of 54 families which had at least two relatives diagnosed with schizophrenia. Non-parametric linkage analysis provided significant evidence for a schizophrenia susceptibility locus (SSL) on chromosome 13q32 (score 4.18; p= 0.00002) and suggestive evidence for 8p21 (score 3.64; p=0.0001). Additional regions providing some evidence included 7q11, 14q13 and 22q11. Given the probable heterogeneity, we have now subdivided the 54 families based on whether or not any first or second degree relatives of the proband had been given a diagnosis (based on direct assessment) of a SSPD or psychotic affective disorder (PAD). Seven families had at least one relative with a diagnosis of SSPD and six families had at least one relative with a diagnosis of a PAD. Non- parametric linkage analyses of markers throughout the genome suggests these two subgroups of families may be associated with different SSL. The strongest evidence for a SSL for the families segregating both schizophrenia and SSPD is found for 8p21-22 (score 5.04; p=0.000001)and 1pcen-1p21 (score 2.72; p= 0.0062). The strongest evidence for a SSL for the families segregating both schizophrenia and PAD is found for 22q13 (score 2.94; p=0.0044)and 3p25-3p22 (score 2.71; p=0.008). The identification of genetically more homogenous subgroups of families will facilitate the identification of SSL.

Program Nr: 530 from the 1999 ASHG Annual Meeting

A novel nonsyndromic recessive form of deafness maps to 4q28 and demonstrates incomplete penetrance. *S. Riazuddin[1,2], C.M. Castelein[3], T.B. Friedman[1], A.K. Lalwani[3], N. Liburd[1], S. Naz[2], T.N. Smith[1], S. Riazuddin[2], E.R. Wilcox[1]*. 1) Laboratory of Molecular Genetics, NIDCD, 5 Research Ct., 2A-19, Rockville, MD 20850-3227; 2) Centre for Excellence in Molecular Biology, Canal Bank Road, Niaz Thokar Baig, Punjab University, New Campus, Lahore, Pakistan; 3) Department of Otolaryngology-Head and Neck Surgery, University of California, San Francisco, 533 Parnassus Ave., Rm U490A, San Francisco, CA 94143-0526.

Congenital nonsyndromic deafness is usually inherited as a simple Mendelian trait with extreme heterogeneity. We report here the localization of a novel recessive nonsyndromic deafness locus (DFNB26) on chromosome 4q28 segregating in a large consanguineous Pakistani family. Thirty-three members of this extended family have enrolled in our study, among which are seven deaf individuals from five different consanguineous marriages. The seven deaf family members with severe to profound hearing loss share identical genotypes at 5 different closely linked STRPs. A maximum LOD score of 6.22(q = 0) was observed at D4S1610 based on an affecteds-only calculation. Haplotype analysis defines a maximum interval of 1.5 cM for this locus. We are generating a radiation hybrid map and BAC contig of this region as we attempt to identify the responsible gene. Surprisingly, there are four individuals with normal hearing that are homozygous for the same haplotype as their affected siblings. We hypothesize that there is a modifier inherited by these four individuals, thus compensating for their inherited DFNB26 locus. Because of the large number of enrolled family members, we should be able to map and identify the modifier that allows four normal individuals to escape the deafness inherited by their siblings.

Program Nr: 531 from the 1999 ASHG Annual Meeting

An autosomal dominant thrombocytopenia gene maps to chromosomal region 10p. *A. Savoia[1], M.E. Del Vecchio[1], A. Totaro[1], S. Perrotta[2], G. Amendola[3], A. Moretti[4], L. Zelante[1], A. Iolascon[4].* 1) Medical Genetic Service, IRCCS Ospedale CSS, San Giovanni Rotondo, Foggia, Italy; 2) Department of Pediatrics, II University of Naples, Naples; 3) San Leonardo Hospital, Castellamare di Stabia, Naples; 4) Department of Biomedicine of Evolutive Age, University of Bari, Bari.

Inherited thrombocytopenias are rare and heterogeneous disorders with autosomal and X-linked traits. In the majority of cases, the molecular basis of the disease is unknown although, the defect is likely to affect thrombocytopoiesis and the regulation of the normal platelet count. We report a genome-wide search in a large Italian family with autosomal dominant thrombocytopenia. Patients had a moderate thrombocytopenia with minimal symptoms characterized by normocellular bone marrow, normal medium platelet volume, and positive aggregation tests. Under the assumption of complete genetic penetrance, marker D10S197 gave a maximum two-point LOD score value of 3.91 at recombination fraction (q) of .00. The two flanking microsatellites D10S548 and D10S208 showed a linkage to the hrombocytopenia locus (*THC2*) with a maximum LOD score of 4.96 and 3.57 at q of .07 and .09, respectively. The marker density was further increased with nine additional microsatellites. Markers D10S588 and D10S1771 yielded the maximum two-point LOD score values of 8.12 and 7.52 (q=0), respectively. A centromeric recombination was evident between D10S588 and D10S1639. Another crossing over between D10S586 and D10S572 established the distal limit of the disease-region at D10S572. Microsatellite analysis showed the disease locus linked to chromosome 10p11.1-12, within a candidate region of 6 cM between markers D10S586 and D19S1639 The localization of the *THC2* locus represents an important step in the understanding of the genetic basis of inherited thrombocytopenias. New families will be tested for linkage to the chromosome 10p. Pedigrees that are not compatible with this locus could then be used for genome-wide search and localization of other genes. The search of the gene through the candidate gene approach could add clues to the understanding, at the functional level, of the molecular defects causing the platelet reduction.

Program Nr: 532 from the 1999 ASHG Annual Meeting

The NCBI dbSNP database for Single Nucleotide Polymorphisms and other classes of minor genetic variation.
S.T. Sherry, M. Ward, K. Sirotkin. NCBI, NIH, Bethesda, MD.

A key aspect of research in genetics is associating variations with heritable phenotypes. The most common variations are single nucleotide polymorphisms (SNPs), which occur approximately once every 100 to 300 bases in a large sample of aligned human sequence. Because SNPs are expected to facilitate large-scale association genetics studies, there has recently been great interest in SNP discovery and detection. In collaboration with the National Human Genome Research Institute, the National Center for Biotechnology Information (NCBI) has established the dbSNP database (http://www.ncbi.nlm.nih.gov/SNP) to serve as a central repository for molecular variation.

Designed to serve as a general catalog of molecular variation to supplement GenBank. Database submissions can include a broad range of molecular polymorphisms: single base nucleotide substitutions, short deletion and insertion polymorphisms, microsatellite markers, and polymorphic insertion elements such as retrotransposons. Once described, these variations exist as a public resource for future research, as dbSNP entries include information on the flanking sequence surrounding the variation, the specific experimental conditions necessary to characterize the variation, and population genetic variation information as either population-specific allele frequencies or individual genotypes.

As with all NCBI projects, the data in dbSNP are freely available to the scientific community and are available in a variety of formats via FTP from the SNP homepage. Submission instructions and online queries are accessible via the dbSNP homepage.

Program Nr: 533 from the 1999 ASHG Annual Meeting

Minimization of the Mucolipidosis Type IV candidate region on human chromosome 19 by haplotype analysis and detailed physical mapping. *S.A. Slaugenhaupt[1], J.S. Acierno[1], L.A. Helbling[1], C. Bove[2], G. Bach[4], L. Ashworth[5], E. Goldin[3], R. Schiffmann[3].* 1) Harvard Institute of Human Genetics, Harvard Medical School, Boston, MA; 2) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown, MA; 3) Developmental and Metabolic Neurology Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 4) Department of Human Genetics, Hadassah University Hospital, Jerusalem, Israel; 5) Human Genome Center, Lawrence Livermore National Laboratory, Livermore, CA.

Mucolipidosis Type IV (MLIV) (MIM 252650) belongs to a group of inherited metabolic diseases known as the lysosomal storage disorders. It was first described in 1974 as a new variant of the mucolipidoses and was characterized by corneal clouding and abnormal systemic storage bodies. The absence of mucopolysaccharide excretion and the lack of identifiable lysosomal enzyme changes distinguish it from the mucopolysaccharidoses and from the other mucolipidoses. MLIV is a progressive neurological disease that usually presents during the first year of life with mental retardation, corneal opacities, and delayed motor milestones. To date more than 80 MLIV patients have been reported, the majority belonging to the Ashkenazi Jewish (AJ) population.

Using 13 AJ families, we originally mapped the gene to a 5.62 cM region on chromosome 19p13.2-13.3. Detailed analysis of 65 MLIV chromosomes (33 families) now demonstrates that two founder haplotypes account for 95% of the disease chromosomes in the AJ population. Examination of ancestral recombinants has narrowed the candidate region to 1.2 cM. We have constructed a detailed BAC and cosmid map that spans 1.4 Mb and includes the entire MLIV candidate region. We have recently started gene identification using methods including direct sequence prediction, EST mapping, exon trapping and cDNA selection. Isolation of the MLIV defect will permit a genetic prenatal test, a carrier test for the AJ population, as well as a simple tool for diagnosis and differentiation from the other lysosomal storage disorders.

Program Nr: 534 from the 1999 ASHG Annual Meeting

Linkage disequilibrium mapping identifies a Class III Major Histocompatibility Complex (MHC) susceptibility haplotype to Crohn's disease in Ashkenazi Jews. *K.D. Taylor, H. Yang, T.D. Hang, Y-C. Lin, S.R. Targan, N. Fischel-Ghodsian, J.I. Rotter.* Division of Medical Genetics and Inflammatory Bowel Disease Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Background: Crohn's disease (CD) is a complex genetic disease. Ashkenazi Jews have a 2-4 fold increased susceptibility to CD compared with non-Jews. We, along with others, have observed evidence for linkage of CD to the MHC in both Jews and non-Jewish Caucasians. **Aim:** To characterize this genetic susceptibility to CD further using a linkage disequilibrium mapping approach with both population-based and family-based study designs in this high risk ethnic group. **Methods:** The case control panel consisted of 108 CD and 69 controls. The family panel consisted of 56 families with at least one member affected with CD and none with ulcerative colitis (196 total). All subjects were Ashkenazi Jews. Both panels were typed with 21 MHC markers spaced 0.2-0.4 Mb. The association of markers with CD in the case control panel was tested by chi-square tests. The TDT was performed in the family panel with single markers individually as well as with 2-, 3-, and 4-marker haplotypes using Genehunter 2.0. **Results:** Notch4 allele 2 was associated with CD in both the case control (p=0.011) and family panels (31 transmitted to affecteds (T), 14 not transmitted (NT); p=0.011). A 2-2 haplotype formed with the adjacent SNP marker HSP-HOM yielded T 29, NT 11 (p=0.0044). Incorporation of the next marker in the series, D6S273, created a Notch4-->HSP-HOM-->D6S273 2-2-4 haplotype that yielded 16 T, 2 NT (p=0.00097). These 3 markers span 0.5 Mb within the MHC Class III. **Conclusions:** These observations strongly suggest that a genetic variation in linkage disequilibrium with this MHC Class III 2-2-4 haplotype contributes to susceptibility to CD in Ashkenazi Jews. The association reported here is the strongest that we have observed between MHC markers and CD in this population to date. When combined with other observed associations to CD in this region, these results raise the possibility that multiple genes in the MHC contribute to susceptibility to CD and illustrate the complexity of even one chromosomal region in a common disese.

Program Nr: 535 from the 1999 ASHG Annual Meeting

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis maps to chromosome 3q27. *S. Weber[1], K. Hoffmann[2], K. Saar[2], N. Jeck[1], M. Boeswald[1], E. Kuwertz-Broeking[1], I. Meij[1], N. Knoers[1], P. Cochat[1], T. Sulakova[1], M. Soergel[1], F. Manz[3], H.W. Seyberth[1], K. Schaerer[4], A. Reis[2], M. Konrad[1]*. 1) University Children's Hospital, Marburg, Germany; 2) Mikrosatellitenzentrum, Max-Delbrueck-Centre, Berlin, Germany; 3) Research Institute of Child Nutrition, Dortmund, Germany; 4) Department of Pediatric Nephrology, University Childrens Hospital, Heidelberg, Germany.

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC, MIM 248250) associated with chronic renal failure is a complex renal tubular disorder characterized by hypomagnesemia, hypercalciuria, advanced nephrocalcinosis, polyuria, hyposthenuria, low citrate excretion and a low glomerular filtration rate. Recurrent urinary tract infections, nephrolithiasis, incomplete distal tubular acidosis and eye involvement have also been reported. The mode of inheritance is autosomal recessive. To date, the underlying genetic defect and pathophysiology are unknown but a primary defect in the reabsorption of divalent cations in the medullary thick ascending limb of the loop of Henle (mTAL) has been proposed. To identify the underlying genetic defect we performed linkage analyses in eight families, including three with consanguineous marriages. After exclusion by haplotype analyses of several candidate genes coding for proteins involved in tubular fluid and electrolyte transport and loci for dominant isolated renal magnesium loss and familial hypomagnesemia with hypocalcemia (11q23 and 9q12-22.2 respectively) we performed a whole genome scan and found linkage to microsatellite markers on chromosome 3q27. A maximum two-point LOD score (Zmax) of 5.208 was found for D3S3530 at a recombination fraction Q= 0.00, whereas multipoint analysis gave a Zmax of 7.368 around marker D3S2398. Haplotype analysis revealed crucial recombination events reducing the critical interval for this locus (*HOMG3*) to 6.6 cM between markers D3S1580 and D3S3663. The identification of *HOMG3* will not only provide insight into the pathophysiology of FHHNC but might also give important clues into mechanisms of renal magnesium and calcium handling.

Program Nr: 536 from the 1999 ASHG Annual Meeting

Power of Variance Component Linkage Analysis to Detect Quantitative Trait Loci. *J.T. Williams, J. Blangero.* Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

Variance component methods for quantitative trait linkage analysis are highly flexible and provide superior statistical properties in many situations. To assist investigators in designing or evaluating linkage studies we determined the sample size required to achieve any desired power in variance component linkage analysis of a quantitative trait. For simplicity we consider an additive model comprising effects due to a single QTL, residual additive genetic factors, and individual-specific environmental variation. Exact expressions for the required sample size are given for sibpairs, sib trios, nuclear families having two and three sibs, and for arbitrary relative pairs. For larger sampling structures such as extended pedigrees the relevant equations are solved numerically. The power of the variance component method is dominated by the QTL-specific heritability, which is itself a function of the QTL allele frequency and the displacement between homozygote means. Comparative power curves are presented for sibships of size 2-4, nuclear families having 2-4 sibs, and for an extended pedigree of 48 individuals. Our results indicate that power is increased when the QTL acts in the presence of nonzero residual additive genetic variance. Omission of parental information in sibpair analysis will result in relatively little loss of information only for traits with low heritabilities. The procedures are easily applied to other covariance models and pedigree structures.

Program Nr: 537 from the 1999 ASHG Annual Meeting

Genome-wide linkage scan for familial idiopathic scoliosis. *C.A. Wise[1], R. Barnes[2], J.A. Herring[1], J.D. Gillum[1], L. Macleod[1], H.H. Hobbs[2], A.M. Bowcock[3], M. Lovett[3].* 1) Research Dept, Texas Scottish Rite Hospital, Dallas, TX; 2) Center for Human Genetics, University of Texas Southwestern Medical Center, Dallas, TX; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MO.

Idiopathic scoliosis (IS) is defined as lateral curvature of the spine of unknown etiology. IS in human populations has estimated occurrences of 1.5-3%, 0.3-0.5%, and 0.2-0.3% for curves over 10, 20, and 30 degrees, respectively. An apparent genetic basis for IS is well recognized clinically, and a multifactorial inheritance pattern has been proposed. More rarely, the disease appears to be inherited in an autosomal dominant fashion with reduced penetrance. We are ascertaining and collecting blood from pedigrees showing such an inheritance pattern and combining stringent diagnostic criteria with conservative methods of genetic analysis to positionally clone genes predisposing to IS. Probands having clinically relevant idiopathic scoliosis (50 degree curves or greater) from multiplex families are being identified. Currently DNA samples have been collected from 21 pedigrees containing 154 individuals. A genome-wide scan in one large family (seven affected members of 14 sampled) was conducted with 385 polymorphic microsatellite markers at approximately 10 cM resolution. Affecteds-only linkage analyses, using both parametric and nonparametric methods, produced evidence for linkage with loci on chromosomes 6p, distal 10q, and 18q with maximum non-parametric lod (NPL) scores of 1.42 (p=0.020), 1.60 (p=0.019), and 6.33 (p=0.002) respectively. A genome-wide search was conducted in a second large kindred (seven affected individuals of 17 sampled) using 200 microsatellite markers at an approximate resolution of 25 cM. The same analyses produced maximum evidence for linkage at chromosome 4q and again at distal chromosome 10q, with NPL scores of 5.08 (p=0.015) and 2.55 (p=0.033), respectively. Interestingly, duplication of the common 10q region was recently correlated with the presence of scoliosis (p<.001). The combined data suggest that IS is genetically heterogeneous, but that a limited number of loci may be involved.

Program Nr: 538 from the 1999 ASHG Annual Meeting

Genetic Mapping of a Novel Syndrome of Terminal Osseous Dysplasia and Pigmentary Defects to Human Chromosome Xq27.3-Xqter. *W.Z. Zhang[1,2], R. Amir[2], D.W. Stockton[2], I.B. Van den Veyver[2,3], C. Bacino[2], H.Y. Zoghbi[1,2,4]*. 1) Howard Hughes Medical Institute; 2) Departments of Molecular and Human Genetics; 3) Obstetrics and Gynecology; 4) Pediatrics, Baylor College of Medicine, Houston, TX 77030.

We studied a four-generation family with ten affected females manifesting one or more of the following features: osseous dysplasia of the metacarpals, metatarsals, and phalanges leading to brachydactyly, camptodactyly and other digital deformities; pigmentary defects on face and scalp; and multiple frenulae. There are no affected males and one of the affected females had recurrent spontaneous abortions, consistent with an X-linked dominant male lethal mutation. X inactivation studies using the methylation assay at the androgen receptor locus demonstrated a skewed pattern of X inactivation in seven affected females tested and a random pattern in two unaffected females, thus confirming the X-linked inheritance. To map the gene for this disorder, we undertook genotypic analysis of DNAs from nine affected females and five unaffected individuals (three females and two males) using forty markers evenly distributed throughout the X chromosome. Among the markers tested, thirty-two were informative. Two-point linkage analyses using these markers excluded most of the X chromosome and demonstrated linkage to a region on the long arm from marker DXS548 to Xqter. Assuming 90% penetrance, we obtained a maximum lod score of 3.16 at a recombination frequency of zero for five markers (DXS1123, DXS1113, FRAXF, BGN and DXS1108) in Xq27.3-Xq28. Multipoint linkage analysis confirmed the mapping of this gene to Xq27.3-Xqter. This disorder is similar to the condition reported in a sporadic case by Horii et al (Am J Med Genet. 80: 1-5, 1998) and in cases 2 and 3 by Bloem et al (J Bone Joint Surg [Br]. 56-B (4): 746-51, 1974). In these cases, digital fibromas were a major finding, in contrast to the family we studied where they are prominent in only one female. In summary, we describe and map a novel X-linked syndrome, which should facilitate the identification of the gene causing this disorder.

Program Nr: 539 from the 1999 ASHG Annual Meeting

A genome-wide portrait of short tandem repeats. *C. Zhao, J. Heil, J.L. Weber.* Center for Medical Genetics, Marshfield Medical Research Foundation, Marshfield, WI.

The rapidly growing volume of human genomic sequence offers the opportunity to gain a genome-wide perspective on the relative frequencies, lengths, and organization of short tandem repeats (STRs, also called microsatellites). We have recently completed a computer screen for all mono-, di-, tri-, and tetranucleotide repeats in over 150 mb of human genomic BAC DNA from the Sanger, Washington University, and MIT Sequencing Centers. Emphasis was placed on runs of STRs which are long enough to likely be polymorphic (10 or more uninterrupted repeats for mononucleotides, 12 repeats for dinucleotides, 8 for trinucleotides and 6 for tetranucleotides). Permuted and complementary sequences were combined into alphabetically minimal groups. For mononucleotides (2 types), A repeats were far more common and longer than Cs. For dinucleotides (4 types), AC repeats were strongly predominant over AGs and ATs, and long CG repeats were virtually absent. For trinucleotides (10 types), the most common repeats in order of decreasing frequency were AAT, AAC, AAG, ATC, and AGG. For tetranucleotides (33 types), the top sequences in decreasing frequency were AAAT, AAAC, AAAG, AAGG, AGAT, ATCC, AATG, and AGGG. For longer runs of tetranucleotides with 10 or more repeats, the most frequent in decreasing order were AAAT, AAAG, AGAT, AAGG, and ATCC. When extrapolated to the entire genome, our results indicate that there are likely to be about 1.1 million polymorphic mononucleotide STRs and an additional 200,000 polymorphic di, tri, and tetranucleotide STRs. Since there are thought to be about 3 million total diallelic polymorphisms, our results indicate that STRs comprise a substantial fraction of all DNA polymorphism in the human gene pool. In addition, the approximately 10,000 STRPs developed to date are only a small fraction of available sequences. Enormous numbers of useful STRPs await characterization.

Program Nr: 540 from the 1999 ASHG Annual Meeting

Statistically significant association of sequence variants in the *ABCR* gene with age-related macular degeneration. *R. Allikmets, and the International ABCR Screening Consortium.* Columbia University, New York, NY.

Age-related macular degeneration (AMD) is the leading cause of untreatable central visual impairment among the elderly and has been associated both with environmental and with genetic factors. Previously we have identified disease-associated variants in the *ABCR* gene in a subset of patients affected with this complex disorder. We have now tested our original hypothesis, that *ABCR* is a dominant susceptibility locus for AMD, by screening >1300 unrelated AMD patients of Caucasian origin and >1500 control individuals for the three frequent variants found in *ABCR*. AMD patients and controls, matched by age and/or ethnicity, were independently ascertained in 15 laboratories in the U.S., UK, France, Italy, Spain, Sweden, Germany, and The Netherlands. The *ABCR* gene was screened by either SSCP, DGGE or PCR-RFLP methods for three amino acid-changing variants, G1961E, D2177N, and R943Q. Respective positive controls were included in each experiment and variants were confirmed by direct sequencing. Statistical analysis was performed on accumulated data using Fisher's exact test or c^2 test. G1961E and D2177N mutations were detected in one allele of *ABCR* in 51 patients (~4%), and in 13 controls (~0.9%). Fisher's exact test confirmed that these two variants are associated with AMD at a statistically significant level ($P < 0.000001$). Mutations are found predominantly in patients with the dry (non-neovascular) form of the disorder ($P = 0.0014$). Frequency of the common R943Q polymorphism, used to assess the correlation of patient and control populations, was very similar between patients and controls in all groups (7-10%, $P = 0.23$, with c^2 test). Our data confirms that some *ABCR* variants are associated with AMD phenotype(s). This association is statistically significant when analyzed in large patient/control populations and the two variants alone account for about 4% of all *ABCR* variants associated with AMD. Defining a subset of AMD patients in which heterozygous *ABCR* alterations are associated with the disease will permit presymptomatic testing of high-risk individuals and may lead both to earlier diagnosis of AMD and to new strategies for intervention and prevention.

Program Nr: 541 from the 1999 ASHG Annual Meeting

Single nucleotide variants in XIST: Test of association with X inactivation patterns.. *J.M. Amos-Landgraf, R.M. Plenge, H.F. Willard.* Genetics, Case Western Reserve Univ, Cleveland, OH.

Many X-linked disorders have been reported to manifest to some degree in females. This is likely due to preferential inactivation of the X chromosome carrying the normal allele. The process of X chromosome inactivation (XCI) is believed to be a random event whereby either parental X chromosome has an equal probability of becoming inactivated. The choice of which X chromosome is to be inactivated appears to be random; however, alleles have been identified in inbred mouse strains that control XCI patterns resulting in varying degrees of skewed XCI ratios. These alleles, termed X inactivation controlling element (Xce) alleles, map to the X inactivation center (XIC) and have only been identified in mice. To determine if similar Xce alleles exist in humans, we have identified markers in the X inactivation center (XIC), and are constructing haplotypes to relate these variants to the observed X inactivation ratios. PCR primers were designed utilizing GenBank sequence of PAC 92E23, which contains the XIST gene, and the products directly sequenced . We have sequenced 20 kb of the XIC in 15 unrelated X-chromosomes, identifying 15 single nucleotide changes, and 2 insertion/deletion changes. Nine of the single nucleotide variants (SNVs) were identified exclusively on two unrelated X-chromosomes. Three SNVs have been genotyped in 113 females and have minor allele frequencies of 5% -10%. To determine if these single nucleotide polymorphisms (SNPs) identify potential Xce alleles, genotypes were compared with blood XCI ratios to test for association. There was no significant association of skewed XCI ratios (individuals with ratios of >80:20) with any of the 3 SNPs genotyped, although a previously described variant in the XIST promoter is associated with preferential inactivation (Nature Genetics 1997 vol.17: 353). Extension of this approach to much larger populations of females should uncover possible genetic influences on X inactivation patterns as determined by the XIC and XIST.

Program Nr: 542 from the 1999 ASHG Annual Meeting

Somatic sequence variation at the Friedreich ataxia locus includes complete contraction of the expanded GAA triplet repeat, significant length variation in serially passaged lymphoblasts, and enhanced mutagenesis in the flanking sequence. *S.I. Bidichandani[1], S.M. Purandare[2], E.E. Taylor[1], G. Gumin[1], H. Machkhas[1], Y. Harati[1], R.A. Gibbs[3], T. Ashizawa[1], P.I. Patel[1,3,4].* 1) Neurology, Baylor Col Medicine, Houston, TX; 2) Pathology, Baylor Col Medicine, Houston, TX; 3) Molecular and Human Genetics, Baylor Col Medicine, Houston, TX; 4) Neuroscience, Baylor Col Medicine, Houston, TX.

The majority of Friedreich ataxia patients are homozygous for large GAA triplet repeat expansions in intron 1 of the *X25* gene. Systematic analysis of lymphoblastoid cell lines passaged 20 - 39 times allowed examination of instability of expanded GAA repeats in 23 chromosomes bearing 97 to 1250 triplets. Southern analyses revealed 18 events of significant changes in length ranging from 69 to 633 triplets, wherein the *de novo* allele gradually replaced the original over 1 to 6 passages. Contractions and expansions occurred with equal frequency and magnitude. This behavior is unique in comparison to other large, non-coding triplet repeat expansions ([CGG]n and [CTG]n) which remain relatively stable under similar conditions. We also report a rare patient, who having inherited two expanded alleles, showed evidence of contracted GAA repeats ranging from 9 to 29 triplets in DNA from two independent peripheral blood samples. Furthermore, given that triplexes in transcribed templates cause enhanced mutagenesis, and since the GAA triplet repeat is known to adopt a triplex structure, the poly(A) tract and a 135-bp sequence situated immediately upstream were examined for somatic mutations. The poly(A) tract showed enhanced instability, with a preponderance for deletion when in cis with the GAA expansion. The 135-bp upstream sequence was found to harbor a three-fold excess of point mutations in DNA derived from individuals homozygous for the expansion compared with normal controls. These data are likely to have important mechanistic and clinical implications.

Program Nr: 543 from the 1999 ASHG Annual Meeting

Deletion of the Prader-Willi syndrome imprinting center in mice. *C.I. Brannan, S.M. Blaydes.* Dept Molecular Genetics & Microbiology, University of Florida, Gainesville, FL.

Deletion of a region nearby and including the first exon of the *SNRPN* gene has been shown to cause Prader-Willi syndrome (PWS) upon paternal transmission. This element, dubbed the PWS Imprinting Center (PWS-IC) appears to be responsible for the coordinate expression of multiple paternally expressed genes mapping in the 15q11-q13 region. Previously, we have shown that a similar PWS-IC element exists near the murine *Snrpn* gene and is required for imprint resetting which must occur during gametogenesis. We now demonstrate that the PWS-IC is also required in somatic tissues. Chimeric males derived from male embryonic stem (ES) cell line harboring a deletion of the PWS-IC on the paternal chromosome show abnormal levels of methylation at sites within *Zfp127* and *Ndn*. These results suggest that the PWS-IC is required for the *de novo* establishment and/or maintenance of the paternal imprint. Finally, as progeny derived from germline transmission of this PWS-IC mutation from male chimeras are not viable, it has not been possible to establish a line of mice harboring this deletion. To solve this problem, we have recently deleted the PWS-IC in an XO ES cell line. Female chimeras from this cell line are fertile. Offspring derived from these females will be useful for genetic complementation studies aimed at identifying genes involved in the murine PWS phenotypes.

Program Nr: 544 from the 1999 ASHG Annual Meeting

FMR1 knockout mouse shows a strain-specific severe learning impairment: A robust model for the fragile X syndrome. *W.T. Brown, A. Rabe, R. Dumas, H. Haubenstock, C. Dobkin.* Dept Human Genetics, NYS Inst Basic Research, Staten Island, NY.

Fmr 1 gene knock out (ko) mice are a model for the human Fragile X mental retardation syndrome. However, fmr1 ko mice with a C57BL/6-129/OlaHsd hybrid background have been reported to have only a mild learning deficiency (Bakker et al., 1994). We examined the effect of this ko mutation on spatial learning ability in mice with either an FVB/N-129/OlaHsd hybrid background or a C57BL/6 background. When FVB-129 mice unaffected by the recessive FVB vision impairment mutations were tested, the ko mice showed a profound deficiency in their ability to learn the position of a hidden escape platform in a "cross" water maze in comparison to littermate controls. In contrast, ko mice with a C57BL/6 background learned the maze just as well as their littermates. The C57Bl/6 ko mice did show a mild deficiency in the "reversal" phase of this test, which is a more complex task. FVB/N-129 ko mice also showed differences from control littermates in their hippocampal vs non-hippocampal responses in fear conditioning, differences that were not apparent in C57BL/6 ko mice. Thus, silencing the Fmr1 gene profoundly interfered with specific learning behaviors in FVB/N-129 hybrid mice but only slightly affected mice with a C57BL/6 background. This indicated that the Fmr1 knockout mutation is a robust strain specific model for the human mental retardation syndrome. The clear impairment in FVB-129 ko mice will facilitate testing of potential therapies and investigation of the developmental etiology of the fragile X syndrome. The strain dependence of the ko phenotype may allow the identification of genes that interact with Fmr1.

Program Nr: 545 from the 1999 ASHG Annual Meeting

The *SNRPN* exon 1 region is necessary for the postzygotic maintenance of the paternal imprint. *K. Buiting[1], B. Bielinska[2], C. Lich[1], M. Krajewska-Walasek[2], B. Horsthemke[1].* 1) Institut für Humangenetik, Universitätsklinikum Essen, Essen,Germany; 2) Department of Genetics, The Children's Memorial Health Institute, Warsaw, Poland.

A small subset of patients with Prader-Willi syndrome (PWS) and Angelman syndrome (AS) have apparently normal chromosomes of biparental origin, but the paternal chromosome carries a maternal imprint or the maternal chromosome carries a paternal imprint, respectively. In some of these cases, the incorrect epigenotype is the result of an imprint switch failure in the parental germ line caused by a microdeletion of the imprinting center (IC). In all PWS families studied so far, the IC deletions always included *SNRPN* exon 1 and were on the chromosome inherited from the paternal grandmother.

Recently we identified another PWS patient with a typical IC deletion of about 200 kb. Methylation and microsatellite analyses of blood DNA revealed that the father of the PWS patient is mosaic for the deletion. Since he transmitted the deletion to his affected son, the deletion must also be present in his germ cells, indicating that it must have occurred postzygotically, but prior to the separation of germ cells and somatic cells. In contrast to all other PWS families with IC microdeletions, in this family the affected chromosome is of grandpaternal origin. Unexpectedly, methylation analysis at four loci outside the deletion (*NDN*, u1D, u1B and PW71) showed that the deletion chromosome in both the father and the patient has a maternal methylation imprint. The postzygotic paternal to maternal imprint switch in the father suggests that the *SNRPN* exon 1 region is not only required for the establishment, but also for the maintenance of the paternal imprint.

Supported by the Deutsche Forschungsgemeinschaft.

Program Nr: 546 from the 1999 ASHG Annual Meeting

Identification of Hirschsprung Disease Susceptibility Loci by Linkage Disequilibrium Analysis in the Old Order Mennonites. *M.M. Carrasquillo, A. Chakravarti.* Genetics/Ctr Human Genetics, Case Western Reserve Univ, Cleveland, OH.

Hirschsprung disease (HSCR) is characterized by lack of enteric ganglia and shows a complex pattern of inheritance with mutations in seven different genes (EDNRB, EDN3, ECE1, SOX10, RET, GDNF and NTN), but most mutations show reduced penetrance. A hypomorphic missense mutation, W276C, in the endothelin receptor-B gene (EDNRB) was found in a large number of HSCR cases in the genetically isolated Old Order Mennonite population from Lancaster and Berks Counties, PA. However, W276C is neither necessary nor sufficient for HSCR. To identify additional genes which contribute to Mennonite HSCR we conducted linkage disequilibrium analyses of RET, which showed some association in a genomic screen. We generated and tested 14 new single nucleotide polymorphisms (SNPs) and a novel microsatellite marker in a region of ~ 250 kb encompassing RET. These 15 new markers and 6 previously reported SNPs have an average intermarker distance of ~12 kb. We identified significant association of RET SNPs with respect to chromosomes transmitted and untransmitted to affecteds. Furthermore, haplotype analysis for all markers revealed 5 major haplotypes in this region in 30 families studied. One of the haplotypes, haplotype a, is more often transmitted to affected individuals, suggesting that this haplotype carries a RET susceptibility variant, allowing us to narrow down the genomic region harboring this RET variant to 34 kb conserved identical by descent (IBD) among affected individuals carrying haplotype a. We are sequencing this region to search for the culprit change. In addition, we are conducting additional tests to search for genomic rearrangement in this region of 10q11.2.

Program Nr: 547 from the 1999 ASHG Annual Meeting

Transgenic animals carrying pathological alleles at the MJD1 locus exhibit a mild and slowly progressive cerebellar deficit. *C. Cemal, C. Huxley, A. McGuigan, S. Chamberlain.* Molecular Genetics, Imperial College of Science , Technology and Medicine, London, UK.

The generation of a representative mouse model for Machado-Joseph disease or spinocerebellar ataxia 3 (SCA3) should enhance a greater understanding of the role of repeat length, tissue specificity and level of expression on the pathology of this disease. We have previously reported the generation of human yeast artificial chromosome constructs encompassing the MJD1 locus into which expanded triplet repeat motifs (n=76 or 84) have been introduced by homologous recombination. Transgenic animals subsequently generated using these constructs demonstrate pathological alleles corresponding to a polyglutamine tract length of either 73,74,76 or 84 repeats in the four founders identified to date. The animals characteristically demonstrate a mild and slowly progressive cerebellar deficit, manifesting as early as 4 weeks of age with a slightly kyphotic posture and a fluid but abnormal gait. As the disease progresses, pelvic elevation becomes markedly flattened, accompanied by motor and sensory loss and hypotonia. In contrast, a transgenic animal carrying the wild-type (CAG15) allele at the MJD1 locus appears completely normal at 12 months. The founders show no evidence of early morbidity and exhibit normal growth and fecundity. Although the initial founder (CAG)76 failed to transmit the YAC transgene, transmission to 50% of offspring has been detected in animals carrying alleles corresponding to either CAG73 or CAG84. Further investigation of these animals to elucidate the role of nuclear inclusions in the degenerative process associated with this disorder is currently underway.

Program Nr: 548 from the 1999 ASHG Annual Meeting

Glutathione peroxidase 3: Identification of promoter region polymorphisms and association with age-related maculopathy. *Y.P. Conley[1], M.B. Gorin[1,2], T.S. Mah[2], D.E. Weeks[1], R.E. Ferrell[1]*. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA 15261; 2) Department of Ophthalmology, University of Pittsburgh, Pittsburgh, PA 15261.

Age-related maculopathy (ARM) is a late-onset, progressive, complex genetic disorder for which oxidative damage has been proposed as a potential etiology. The glutathione peroxidases (GPX) are a family of at least four genes encoding enzymes which catalyze the reduction of hydrogen peroxide, lipid peroxides and organic hyperoxide by glutathione and protect cells from oxidative damage. GPX3 is expressed in a variety of tissues, including eye and brain. To assess the possible role of GPX3 in ARM, we sequenced the five exons and the 5' flanking region of GPX3 from ARM cases and controls (N=10). Two single nucleotide polymorphisms were found in the 5'-flanking region of the gene, an A/G at position -623 and an A/C at position -302. No variation was observed in the coding sequence. The -623G and -302A alleles were in complete linkage disequilibrium. We examined the -623 A/G polymorphism in 518 unrelated ARM-affected individuals (both exudative and nonexudative cases) and 46 individuals age >70 years with no evidence of ARM. The frequency of the A allele was 0.84 among the ARM cases and 0.65 among the controls ($0.001 < p < 0.005$), giving an odds ratio of 2.72 (95% C.I. = 2.1-3.3) for ARM among carriers of the A allele. This result is consistent with the hypothesis that oxidative damage contributes to ARM and that genetic variation in the genes encoding anti-oxidative enzymes may contribute to ARM susceptibility.

Program Nr: 549 from the 1999 ASHG Annual Meeting

A putative imprinting control region in 11p15.5 and its loss of methylation in Beckwith-Wiedemann syndrome.

C.D Day[1], N.J. Smilinich[1], G.V. Fitzpatrick[1], N. Diaz-Meyer[1], R.L. Titus[1], G.M. Caldwell[1], A.C. Lossie[2], A.C. Smallwood[3], J.A. Joyce[3], P.N. Schofield[3], W. Reik[3], R.D. Nicholls[4], R. Weksberg[5], D.J. Driscoll[2], E.R. Mayer[3], P.R. Cooper[1], T.B. Shows[1], M.J. Higgins[1]. 1) Roswell Park Cancer Institute, Buffalo, NY; 2) University of Florida College of Medicine; 3) Universities of Birmingham and Cambridge, and Babraham Institute, UK; 4) Case Western Reserve University School of Medicine, Cleveland, OH; 5) Hospital for Sick Children, Toronto, ON, Canada.

Imprinting control elements are proposed to exist within the *KvLQT1*locus since multiple chromosome rearrangements associated with Beckwith-Wiedemann syndrome (BWS) disrupt this gene. We have identified an evolutionarily conserved CpG-island (*KvDMR1*) in an intron of the *KvLQT1*gene which is methylated in the ovary, unmethylated in sperm, and exhibits differential methylation in all human and mouse somatic tissues tested. Strand-specific RT-PCR analysis of the human and syntenic mouse loci demonstrated the presence of a *KvDMR1*-associated RNA transcribed exclusively from the paternal allele and in the opposite orientation with respect to the maternally expressed *KvLQT1* gene. Loss of imprinting at *IGF2*, generally through an *H19*-independent mechanism, is associated with a large percentage of patients with BWS. Among twelve cases of BWS with normal *H19* methylation, five showed demethylation of *KvDMR1* in fibroblast or lymphocyte DNA, while in four cases of BWS with *H19* hypermethylation, methylation at *KvDMR1* was normal. Thus, inactivation of *H19* and hypomethylation at *KvDMR1* represent distinct epigenetic anomalies associated with biallelic expression of *IGF2*. We propose that *KvDMR1* and/or its associated antisense RNA (*KvLQT1-AS*) represents an additional imprinting control element or center in the human 11p15.5 and mouse distal 7 imprinted domains. To test this hypothesis we are carrying out targeted mutagenesis of *KvDMR1* in the mouse and assessing the expression of 11p15.5 imprinted genes in BWS patients with and without loss of methylation at *KvDMR1*. Supported by CA63333.

Program Nr: 550 from the 1999 ASHG Annual Meeting

Expression analysis of ataxin-7 reveals restricted localization of an alternate isoform. *D.D. Einum[1], L. Gouw[1], A. Matilla[2], J. Townsend[3], Y.H. Fu[4], L.J. Ptacek[1,2]*. 1) Dept Human Genetics, Univ Utah, SLC, UT; 2) Howard Hughes Medical Institute, Univ Utah, SLC, UT; 3) Dept Surgical Pathology, Univ Utah, SLC, UT; 4) Dept Neurobiology and Anatomy, Univ Utah, SLC, UT.

Spinocerebellar ataxia type 7 (SCA7) is an inherited disorder characterized clinically by ataxia and vision loss and pathologically by degeneration of cerebellar and brainstem neurons, as well as retinal photoreceptor cells. SCA7 is caused by expansion of a CAG repeat that encodes polyglutamine in the translated protein, ataxin-7. Similar to other polyglutamine disorders, cell death is restricted to specific neurons despite widespread expression of SCA7 transcripts. However, we have identified an alternate SCA7 transcript, termed SCA7.3, that exhibits an expression pattern restricted primarily to the CNS. We hypothesize that cell-specific degeneration in SCA7 is due to polyglutamine expansion within an alternate ataxin-7 isoform exhibiting restricted expression. To examine this possibility, we have developed antibodies and utilized them to examine the expression patterns of distinct ataxin-7 isoforms. Immunoblotting experiments revealed that ataxin-7 is translated, at variable levels, in all peripheral and CNS tissues examined. In contrast, ataxin-7.3 expression is limited to CNS tissues. Furthermore, immunohistochemical staining demonstrated that ataxin-7 and ataxin-7.3 reside in disparate subcellular locales of cerebellar Purkinje cells, neurons which are primarily affected in SCA7 patients. The demonstration that ataxin 7.3 exhibits a tissue distribution restricted primarily to the CNS, as well as a subcellular localization distinct from that of other ataxin-7 isoforms, raises the possibility that the specific pattern of cell death in SCA7 patients is due to polyglutamine expansion within an alternate ataxin-7 isoform. The potential role of ataxin-7.3 in SCA7 pathogenesis is currently under investigation.

Program Nr: 551 from the 1999 ASHG Annual Meeting

Identification of a testis-specific gene in the Prader-Willi syndrome region on chromosome 15. *C. Faerber[1], J. Neesen[2], S. Gross[1], K. Buiting[1], B. Horsthemke[1]*. 1) Institut fuer Humangenetik, Universitaetsklinikum Essen, Essen, Germany; 2) Institut fuer Humangenetik, Universitaet Goettingen, Goettingen, Germany.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are caused by the loss of function of imprinted genes within a 2-3 Mbp chromosomal domain in proximal 15q. Whereas Angelman syndrome can be caused by mutations in a single gene (*UBE3A*), which in brain is expressed from the maternal chromosome only, PWS appears to be a contigous gene syndrome. So far, four paternally expressed genes have been identified within the PWS critical region (*ZNF127*, *NDN*, *SNRPN* and *IPW*).

We have identified a novel gene which maps about 300 kb centromeric of *SNRPN*. It was identified by subcloning of a CpG-island close to D15S13 (189-1). The CpG-island was found to be 100% unmethylated in sperm cells, 20% unmethylated in fetal ovary and adult testis, and fully methylated in all other investigated tissues. Northern blot analysis with a probe downstream of the CpG-island revealed a testis-specific transcript of 7.5 kb. Preliminary RNA in situ hybridization data suggest that the gene is expressed in spermatocytes. It is intronless and has an open reading frame of 3.5 kb encoding a 121 kDa protein of unknown function. An unusual polyadenylation signal is provided by a solitary long terminal repeat (LTR) at the 3' end of the gene. Following the HUGO nomenclature, the gene was termed *c15orf2* (chromosome 15 open reading frame 2). To investigate the imprinting status of *c15orf2*, we have identified four polymorphisms within the 3'UTR and analyzed DNA and RNA samples of three adult testes. Interestingly, we found biallelic expression of c15orf2. Therefore, *c15orf2* is the first gene reported to escape from genomic imprinting in the PWS critical region, although the imprinting status of *c15orf2* may be different in earlier developmental stages. It is tempting to speculate that the protein encoded by *c15orf2* may play a role in spermatogenesis.

Part of this work was supported by the Deutsche Forschungsgemeinschaft.

Program Nr: 552 from the 1999 ASHG Annual Meeting

A murine model of triplet repeat instability demonstrates dramatic age dependent, expansion biased somatic mosaicism. *M.Teresa Fortune[1], C. Vassilopolus[1], M.I. Coolbaugh[2], M.J. Siciliano[2], D.G. Monckton[1]*. 1) Division of Molecular Genetics, University of Glasgow, Glasgow, UK; 2) Department of Molecular Genetics, U.T. M.D. Anderson Cancer Center, Houston TX.

Myotonic dystrophy (DM) is one of an increasing number of diseases whose phenotype has been connected to an expansion of a triplet repeat. Expansion over time and variation of the mutation rate between the somatic tissues of an individual is thought to at least partially account for the tissue specificity and progressive nature of the symptoms. The level of instability of the repeat in DM patients is affected by several factors including the initial size of the progenitor allele and the age of the patient. To investigate the behaviour of the expanded CTG repeat in multiple tissues over time, murine models have been developed containing the *Dmt* transgene which is derived from the human DM locus and consists of ~161 CTG repeats. An investigation of instability was carried out on four of the lines generated on a range of somatic tissues using small pool PCR. Initial observation of 20 month old male and female mice from each line revealed minimal levels of instability in three of the lines. In the fourth, *Dmt*-D, expansion biased instability, which varied greatly between tissues, was observed. To further investigate the effect of age on stability on *Dmt*-D, mice were sampled at 2, 6 and 13 months, and instability was found to increase with age as in humans. Stability in regions of the brain from a 12 month old *Dmt*-D mouse was also studied and as with humans and other mouse models only minimal instability was observed in cerebellum. Kidney, the most unstable tissue, demonstrated dramatic instability with expansion events of over 500 repeats observed in old mice. Moreover, the distribution of variability was clearly trimodal, suggesting not just tissue specific, but also cell-type specific modifiers of instability. These mice should provide an excellent model system for further investigating the molecular mechanisms controlling somatic mosaicism at triplet repeat loci.

Program Nr: 553 from the 1999 ASHG Annual Meeting

Multiparameter SNP test identifies polymorphisms in genes from the renin-angiotensin system as predictors of dyslipoproteinemia and, in combination with lipase polymorphisms, of coronary artery disease. *H. Funke[1,2], G. Assmann[1,2], S. Rust[2], H. Schulte[2], E. Köhler[3], M. Grow[4], H. Erlich[4], S. Cheng[4].* 1) Inst Clinical Chemistry, Univ Muenster, Muenster, Germany; 2) Inst Atherosclerosis Res, Univ Muenster, Germany; 3) Salzetalklinik, Bad Salzuflen, Germany; 4) Roche Molecular Systems, Alameda, CA.

In recent years mutations in numerous candidate genes have been proposed as coronary artery disease (CAD) risk modifyers. Often observed conflicting results from different studies are thought to be a consequence of the relatively small contribution to disease formation of a single modifyer gene. Larger effects are expected to result from gene/gene interaction. In an attempt to identify such interaction we have analyzed 34 dimorphic polymorphisms previously suggested as CAD markers in 1000 male myocardial survivors with confirmed CAD and in 1003 male controls from the same region of Germany. Using a c2-test three markers showed genetoype frequencies which differed between the cases and the controls. These markers were apo B 71Ile ([af]=0.329 in cases, [af]=0.300 in controls; $p<0.01$), apo CIII del(T)-625 (af=0.386 vs. af=0.434; $p<0.01$), and ELAM Ser128Arg (af=0.113 vs. af=0.089; $p<0.05$). Subsequent analysis of the association of all 34 SNPs with quantitative intermediate phenotypes (QIP) of CAD identified numerous significant associations. For a more condensed analysis both QIP and SNPs were grouped on the basis of the metabolic pathways they originate from. While gene polymorphisms in genes of the renin angiotensin system (RAS)were associated with changes in blood pressure (ACE ins/del with diast. and syst. BP; $p<0.05$) they also showed a close association with plasma lipoproteins (AGT235 with triglic. and Lp(a); ATIIR1166 with HDL-chol, apoAI, and Lp(a); all $p<0.05$). When RAS polymorphisms and polymorphisms from the lipoprotein lipase (LIPC) gene, neither of which was associated with CAD when tested alone, were analyzed in pairs significant associations with CAD were seen. These data further strengthen the link between high blood pressure and lipoprotein metabolism disorders in the pathophysiology of CAD.

Program Nr: 554 from the 1999 ASHG Annual Meeting

Specific sequence polymorphisms in the *RET* proto-oncogene are over-represented in individuals with Hirschsprung disease and may represent loci modifying phenotypic expression. *O. Gimm[1], S. Borrego[2], M.E. Sáez[2], A. Ruiz[2], M. López-Alonso[3], C. Eng[1], G. Antiñolo[2].* 1) Human Cancer Genetics Program, Ohio State University, Columbus, OH; 2) Unidad de Genética Médica y Diagnóstico Prenatal, Sevilla, Spain; 3) Departamanto de CirugÍa Infantil, Hospital Universitario Virgen del RocÍo, Sevilla, Spain.

Hirschsprung disease (HSCR), a common genetic disorder (1 in 5000 life births), is characterized by functional intestinal obstruction secondary to enteric aganglionosis. Usually occurring as isolated cases, HSCR can be familial with reduced penetrance and male predominance. Even though six putative susceptibility genes have been identified (*RET, GDNF*, *NTN*, *EDNRB*, *EDN3*, *SOX10*), only germline mutations in the *RET* proto-oncogene account for a significant minority (up to 50%) of familial HSCR. In contrast, only 3% of sporadic HSCR in a population-based series carry germline *RET* mutations. We prospectively ascertained 64 incident cases of sporadic HSCR from the Western Andalusia region. We examined allelic frequencies at 7 polymorphic loci within *RET* in this population-based series to determine if polymorphic sequence variants could act as low penetrance predisposing alleles. For two loci, c.135A/G (exon 2) and c.2307C/G (exon 13), the rarer polymorphic allele was over-represented among HSCR cases versus controls. 75 of 128 (59%) HSCR chromosomes tested carried the c.135A/G variant A compared to 32 of 200 (16%) control chromosomes ($p<0.0001$). Further, 39 of 128 (30%) HSCR chromosomes tested carried the c.2307C/G variant C compared to 28 of 200 (16%) control chromosomes ($p=0.0005$). In contrast, 2 other polymorphisms, c.2071G/A (exon 11) and c.2712C/G (exon 15), which are in linkage disequilibrium, were under-represented in the HSCR individuals compared to controls. The polymorphic allele (c.2071A resp. c.2712G) was found in 16 of 128 (12%) HSCR chromosomes compared to 47 of 200 (23%) control chromosomes ($p=0.02$). In conclusion, polymorphisms in the *RET* proto-oncogene appear to predispose to HSCR in a complex, low penetrance fashion and may also modify phenotypic expression.

Program Nr: 555 from the 1999 ASHG Annual Meeting

Genome-wide linkage analyses in the lupus-prone mouse strain, BXSB. *M.E.K. Haywood[1], M.B. Hogarth[1], J.H. Slingsby[1], S.J. Rose[1], E.M. Thompson[2], M.A. Maibaum[1], M.J. Walport[1], B.J. Morley[1]*. 1) Rheumatology Section, Imperial College, Hammersmith, London, U.K; 2) Histopathology, St.Mary's Hospital, London, U.K.

The BXSB mouse strain, derived from an original cross between a C57BL/6 female and an SB/Le male, spontaneously develops a number of phenotypic features which markedly resemble the human disease, systemic lupus erythematosus (SLE). We have established reciprocal backcrosses with the non-autoimmune strain C57BL/10 (B10) and analysed 350 (BXSBx(B10xBXSB)F_1) and 286 (B10x(B10xBXSB)F_1) male backcross mice for a range of phenotypic traits associated with the development of SLE. The mice were genotyped using 93 microsatellite markers and linkage of these markers to disease was studied by extreme phenotype and quantitative trait locus analyses.

We have identified four areas of genetic linkage to disease on chromosome 1 (*Bxs1-4*), a transgressive interval on chromosome 3 (*Bxs5*) and a further interval on chromosome 13 (*Bxs6*) which were associated with various aspects of the phenotype. Additional potential linkages were also identified on chromosomes 2, 8, 10, 11, and 19.

Our analysis suggests that there are multiple genes involved in susceptibility to lupus in BXSB mice. The intervals we have identified segregate with phenotype; *Bxs1* and *Bxs2* were linked to nephritis and splenomegaly, while *Bxs3* was linked to autoantibody production. Disease onset was dependent on BXSB-derived intervals, disease being delayed in backcross mice in comparison to BXSB parental mice. The severity of disease was also linked to BXSB homozygosity, indicating that gene dosage effects are important in this model. There was one exception to this in the backcross to B10, where high levels of antinuclear antibody (ANA) production were linked to B10 derived intervals. The transgressive interval on chromosome 3 provides either a B10 disease susceptibility allele or a BXSB protective allele, and is an excellent candidate locus for modulating ANA levels.

Program Nr: 556 from the 1999 ASHG Annual Meeting

A Mouse Model for Spinal Muscular Atrophy. *H. Hsieh-Li[1], J. Chang[2], Y. Jong[3], H. Li[1].* 1) Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan, ROC; 2) Department of Medical Research, China Medical College Hospital, Taichung, Taiwan,ROC; 3) Department of Pediatrics, Division of Pediatric Neurology, Kaohsiung Medical College, Kaohsiung, Taiwan,ROC.

Homozygous mutation of the telomeric SMN (SMN-T) gene in humans is associated with proximal spinal muscular atrophy (SMA), a severe motor neuron disease leading to muscle weakness with an onset predominantly in infancy and childhood. To further understand the functional role of the SMN gene in SMA, we produced mouse lines carrying a knockout mutation of the mouse Smn gene and transgenic mouse lines that expressed the human centromeric SMN (SMN-C) gene. Mice with the homozygous Smn knockout mutation died during the peri-implantation stage. Transgenic mice harboring the human SMN-C with the Smn gene knockout showed pathological changes in spinal cord and skeletal muscle similar to SMA patients. The severity of the pathology in the knockout-transgenic mice is correlated with the amount of intact SMN protein. The knockout-transgenic mice clearly demonstrate that the SMN-T gene is responsible for SMA and should be useful in elucidating the molecular mechanisms of the SMN gene and in the design of therapeutic protocols for SMA patients.

Program Nr: 557 from the 1999 ASHG Annual Meeting

Quantitative Studies of the Fragile X Mental Retardation 1 (FMR1) Gene Product, FMRP. *A. Kenneson[1], C.H. Hagedorn[2], S.T. Warren[1]*. 1) Departments of Biochemistry, Genetics, and Pediatrics, Emory University, Atlanta, GA, and Howard Hughes Medical Institute, Atlanta, GA; 2) Department of Medicine, Emory University, Atlanta, GA.

The Fragile X Mental Retardation 1 (FMR1) protein product, FMRP, is an RNA-binding protein which is necessary for normal cognitive function, as the lack of functional FMRP results in fragile X syndrome. Within cells, FMRP shuttles between the nucleus and the cytoplasm, where it is associated with translating polyribosomes. Using purified flag-tagged murine FMRP expressed in Sf9 cells as a standard, we developed the first quantitative assay for the accurate measurement of FMRP levels. The assay is slot blot-based, and uses the anti-FMRP antibody, MAb1a. Two experiments using this assay are described here. In the first, FMRP levels in EBV-transformed human B cells were measured relative to eIF4e, the rate-limiting factor in eukaryotic translation. eIF4e levels were quantified using purified human eIF4e as a standard. The molar ratio of eIF4e:FMRP was 3.38 (se=0.09, N=8), with 2.87×10^6 (se=0.13×10^6, N=8) molecules of FMRP per cell, and 9.68×10^6 (se=0.39×10^6, N=8) molecules of eIF4e per cell. The low level of FMRP relative to other components of the translation machinery is consistent with the hypothesis that FMRP is involved in the regulation of a subset of mRNAs, rather than in global regulation of translation.

The assay was also used to quantify FMRP levels in lymphocytes isolated from peripheral blood samples. The amount of FMRP in these specimens does not vary greatly between individuals: 2.24×10^{-15} moles of FMRP per microgram of total cellular protein (se=0.13×10^{-15}, N=9). This suggests that FMRP levels are tightly regulated in lymphocytes, and raises the possibility that FMRP quantification may be performed on peripheral blood samples. The quantitative nature of this assay makes it ideal for the accurate measurement of FMRP in patients with potential reductions of FMRP levels, and in female carriers of full mutations.

Program Nr: 558 from the 1999 ASHG Annual Meeting

The peroxisome-proliferator-actived receptorg2 gene codon 12 mutation in early-onset extremely obese individuals: a gain of function mutation? *W.D. Li, J.H. Lee, R.A. Price.* Behavioral Genetics Laboratory, Department of Psychiatry, Univ Pennsylvania Medical Center, Philadelphia, PA 19104.

The Peroxisome Proliferator Activated Receptor g2 (PPARg2), a nuclear transcription regulator, is a key factor in adipocyte differentiation. Several mutations of human PPARg2 gene have been found in obese patients, some associated with lower and others with higher body mass index (BMI). **Methods:** To study the role of PPARg2 codon 12 mutations (Pro/Ala) in human obesity, we screened for sequence variants in 243 unrelated obese (BMI>27kg/m^2, including 208 extremely obese with BMI>40kg/m^2) individuals, and 157 normal weight controls (BMI<27kg/m^2) using PCR-SSCP and sequencing. We compared the mutation frequencies in obese and normal weight groups and detected associations between codon12 mutation and several obesity related phenotypes including obesity status, age of onset, fasting glucose and NIDDM. **Results:** 1) In the obese group (N=243), the frequency of codon 12 mutations (63/243, 25.93%) was higher than in normal weight (21/157, 13.38%) individuals (c^2=9.06, p=0.0026). The results remained significant when restricted to Caucasian women (c^2=5.03, p=0.0249). In all 400 obese and normal weight individuals, adjusted by age and sex, logistic regression showed an association of codon 12 and obesity affection status (odds ratio 2.3, 95% CI 1.3-3.9). 2) Among 243 unrelated obese individuals, the number of copies of the codon12 mutation predicted age of onset (Pro/Pro, 14.12±10.00; Pro/Ala, 10.15±8.41; Ala/Ala, 7.75±8.26, t=-2.719, p=0.0072). 3) The codon 12 mutation also was associated with lower fasting glucose (Pro/Pro 6.27±3.51mmol/L, Pro/Ala+Ala/Ala 4.93±1.19mmol/L, P<0.001) in the obese group. 4) A marginally significant association was found between the Pro/Pro genotype and NIDDM. **Conclusion:** The association of the PPARg2 codon12 mutation with a higher level of obesity, earlier age of onset, lower serum glucose and NIDDM are consistent with the known effects of PPAR g on adipocyte differentiation and the mediation of PPARg of thiazolidinedione (TZD) in the treatment of diabetes. Functional analysis of PPARg2 is in progress and will be reported.

Program Nr: 559 from the 1999 ASHG Annual Meeting

Genome scan identifies a locus affecting gamma globulin expression in human beta-cluster YAC transgenic mice.
S.D. Lin, P. Cooper, E.M. Rubin. Genome Science Department, Lawrence Berkeley National Lab, Berkeley, CA.

Disorders of beta-globin structure and expression represent among the most common Mendelian inherited causes of disease. Genetic factors affecting gamma-globin gene expression, a major modifier of the severity of both beta-thalassemia and sickle cell anemia, have been difficult to study in mice since the mouse has no equivalent to human gamma globin. To genetically screen for loci affecting gamma expression, we have created YAC transgenic mice containing the entire human beta-globin gene cluster, including the gamma globin gene. Since it has been shown that human gamma-globin transgenes are inactivated prenatally in mice, the 240 kb YAC transgene used for these studies contained a Greek hereditary persistence of fetal hemoglobin (HPFH) allele. The Greek HPFH allele differs from wild type by a single base G to A in the gamma promoter and results in the production of 5-10% gamma globin levels in both humans and transgenic mice into adulthood. FVB mice containing the human transgene were crossed with several different inbred strains and human gamma/beta globin ratio assessed at 10, 15, 30 and 60 days after birth in the various F1 hybrid transgenic mice. The gamma/beta globin ratio of the C3HeB/FVB hybrid transgenics was significantly elevated compared to the FVB transgenics throughout the sampling period. To map the loci involved in regulating gamma globin expression we generated 183 backcross transgenic animals. A 20 cM genome scan followed up by more densely spaced marker analysis of promising loci was performed to map loci affecting gamma globin expression. The most promising locus was mapped to a 4.4 cM interval of chromosome 1 with lod score of 4.3. Work is underway to fine map and clone this gene. Combining the transgenic modeling of a long studied disease-causing human gene cluster with quantitative trait analysis has resulted in the identification and mapping of a locus that impacts on gamma globulin expression.

Program Nr: 560 from the 1999 ASHG Annual Meeting

Search for autism susceptibility loci: genome screen follow-up and fine mapping of a candidate region on chromosome 7q. *E. Maestrini[1], International Molecular Genetic Study of Autism Consortium[2]*. 1) Wellcome Trust Centre, Univ Oxford, Oxford, England; 2) http://www.well.ox.ac.uk/~maestrin/iat.html.

Autism is a neurodevelopmental disorder with a strong genetic component, characterised by impairments in reciprocal social interaction and communication, and restricted and stereotyped patterns of interests and activities. The genetics of the disorder is complex, probably involving the action of several genes. A two-stage genome screen for autism susceptibility loci has been recently completed by the International Molecular Genetic Study of Autism Consortium (IMGSAC, 1998). In the first stage 39 families were typed with 354 markers, and in the second stage 60 additional families were typed using a subset of 175 markers that focused on the interesting regions identified in stage 1. We identified regions on 6 chromosomes (4,7,10,16,19 & 22) each with a maximum multipoint lod score (MLS) greater than 1. A region on chromosome 7q was the most significant (MLS=3.5 in the UK families subset). The second stage of the genome screen has now been completed by typing all 99 families with the collection of 354 markers. The final results confirm the previously reported findings, with the chromosome 7 locus remaining the most significant; in addition regions on chromosomes 1,2,9 & 17 have been identified with an MLS greater than 1. All regions providing an MLS greater than 1 are currently being investigated in a further set of 60 relative-pair families. Other independent studies also reported suggestive evidence of linkage in the 7q region, suggesting that this locus may have a considerable genetic effect in autism. We have further analysed the 7q region by genotyping 51 additional markers in 131 families, including 14 novel microsatellites from candidate genes. The new data provided further support for linkage with an MLS of 4.45 in all families. Linkage disequilibrium mapping is currently being carried out with microsatellite and single nucleotide polymorphism markers using the transmission disequilibrium test. Preliminary evidence of association will be presented. Candidate genes which map close to the linkage peak are also currently being screened for mutations in autistic patients.

Program Nr: 561 from the 1999 ASHG Annual Meeting

Co-localization of CBP with expanded polyglutamine-containing androgen receptor. *A.R.V. McCampbell[1], A.A. Taye[1], J.L. Walcott[3], D.E. Merry[2], K.H. Fischbeck[1].* 1) Neurogenetics Branch, NINDS, Bethesda, MD; 2) Department of Neurology, University of Pennsylvania, Philadelphia, PS; 3) Department of Pharmacology, University of Pennsylvania, Philadelphia, PA.

Spinal and bulbar muscular atrophy is a neurodegenerative disorder caused by a polyglutamine expansion in the androgen receptor (AR). At least seven other disorders, including several spinocerebellar ataxias and Huntingtons disease, share this type of mutation. A pathological hallmark of these diseases is the formation of intranuclear inclusions. These inclusions are thought to be seeded by the polyglutamine-containing portion of the mutated gene product. While the specific role of the inclusions remains controversial, nuclear localization of the mutant protein has been implicated in the neuronal toxicity of expanded polyglutamines. This has prompted our search for nuclear factors whose disruption could be detrimental to the cell. Recent work has demonstrated that the CREBbinding protein (CBP) interacts with normal androgen receptor. CBP, an important mediator in multiple signaling pathways, may be present in limiting quantities. Given that CBP interacts with the N-terminal region of the androgen receptor and its importance in intracellular signaling, we have looked at the distribution of CBP in cells expressing truncated forms of the androgen receptor with varying lengths of polyglutamine repeats. In a mouse motoneuronneuroblastoma fusion cell line, those cells with intranuclear inclusions showed a redistribution of CBP to the inclusion. Similar results were obtained in transgenic mice expressing the same AR constructs driven by the PRP promoter. These data suggest that CBP sequestration by expanded polyglutamine-containing AR may be a mechanism of neuronal toxicity in this disease.

Program Nr: 562 from the 1999 ASHG Annual Meeting

Localization of DNA replication origins at human triplet repeat loci by Kinetic PCR. *T. Nenguke, N. Arnheim.* Molecular Biology, 'Univ Southern California, Los Angeles, CA.

Instability of trinucleotide repeats is believed to be due to their ability to form unusual DNA structures, possibly during DNA replication. Triplet repeats cloned into bacterial plasmids have been shown to stall replication forks most likely by formation of secondary structures in a manner dependent on the orientation of the repeat tract with respect to an origin of DNA replication. Studies in yeast have shown that instability of trinucleotide repeat tracts is also orientation dependent. We have set out to correlate the positions and proximities of origins of DNA replication with respect to the wide range of instabilities observed in the different human trinucleotide repeat diseases. DNA from unsynchronized human tissue culture cells was isolated and short nascent strands (0.5-1.5 kb) were obtained by extrusion, followed by neutral-sucrose gradient centrifugation and agarose gel electrophoresis. This nascent DNA was subsequently used as template for Kinetic PCR using primer pairs set at uniform intervals throughout the candidate region. Kinetic PCR can quantitate the number of starting template molecules for each target region. The primer pairs giving the largest amount of PCR product must be close to an origin of DNA replication. We were able to quantitate the accumulation of PCR product for primer pairs covering non-repetitive sequences in a 40 kb human genomic sequence which includes the HD gene. To date we have localized an origin of replication at the HD gene locus close to the triplet repeats. Studies to localize the position of replication origins and the orientation of the triplet repeats at several other disease loci are currently underway.

Program Nr: 563 from the 1999 ASHG Annual Meeting

Effects of FBN2 mutations on fibrillin-1 deposition in the extracellular matrix of CCA fibroblast cell strains. *E.A. Putnam[1], I. Kaitila[2], D.M. Milewicz[1]*. 1) Dept Internal Med/Div Med Gen, Univ Texas Medical Sch, Houston, TX; 2) Helsinki Univ Central Hosp, Finland.

Congenital contractural arachnodactyly (CCA) is an autosomal dominant disorder similar to Marfan syndrome (MFS). CCA results from mutations in FBN2 encoding fibrillin-2 (fib-2), while MFS results from mutations in FBN1 encoding fibrillin-1 (fib-1). Both proteins are found in 10-12 nm microfibrils in the extracellular matrix (ECM), but it is unknown if fib-2 and fib-1 are found in heterogeneous microfibrils, or if the proteins segregate to individual microfibrils. Dermal fibroblast cell strains were used to examine the effect of a FBN2 mutation on fib-containing microfibril deposition, even though this cell type produces primarily fib-1. A fibroblast cell strain was analyzed, containing an unusual deletion/insertion mutation in the genomic DNA of a patient with classic familial CCA. This mutation resulted in the replacement of exon 24 by exon 23 in the mRNA, predicting the replacement of the 8-cysteine domain by an EGF-like domain. Pulse-chase analysis of the fib produced by the patient fibroblast strain demonstrated that normal amounts of fib were synthesized, secreted, and processed by these cells, but that there was a decrease in fib deposition into the ECM. Similar results were obtained from the analysis of cells established from the patient's affected father. Immunoprecipitation analysis using antibodies specific for fib-1 and fib-2 showed approximately 40 times more fib-1 produced than fib-2. Using fib-1 specific antibodies, immunofluorescence analysis of the mutant cell strains confirmed that the amount of fib-1 containing microfibrils was reduced compared to control cells, similar to results from MFS cell strains. Pulse-chase analysis of 7 other CCA fibroblast strains with different characterized FBN2 mutations showed decreased fib-1 ECM deposition in 5 of these strains. These results demonstrate that FBN2 mutations have an effect on fib-1 deposition into the ECM, indicating that fib-1 and fib-2 interact to form microfibrils. The similarities in CCA and MFS phenotypes may result from disruption of fib-1 microfibrils by mutant fib-2.

Program Nr: 564 from the 1999 ASHG Annual Meeting

Clinical and pathologic characterization of epilepsy in patients with monosomy 1p36, and the search for candidate genes. *S.K. Shapira, H.A. Heilstedt, D.E. Starkey, D.L. Burgess, A.K. Chedrawi, A.E. Anderson, B. Tharp, C.L. Carrol, D. Armstrong, Y.-Q. Wu, J.L. Noebels, L.G. Shaffer.* Baylor College of Medicine, Houston, TX.

Monosomy 1p36 is a recently recognized chromosomal deletion syndrome with a spectrum of clinical features, including hypotonia, psychomotor retardation, and seizures. These neurologic features of the syndrome often lead to the initial cytogenetic evaluation. In the current study, an extensive clinical evaluation was performed on 21 patients with monosomy 1p36, in which most had a neurologic exam, EEG, brain MRI scan, and molecular delineation of the deletion size. All patients had hypotonia and developmental delay, and 95% (20/21) had moderate-to-severe mental retardation. Seizures occurred in 48% of patients (10/21) and epileptiform abnormalities on EEGs were present in 37% (7/19). Brain MRI scans showed leukoencephalopathy in 76% of patients (13/17). Postmortem neuropathologic evaluation in one case demonstrated extensive neuronal and glial heterotopias, and polymicrogyria. To evaluate for the molecular basis of epilepsy in these patients, the candidate gene approach was used. Recent studies indicate that mutations in some potassium (K^+) channel genes result in susceptibility to epilepsy or other neurologic abnormalities. The K^+ channel b subunit gene, *KCNA2B,* which has sequence homology to the *Shaker* subfamily of *Drosophila* voltage-gated K^+ channel genes, had been previously localized to 1p36. PCR primers based on the $3^{'}$ untranslated region of human *KCNA2B* were used to screen a BAC library, yielding one positive clone. Evaluation of this BAC by STS content mapping showed that it also contained marker D1S2633, thus placing *KCNA2B* on the physical map. FISH analysis of lymphoblastoid cell lines with the BAC DNA, demonstrated that *KCNA2B* was deleted in 5 of the 19 patients studied by EEG; all 5 had epileptiform EEGs and seizures. Two patients with epileptiform EEGs who were not deleted for the BAC are under further investigation for candidate loci. These results suggest a strong correlation between deletion of *KCNA2B* and epileptiform abnormalities on EEGs in patients with monosomy 1p36.

Program Nr: 565 from the 1999 ASHG Annual Meeting

A potential autism susceptibility marker on chromosome 15 includes a genomic deletion at D15S822. *J.S. Sutcliffe[1], E.L. Nurmi[1], J.L. Haines[1], J. Piven[2], S.E. Folstein[3], and the Collaborative Linkage Study of Autism[1,2,3]*. 1) Program in Human Genetics, Vanderbilt Univ Medical Center, Nashville, TN; 2) UNC Developmental Disabilities Research Center, Charlotte, NC; 3) New England Medical Center, Boston, MA.

Autism is a neurodevelopmental disorder characterized by deficits in social interaction and language development and repetitive or stereotyped behaviors. Neurological findings may include mental retardation, epilepsy, hypotonia, motor sterotypies such as hand flapping, and self-injurious behaviors. While autism has a complex etiology, evidence from twin and family studies indicates a strong genetic component. Chromosome 15q11-q13 is implicated in autism based on observations of chromosomal duplications and evidence for linkage and increased recombination in the autistic population. Screening for autism susceptibility loci in multiplex families by the Collaborative Linkage Study of Autism (CLSA) project identified several instances of informative null alleles at marker D15S822 in a region where linkage and excess recombination have been detected. Southern analysis at the marker locus revealed common variant fragments, consistent with deletion junctions, in all individuals with null alleles. PCR amplification and sequence analysis of a deletion-specific fragment indicates the deletion is ~5-kb and identical in unrelated individuals. To determine whether the deletion has any statistical relevance to autism, a duplex PCR assay was developed to amplify deleted and nondeleted chromosomes, and this was applied to the CLSA multiplex and simplex autism patient set and controls. The null allele frequency in unrelated individuals was 10/545 (1.8%) chromosomes in the autism population and 2/606 (0.3%) in unrelated control chromosomes, with $p = 0.017$, suggesting it is a potential susceptibility marker in the autism population. It is unclear whether this deletion has a functional effect on any gene, although BLAST analysis identified multiple ESTs representing three exons encoding an apparently novel gene located 8 kb from the deletion. Northern analysis reveals expression of a moderate-abundance, testis-specific transcript of 1 kb.

Program Nr: 566 from the 1999 ASHG Annual Meeting

Early onset Non Insulin Dependent Diabetes Mellitus (NIDDM) - a link with paternal duplication of 6q24 and Transient Neonatal Diabetes Mellitus (TNDM). *I.K. Temple[1], R.J. Gardner[2], D.J.G. Mackay[2], D.O. Robinson[2], G. Valerio[3], A. Franzese[4], J.C.K. Barber[2], J.P.H. Shield[5]*. 1) Wessex Clinical Genetics Service, Princess Anne Hospital, Southampton, Hampshire, UK; 2) Wessex Regional Genetics Laboratory, Salisbury Health Care NHS Trust, Salisbury, UK; 3) Department of Pediatrics, University of Udine Medical School, Udine, Italy; 4) Department of Pediatrics, University Frederico 11, Naples, Italy; 5) Department of Child Health, Institute of Child Health, Bristol, UK.

Transient Neonatal Diabetes Mellitus (TNDM) is a rare disorder with an incidence of 1 in 400,000. The gene has been mapped to chromosome 6q24 and is predicted to be imprinted. We have performed a clinical and molecular study of 30 patients with TNDM and their relatives. We were able to divide the patients into three aetiological groups and no significant clinical differences were demonstrated between them:- Group 1 : Paternal uniparental isodisomy of chromosome 1 was found in 11 cases (37%). There was no significant family history. Group 2: A paternal duplication of chromosome 6q24 was present in a further 11 patients (37%)and accounted for all familial cases. Two relatives from two pedigrees were found to have developed type 2 diabetes; a paternal cousin during her first pregnancy and a sibling in his teenage years. Neither individual had an early history of TNDM. Both were shown to carry a paternally inherited 6q duplication. It was demonstrated using fluorescent PCR, was not visible using standard cytogenetic techniques and was apparently identical to that found in the proband. Group 3: In 8 TNDM patients no molecular anomaly has yet been demonstrated. NIDDM was reported in 4 maternal grandparents. This represents the largest cohort of TNDM patients to be studied and the molecular cause was determined in 74% of cases. The findings of early onset NIDDM in relatives of TNDM patients broadens the clinical spectrum of the disorder. It also lends support to the possibility that the gene for TNDM may have implications for more common types of diabetes.

Program Nr: 567 from the 1999 ASHG Annual Meeting

Mutations in a novel gene encoding a RBCC protein underlie Mulibrey Nanism. *K. Avela[1], N. Idänheimo[1], M. Lipsanen-Nyman[2], E. Seemanová[3], S. Rosengren[4], J. Perheentupa[2], A. de la Chapelle[5], A.-E. Lehesjoki[1]*. 1) Folkhälsan Institute of Genetics and Department of Medical Genetics, University of Helsinki, 00280 Helsinki, Finland; 2) Childrens Hospital, University of Helsinki, 00290 Helsinki, Finland; 3) Institute of Biology and Medical Genetics, 2nd Medical School, Charles University, 150 06 Prague-Motol, Czech Republic; 4) Childrens Hospital, Connecticut, USA; 5) Division of Human Cancer Genetics, Department of Medical Microbiology and Immunology, Comprehensive Cancer Center, Ohio State University, Columbus, Ohio 43210, USA.

Mulibrey Nanism (MUL; MUscle-LIver-BRain-EYe Nanism; MIM 253250) is an autosomal recessive disorder in which the clinical presentation is pleiotropic involving multiple tissues of mesodermal origin. Typical clinical features include growth failure of prenatal onset, dysmorphic features, constrictive pericardium with consequent hepatomegaly, yellowish dots in the ocular fundi, and a J-shaped sella turcica. The incidence of MUL is highest in Finland, and the reported non-Finnish MUL patients are mostly sporadic cases. We have previously assigned the MUL gene by linkage and linkage disequilibirium analysis to chromosome 17q and constructed a physical contig of bacterial clones over the critical MUL region. Here we report the identification of the MUL gene using a positional candidate gene approach. We have identified four different mutations in a gene that encodes a novel RBCC protein. Our data indicate that mutations in this novel gene cause the multi-organ phenotype, MUL.

Program Nr: 568 from the 1999 ASHG Annual Meeting

Multiple *CYP1B1* mutations and incomplete penetrance in an inbred population segregating Primary Congenital Glaucoma suggest frequent *de novo* events and a dominant modifier locus. *B.A. Bejjani[1], D.W. Stockton[1], R.A. Lewis[1,2], K.F. Tomey[2], D.K. Dueker[2], M. Jabak[2], W.F. Astle[2], J.R. Lupski[1]*. 1) Baylor College of Medicine, Houston, TX; 2) King Khaled Eye Specialist Hospital, Saudi Arabia.

Primary Congenital Glaucoma (PCG) is an autosomal recessive disorder caused by unknown developmental defect(s) of the trabecular meshwork and anterior chamber angle. Recently, we reported three distinct mutations in *CYP1B1*, the gene for cytochrome P4501B1, in 25 Saudi families segregating PCG. In this report 37 additional families were analyzed and the initial finding of decreased penetrance confirmed. Mutations and intragenic single nucleotide polymorphisms (SNPs) were also analyzed after direct sequencing of *CYP1B1* coding exons. Eight distinct mutations were identified: G61E, R469W, and D374N, the most common Saudi mutations, account for 72%, 12% and 7% of the PCG chromosomes, respectively. Five additional homozygous mutations (two deletions and three missense mutations) were detected, each in a single family. Affected individuals from 5 families had no *CYP1B1* coding region mutations, and each had a unique SNP profile. The identification of eight distinct mutations in a single gene, against at least four distinct haplotypes, suggests a relatively recent occurrence of multiple mutations in *CYP1B1* in Saudi Arabia. The data presented demonstrate decreased penetrance for the PCG phenotype in the Saudi population, because 38 apparently unaffected individuals from 20 families, two of whom were subsequently diagnosed with glaucoma, have mutations and haplotypes identical to their affected siblings. Two other individuals had abnormal ocular findings that are consistent with glaucoma. Analysis of these 20 kindreds suggests the presence of a dominant modifier locus that is not genetically linked to *CYP1B1*. Linkage and Southern analyses excluded a number of functional candidate modifier loci.

Program Nr: 569 from the 1999 ASHG Annual Meeting

Functional characterization of the Opitz syndrome gene product (midin): evidence for homodimerization and association with microtubules throughout the cell cycle. *S. Cainarca, S. Messali, A. Ballabio, G. Meroni.* Telethon Inst Genetics & Med, Milan, Italy.

Opitz syndrome (OS) is a multiple congenital anomaly manifested by abnormal closure of midline structures. The gene responsible for the X-linked form of this disease, MID1, encodes a protein (midin) that contains a RING, two B-boxes, a coiled-coil (the so-called tripartite motif) and an RFP-like domain. The tripartite motif is characteristic of a family of proteins, named the B-box family, involved in cell proliferation and development. Since the subcellular compartmentalization and the ability to form multiprotein structures both appear to be crucial for the function of this family of proteins, we have studied these properties on the wild-type and mutated forms of midin. We found that endogenous midin is associated with microtubules throughout the cell cycle, colocalizing with cytoplasmic fibers in interphase and with the mitotic spindle and midbodies during mitosis and cytokinesis. Consistent with the evidence obtained by gel filtration analysis, immunoprecipitation experiments demonstrated the ability of the tripartite motif to mediate midin homodimerization, showing that midin exists in the form of large protein complexes. Single domain deletions revealed the coiled-coil as essential for homo-interactions while the other domains are probably necessary to mediate interaction with proteins other than midin. Preliminary data suggest that hetero-interaction can occur with members of the B-box family and with other proteins identified through a two-hybrid screening. Functional characterization of altered forms of midin, resulting from mutations found in OS patients, revealed that association with microtubules is compromised, while the ability to homodimerize and form multiprotein complexes is retained. We suggest that midin is involved in the formation of multiprotein structures acting as anchor points to microtubules and that impaired association with these cytoskeletal structures causes Opitz syndrome developmental defects.

Program Nr: 570 from the 1999 ASHG Annual Meeting

Identification and characterization of 4 large (1.4 kb-39 kb) deletions in TSC2 using long range PCR suggests diverse deletion mechanisms. *S.L. Dabora[1,2,3], D. Franz[4], S. Jozwiak[5], D.J. Kwiatkowski[1,2,3]*. 1) Div. of Hematology, Brigham & Women's Hospital, Boston, MA; 2) Dept. of Adult Oncology, Dana-Farber Cancer Institute, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Div. of Pediatric Neurology, Children's Hospital medical Center, Cincinati, OH; 5) Dept. of Child Neurology, Children's Memorial Hospital, Warsaw, Poland.

Large deletions ranging in size from several hundred base pairs to over 100 kb account for an estimated 20% of all TSC2 mutations (Jones et al., 1999; Am. J. Hu. Gen. 64:1305-1315). We have developed a long range PCR-based method for detecting large deletions in TSC2 to avoid the limitations and difficulties associated with Southern blotting, pulsed-field gel electrophoresis and fluorescence in-situ hybridization analysis . A series of PCR primers were designed such that 13 overlapping genomic segments of the TSC2 gene are amplified, ranging in size from 2.6 kb to 12.7 kb. Agarose gel electrophoresis is then used to detect deletions. Additional PCR reactions are performed using subsets of these primers such that a single forward primer 5 to the first exon is combined with a collection of 6 reverse primers spanning the TSC2 genomic region and located between 15 kb and 40 kb from the forward primer. In this nested, multiplex reaction, amplification occurs only in the presence of a large deletion in TSC2. This series of 14 PCR reactions have been used to screen 50 TSC patient samples (partially screened for small mutations in TSC1 and TSC2) and large deletions have been detected in 4 of these. The deletions range in size from 1.4 kb to 39 kb and the deletion junctions of each have been sequenced. In one case, Alu-mediated recombination appears to be the mechanism of deletion. In the second case, there is a 3 base pair sequence shared at the deletion junction which may have led to illegitimate recombination. In the last two cases, there is no homology at the deletion junctions. In one of these a 10 bp duplication of the end sequence occurred. In the other, 6 random bases were inserted at the deletion junction. We are extending this analysis using additional primer combinations.

Program Nr: 571 from the 1999 ASHG Annual Meeting

Genetic evidence for cooperative interaction of polycystins 1 and 2, which are mutated in polycystic kidney disease (ADPKD). *C.C. Deltas[1], R. Mean[1], G. Kyriakides[2], M. Hadjigavriel[2], K. Demetriou[3], A. Pierides[3], M. Koptides[1].* 1) Dept Molecular Genetics, Cyprus Inst Neurology & Gen, Nicosia, Cyprus; 2) Paraskevaidion Surgical and Transplantation Center; 3) Dept of Nephrology, Nicosia General Hospital, Nicosia, Cyprus.

Mutations in the PKD1 and PKD2 genes are responsible for adult onset ADPKD1 or 2. The gene products, polycystins 1 and 2, are membranous glycoproteins with extracellular and short cytoplasmic domains. The large extracellular domain of polycystin 1 is predicted to act as a receptor to an unknown ligand which transmits signals from the extracellular environment to the cell. A downstream effect may be the opening of a Ca++ ion channel, polycystin 2. Previously, we showed that focal cyst formation in ADPKD2 may be the result of somatic mutations which inactivate the wild type allele of polycystin 2 (Koptides et. al, 1999, Hum Mol Genet 8: 509-513). Here, we investigated the hypothesis that renal epithelial cells of a patient with ADPKD1, become cystic because of the occurrence of somatic mutations in either the PKD1 or the PKD2 gene. By linkage analysis we showed that ADPKD in family CY1609 was due to a germinal mutation in the PKD1 locus. During a transplant operation of a patient, one kidney was resected and used for further experimentation. We isolated DNA from epithelial cells lining the inner wall of 23 large well separated cysts. We tested the PKD1 and the PKD2 genes for loss of heterozygosity (LOH) using flanking and intragenic markers, and for mutations using the SSCP screening method. LOH was detected in a single cyst for the wild type PKD1 gene with marker SM6. Screening of the PKD2 gene revealed that three cysts had the same mutation we had reported previously (197-203insC). Also, three other cysts showed unique SSCP variants that are presently under investigation. Our data support the hypothesis that somatic mutations in either PKD gene can trigger cyst formation on the background of an inherited PKD1 defect. Also, we suggest that regulation of normal kidney development requires that polycystins 1 and 2 are present at a minimum threshold level. Funded by the Cyprus Kidney Association and CYPRUS TELETHON 98.

Program Nr: 572 from the 1999 ASHG Annual Meeting

Gene targeting of dystrophin Dp260 isoform. *R. Gaedigk[1], K.M. Fitzgerald[1], S.A. Giambrone[1], G.W. Cibis[1], D.M. Pinson[2], W.J. Brunken[3], R.A. White[1].* 1) Genetics, The Children's Mercy Hospital, Kansas City, MO; 2) Department of Pathology, Univ. of Kansas School of Medicine, Kansas City, KS; 3) Massachusetts General Hospital and Harvard Medical School, Charlestown, MA.

Dystrophin is the largest identified human gene and spans at least 2.4 Mb on chromosome Xp21. It is known to be differentially expressed. Several isoforms have been identified with at least seven different promoters regulating transcription. The Dp260 isoform is preferentially expressed in retina and to lower amounts in most other tissues. Dp260 includes a specific first exon located at the 3' end of intron 29. An abnormal electroretinogram (ERG) observed in boys with Duchenne muscular dystrophy (DMD) is thought to be caused by a lack of Dp260. To learn more about the function of this isoform we performed a knockout experiment by replacing this specific R1 exon with the neomycin gene without interrupting the reading frame of the full length Dp427 as well as the remaining dystrophin isoforms Dp140, Dp116 and Dp71. A pathological analysis of the generated Dp260 deficient mice showed no identifiable phenotypic abnormality in kidney, liver, spleen, testis, brain, lung, muscle, heart, GI tract and bone. However, electroretinogram recordings on Dp260 knock-out mice resulted in increased b-wave implicit time in Dp260-null mice. ERG analyses were also performed for normal, *mdx*, and *mdx*^{Cv3} mice. Neither the Dp260-null or *mdx*^{Cv3}mice demonstrate the negative ERG phenotype seen in boys with DMD. This could represent a difference in retinal circuitry between species. The dystrophin isoform Dp260 is responsible in part for the abnormal ERGs seen in DMD. Immunohistochemistry of the retina of Dp260 deficient mice will provide further insight into the function of this isoform. ^{Cv3}.

Program Nr: 573 from the 1999 ASHG Annual Meeting

Desmin gene mutations in myofibrillar myopathy. *L.G. Goldfarb, K.-Y. Park, C. Semino-Mora, H.-S. Lee, S. Litvak, K. Sivakumar, M.C. Dalakas.* Clinical Neurogenetics Unit and Neuromuscular diseases section, MNB/NINDS/NIH, Bethesda, MD 20892.

Myofibrillar myopathy has been defined as amorphous accumulation of myofibrillar proteins in the sarcoplasm of muscle fibers. The disease is expressed as proximal and distal limb muscle weakness combined in some cases with cardiac conduction blocks, arrhythmias and congestive heart failure. Most patients show familial autosomal dominant or autosomal recessive patterns of inheritance, and a significant number of patients are sporadic. We report data on ten patients from four families and two sporadic cases of myopathy associated with pathogenic mutations in the desmin gene. The A337P mutation was identified in two siblings with late-onset skeletal myopathy and mild cardiac involvement. A heterozygous R406W mutation was present in a sporadic case with early-onset and relentlessly progressive skeletal and cardiac myopathy. Compound heterozygosity for two mutations, A360P and N393I, was detected in three siblings with extremely aggressive childhood-onset cardiomyopathy. Heterozygosity for N342D and I451M mutations was found in two families with relatively late onset of skeletal myopathy and no cardiac pathology. Finally, a splicing defect with deletion of the entire exon 3 was identified in a sporadic patient with slowly progressive cardiac and skeletal myopathy. None of these mutations was present in unrelated control individuals. Expression studies demonstrated inability of the mutated desmin to construct a filament network.

Program Nr: 574 from the 1999 ASHG Annual Meeting

Positional cloning of the gene responsible for Limb Girdle Muscular Dystrophy 1A. *M.A. Hauser[1], P. Salmikangas[2], S.K. Horrigan[3], K.D. Viles[1], U.M. Torian[1], U. Taivainen[2], L. Bartoloni[4], J.M. Stajich[1], P.C. Gaskell[1], J.R. Gilbert[1], C.A. Westbrook[4], J.M. Vance[1], M.A. Pericak-Vance[1], O. Carpén[2], M.C. Speer[1].* 1) Duke University Medical Center, Durham, NC; 2) University of Helsinki, Helsinki, Finland; 3) Georgetown University, Washington DC; 4) University of Illinois at Chicago, Chicago, IL.

We have positionally cloned the gene responsible for an autosomal dominant form of Limb Girdle Muscular Dystrophy (LGMD1A). We have previously reported a large North American family of German descent in which this adult onset disease is segregating. Symptoms include progressive weakness of the hip and shoulder girdles, as well as a distinctive dysarthric pattern of speech. Antibody staining shows that the dystrophin-associated glycoprotein complex is normal in muscle from these patients, indicating that the defect in LGMD1A involves a pathway that is entirely distinct from that of the autosomal recessive LGMD2 families. After linking LGMD1A to a region of about 2 megabases on 5q31, we identified a candidate gene that is expressed primarily in skeletal muscle. Analysis of cDNA sequence revealed this gene to be identical to myotilin, a novel sarcomeric protein that we have recently described. The amino terminus of myotilin is unique, whereas the carboxy teminus contains immunoglobulin-like domains that are homologous to titin. Myotilin is expressed in skeletal and cardiac muscle, and co-localizes with a-actinin. Yeast two-hybrid analysis indicates that the first 150 amino acids of myotilin interact with a-actinin. Initial characterization of this transcript has supported its involvement in the pathogenesis of LGMD1A. We have identified a C®T missense mutation in affected individuals that results in the conversion of threonine 57 to isoleucine. This change is present in all of the affected individuals that have been examined, yet has not been detected in 410 normal chromosomes. The effects of this alteration upon binding to a-actinin are under investigation. An additional base change in the 3' untranslated region also co-segregates with the disease. Mutation screening in additional unlinked autosomal dominant LGMD families is underway.

Program Nr: 575 from the 1999 ASHG Annual Meeting

Germline origins in the human factor IX gene: frequent somatic mosaicism with GC to AT. *R.P. Ketterling[1], J.B. Drost[2], X. Li[2], A. Mengos[2], C.K. Kasper[3], S.S. Sommer[2].* 1) Biochem/Molecular Biol, Mayo Clinic/Fdn, Rochester, MN; 2) Dept of Molecular Genetics, City of Hope Natl Med Cntr, Duarte, CA; 3) Orthopaedic Hospital, Los Angeles, CA.

The factor IX gene is advantageous for analyzing spontaneous germline mutations in humans. For 91 origin individuals (56 females and 35 males), the sequence of the leukocyte DNA was visualized directly by genomic sequencing for the presence or absence of the causative mutation. Somatic mosaicism was detected in 11 percent (7 females and 3 males) of these individuals with an estimated sensitivity of one mutant copy to 20 normal copies. Six of the ten defined somatic mosaics had GC to AT transitions at non-CpG dinucleotides. The preferentially embryonic occurrence of this *F9* mutation type over all other types (p=0.0024, Fishers Exact Test) may be responsible for its relatively more frequent observation as a causative mutation in the *F9* gene. In addition, since mutations occurring earlier in development have a higher probability of being inherited from the individual and, consequently, fixed in a population, this observation may help explain the AT mutational pressure (independent of CpG methylation-mediated transitions) which has maintained a GC content of 40 percent in the *F9* gene.

Program Nr: 576 from the 1999 ASHG Annual Meeting

Mutational analysis of a cohort Leber Congenital Amaurosis families. *R.A. Lewis[1], E.B. Abboud[2], A. Al-Rajhi[2], M. Leppert[3], J.R. Lupski[1], D.W. Stockton[1]*. 1) Baylor College of Medicine, Houston, TX; 2) King Khaled Eye Specialist Hospital, Kingdom of Saudi Arabia; 3) University of Utah, Salt Lake City, UT.

Leber Congenital Amaurosis (LCA) is known to be a clinically and genetically heterogeneous autosomal recessive retinal dystrophy and the most common genetic cause of congenital visual impairment in infants and children. Profound visual loss, characteristic behaviors, and markedly diminished electroretinograms typify the disorder. Mutations in two genes have been identified that cause recessive LCA, and a third gene has been associated with a sporadic or possibly dominant form. The first is in a retina-specific guanylate cyclase on chromosome 17p13, the second is the gene for a retinal pigment epithelium-specific protein, RPE65, on chromosome 1p31, and the third is the gene *CRX*, an OTX-like transcription factor on chromosome 19q13. Mutational screening of 45 multiplex families segregating recessive LCA and 4 families with a single affected member was evaluated at the three loci by direct DNA sequencing from intronic primers flanking the coding exons of each gene with standard techniques. Mutations were identified in only 8 (16%) of the families analyzed. The known heterogeneity of LCA is thus documented further. If these identified genes represent the most substantial contributions to this complex disease phenotype, we may expect more than 20 additional genes will be identified.

Program Nr: 577 from the 1999 ASHG Annual Meeting

Sjögren-Larsson syndrome: mutation analysis of the fatty aldehyde dehydrogenase gene in 60 probands. *Z. Lin, G. Carney, W.B. Rizzo.* Pediatrics and Human Genetics, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA.

Sjögren-Larsson syndrome (SLS) is an autosomal recessive disorder characterized by ichthyosis, mental retardation and spastic diplegia or tetraplegia. The disease is caused by mutations in the gene encoding fatty aldehyde dehydrogenase (FALDH), an enzyme that is necessary for oxidation of long-chain aliphatic aldehydes. To determine the genetic basis for SLS, we performed mutation analysis on 60 SLS probands from throughout the world. All patients were confirmed to have deficient FALDH enzyme activity in cultured skin fibroblasts. Mutations were detected by sequencing FALDH exons amplified by PCR from genomic DNA or by RT-PCR using fibroblast RNA. Among the SLS probands, 47 different mutations were detected including 10 deletions, 2 insertions, 21 missense mutations, 3 nonsense mutations, 3 complex deletion/substitutions, and 8 splice-site mutations. In addition, 4 single nucleotide polymorphisms (SNPs) (3 intronic and 1 exonic silent polymorphism) were found and their allele frequencies determined. Thirty-four of the mutations were private and the remaining mutations were carried by more than one proband. Haplotype analysis using the SNPs indicated that at least 3 of the common mutations (233G>A; 682C>T; 798+1delG) arose independently on multiple occasions. All of the splice-site mutations led to exon skipping or utilization of cryptic splice sites. The amino acid substitutions were distributed throughout the FALDH protein. Most of these mutations caused a profound reduction of enzyme catalytic activity when overexpressed in mammalian cells, but one mutation (798G>C) that altered the last nucleotide in exon 5 appeared to have a greater affect on mRNA stability. Our results indicate that SLS is caused by a variety of mutations, which will provide a framework for DNA diagnosis and understanding the correlation between structural and functional alterations in the enzyme.

Program Nr: 578 from the 1999 ASHG Annual Meeting

The *GJB3* gene also underlies non-syndromic recessive deafness. *X.Z. Liu[1,2], X.J. Xia[1], L.R. Xu[3], A. Pandya[1], C.Y. Liang[3], S. Blanton[1], K.P. Steel[4], S.D.M. Brown[5], W.E. Nance[1].* 1) Dept. of Human Genetics; 2) Dept. of Otolaryngolgoy, Medical Col of Virginia/VCU, Richmond, VA.USA; 3) Dept. of Otolaryngology, West China Univ of Medical Sciences, Chengdu, China; 4) MRC Institute of Hearing Research, Nottingham, UK; 5) MRC Mammalian Genetics Unit, Harwell, UK.

Mutations in the *GJB3* gene (Cx31) can cause a dominant non-syndromic form of hearing loss (DFNA2). To determine whether mutations at this locus can also cause non-syndromic recessive deafness, we screened 25 Chinese families with recessive deafness and identified affected individuals in two families who were compound heterozygous Cx31 mutations. The three affected individuals in the two families were born to non-consanguineous parents and had an early onset deafness. In the both families, differing SSCP patterns for the PCR of primer 3FR were observed in affected and unaffected individuals. Sequence analysis in the both families demonstrated an in-frame 3-bp deletion (423-5delATT) in one allele, which leads to the loss of an isoleucine residue at codon 141, and a 423A ® G transversion in the other allele, which creates an isoleucine-to-valine substitution at codon 141 (I141V). Neither of these two mutations was detected from 100 unrelated control subjects. The altered isoleucine residue lies within the third conserved a-helical transmembrane domain (M3), which is critical for the formation of the wall of the gap junction pore. This residue is conserved in mouse Cx31 and rat Cx31, whereas the other b-type connexins contains a phenylalanine at this position. Both the deletion of the isoleucine residue 141 and its substitution to valine in the two families could alter the structure of M3, and impair the function of the gap junction. We propose that mutations in families with dominant Cx31 mutations should have a dominant negative effect, since the normal hearing status of heterozygous carriers in our two recessive families provided no evidence that haploinsufficiency is a plausible alternative. The present data demonstrate that like Cx26, Cx31 can lead to both recessive and dominant non-syndromic forms of deafness. Work supported by the Jeffress Research Grant J-523, the Defeating Deafness, and NIHR01 grant-DC02530.

Program Nr: 579 from the 1999 ASHG Annual Meeting

Mutations in COL11A2 alter the structure of the tectorial membrane causing nonsyndromic hearing loss at the DFNA13 locus. *W.T. McGuirt[1], S.D. Prasad[1], A.J. Griffith[2], D.H. Kunst[3], K.B. Shpargel[2], R.F. Mueller[4], H.G. Brunner[3], C.W.R.J. Cremers[3], G.V. Camp[5], R.J.H. Smith[1].* 1) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa; 2) National Institute on Deafness and Other Communication Disorders, NIH; 3) Department of Otorhinolaryngology, University Hospital, Nijmegen The Netherlands; 4) Department of Clinical Genetics, St James's Hospital, Leeds, UK; 5) Department of Genetics, University of Antwerp, Belgium.

Inherited hearing impairment most often presents without other associated features and is referred to as non-syndromic hearing loss (NSHL). These losses are further classified by mode of inheritance (DFNA, dominant; DFNB, recessive; DFN, X-linked), using an integer suffix to specify hearing loss loci in order of discovery. To date, 26 autosomal dominant non-syndromic sensorineural hearing loss (ADNSHL) loci have been mapped (DFNA1-26) and nine ADNSHL genes have been cloned. This report describes mutations in a specific collagen gene, COL11A2, in two large families with ADNSHL at the DFNA13 locus. Mutations in COL11A2 have been associated with a spectrum of phenotypes that typically include midface hypoplasia, cleft palate, precocious arthritis and sensorineural hearing loss. The presence of isolated hearing loss in the described families represents the mildest phenotype associated with COL11A2 mutations. Additionally, we identified a COL11A2 mutation that produces a premature stop codon in an individual with a severe recessive form of otospondylomegaepiphyseal dysplasia (OSMED). Evaluation of the Col11a2 mouse mutant by auditory brainstem response testing demonstrates moderate-to-severe hearing loss. Col11a2 was localized to the otic capsule, spiral limbus, lateral wall of the cochlea, and saccular and utricular maculae by in situ hybridization. Histologic analysis of the cochlea in this mouse model revealed widely disorganized collagen fibrils in the tectorial membrane by electron microscopy. This result is consistent with the proposed role of COL11A2 in controlling interfibrillar spacing.

Program Nr: 580 from the 1999 ASHG Annual Meeting

A novel zinc finger gene in 8q24.1 is mutated in patients with tricho-rhino-phalangeal syndrome type I. *P. Momeni[1], G. Gloeckner[2], O. Schmidt[1], A. Rosenthal[2], B. Horsthemke[1], H.-J. Lüdecke[1]*. 1) Institut für Humangenetik, Universitätsklinikum, Essen, Germany; 2) Abteilung Genomanalyse, Institut für Molekulare Biotechnologie, Jena, Germany.

The tricho-rhino-phalangeal syndrome type I (TRPS I) is characterized by sparse scalp hair, pear-shaped nose, long philtrum, protruding ears, cone-shaped epiphysis and short stature. Based on chromosomal aberrations in patients with this disease, we mapped the affected gene to 8q24.1, centromeric to *EXT1*.

In order to identify the *TRPS* gene, we have constructed a PAC clone contig spanning several chromosomal breakpoints of TRPSI patients. Based on large scale genomic sequencing, exon prediction, cDNA cloning and exon-connecting RT-PCR, we have identified a gene which spans a translocation and an inversion breakpoint, respectively, in two patients with TRPSI. Northern blot analysis identified two transcripts of 7 and 11 kb in fetal tissues. The 7 kb transcript is encoded by six exons located within 200 kb of genomic DNA. It has an open reading frame of 3,843 bp, which code for 1,281 amino acids. Interestingly, the predicted protein sequence contains several zinc finger motifs of different types. A pair of C_2H_2 zinc fingers at the carboxy-terminus of the protein shows highest homology with a characteristic carboxy-terminal pair of zinc fingers in *IKAROS* transcription factor proteins. This domain mediates protein-protein interaction. Another zinc finger is of the C_2C_2-type, which shows significant homology to many GATA-binding transcription factors. In addition, there are six other domains with the potential of forming C_2H_2 zinc fingers of hitherto unknown function. By sequence analysis of the entire coding region in seven unrelated patients with apparently normal chromosomes, we identified four different mutations in three exons. Two are C to T transitions creating TGA stop codons. The other two mutations are an 1 and 4 bp insertion, respectively, which lead to premature stop codons. These findings strongly suggest that we have identified the *TRPS* gene. We are grateful to all physicians who referred patients to us, and to the Deutsche Forschungsgemeinschaft for financial support.

Program Nr: 581 from the 1999 ASHG Annual Meeting

Identification of a common Ile1173Phe mutation in the canalicular multispecific organic anion transporter gene in patients with Dubin-Johnson Syndrome of Iranian-Jewish origin. *R. Mor-Cohen, A. Zivelin, N. Rosenberg, U. Seligsohn.* Institute of Thrombosis and Hemostasis, Chaim Sheba Medical Center, Tel-Hashomer and Sackler Faculty of medicine , Tel-Aviv University, Israel.

Dubin-Johnson Syndrome (DJS) is an autosomal recessive genetic disorder manifested by conjugated hyperbilirubinemia and accumulation of a dark pigment in the liver. The disorder has recently been associated with mutations in the canalicular multispecific organic anion transporter (cMOAT) gene (Hepatology 25:1541, 1997; Am J Hum Genet 64:739, 1999). We used SSCP and DNA sequencing in search for mutations and polymorphisms in the cMOAT gene, and employed PCR and restriction analysis for their detection, in a previously described cluster of patients with DJS of Iranian-Jewish origin (Q J Med 39:549,1970). all 17 subjects examined (of 9 unrelated families) were homozygous for an Ile1173Phe mutation due to A®T subtitution in nucleotide 3517 in exon 25. The predicted change in the amino acid sequence is at the transmembrane domain of cMOAT. In the general Iranian-Jewish population heterozygosity for this mutation was observed in 5/133 subjects tested (3.8%), whereas none of 100 subjects of other Jewish ethnic groups carried the mutation. The following three polymorphisms in the cMOAT gene were identified and their frequency determined in the general Iranian-Jewish population: 1) 1-24(C®T) in the 5'UTR (6/78 alleles-7.7%); 2) Val417Ile in exon 10 (35/116 alleles-30%); 3) 4147-35(G®A) in intron 29 (10/120 alleles-8.3%). Analysis of the polymorphisms in the 17 DJS patients disclosed that all 34 alleles had the same haplotype (1-24C, 417Ile, 4147-35A). These data provide strong evidence for a novel mutation causing DJS and suggest a founder effect.

Program Nr: 582 from the 1999 ASHG Annual Meeting

Splicing enhancer mutations that perturb alternative splicing: a new mechanism causing familial growth hormone deficiency. *C.T. Moseley[1], J.A. Phillips III[1], M.A. Prince[1], P.E. Mullis[2]*. 1) Department of Pediatrics, Division of Genetics, Vanderbilt University School of Medicine, Nashville, TN, USA; 2) Department of Pediatrics, Division of Endocrinology, University Children's Hospital, Inselspital, Bern, Switzerland.

Growth hormone deficiency (GHD) occurs in ~ 1/4000 births. We have found a series of dominant-negative human growth hormone (GH1) gene mutations that cause isolated GHD (IGHDII) because the mRNAs produced have exon 3 (E3) skipping, resulting in large amounts of only 17.5 kDa protein isoforms that are usually present in trace amounts. Normal GH1 splicing removes introns (IVSs) 1-4 to yield mRNA that contains exons 1-5 and encodes 22 kDa mature GH. Alternative GH1 splicing uses different combinations of splice sites and can yield mRNAs encoding 20, 17.5, 11.3, or 7.4 kDa isoforms. Previously we reported novel intron splicing enhancer (ISE) mutations in IVS3 that can also cause increased production of 17.5 kDa isoforms from E3 skipping that results in IGHDII. We report here our discovery of a GH1 exon splicing enhancer (ESE) found through studies of a natural mutation from an IGHDII individual. This mutation (E3+5 A®G) alters an ESE motif (GAAGAA®GAAGGA) which immediately follows the weak IVS2 3' splice site that must be used to produce 22 kDa GH. RT-PCR amplification of transcripts from an expression construct containing the ESE mutation yielded small amounts of the normal 22 but large amounts of 20 and 17.5 kDa mRNAs. Interestingly, the resulting 20 kDa isoforms arise from decreased use of the weak IVS2 3' splice site as well as increased use of a strong, cryptic 3' splice site in E3 following the ESE. Our data indicate that E3+5 A®G perturbs an ESE and that IGHDII may be caused by the increased production of both 20 and 17.5 rather than 17.5 kDa isoforms alone. Our findings are of general interest because they suggest that 1) both ESEs and ISEs regulate alternative splicing of GH1 transcripts, and mutations in either can cause IGHDII and 2) mutations of homologous splicing enhancers that regulate alternative splicing in other genes may cause a variety of genetic diseases.

Program Nr: 583 from the 1999 ASHG Annual Meeting

DGGE Analysis of the Tissue Non-Specific Alkaline Phosphatase Gene in Hypophosphatasia. *S.R. Mumm[1], J. Jones[1], P.S. Henthorn[2], M.C. Eddy[3], M.P. Whyte[1,3].* 1) Div Bone & Mineral Diseases, Washington Univ Sch Med, St Louis, MO; 2) School of Vet Med, Univ of Pennsylvania, Philadelphia, PA; 3) MRU, Shriners Hospital for Children, St Louis, MO.

Hypophosphatasia is a heritable form of rickets/osteomalacia for which there is no established medical treatment. This inborn error of metabolism manifests an extraordinary range of clinical severity spanning death in utero to premature loss of teeth. To delineate the molecular pathology causing the extreme clinical variability and various patterns of inheritance of hypophosphatasia, we initiated comprehensive mutational analysis of the tissue non-specific isoenzyme of alkaline phosphatase (TNSALP) gene in our large patient population. Genomic DNA from more than 120 probands, spanning the entire clinical spectrum, is being studied. Selecting initially 10 patients, single-strand conformational polymorphism (SSCP) analysis was used to detect mutations in the TNSALP gene. SSCP was performed using genomic DNA and primer sets that spanned each of the translated exons 2-12, including splice sites. We have detected approximately 70% of the potential mutations (assuming two mutations for each patient, and autosomal recessive inheritance). This success rate is in accord with published efficiencies for SSCP. To increase the efficiency of mutation detection, we are developing the technique of denaturing gradient gel electrophoresis (DGGE) for the TNSALP gene. Thus far, DGGE primers and conditions have been developed for exons 5, 10, and 12 (these exons contained the largest number of mutations as determined by the SSCP analysis). All of the known mutations (as determined by SSCP) have been detected by the DGGE analysis. In addition, new mutations were detected in exon 10 for two patients; these mutations were undetected by SSCP. Hence, our preliminary results suggest that the DGGE analysis will be more efficient than SSCP. The DGGE primers for the remaining exons are being developed and tested on the patient DNAs. Characterization of the TNSALP mutations in our large patient population will elucidate the molecular pathology and inheritance patterns, and should improve prognostication for hypophosphatasia.

Program Nr: 584 from the 1999 ASHG Annual Meeting

Correlation between hemochromatosis gene (*HFE*) mutations and mild iron overload expression. *C. Mura, G. Le Gac, O. Raguenes, AY. Mercier, C. Ferec.* Lab Biogenetique, CHU, UBO, Brest, France.

Hereditary hemochromatosis (HHC) is a common autosomal recessive genetic disorder of iron metabolism characterized by increased intestinal iron absorption. HFE gene, encoding a protein which seems to play a role in iron uptake by interacting with the transferrin receptor, is clearly involved in HHC. Two main mutations have been described, C282Y and H63D substitutions accounting for approximately 90% of the HC chromosomes. We previously reported on the increase of the S65C variant in HC chromosomes neither carrier of C282Y nor H63D. In addition, C282Y homozygotes were clearly associated with a more severe form of the disease than individuals carrying other genotypes. A series of 708 patients with various symptoms which could suggest an iron overload but without reaching clinical HC criteria was analysed for HFE mutations and a phenotype-genotype correlation was established. Most of the patients were selected because of an iron marker value above the threshold defined for iron overloading, among them 67% showed a serum ferritin above the threshold. We identified 45% of carrier chromosomes in the studied group of patients. In addition, significantly higher frequencies of compound C282Y/H63D heterozygous and H63D/H63D homozygous genotypes were found than in HC probands and controls; whereas compound C282Y/S65C or H63D/S65C heterozygotes were not significantly increased. The iron marker values, i.e. transferrin saturation percentage, serum ferritin and serum iron concentrations were significantly higher in each group of patients who carried at least one HFE mutation compared with controls. Thus, these patients seem to constitute an intermediate phenotypic group that shows mild iron overload, and compound heterozygotes and homozygotes, as also found in HC probands, present a potential risk of developing complications that may have implication in genetic counseling.

Program Nr: 585 from the 1999 ASHG Annual Meeting

Gene dosage of a 6p25 gene causes defects of the anterior chamber of the eye: FKHL7 or HFH1? *D.Y. Nishimura[1], C.C. Searby[1], D.S. Walton[2], S.R. Patil[1], A.B. Kanis[1], E.M. Stone[1], W.L.M. Alward[1], V.C. Sheffield[1]*. 1) University of Iowa, Iowa City, IA; 2) Harvard Medical School, Boston, MA.

We recently used positional cloning methods to identify the human transcription factor gene FKHL7 as a cause of glaucoma resulting from developmental defects of the anterior chamber of the eye. Some reported mutations suggest a haploinsufficiency model of disease development. We have now identified patients with 6p25 duplications and anterior chamber defects of the eye. Molecular techniques were used to characterize the extent of the duplications within the 6p25 region. Among the cases identified are four members of a family with congenital iris hypoplasia and a microduplication involving 6p25. In addition, we identified a single proband with Peters anomaly and a 6p25 duplication. The association of these two independent duplication events with developmental defects of the anterior chamber of the eye indicates that dosage of a gene or genes within this interval is important for normal development of the eye to occur. The FKHL7 transcription factor is located within the duplicated region and is thus a strong candidate for being one of these genes. However, the duplications also encompass a region on 6p25 for which a second locus involved in eye development has been postulated. We have analyzed a second forkhead transcription factor gene, Hfh1 as a possible candidate gene for this second locus. This gene is also contained within the duplicated region. No Hfh1 mutations were found in probands with anterior chamber defects although novel FKHL7 mutations have been found in these patients, providing additional support for the involvement of FKHL7 mutations in causing anterior chamber defects. The results of this study demonstrate that linked families with no apparent mutations in FKHL7 should be carefully screened for duplications or deletions of the entire FKHL7 gene.

Program Nr: 586 from the 1999 ASHG Annual Meeting

Dysferlin and the dystrophin-associated proteins. *F. Piccolo, D.P. Venzke, K.P. Campbell.* Howard Hughes Medical Inst., University of Iowa, Iowa City, IA.

Recently, the dysferlin gene has been cloned and mutations in it have been described in both MM (Miyoshy Myopathy) and LGMD2B (autosomal recessive Limb Girdle Muscular Dystrophy type B) patients (Bashir et al. Nature Gen., 1999; Vol.20, 37-42 and Liu et al. Nature Gen., 1999; Vol.20, 31-36). Dysferlin has been predicted to be homologous to the fertilization factor Fer-1 of C. elegans but the role of this protein in mammalians remains unknown. To assess the function of dysferlin in skeletal muscle, we first developed a mouse monoclonal and two rabbit polyclonal antibodies. Here we demonstrate by immunofluorescence (IF) and western blot that dysferlin is a membrane protein present at the sarcolemma. Because of its membrane localization and because sarcoglycans (which genes are responsible for LGMD2D (alpha-SG), 2E (beta-SG), 2C (gamma-SG), and 2F (delta-SG)) are components of the dystrophin glycoprotein complex (DGC), we hypothesize that dysferlin could be a new member of the dystrophin associated protein family. To test this hypothesis, we analyzed by IF a large cohort of Duchenne/Becker Muscular Dystrophy (D/BMD) and LGMD2 muscle biopsies from sporadic cases (sarcoglycanopathies and non-sarcoglycanopathies). Interestingly, we found that 20 percent of D/BMD and 80 percent of the sarcoglycanopathies present a secondary deficiency of dysferlin, indicating a relation between dysferlin and the DGC. To better understand the nature of this relationship, we isolated the DGC from rabbit skeletal muscle and tested for the presence of dysferlin by western blot. Preliminary data indicate that dysferlin is a structural component of the sarcolemma but it is not an integral component of the DGC. We were also able to estimate that 50 percent of the LGMD2 non sarcoglycanopathies present a deficiency of dysferlin at the sarcolemma. These results suggest that dysferlinopathies are extremely frequent among LGMD patients and a screening with antibodies against dysferlin is highly recommended for diagnostic purposes.

Program Nr: 587 from the 1999 ASHG Annual Meeting

KCNE1 like gene id deleted in AMME contiguous gene syndrome: identification and characterization of the human and mouse homologs. *A. Renieri[1], F. Vitelli[1], M. Piccini[1], I. Meloni[1], L.J. Galietta[2], O. Moran[3], A. Bulfone[4], S. Banfi[4], B. Pober[5].* 1) Dept Molec Biol, Medical Genetics, University of Siena, Siena, Italy; 2) Genetica Molecolare, Istituto G. Gaslini Genova, Italy; 3) Istituto di Cibernetica e Biofisica del CNR, Genova; 4) Telethon Institute of Genetics and Medicine (TIGEM), 20132 Milan, Italy; 5) Dept. Genet., Yale University, School of Medicine, New Haven CT.

We describe the identification and characterization of a new gene deleted in the AMME contiguous gene syndrome. This gene is predominantly expressed in heart, skeletal muscle, spinal cord and brain. Screening of placenta and NT2 cDNA libraries enabled us to obtain the 1.5 Kb full length transcript which shows a 426bp open reading frame. Since, the resulting 142 amino acids peptide has a single putative transmembrane domain and a weak but suggestive homology with KCNE1 (minK), a protein associated with KCNQ1 potassium channel (KVLQT1), we named this new gene KCNE1 Like (KCNE1L). To get more insight into this new member of an apparently distinct protein family, we have identified and characterized the homologous mouse gene (Kcne1l), which encodes a peptide of 143 amino acids with 91% homology and 80% identity. Expression pattern of mouse Kcne1l in the developing embryo revealed strong signal in ganglia, in the migrating neural crest cells of cranial nerves, in the somites and in the myoepicardial layer of the heart. We are currently exploring the possibility that the expression of KCNE1L could modulate the currents expressed by KCNQ1-3 genes, in oocytes of Xenopus laevis. The specific distribution in adult tissues, the putative channel function and the expression pattern in the developing mouse embryo suggests that KCNE1L could be involved in the development of the cardiac abnormalities, as well as of some neurological signs observed in the patients with AMME contiguous gene syndrome.

Program Nr: 588 from the 1999 ASHG Annual Meeting

Isolation of a novel motor-like protein that interacts with Retinitis Pigmentosa GTPase Regulator (RPGR) in the rod outer segments of the retina. *R. Roepman[1], N. Bernoud-Hubac[2], D. Schick[2], A. Maugeri[1], H.H. Ropers[1,3], W. Berger[3], F. Cremers[1], P. Ferreira[2].* 1) Dept. of Human Genetics, University Hospital Nijmegen, Nijmegen, The Netherlands; 2) Dept. of Pharmacology, Medical College of Wisconsin, Milwaukee, WI; 3) Max-Planck Institute of Molecular Genetics, Berlin, Germany.

The Retinitis Pigmentosa GTPase Regulator (*RPGR*) gene that is involved in X-linked retinitis pigmentosa type 3 (RP3) is ubiquitously expressed, in contrast to the disease phenotype that is restricted to the neural retina layers of the eye. The function of RPGR is not known, though its N-terminal half consists of a RCC1-like domain (RLD) in which most RP3 mutations, including all of the missense mutations, were found. RCC1 is a guanine-nucleotide exchange factor (GEF) of the Ras-like GTPase, Ran. Ras-related proteins and their modulators are often key mediators of protein trafficking in a vectorial fashion. Our goals are to understand the role of normal and mutated RPGR, respectively, in retinal function and pathogenesis of RP3. The RLD of RPGR was used in a yeast two-hybrid screen of two bovine retina cDNA libraries to identify substrates that interact with RPGR in the retina. We identified a novel, RPGR-binding protein (RPGR-BP) that shows preferential expression in the retina. The human orthologue has been isolated and interaction with RPGR has been confirmed. Chromosomal mapping positioned the corresponding gene at 14q11. RPGR-BP has no striking homology to any protein with a known function, however analysis of its primary structure suggests that it is a novel motor protein. Immunohistochemical studies of RPGR and RPGR-BP revealed a co-localization in the rod outer segment layer of the retina. The motor protein-like structure of RPGR-BP and its localization in the rod outer segments hints towards an involvement in rod photoreceptor-specific membrane transport processes. Studies towards the exact nature of this involvement are underway.

Program Nr: 589 from the 1999 ASHG Annual Meeting

Is guanylate cyclase activating protein 3 (GCAP3) the fourth gene for Leber's congenital amaurosis ? *J.-M. Rozet[1], I. Perrault[1], S. Gerber[1], D. Ducroq[1], I. Ghazi[2], J.-L. Dufier[2], A. Munnich[1], J. Kaplan[1].* 1) Unité de Recherches sur les Handicaps Génétiques de l'Enfant, INSERM U393, Hôpital Necker, Paris, France; 2) Service d'Ophtalmologie, Hôpital Necker, Paris, France.

The retinal-specific guanylate cyclase gene (retGC1) which accounts for about 1/5 cases of Leber's congenital amaurosis (LCA), represents the major disease causing gene in LCA. So far, three guanylate cyclase activating proteins (GCAP) have been identified. All three forms were found to stimulate retGC1 in low $[Ca^{2+}]_{free}$ leading to restoration of cGMP concentration after hyperpolarization of the plasma membrane following the photo-excitation in the retina. Defects in GCAPs are expected to result in the inability of photoreceptor cells to restore the cGMP level, a situation functionally equivalent to defects in the retGC1 gene. Thus, GCAPs were considered as excellent candidate genes for LCA. So far, GCAP1 and GCAP2 have been excluded as LCA causing genes. We report here the study of the GCAP3 gene in 84 patients affected with LCA. All four exons as well as the intron-exon boundaries were screened for mutations using SSCP and direct sequencing. Five different nucleotide substitutions were identified in four families and were absent in 80 controls. One of these changes alters an amino acid in the EF2 motif which is highly conserved across GCAPs and in the calmodulin gene. Two other changes alter an amino acid conserved in GCAP1. Interestingly, one patient was found to harbor mutations in each of GCAP3 alleles, inherited from his healthy parents, raising the question of whether GCAP3 could be the fourth gene responsible for LCA.

Program Nr: 590 from the 1999 ASHG Annual Meeting

Characterization of the *NPHP1* locus: Mutational mechanism involved in the large deletion observed in familial juvenile nephronophthisis patients. *S. Saunier[1], F. Blanchard[2], J. Calado[2], J. Weissenbach[3], C. Antignac[1]*. 1) Division Signal Transduction, Beth Israel Deaconee MC, HIM, Boston, MA; 2) INSERM U423, Hopital Necker, Paris, France; 3) CNS, Evry, France.

Familial juvenile nephronophthisis (NPH) is an autosomal recessive, genetically heterogeneous, kidney disorder, representing the most frequent inherited cause of chronic renal failure in children. A gene, *NPHP1*, responsible for approximately 85% of the purely renal form of nephronophthisis, was identified by a positional cloning strategy. The major *NPHP1* gene defect is a large homozygous deletion of ~250 kb found in about 80% of the patients. In this study, by large scale genomic sequencing and pulse field gel analysis, we have characterized the complex organization of the *NPHP1* locus and determined a mutational mechanism which results in the large deletion observed in most NPH patients. We showed that *NPHP1* is flanked by two large inverted repeats of ~330 kb (proximal copy-330RI, distal copy-330RII). In addition, a second sequence of 45 kb (45RI) located adjacent to 330RI repeat was shown to be directly repeated 250 kb away within 330RII repeat abolishing the STS 804H10R present in 330RI. The patients deletion breakpoint is located within the 45 kb repeat, suggesting an unequal recombination between the two homologous copies of the smaller repeat. This event could be the result of chromosomal misalignment followed by unequal cross-over or by the formation of a loop structure on a single chromosome, leading to the 250 kb deletion observed in the patients. Moreover, we demonstrated a non pathologic rearrangement involving the two 330 kb inverted repeats found in 11 patients, and also observed in 1,2% of control individuals in the homozygous state. This rearrangement could be explained by a mispairing of the 330 kb inverted repeat followed by double recombination, leading to the complete absence of 804H10R and the presence of another copy of the 45RII repeat. This complex rearrangement, as well as the common deletion found in most of NPH patients, illustrate the high level of rearrangements occuring in the centromeric region of chromosome 2.

Program Nr: 591 from the 1999 ASHG Annual Meeting

New mutations in collagen VIa**1,** a**2 genes cause autosomal dominant muscular dystrophy.** *P.C. Scacheri[1,5], E.M. Gillanders[2], S. Subramony[3], V. Vedanarayayanan[3], C.A. Crowe[4], M. Bingler[1], E.P. Hoffman[5].* 1) Biochem. & Molecular Genetics, University of Pittsburgh, Pittsburgh, PA; 2) NIH-NHGRI, Bethesda, MD; 3) Unversity of Mississippi Med Ctr, Jackson, MS; 4) MetroHealth Med Ctr, Cleveland, OH; 5) Children's Nat'l Med Ctr, Washington DC.

We collected 3 large families diagnosed with autosomal dominant limb-girdle muscular dystrophy. Both intra- and interfamilial variability was seen; symptoms ranged from loss of ambulation to a relatively mild myopathy. Muscle biopsy findings include marked fatty infiltration and increased connective tissue, with evidence of fiber degeneration/regeneration and variable fiber size. Through genome-wide linkage studies, we linked these 3 families to the Bethlem myopathy locus on chromosome 21q (Zmax 7.68, q=0.05). Bethlem myopathy is defined as a benign congenital myopathy with joint contractures caused by mutations in collagen VI genes. Despite phenotypic overlap, our patients have a more dystrophic phenotype than typically seen in Bethlem myopathy. Most of the Bethlem mutations reported to date are dominant negative, and involve glycine substitutions in the triple helical domains of collagen VIa1 and a2. We identified the causative mutations in all three of our families using SSCP analysis and direct sequencing of genomic DNA. Family 1 has a glycine to aspartic acid substitution in the triple helical domain of collagen VIa1 (G341D). Family 2 has a lysine to arginine substitution in the amino globular domain of collagen VIa1 (K121R). Family 3 has an aspartic acid to asparagine substitution in the carboxy globular domain of collagen VIa2 (D354N). All affected patients were heterozygous for the mutations, and base substitutions were not found in 95 unrelated individuals. Mutations in the globular domains of colVIa1 or colVIa2 are not previously reported, and may account for the more dystrophic phenotype in our families. We hypothesize that these collagen VI mutations disrupt the assembly of multimeric collagen VI proteins, which ultimately disturb protein/protein interactions in the basal lamina and lead to an abnormal development or regeneration of muscle.

Program Nr: 592 from the 1999 ASHG Annual Meeting

Unsuspected Saethre-Chotzen syndrome patients with insertions and deletions in a normally mutant-free region of the TWIST gene. *F.V. Schaefer, C.A. Shults, C.M. Outlaw.* Molecular Genetics, HA Chapman Inst Medical Gen, Tulsa, OK.

Apert, Crouzon, Jackson-Weiss or Pfeiffer syndromes have been unified by the discovery that most are the result of different mutations in common regions of the FGFR1,2&3 genes. However, 25% of patients do not have a mutation within the tested regions of these genes. We examined the hypothesis that a portion of the patients have unrecognized Saethre-Chotzen syndrome with mutations in TWIST.

The TWIST gene is composed of a coding region that involves a DNA-binding region followed by a helix-loop-helix (HLH) motif characteristic of transcriptional regulators. All Saethre-Chotzen syndrome patients that have been published have either a mutation in the DNA-binding-HLH motif, a stop mutation that eliminates this structure or a deletion of the entire gene. A panel of craniosynostosis patients that had proved not to have the predicted mutations in the FGFR genes were tested for alterations in the TWIST gene by PCR amplification, gel electrophoresis and DNA sequencing.

The results of the testing showed (1) about 20% (4/20) were found to have a detectable mutation in the TWIST gene. The mutations included a 3bp insertion, a 21bp insertion, an 18bp deletion and a gly to ser point mutation. All these gene alterations were in phase and none resulted in protein truncation. (2) Strikingly, **all** these mutations were located in the coding upstream of the DNA-binding-HLH region where no previous mutations causing classical Saethre-Chotzen syndrome had been described.

These results lead to the conclusions that (1) there are mutations causing Saethre-Chotzen syndrome in a region of the gene not previously suspected to be integrally involved in gene function or pathology. (2) These mutations may lead to unique symptomology recognized to be craniostenosis but not classical Saethre-Chotzen syndrome. (3) Saethre-Chotzen patients with mutations in the TWIST gene do appear to contribute more significantly than previously suspected to the over all craniosynostosis population. Consequently, patients should be examined for TWIST as well as FGFR mutations.

Program Nr: 593 from the 1999 ASHG Annual Meeting

Mutations that result in premature termination codons in the COL5A1 gene of type V collagen produce Ehlers-Danlos syndrome (EDS) type I or II. *U. Schwarze[1], M. Atkinson[1], D.S. Greenspan[2], P.H. Byers[1].* 1) University of Washington, Seattle, WA; 2) University of Wisconsin, Madison, WI.

EDS types I and II are characterized by skin hyperextensibility and fragility, and joint hypermobility. Linkage studies suggest that most affected individuals have mutations in either the COL5A1 or COL5A2 genes that encode the chains of type V collagen, a ubiquitous protein associated with large fibrils in the extracellular matrix. Despite these findings only a small proportion of mutations have been identified by examination of cDNA synthesized from RNA derived from cells of affected individuals. To try to identify the remaining classes of mutations, we studied cells from 16 individuals with EDS type I or II. We isolated mRNA from their cultured dermal fibroblasts, screened large overlapping fragments of the COL5A1 and COL5A2 cDNA by polyacrylamide gel electrophoresis to identify insertion/deletion mutations, and then used expressed polymorphic sequences in the COL5A1 gene to determine if both alleles were expressed. In cells from 2 individuals there were splice site mutations in different regions of the COL5A1 gene (IVS4-2AG and IVS14-11TA) both of which resulted in complex splice abnormalities. Of the remaining 14, 13 were heterozygous for at least one of 4 coding sequence polymorphisms in COL5A1 and, of these, 6 had stable mRNA from only one allele. We screened 66 exons of COL5A1 genomic DNA by electrophoresis of amplified exons on heteroduplex gels and sequenced variant fragments. We identified the causative mutations in 4 of these individuals. In exon 49 of the 66 exon gene 3900CinsC results in a downstream stop in exon 50, 3886delC in exon 49 and 4147delC produce the same stop in exon 58, and 4201GinsA produces a stop in exon 57. In each instance sequence of the stable mRNA identified only the normal allele. These results suggest that more than a third of affected individuals have mutations that lead to premature termination codons in one COL5A1 allele which are destabilized by the pathway of nonsense mediated decay. These result in production of half the normal amount of type V collagen, alter fibril formation, and lead to marked biomechanical abnormalities. (AR21557).

Program Nr: 594 from the 1999 ASHG Annual Meeting

Are genes contiguous to glucocerebrosidase involved in patients with Gaucher disease who have parkinsonian symptoms? *E. Sidransky[1], N. Tayebi[1], M. Callahan[1], D. Stone[1], V. Madike[1], J.J. Filiano[2], B. Bembi[3], A. Tylki-Szymanska[4], E.I. Ginns[1]*. 1) DHHS/PHS, NSB/NIMH/NIH, Bethesda, MD; 2) Dept of Pediatric Neurology, Children's Hosp at Dartmouth, Lebanon, NH; 3) Gaucher Center, Trieste, Italy; 4) Children's Memorial Health Inst, Warsaw, Poland.

There have been several reports of adult patients with Gaucher disease, the inherited deficiency of lysosomal glucocerebrosidase (GC), and parkinsonian symptoms. We evaluated a female patient diagnosed with Gaucher disease at age 19 because of mild anemia. An elective splenectomy was performed at age 34. She developed a tremor at age 42 and rapid deterioration of her gait followed. A pallidotomy performed at age 47 resulted in no significant improvement. On examination she had impaired horizontal saccadic eye movements, but no hematologic or skeletal abnormalities. Neurologic symptoms were not improved with enzyme replacement, but she showed some response to L-dopa. Sequencing of the synuclein gene failed to identify any mutations. Sequencing of the 11 exonic regions of the GC gene revealed the mutation L444P on the paternal allele and D409H on the maternal allele. Southern analyses showed the maternal allele had an additional 15 kb fragment resulting from a recombination between metaxin and its pseudogene. Metaxin, a convergently transcribed gene located adjacent to the GC pseudogene, encodes for a 317 aa protein which is part of a preprotein import complex in the outer membrane of the mammalian mitochondrion. Sequencing of the extra fragment confirmed a duplication carrying a fusion gene. Analysis of a highly polymorphic tetranucleotide (AAAT) repeat located 3' to the GC gene revealed 3 allelic forms, suggesting a duplication of the region encompassing the GC pseudogene and metaxin. Three additional patients with Gaucher disease and parkinsonian symptoms have been identified. Sequencing has revealed that there is no shared genotype among these parkinsonian patients, whose genotypes are N370S/IVS2+1, N370S/recombinant allele, and G377S/G377S. Further analyses of the GC locus in these patients are being performed to explore the possible association of the parkinsonian symptoms and alterations in contiguous genes.

Program Nr: 595 from the 1999 ASHG Annual Meeting

Disturbed interaction between Huntingtin and HIP3 implicates defects in neuronal endocytosis in the pathogenesis of HD. *R.R. Singaraja[1], S. Hadano[2], M. Metzler[1], C. Wellington[1], B. Leavitt[1], W. Balch[3], S. Bannykh[3], K. Fichter[1], A. Hackam[1], L. Gan[1], T. Zhang[1], A. Yassa[1], K. McCutcheon[1], J.M.L. Michel[1], V. Chopra[1], S. Sherer[4], D. Geitz[5], M.R. Hayden[1].* 1) Medical Genetics/CMMT, University of British Columbia, Vancouver, British Columbi, Canada; 2) Tokai University School of Medicine, Kanagawa , Japan; 3) Scripps Research Institute, La Jolla, California, USA; 4) Dept of Gen., HSC, Toronto, ON, Canada; 5) Dept of Human Genetics, University of Manitoba, Winnipeg, MAN, Canada.

Huntington Disease (HD) is caused by an expansion of a polyglutamine tract in the coding region of a novel gene. Despite it's cloning approximately 6 years ago, the normal function of huntingtin is still unclear. We have isolated a novel huntingtin interacting protein, termed HIP3, utilizing the yeast two hybrid system. The HIP3 protein contains several ankyrin repeats and shows striking similarity (38%) to the yeast protein Akr1which is essential for endocytosis in S. cerevisiae. The HIP3 protein is expressed predominantly in the brain, and is found in neurons of regions including the cortex, striatum and hippocampus, all areas affected in Huntington disease. Deconvolution confocal microscopy revealed HIP3 immunoreactivity in structures associated with the Golgi complex. HIP3 shows decreased interaction with mutant huntingtin, as measured by semi-quantitative b-galactosidase assays and by in-vitro binding assays. This data, together with the fact that the HIP1 homologue in yeast, Sla2, has an essential role in endocytosis, indicates a role for wild type huntingtin in the vesicle transport pathways of neurons, and shows that the pathogenesis of HD is associated with disturbed interactions with proteins essential for endocytosis in neurons.

Program Nr: 596 from the 1999 ASHG Annual Meeting

Human aryl-hydrocarbon interacting protein-like 1 gene (*AIPL1*), a candidate for inherited retinal disorders: mapping to 17p13, characterization and mutation testing. *M.M. Sohocki[1], S. Blackshaw[2], C.L. Cepko[2], L.S. Sullivan[1,3], S.P. Daiger[1,3]*. 1) Human Genetics Center, School of Public Health, University of Texas HSC, Houston, TX; 2) Dept. of Genetics and Howard Hughes Medical Institute, Harvard Medical School, Boston, MA; 3) Dept. of Ophthalmology and Visual Science, University of Texas HSC, Houston, TX.

In a previous study, we mapped retina/pineal-expressed EST (expressed sequence tag) clusters as candidate genes for inherited retinal disorders(Genomics 58:29-33,1999). Two EST clusters, THC220430 and THC90422, map to 17p13. Several loci causing inherited retinal degeneration map to this region, including autosomal dominant cone-rod dystrophy (CORD5), recessive cone-rod dystrophy and central areolar choroidal dystrophy.

In the current study, we determined that the cDNAs of these two EST clusters overlap and represent coding sequences of a single gene. This gene has high sequence similarity to human aryl hydrocarbon-interacting protein (*AIP*), a member of the FKBP family, and has been named aryl hydrocarbon-interacting protein-like-1 (*AIPL1*). AIP has been implicated as a molecular chaperone and/or nuclear targeting factor in Ah-mediated signaling; therefore, it is possible that AIPL1 performs a similar nuclear transport or protein folding function in the retina and pineal gland. The genomic structure of *AIPL1* was characterized; the gene contains four exons encoding a protein 384 amino acids in length, with a molecular mass of 43,865 daltons, and a deduced pI of 5.56. In addition, *in situ* hybridization of AIPL1 indicated a very high photoreceptor-specific expression, strengthening *AIPL1* as a candidate gene for retinal degeneration.

We are currently screening for mutations in patient samples from families with inherited retinal diseases mapping to the *AIPL1* region of 17p13.

Supported by grants from the Foundation Fighting Blindness, the George Gund Foundation, by the William Stamps Farish Fund and the M.D. Anderson Foundation, by NIH Grant EY07142, and by NIH-NEI National Institutional Service Award EY07024.

Program Nr: 597 from the 1999 ASHG Annual Meeting

Organization and mutations of the human Chediak-Higashi syndrome gene (*CHS1*) in the childhood and adult forms of the disorder. *R.A. Spritz[1], M.A. Karim[1], K. Suzuki[1], D.L. Nagle[2], K.J. Moore[2]*. 1) Human Medical Genetics Program, Univ Colorado Health Sci Ctr, Denver, CO; 2) Millennium Pharmaceuticals, Inc., Cambridge, MA.

Chediak-Higashi syndrome (CHS) is an autosomal recessive disorder characterized by hypopigmentation, bleeding tendency, and severe immunodeficiency. Most patients present in childhood with recurrent bacterial infections due to neutropenia and lack of natural killer (NK) cell activity. About 85-90 percent of CHS patients develop an accelerated lymphoproliferative phase that is fatal unless treated by bone marrow transplantation. However, about 10-15 percent of patients have few or no severe infections, develop no accelerated phase, and survive to adulthood. Patients with such adult CHS develop progressive neurologic disease that is debilitating and often fatal. We previously described the cloning of the human gene and mutations of the *CHS1* gene in patients with severe childhood CHS. All of these patients, as well as those in mice with the homologous disorder, *beige*, have "protein-null" mutations: frameshifts, nonsense mutations, or deletions that would abolish expression of full-length CHS1 polypeptide. We have now defined the exon-intron organization of the human *CHS1* gene, which consists of 54 exons distributed over >100 kb, and we have used this information to search for *CHS1* gene mutations in 18 new patients with CHS. We identified a number of novel frameshift and nonsense mutations, particularly in patients with the severe childhood form of CHS. Of greater interest, we identified missense mutations in patients with the clinically milder "adult" form of the disorder. Our results establish that the classic childhood and the milder adult forms of CHS are allelic, resulting from protein-null and missense mutations of the *CHS1* gene, respectively. In several patients with the clinical diagnosis of Chediak-Higashi syndrome we found no mutations of the *CHS1* gene. Genetic analysis in some of these families appeared to exclude the 1q43 region, suggesting the possibility of locus heterogeneity for the Chediak-Higashi syndrome in man.

Program Nr: 598 from the 1999 ASHG Annual Meeting

Werner protein (WRN) interacts with a subunit of DNA polymerase δ, an essential enzyme in DNA replication.
A.M. Szekely, Y-H. Chen, C-Y. Zhang, S.M. Weissman. Department of Genetics, Yale University Sch Medicine, New Haven, CT.

Werner syndrome (WS) is a rare autosomal recessive disorder with many features of premature aging. The clinical and cellular phenotypes of WS show remarkable similarity to normal human aging. The defective gene for WS (WRN) displays significant homology to the RecQ family of DNA helicases, however its precise function is largely unknown.

To obtain insights into the function of WRN gene, we screened for proteins that specifically interact with the WRN gene product. Using the yeast two-hybrid system we isolated p50, a key subunit of the human DNA polymerase δ enzyme complex essential in DNA replication and implicated in DNA repair. The interaction between the WRNp and p50 is specific, mediated by the C terminus portion of WRNp (WRNCTp) and occurs both in vitro and in vivo. In mammalian cells we found that WRNp predominantly localizes to the nucleolus via its C terminus domain, while p50 is detected exclusively in the nucleoplasm. Intriguingly, in co-transfection experiments WRNp recruits p50 into the nucleolus upon their in vivo interaction. Further analysis of components of this protein complex is under way. Moreover, novel candidate proteins, some without homology to known genes, were also isolated by their virtue of specific interaction with WRNCTp.

Our data indicate that WRNp can directly associate with other proteins both in vitro and in vivo. The interaction between WRNp and a subunit of DNA polymerase δ may provide the molecular link to the findings that replication initiation is impaired in WS cells. Moreover, our data suggest that WRNp may be part of multiple protein complexes with dynamic changes in their composition and subcellular/subnuclear localization. Unraveling the precise function of WRN gene may provide insights into molecular mechanisms that underlie the rate and variability of human aging including susceptibility to age-related disorders.

Program Nr: 599 from the 1999 ASHG Annual Meeting

Filamin 2, a Muscle-Specific Form of Filamin, Interacts with g-sarcoglycan, a Member of the Dystrohin Glycoprotein Complex. *T.G. Thompson[1], S. Watkins[2], Y. Chan[1], M. Speer[3], M. Brosius[1], J. Vance[3], A. Hack[4], E. McNally[4], H. Lidov[1], M.P. Vance[3], L. Kunkel[1]*. 1) Department of Medicine, Genetics division, Children's Hospital, Boston, MA; 2) Center for Biological Imaging, University of Pittsburgh, Pittsburgh, PA; 3) Department of Medicine, Duke University Medical Center, Durham, NC; 4) Department of Medicine, Section of Cardiology, University of Chicago, Chicago, IL.

Mutations in genes encoding for the sarcoglycans, a subset of proteins within the dystrophin glycoprotein complex (DGC), produce a limb-girdle muscular dystrophy phenotype; however, the precise role of this group of proteins in skeletal muscle is not known. In order to better understand the role of the sarcoglycan complex, we looked for sarcoglycan interacting proteins with the hope of finding novel members of the DGC. Using the yeast two-hybrid method, we have identified a skeletal muscle-specific form of filamin, which we term filamin 2 (FLN2), as a g-sarcoglycan interacting protein. Previous studies of filamin family members have determined that these proteins are involved in actin reorganization associated with cell migration, adhesion, force transduction, differentiation, and survival. The predicted FLN2 protein is 74% identical to FLN1, and, by northern and western analysis, FLN2 appears to be expressed in only the skeletal and cardiac muscles. In addition, using immunoglold electron microscopy and confocal immunofluorescence, we determined that FLN2 is located at the sarcolemmal membrane and within the contractile apparatus, suggesting that FLN2 accomplishes comparable tasks in muscle cells as FLN1 in nonmuscle cells. Interestingly, we have localized FLN2 to a region overlapping with the LGMD1E region on chromosome 7 and are currently searching for FLN2 mutations in LGMD1E families. The finding of FLN2 as a sarcoglycan complex member introduces new implications for the pathogenesis of muscular dystrophy.

Program Nr: 600 from the 1999 ASHG Annual Meeting

Molecular Pathology of the SMN and H4F5 genes in Spanish SMA patients. *E.F. Tizzano[1], Y. Martin[2], BM.J. Barcelo[1], I. Cusc[1], M. Cornet[1], E. Bussaglia[1], A. Valero[2], C. Hernandez- Chico[2], C. Soler[1], M. Baiget[1].* 1) Genetics, Hospital Sant Pau, Barcelona, Barcelona, Spain; 2) Genetics, Hospital Ramon y Cajal, Madrid, Spain.

Spinal muscular atrophy (SMA) is classified by age of onset and maximal motor milestones achieved in type I (severe form), type II (intermediate form) and type III (mild/moderate form). We have analyzed 364 families (169 type I, 119 type II and 79 type III) looking for mutations in the SMA determining gene SMN (Survival Motor Neuron) located at 5q31. Three hundred and eight patients (85%)have deletions of the exon 7 and 8 of the SMN telomeric gene; in 18 patients(5%) centromeric-telomeric hybrid genes were detected; 7 cases (2%) showed a 4bp deletion in exon 3 (delAGAG) and in one type II case, an 11 bp duplication in the exon 6 was detected. In the remaining 28 patients (7%), no mutation so far was identified. All types of mutations described were associated with the three different phenotypes. The delAGAG of exon 3 was detected in one type I case, three type II and three type III cases. Haplotype analysis using microsatellite DNA markers flanking the SMA locus revealed that the 4bp deletion was found on the background of a same haplotype suggesting that a single mutational event was involved in the seven families. Extremely different phenotypes were found in two of these families: in one consanguineous familiy, one homozygous daughter was minimally affected while her three homozygous sisters were wheelchair bounding since their infancy. In the second family, while a 65 years old male showed a mild phenotype, his sister was wheelchair bounded during adolescence. To determine factors influencing the final phenotype we have performed analysis of the gene H4F5, the nearest gene located at the 5' end of the SMN gene. Analysis of PCR products of marker 212 showed that 92% of the Spanish type I chromosomes had 0 or 1 PCR product in comparison with 64% of type II chromosomes and 46% of type III chromosomes. These results support the hypothesis that H4F5 may be a modifier gene for SMA. Expression studies of this gene in human CNS are in progress. Supported by FIS 98-556 and Telemarato TV3.

Program Nr: 601 from the 1999 ASHG Annual Meeting

Analysis of chromosomal breakpoints in patients with Rieger Syndrome: effects on PITX2. *D.G. Trembath[1], E.V. Semina[1], B.U. Zabel[2], J.C. Carey[3], D.H. Jones[1], J.C. Murray[1]*. 1) University of Iowa, Iowa City, IA; 2) University of Mainz Hospital, Mainz, Germany; 3) University of Utah, Salt Lake City, UT.

Rieger syndrome is an autosomal dominant disorder characterized by eye abnormalities and dental hypoplasia. Semina et al. cloned the gene responsible for Rieger syndrome, *PITX2*, using two patients with balanced translocations near the gene: one between 4q26 and 16q22 and the other between 4q27 and 11q21. It is our hypothesis that these translocations either produce chromosomal rearrangements that delete *PITX2* or interrupt regulatory elements necessary for proper *PITX2* expression.

Using a cosmid map of 4q25-27, we subcloned the breakpoint regions on chromosome 4. We then cloned the 16:4 and 4:11 breakpoints via panhandle PCR (PH PCR), a novel technique for amplifying unknown regions of DNA. The 16:4 breakpoint is 18 kb telomeric to the 5'UTR of *PITX2* on chromosome 4 and occurs in a long terminal repeat (LTR). Using chromosome 16 sequence obtained from PH PCR, we identified a BAC covering the translocation region. The translocation on 16 maps near CHLC marker GATA71F09 and a novel CA repeat. To analyze the 4:16 translocation sequence, we have attempted to amplify this region from the patient's genomic DNA. This has revealed an apparent rearrangement of chromosome 16 sequence, resulting in a deletion of the 18 kb sequence telomeric of *PITX2* and possibly the gene itself.

The 4:11 breakpoint occurs in an Alu repetitive element approximately 60 kb telomeric of *PITX2* on chromosome 4, and in a MIR repetitive element on chromosome 11, between markers D11S901 and D11S1354. The 4:11 translocation creates a novel GATA binding site at the breakpoint that may potentially down regulate *PITX2*.

Future work will include delineating the nature of the potential deletion on the 4:16 chromosome and transient transfection studies to determine if down regulation of *PITX2* is occurring on the 4:11 chromosome.

Program Nr: 602 from the 1999 ASHG Annual Meeting

Functional haploinsufficiency of the elastin gene (ELN) in patients with isolated supravalvular aortic stenosis (SVAS). *Z. Urban[1], E.C. Davis[2], J. Zhang[3], M.R. Wallace[3], V.V. Michels[4], S.N. Thibodeau[4], B. Eyskens[5], K. Devriendt[5], C.D. Boyd[1]*. 1) Pacific Biomedical Res Ctr, Univ Hawaii, Honolulu, HI; 2) Cell Biology and Neuroscience, University of Texas Southwestern Medical Center, Dallas, TX; 3) Pediatric Genetics, University of Florida, Gainesville, FL; 4) Medical Genetics, Mayo Clinic, Rochester, MN; 5) Center for Human Genetics, Leuven, Belgium.

Supravalvular aortic stenosis (SVAS) is an autosomal dominant segmental stenotic arterial disorder caused by mutations in the elastin gene (ELN). We've previously characterized eight ELN mutations in families with isolated SVAS. Most of these mutations were point mutations resulting in premature termination codons. To study the molecular mechanism underlying SVAS, we've analyzed the expression of the elastin gene in skin fibroblast samples from SVAS patients. We've shown by RT-PCR analysis that a splice site mutation (IVS15-3CtoG), a frame shift mutation (1195delG) and a base substitution (1829GtoA, 610ArgtoGln), all result in a marked reduction or complete lack of expression of the mutant allele. The first two mutations resulted in at least 100-fold reduction in allele specific expression while mutation 1829GtoA resulted in a 4-8-fold reduction. These results were consistent with nonsense mediated decay (NMD) of the products of mutations IVS15-3CtoG and 1195delG and an as yet unknown mechanism affecting the stability of the mRNA products of the 1829A allele. Furthermore, we've demonstrated by Northern blot analysis that mutations result in an overall reduction of the steady state levels of elastin mRNA. Reduction of tropoelastin (the soluble precursor of elastin) synthesis and secretion paralleled the reduced steady state mRNA levels in SVAS fibroblasts assayed by metabolic labeling and immunoprecipitation. Finally, electron microscopic analysis of dermal elastic fibers in SVAS patients indicated an altered structure with discontinuities in the amorphous (elastin) component of the fiber. We conclude that despite molecular differences of the mutations responsible for SVAS, the unifying mechanism underlying this disorder is functional haploinsufficiency.

Program Nr: 603 from the 1999 ASHG Annual Meeting

Molecular and cellular defects in the CLN1 and CLN5 disorders. *J. Vesa[1], T. Klockars[2], J. Isosomppi[2], M. Savukoski[2], O. Heinonen[2], A. Kyttala[2], A. Jalanko[2], L. Peltonen[1].* 1) Human Genetics, UCLA School of Medicine, Los Angeles, CA; 2) Human Molecular Genetics, National Public Health Institute, Helsinki, Finland.

Neuronal ceroid lipofuscinoses (NCL) are a group of genetic neurodegenerative disorders caused by a defect in different genes, five of which have been identified by positional cloning. Clinically the most severe are two childhood forms, CLN1 and CLN5, both enriched in the Finnish population. A mutation in palmitoyl protein thioesterase (PPT) gene leads to CLN1 and a mutation in a novel gene is underlying CLN5. Over twenty mutations in the PPT gene have been reported, Arg122Trp being the most prevalent representing 98% of Finnish CLN1 alleles. PPT is an N-glycosylated lysosomal enzyme and its function is to remove palmitate groups from proteins. Wild-type PPT is targeted to lysosomes via mannose 6-phosphate receptor-mediated pathway and in vitro expression of PPT in mouse primary neurons shows transport of PPT to neuronal processes as well as co-localization with a presynaptic vesicle membrane protein, synaptophysin. A significant amount of PPT gets also secreted in both fibroblasts and primary neurons. Monitoring of mRNA levels by in situ hybridization of mouse brain sections revealed notable increase of PPT transcript postnatally just before the early synaptogenic period. The highest expression was found in the cerebral cortex, hippocampal cells, dentate gyrus granule cells and hypothalamus. The recently isolated CLN5 gene encodes a 46 kDa polypeptide with two potential transmembrane domains. Three disease mutations have been characterized: one 2 bp deletion enriched in Finland, one nonsense and one missense mutation. Based on the preliminary immunofluorescence data, wild-type CLN5 is intracellularly located in vesicles, most probably representing components of endocytotic pathways. Interestingly, three other CLN proteins represent lysosomal proteins: CLN1 and CLN2 are soluble enzymes and CLN3 is a membrane protein. Similar intracellular targeting of CLN proteins suggests their interactions or participation in the same metabolic pathways essential for normal neocortex development.

Program Nr: 604 from the 1999 ASHG Annual Meeting

A cellular assay distinguishes normal and mutant TIGR/myocilin protein. *D. Vollrath, Z. Zhou.* Dept of Genetics, Stanford Univ School of Medicine, Stanford, CA.

Glaucoma is a blinding eye disease that affects approximately 70 million people worldwide. Mutations in the gene *TIGR/MYOC* have been shown to cause the most common form of the disease, primary open angle glaucoma, in selected families. Amino acid sequence variants of the gene have been found in 2-4% of sporadic primary open angle glaucoma cases. However, of the over 40 amino acid variants described, most are rare and it is often difficult to definitively distinguish between a deleterious mutation and a benign variant solely on the basis of relative frequencies in patient and control groups. The function of the TIGR/myocilin protein is unknown and an assay to functionally classify variants is lacking. We sought to develop a biochemical assay to distinguish different forms of TIGR/myocilin. We investigated the Triton X-100 detergent solubility characteristics of mutant and normal forms of the protein, expressed by transfection in cell culture. We observed a clear difference in the behavior of the two types of TIGR/myocilin; all 12 mutant proteins tested were substantially Triton insoluble, while normal protein and controls were completely soluble. We also tested seven ambiguous variant proteins and classified them as mutant or normal on the basis of their Triton solubility. The results in some cases validated, and in other cases contradicted, earlier classifications of these variants. To our knowledge, Triton solubility is the first example of a general difference in the properties of mutant and normal forms of TIGR/myocilin. The assay we have developed will be useful for discerning protein functional information from the location of mutations, will aid genetic counseling of individuals with TIGR/myocilin variants, and may provide a clue to understanding the mechanism by which mutations in *TIGR/MYOC* cause glaucoma.

Program Nr: 605 from the 1999 ASHG Annual Meeting

Analysis of Spinocereballar Ataxia Type 1 (SCA1) Knock-in mice. *K. Watase[1,2], D. Lorenzetti[2], B. Xu[2], D. Armstrong[2], H.T. Orr[3], H.Y. Zoghbi[1,2].* 1) Howard Hughes Medical Institute; 2) Baylor College of Medicine, Houston, TX; 3) University of Minnesota, Minneapolis, MN.

Spinocerebellar ataxia type 1 (SCA1) is an autosomal dominant neurodegenerative disorder characterized by progressive ataxia, and selective neuronal loss within the cerebellar cortex and brain stem. To elucidate the pathophysiology of SCA1 and to evaluate repeat length instability in the context of the SCA1 genomic locus, we generated knock-in mice by inserting an extended tract of 78 CAG repeats into the mouse *Sca1* locus ($Sca1^{78Q}$). The levels of mutant ataxin-1 in $Sca1^{78Q/2Q}$ mice are comparable to the levels of the endogenous protein. Histological examination of brain tissue from mutant mice did not reveal detectable neuropathological changes; immunohistochemical analysis with anti ataxin-1 antibodies failed to detect neuronal intranuclear inclusions in mutants up to 15 months of age. Neither $Sca1^{78Q/2Q}$ nor $Sca1^{78Q/78Q}$ mice show any overt ataxic phenotype. Analysis of motor performance on the rotating rod was done on $Sca1^{78Q/78Q}$ mice (n = 7) and wild type (WT) littermates (n = 5) at 3, 6, and 9 months of age. Both groups performed similarly at 3 and 6 months, however at 9 months $Sca1^{78Q/78Q}$ mice had reduced mean time on the rotating rod compared to WT (112 ± 16 sec vs 261 ± 37 sec, respectively, $p < 0.05$). $Sca1^{78Q/2Q}$ mice show intergenerational repeat instability (+2 to -6) at a frequency of 10% in paternal transmissions (n = 90), and 65% in maternal transmissions (n = 62). Contraction accounted for 39/40 changes and the intergenerational instability increased in frequency and magnitude as the mother aged. In paternal transmissions, expansions and contractions were observed at similar frequencies. These data suggest that the toxicity of mutant ataxin-1 when expressed at endogenous levels is only manifested after prolonged exposure which is reminiscent of the human disease (78Q causes disease ^{3} 4 years). Although large intergenerational expansions or contractions were not observed in the $Sca1^{78Q/2Q}$ mice, the pattern and direction of repeat instability are similar to those observed in human SCA1.

Program Nr: 606 from the 1999 ASHG Annual Meeting

Glypican 3 (GCP3) deletions: the phenotypic spectrum in overgrowth syndromes. *R. Weksberg[1], M. Li[1], C. Shuman[1], E. Cutiongco[1], H.A. Bender[2], C. Stevens[3], L. Wilkins-Haug[4], S.L. Wong[5], J. Squire[1]*. 1) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 2) Regional Genetics Center, South Bend, IN; 3) T.C. Thompson Children's Hospital, Chattanooga, TN; 4) Brigham & Women's Hospital, Boston, MA; 5) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

Simpson-Golabi-Behmel syndrome (SGBS) is an X-linked overgrowth syndrome caused by deletions in GPC3, a cell surface proteoglycan believed to function in modulating growth factor activity. SGBS is characterized by pre-and postnatal overgrowth, a characteristic facies and a spectrum of congenital malformations which overlaps other overgrowth syndromes. Using clinical criteria, we selected 79 male overgrowth patients in the following categories: SGBS (n=18), query SGBS (n=26) and Beckwith-Wiedemann syndrome (BWS) (n=35). Using exon-specific PCR and Southern blot analysis, we identified 5 GPC3 deletions among the 18 SGBS patients. In none of these cases was a clear family history present and 1 patient had an atypical facies for SGBS. In the screen of 26 query SGBS patients, 1 GPC3 deletion was identified in a patient belonging to a pedigree in which a maternal first cousin had previously been diagnosed with Perlman syndrome. No GPC3 deletions were identifed in a screen of 35 BWS patients. Among our results and all the GPC3 deletions published to date, there are no clear phenotypic correlations for specific deleted exons. However, our results validate the specificity of the following clinical findings in patients with GPC3 deletions: skeletal and hand anomalies and supernumerary nipples. Our data also indicates that nephroblastomatosis should be included in the phenotypic spectrum of GPC3 deletions and SGBS. Given that the combined frequency of GPC3 deletions in our patients and the literature is only 33%, we directly sequenced all GPC3 exons in 10 SGBS patients and failed to identify any mutations, raising the possibility of alternative silencing mechanisms and/or other genes in the pathogenesis of SGBS.

Program Nr: 607 from the 1999 ASHG Annual Meeting

X-Linked Hypophosphatemia (XLH): Mutations Compromising PHEX Structure Reflect A Severe Phenotype.

M.P. Whyte[1,2], P.T. Christie[3], M.N. Podgornik[1], P.H. Dixon[3], M.C. Eddy[1], C. Wooding[3], D. Trump[3], M. Grieff[2], S. Mumm[2], D. Schlessinger[2], R.V. Thakker[3]. 1) Metabolic Research Unit, Shriners Hospital for Children, St Louis, MO; 2) Washington University School of Medicine, St Louis, MO; 3) Medical Research Council, Molecular Endocrinology Group, Hammersmith Hospital, London, UK.

XLH is the most common heritable form of rickets. Approximately 100 different mutations compromising the structure of the PHEX (phosphate-regulating gene with homologies to endopeptidases on the X-chromosome) gene product have been reported in patients worldwide. Nevertheless, PHEX gene defects have not been identified in approximately 33 percent of patients and the pathogenesis of this sex-linked dominant disorder is unclear because the substrate for the putative PHEX-encoded endopeptidase has not been characterized. To explore variable disease severity among XLH families, we performed phenotype/ genotype analysis using a large population of children treated at one institution during the past 15 years. All were receiving therapy with 1,25(OH)2D3 and phosphate supplementation. To date, 60 unrelated probands have had molecular studies of the 2,247 bp PHEX coding region. Different gene defects have been identified in 25 of these XLH families. However, in 13 additional XLH families RT-PCR with DNA sequence analysis failed to reveal a PHEX mutation, thereby excluding a defect in the coding region of the PHEX gene. XLH probands with PHEX mutations were compared to XLH probands in whom no PHEX mutation was identified. Height and arm span Z-scores were used as the principal clinical determinants of XLH severity. TmP/GFR was used as an independent (biochemical) determinant. Medically-treated patients with vs without PHEX mutations had different height and arm span Z-scores (-1.80 vs -0.95, $p = 0.036$ and -1.67 vs -0.61, $p = 0.019$, respectively) and TmP/GFR values (1.90 vs. 2.30, $p = 0.016$, respectively). At diagnosis (untreated) height Z-scores were different (-1.80 vs. -0.41, $p = 0.011$). Only children with mutations had undergone osteotomies. We conclude that disruption of the PHEX gene product is associated with the most severe phenotype in XLH.

Program Nr: 608 from the 1999 ASHG Annual Meeting

The spinal muscular atrophy protein, SMN, fails to form nuclear gems in some mammalian cell types which also lack coiled bodies. *P.J. Young[1], T.T. Le[2], N.T. Man[1], A.H.M. Burghes[2], G.E. Morris*[1]*. 1) MRIC Biochemistry Group, North East Wales Institute, WREXHAM, UK; 2) Dept of Medical Biochemistry, Ohio State University, COLUMBUS, OH.

Spinal muscular atrophy (SMA) is caused by mutations in a gene encoding SMN (survival of motor neurons) protein, leading to reduced SMN levels and loss of motor neurons. SMN is present in the cytoplasm of all cells and in distinct nuclear structures called gems, which associate with nuclear coiled bodies (CBs) and have an indirect role in pre-mRNA splicing. The distribution of nuclear gems and CBs was determined in human, rabbit and pig tissues using monoclonal and polyclonal antibodies against SMN, SMN-interacting protein-1 (SIP-1) and coilin p80 protein. Although SMN and SIP-1 are present in all tissues, nuclear gems were not detected in cardiac and smooth muscles, blood vessels, stomach, skin and spleen. Gems were most abundant in larger neurons of the brain and spinal cord, but they were also present in skeletal muscle, glial cells, liver parenchymal cells, islets of Langerhans and several epithelial cell types. Nuclear CBs were only found in those cell types which also contain gems. Over-expression of SMN in COS-7 cells produced supernumery nuclear bodies which also contained SIP-1 and coilin p80, confirming the close relationship between gems and CBs. However, gems are not essential for CB formation since fibroblasts from SMA patients still contained CBs, although SMN was undetectable and SIP-1 remained in the cytoplasm.
We conclude that gem formation is not determined by high cytoplasmic SMN concentrations alone and a cell-specific factor may be required for formation of both gems and CBs. Our data support the view that nuclear bodies are storage sites which are not essential for nuclear RNA splicing. *We thank the Muscular Dystrophy Association (USA) for grant support, Angus Lamond (University of Dundee) for p80 antibodies and Matt Dunckley (Imperial College School of Medicine, London) for human and pig tissues. .*

Program Nr: 609 from the 1999 ASHG Annual Meeting

The ABCR gene in recessive and dominant Stargardt diseases: a genetic pathway in macular degeneration. *K. Zhang[1], D.C. Garibaldi[1], M. Kniazeva[2], A. Hutchinson[2], M. Han[3], M. Dean[3], R. Allikmets[3,4]*. 1) Wilmer Eye Inst, Johns Hopkins Medical Inst, Baltimore, MD; 2) Dept of Molecular, Cellular and Developmental Biology, Univ of Colorado, Boulder, CO; 3) Laboratory of Genomic Diversity, National Cancer-Institute-FCRDC, Frederick, MD; 4) Dept of Ophthalmology and Pathology, Columbia Univ., New York, NY.

Stargardt disease (STGD) is a juvenile onset macular dystrophy which can be inherited in both an autosomal recessive and dominant manner. Genes involved in dominant STGD have been mapped to human chromosomes 13q (STGD2), 6q (STGD3) and 4p (STGD4). Here, we identify a new kindred with dominant STGD, and demonstrate genetic linkage to the STGD3 locus. Because of a more severe phenotype of one of the patients in the family, the gene responsible for recessive STGD1, ABCR, was analyzed for sequence variants in all family members. One allele of the ABCR gene was shown to carry a stop codon-generating mutation (R152X) in three family members, including the patient who had also inherited STGD3. More specifically, the combination of alleles from both the STGD1 and STGD3 loci appear to result in earlier onset of disease, with a more severe clinical phenotype. A grandparent of the patient with both the STGD1 and STGD3 mutations developed age-related macular degeneration (AMD), consistent with our earlier observation that some variants in the ABCR gene may increase susceptibility to AMD in the heterozygous state. Based on these results, we propose that there is a common genetic pathway in macular degeneration that includes genes for both recessive and dominant STGD.

Program Nr: 610 from the 1999 ASHG Annual Meeting

Variable loss of function of OSF2/CBFA1 correlates with variable expressivity in cleidocranial dysplasia and primary dental abnormalities. *G. Zhou[1], Y. Chen[1], L. Zhou[1], C. R. Greenberg[2], K. Thirunavukkarasu[1], G. Karsenty[1], B. Lee[1]*. 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Human Genetics, University of Manitoba, Winnipeg, MB.

Cleidocranial dysplasia (CCD) is a dominantly inherited skeletal dysplasia characterized by hypoplastic or absent clavicles, large fontanelles, dental anomalies, and delayed skeletal development. Previously we and other groups reported that mutations in the osteoblast-specific transcription factor OSF2/CBFA1 cause CCD. To further correlate OSF2/CBFA1 mutations in different functional domains with the CCD phenotype, we studied twenty-six independent cases of CCD and a total of fifteen new mutations were identified. The majority are missense mutations that affect conserved residues in the runt domain and abolish DNA binding by electrophoretic mobility shift assay (EMSA). These and mutations which result in premature termination in the runt domain produce the phenotype by haploinsufficiency of OSF2/CBFA1. Additionally, we have identified a R391X mutation which encodes for a protein truncated for half of the putative transactivation PST domain. Interestingly, we have found a putative hypomorphic mutation (a T200A substitution) in a highly conserved position of the runt domain which does not affect DNA binding or transactivation in vitro. In this family the father only has primary teeth anomalies, while the sons have the classical CCD skeletal features. This may represent a third type of mutation producing a hypomorphic effect associated with significant clinical variability including an isolated dental phenotype. Alternatively, this might signify alteration of an independent function such as heterodimerization which has been previously attributed to the runt domain. Together these data show that loss of function due to alteration in all three domains (Runt, PST, Q/A) of OSF2/CBFA1 gives rise to clinical variability in the CCD phenotype, and in some cases, mutations may be associated with primary dental anomalies.

Program Nr: 611 from the 1999 ASHG Annual Meeting

Advantages of FISH for characterising delivery of helper-dependent adenoviral vectors for gene therapy. *O.A. Bodamer, B. Mull, B. Lee, A.L. Beaudet.* Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Fluorescence in Situ Hybridization (FISH) is a widely used molecular technique for the detection of human DNA sequences and their localization on metaphase chromosomes and interphase nuclei. Probe preparation typically relies on high quality human DNA from YAC, PAC, BAC or cosmid contigs. We report on the use of FISH for the detection of viral DNA within interphase nuclei, an approach which may allow assessment of efficacy of gene transfer. Human fibroblasts were infected with increasing concentrations of helper-dependent adenoviral vector containing the BOS-ASS (argininosuccinate synthetase) cDNA and human genomic stuffer DNA (100 MOI, 1000 MOI, 10000 MOI) for 4 hrs, 12 hrs, 24 hrs, 48 hrs and 96 hrs respectively. Helper virus contamination of BOS-ASS vector preparation was minimal (~5%) as judged by Southern blotting. FISH was done using the standard FISH protocol currently in use at the Cytogenetics Laboratory at Baylor College of Medicine. BOS-ASS vector and helper virus particles were detected following the in situ hybridization of extracted interphase nuclei by the use of digitoxin labeled adenoviral backbone and helper virus DNA respectively. There was good correlation between the dose of infection and the number of FISH signals for BOS-ASS vector and helper virus respectively. Helper-dependent adenoviral vectors are hard to titer because they do not form plaques. FISH allows a biologically meaningful direct measurement of the number of vector and helper genomes delivered to tissues such as liver and on metaphase cells to determine if vector DNA is integrated in the host genome or not. Both viral DNA sequences can also be conveniently detected using two-color FISH. FISH may consequently play an important role for the *in-vivo* assessment of gene transfer in human trials.

Program Nr: 612 from the 1999 ASHG Annual Meeting

Synergistic effect of histone hyperacetylation and DNA demethylation in the reactivation of the FMR1 gene. *P. Chiurazzi[1], M.G. Pomponi[1], R. Pietrobono[1], C.E. Bakker[2], G. Neri[1], B.A. Oostra[2].* 1) Institute of Medical Genetics, Catholic University, and Centro Ricerche per la Disabilita' Mentale e Motoria, Associazione Anni Verdi, Rome, Italy; 2) Department of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

Most fragile X syndrome patients have an expansion of a (CGG)n sequence with more than 200 repeats (full mutation) in the promoter region of the FMR1 gene, responsible for this condition. Hypermethylation of the expanded repeat and of the FMR1 CpG island is almost always present and apparently suppresses transcription, resulting in the absence of the FMR1 protein. We recently showed that transcriptional reactivation of FMR1 full mutations can be achieved by inducing DNA demethylation with 5-azadeoxycytidine (5-azadC). Given that the level of histone acetylation is another important factor in regulating gene expression, we treated lymphoblastoid cell lines from nonmosaic full mutation patients with three drugs capable of inducing histone hyperacetylation. We report a consistent, although quantitatively modest, reactivation of FMR1 with 4-phenylbutyrate (4-PBA), sodium butyrate (BA) and trichostatin A (TSA), as shown by RT-PCR. However, combining these drugs with 5-azadC results in a 2- to 5-fold increase of FMR1 mRNA levels obtained with 5-azadC alone, thus showing a marked synergistic effect of histone hyperacetylation and DNA demethylation. Lastly, we treated the cell lines with acetyl-L-carnitine (ALC), a compound with a chemical structure similar to that of butyrate. The effect of ALC on FMR1 reactivation was similar to that of 4-PBA and BA. It is worth noting that ALC, an approved drug, was found to be effective in the treatment of hyperactivity in an experimental animal model. Preliminary data suggest that a similar effect is present in fragile X syndrome patients treated with ALC. P.C. is recipient of Telethon fellowship 283B. Supported by Telethon grant E.245 to G.N. and Associazione Anni Verdi, Roma.

Program Nr: 613 from the 1999 ASHG Annual Meeting

Mammalian artificial chromosome ST1. *M.H. Shen[1], J. Mee[2], F. Brook[3], J. Nichols[2], J. Yang[1], A. Smith[2], R. Gardner[3], W. Brown[1]*. 1) Dept Biochemistry, Univ Oxford, Oxford OX1 3QU, England; 2) Centre for Genome Research, Univ Edinburgh, Edinburgh EH9 3JQ, Scotland; 3) Dept Zoology, Univ Oxford, Oxford OX1 3PS, England.

Generation of a mammalian artificial chromosome (MAC) should help us understand the DNA sequence elements required for chromosome function during mitosis and meiosis. MACs may also be useful as vectors for introducing large DNA fragments into cells or animals. We have engineered a 4.5 Mb mini-chromosome, termed ST1, that consists of 3.0 Mb mouse centromeric DNA and 1.5 Mb human DNA including an array of <100 kb alphoid satellite sequence. ST1 is structurally and mitotically stable in cultured cells of chicken, murine or human origin. We have transferred ST1 into mouse ES cells and established chimeric animals from these cells. The mini-chromosome is stable in these animals and can be transmitted through the female germ line. These results help define the molecular and cellular requirements for MAC construction.

Program Nr: 614 from the 1999 ASHG Annual Meeting

Neural stem cells for the treatment of the twitcher mouse model of Krabbe disease. *D.A. Wenger[1], E.Y. Snyder[2], R.M. Taylor[3], M.T. Vanier[4], M.A. Rafi[1], P. Luzi[1], J. Datto[1]*. 1) Dept Neurology, Jefferson Medical Col, Philadelphia, PA; 2) Dept Neurology, Harvard Medical School, Boston, MA; 3) Faculty of Veterinary Sci, University of Sydney, Australia; 4) INSERM U189, Oullins, France.

Krabbe disease is an autosomal recessive disorder of humans and certain animals, including twitcher (twi) mice, caused by the deficiency of galactocerebrosidase (GALC) activity. This lysosomal enzyme is responsible for the degradation of certain galactolipids, gal-ceramide and psychosine. The accumulation of psychosine in white matter causes death to oligodendrocytes (OLG) resulting in the loss of myelin and presence of characteristic globoid cells. Therefore therapy strategies could include either supplying GALC activity to OLG healthy enough to produce myelin, or replacement of dead or dying OLG with new ones that contain GALC activity. Neural stem cells (NSC) are immature brain cells that can be cultured, and once injected into the brain, can differentiate into several cell types, including OLG. Initially, unmodified NSC, (clone C17.2), were injected intracerebroventricularly into newborn twi mice. The cells engrafted throughout the brain and differentiated into healthy OLG. Donor cells can be detected by a X-gal histochemical reaction. In regions of NSC engraftment, normal appearing myelin can be clearly visualized, while axons in non-engrafted areas do not show myelination. Because these mice did not show complete phenotypic or biochemical correction, NSC were transduced with a retroviral vector containing human GALC cDNA (MFG-GALC). Three subpopulations of NSC were isolated, and these express 78, 94 and 99 nmol/h/mg prot of GALC activity vs 5-7 in untransduced NSC clones. These will have more GALC activity to donate to OLG of the recipient. At this time all newborn mice from 7 litters of heterozygous twi matings have been injected with over-expressing NSC. Twi mice from currently injected litters will be evaluated clinically, and the brains will be examined biochemically for GALC activity and lipids, and neuropathologically for myelination and the presence of GALC antigen. The successful use of NSC for this disorder has implications for the treatment of other neurodegenerative disorders.

Program Nr: 615 from the 1999 ASHG Annual Meeting

Fine mapping of a neuroblastoma tumor suppressor candidate gene region in 1p36.2-3, and mutation analysis of the cortistatin gene localized to the region. *F. Abel[1], K. Ejeskar[1], R.M. Sjoberg[1], P. Kogner[2], T. Martinsson[1]*. 1) Dept Clin Genetics, Sahlgrenska Univ Hosp, Gothenburg, Sweden; 2) Childhood Cancer Research Unit, Karolinska Hosp, Stockholm, Sweden.

Neuroblastoma is a childhood tumor originating from the neural crest. A common genetic feature of neuroblastomas, also being an important prognostic factor, are deletions of chromosome region 1p. The deletion of 1p often involves a deletion of varying size, with a consensus region within the most distal bands 1p36.2-3. The neuroblastoma SRO (shortest region of overlap of deletions) presented earlier by our group is defined distally by the cluster of loci D1S80/D1Z2/CDC2L1 and proximally by loci D1S244 i.e. app. 25 cM. The 1p deletions are, however, not restricted to neuroblastoma tumors. In fact a large spectrum of tumor types display deletions to varying degree of distal 1p. We have exploited the possibility of using deletions of other tumor types, preferentially that of germ cell tumors, and combining those with that of the neuroblastoma SRO. Also in germ cell tumors distal 1p-deletion have been shown to have prognostic significance. We found in our germ cell tumors a SRO ranging from D1S508 to D1S200. Interestingly, this region only partially overlapped (app. 5cM) with our neuroblastoma SRO in region D1S508 to D1S244. We have thus focused on analyzing this smaller region in search for genes involved in the genesis of different cancers. We have performed radiation hybrid mapping of a large number of markers, STSs, ESTs and others known to reside in 1p. We have also initiated the development of a BAC contig of the region. FISH, and fiber-FISH mapping of BACs were also performed. Cortistatin (CORT) is highly homologous to somatostatin, and the presence of somatostatin in neuroblastoma tumors has been shown to have a favorable prognostic value. Here we have localized CORT to the neuroblastoma consensus region, defined the genomic organization of the gene and performed mutation analyses and gene expression studies of neuroblastoma primary tumors. No evidence has yet however been found to confirm CORT to be a neuroblastoma tumor suppressor gene.

Program Nr: 616 from the 1999 ASHG Annual Meeting

Identification of Thy-1 as a putative tumor suppressor gene for ovarian cancer. *H.R. Abeysinghe[1], S.J. Pollock[1], P. Keng[2], J. Xu[1], M. Halterman[3], H.J. Federoff[3], N.L. Guckert[1], B. Cohen[1], N. Wang[1]*. 1) Dept. of Pathology and Laboratory Medicine; 2) Dept. of Radiation Oncology; 3) Center for Aging and Development Biology, University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642.

Microcell-mediated transfer of chromosome 11 into the human ovarian cancer cell line SKOV-3 results in complete and partial suppression of tumorigenicity in mice. To identify the differentially expressed transcripts associated with tumor suppression, cDNA population from the slow-growing tumorigenic clone 11(H)8-3, tumorigenic clone 11(H)8-4 and SKOV-3 cells were subtracted from the non-tumorigenic clones, 11(H)7-2 and 11(C)9-8. The differentially expressed transcripts were cloned, sequenced, characterized, and their expression confirmed by northern analysis. A cDNA transcript corresponding to the Thy-1 gene, located at chromosome 11q23-24, was found to be exclusively expressed in the two non-tumorigenic clones, 11(H)7-2 and 11(C)9-8. This expression pattern was confirmed by immunocytochemistry and flow cytometry at the protein level. Thy-1 was also shown to be expressed in normal ovarian tissue. However, no Thy-1 expression was detected in five ovarian tumor lines examined. The entire cDNA of the Thy-1 gene was cloned and was found to be different from the published sequence. The cloned Thy-1 sequence was confirmed in DNA samples derived from both normal male and female. Transfection of Thy-1 cDNA into SKOV-3 with its subsequent expression reduced tumor growth but did not suppress it completely. However, transfection of Thy-1 antisense into cells from the non-tumorigenic clone 11(C)9-8 resulted in almost complete inhibition of expression, and the restoration of tumorigenicity in two of three animals inoculated. Cells derived from these two tumors did not express any detectable Thy-1. These observations indicate that Thy-1 is a putative tumor suppressor gene for ovarian cancer.

Program Nr: 617 from the 1999 ASHG Annual Meeting

Retrospective analysis of the Wijnen et al. logistic model in 43 HNPCC families. *K. Aittomaki[1], C. Gaff[1], J. St.John[2], F. Macrae[2], R.J.M. Gardner[1].* 1) Victorian Clin. Genet. Service, Melbourne, Victoria, Australia; 2) Department of Gastroenterology, Royal Melbourne Hospital, Australia.

Genetic testing for HNPCC remains complicated with a large number of mutations scattered along several genes. Special features of family history, MSI testing and immunohistochemistry can be used as tools to select families for genetic testing. Based on data from 184 families with 47 mutations in MLH1 and MSH2 Wijnen et al have developed a logistic model to calculate the probability of finding a mutation in a given family using the mean age at diagnosis of colorectal cancer (CRC), Amsterdam positive/negative and presence/absence of endometrial cancer as criteria. They suggest that direct genetic testing without prior MSI should be done in families with ³ 0.2 likelihood of finding a mutation. In others, MSI testing should be performed prior to genetic screening. To evaluate the usefulness of the Wijnen et al. logistic model, we have retrospectively analysed 43 HNPCC families with the model. Of these, 20 families have an identified mutation whereas 23 had a negative PTT result for mutations in MLH1 and MSH2. The mean age at diagnosis of CRC was 44.1 years in families with a mutation and 53.7 in mutation negative families. In both groups 12 families were positive for Amsterdam criteria and the number of families with endometrial cancer was 8 and 5, respectively. When analyzed, 75% (15) of the mutation positive families had a probability score of 0.2 or higher. In 74% (17) of the mutation negative families the score was lower than 0.2 suggesting the use of MSI testing prior to screening for mutations. We conclude that the Wijnen et al. logistic model can be used as a screening method for direct genetic testing for HNPCC. However, it is important to realize that it cannot be used as a tool for selecting families for genetic testing. The purpose of this model is to help in minimizing the need for other tests such as MSI. This is particularly important in countries like Australia where due to migration families have relatives overseas and accessing tumour blocks for MSI testing is often difficult, time consuming and expensive, if not impossible.

Program Nr: 618 from the 1999 ASHG Annual Meeting

False negative results in BRCA testing from paraffin-embedded tumors. *M. Alvarez-Franco, E. Matloff, A.E. Bale.* Genetics, Yale University, New Haven, CT.

BRCA 1 & 2 testing is often sought by healthy women in high-risk families who wish to determine if they are at increased risk for breast/ovarian cancer. Three mutations (185delAG & 5382insC in BRCA1; 6174delT in BRCA2) are found frequently in Ashkenazi Jews. Typically an affected family member, who can serve as a positive control, is tested along with at-risk relatives. Testing unaffected individuals without testing affected relatives can lead to ambiguous results. A negative test may indicate that the subject is in fact a true negative, the family carries a mutation not detected by the test, or breast cancer in the family represents a sporadic clustering. In kindreds with no living affected members, archived pathology specimens can be analyzed as a means of determining whether one of these mutations segregates in the family. We obtained tissue blocks from deceased probands in 11 Ashkenazi Jewish families in which no living, affected relatives were available for testing. DNA extracts from blocks were analyzed for the mutations by PCR and direct sequencing of BRCA1 exons 2 and 20 and BRCA2 exon 11. 185delAG was found in 3 samples, 5382insC in 2, and no mutation in 4. Two blocks failed to amplify, even with nested primers. Heterogeneity of tumor tissue was a potential problem in this study. In one of the families, a 5382insC mutation was detected in one region of a breast tumor while another area was negative. It is very unlikely that this result represents a somatic, tumor-specific genetic alteration resulting in creation of a founder mutation. Although unusual, it appears that portions of this tumor lost the mutant 5382insC allele. To evaluate the prevalence of this phenomenon, tissue blocks from other families with known mutations were tested. In a family with a 185delAG mutation, paraffin-embedded colon tumor tissue lost the mutant allele almost completely. Testing tissue blocks for founder mutations in Ashkenazi Jews and other ethnic groups should be considered in families with no living, affected relatives. If tumor tissue is used as a source of DNA, then several regions of the tissue should be sampled for the presence of mutations.

Program Nr: 619 from the 1999 ASHG Annual Meeting

Identification of differentially expressed genes which are down regulated in human malignant mesothelioma (MM) using suppression subtractive hybridization (SSH). *S. Apostolou, J. Klein, D. Roberts, J.R. Testa.* Medical Oncology, Fox Chase Cancer Center, Philadelphia, PA.

MM is a highly aggressive mesodermal neoplasm characterized by a long latency following exposure to asbestos. The length of the latent period suggests that multiple genetic alterations may be required for tumorigenic conversion of a mesothelial cell. The most frequent sites of chromosomal loss in MM include 1p21-p22, 3p21, 6q15-21 and 22q, implying that tumor suppressor genes (TSGs) reside in these regions.

To determine which TSGs are localized in these and other chromosome sites of interest, a PCR-based technique, SSH, was used to identify genes expressed in normal mesothelial cells (tester), but absent in MM (driver) cell lines. Following cDNA synthesis from tester and driver, cDNA was digested with *Dpn*II, and tester cDNA was separated into two independent adapter ligated populations. Each tester was hybridized with a different *Dpn*II digested driver, prior to being combined and incubated with an additional adapter-ligated tester/driver hybridization reaction. Tester:tester hybridization products, each containing single stranded cDNA from the individual adapter-ligated cDNA populations, were PCR-amplified and radiolabeled. The final difference products, representing the mRNA present in mesothelial cells but missing in MM cell lines, were separated by electrophoresis in denaturing polyacrylamide gels. Following autoradiography, 50 bands were excised from the gel, and the DNA was eluted then cloned. The inserts were PCR-amplified and sequenced to determine their identity. To validate this technique, 3 clones, annexin VIII, tissue plasminogen activator, and integrin, were randomly chosen to analyze their expression in MM compared to normal mesothelial cells by RT-PCR. These clones possessed differential patterns of expression in MM, including the MM cell lines used in the SSH experiment. Currently, the remaining 47 clones are being investigated for their role in MM. Undoubtedly, the use of SSH to identify differentially expressed genes will lead to a greater understanding of the molecular alterations in MM.

Program Nr: 620 from the 1999 ASHG Annual Meeting

The 8p22 tumor suppressor gene site: identification of novel expressed sequences. *Z.H. Arbieva[1], S.L. Edassery[1], K. Banerjee[1], S.Y. Kim[1], S.K. Horrigan[2], C.A. Westbrook[1]*. 1) Section of Hematology/Oncology, Department of Medicine, Univ Illinois at Chicago, Chicago, IL; 2) Department of Pediatrics, Lombardi Cancer Center, Georgetown University Medical Center, Washington, DC.

The short arm of chromosome 8 is a frequent site of allelic deletions in a wide variety of epithelial tumors. Clinical correlations, as well as functional chromosome transfer studies, have provided supporting evidence that this region contains a tumor suppressor gene (TSG) which is associated with invasiveness and/or tumorigenicity in prostate, colorectal, breast, and other types of cancers. An interval of approximately 1 Mb centered at the MSR marker on 8p22 has emerged as a likely site for TSG activity, based on the high degree of allelic loss and the presence of homozygous deletions in a metastatic prostate tumor sample and a pancreatic cancer cell line. To map this interval and identify candidate genes, we prepared a sequence-ready contig of bacterial clones, making an effort to integrate markers with the Radiation Hybrid Database (Rhdb). Transcribed units within the interval were identified by several strategies including placement of unmapped ESTs from Rhdb, exon amplification, as well as searching and mapping of ESTs from the Human Transcript Map and other published sources. Our effort resulted in the identification of seven unique expressed sequences situated within the target interval; six of them are expressed in a panel of epithelial cell lines and therefore represent viable candidates for the TSG. Analysis of available sequence to date has revealed that two ESTs show minor homology to known genes including a phosphokinase; the others have no known homologies. Full-length sequence assembly is ongoing, and has been completed for three clones. Mutational analysis of these genes and more detailed expression studies are now underway to test them as candidates for the 8p22 TSG.

Program Nr: 621 from the 1999 ASHG Annual Meeting

Deletion mapping identifies a major target site of LOH on chromosome 11q23 in cervical carcinoma. *H. Arias[1,2], J.M. Fakruddin[2], N. Beleno[1], G. Martinez[1], V.V.V.S. Murty[2].* 1) Dep. Immunology, Instituto Nacional de Cancerologia,Cl 1 No. 9-85. Bogota, DC, Colombia; 2) Department of Pathology, College of Physicians & Surgeons of Columbia University, 630 West 168th Street, New York, NY 10032.

Functional studies have shown that the chromosome 11 suppresses tumorigenicity in HeLa cells and other histologic types of cervical carcinoma where the critical region mapped to 11q13-q23. Loss of heterozygosity (LOH) studies has further suggested that one or more tumor suppressor genes relevant to cervical carcinoma maps to chromosome 11. In order to characterize allelic deletions and identify sites of candidate tumor suppressor gene(s), we performed a detailed deletion mapping of chromosome 11 using 30 normal-tumor DNAs from cervical carcinoma assaying 22 polymorphic markers mapped to both the short and long arms. Twenty-four (80%) tumors exhibited LOH at one or more loci with 40% at 11p and 70% at 11q had allelic deletions. The pattern of LOH identified 5 common sites of deletions, 2 on short arm (11p15 with 31%, 11p12-13 with 29%) and 3 on the long arm (11q13 with 37%, 11q23 with 60%, 11q25 with 44%). The region at 11q23 had highest frequency of LOH with the minimal region of deletion spanned by markers D11S4167, D11S1353, D11S4144 and D11S4094, a genetic distance of 6-cM. These data suggest that a candidate tumor suppressor gene lie within this interval that may be important in cervical carcinogenesis.

Program Nr: 622 from the 1999 ASHG Annual Meeting

Molecular characterization of FRAXB and comparative fragile site instability in tumor cell lines. *M.F. Arlt[1], J.M. Fang[1], D.G. Beer[2], T.W. Glover[1]*. 1) Departments of Pediatrics and Human Genetics; 2) Department of Surgery, University of Michigan, Ann Arbor, MI.

Common fragile sites are loci that show gaps or breaks on metaphase chromosomes when cells are grown under conditions that impair DNA synthesis. These fragile site regions span hundreds of Kb. The colocalization of common fragile sites and translocation breakpoints suggests that fragile sites play a role in genomic rearrangements seen in cancer. The best-studied common fragile site is FRA3B, lying within the *FHIT* gene at 3p14.2. *FHIT*/FRA3B shows many aberrations in cancer, including deletions, translocations, and aberrant splicing, suggesting that *FHIT* is a tumor suppressor gene. These studies have raised the question of what properties other common fragile sites and associated genes display in tumorigenesis. FRAXB is a frequently-expressed fragile site mapping to Xp22.3. We have identified YACs that span FRAXB. Like FRA3B, it spans hundreds of Kb. The STS gene is also contained on this YAC. We have investigated three common fragile sites (FRA3B, FRAXB, FRA7H) for deletions in tumor cell lines. Cell lines with *FHIT*/FRA3B alterations were chosen in order to evaluate the relative frequencies of instability at other fragile sites. About 33% of the cell lines had homozygous deletion of FRA3B sequences using genomic PCR assays. Hemizygous deletions at FRAXB were seen in 25% of cell lines. To date, no deletions have been detected at FRA7H. Southern blot analysis to detect hemizygous deletions is underway. We have also examined the expression of genes associated with fragile sites (FHIT at FRA3B; *STS*, *TLR5a*, and *GS1* at FRAXB) in these cell lines. Approximately 86% of cell lines had alterations or deletions in the *FHIT* transcript. *STS* and *GS1* were deleted in only 29% of cell lines and no aberrant transcripts were noted. *TLR5a* was not altered in the cell lines examined. We have shown that deletions occur at FRAXB in addition to FRA3B, suggesting that instability at fragile sites might be a general phenomenon in some tumors. In contrast, gene alterations are much more common at *FHIT*/FRA3B than at *STS*/*TLR5a*/FRAXB, possibly due to the position of FRA3B within the large *FHIT* locus.

Program Nr: 623 from the 1999 ASHG Annual Meeting

Mapping of Chromosomal Imbalances in Sporadic Basal Cell Carcinoma by CGH and LOH. *K.J Ashton[1], B.F Williams[2], S.R Weinstein[3], D.J Maguire[4], L.R Griffiths[1].* 1) Genomics Res Ctr, Sch Hlth Sci, Griffith University-Gold Coast, Southport QLD, Australia; 2) Perceptive Scientific International, Chester, United Kingdom; 3) Deparatment of Pathology, Gold Coast Hospital, Southport QLD, Australia; 4) School of BBS, Griffith University-Nathan, Nathan QLD, Australia.

Comparative genomic hybridization (CGH) has become a powerful investigative tool in tumorigenesis allowing the mapping of chromosomal imbalances to normal metaphase spreads. In conjunction with tissue microdissection and degenerate oligonucleotide-primed polymerase chain reaction (DOP-PCR), CGH can be used to investigate tumors stored as paraffin embedded tissue. We have used this approach to define chromosomal imbalances present in eleven sporadic basal cell carcinoma (BCC) biopsies. We have shown several losses at 9q, which contains the putative tumor suppressor gene *Patched*. This gene maps to 9q22.3 and has been implicated in Gorlin's syndrome (a familial form of BCC) and several sporadic BCCs. These results were validated by the use of four microsatellite markers mapping across 9q21-qter to determine loss of heterozygosity (LOH). In addition other more novel chromosomal imbalances have been identified by CGH including gains on chromosomes 6, 11, 18 and 20 which were not associated with the 9q loss. This study may have important implications in the genetic characterization of BCC tumorigenesis.

Program Nr: 624 from the 1999 ASHG Annual Meeting

Comprehensive evaluation of HER-2/*neu* gene status in Breast cancer by FISH and Immunohistochemistry (IHC) methodologies. *V.R. Babu, C. Hashimoto, I. Klisak, S. Pham, J.B. Peter.* Specialty Laboratories, Santa Monica, CA.

HER-2/*neu* gene amplification/over expression has prognostic value in breast cancer treatment. The literature reveals discordant results between FISH and IHC detection methodologies. To assess the relative roles played by these techniques in clinical practice, we conducted a retrospective, blind study in which formalin-fixed paraffin-embedded sections from 40 breast cancer patients including six controls were subjected to FISH and IHC testing. FISH was done using PathVysion^{TM} kit (Vysis). If a tumor has an aggregate ratio of equal or greater than 2 between HER-2/*neu* gene copy number and chromosome 17 centromere, it was considered amplified; less than 2 was scored as unamplified. For IHC, Dako Antibody (A0485) was used with the following scoring criteria based on staining intensity: 0, 1+ unamplified; 2+, 3+ amplified. 100% concordance was obtained on all controls. Of the 34 test cases, by both methods, 23 were unamplified and 4 amplified. Seven had discordant results. A scond prospective study of 11 new consecutive cases was undertaken using adjacent tissue sections for IHC and FISH. Tumor cells were identified by H & E stain prior to FISH scoring. Of the 11, seven were unamplified and two amplified by both methods. There were two discordant results. The combined results revealed that 1) there was 100% concordance between FISH and IHC for unamplified patients 2) only 75% of IHC 3+ (6 of 8) positive cases had gene amplification by FISH 3) none (7 of 7) of IHC 2+ positive cases showed gene amplification by FISH. A repeat study with sequential H & E and FISH scoring on one of the patients with discordant results produced the same results. We conclude that IHC is an efficient screening method in the investigation of HER-2/*neu* gene amplification/over expression and FISH is a useful, objective, confirmatory technique for all IHC 'positive' cases. Since only 25% of breast cancers show HER-2/*neu* gene amplification/over expression, the proposed reflex protocol has significant cost benefits to patients. As further methodological enhancements emerge, the proper placement of IHC 2+ and 3+ cases with respect to FISH testing might become clear.

Program Nr: 625 from the 1999 ASHG Annual Meeting

Mutations in the VHL gene as biomarkers of histological discrimination in renal epithelial neoplasia. *N. Barnabas[1], M. Amin[1], K.R Pindolia[1], R. Nanavati[1], M.B. Amin[2], M.J. Worsham[1].* 1) Cancer Genetics Research, Henry Ford Health Systems, Detroit, MI; 2) Emory University, Atlanta, GA.

Renal epithelial neoplasm's (REN) with abundant granular cytoplasm include oncocytomas, eosinophillic variants of chromophobe, papillary renal carcinoma (RCC), collecting duct carcinoma and some conventional (clear cell) RCC. There is controversy whether granular RCC not otherwise specified (NOS) is a distinctive subtype of RCC. To determine if mutations in the VHL gene could serve as ancillary diagnostic markers for histologic subtypes of REN, we analyzed 69 REN-53 carcinomas: 25 clear cell (CC): 18 conventional RCC's (including 4 mixed : clear and granular cells and 14 with clear histology) plus 7 RCC-NOS, 15 chromophobes (CP, including 6 with classic and 9 with eosinophilic histology); 14 papillary (PC), and 16 oncocytomas (OC), benign lesions). Exons 1,2 and 3 of the VHL gene were evaluated using sequencing analysis . Six of the 7 granular RCC-NOS cases had potential mutants in tumors compared to normal tissue, as did 5/14 cases of conventional clear cell carcinoma and 3/4 of mixed call carcinoma. In the CC group, the high frequency of VHL mutations of 60 percent in conventional and granular RCC-NOS suggest that the latter is a histologic variant encountered in conventional RCC and is associated with high-grade histology. Potential mutants were observed in 40 percent of CP patients and were absent in OC and PC. The majority of the these mutations in the CP group were clustered in the eosinophillic subtype (4/9). Involvement of exon 3 was observed exclusively in the CC group. The latter may aid in morphological distinction between CC and CP with clear cells. No mutations were observed in exon 2 in either CC or CP. Similarly, diagnostic differentiation between CP and OC, particularly in the presence of granular cytoplasm, which is problematic at the microscopic level, would be facilitated at the molecular level by VHL shifts if favor of CP over OC. An example of sequencing analysis in one CC (CL13) case revealed an ins G at codon 206 resulting in a frameshift mutation in exon 3. Mutations in the VHL gene may serve as biomarkers of histologic discrimination in REN.

Program Nr: 626 from the 1999 ASHG Annual Meeting

Identification of novel tumor associated antigens in a cohort of patients undergoing an immunotherapeutic clinical trial for advanced stage melanoma. *B.R. Bellows[1], R.M. Conry[2], M.C. Bonnet[3], A.F. LoBuglio[2], T.V. Strong[2].* 1) Department of Human Genetics, University of Alabama at Birmingham, Birmingham, Alabama; 2) Comprehensive Cancer Center, University of Alabama at Birmingham, Birmingham, Alabama; 3) Cancer Program, Pasteur Meuriex Connaught, Leon, France.

The identification of novel tumor associated antigens may be biologically useful for a number of reasons, including identifying genes important in the progression of cells from normal to the malignant state, identifying targets for cancer detection/diagnosis, providing insight into mechanisms of immune rejection/escape, and expanding targets for immunotherapeutic treatments. A number of these antigenic proteins have been identified, and human clinical observations suggest that immune responses to such antigenic proteins may act to excel tumor destruction through natural defense mechanisms. In this study, a group of 9 stage IV melanoma patients recieved escalating doses of canarypox virus (ALVAC) encoding rhIL-12 intra-tumorally in accessible melanoma nodules. Sera was collected from each patient on day 0, 18, and 43 of treatment. Sera from patient #1, who has experienced a complete response to treatment and has subsequently been disease free for 21 months, was used to screen a cDNA library synthesized from the human melanoma cell lines MEL 624 and MEL 888 in a SEREX strategy. Six immunologically reactive clones have been isolated and partially characterized. These 6 proteins (5 full length proteins and 1 partial sequence) have not been previously implicated as tumor antigens and are not immunologically reactive with a panel of 10 normal sera. Furthermore, 1 of these proteins is reactive with multiple patients, indicating a possible shared antigen. Isotype analysis of the antibody response to these proteins has been established, revealing both IgG1 and IgG3 antibody responses to several proteins. Expression of the genes in the autologous tumor from the reactive patients and in normal tissue is currently being investigated.

Program Nr: 627 from the 1999 ASHG Annual Meeting

Acquired Monosomy 7 in Donor Cells Three Months Post Stem Cell Transplant. *P.K. Berry[1], J.A. Brochstein[3], K. Richkind[2], B. Adler Brecher[3]*. 1) Genzyme Genetics, Yonkers, NY; 2) Genzyme Genetics, Santa Fe, NY; 3) Pediatric Stem Cell Transplant Program, Hackensack University Medical Center.

Three months after unrelated umbilical cord blood transplantation for acute leukemia, a 10 month old baby girl was found to have monosomy 7 in 4 of the 20 male donor cells evaluated by classical cytogenetics. Interphase FISH analysis revealed, in addition to 17% monosomy 7 in donor cells, that 4% of the cells were female. The original donor cells were examined using interphase FISH and were male and negative for monosomy 7. Over the course of the next six weeks there was an increase in monosomy 7 cells, which peaked at approximately 42% in the donor cells. Concurrently the percent of female cells determined by interphase FISH also increased and peaked around 80%. It is interesting to note that interphase FISH consistently detected a higher percentage of female cells than classical cytogenetics. Flow cytometry at this point was most consistent with recurrence of the patient's precursor B-cell ALL and the DNA content showed a diploid pattern with an intermediate S-phase fraction. Chemotherapy was initiated approximately six weeks after the initial identification of aberrant host cells. Subsequently, the number of both the female cells and the monosomy 7 donor cells decreased. Eight weeks later the marrow returned to apparently normal male cells by classical cytogenetics and interphase FISH. Secondary MDS in donor cells is rare, only four cases having been reported in the literature. This is the first case of MDS in donor cells presenting in such a short time post stem cell transplantation and identified in cord blood-derived donor cells. These findings underscore the importance of both classical cytogenetics and FISH studies to monitor the course of bone marrow transplants, both from same sex and opposite sex donors, as well as, those where chromosome markers are present in the recipient cells.

Program Nr: 628 from the 1999 ASHG Annual Meeting

Psychosocial factors predicting genetic testing decisions in members of hereditary breast and ovarian cancer families. *B.B. Biesecker[1], N. Ishibe[2], D.W. Hadley[1], T.R. Giambarresi[2], R.G. Kase[2], C. Lerman[3], J.P. Struewing[4]*. 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Genetic Epidemiology Branch, NCI/NIH, Bethesda, MD; 3) Lombardi Cancer Center, Georgetown University Medical Cntr Washington DC; 4) Laboratory of Population Genetics, NCI/NIH, Bethesda, MD.

Much is yet to be learned about the most effective ways to provide counseling to persons interested in BRCA1/2 testing. The goal of our study was to identify factors associated with genetic testing decisions in a cohort of hereditary breast and ovarian cancer families. These extended families are known to carry BRCA1 or BRCA2 mutations. Personality traits, family functioning and sociodemographics were self-assessed using psychometric instruments at baseline. Among 172 individuals who participated in pre-test education and counseling, 135 (78 percent) chose to undergo genetic testing and 37 (22 percent) chose not to be tested. Individuals who chose to undergo genetic testing were more likely to be older (>40 yrs), to have higher levels of optimism and to report higher levels of cohesiveness in their families. A better understanding of factors which influence interest in predictive testing may help to inform the counseling that occurs prior to genetic testing.

Program Nr: 629 from the 1999 ASHG Annual Meeting

Low frequency of p53 gene mutations in breast cancers of Japanese-American women. *H. Blaszyk[1], C.H. Buzin[2], S.E. Tang[2], A. Shibata[3], J.M. Cunningham[1], R.K. Ross[4], J.S. Kovach[2]*. 1) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Molecular Medicine, City of Hope, Duarte, CA; 3) Epidemiology and Health Research, Stanford University School of Medicine, Stanford, CA; 4) Preventive Medicine, USC/Norris Comprehensive Cancer Center, Los Angeles, CA.

Differences in frequencies and patterns of somatic p53 gene mutations among racially and geographically diverse populations presumably reflect exposure to different mutagens or different responses to certain mutagens. Upon emigration to the United States, Japanese women experience, over several generations, a 4-5 fold increase in the incidence of breast cancer. To determine whether this increased incidence is associated with a change in the frequency and/or type of p53 gene mutation in their tumors, we examined paraffin-embedded samples of primary breast cancers from Japanese-American women in Los Angeles County, CA. Mutations in exons 5-9 and adjacent intronic regions of the p53 gene were identified and confirmed by direct sequencing. Seven mutations, including 5 missense, were detected in 44 primary breast cancers, a frequency of 16%. There were six transitions and one transversion, including a very rare nonsense mutation at codon 242. As expected, overexpression of P53 protein, detected by immunohistochemistry, occured in tumors with missense mutations; tumors with nonsense or splice junction mutations had no detectable P53 protein. The frequency of p53 gene mutations showed no increase over that previously found in breast cancers of native Japanese and U.S. women. The increased incidence of breast cancer in Japanese-American women is unlikely to be due to a single dominant mutagen and probably multifactorial in nature, warranting further studies.

Program Nr: 630 from the 1999 ASHG Annual Meeting

No association between a (CA)n repeat in the promoter region of the insulin-like growth factor-1 (IGF-1) gene and sporadic prostate and breast cancer cases. *S. Bochum[1], L. Correa-Cerro[1], J. Haeussler[1], O. Cussenot[2], T. Paiss[3], W. Vogel[1]*. 1) Dept. of Medical Genetics, University of Ulm, Germany; 2) Saint Louis Hospital, Paris, France; 3) Dept. of Urology, University of Ulm, Germany.

IGF-1 is a potent mitogen and stimulates growth and inhibits apoptosis of prostate epithelial cells. Recently, several studies suggested that elevated serum IGF-1 levels may be an important predictor of risk for prostate cancer. Chan et al. reported that men in the highest quartile of IGF-1 serum levels had a more than 4 times greater risk developing prostate cancer than men in the lowest quartile, regardless of their baseline level of PSA. Thus, the association between circulating IGF-1 level and risk of prostate cancer seems to be stronger than that of any previously reported risk factor, though there is still some debate. IGF-1 is also implicated in the development and progression of breast cancer and high serum levels have been correlated with breast cancer risk, too. Low IGF-1 serum levels on the other hand are associated with an increased risk for osteoporosis in men. In the latter case a correlation of the IGF-1 serum level and a polymorphic (CA)n repeat in the promoter region about 300 bp upstream the start codon of the IGF-1 gene was shown, indicating functionally different alleles. Because misclassifications of serum IGF-1 levels resulting from variations in measurement accuracy are possible, the detection of a predictive marker on the DNA level could be of great importance for disease prevention and detection. Therefore, we used the polymorphic (CA)n repeat to look for an association in 345 sporadic prostate and in 72 sporadic breast cancer cases and compared them with 182 controls. Neither of these two studies detected any difference in the allele distribution of cases and controls by contingency tables (chi-square-test) or an association between alleles and cancer risk by logistic regression analysis. This result remained unchanged after stratification by age of disease onset or - in the case of prostate cancer - Gleason score. Thus, we conclude that the (CA)n repeat in the IGF-1 gene is not a useful predictor of sporadic prostate or breast cancer at least in the European population.

Program Nr: 631 from the 1999 ASHG Annual Meeting

Positional cloning of a renal cell carcinoma associated familial t(2;3) translocation breakpoint. *D. Bodmer[1], M. Eleveld[1], T. Dijkhuizen[2], I. Janssen[1], M. Weterman[1], H. Janssen[1], A. Geurts van Kessel[1].* 1) Human Genetics, University Hospital Nijmegen, Nijmegen, Gelderland, The Netherlands; 2) Medical Genetics, University of Groningen, Groningen, The Netherlands.

Hereditary renal cell carcinomas (RCC) occur rare and are often reported as a consequence of Von Hippel Lindau (VHL) disease. Also, some RCC families have been encountered exhibiting balanced translocations between chromosome 3 and other chromosomes. In one of these cases, t(3;8), the breakpoint has been cloned and found to occur within a gene on chromosome 3, designated FHIT. Subsequently, it was found that in t(3;8) family members the FHIT gene is fused to another gene on chromosome 8, designated TCR8. The exact role of these (fusion) genes in renal oncogenesis still remains to be established. Recently, we have identified a RCC family with a t(2;3)(q35;q21) chromosome translocation. We have set out to clone the breakpoints involved. To this end, a YAC/PAC/cosmid contig has been established that covers the 3q21 breakpoint region. Currently, we are characterizing breakpoint spanning PACs and cosmids in detail and are searching for gene(s) neighboring and/or spanning the breakpoint. Interestingly, we recently encountered a sporadic RCC case showing the same t(2;3)(q35;q21) as was found in the family. Detailed investigation of tumormaterial using our YAC/PAC/cosmid contig revealed that the 3q21 breakpoint in the sporadic case is not identical to that in the familial case, and is positioned more than 300 kb towards the telomere.

Program Nr: 632 from the 1999 ASHG Annual Meeting

Cytogenetic, molecular cytogenetic, and mutational analysis of 8q24.1 (EXT1) in 47 osteochondroma and chondrosarcoma specimens. *A.K. Boehm, C. Orndal, M. Nelson, E. McComb, J. Neff, R. Robocki, J.A. Bridge.*
Department of Pathology and Microbiology, University of Nebraska Medical Center, Omaha, NE.

Osteochondroma most frequently arises sporadically and as a solitary lesion, but may also arise as multiple lesions characterizing the autosomal dominant disorder hereditary multiple exostoses (HME) and the contiguous gene syndromes, DEFECT-11 and Langer-Giedion syndrome (LGS). HME is genetically heterogeneous. Multiple germline mutations of two putative tumor suppressor genes, EXT1 (8q24.1) and EXT2 (11p11-12), have been demonstrated in HME families. In this study, cytogenetic analyses of 47 sporadic and hereditary osteochondroma and chondrosarcoma revealed loss or structural rearrangements of 8q24.1 and 11p11-12 in nearly all clonally abnormal osteochondromas (13/15 tumor specimens). Subsequently, molecular cytogenetic studies were performed on these specimens utilizing an 8q24.1 cosmid probe (locus D8S51, within the minimal LGS deletion region) and a chromosome 8 specific centromeric probe (control for chromosome 8 copy number) to determine the presence and frequency of submicroscopic deletions. Loss of 8q24.1 was found in 20 of 26 (77%) osteochondromas and 13 of 21 (62%) chondrosarcomas. Lastly, these specimens were subjected to sequence analysis studies of exon 6 (the site of a known deletion hotspot in some HME families). No functional mutations of this exon were detected. It is important to note, however, that these studies do not exclude the possible presence of mutations involving other EXT1 exons. In conclusion, these data indicate that a significant subset of sporadic osteochondromas and chondrosarcomas harbor somatic genetic aberrations at the EXT1 locus, and that loss or mutation of EXT1 may be important in the pathogenesis of sporadic as well as hereditary osteochondromas and chondrosarcomas. Additional studies aimed at the examination of other EXT1 and EXT2 exons may reveal an even higher frequency of deletions or functional mutations of these putative tumor suppressor genes in these neoplasms.

Program Nr: 633 from the 1999 ASHG Annual Meeting

Gene variation and cancer risk: generation of complex haplotypes at the *ATM* locus. *P.E. Bonnen, D.L. Nelson.*
Human and Molecular Genetics, Baylor College of Medicine, Houston, TX.

The majority of cancer cases are sporadic, yet it is likely that all tumors carry genetic lesions. Whether genetic variation in the human population leads to differences in cancer predisposition is unknown. The complexity of this question leads to a need for new methods to explore the effects of functional variants of genes and the interactions of multiple genes. We aim to develop haplotypes and perform association studies to determine if haplotypes at specific cancer-associated genes lend increased or decreased risks for cancer. We hypothesize that functional variants of genes involved in familial cancer participate in sporadic cancer. *ATM* is the gene responsible for the autosomal recessive disease ataxia-telangiectasia (AT). AT is characterized by cerebellar ataxia, oculocutaneous telangiectasia, sensitivity to ionizing radiation, increased incidence of tumors, and chromosomal instability. Heterozygotes are at risk for developing cancer, especially breast cancer. The gene spans 184 kb and contains 66 exons. We used gel-based re-sequencing to examine 29 regions (a total of 13.5 kb) across the *ATM* gene in five unrelated individuals of varied ethnic origin. We detected 17 single nucleotide polymorphisms (SNPs) over these regions. We then used allele specific oligonucleotide (ASO) hybridization assays to determine the genotypes of 9 CEPH families (87 individuals) and 266 samples from four different ethnic origins. Analysis of these data with the program EMHAPFRE has allowed definition of haplotypes and their frequencies. Our next aim is to determine the prevalence of these haplotypes in populations such as AT, breast cancer, and appropriate controls; haplotypes showing an association can be further investigated to determine their contributory functional variation. This study is part of a larger project that aims to develop haplotypes for numerous other cancer-associated genes (e.g. *p53* and *BRCA1*)and to examine the potential combined effects of these genes with *ATM*.

Program Nr: 634 from the 1999 ASHG Annual Meeting

Tracking BMT Patients Using FISH on Flow-sorted Cell Populations. *L.J. Brothman[1], Z. Chen[1], R.H. Adams[1], W.F. Green[3], X.L. Zhu[1], A.R. Brothman[1,2].* 1) Dept. of Pediatrics; 2) Dept. Hum. Genet; 3) Dept. of Int. Med., Univ of Utah, Salt Lake City, UT.

A test was devised to study different cell populations in patients following sex-mismatched bone marrow transplant (BMT). Populations of granulocytes, monocytes, T, B, NK and CD34+ cells were sorted directly onto microscope slides using a BD FACSVantage flow cytometer equipped with an automatic cell deposition unit, with 500 cells/spot. Slides were dried and fixed with 3:1 MeOH:acetic acid prior to FISH. FISH with an X a- and Y-classical satellite probe (DXZ1, DYZ1, Oncor or Vysis) was performed on each of the cell populations. Two patients were initially evaluated and 5-7 sorts each were done following BMT. Patient #450, male, was diagnosed in utero with infantile metachromatic leukodystrophy and underwent an unrelated BMT at 3 mo. of age. Evaluation at day 100 revealed autologous BM reconstitution, persistent abnormal levels of aryl sulfatase A and a 46,XY host karyotype. At 7 mo., a second unrelated BMT was done, and cytogenetics performed 1 mo. later showed XX and XY cells. Initial evaluation of sorted cells showed the T-cells were primarily donor in origin, but NK cells and granulocytes were primarily of host origin. Because of the apparent partial engraftment, immunosuppression was stopped and the patient was monitored clinically. Additional FAC-sorted FISH demonstrated progressive donor engraftment of all cell lines tested. Patient #337, male, was diagnosed with Wiskott-Aldrich Syndrome at 6 mo. of age and underwent HLA-matched cord blood transplant at 18 mo. from his female sibling. BM cytogenetic evaluation at 100 days post BMT revealed 73% XY host cells and 27%XX cells. Cells were sorted to identify lineage origin; B-cells and granulocytes were >50% XY, while T-cells were nearly all XX (95%). He was tapered off immunosuppression and his pattern of engraftment followed with additional sorted samples. FAC sorted FISH analysis can be an invaluable tool for quick and accurate definition of cell line engraftment in patients who have a mixed chimeric pattern of engraftment following BMT. This information can be a useful guide to immunosuppression and clinical management.

Program Nr: 635 from the 1999 ASHG Annual Meeting

Quality Control in Haematological diagnosis through Cytogenetics and Molecular study in Patient with suspicion of LEUKEMIA Ph+. *R. Burgos[1], P.E. Leone[1,2], J.C. Pérez[1], V. Dávalos[1], M.E. Sánchez[1,2], J.C. Santos[1], C. Paz-y-Mino[1,2]*. 1) Hum Mol Genet & Cytogen Lab., Ecuadorian Catholic University, Quito, Ecuador; 2) Medicine Faculty. Ecuadorian Catholic University.

Cytogenetic and molecular studies are employed to diagnosis of leukemia and serve in order to improve the diagnosis and could be used as a quality control for haematological diagnosis. One of the most characteristic alterations in leukemia are the Philadelphia chromosome (Ph+), which is product of translocation between 9 and 22 chromosomes t(9;22) (q34; q11), affecting the BCR-ABL oncogene. This aberration is presented in 95% of individuals with LMC and approximately 15% with LLA. We analyzed 75 individuals that presented diagnosis for leukemia; 35 with Chronic Myeloid Leukemia (CML) and 40 with Acute Lymphoblastic Leukemia (ALL). All individuals were studied for cytogenetic and molecular level using Reverse Transcription Polymerase Chain Reaction (RT-PCR), which has detected 37.5%(ALL) and 62.8%(CML) of all cases that present the re-arrangement t(9; 22) (q34; q11), BCR-ABL oncogene. This data suggests that exists a high percentage of individuals with erroneous diagnosis in Ecuador, according to what was proved in haematological reevaluation of previous diagnosis. We suggest the necessity to apply both of techniques in order to discard or confirm the presumed diagnosis and increase specificity and sensibility of diagnosis. This study is supported by BID-Fundacyt Project.

Program Nr: 636 from the 1999 ASHG Annual Meeting

A minimally invasive assay detects a BRCA2 germline mutation. *T.J. Byrne, M.T. Reece, M.A. Lane, L. Adams, G.M. Cohn.* Ob/Gyn Research, Baystate Medical Center, Springfield, MA.

Many individuals at risk for heritable BRCA1 or BRCA2 mutations may not receive appropriate screening and/or treatment without a definitive molecular diagnosis. Currently, clinical genetic testing requires gene sequencing which is expensive and time consuming. Earlier, we reported the development of an antibody-based assay that correlated with BRCA1 gene alterations in surgical specimens. Subsequently, this assay applied to buccal cells was predictive of BRCA1 gene mutations among at risk individuals. Here, we present a similar assay for BRCA2. Immunoreactivity for antibodies directed against the BRCA2 carboxy and amino terminal groups was observed in buccal cells of low risk controls. A reduction in carboxy group reactivity, relative to amino group reactivity, was noted in the buccal cells of an individual found to have a BRCA2 germline mutation. These results suggest that a simple, antibody-based assay, may serve as a rapid, minimally invasive and inexpensive clinical tool for detecting BRCA1 and BRCA2 mutations that result in protein trunctions.

Program Nr: 637 from the 1999 ASHG Annual Meeting

Characterization of a Carboxypeptidase-A Inhibitor Identified by DD-PCR in Primary Ovarian Tumors and Cell Lines. *G. Callahan, V. Shridhar, L. Hartmann, D.I. Smith.* Experimental Pathology, Mayo Foundation, Rochester, MN.

One in seventy American women will be diagnosed with ovarian cancer and one in a hundred will succumb to the disease. This high mortality rate dictates the necessity for earlier detection and prevention. In order to find genes related to the development of ovarian cancer, we performed differential display PCR analysis on short-term culture, normal ovarian epithelial cells versus four low-passage ovarian cancer cell lines established at Mayo and OVCAR5. We have isolated an interesting candidate gene, which is highly expressed in normal ovarian epithelial cells, but completely absent in 2 of the 5 tested tumor-derived cell lines. Sequencing followed by EST-based walking allowed us to generate the open reading frame for this gene. It codes for a protein that is 222 amino acids long with 85% identity to the mouse latexin protein. In mouse and rat, latexin has been shown to be an inhibitor of carboxypeptidase A, and it contains two potential Ca^{2+}/calmodulin-dependent protein kinase sites and one c-GMP-dependent protein kinase phosphorylation site. On Northern blots, a 2kb transcript was observed at very high levels in normal ovarian epithelium with absence of expression in 2 of 5 ovarian cancer cell lines and 6 of 12 primary ovarian tumors, including 4 out of 8 early stage tumors. In addition, we were able to induce expression in a dose-dependent manner in OV-202 upon 5-aza-2'-deoxycytidine treatment, implicating methylation as one of the mechanisms for inactivation of this gene. Using the Stanford G3 radiation hybrid mapping panel, we localized this gene to human chromosome 3q25. Transfection experiments are currently in progress to examine the gene's functional relevance to ovarian cancer progression.

Program Nr: 638 from the 1999 ASHG Annual Meeting

Lung cancer risk associated with family histories of smoking and lung cancer. *C.L. Carpenter[1], S.J. London[2]*. 1) Preventive Medicine, USC/Norris Compr Cncr, Los Angeles, CA; 2) National Institute of Environmental Health Sciences, Research Triangle Park, NC.

Genetic susceptibility to smoking may increase lung cancer risk because of increasing the likelihood of heavier smoking patterns and greater difficulty in quitting. Family history, often used as a surrogate estimator of genetic susceptibility, has been studied extensively in relationship to disease susceptibility but not in relationship to exposure susceptibility. To assess the lung cancer risk of family history of smoking and family history of lung cancer, we conducted analyses from a population-based case-control study of lung cancer in African American and Caucasian residents of Los Angeles County who ranged in age from 40 to 85 years. In-person interviews elicited smoking history, dietary patterns, occupational exposure and information about other related covariates. Study participants were asked about histories of lung, other cancers and smoking patterns for each of their primary family members (parents, siblings and children). Unconditional logistic regression was used to estimate odds ratios (OR) and 95% confidence intervals (CI). Analyses were restricted to 354 cases and 721 controls that had complete information on smoking and family history. Eleven percent of study participants (14% cases, 10% controls) had a positive family history of lung cancer and 88% of participants (94% cases, 86% controls) had a positive family history of smoking.

Family history of lung cancer was moderately associated with increased risk of lung cancer (OR=1.63; 95% CI = 1.02-2.60), adjusting for family history of smoking, age, race, gender, total pack-years and years since quitting. Family history of smoking was also moderately associated with lung cancer risk (OR=1.78; 95% CI=1.02-3.11), adjusting for family history of lung cancer and study covariates.

Our results suggest that family history of lung cancer and family history of smoking may have independent effects on lung cancer risk.

Program Nr: 639 from the 1999 ASHG Annual Meeting

Absence of germline MSH6 mutations in hereditary nonpolyposis colorectal cancer (HNPCC) and endometrial cancer kindreds. *R.B. Chadwick[1,2], T.W. Prior[2], R. Pyatt[2], C.K. Johnson[1], T.H. Niemann[2], H. Hampel[1], J.S. Graham[1], A. de la Chapelle[1]*. 1) Division of Human Cancer Genetics, Ohio State University, Columbus, OH; 2) Department of Pathology, Ohio State University, Columbus, OH.

Inherited mutations in genes involved in DNA repair lead to early development of colorectal cancer. The primary genes which have been implicated in the familial cancer syndrome known as hereditary nonpolyposis colorectal cancer (HNPCC) are the MSH2 and MLH1 genes. In HNPCC kindreds there is also a greater susceptibility to endometrial cancer. The protein products of the MSH2 and MLH1 genes recognize DNA mismatches and form complexes with each other and with the PMS1, PMS2 and MSH6 proteins. Loss of DNA repair function due to mutation and genomic deletion of both copies of the MSH2 or MLH1 genes leads to a mutator phenotype and tumors which develop in these individuals display microsatellite instability (MSI). There has been a recent report of hereditary mutations being found at a high rate in the MSH6 gene and that tumors which develop in these individuals are not MSI positive or are weakly MSI positive. This study was undertaken in order to determine the mutational frequency of the MSH6 gene in both MSI positive and MSI negative colorectal and endometrial cancers. Individuals from ten MSI positive and five MSI negative HNPCC families were screened for mutations in the MSH6 gene by direct sequencing of all ten exons and flanking intronic regions. Using the same method individuals from ten MSI negative and 14 MSI positive endometrial cancer families were screened for MSH6 mutations. In DNA isolated from blood, only minor amino acid changes were found in the MSH6 gene which are unlikely to be pathogenic. However, in DNA isolated from tumors somatic pathogenic truncating mutations were found. Hence, this study suggests that germline mutation in the MSH6 gene is not a frequent cause of predisposition to familial colorectal and endometrial cancers, but somatic mutations may play a role in the transformation process of cancers in these organs.

Program Nr: 640 from the 1999 ASHG Annual Meeting

Germline polymorphisms in the methylenetetrahydrofolate reductase (MTHFR) and cytochrome-P450 1A1 (CYP1A1) genes and B-cell neoplasm susceptibility. *S.O. Chan, S.L. Gersen.* DIANON Systems, Inc, Stratford, CT.

A recent study indicated that germline polymorphisms, C667T and C4887T, in the MTHFR and CYP1A1 genes, respectively increase the susceptibility of women to endometrial cancer. The association of these polymorphisms with B-cell neoplasms was investigated. Allele specific PCR was used to determine genotypes. Genotype frequency of the MTHFR polymorphism was established for 91 patients with various B-cell neoplasms and was compared with the frequency in 186 controls. No significant association between the C667T polymorphism and risk of B-cell neoplasm was found, with an odds ratio of 0.97 (95% confidence interval: 0.64-1.49, P=0.8936). The frequency of the C4887T polymorphism was determined in 137 patients and was compared with the frequency in 100 controls. A significant association between the C4887T polymorphism and risk of B-cell neoplasm was found, with an odds ratio of 10.38 (95% confidence interval: 1.34-80.74, P=0.0062). Thus, this study suggests that the C4887T polymorphism in the cytochrome-P450 1A1 gene may influence susceptibility to B-cell neoplasms. Larger sample sizes are required to corroborate these findings.

Program Nr: 641 from the 1999 ASHG Annual Meeting

A Functional Genetic Strategy to Identify Novel Genes in the Chromosome 3p12-Mediated Pathway to Tumorigenesis in the Kidney. *D.S. Chandler, S.T. Lott, D.L. Tirpak, A.M. Killary.* Department of Pathology and Laboratory Medicine, UT M.D. Anderson Cancer Center, Houston, TX.

High frequency loss of heterozygosity, homozygous deletion, cytogenetic aberrations and our own physical mapping and functional complementation studies have implicated chromosome 3p12 to contain an important tumor suppressor gene for renal cell carcinoma. Our laboratory has taken a functional genetic strategy to identify novel genes involved in the chromosome 3p pathway to tumorigenesis in the kidney. Defined microcell hybrid clones were previously constructed by the transfer of a 3p centric fragment encompassing 3p12-q11 into three different RCC cell backgrounds. Transfer of this 3p fragment resulted in dramatic tumor suppression concomitant with rapid cell death of RCC cells *in vivo* and allowed the physical mapping of a novel tumor suppressor locus *NRC-1* into the 3p12 interval. We now report the utilization of these hybrid clones, differing by only 1-2 Mb within 3p12 and yet phenotypically differing greatly in their ability to form progressive tumors in athymic nude mice, as starting materials to identify downstream genes in the 3p12 pathway to tumorigenesis. PCR select subtractive hybridization was used to identify cDNAs that were differentially expressed between microcell hybrids suppressed or unsuppressed for tumorigenecity *in vivo*. Nine hundred partial cDNA clones were identified using PCR select subtraction. Nine of ten cDNAs selected at random were sequenced and found to be novel cDNAs with sequence similarities including genes involved in transcriptional regulation and cell adhesion. In addition, RNase protection assays identified cDNAs that were expressed exclusively in hybrids suppressed for tumorigenicity and absent or downregulated for expression in RCC parental cell lines. We are currently screening for differential expression of PCR-select clones using microarray technology and RNase protection assays. The long term goal of these studies will be the definition of genetic pathways to tumorigenesis in the kidney.

Program Nr: 642 from the 1999 ASHG Annual Meeting

Bcl 10 is not commonly mutated in multiple primary solid tumors. *J.G. Chang[1], H.H. Lee[1], N.M. Wang[1], K.T. Yeh[2], F.J. Tsai[1], C.H. Tsai[1]*. 1) Dept Medical Res,Div Molec Med, China Medical Col Hosp, Taichung, Taiwan; 2) Department of Pathology, Changhua Christian Hospital, Changhua.

The Bcl 10 gene was recently discovered to be involved in the pathogenesis of lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma) and several types of tumorous cell lines. We examined the Bcl 10 gene in a panel of cancers along with their corresponding non-tumorous tissue by PCR-SSCP and direct sequencing. A total of 8 different types of carcinoma and their paired non-tumorous tissues were studied; and it included 33 breast cancers, 39 gastric cancers, 30 cervical cancers, 31 thyroid cancers, 33 oral cancers, 47 lung cancers, 34 hepatoma and 30 colo-rectal cancers. There were three gene alterations found in this screening: (1) a CTG to CTC change at codon 8 which did not alter the amino acid sequence, (2) a GCA to TCA mutation at codon 5 which changes the amino acid alanine to serine, and (3) a GGA to GAA mutation at codon 213 which changes glycine to glutamic acid. No other gene alteration was detected in the cancerous tissues. However, these mutations were also found in the paired non-tumor tissues and normal individuals' tissues. Therefore, these three changes may be the polymorphic forms of the gene and have no relationship with pathogenesis of malignancy. We suggest that the Bcl 10 gene is rarely involved in the pathogenesis for most types of cancers, and the changes in the tumor cell lines, such as p16 mutation in most of cell line, which may be due to in vitro selection.

Program Nr: 643 from the 1999 ASHG Annual Meeting

Increased incidence of thyroid cancer in first-degree relatives of probands with non-medullary thyroid cancer: a case-control-cohort study. *P.O. Chappuis[1,2], H. Renard[3], T. Kantemiroff[1], K. Sanders[1], A. MacMillan[1], M.J. Black[2], D.E. Goldgar[3], W.D. Foulkes[1,2].* 1) Depts Medicine and Human Genetics, Montreal General Hospital, McGill University, Montreal, QC, Canada; 2) Cancer Prevention Research Unit and Dept. Head and Neck Surgery, SMBD-Jewish General Hospital, McGill University, Montreal, QC, Canada; 3) Unit of Genetic Epidemiology, IARC, F-69372, Lyon, Cedex 08, France.

Non-medullary thyroid cancer (NMTC) is uncommon (~1.5% of all cancers in Canada) but its incidence in Canada is increasing, especially in women (6% increase per year 1987-1996, P=0.01). The heritable fraction of NMTC is uncertain, but families with several cases of NMTC +/- goitre have been reported, and 2 loci (MNG1 and TOC) have been identified. We conducted a case-control-cohort study of 176 prevalent cases (66% of all eligible cases) of NMTC diagnosed 1986-1996 at McGill University teaching hospitals and 198 hospital-based age, sex and ethnically-matched controls. Family history of cancer and thyroid disease was recorded for all first-degree relatives (FDR) of cases and controls. 70.5% of the cases and 72.2% of the controls were females. The ages at interview of cases and controls did not differ (means 48.8 yrs and 48.9 yrs respectively). There were 1157 FDR of cases and 1233 FDR of controls. The mean ages of case and control relatives was 46.9 yrs and 50.2 yrs respectively. There were 10 reported thyroid cancers in case relatives and 2 in control relatives. In a survival analysis, the case and control relatives curves were significantly different (P=0.009, log-rank). The incident rate ratio (IRR) was 5.7 (95%CI: 1.2-53.4, P=0.006). Of note, prostate cancer was also in excess (IRR=3.0, P=0.03). No other cancer site was significantly over-represented. For thyroid cancer, there was no difference in incidence ratio according to the sex of the proband, but the increased risk in case relatives was largely confined to female relatives (IRR 8.7, P=0.008). In a Cox proportional hazards model, the estimated hazard ratio was 6.0 (1.3-27.3, P=0.021). These data show that NMTC has a moderate but real familial component. The underlying genetic basis awaits elucidation.

Program Nr: 644 from the 1999 ASHG Annual Meeting

Hypermethylation at an upstream STAT-binding site inhibits STAT-mediated p21/WAF1 induction in human rhabdomyosarcomas. *B. Chen[1,2], L. He[1], V.H. Savell[1,2], J.J. Jenkins[3], D.M. Parham[1,2]*. 1) Department of Pathology, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Arkansas Children's Hospital, Little Rock, AR; 3) Department of Pathology and Laboratory Medicine, St. Jude Children's Research Hospital, Memphis, TN.

p21/WAF1 functions as a negative regulator of cell proliferation by inhibiting cyclin-dependent kinase activity and blocking the G1-S transition. Levels of p21/WAF1 are often abnormally low in human rhabdomyosarcomas, which resemble fetal muscle but fail to undergo growth arrest or to differentiate. To understand the cause of decreased p21/WAF1 expression in this cancer, we examined the methylation pattern of the p21/WAF1 promoter region in primary rhabdomyosarcomas and rhabdomyosarcoma cell lines. Hypermethylation at a STAT (signal transducers and activators of transcription)-responsive element, SIE-1, was detected in 13 of 26 (50%) primary rhabdomyosarcomas and 2 of 5 rhabdomyosarcoma cell lines. All primary tumors with hypermethylation at SIE-1 showed decreased p21/WAF1 expression compared to normal skeletal muscle. The SIE-1 element is a binding site of STAT proteins, which mediate induction of p21/WAF1 expression following activation by a variety of ligands such as interferon-gamma. However, in rhabdomyosarcoma cell lines hypermethylated at SIE-1, activated STAT proteins failed to induce p21/WAF1 expression, and cells continued to proliferate in the presence of interferon-gamma. In vitro DNA-protein binding experiments indicated that CpG methylation at SIE-1 significantly reduced STAT binding. Furthermore, CpG methylation of luciferase reporter constructs containing SIE-1 significantly inhibited the reporter gene activity and the induction in response to interferon-gamma. These results indicate that hypermethylation at SIE-1 inhibits STAT-mediated up-regulation of p21/WAF1 expression through directly blocking protein-DNA binding. Our findings suggest a new mechanism by which aberrant DNA methylation results in reduced signal transduction and deficient cell cycle regulation in rhabdomyosarcomas.

Program Nr: 645 from the 1999 ASHG Annual Meeting

Mutational analysis of the hSNF5/INI1 gene in rhabdoid tumor. *T.T.-L. Chen, J. Savla, C.F. Timmons, N.R. Schneider, G.E. Tomlinson.* Univ. Texas Southwestern Med., Dallas, TX.

Rhabdoid tumors are extremely aggressive malignant tumors of the kidney which occur in early infancy. Approximately 10-15% of renal rhabdoids are associated with central nervous system (CNS) tumors of various histologies. Monosomy 22 has been reported as a karyotypic finding in some rhabdoid tumors. The hSNF/INI1 gene localized to chromosome 22q11.2 has been reported to be mutated in primary rhabdoid tumors. Using single strand conformation polymorphism analysis, we studied tumor and normal DNA from 4 children who with renal rhabdoid tumors, two of whom also developed a second primary tumor of the CNS. The full open reading frame of the hSNF/INI1 gene was analyzed using primers derived from the exon-intron junctions. Abnormal bands were sequenced to determine mutations. Truncating mutations in germline DNA at codons 91 and 198 occurred in the patients with both renal and CNS primary site tumors. In each case, loss of the normal allele was observed in the tumor tissue. In each of the CNS tumors, the loss of one copy of chromosome 22 was observed. In one of the renal rhabdoid tumors, a second mutation of the hSNF/INI gene was acquired; in the other renal rhabdoid, a loss of the normal allele was observed. We also analyzed germline and tumor DNA from 2 patients with renal rhabdoid tumors who did not develop second primaries tumors of the CNS. In one of these we found an acquired termination mutation at codon 47 which was not present in the germline DNA. We have thus found that the hSNF5/INI1 gene plays an important role in rhabdoid tumors. The observed germline and acquired mutations support the concept that the hSNF5/INI gene acts as a tumor suppressor gene, mutation of which may account for the predisposition to separate primary tumors in the subset of rhabdoid tumor patients who develop both renal and CNS tumors.

hSNF5/INI1.

Program Nr: 646 from the 1999 ASHG Annual Meeting

A de novo DNA sequence related to the metastasis of colorectal cancer. *S.-D. Cheng.* Dept Anatomy, Chang Gung Univ, Col Medicine, Kweishan, Taiwan, R. O. C.

A DNA sequence, temporally named UK1, which is partially homologous to the cDNA of NM23H1 gene, was obtained by screening human genomic lambda library. It was localized at chromosome 7p12 with fluorescence in situ hybridization (FISH). With FISH it was further examined on the interphase nuclei of the colorectal cells. The cells were from the short term primary culture of colorectal cancer tissues, and the patients' normal colon tissues are as control. The Dukes' stage differentiates the various grades of the colorectal cancer depending on the area invaded by the tumor. Of stages A and B tumor cells do not invade lymph nodes. Either stage represents for the nonmetastasis of tumor, with more than 80.4+/-5.6% of nuclei have two copies of the FISH signals indicating the nondeletion of the UK1 sequence (n=24). On the other way, the stage C with lymph nodes invaded and stage D with distant organ(s) invaded represent for the metastasis of tumor cells (n=27). Among the examined nuclei only 66.0+/-6.6% is not deleted of the FISH signals. The control group with the normal tissues from thirteen cases of various stages show at least 94.3+/-0.7% of nuclei have two copies of the FISH signals indicating the hybridization efficiency of the probe. Currently, we have subcloned the EcoRI fragments of UK1 lambda probe into plasmid Bluescript SK(+), and are acquiring their DNA sequences. The goal of this study is pursuing the prospective gene UK1, which maybe relate to the metastasis of colorectal cancer cells.

Program Nr: 647 from the 1999 ASHG Annual Meeting

Gains and losses of chromosomal regions in prostate cancer cell lines with varying metastatic potential as detected by comparative genomic hybridization. *L.W. Chu, C.A. Pettaway, S. Pathak, J.C. Liang.* U.T.M.D. Anderson Cancer Center, Houston, TX.

Recently, Pettaway et al. [1] established an *in vivo* tumor progression model in which subclones of the PC3M and LNCaP cell lines were selected for varying metastatic potential after successive orthotopic implantation in the prostate of nude mice. PC3M and selected variants, PC3M-Pro4 and PC3M-LN4, represent aggressive androgen-independent tumors which can metastasize. However, PC3M-LN4 had a greater incidence of distant metastases. Orthotopic injection of LNCaP, an androgen-dependent cell line, resulted in LNCaP-Pro5 line that is slightly metastatic and LNCaP-LN3 line that readily metastasizes to the lymph nodes and liver after intrasplenic inoculation. In this study, we used comparative genomic hybridization (CGH) to compare the chromosomal abnormalities between the parental cell lines and their respective variants. PC3M showed gains of 8q22-qter, 10q11-q22, 17q22-q24, 18q23, 20q13, and Xq27-qter and losses of 13q34, 17p13, and Y. The two sublines, PC3M-Pro4 and PC3M-LN4, retained most of these aberrations but showed an additional gain of 19q. Furthermore, PC3M-Pro4 had unique gains on 1q32 and 3q13 while PC3M-LN4 had specific gains on 1q21-22 and 18p12-21 suggesting these abnormalities may be important for the different metastatic potential of these two sublines. CGH analysis of LNCaP showed a gain on 3q28-qter and losses on 13q21-qter and Y. In addition to all the abnormalities of the parental LNCaP line, LNCaP-Pro5 and LNCaP-LN3 shared a gain of whole chromosome 3 and losses on 6p21-q16 and 13q14. Moreover, LNCaP-Pro5 had a unique gain on 13q12-q13 and LNCaP-LN3 had specific losses on 16q23-qter and 21q22. Interestingly, regions of loss detected in these cell lines correlated well with LOH at 6q21-q22, 13q14, 16q23-qter, and 21q22 in prostate tumors [2]. Our data suggests that CGH can detect unique abnormalities which distinguish tumors of differing metastatic potential.

Program Nr: 648 from the 1999 ASHG Annual Meeting

DNA replication arrest in the xeroderma pigmentosum variant following ultraviolet irradiation involves double-strand breaks and recombination, mediated by the hMre11-hRad50-NBS1 complex. *J.E. Cleaver[1, 2], C.L. Limoli[3].*
1) UCSF Cancer Ctr, Univ California, San Francisco, San Francisco, CA; 2) Dept of Dermatology, Univ California, San Francisco, San Francisco, CA; 3) Dept. of Radiology/Radiation Oncology, Univ California, San Francisco, San Francisco, CA.

Xeroderma pigmentosum (XP) is an autosomal recessive DNA repair disorder characterized by UV sensitivity and a genetic predisposition to solar induced skin cancer. Complementation groups XPA-G exhibit defects in nucleotide excision repair (NER) while the variant (XPV) exhibits defective translesion postreplication repair, but retains otherwise normal NER. To delineate the molecular nature of the bypass replication defect in XPV, SV40 transformed human fibroblasts were exposed to UV light and examined for the appearance of nuclear foci by fluorescence immunolocalization using a polyclonal antibody specific to hMre11. Mammalian Mre11 exists as a multiprotein complex with Rad50 and NBS1, involved in the recombinational repair DNA double-strand breaks (DSB). Normal, XPA and XPV cells all show X-ray inducible Mre11-Rad50-NBS1 foci (~ 25-50% foci positive cells after 6 Gy), but normal and XPA cells do not show any UVC-inducible foci. XPV cells however, show foci positive cells following UVC exposure (~ 10-15% after 12 Jm-2). Colocalization experiments suggest that the Mre11-Rad50-NBS1 foci seen after UV irradiation in XPV cells are distinct from repair complexes containing the Rad51 protein. Antibodies specific to BrdU and PCNA indicate a fraction of the UV-induced foci in XPV cells are present in replicating cells. Thus, the formation of UV-induced Mre11-Rad50-NBS1 nuclear foci constitutes a distinguishing feature of the XPV versus other XP cells. The inability to bypass bulky DNA adducts during replication leads to DNA intermediates recognized by the Mre11-Rad50-NBS1 complex, which then mediate their resolution by strand exchanges involving the transient formation of DNA DSBs. Work support by NIH grants 1RO1-CA73924 (C.L.L) and 1RO1-CA8061 (JEC).

Program Nr: 649 from the 1999 ASHG Annual Meeting

Mutational ananlysis of candidate breast tumour suppressor genes located at 16q24.3. *A.M. Cleton-Jansen[1,2], E.W. Moerland[1], H.M. Van Beerendonk[1], A. Savoia[3], D.F. Callen[4], G.J.B. Van Ommen[2], C.J. Cornelisse[1]*. 1) Department of Pathology, Leiden University Medical Centre, Leiden, The Netherlands; 2) Department of Human Genetics, Leiden University Medical Centre, Leiden; 3) Servizio di Genetica Medica, IRCCS-Ospedale CSS San Giovanni Rotondo, Italy; 4) Dep. Cytogenetics and Molecular Genetics, Adelaide Women's and Children's Hospital, Australia.

The long arm of chromosome 16 is involved in loss of heterozygosity (LOH) in more than 50% of breast tumours. This strongly suggests the presence of one or more tumour suppressor genes (TSG) on 16q. Proof for its TSG function is the repeated identification of inactivating mutations in the retained copy of a gene in tumours with LOH. Dense LOH mapping with microsatellite markers identified a region at the most distal part of 16q as smallest region of overlap, i.e. 16q24.3. As part of an international collaborative effort a physical and transcription map was constructed to find candidate TSGs. The region with 7 mapped genes comprises 750 kb and as a result of the constructed map at least 20 new genes could be identified. From this total of 27 genes the most likely candidates were screened for mutations. Prior to mutation screening the exon-intron boundaries were determined to be able to design primers for analysis of genomic DNA. Although not 100% efficient the single strand conformation polymorphism (SSCP) analysis was selected as the preferred system for mutation screening because this method is easily set up, which is a prerequisite when a number of different genes must be tested. In addition RT-PCR products were screened for splice mutants and Southern blot analysis was applied to identify possible large genomic deletions. We screened BBC1, FAA, GAS11, PISSLRE, MC1R, SPG7, Copine VII and 3 other transcripts with unknown function in a panel of 15-20 breast tumours with LOH restricted to 16q24 to ensure that a gene at this region is target for LOH and not another TSG at 16q. None of these genes showed tumour restricted alterations. In conclusion, we have excluded 10 genes mapping to the candidate region at 16q24.3 as TSG. The real target of LOH at this region remains to be identified.

Program Nr: 650 from the 1999 ASHG Annual Meeting

Identification of consistent aberrations in myxopapillary ependymoma tumours. *N. Coleman[1], D. Sanoudou[1], O. Tingby[1], M.A. Ferguson-Smith[2], V.P. Collins[1].* 1) Dept Pathology, University of Cambridge, Cambridge, England; 2) Dept Veterinary Medicine, University of Cambridge, Cambridge, England.

Myxopapillary ependymomas (ME) are a benign variant of ependymomas, usually located at the cauda equina. They have a tendency for slow growth and local recurrence without progression. They may also spread within the nervous system and occasionally metastasise extraneurally. The overall survival depends on the extent of surgical removal of the tumour. Previous studies agree on the rare immunocytochemical identification of p53 expression and the low proliferative activity. The presence of the bcl-2 oncoprotein has also been shown immunohistochemically. Limited cytogenetic analysis of rare ME tumours cell cultures has not demonstrated any consistent chromosomal abnormality. In the present study frozen tissue from seven ME patients was analysed by comparative genomic hybridisation (CGH), microsatellite markers and interphase fluorescent in situ hybridisation (FISH). All seven cases had gain of chromosomes 9 and 18. Chromosome 9 was present in either three or four copies. Chromosome 18 was present in four copies, which appear to arise from the duplication of both chromosome 18 alleles. Other aberrations included gains on chromosomes 3, 4, 5, 7, 8, 13, 17, 20 and X, and losses on chromosomes 10 and 22. These findings represent the first steps towards understanding the molecular mechanisms involved in the development of this tumour form.

Program Nr: 651 from the 1999 ASHG Annual Meeting

Microsatellite Instability (MSI) *In Vitro* vs.*In Vivo*? *M.I. Coolbaugh-Murphy[1], A. Maleki[1], L.C. Strong[2], P.M. Lynch[3], M. Frazier[3], D.G. Monckton[5], B.W. Brown[4], M.J. Siciliano[1]*. 1) Molecular Genetics; 2) Experimental Pediatrics; 3) GI Oncology; 4) Biomathematics,UT-MD Anderson Cancer Center, Houston, TX; 5) Molecular Genetics, Univ. of Glasgow, Glasgow, U.K.

MSI, associated with several types of cancer, is seen by PCR detection of new alleles. Variant fragments need to be well represented in the tumor to be so detected. For detection and quantitation of rare variant fragments, small pool PCR (SP-PCR) may be done. SP-PCR uses DNA diluted down to less than 1ge. Analysis of many small pools can identify infrequent fragments which would be hidden by standard PCR procedures. Conducting such analyses on HNPCC and LFS DNA, at the usually stable DM locus, suggested that as ge. decreased from 10 ge. to <1 ge., the frequency of detection of unobserved variants increased. Is this due to true detection of infrequent mutants or PCR artifact generation as ge. decreases? Therefore, PCRs were conducted on multiple 1ge's of HNPCC tumor DNA and after the 5 cycles, 1/2 of each reaction mixture was removed and set aside (aliquot B). Each remaining portion (aliquot A) completed the nested PCR analysis. If a variant was seen in any of those pools, its (aliquot B) was diluted to single molecules and nested PCR conducted on each. Recovery of the variant seen in (aliquot A) indicated that it was present in the original DNA or generated in one of the first five rounds of amplification. Any fragment seen after expansion of (aliquot B) that was not seen in (aliquot A), must be PCR artifact. We report here that the artifact frequency is 0.005 as determined by this procedure. Thus artifact is not seen as a factor in MSI. To determine the optimal ge. level for accurately detecting and quantitating mutation frequency, reconstruction experiments were conducted. DNAs of two heterozygotes with different alleles at the DM locus were mixed together in various proportions. We then identified the ge. level at which the less frequent alleles remain detectable at the expected frequency. The upper limit for optimum allele detection was <5 ge. Whereas, optimal frequency determination and isolation of alleles occurs at 0.8 ge.(1.6 alleles) per reaction. *In Vitro*.

Program Nr: 652 from the 1999 ASHG Annual Meeting

Linkage analysis of 153 prostate cancer families over a 30 cM region containing the putative susceptibility locus HPCX. *K.A. Cooney[1], H. Chen[1], M.E. Ray[1], K. Brierley[1], E. Perrone[1], C.H. Bock[1], E. Gillanders[2], E.M. Lange[1]*. 1) Departments of Internal Medicine, Surgery, Radiation Oncology and Biostatistics, University of Michigan, Ann Arbor, MI; 2) Cancer Genetics Branch, National Human Genome Research Institute, Bethesda, MD.

Epidemiological studies have provided data to support the hypothesis that there are genes on the X chromosome that may contribute to prostate cancer susceptibility. A recent linkage study of 360 prostate cancer families described evidence for a prostate cancer predisposition gene termed HPCX, which maps to Xq27-28. To confirm the potential contribution of this locus to prostate cancer susceptibility in an independent set of families, we studied 153 unrelated prostate cancer families who are participants in the University of Michigan Prostate Cancer Genetics Project. Families selected for this analysis have at least two living members affected with prostate cancer that are related in a way that they could potentially share one copy of the X chromosome. DNA samples were genotyped using a panel of seven polymorphic markers spanning 30 cM and containing the HPCX candidate region. The resulting data was analyzed using both nonparametric (NPL) and parametric linkage methods. Analysis of all 153 families resulted in positive NPL Z-scores across the entire candidate interval (NPL Z-scores 0.23-1.06 with corresponding one-sided p-values 0.41 and 0.15, respectively). The eleven African American families had negative NPL Z-scores across the same 30 cM interval. Analysis of the 140 Caucasian families produced a maximal NPL Z-score of 1.20 with a corresponding one-sided p-value of 0.12 at marker DXS1113. The subset of families with no evidence of male-to-male disease transmission and with early-onset prostate cancer (average age within a family < or = 65 years) contributed disproportionately to the evidence for linkage in the entire dataset [maximum NPL Z-score 1.51 (p-value 0.07) at DXS1108]. In conclusion, this study of 153 families, each with two or more living members with prostate cancer, provides some additional support for the existence of a prostate cancer susceptibility gene at Xq27-28.

Program Nr: 653 from the 1999 ASHG Annual Meeting

The LOXL2 gene, a putative tumor suppressor, maps to the minimally deleted region at 8p21 in lung, colon, prostate and breast cancer, and shows high frequency of allelic loss in colon and esophageal tumors. *K. Csiszar[1], S.F.T. Fong[1], C. Jourdan-Le Saux[1], L. Asuncion[1], E. Dietzch[2], M.I. Parker[2]*. 1) Pacific Biomedical Research Center, University of Hawaii, Honolulu, HI; 2) Dept of Medical Biochemistry, UCT Medical School, Cape Town, South Africa.

We have mapped LOXL2, a new member of the lysyl oxidase (LOX) gene family, to chromosome 8p21, the minimally deleted region in the four most common cancers, carcinomas of the lung, colon, prostate and breast. Although several genes have been localized to this locus, no tumor suppressors with demonstrated loss of function have been identified. LOXL2, a putative new tumor suppressor, has been shown to play a role in cell adhesion. Loss of this function, through frequent deletions and allelic losses of the LOXL2 gene, may contribute to the development of an invasive tumor phenotype in these malignancies. To confirm this hypothesis, we have localized the LOXL2 protein in normal colon and in colonic adenocarcinoma, examined the expression pattern of the LOXL2 gene in several tumor cell lines and assessed the deletional status of the LOXL2 gene using a new intragenic microsatellite in a series of colon and esophageal carcinomas. Immunohistochemical analysis localized the LOXL2 protein in the submucosa in normal colon but in the mucosa of a differentiated adenocarcinoma. Northern analysis of prostate and colon cancer cell lines and osteosarcoma cells indicated reduced mRNA levels in ras-transformed osteosarcoma (AD15) and in prostate cancer cells (DU145) and complete loss of expression of the LOXL2 gene in all colon cancer cell lines (HCT-116, HCT-15, DLD-1). Allelic changes of the LOXL2 gene were observed in 50% of 64 sporadic colon carcinomas, 16% of which were microsatellite instability (MI). In 68 esophageal tumor DNA samples, 36% demonstrated allelic changes with 7% MI. In both these cancers, males had more loss of heterozygosity (LOH) while females had more MI, indicating a gender-specific mutational mechanism. These results strongly suggest that the LOXL2 gene is affected by high frequency of deletions and may have an important role in the pathogenesis of colon and esophageal carcinomas.

Program Nr: 654 from the 1999 ASHG Annual Meeting

Combined use of microsatellite instability, immunohistochemistry and promoter hypermethylation to prescreen HNPCC mutations. *K.S. DAHAN[1], C. SEMPOUX[2], A. KARTHEUSER[3], M. SMAERS[1], P. CAMBY[2], R. DETRY[3], Ch. VERELLEN-DUMOULIN[1], J. RAHIER[2]*. 1) Genetics; 2) Pathology; 3) Surgery, U.C.L. Saint-Luc, BRUSSELS, BELGIUM.

Many studies demonstrated microsatellite instability (MSI) in tumors from hereditary non polyposis colorectal cancer (HNPCC) patients fitting the Amsterdam criteria. HNPCC is often associated with a germline mutation in 1 of the 2 major genes *hMLH1* and *hMSH2* responsible for repairing mismatches (MMR). However, MSI could be found in sporadic colorectal cancer (CRC) correlated to a MMR gene mutation in patients not fulfilling these criteria. To determine biological selection for these HNPCC, 92 consecutive surgical unselected CRC were studied. To evaluate the MSI, DNA from tumor and normal tissue was used for at least 4 (CA)n and 1 poly-A repeats. Three groups were defined: with <30% of markers showing instability (MSI-L, n=3, 3%), with >30% (MSI-H, n=16, 17%) and those without instability (MSS, n=73, 79%). Immunohistochemistry was performed on the same tumors with antibodies against hMLH1, hMSH2 and P53. No MSS nor MSI-L tumor had altered expression of either *hMLH1* or *hMSH2*. MSI-H cases demonstrated absence of staining for these proteins in 12 out 16(75%). Absence of hMLH1 occured in 10 tumors(83%). P53 expression was mainly focal in the MSI tumors (15 of 19, 79%) whereas it was diffuse in 3. Out of 73 MSS tumors, 56 (77%) had diffuse P53 activation whereas focal P53 expression was observed in 13 (no detection in 4).In 8 MSI-H CRC without hMLH1 expression, a *Hpa*II restriction enzyme assay was performed to look for promoter hypermethylation. The *hMLH1/calcitonin* ratio demonstrated hypermethylation of the *hMLH1* promoter in 1 of them. **Conclusion:** Out of 16 MSI-H tumors, normal expression of hMLH1 and hMSH2 is present in 4 whereas in 12, altered hMLH1 expression is responsible for CRC independent of P53 involvment. Lack of protein without promoter hypermethylation suggest either a germline or a somatic *hMLH1* mutation in 7 MSI-H tumors. The challenge to detect HNPCC from unselected CRC could be taken up by simultaneous analysis of MSI with protein expression and methylation status of the hMLH1 promoter.

Program Nr: 655 from the 1999 ASHG Annual Meeting

P53 genotyping is not an effective concept for molecular testing head and neck cancer. *R. Dahse[1], W. Fiedler[1], F. von Eggeling[1], S. Koscielny[2], E. Beleites[2], G. Ernst[1], U. Claussen[1].* 1) Institute of Human Genetics, Jena, Germany; 2) Clinic of ENT Diseases, Jena, Germany.

P53 mutations are currently recognized as the most common genetic alteration in human tumors. The purpose of our study was to prove the significance and reliability of p53 genotyping in head and neck cancer as a possible marker permitting the prediction of tumor behavior and clinical outcome. P53 genotyping in our study refers to highly sensitive molecular screening in order to detect structural alterations in the nucleic acid sequence of the gene. Exons 2-11 and adjacent intronic regions were screened for mutations by direct genomic sequencing or by bi-directional dideoxyfingerprinting in 66 primary tumors of the larynx, pharynx and oral cavity. Alterations in the hot spot region' of the p53 gene were detected in 36% (24 of 66) of the analyzed tumors, no mutation was found in our cohort outside exons 5-8. The frequency of p53 mutation did not correlate with the tumor stage or tumor site. The recurrence rate in patients with p53 alterations was not significantly higher compared to patients without a p53 mutation in their primary tumors. Summarizing the results of our study we found only limited reliability of p53 genotyping as an effective concept for prognostic differentiation in head and neck cancer. Molecular tests for tumor prognostication focusing on single parameters of cell cycle control seem to be insufficient owing to the complex interaction between many involved genes and proteins. Therefore, future efforts in searching for reliable prognostic markers should be focused on multiplex analysis systems for mutation detection or differences in gene expression patterns.

Program Nr: 656 from the 1999 ASHG Annual Meeting

Comparative genomic hybridization (CGH) in inherited and sporadic ovarian tumors in Israel. *M. Daniely[1], Y. Patael[2], W. Gottlieb[3], A. Aviram[1], A. Kruglikova[2], G. Ben-Baruch[3], E. Friedman[2].* 1) Human Genetics, Sheba Medical Ctr, Tel-Hashomer, Israel; 2) The Susanne Levy Gertner Oncogenetics Unit, Sheba Medical Center, Tel-Hashomer, Israel; 3) The Oncologic Gynecology Unit, Sheba Medical Center, Tel-Hashomer, Israel.

To gain insight into the molecular mechanisms involved in sporadic and inherited ovarian cancer, we analyzed 23 ovarian tumors form Jewish Israeli ovarian cancer patients by CGH: 18 invasive epithelial tumors (5 from BRCA1 or BRCA2 germline mutation carriers), two primary peritoneal carcinomatosis, and one each of pseudomyxoma peritoneii, sertoli cell tumor, and a normal ovary from a BRCA1 mutation carrier. The most common abnormality was amplification of 8q22.1-ter (in 8 primary tumors), followed by 1q22-32.1, 3q, 10p and 12p amplifications, and 9q and 16q21-24 deletions (noted in 3-4 tumors each). There were no differences between sporadic and inherited tumors; the type of genetic changes in primary peritoneal tumors and primary epithelial ovarian cancers, though the mean number of alterations in the latter was 8/tumor and in the former 3.5/tumor; there was an amplification of chromosome 6 in 2/3 metastases, which was not present in the primary tumor; amplification of 3q and deletion of chromosome 22 were restricted to women in whom the disease was diagnosed after the age of 55 years. Lastly, there were no alterations in the normal ovary, the pseudomyxoma peritoneii, and in metastases from a mucinus adenocarcinoma and its metastases. We conclude that a. the molecular mechanisms involved in ovarian cancer tumorigenesis in inherited and sporadic cases are closely related. b. multiple changes are involved in epithelial ovarian cancer c. the same mechanisms are operative in primary peritoneal carcinomatosis and d. pseudomyxoma peritoneii has a distinct molecular pathway for its development.

Program Nr: 657 from the 1999 ASHG Annual Meeting

Identification of proteins that interact with nibrin, the protein mutated in Nijmegen breakage syndrome. *A. Desai-Mehta[1,2], P. Concannon[1,2]*. 1) Molecular Genetics, Virginia Mason Research Center, Seattle, WA; 2) University of Washington School of Medicine, Seattle, WA.

Nijmegen breakage syndrome (NBS), an autosomal recessive disorder, is characterized by microcephaly, growth retardation, chromosomal instability, radiation sensitivity and a high incidence of malignancies, particularly of lymphoid origin. The NBS1 gene, encoding the protein nibrin, has recently been cloned and characterized in our laboratory. In normal fibroblasts, nibrin is localized to the nucleus and homogeneously distributed. Upon exposure of cells to ionizing radiation, nibrin forms distinct nuclear foci. The proteins, Mre11 and Rad50, which participate in DNA double-strand break repair, complex with nibrin in these nuclear foci and immunoprecipitation studies suggest the presence of additional, unidentified proteins. NBS cells which lack nibrin do not form foci upon irradiation, suggesting a role of nibrin in relocalizing this protein complex. The yeast two hybrid system was used to identify additional proteins that form part of these foci and interact with nibrin. Approximately two million clones from a human activated lymphocyte library were screened. After eliminating potential false positives, seven known genes were identified as well as several anonymous ESTs and genomic sequences. Given the defects in cell cycle checkpoint control in NBS cells, the identification of the G0/G1 transition gene GOS3 was of particular interest, as was the human Polycomb homolog hPc2 which is known to form nuclear foci, similar to nibrin. Two proteins, IL-2Rb and linker for T cell activation (LAT) involved in T cell proliferation, which is also defective in NBS cells, were identified although these proteins are localized to the cytoplasm. However, fluorescence microscopy revealed that, in contrast to fibroblasts, nibrin does not display nuclear localization in B and T cells thus raising the possibility of cytoplasmic interactions with IL-2Rb or LAT. All of these candidate interacting partners for nibrin are currently being tested for co-localization in cells and focus formation following irradiation.

.

Program Nr: 658 from the 1999 ASHG Annual Meeting

Frequent splicing mutation of the ATM gene in breast cancer. *T. Dork[1], M. Nicke[1], K. Klopper[1], R. Bendix[1], M. Stuhrmann[1], M. Bremer[2], D. Rades[2], J.H. Karstens[2].* 1) Institute of Human Genetics; 2) Department of Radiation Oncology, Medical School Hannover, Germany.

The ATM gene that is mutated in ataxia-telangiectasia (A-T) encodes a large, predominantly nuclear protein kinase with an essential role in the repair of radiation-induced DNA damage. Obligate heterozygotes within A-T families have been shown to exhibit increased cellular radiosensitivity and to be at an increased risk to develop cancer, in particular breast carcinoma. We have searched for a frequent ATM gene mutation in German A-T families and in a population-based cohort of German breast cancer patients which should be useful in further epidemiological studies. Homozygosity for a new splicing mutation, 1066-6T®G in intron 10, was identified in 1 out of 30 A-T patients. This polypyrimidine tract substitution results in the loss of exon 11 in ATM mRNA from this patient which causes a frameshift. Heterozygosity for the same mutation was observed in 7 out of 870 consecutive breast cancer cases (0.8 %) and in 3 out of 450 controls from the general Lower Saxonian population (0.6 %). Transcript analyses in primary lymphocytes obtained from three of the heterozygous breast cancer patients confirmed exon skipping in about half of their ATM mRNA in each case. In conclusion, we have identified a new ATM gene mutation that is common in A-T and breast cancer patients and is frequent in the German and possibly other Central European populations. This finding enables a rapid molecular testing of A-T heterozygosity which will be useful for prospective studies of radiosensitivity and for large-scale association studies to investigate the relative risks of cancer in heterozygous carriers.

Program Nr: 659 from the 1999 ASHG Annual Meeting

Inherited risk of paraganglioma tumors. *C.M. Drovdlic[1], B.E. Baysal[2], B.J. Devlin[2], J. Peters[1,3], E. Myers[3], W.S. Rubinstein[1,3]*. 1) Univ. of Pittsburgh Graduate School of Public Health; 2) Dept. of Psychiatry, Univ. of Pittsburgh Medical Center; 3) Univ. of Pittsburgh Cancer Institute: Pittsburgh, PA.

Paraganglioma (glomus) tumors (PGLs), are mostly benign tumors of the head and neck which affect approximately 1 in 30,000 individuals. These growths can occur sporadically, but reportedly 7-50% are hereditary in nature. A major gene responsible for these tumors, *PGL1*, has been located on chromosome 11q23, but has not yet been identified. This gene is inherited in an autosomal dominant fashion, but exhibits genetic imprinting through maternal lineages such that children of carrier mothers are rarely, if ever, affected. This often makes heritable cases difficult to identify as the tumor can "hide" through several generations of maternal transmission. We are interested in determining the proportion of these tumors that are hereditary, identifying any other cancers or tumors associated with PGL, and assessing the PGL knowledge and attitudes of affected individuals. We will begin characterizing hereditary and sporadic tumors through acquisition of detailed family/medical history. We will identify patients with hereditary PGL by positive family history or multifocality. Cases in which the hereditary status is ambiguous will be analyzed molecularly by identifying subjects that carry a common PGL-1 disease marker. Through a probability model we will then determine the proportion of hereditary versus sporadic PGL in our subject population. Subjects will answer questionnaires to determine how well informed they feel about PGL, and how recurrence risk perception differs based on whether an affected individual believes he/she has a hereditary PGL. Attitudes towards possible future gene testing for affected individuals and their family members will also be assessed. The ability to identify hereditary PGL and any associated cancers or tumors serves to identify other family members at risk, which has important genetic counseling implications. The overall goal of this project is to add to the body of knowledge concerning these rare tumors in order to enable the refinement of genetic counseling and medical management for patients and families suffering from such tumors.

Program Nr: 660 from the 1999 ASHG Annual Meeting

Two polymorphisms in the VHL-associated gene *CUL2* are over-represented in pheochromocytoma patients without somatic *CUL2* mutations. *E.M. Duerr[1,2], O. Gimm[1], J.B. Kum[1,2], S.C. Clifford[3], S.P. Toledo[4], E.R. Maher[3], P.L. Dahia[1,2], C. Eng[1]*. 1) Human Cancer Genetics Program, Ohio State University, Columbus, OH; 2) Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA; 3) Department of Pediatrics and Child Health, University of Birmingham, Birmingham, UK; 4) Endocrine Genetics Unit, University of São Paulo, São Paulo, Brazil.

Most pheochromocytomas occur as sporadic tumors; about 10% have a hereditary background. These usually benign hereditary tumors are most frequently associated with multiple endocrine neoplasia type 2 (MEN 2A and 2B) and von Hippel-Lindau disease (VHL). While these two major hereditary forms of pheochromocytomas have been associated with germline mutations of the *RET* and *VHL* genes, respectively, the molecular pathogenesis of sporadic pheochromocytomas is largely unknown. Cul2 has been recently identified as a putative tumor suppressor and interacts with pVHL. We analyzed a series of 26 distinct pheochromocytomas for mutations in the whole coding region of this gene to determine whether *CUL2* plays a role in the pathogenesis of sporadic pheochromocytoma. Except for one sporadic tumor which had a hemizygous gene deletion, we did not find any somatic mutations in *CUL2*. However, we found three novel polymorphisms in the gene. One of these variants, IVS5-6C/T as well as another previously described one, c.2057G/A, were found to be over-represented amongst the pheochromocytoma patients when compared to a race-matched control group. 43 of 52 (83%) pheochromocytoma chromosomes tested carried the IVS5-6C/T variant C compared to 28 of 52 (54%) control chromosomes ($p<0.005$). Further, 34 of 48 (71%) pheochromocytoma chromosomes tested carried the c.2057G/A variant G compared to 22 of 48 (46%) control chromosomes ($p<0.01$). While our findings suggest that *CUL2* does not play a major role in the pathogenesis of pheochromocytomas, it remains unclear whether epigenetic mechanisms are involved in its inactivation in VHL-associated tumors. Of interest, the potential role of over-represented sequence variants acting as low penetrance susceptibility alleles for pheochromocytoma development requires further investigation.

Program Nr: 661 from the 1999 ASHG Annual Meeting

Reproducibility of a fluorescent-based test for three *BRCA1*/*BRCA2* mutations in blood and paraffin tissue samples. *S.M. Ebbers[1], G. Hirsh-Yechezkel[2], A. Chetrit[2], B. Modan[2], J.P. Struewing[1]*. 1) Laboratory of Population Genetics, NCI, Bethesda, MD; 2) Department of Clinical Epidemiology, Chaim Sheba Medical Center, Tel Hashomer, Israel.

The 185delAG and 5382insC mutations in *BRCA1* and the 6174delT mutation in *BRCA2* are common founder mutations among Jewish breast and ovarian cancer cases. We examined the reproducibility of a multiplex PCR-based assay in two different sample types (blood and paraffin slides) from the same person. Subjects were 40 women with ovarian cancer, 11 of whom carried one of the three mutations, drawn from a larger case-control study. For each subject, DNA from both a blood sample and a paraffin section on a slide were tested blindly. Paraffin samples were scraped off the slides, digested with a simple digestion buffer, and used directly in the PCR reaction. The assay consists of a multiplex PCR reaction for exons 2 and 20 in *BRCA1* and a portion of exon 11 in *BRCA2*. The forward primer pair of each set was labeled with a fluor such that the mutations, all small insertion or deletions, could be detected as length polymorphisms using an ABI 310 sequencer and Genescan analysis. After correcting data entry errors, the results of the assay were identical for blood and paraffin samples for 39 of the 40 subjects. Microsatellite analysis of the discrepant samples suggests that they were not derived from the same individual. Our results suggest that when testing for specific founder mutations in epidemiologic studies of *BRCA1/2*, paraffin-derived DNA may be an acceptable material for analysis.

Program Nr: 662 from the 1999 ASHG Annual Meeting

_BRCA_1, _BRCA_2 and Pedigree Genetic Analysis to Determine Genetic Risk in the UK Royal Marsden Hospital Tamoxifen Prevention Trial. *R.A. Eeles[1,2], T.P. Powles[2], S. Ashley[2], D.F. Easton[3], L. Assersohn[2], N. Sodha[2], M. Dowsett[1], B. Gusterson[1], A. Tidy[2], G. Mitchell[1,2], Z. Kote-Jarai[1]*. 1) Institute of Cancer Research, Sutton, Surrey, SM2 5NG, UK; 2) Royal Marsden NHS Trust, Sutton, Surrey, SM2 5PT, UK; 3) CRC Genetic Epidemiology Unit, Strangeways Research Laboratories, Cambridge, CN1 4RN, UK.

In the Royal Marsden Hospital tamoxifen prevention study, 2500 women at increased risk of developing breast cancer because of a family history of the disease were randomised to receive tamoxifen 20 mg daily or placebo for 8 years. 70 women developed primary breast cancer; 36 whilst on placebo, 34 on tamoxifen. Family history out to at least 2nd degree relatives was taken from all women in the study. DNA from peripheral blood from 67 of the 70 women was analysed for coding mutations in the *BRCA*1 and *BRCA*2 genes by CSGE analysis of the entire coding region of both genes. 7 mutations were found, 2 in *BRCA*1 and 5 in *BRCA*2, 4 would be expected to be pathogenic as these were nonsense/frameshifts. 3 were rare variants which were not present in 100 normal controls. The posterior probability of carrying a breast cancer predisposition gene in the individuals who developed breast cancer was assessed using the Cyrillic genetic risk package, based on the Claus model (Claus *et al.*, 1991*). 26 women had <50% posterior probability of harbouring a breast cancer predisposition gene and 44 had a ³50% chance of having a breast cancer predisposition gene. In the former group of 26 women, 8 had been taking tamoxifen and 18 placebo. In the group of women with ³50% probability of having a breast cancer gene, 26 had been taking tamoxifen and 18 placebo. The differences between the numbers of women taking tamoxifen who subsequently developed cancer in the two groups divided by <50% or ³50% genetic risk was significant at (p=0.04). These preliminary data suggest that tamoxifen prevention may be more effective in women with a <50% chance of harbouring a breast cancer predisposition gene. A meta analysis of the interaction of genetic status with tamoxifen chemoprevention effectiveness should be conducted to test this hypothesis.
*Claus et al. Am J Epidemiol, 48, 1991.

Program Nr: 663 from the 1999 ASHG Annual Meeting

Alterations of 1q and 16q and der (1;16) detected by FISH and CGH in breast lobular carcinoma in situ. *J.E. Etzell, S. DeVries, K. Chew, B.M. Ljung, F.M. Waldman.* Cancer Center, UCSF, San Francisco, CA.

Frequent gain of chromosome arm 16q (63%) and loss of 1q (79%) have been identified in infiltrating lobular carcinoma (ILC). Lobular carcinoma in situ (LCIS) may represent both a precursor to infiltrating carcinoma and a marker of an overall field defect. This study was undertaken to identify genomic alterations in LCIS and to investigate the role of formation of a der (1;16) (q10;p10) chromosome in the infiltrating and in situ lesions. Comparative genomic hybridization (CGH) was used to identify chromosomal alterations in 17 cases of pure LCIS (no evidence of invasive carcinoma) using DNA microdissected from archival sections following DOP-PCR amplification. The mean number of alterations was 1.9 per tumor for these in situ lesions, compared to 5.8 per tumor for invasive lobular tumors. Loss involving 16q was the most frequent alteration in LCIS (88%). Gain of 1q was present in 41% of cases, and was associated with 16q loss. Presence of a derivative (1;16) chromosome was determined by fluorescence in situ hybridization (FISH) using satellite probes for chromosome 1 (pUC1.77) and chromosome 16 (pHUR195 and pSE16-2). Co-localization of the chromosome 1 and 16 signals was used to define the presence of the derivative chromosome (counts greater than the control mean+2SD were considered positive). The infiltrating and in situ cancers both showed a high frequency of classical satellite co-localization (60% and 64%, respectively). Although weak signal intensity prevented scoring of co-localization using the pSE16-2 alpha satellite probe in the archival LCIS sections, this probe showed 95% co-localization with pUC1.77 in the invasive tumors (fresh imprint preparations were used). The higher frequency of pSE16-2 is consistent with its centromeric location relative to pHUR195. These data suggest that formation of a derivative (1;16) chromosome occurs in almost all infiltrating and in situ lobular carcinomas. E-cadherin, a tumor suppressor gene located on 16q, is abnormally expressed in most LCIS and ILC. We propose that formation of the der (1;16) is a mechanism leading to loss of 16q, which is then selected for during tumor development.

Program Nr: 664 from the 1999 ASHG Annual Meeting

Candidate genes causing familial oesophageal cancer associated with the skin condition tylosis (focal NEPPK).

K.E. Evans[1], J.M. Risk[1], G. Kuhlenbaeumer[2], H.S. Mills[1], A. Ellis[1], D.T. Bishop[3], V. Timmerman[4], D.P. Kelsell[5], J.K. Field[1]. 1) Molecular Genetics and Oncology Group, Clinical Dental Sciences, The University of Liverpool, Liverpool, UK; 2) Westfälische Wilhelms-Universit ät, Münster, Dept. of Neurology, Albert-Schweitzer-Str. 33, D-48129 Münster, Germany; 3) ICRF Genetic Epidemiology Lab, St. James' University Hospital, Leeds, LS9 7TF. UK; 4) Dept. Molecular Genetics, Flanders International University for Biotechnology (VIB), Lab of Neurogenetics, Born-Bunge Foundation (BBS), Univ. of Antwerp (UIA), Antwerpen, Belgium; 5) Centre for Cutaneous Research, St. Bartholomew's and the Royal London School of Medicine and Dentistry, 2 Newark St., London, E1 2AT. UK.

Focal non-epidermolytic palmoplantar keratoderma (NEPPK), or tylosis, is an autosomal, dominantly inherited disorder of the skin that manifests as focal thickening of the palmar and plantar surfaces. In three families, the skin disorder co-segregates with oesophageal cancer and oral lesions. The tylosis oesophageal cancer (TOC) gene locus has been mapped to 17q25, a region that may also be implicated in the development of sporadic squamous cell oesophageal carcinoma, Barrett's adenocarcinoma of the oesophagus, and breast cancer. We now show that the integration of the genetic and physical maps of this region refines the location of the TOC locus and maps a number of candidate genes and ESTs. Several structural candidates such as envoplakin (EVPL)and integrin b4 (ITGB4) have been excluded as the TOC gene on this basis. However, one other candidate gene and 2 ESTs have been mapped within the TOC minimal region. In addition, analysis of sequence data generated from one clone spanning approximately one third of the minimal region has identified further promising gene fragments. Investigation of tissue expression patterns and isolation of full length cDNA sequences will allow further chracterisation of these genes and lead to mutation analysis of patient samples. It now appears that we are close to isolating the gene responsible for this familial form of squamous cell oesophageal carcinoma that may also play a role in sporadically occurring disease.

Program Nr: 665 from the 1999 ASHG Annual Meeting

Jumping translocations in leukemia and lymphoma. *Y. Fan[1,2], K. Rizkalla[2], B.F. William[3], C.J. Engel[4].* 1) Cytogenetics Lab, London Health Sciences Ctr, London, ON, Canada; 2) Department of Pathology, The University of Western Ontario, Canada; 3) Blood Transfusion and Hematology Lab, St. Joseph's Health Ctr, London, ON, Canada; 4) Department of Surgery, London Health Sciences Ctr, London, ON, Canada.

Jumping translocation (JT) is a rare cytogenetic aberration in leukemia and lymphoma, and its etiologic mechanisms are not clearly known. We report two cases with jumping translocations. One had follicular lymphoma and JTs of 1q onto the telomeric regions of 5p, 9p and 15q in three cell lines, co-existing with the specific translocation t(14;18)(q32;q21). The second case had acute myeloid leukemia and JTs of 11q, as the sole aberration, onto multiple derivative chromosomes in each of the abnormal cells. A total of 17 telomeric regions were seen as the recipients of 11q in this case, and 9q was always involved as one of the recipients in all abnormal cells. FISH confirmed the identification of 11q material in the derivative chromosomes. While 1q has been the most common donor of acquired JTs, this is the first report on JTs of 11q. Different from all previously reported JTs which involved a single derivative chromosome in each cell line and led to a mosaic trisomy, multiple derivatives in most of the abnormal cells in this case had led to a tetrasomy, or a pentasomy of 11q. The pattern of chromosome involvement as the recipients of 11q appears to show a continuing evolutionary process of jumping, stabilization and spreading of the donor material onto other chromosomes. Cases with acquired and constitutional JTs in the literature were reviewed. Somatic recombinations between the interstitial telomeric or subtelomeric sequences of a derivative chromosome and the telomeric sequences of normal chromosomes are believed to be the underlying mechanism of JTs and their clonal evolution. Recombinations between the telomeric sequences may frequently occur in human malignant cells, but are not noticeable until a telomeric region has been involved in a rearrangement and has served as the vehicle for a jumping translocation.

Program Nr: 666 from the 1999 ASHG Annual Meeting

Both Homologues Of FRA3B Are Involved In Translocation In An Esophageal Adenocarcinoma. *J.M. Fang[1], M.F. Arlt[1], D.G. Beer[2], T.W. Glover[1].* 1) Department of Pediatrics & Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Surgery, University of Michigan, Ann Arbor, MI.

Common fragile sites are loci that are especially sensitive to forming gaps or breaks on metaphase chromosomes when DNA synthesis is perturbed. They have also been shown to be hot spots for translocations, deletions and SCEs in vitro. Because of their high instability and their co-localization with translocation breakpoints, common fragile sites have been suggested to play a mechanistic role in chromosome breakage and rearrangement in cancer cells in vivo. Direct tests of this hypothesis are now possible with the cloning of common fragile site loci. FRA3B, the most frequently seen common fragile site, spans the FHIT gene, which shows deletions and aberrant transcripts in many different type of cancers. In addition to deletions within the FHIT gene, FRA3B may also lead a high rate of chromosome translocations that could influence genes in addition to FHIT. Two translocations in the FHIT gene have previously been reported. Here we report translocations in both homologues of chromosome 3 in a primary esophageal adenocarcinoma cell line. These cells show no FHIT transcript by RT-PCR. The karyotype revealed translocations of both homologues of chromosome 3: t(3;16) and t(3;4). The breakpoints of both translocations were narrowed to the FHIT/FRA3B region by FISH. Using 3' RACE, a chimeric transcript resulting from the t(3;16) was identified which contains exons 1, 2, and 4 of the FHIT gene and an extra ~400 bp of sequence which maps to chromosome 16p13.3. We are currently testing for other chimeric transcripts produced by the translocations in this tumor and for function of the transcripts. These data suggest that FRA3B, or other common fragile sites, can be "hot spots" for chromosome translocation and for creation of chimeric transcripts which may play a role in tumor development.

Program Nr: 667 from the 1999 ASHG Annual Meeting

Tetranucleotide repeat sequences are more stable than dinucleotide repeats in cultured mammalian cells. *R.A. Farber[1], J.S. Lee[1,2], J.L. Genova[1], M.G. Hanford[1]*. 1) Dept. of Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, NC; 2) Chosun University, Republic of Korea.

There have been conflicting reports regarding the relative stabilities of microsatellites with repeat units of different lengths, based on various types of studies. We have made a direct comparison of the rates of insertion and deletion mutations for a dinucleotide-repeat sequence [$(CA)_{17}$] and a tetranucleotide-repeat sequence [$(AAGA)_{17}$] in immortalized, nontumorigenic, mismatch-repair-proficient mouse CAK cells and in the H6 clone of the mismatch-repair deficient (*hMLH1*$^-$) colorectal cancer cell line HCT116. A plasmid vector that contained either of these sequences near the 5' end of a neomycin-resistance (*neo*) gene, such that the gene was translated out of frame, was transfected into the cells by electroporation, and transfected clones were selected for resistance to hygromycin. (The plasmid became integrated into the genome of the recipient cells.) Fluctuation analysis was carried out to measure the rates of mutation to resistance to the neomycin analogue G418. Mutation rates of the tetranucleotide repeat were approximately 10-fold lower than those of the dinucleotide repeat in the mismatch-repair-proficient cells and about 5-fold lower in the mismatch-repair-deficient cells. In addition, up to 52 independent H6 subclones were assayed by PCR for instability of several different endogenous uninterrupted tetranucleotide and dinucleotide repeats. The tetranucleotide repeats were found to be 3- to 15-fold more stable than the dinucleotide repeats (mean difference = 5-fold). The results of these direct analyses demonstrate that tetranucleotide repeats have considerably greater stability than dinucleotide repeats in two different types of cultured somatic cells.

Program Nr: 668 from the 1999 ASHG Annual Meeting

Family history information: developing a cancer risk assessment strategy. *C.D. Farrell, M.J. Rosenblatt, M. Skipper.* Roswell Park Cancer Inst, Buffalo, NY.

The ability to determine cancer risk status is important for both medical management and for identification of patients as candidates for participation in cancer genetic research. The best method for assessment of inherited risk is family history.

A comparative study of 3 different sources of family history information for a given patient was undertaken to determine the extent and type of information obtained, existence of discordances and omissions, and the ability to use this information to categorize cancer risk. Medical records of 192 randomly selected patients were reviewed for preselected elements relevant to risk classification. Of these 192 patients, 125 agreed to provide their information by telephone interview, and 83 had previously completed a voluntary questionnaire. In order to assign cancer risk, criteria were developed based upon established criteria for known cancer genetic syndromes and integrating phenotypic characteristics documented in association with increased risk for cancer associated genes. The classifications were designated as: high, moderate, general population, or indeterminate.

Preliminary results indicate that family history information was obtained on all patients; however, some information necessary for risk categorization was deficient in 33.9% of medical records. The family history information generally was found in 1-3 places, but this was not consistent across all records. There were 45 different locations noted, supporting the necessity for one designated location that would allow for access and updating. Telephone interview resulted in the ability to categorize 84.6% of those designated indeterminate by medical records. Concordance of risk categorization was 55.2% between the medical record and the telephone interview. There was greater concordance between the telephone interview and the questionnaire, but there were fewer numbers in this comparison. Further results of this study will be discussed, as will the risk categorization criteria and elements designated as critical for family history risk assessment.

Program Nr: 669 from the 1999 ASHG Annual Meeting

Genomic Differences within cystic and squamous components of an ovarian teratoma when grown in Primaria Plastic and Normal Tissue Culture Plastic with RPMI or LHC-9 media. *S.A. Faruqi, R.B. Deger, H. Javid, J.S. Noumoff.* OB/GYN, Div Gynecologic Oncol, Crozer-Chester Medical Ctr, Upland, PA.

Benign cystic and malignant squamous components of an ovarian teratoma were grown simultaneously on Primaria, a positively charged dish (Beckton Dickinson,Franklin Lakes,N.J.), and normal tissue culture plastic (NCTP)using two different media, RPMI with serum and the serum free media LHC-9 (Biofluids, Rockville, MD). The cyst showed both diploid and polyploid cells in the Primaria with RPMI (32:7) and in the Primaria with LHC-9 (28:1) whereas no polyploid cells were seen in the NTCP with RPMI (27:0) or in the NTCP with LHC-9 (16:0).
The squamous component did show both diploids and polyploids in all cultures except Primaria with LHC-9, where dividing cells were absent in the majority of the cultures. Only one culture out of three showed two dividing cells, both of which were polyploids. Both cystic and the squamous components contained significant variations in the presence or absence of certain specific markers. The marker del(4)(q22.1)reported earlier in dermoid tumor was also present in this material as well and so was trisomy 12 which is generally present in most of the germ cell tumors. The most interesting abnormality found both in cystic and squamous components was del(22)(q12.1) but a translocation with chromosome 9 could not be detected. Deletion 22q was seen in the NTCP with either RPMI or LHC-9 but it was absent in Primaria. The chromosomal variation within and between these cultures have significant implications in the complete recovery of the tumor genome.

Program Nr: 670 from the 1999 ASHG Annual Meeting

Human papillomavirus (HPV) study of 482 pathological specimens by PCR-direct sequencing (PCR-DS) approach. *J.C. Feoli-Fonseca[1], L.L. Oligny[1], P. Brochu[1], P. Simard[1], W.V. Yotov[2].* 1) Pathology, Hosp. Ste-Justine, U. Montreal, Montreal, Quebec, Canada; 2) Pediatrics, Hosp. Ste-Justine, U. Montreal, Montreal, Quebec, Canada.

Human papillomaviruses (HPV) are etiological agents for cervical cancer and some other human diseases. Using our two-tier PCR-direct sequencing (PCR-DS) approach for HPV detection and typing, we tested 482 pathological specimens and found 354 of them (73.4%) HPV-positive. Most of the specimens (79%) were diagnosed as cervical intraepithelial neoplasia (CIN) grade I-III. Four most frequently found isolates accounted for 56 % of all sequences: HPV6, 16, 11 and 31 (24.2%, 20.5%, 6.6%, and 4.5%, respectively). Some unexpected results of our study are: strong relative increase of HPV types of unknown cervical cancer risk in co-infections; high, for a PCR-based method, number of individual viral isolates (sequences) from co-infections (20.7% of all isolates); higher incidence of high-risk HPV types 31 and 56 than HPV18; new data indicating that the HPV evolutionary patterns are quite complex. We placed for the first time some novel (identified by our study) and known human and animal papillomaviruses in a common clade, contradicting previous hypothesis that genetic diversity in HPV came late in evolution, after the divergence of the human species from its non-human predecessors. In the course of this study we created a new HPV database for quick search and identification of known and novel HPV types based on a short part of the consensus region determined by primers MY09/11 and GP5/GP6. To our knowledge, this is the largest sequencing-based single-laboratory study of HPV.

Program Nr: 671 from the 1999 ASHG Annual Meeting

Differential analysis of telomerase activity in microdissected breast cancer samples. *W. Fiedler[1], C. Mueller[1], U. Riese[1], R. Dahse[1], F. von Eggeling[1], H. Kosmehl[2], G. Ernst[1], U. Claussen[1]*. 1) Inst Human Genetics, Jena, Germany; 2) Inst Pathology, Jena, Germany.

A differentiated molecular analysis of tumor tissue samples is complicated in general by three aspects: (i) genetic heterogeneity of the tumor tissue itself, (ii) morphological heterogeneity within the samples and (iii) the a priori unknown ratio between tumor cells and non-tumorous cells within the sample. To overcome these problems in the analysis of telomerase activity in breast cancer we performed microscopic evaluation of each tumor sample and subsequent tissue microdissection of unstained cryostat sections under an inverted microscope with the help of a micromanipulator and extended glass needles. Thus, the specific assignment of telomerase activity to distinct tissue areas including small lesions and stroma cells was possible in 134 cases of breast cancer. In total, 108 of them (80 %) expressed telomerase. Corresponding non-tumorous tissue stroma free of infiltrating lymphocytes was telomerase negative in 41 samples tested. Only 3/10 ductal carcinoma in situ (DCIS) exhibited telomerase activity. Variations of the telomerase status were found in 34 of 73 (45 %) samples by analyzing several areas of one tumor. In 6 of 23 samples intraductal and invasive growing tumor areas analyzed in parallel, the finding of different levels of telomerase activity displayed tumor heterogeneity. Our results indicate that microdissection of histological sections enables investigations of pure populations of morphologically well defined cells. The direct correlation of the telomerase activity to specific histological findings provide a more differentiated view into cancerogenesis and tumor progression.

Program Nr: 672 from the 1999 ASHG Annual Meeting

BTAK overexpression is associated with aggressive bladder cancer. *G.C. Fraizer[1], H. Zhou[2], M. Diaz[1], C. Joy[1], I. Lee[1], C. Reznikoff[3], M. Liebert[1], H.B. Grossman[1], S. Sen[2].* 1) Urology,Univ. of Texas M.D.Anderson Cancer Ctr., Houston, TX; 2) Pathology and Lab Medicine, Univ. of Texas M.D.Anderson Cancer Ctr., Houston, TX; 3) Human Oncology, Univ. of Wisconsin.

Accumulation of extensive genetic abnormalities and chromosomal aneuploidy has been associated with high stage, aggressive bladder cancer. Specifically, amplification of chromosome 20q has previously been associated with invasive bladder cancer, but the gene(s) involved were unknown. We hypothesize that a candidate gene for invasive bladder cancer development may be BTAK, a centrosome associated serine/threonine kinase that has recently been identified and located at 20q13 in the amplicon that is often amplified in bladder tumors. This finding led us to ask whether BTAK may be overexpressed in bladder tumors. Using immunofluorescence staining, northern and western blot analyses, we present the first evidence that BTAK expression is higher in some bladder tumors and cell lines than in adjacent normal bladder tissue and normal urothelial cells. We also demonstrate that BTAK expression levels are correlated with tumor stage. BTAK expression is: 1) higher in invasive bladder tumors than non-invasive, 2) low in bladder tumor cell lines derived from low grade tumors and 3) higher in an E7 transformed urothelial cell line with 20q amplification than in an E6 transformed line which lacks 20q amplification. Our hypothesis is that high BTAK expression in bladder urothelium leads to aneuploidy and aggressive tumor development. While superficial bladder tumors commonly recur, most never progess to invasive and potentially lethal bladder cancer. Identifying biomarkers, such as BTAK, that may indicate which tumors are likely to progress can help guide appropriate therapy. Furthermore because it is likely that aneuploidy contributes to tumor progression, understanding mechanisms of aneuploidy will be important for the development of new treatments directed at biologically aggressive bladder cancer.

Program Nr: 673 from the 1999 ASHG Annual Meeting

Germ-line *NF2* mutation type, location, and phenotype in neurofibromatosis 2. *J.M. Friedman[1], R. Woods[2], H. Joe[2], D.G.R. Evans[3], A. Wallace[3], V.F. Mautner[5], L. Kluwe[4], D.M. Parry[6], G.A. Rouleau[7], M.E. Baser[8].* 1) Dept. of Medical Genetics, Univ. of British Columbia, Vancouver, Canada; 2) Dept. of Statistics, Univ. of British Columbia, Vancouver, Canada; 3) St. Mary's Hospital, Manchester, U.K; 4) University of Hamburg, Hamburg, Germany; 5) Klinikum Nord Ochsenzoll, Hamburg, Germany; 6) National Cancer Institute, Bethesda, U.S.A; 7) McGill University, Montreal, Canada; 8) Los Angeles, USA.

Germ-line neurofibromatosis 2 (*NF2*) mutation type is associated with phenotypic differences, but the effect of mutation location is unknown. We reviewed NF2 genotype-phenotype data from 101 patients in 47 families with splice-site mutations, and 198 patients in 161 families with nonsense or frameshift mutations. Patients were stratified by mutation type and proband status, then group comparisons were made in probands using the t-test or Fisher's exact test, with similar comparisons made in non-probands by means of a mixed effects model to allow for familial dependence. Probands with splice-site mutations had a higher age at onset of symptoms (mean $\pm$ SE: 23.9 $\pm$ 2.0 yrs versus 18.0 $\pm$ 1.0 yrs, p = .007) and a higher age at diagnosis (31.5 $\pm$ 2.5 yrs versus 23.9 $\pm$ 1.2 yrs, p =.004) than probands with nonsense or frameshift mutations. Non-probands with splice-site mutations had a higher age at onset of symptoms (23.2 $\pm$ 2.1 yrs versus 17.6 $\pm$ 1.5 yrs, p = .034), fewer intracranial meningiomas (0.5 $\pm$ 0.7 versus 1.9 $\pm$ 0.6, p = .027), and possibly a lower prevalence of spinal tumors (46.5% versus 66.7%, p = .078) than non-probands with nonsense or frameshift mutations. Mutation location (exons 1-13 versus 14-15) was not significantly associated with number of meningiomas, presence of spinal tumors, or age at diagnosis in either mutation group. However, the age at onset of symptoms was higher in non-probands with splice-site mutations affecting exons 14-15 compared to exons 1-13 (30.5 $\pm$ 3.7 yrs versus 20.6 $\pm$ 2.3 yrs, p = .034). No such association was seen among patients with nonsense or frameshift mutations. These results are consistent with previous NF2 genotype-phenotype correlation studies, and suggest that germ-line *NF2* alleles with splice-site mutations in 3' exons may produce a partially functional protein product.

Program Nr: 674 from the 1999 ASHG Annual Meeting

Functional homologies shared between ATM and TEL1p from *S.cerevisiae*. *E. Fritz[1], A.A. Friedl[2], F. Eckardt-Schupp[1], M.S. Meyn[3].* 1) GSF, Inst Radiation Biology, Neuherberg, Germany; 2) Dept of Radiobiology, University of Munich, Germany; 3) Hospital for Sick Children, Toronto, Canada.

Atm, the gene defective in the human genetic disorder ataxia-telangiectasia (A-T), is a member of a family of eukaryotic proteins that are involved in regulating cellular responses to DNA damage. The *S.cerevisiae* protein Tel1p is the closest known homolog of ATM, sharing 45% identity in the kinase domain and 21% in the rest of the protein. Tel1-deficient yeast cells express a similar phenotype to that of cultured A-T cells, including chromosome loss, hyperrecombination and telomere shortening. The high sequence homology and overlapping phenotypes of the two mutants prompted us to analyze functional properties shared between ATM and Tel1p in cross-complementation analyses. The complete *TEL1* coding sequence (8361 bp) was cloned into a mammalian expression vector. Upon stable transfection into A-T fibroblasts, expression of *TEL1* was confirmed by RT-PCR. Phenotypic analyses of *TEL1*-transfected A-T cells showed that i) *TEL1* reduces hyperrecombination, as measured in fluctuation analyses of spontaneous intrachromosomal recombination events; ii) *TEL1* partly complements ionizing radiation (IR)-induced apoptosis, but not reduced colony survival of A-T cells after IR; iii) *TEL1* extends the length of telomeres, as measured by analyzing the mean length of terminal restriction fragments; iv) *TEL1* had no effect on basic and IR-induced cell cycle progression as well as basic and IR-induced p53 protein amount and DNA binding activity. These data indicate that TEL1p can partially substitute for ATM in human cells and strongly suggest that TEL1p shares functional properties with ATM. In addition, our results demonstrate that the hyperrecombination phenotype of A-T cells can be uncoupled from cell cycle regulation. By complementing a specific subset of A-T defects, *TEL1*-transfected A-T cells may provide useful tools to decipher the multiple cellular pathways regulated by ATM. Analyses of protein expression and activity in TEL1p-complemented A-T cells should allow insights into how p53 and other proteins downstream of ATM regulate genetic recombination, telomere metabolism and radiosensitivity.

Program Nr: 675 from the 1999 ASHG Annual Meeting

Loss of heterozygosity in Renal Cell Carcinoma and correlation with clinicopathological data. *C. Gallou[1], D. Joly[2], A. Méjean[3], R. Grifone[1], M. Perennou[1], D. Droz[4], R. Bouvier[5], C. Junien[1], C. Béroud[1]*. 1) INSERM U 383, hôpital Necker-Enfants malades, PARIS Cedex 15, FRANCE; 2) Service de néphrologie, hôpital Necker-Enfants malades, PARIS Cedex 15, FRANCE; 3) Service d'urologie, hôpital Necker-Enfants malades, PARIS Cedex 15, FRANCE; 4) Laboratoire d'anatomie pathologique, hôpital Necker-Enfants malades, PARIS Cedex 15, FRANCE; 5) Laboratoire d'anatomie pathologique, hôpital Edouard Herriot, LYON, France.

Renal Cell Carcinoma (RCC) accounts for more than 90% of adult kidney cancer and is the eleventh most frequent cancer. Cytogenetic and molecular studies showed several recurrent abnormalities including alterations of chromosome 14 in 30% of cases. These data indicates that at least one gene is involved in renal tumorigenesis on this chromosome. A previous study in our laboratory, on 148 tumors, led to the following conclusions: a) there is a loss of 14q (LOH) in 28% of RCC; b) a significant correlation between the loss of 14q and the high grade or stage of the tumor is observed; c) no commonly deleted region can be defined. To confirm these results and identify a candidate region, we collected 100 new tumors and used 14 microsatellites markers (CA)n spreading along the long arm of chromosome 14 to look for LOH. Preliminary results show a partial or complete loss of 14q in 37% of cases. Two tumors have a partial loss of the chromosome and allowed the definition of a commonly deleted region localized between 14q21.3 and 14q23.3. The study of new regional markers and other tumors should help to refine this interval. We confirm the correlation between 14q LOH and the two main prognostic factors of RCC: tumors grades and stages. We observe 14q LOH in 39% of tumor of low stage (I-II) versus 60% for high stage (III-IV) and an increase of 33% to 62% for the tumors of grade 1 to 4. These data suggest that there is at least one tumor suppressor gene on chromosome 14 and that his alteration is critical for malignant phenotype. So, the loss of 14q could be considered as a new prognostic factor if we can demonstrate that it is independent from the tumors grades and stages. A survival study on patients studied in 1993 is in progress to validate this hypothesis.

Program Nr: 676 from the 1999 ASHG Annual Meeting

BRCA1 mutation analysis in at-risk African-American Families: results and implications. *L. Gayol[1], T. Scholl[2], H. Basterrechea[1], I. Pfeifer[1], J. Davies[1], E. Perera[1], S. Smith[3], J.F. Arena[1], L. Baumbach[1]*. 1) Pediatrics, Univ. of Miami Sch. of Med, Miami, FL; 2) Myriad Genetics Laboratories, Salt Lake City, UT; 3) Epidemology, Univ. of Miami Sch. of Med, Miami, FL.

The incidence of *BRCA1*germ-line mutations in at-risk individuals is controversial. In Caucasians, the detection of *BRCA1* mutations varies from 5-40%. Even more controversial is the incidence of *BRCA1* mutations and genetic variants in at-risk African-Americans (AA), which has been reported as ranging from very low to incidences equalling those in Caucasians.

We report our results of completed analyses of *BRCA1* in 20 AA families at-risk for breast/ovarian cancer. These families are subdivided into three categories: high-risk (HR); three affected 1st degree relatives; 10 families), moderate-risk (MR; two affected 1st degree relatives, 7 families) and undetermined risk (UR; single affected with medical information being updated, 3 families). We have screened the entire *BRCA1* coding sequence for mutations and other genetic variants using exon-specific PCR primers, followed by SSCP analysis, and DNA sequencing as described (AJHG,63:A325).

To date, we have identified only <u>one</u> deleterious mutation (3875 del GTCT), which occurred in a MR family. However, two different AA-specific intronic polymorphisms were detected in two HR unrelated families in which a *BRCA1* disease-causing mutation was not otherwise detected. To investigate a possible effect on *BRCA1* splicing, analysis of *BRCA1* mRNA was performed using DNA and RNA extracted from patients' peripheral blood. These results indicated that wild-type *BRCA1* mRNA was produced from variant-containing alleles, although alternatively spliced products, including deleted transcripts, were detectable at low levels. In addition, a novel missense mutation was detected in exon 19 (W1718C) in the second HR family only, and appears to co-segregate with breast cancer. In conclusion, our data support a low germ-line *BRCA1* mutation rate in AA patients, and suggest a possible role for AA-specific *BRCA1* variants in modulating breast cancer risk.

Program Nr: 677 from the 1999 ASHG Annual Meeting

Pathogenetic significance of constitutional missense mutations of the cancer-predisposing genes *MLH1* and *MSH2*. *M. Genuardi[1], S. Carrara[1], L. Della Puppa[2], O. Caluseriu[1], V. Rovella[1], M. Ponz de Leon[3], M. Pedroni[3], M. Anti[4], M. Boiocchi[2], A. Viel[2], G. Neri[1]*. 1) Institute of Medical Genetics, Catholic Univ Sch Medicine, Rome, Italy; 2) Experimental Oncology 1, Centro di Riferimento Oncologico, Aviano; 3) Department of Internal Medicine, Univ of Modena; 4) Institute of Internal Medicine and Geriatrics, Catholic Univ Sch Medicine, Rome, Italy.

Hereditary nonpolyposis colorectal cancer or Lynch syndrome (LS) is a cancer-predisposing condition determined by mutations in genes involved in the DNA mismatch repair (MMR) system. The majority of constitutional mutations detected in LS families affect the *MLH1* and *MSH2* genes by determining the production of truncated polypeptides. Missense mutations are also observed, but their pathogenetic significance has not been systematically ascertained so far. To determine the role played by *MLH1* and *MSH2* missense variants in cancer susceptibility, we have investigated the following genetic and biological characteristics associated with 6 *MLH1* and 4 *MSH2* missense changes identified in Italian LS families: 1) co-segregation with disease phenotype and/or *bona fide* pathogenetic mutations; 2) presence of the variant in healthy control subjects; 3) evolutionary conservation of the involved aminoacid and type of aminoacid change; and 4) presence/absence of microsatellite instability (MSI) in tumor DNA, which can be considered as a sort of *in vivo* biological assay aimed at determining the functional status of the MMR machinery. Overall, 9 variants did not fulfill $\geq$2 pathogenicity criteria. MSI was investigated in tumor samples from carriers of 9 different missense mutations. Only 3/9 tested variants were associated with MSI in tumor DNA. In addition, 4 variants were not present in affected pedigree members, and 5 variants were observed at low frequencies in the control population. Based upon these results, we conclude that most *MLH1* and *MSH2* missense changes investigated in this study are unlikely to act as major causative factors in colorectal cancer susceptibility and development.

Program Nr: 678 from the 1999 ASHG Annual Meeting

The generation of a sequence-ready contig encompassing the cervical tumor suppressor gene (TSG) on 6p23. *D.S. Gerhard[1], Z. Xu[1], L. Nguyen[1], Y. Li[1], A. Mungall[2], S. Beck[2], P. Huettner[1], J.S. Rader[1]*. 1) Depts of Genetics, Gynecology/Oncology, Pathology, Box 8232, Washington University School of Medicine, St Louis, MO; 2) Sanger Centre, Wellcome Trust Genome Campus, Hinxton, England.

Invasive cervical cancer (ICC) is the fifth most common malignancy in the world, with ~500,000 cases each year. Infection by the human papillomavirus (HVP) increases the risk of cervical cancer; 75-90% of tumors are virus-positive. However, HPV infection alone is not sufficient for the development of cervical cancer since up to 70% of women in some populations are infected, yet the malignancy develops in less than 8%. We have previously showed that a large number of cervical tumors have lost all or part of 6p, suggesting that a TSG is localized there. A study of the precursor lesions, cervical intraepithelial neoplasia, found that they too had deletions of 6p. Characterization of 107 tumors with 22 markers spanning about 70 cM of 6p and found that 57/107 (53%) lost at least 6p21-6p23; some deletions were larger. Fifty-two out of 57 tumors (91%) had a loss at 6p23. Deletions were found in tumors of all stages and histologic types. Seven tumors appear to have small interstitial deletions of 6p23 and they provide the boundaries of the candidate region. The smallest region of loss is flanked by D6S443/S429 and D6S1578, loci separated by ~1 cM. We obtained YACs containing markers from this location that had been previously identified by others. The clones were characterized with the polymorphic markers used in the tumor analysis as well as STSs and ESTs provisionally mapped to this region. We used SEGMAP to generate the size and estimate the distance between the markers. We then converted this contig into PACs and BACs. The conversion was done by: a) PCR screening of RPCI1, 3 and 11 libraries (2 PACs and 1 BAC) and b) search of sequence databases. We identified 82 clones spanning a region of ~ 1Mb, with an average depth of 8 clones per marker. All clones were assayed for their STS content. This contig is a valuable resource in the search for the cervical TSG.

Program Nr: 679 from the 1999 ASHG Annual Meeting

Different subcellular localization and cell cycle expression patterns of the Bloom syndrome and Werner syndrome helicases. *V. Gharibyan, H. Youssoufian.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Bloom syndrome (BS) and Werner syndrome (WS) are caused by deficiencies of a related class of DNA helicases. However, their phenotypes differ markedly. BS is characterized by growth retardation, immune deficiency, cancer susceptibility and excessive numbers of sister chromatid exchanges, while the major feature of WS is premature aging. To begin to understand the molecular basis for the phenotypical differences, we generated a novel polyclonal antibody to the human BS helicase, Blm, and compared the subcellular localization and expression of Blm to the WS helicase, Wrn. We detected the 170 kDa Blm antigen in wild type but not BS cells. Blm was localized to punctate nuclear structures. The level of Blm but not Wrn was 3.6 fold-higher in G1/S- compared to G0-synchronized fibroblasts. Blm-positive cells invariably expressed topoisomerase IIa, while topoisomerase IIb was expressed constitutively. Transfections of Blm deletion mutants demonstrated that the C-terminal domain mediates nuclear entry and the central helicase domain is necessary for producing the punctate pattern. By subcellular fractionation, Blm was found primarily in high-salt extracts of the nucleoplasm and the nuclear matrix and was enriched in G1/S- compared to G0-synchronized cells. There was no interaction between Blm and Wrn or topoisomerases IIa and IIb in extracts from fibroblasts. These results demonstrate that Blm is targeted to specific nuclear structures, and its expression is enhanced during cell growth. The known nucleolar localization of Wrn, its invariant expression during the cell cycle, and the lack of interaction between Blm and Wrn suggest distinct roles for Blm and Wrn in processes such as DNA repair or recombination.

Program Nr: 680 from the 1999 ASHG Annual Meeting

Expression profile of the adrenal gland from patients with primary bilateral adrenocortical diseases: Primary pigmented adrenocortical disease (PPNAD) (associated with Carney Complex) and massive macronodular adrenocortical disease (MMAD). *C. Giatzakis, S.E. Taymans, C.A. Stratakis.* UGEN, DEB, NICHD, NIH, Bethesda, MD.

The use of high density cDNA filter arrays (HDFA) to compare the expression of thousands of genes between normal and pathologic tissues, allows for the identification of multiple potential target genes involved in adrenocortical tumorigenesis. This study focuses on the expression profile of the adrenal gland from patients with PPNAD associated with Carney Complex (CNC-MIM160980) and MMAD. The adrenal gland of PPNAD is characterized by multiple, small, pigmented (black or brown), adrenocortical cortisol-producing nodules surrounded by internodular atrophy within normal-sized or small glands. Patients with PPNAD exhibit ACTH - independent hypercortisolism and mostly atypical forms of Cushing syndrome (CS). MMAD, unlike PPNAD, almost always leads to frank CS and the adrenal glands are massively enlarged. An HDFA containing approximately 4000 IMAGE cDNA clones was used to examine the expression profile of 3 PPNAD tumors from patients with CNC and one adrenal gland derived from a patient with MMAD. The expression profile of a normal adrenal gland was used as a control. Comparative expression analysis of the PPNAD adrenals versus the normal revealed 8 array elements that displayed altered density ratios of >2 fold in all three PPNAD specimens. All of those differentially expressed genes were repressed in the PPNAD. Three genes exhibited the greatest differences: a) Ubiquitin carrier protein E2-EPF, b) Ubiquitin conjugating enzyme G2, c) Tuberin. Analysis of the expression profile of the MMAD adrenal revealed a greater number of putative differentially expressed genes at a ratio of >2 (approx. 260 genes). We conclude that HDFA is an effective and reproducible way to study differential gene expression. We also conclude that abnormalities of the ubiquitin conjugating enzyme system may be important steps in the process of adrenocortical tumorigenesis in PPNAD. This finding may provide a molecular link between PPNAD/CNC and the chromosomal instability that is observed in this condition.

Program Nr: 681 from the 1999 ASHG Annual Meeting

Scoresheet for family physicians to evaluate family history of breast and ovarian cancer. *C.A. Gilpin, N.L. Carson, A.G.W. Hunter.* Dept. of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada.

Breast and ovarian cancers are relatively common conditions in the general population with 5-10% of cases being due to an inherited predisposition. The medical community and general population have become aware that genetic testing is available to look for BRCA1 and BRCA2 mutations, but what is not clear to these groups is who should be considered for the genetic counselling and possible subsequent testing. In Canada, BRCA1 and BRCA2 testing is available through research projects to defined high-risk families, at no monetary cost to the individual. Genetic counselling is also available through research programs and these programs have been overwhelmed by interest from the public. A scoresheet was developed for referring physicians to evaluate a family's genetic risk of familial breast or ovarian cancer. This simple tool identifies high-risk families who could be considered for genetic counselling. A more complex assessment is carried out in the Genetics clinic to determine if an individual meets testing criteria.

A comparison study of risk assessment methods was completed for 143 unaffected probands, where genetic testing of an affected sister was complete. Assessments using Claus tables and Bayesian analysis and probability calculations in BRCAPRO were compared to our scoresheet values. A cut-off value was assigned, above which a woman should be referred for genetic counselling and below which her risk of breast or ovarian cancer is not significantly increased. Our target was to ascertain women with double the lifetime risk for breast or ovarian cancer. We have shown that this scoresheet consistently identifies women whose calculated lifetime risk of developing breast cancer (100%) and ovarian cancer (77%) is double that of the general population. It identified 97% of women from families where a mutation was found. Those missed were from low-risk control families.

Program Nr: 682 from the 1999 ASHG Annual Meeting

Genotype-phenotype relationships in American melanoma-prone families with CDKN2A and CDK4 mutations.
A.M. Goldstein, J.P. Struewing, A. Chidambaram, M.C. Fraser, M.A. Tucker. National Cancer Inst, Bethesda, MD.

Two genes have been implicated in malignant melanoma (MM) pathogenesis. CDKN2A/p16 is a tumor suppressor gene with germline mutations detected in about 25% of MM families some of whom also have pancreatic cancer. CDK4 is an oncogene with germline mutations found in only 3 kindreds. We compared 104 MM cases from 17 p16 families and 12 MM cases from 2 CDK4 families. Recurrent p16 mutations were Val126Asp (n=3 families) and Gly101Trp (n=4). Five p16 families (29 MM cases), each with different mutations, Arg87Pro, Gly101Trp, Val126Asp, IVS2+1, 234del14, had pancreatic cancer. Both CDK4 families had the Arg24Cys mutation. We used nonparametric statistics to test for differences in median age at first MM diagnosis and numbers of MM tumors. The three recurrent mutations were haplotyped to assess whether the alterations occurred de novo or were founder mutations. Despite the hypothetical differences of action between the tumor suppressor p16 and dominant oncogene CDK4, median age at MM diagnosis (34.2 years, p=.70) and numbers of MM tumors (1.0, p=.73) were indistinguishable between MM cases from p16 versus CDK4 families. The major difference between the two groups was the association of pancreatic cancer in the p16 families. However, there were no significant differences in median age at diagnosis (p=.10) or tumor number (p=.58) between MM cases from families with pancreatic cancer (31.2 yrs; 1.0 tumors) versus families without pancreatic cancer (36.2 yrs; 1.0 tumors). Analysis of markers flanking the CDKN2A locus revealed common haplotypes for families with the Val126Asp and Gly101Trp mutations. These two founder mutations were observed in families with and without pancreatic cancer suggesting that other factors, genetic and/or environmental, may be involved in the development of pancreatic cancer. The CDK4 families, one of Irish and one of German descent, also shared a common haplotype at 6 markers flanking CDK4. Thus, the 3 recurrent missense mutations observed in these MM families- Val126Asp and Gly101Trp CDKN2A mutations and the Arg24Cys CDK4 mutation- each showed evidence for a common founder regardless of the mechanism of action of the respective gene.

Program Nr: 683 from the 1999 ASHG Annual Meeting

The role of cis- and trans-acting factors in aberrant *IKAROS* splicing in childhood leukemia. *P.A. Goodman, C.M. Wood, B.D. Juran, L. Sun, M.L. Crotty, F.M. Uckun.* Molecular Genetics, Parker Hughes Cancer Ctr/HI, St Paul, MN.

Ikaros (IK) is a zinc finger-containing transcription factor required for normal lymphocyte development, and germline mutant mice expressing only non-DNA binding dominant-negative isoforms of Ikaros develop an aggressive form of lymphoblastic leukemia between three and six months of age. Elevated expression of alternatively spliced dominant-negative Ikaros isoforms, lacking the DNA domain, as well as Ikaros isoforms with an in-frame deletion of 10 amino acids (D KSSMPQKFLG) have been observed in primary leukemic cells from children with acute lymphoblastic leukemia (ALL) (Proc. Natl. Acad. Sci. USA 96:680-685, 1999). The 10 amino acids involved in this deletion are encoded by the 3' end of exon 6, upstream of the transcription activation domain. Subsequent amplification and genomic sequence analysis of the corresponding exon 6-exon 7 splice junction regions from leukemic cells expressing the deletion variant demonstrated no mutation in the region spanning the cryptic splice site, or the predominant 5' (donor) or 3' (acceptor) splice sites. We then determined whether the deletion was mono- or biallelically expressed. A single nucleotide polymorphism (SNP) was identified affecting the third base of the triplet codon for a proline (CCC or CCA) in the highly conserved bipartite activation region (i.e., A or C at pos. 1002, from the translation start site of IK1). Biallelic expression of deletion and dominant-negative isoforms, along with wild-type isoforms, were observed in leukemic cells suggesting a trans effect on splice site selection. In compiling data from all leukemic clones sequenced (n=128), we observed an expression frequency of 77% 1002 ^{C} allele and 23% 1002 ^{A} allele. We also observed an excess of IK non-DNA binding isoforms (D KSSMPQKFLG) (91% C/9% A) on the C allele, as well as an excess of clones expressing the DNA binding isoforms (D KSSMPQKFLG) on the A allele (42% C/58% A). These results suggest a more subtle cis-acting influence on splice site recognition. Further detailed studies are required to determine the exact influence of both cis- and trans-acting elements on aberrant *IKAROS* expression in childhood ALL.

Program Nr: 684 from the 1999 ASHG Annual Meeting

MEN-1(Burin): Update on a unique phenotypic variant. *J.S. Green, C. Rigatto, P.S. Parfrey, S.M. Kaiser, A.B. Galway, C.J. Joyce, E. Ur.* Departments of Medical Genetics and Medicine, Memorial University, St. John's, NF, Canada.

BACKGROUND: We have previously described four families affected with MEN-1 originating in the Burin Peninsula of Newfoundland. Initial studies suggested a different tumor pattern than observed in other families. In 1997, the same mutation of the MEN-1 gene was identified in all four families. The present study integrates the results of symptomatic presentation, a decade of prospective clinical screening and genotyping in an updated description of this unique variant. METHODS: Prospective and retrospective outcomes assessment, genetic testing and prospective clinical screening (serum calcium, PTH, prolactin, gastrin, abdominal ultrasonography, chest x-ray) of those at 50% or greater risk of disease. Numbers in brackets represent 95% confidence intervals. RESULTS: Data was collected for 199 patients, of whom 165 had genetic testing. 95 of those tested were positive for the MEN-1 mutation, of whom 78 had clinical or biochemical evidence of disease and 17 did not. 70 patients tested negative for the gene. Overall, 94[89,99]%; of clinically affected patients developed hyperparathyroidism, 34[25,43]% developed pituitary tumors (32% PRL, 2% other), 10[4,16]% developed pancreatic tumors (4.3% gastrinoma, 3.3% glucagonoma, 2.3% other), 9[3,15]% developed carcinoid (5.3% lung, 3.3% thymus), and 3[0,6]% developed adrenal lesions (1% tumor, 2% multinodular disease). The initial feature of MEN-1 was hyperparathyroidism in 88[82,94]%, pituitary adenoma in 10[4,16]%, and carcinoid in 2[0,8]%. The penetrance of the disease was 50[39,61]% at age 34, 80[71,89]% at 45 years and 90[83,97]% at 51 years. Median age at diagnosis was 33[29,37] years for hyperparathyroidism, 37[27,45] for pituitary adenomas, 37[32,42] for pancreatic tumors and 42[38,48] for carcinoid. These differences were not statistically significant. CONCLUSIONS: MEN-1 (Burin) is characterized by a higher frequency of pituitary and carcinoid tumors, a lower frequency of pancreatic islet cell tumors, and a later onset than classical MEN-1. Since the same gene is involved as MEN-1 in other families, future studies need to focus on genetic and environmental variables that may influence phenotypic expression.

Program Nr: 685 from the 1999 ASHG Annual Meeting

Targeting of the p16/Rb pathway by methylation results in up-regulation of the p14ARF/p53 pathway in uveal melanoma. *N.A. Gruis[1], J.A.W. Metzelaar-Blok[2], P.A. van der Velden[1], H.M.H. Hurks[2], R.R. Frants[1], M.J. Jager[2]*. 1) Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Dept of Ophthalmology, Leiden Univ Medical Ctr, Leiden, Netherlands.

The p16 (CDKN2A) gene on chromosome 9p21 encodes for the recognized tumor suppressor protein p16 and for a second protein product p14ARF, which originates from an unrelated exon of p16 (exon 1b) spliced onto exon 2 in an alternative reading frame. By means of a competitive RT-PCR, p16 and p14ARF mRNA expression was quantitatively determined in 9 uveal melanoma cell lines. Five out of nine cell lines lacked p16 expression and showed elevated p14ARF mRNA expression. The absence of p16 mRNA expression turned out to be due to hypermethylation of the p16 promoter. Treatment of the hypermethylated cell lines with the agent 5'-aza-2'-deoxycytidine led to re-expression of p16 and reduction of p14ARF mRNA expression. The inverse correlation between p16 and p14ARF mRNA expression might be explained by the interaction between cell cycle control pathways in which p16 and p14ARF play their roles. P16 induces a G1 cell cycle arrest by inhibiting the phosphorylation of retinoblastoma protein (Rb) by the cyclin-dependent kinases, CDK4 and CDK6. If p16 is repressed, phosphorylation of Rb results in the release of E2F transcription factor that stimulates transcription of p14ARF and the related p53-MDM2 pathway. The role of p16 hypermethylation in uveal melanoma was substantiated in primary tumors of which 27% showed p16 methylation, confirming that p16 promoter hypermethylation is a preferential mechanism of p16 inactivation.

Program Nr: 686 from the 1999 ASHG Annual Meeting

The Association of Chromosome 8p Deletion and Tumor Metastasis in Human Hepatocellular Carcinoma. *X.-Y. Guan[1], L.-X. Qin[2], Z.-Y. Tang[2], J.S.T. Sham[1], Z.-C. Ma[2], S.-L. Ye[2], X.-D. Zhou[2], Z.-Q. Wu[2], J.M. Trent[3]*. 1) Clinical Nocology, University of Hong Kong, Hong Kong, P.R.China; 2) Liver Cancer Institute, Shanghai Medical University, Shanghai, P.R. China; 3) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD.

To understand the genetic mechanisms underlying the progression of hepatocellular carcinoma (HCC) metastasis, differences of genomic alterations between 10 pairs of primary HCC tumors and their matched metastatic lesions were analyzed by comparative genomic hybridization (CGH). Several genomic alterations including loss of 8p, 4q, 17p, and 19p, gain of 5p and high-level amplification of 1q12-q22 were detected in two or more cases. The most significant finding is the loss of 8p which was detected in 8 metastatic tumors but only in 3 corresponding primary tumors (p=0.03). This result suggests that the deletion of chromosome 8p might contribute to the development of HCC metastasis. Another interesting finding is the detection of a minimum amplification region at 1q12-q22 in HCC. This result provides a candidate amplification region in HCC for further study to identify amplified oncogenes related to the development or progression of HCC. Finally, this study provides a practicable model to detect specific genetic alterations related to the tumor metastasis through comparing the primary tumor and its corresponding metastatic lesion using CGH technique. Finally, this study provides a practicable model to detect specific genetic alterations related to the tumor metastasis through comparing the primary tumor and its corresponding metastatic lesion using CGH technique.

Program Nr: 687 from the 1999 ASHG Annual Meeting

Different rates of chromosomal changes as measured by comparative genomic hybridization in colon tumors with or without the CpG island methylator phenotype. *B.R. Haddad[1], J. Rone[1], M. Toyota[2], JPJ. Issa[2]*. 1) Institute for Molecular and Human Genetics, Georgetown Univ Medical Ctr, Washington, DC; 2) The Johns Hopkins Oncology Center, Baltimore, MD.

Tumors of the colon arise through a combination of genetic changes (mutations in APC/beta Catenin, K-RAS, p53, TGFbetaRII etc.), genetic instability (microsatellite or chromosome) and epigenetic changes (silencing and methylation of genes such as p16, hMLH1, THBS1, TIMP3, MGMT). A hypermethylator phenotype has recently been described in colon tumors termed CpG Island Methylator Phenotype (CIMP) which results in the simultaneous methylation and silencing of many genes. CIMP affects about half of all cases and is associated with a high rate of K-RAS mutations and a low rate of p53 mutations. We have now studied whole chromosomal changes by Comparative Genomic Hybridization (CGH) in a panel of 24 tumors also typed for CIMP and mutations in K-RAS and p53. 12 tumors had at least one alteration by CGH (4/11 adenomas and 8/13 carcinomas), and 8 tumors had two alterations or more. The most common changes were +20 or +20q (9/24 cases) and -18 or -18q (5/24 cases). Chromosomal changes were more common in CIMP Negative cases: 8/12 CIMP- tumors vs. 4/12 CIMP+ tumors had at least one change. 2/12 CIMP+ tumors had more than one alteration vs. 6/12 CIMP- cases. There were no correlations with K-RAS mutations or p16 methylation, but 7/8 tumors with p53 mutations had chromosomal changes vs. 5/16 tumors without such mutations. Thus, CIMP defines two groups of colon cancers with significantly different genetic changes as well as chromosomal changes as measured by CGH.

Program Nr: 688 from the 1999 ASHG Annual Meeting

The tumor antigene HuR binds specifically to one of five protein-binding segments in the 3'-untranslated region of the neurofibromin messenger RNA. *J. Haeussler[1], J. Haeusler[2], A. Striebel[2], G. Assum[2], W. Vogel[1], W. Krone[2]*. 1) Department of medical genetics, University of Ulm, Ulm, Germany; 2) Department of human genetics, University of Ulm, Ulm, Germany.

Neurofibromatosis type 1 (NF1) is one of the most common genetic disorders in humans, with a prevalence of about 1 in 4000 individuals. The NF1 gene spans about 335 kb genomic DNA and is organized in 60 exons that encode a transcript of 12.1 kb with a largest open reading frame of about 8600 bp. Neurofibromin, the gene product of the NF1 gene, belongs to the family of RAS GTPase activating proteins and has been shown to downregulate Ras activity. Interestingly, the large 3.5 kb 3'-untranslated region (UTR) of the NF1 mRNA shows significant sequence identity between species. 3'-UTRs have been found to affect the function of mRNAs in several ways, including intracellular localiziation of mRNAs, controlling mRNA stability and regulating translation efficiency. Because our knowlege about a specific function of the 3'-UTR of the NF1-mRNA is still in its infancy, we decided to search in this highly conserved structure for protein binding sites. We discovered five RNA fragments (NF1-PBR1-5, NF1-protein binding regions) that were able to undergo specific binding to proteins from cell lysates. In an initial effort to characterize the corresponding binding partners we identified the Elav-like protein HuR, an important component of the mRNA stabilsation machinery and a well known tumor antigene. The 32 kDA protein binds with high specificity to NF1-PBR1, a 38 nt fragment, located about 200 nucleotides downstream of the stop-codon. HuR has been found to interact with AU-rich elements (AREs) in the 3'UTR of many proto-oncogenes, cytokines and transcription factors, thereby regulating the expression of these messenger RNAs. Transient transfection assays with CAT reporter constructs containing or lacking NF1-PBR1 show that this sequence is able to inhibit expression of the reporter gene, indicating that HuR is involved in the fine tuning of the expression of the NF1 gene which codes for a protein functionally integrated into the complex network of Ras-mediated signal transduction.

Program Nr: 689 from the 1999 ASHG Annual Meeting

Structure and expression analysis of human and murine TCL loci. *C. Hallas, Y. Pekarsky, T. Itoyama, K. Huebner, C.M. Croce.* Kimmel Cancer Institute, Thomas Jefferson University, Philadelphia, PA.

The TCL1 and TCL1b oncogenes on human chromosome 14q32.1 are involved in the development of T cell leukemia in humans. Their expression in these leukemias is activated by chromosomal translocations and inversions involving 14q32 region. To investigate the possible involvement of other genes within this region in leukemia, we sequenced and characterized 110 kb human and 70 kb murine tcl loci. Analysis of ESTs, Northern and RT-PCR experiments revealed the presence of two novel human genes in the locus: TNG1 and TNG2 (for TCL neighboring genes 1 and 2). The protein sequences of these two genes do not show any homology in BLAST search. Expression profiles of all four human genes are very similar: all genes are expressed at very low levels in normal bone marrow, lymphocytes and B cell leukemia cell lines, but activated in T cell leukemias with rearrangements in 14q32 region. Surprisingly the 70 kb murine locus besides the tcl1 gene contains five other TCL1 related genes, called tcl1b1 through tcl1b5. The deducted amino acid sequences reveal very high similarity between these five genes suggesting that they are resulting from gene duplication. These genes show about 50 percent homology to the human TCL1b protein. All five genes are expressed in Knowles mouse two cell embryo cDNA library although at different levels and some of these genes are expressed at much lower levels in ES cells and some adult tissues. In contrast, the highest expression level of tcl1 was observed in ES cells and to a much lesser extent in two cell embryo cDNA library, suggesting differences in regulation of expression of murine tcl1 and tcl1b genes.

Program Nr: 690 from the 1999 ASHG Annual Meeting

Role of HMGI-C in familial lipomatosis. *R. Hamid, J.A. Phillips III, G.E. Tiller, J. Pfotenhauer.* Dept Pediatrics/Genetics, Vanderbilt Univ, Nashville, TN.

Lipomas (fat cell tumors) are one of the most common mesenchymal neoplasias in humans. Chromosomal translocations at 12q13-15 in sporadic lipomas have been described which disrupt the HMGI-C (high mobility group protein isoform 1-C) gene and fuse its DNA binding domains to novel transcriptional regulatory domains. This suggests that deranged HMGI-C expression may play a role in the pathogenesis of lipomas. To determine the genetic basis of familial lipomatosis and the role played by the HMGI-C gene, we have ascertained, examined and collected samples from members of a multiplex family with three affected generations with multiple lipomas. Aliquots of DNA from individual family members were used to genotype an intragenic dinucleotide repeat polymorphism within the HMGI-C gene. PCR analysis was done using fluorescently labeled primers and analyzed on an ABI 310 using Genotyper Software. We calculated a LOD score of -5.1 at theta = 0 from our data. These results show that the familial lipomatosis phenotype does not co-segregate with a particular allele of the HMGI-C gene or with sequences within 1 centi Morgan (cM) of the HMGI-C locus in this pedigree. There are additional positional candidate genes (CHOP, SAS, CDK4, MDM2) which localize to 12q but map to greater than 3 cM from the HMGI-C locus. In ongoing studies we are evaluating co-segregation of the above mentioned positional candidate genes to identify the familial lipomatosis locus in our kindred.

Program Nr: 691 from the 1999 ASHG Annual Meeting

Detecting leukemia specific translocations with a RT-PCR-ELISA method. *J. Han[1], S. He[1], D. Venable[1], P. Li[2].* 1) Genaco Biomedical Products, Inc., Huntsville, AL; 2) University of Alabama at Birmingham, Birmingham, AL.

Recurrent chromosome translocations in childhood leukemia are useful cytogenetic markers for monitoring diagnosis, prognosis and treatment. A traditional cytogenetic study, performed on patients' bone marrow cells, is a time consuming and labor intensive procedure that also requires extensive training of the cytogenetic technicians. We are developing a proprietary technology that will allow high throughput detection of multiple translocations at a time. The key feature of the technology is to perform a multiplex RT-PCR and hybridize the PCR products with capture probes covalently linked to ELISA plate. After post-hybridization washes, the captured PCR product is detected by a probe specific to either gene A or gene B that involved in the translocation. A translocation is detected if a microwell containing the capture oligo for gene A is detected by a probe specific for gene B. The method may represent a significant improvement for leukemia diagnosis, it will allow the screening of multiple translocations at a time, and the whole procedure can be completed within hours.

Program Nr: 692 from the 1999 ASHG Annual Meeting

Genomic sequence analysis and SNP identification in genomic regions surrounding genes involved in carcinogenesis. *S.L. Haydel, R.A. Gibbs, D.L. Nelson.* Dept Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Numerous genes have been identified that confer higher risk of development of cancer when mutated. The role of common variants of these genes in conferring elevated (or diminished) risk of cancer is unknown. This project seeks to identify functional variants of genes involved in replication, repair or cell cycle regulation and to develop tools for performing association studies in sporadic cancer. We are determining the genomic sequence of large regions containing candidate genes. Human genomic BAC and PAC libraries are screened using overgo probes designed from cDNAs. A small contig is constructed by STS and restriction fingerprinting analysis, and a single large clone (~150kb) carrying the complete gene is sequenced by the BCM Human Genome Sequencing Center. To date, ten genes are in the sequencing process. These are *MSH6*, *MSH2*, *MSH3*,*MLH1*, *PMS1*, *P53*, *KU80/6*, *HRAS*, *DNA PKCS*and *RECQL*. The *RECQL* sequence is complete. It reveals a gene spanning approximately 30 kb and made up of 15 exons. Within this same BAC clone derived from 12p12 are also genes for islet amyloid polypeptide and glycogen synthase, as well as unknown genes represented by numerous EST similarities. Sequence data are used to identify variable nucleotides by resequencing randomly selected regions of the gene in five unrelated samples. Our goal is to develop 8-12 SNPs per locus in order to provide a rich haplotype for each. Allele frequencies and haplotype structures are determined for each locus by typing 300 ethnically diverse samples and 10 3 generation CEPH families. At present, 8 variable alleles have been identified from 20 sequencing products in the *BRCA2* locus, and allele specific oligonucleotide assays are underway for haplotype studies.

Program Nr: 693 from the 1999 ASHG Annual Meeting

Acute Lymphoblastic Leukemia (ALL) in Children with Down Syndrome (DS): A Report from the Children's Cancer Group (CCG). *N.A. Heerema[1], H.N. Sather[2], M.G. Sensel[2], M.K. Lee[2], B.J. Lange[2], B. Bostrom[2], J.B. Nachman[2], P.G. Steinherz[2], R. Hutchinson[2], P.S. Gaynon[2], F.M. Uckun[1].* 1) Hughes Inst., St. Paul, MN; 2) Children's Cancer Group, Arcadia, CA.

We identified 34 children with DS among 1880 children with ALL treated on risk-adjusted CCG protocols. Fifteen patients (44%) had no cytogenetic abnormalities other than a constitutional (c) +21; ten patients (32%) had 1 or 2 additional abnormalities; five patients (24%) had complex karyotypes with more than two additional abnormalities but with a modal chromosome number (MN) <51; four patients had high hyperdiploidy (MN >51). Known recurring additional cytogenetic abnormalities included an abnormal 9p (3 patients); an abnormal 12p (5 patients); a 14q32 breakpoint (2 patients); an 11q23 breakpoint (1 patient); a +X with modal number <51 (2 patients); and an i(17)(q10) in 2 patients. No DS patients had a t(4;11), a t(1;19), or a t(9;22). DS patients were less likely than non-DS patients to have high white blood cell (WBC; p = 0.02), high platelet counts (p = 0.04), or significantly enlarged lymph nodes. DS patients were more likely to be classified as standard risk (age 1-9 years with WBC <50,000/mL; p = 0.01), but were somewhat less likely to have a rapid response to initial therapy (<25% blasts on day 7; p = 0.10). The majority of patients with or without DS had B-lineage ALL. Event-free survival (EFS) was similar for DS and non-DS patients, with 6-year estimates of 76% (SD=11%) and 75% (SD=2%), respectively (p=0.93). DS patients experienced events within two years of study entry, whereas non-DS patients had fewer early events and more later events. There was a trend for decreased overall survival for DS patients: 6-year estimates were 76% (SD=11%) and 83% (SD=1%), respectively (p=0.17; relative risk=1.64). Four DS patients' first events were toxic deaths; 3 of the 4 patients with other first events also subsequently died of toxicities. These data suggest that with current therapy, children with DS who develop ALL have outcome similar to that of non-DS patients, although the temporal sequence and types of events differ from the those of the non-DS ALL population.

Program Nr: 694 from the 1999 ASHG Annual Meeting

Expression of $p16^{INK4a}$ and $p19^{ARF}$ in squamous cell carcinoma cell lines. *T.N. Heffernan[1], M.F. Shaheen[2], D.T. Cody[1]*. 1) Surgery, SIU School of Medicine, Springfield, IL; 2) Internal Medicine, SIU School of Medicine, Springfield, IL.

$p16^{INK4a}$ and $p19^{ARF}$ ($p14^{ARF}$, p16b) are located on the short arm of chromosome 9 and share the same locus at 9p21. However, the two transcripts have different first exons and the shared second and third exons have alternate reading frames so that the two products lack amino acid identity. Both $p16^{INK4a}$ and $p19^{ARF}$ encode proteins that function in cell cycle regulation. $p16^{INK4a}$ is a cyclin-dependent kinase (CDK) inhibitor that regulates the Rb pathway. It acts by inhibiting CDK4 and CDK6 from binding to cyclin D, thereby causing Rb to be hypophosphorylated so that the cell cycle ceases or is controlled at the G_1/S phase. On the other hand, $p19^{ARF}$ regulates the p53 pathway. It acts by binding to MDM2, thereby inhibiting MDM2 from targeting p53 for ubiquination and degradation so that p53 levels are stabilized and the cell cycle is arrested or controlled at both the G_1/S and the G_2/M phase. Since the short arm of chromosome 9, where $p16^{INK4a}$ and $p19^{ARF}$ are located, is frequently mutated in human cancers, and $p16^{INK4a}$ and $p19^{ARF}$ regulate the cell cycle, expression levels of these genes are ideal targets for study in various cancer cell lines.

We used Western blot analysis to determine expression levels of these genes in the squamous cell carcinoma cell line, SCC-9 (ATCC). The Saos-2 (ATCC) cell line was used as a positive control and normal adult human epithelial keratinocytes (HEKa, Cascade Biologics) were used to determine baseline expression levels. The SCC-25 (ATCC) cell line was used as a negative control.

We were able to demonstrate that the Saos-2 cell line and the HEKa cells both expressed $p16^{INK4a}$ and $p19^{ARF}$; whereas, the SCC-25 cell line, as expected, showed no detectable expression. Using this assay, the SCC-9 cell line did not show expression of either $p16^{INK4a}$ or $p19^{ARF}$. Lack of detectable expression of $p16^{INK4a}$ and $p19^{ARF}$ in the SCC-9 and SCC-25 cell lines may contribute to the uncontrolled cell cycling that leads to squamous cell carcinoma development and supports the idea that inactivation of these genes contributes to carcinogenesis.

Program Nr: 695 from the 1999 ASHG Annual Meeting

Molecular cytogenetic characterization of a highly aberrant plasmocytoma case with 24-color FISH, CGH, multicolor banding (MCB) and region specific FISH probes. *A. Heller[1], H. Starke[1], I.F. Loncarevic[1], G. Senger[2], I. Chudoba[3], U. Claussen[1], T. Liehr[1]*. 1) Inst. Human Genetics and Anthropology, Jena, Germany; 2) Practice of Medical Genetics and Gynaecology, Regensburg, Germany; 3) MetaSystems Inc., Altlussheim, Germany.

A case of a 72 year old female patient suffering from plasmocytoma is reported. In conventional cytogenetic analysis (GTG-banding) a highly complex karyotype with 51 to 53 chromosomes and at least 2 different subclones could be identified. Trisomy 3, 5, 7, 14, 15 and 19 could be observed by GTG-banding and confirmed by 24-color FISH. CGH revealed the following changes: rev ish enh(3,5p,7,8,9,15,19p),dim(1p31p11,13,14q21q31), amp(1q12-q44,5p15.3q15,Xq21q28). Moreover, the involvement of chromosome 1 in complex rearrangements was studied more intensely using the DNA-based high resolution multicolor-banding technique (MCB), based on changing fluorescence intensity ratios along the chromosomes (Chudoba et al., Cytogenet. Cell Genet., in press). Using an MCB probe set for chromosome 1, a partial trisomy 1p11-qter, a partial monosomy 1p11-p31.1, a translocation t(1;7)(p13.3;?) and an inversion p13.3-q21.1 could be identified. An MCB probe set for chromosome 5 and 13 has also been used and revealed complex rearrangements in this case. FISH using a p53 specific probe revealed a heterozygous deletion in 38% of the evaluated nuclei, even though - according to GTG banding - both chromosomes 17 appeared to be normal. Complementary studies using region specific cosmid probes (RB1 on 13q14, AML1 on 21q22, Int2 on 11q13 and MLL on 11q23) are in progress to characterize the highly complex changes of this case in more detail. Acknowledgments: This work was supported by the Madeleine Buehler-Kinderkrebs-Stiftung and a fellowship to A. Heller and H. Starke by the Herbert Quandt Stiftung der VARTA AG.

Program Nr: 696 from the 1999 ASHG Annual Meeting

Reduced expression of dystroglycan in prostate and breast cancer. *M.D. Henry[1], M.B. Cohen[2], M. Durbeej[1], K.P. Campbell[1]*. 1) HHMI, Department of Physiology and Biophysics, Neurology, University of Iowa, Iowa City, IA; 2) Department of Pathology, University of Iowa, Iowa City, IA.

Cellular interactions with the extracellular matrix are an important aspect in the development and progression of many types of cancer. We have elucidated a central role for dystroglycan, a cell surface receptor for several extracellular matrix proteins, in the organization of the laminin-based extracellular matrix during development. Since abnormalities of the laminin-based matrix are hallmarks of metastatic disease, we examined the status of dystroglycan expression in prostate tumors. We examined 15 cases of surgically resected prostate tumors by immunofluorescence analysis to detect the dystroglycan protein. We find a marked reduction of dystroglycan expression in malignant tissues compared to normal prostatic epithelia. This difference was most pronounced in high grade disease. Similar findings were made for mammary ductal adenocarcinomas suggesting that loss or reduction of dystroglycan expression may be a conserved feature of epithelial neoplasia. In conclusion, these data suggest that reduced expression of dystroglycan in prostate and breast may contribute to the abnormalities in the laminin-based extracellular matrix observed in neoplastic diseases, and may therefore contribute significantly to cancer cell invasion and metastasis.

Program Nr: 697 from the 1999 ASHG Annual Meeting

hMLH1 and hMSH2 mutation analysis in 112 suspected HNPCC families. *E. Holinski-Feder[1], Y. Mller-Koch[1], B. Neitzel[1], R. Kopp[3], P. Lohse[2], M. Gross[5], G. Baretton[4], B. Kerker[1], Ch. Neuschfer[1], A. Wirtz[1], J. Murken[1]*. 1) Dep. Medical Genetics; 2) Inst. of Clinical Chemistry; 3) Dep. of Surgery; 4) Dep. of Pathology; 5) Dep. of Gastroenterology, University of Munich, Germany.

To determine the pattern and incidence of MSI status and mutations in the HNPCC genes MLH1 and MSH2 in the german population, 107 families were divided in risk groups according to Amsterdam I/II- (19 families), Bethesda-criteria (36 families) and 51 families with suspected hereditary colorectal cancer, missing the criteria above. Mutation analysis was speeded up by implementing an innovative and cost efficient method called denaturing high-performance liquid chromatgraphy (DHPLC) on the equipement supplied by TRANSGENOMICS. The power of the method resides in its sensitivity and ability to rapidly and reproducably compare amplified sequnces in an automated manner.The analysis conditions for each exon were determined on the basis of the exon specific melting profiles and the software programme WAVEMAKER. Fullfillment of the Amsterdam I criteria is associated with an increased number of MSI-H tumors (13/17) and a increased mutation detection rate (10/24). 36 families fulfilling the Bethesda criteria showed 6 MSI-H tumors and 3 mutations. 51 families not matching the criteria above showed 4 MSI-H tumors and 1 mutation. Two mutations, one published and one unpublished, were found twice in unrelated families pointing towards founder mutations in the german population. To exclude attenuated FAP in these and the other families, mutation analysis of the exons 1-4, 9 of the APC-gene was performed for 75 patients. We found one mutation in exon 4 in one patient out of the Amsterdam I cohort. For the mutation negative Amsterdam I families the hMSH6 gene is currently screened. These results demonstrate the highest incidence of mutations in Amsterdam I families, they underscore the importance of MSI analysis prior to mutation analysis in high risk, but also in low risk families. One third of the Amsterdam I families show MSI-S tumors and are not caused by mutations in hMLH1 or hMSH2 and one familiy would have been missed even by the loose Bethesda criteria.

Program Nr: 698 from the 1999 ASHG Annual Meeting

Microsatellite instability and MLH1 hypermethylation in endometrial carcinomas of the endometrioid subtype.

L.H. Honore[1], D. Whiteside[2], S.E. Andrew[2]. 1) Dept Pathology, Univ Alberta, Edmonton, Alberta, Canada; 2) Dept Medical Genetics, Univ Alberta, Edmonton, Alberta, Canada.

Microsatellite instability (MSI) is a common phenotype of many sporadic tumours and tumours associated with hereditary non-polyposis colorectal cancer (HNPCC). MSI indicates a mutator phenotype due to mutation in genes such as the DNA mismatch repair genes which result in genomic instability. This is hypothesized to accelerate the accumulation of genetic alterations that occur in the development of neoplasia. MSI is found in 17-32% of all sporadic endometrial carcinomas, depending on the samples tested and the assay used. Very few studies have tried to correlate MSI status with clinicopathologic features and findings are contradictory due to the small numbers of studies and the lack of uniformity in MSI detection methods and in case selection. We have undertaken a study of 100 endometrial carcinomas of the endometrioid subtype (UECs) which account for 90% of all endometrial carcinomas. These have been reviewed and selected on the basis of varying grade of tumour and degree of invasion of the myometrium and cervix by a single gynecological pathologist. We used the BAT-26 marker, a highly efficient (99%) marker of MSI to accurately determine the proportion of UECs that demonstrate MSI. Genetic findings are correlated with pathologic findings and the final interpretation includes MSI positivity or negativity, associated genetic changes in the MSI+ cases and the correlation of MSI status with pathologic features of the carcinoma. Recently, it has been shown that up to 90% of MSI+ endometrial tumours demonstrate inactivation of the mismatch repair gene MLHI by epigenetic hypermethylation. The MSI+ tumours in this study will be used to determine the role of MLH1 hypermethylation in this cohort, and if there is any correlation with tumour grade or invasiveness. This will help determine how important epigenetic methylation is in the development of endometrial carcinoma. This sets the stage for studies with additional molecular markers specific to UECs lacking DNA mismatch repair that may prove useful for prognosis and gene therapy.

Program Nr: 699 from the 1999 ASHG Annual Meeting

Population-based estimate of the average age-specific cumulative risk of breast cancer for a defined set of protein-truncating mutations in BRCA1 and BRCA2. *J.L. Hopper[1], M.C. Southey[2], G.S. Dite[1], D.J. Jolley[1], G.G. Giles[3], M.R.E. McCredie[4], D.F. Easton[5], D.J. Venter[2]*. 1) Centre for Genetic Epidemiology, The University of Melbourne, Carlton, Victoria, Australia; 2) Peter MacCallum Cancer Institute, Melbourne, Victoria, Australia; 3) Anti-Cancer Council of Victoria, Carlton, Victoria, Australia; 4) New South Wales Cancer Council, Woolloomooloo, New South Wales, Australia; 5) CRC Epidemiology Unit, University of Cambridge, Cambridge, United Kingdom.

The average breast cancer risk for carriers of a germline mutation in BRCA1 or BRCA2 (penetrance) has been estimated - from the multiple-case families collected by the Breast Cancer Linkage Consortium (BCLC) - to be about 80% to age 70. However, women now being tested for these mutations do not necessarily have the intense family history of the BCLC families. Testing for protein-truncating mutations in exons 2, 11 and 20 of BRCA1, and exons 10 and 11 of BRCA2, was conducted in a population-based sample of 388 Australian women with breast cancer diagnosed before age 40. Onset of breast cancer was analysed in the known, and potential, mutation-carrying first and second degree female relatives of cases found to carry a mutation. Of the 18 mutation-carrying cases (9 BRCA1, 9 BRCA2), only five (1 BRCA1, 4 BRCA2) had at least one affected relative, so family history of breast cancer was not a strong predictor of mutation status in this setting. The risk in mutation-carriers was on average 9 (C.I. 4-23) times the population risk ($p < 0.001$). Penetrance to age 70 was 40% (C.I. 15%-65%), about half that estimated from BCLC families ($p < 0.05$). Extrapolating, about 6% (C.I. 2%-20%) of breast cancer before age 40 may be caused by protein-truncating mutations in BRCA1 or BRCA2. Breast cancer risk in BRCA1 or BRCA2 mutation carriers may be modified by other genetic, or environmental, factors. Genetic counselling may need to take into account the family history of the consultand.

Program Nr: 700 from the 1999 ASHG Annual Meeting

Unusual presentation of desmoid tumors in a family with Familial Adenomatous Polyposis. *C.L. Hunter, G.H. Vance.* Dept Medical & Molecular Gen, Indiana Univ, Indianapolis, IN.

Desmoid tumors are rare fibrous tumors occurring at increased frequency in Familial Adenomatous Polyposis (FAP). FAP is an autosomal dominantly inherited condition resulting from genetic mutations in the Adenomatous Polyposis Coli (APC) gene and predisposing to hundreds of adenomatous colonic polyps. A subset of families with FAP develop extra-colonic features such as desmoid tumors, osteomas, congenital hypertrophy of the retinal pigment epithelium, and supernumerary teeth. It is estimated that individuals with FAP have an 852-fold increased risk for developing a desmoid tumor (Gurbutz, et. al., 1994). Typically, FAP-associated desmoid tumors develop abdominally and either at the time of or following a diagnosis of FAP, i. e.: after polyposis or multiple adenomatous colonic polyps have developed. The average age of FAP-associated desmoid tumor development reported in various FAP registries ranges from the late twenties to early thirties.

We report on a family with a diagnosis of FAP and an unusual presentation of desmoid tumors. The proband presented at age 25 years with a desmoid tumor of the breast and no family history of colon cancer, FAP or of desmoid tumors. During the following 7 years, multiple abdominal and retroperitoneal desmoid tumors as well as multiple adenomatous polyps developed. The proband's daughter presented to her pediatrician at 10 days of age with an infantile (desmoid-like) fibromatosis tumor on her left lower leg. At age 10 years she underwent her first colonoscopy which identified several adenomatous polyps. The third affected family member is the proband's son who underwent his first colonoscopy at age 12 years during which several adenomatous polyps were identified. He has not developed a desmoid tumor. Commercial genetic testing has identified a truncated APC protein in all three individuals. The atypical features seen in this family include 1) two of the three affected family members developing a desmoid tumor as the initial manifestation of their disease, 2) the initial desmoid tumors developing extra-abdominally, and 3) the unusually young age of desmoid tumor development seen in one individual.

Program Nr: 701 from the 1999 ASHG Annual Meeting

Impact of smoking habit and germline p53 mutation on cancer risk. *S. Hwang[1], B.M. Mims[2], G. Lozano[2], L.C. Strong[1]*. 1) Dept Experimental Pediatrics, Univ TX MD Anderson Cancer Ctr, Houston, TX; 2) Department of Molecular Genetics, University of Texas M. D. Anderson Cancer Center, Houston Texas.

The accumulated studies have clearly indicated cigarette smoking as a major risk factor for various cancers in the general population. The unique mutation spectrum of the tumor suppressor gene p53 in smoking-related tumors further strengthened the relationship. It is unknown, however, how cigarette smoking affects the cancer risk in individuals with an inherited p53 mutation. In a familial cohort systematically ascertained through childhood sarcoma patients largely characterized by p53 mutation status, we evaluated the impact of cigarette smoking in smoking-associated-cancer (SAC, including cancers in lung, larynx, oral cavity, and esophagus) risk. The study population included relatives of 540 childhood sarcoma patients, including 44 germline p53 mutation carriers in 10 kindreds, and 4983 relatives in 530 kindreds without evidence of a germline p53 mutation. Association between cigarette smoking and cancer was evaluated using the Cox's proportional hazard models. Smoking was not associated all types of cancer risk in the carriers but was significantly associated with cancer risk in the non-carriers. After adjusted the effects of birth year, sex, and race, we observed statistically significant likelihood change for SAC after adding the effect of cigarette smoking in both models for carriers and non-carriers. Our results revealed a hazard ratio of 4.74 in the non-carriers and a hazard ratio of 10.76 in the carriers for cigarette smoking and SAC risk. Interaction between smoking and carrying germline p53 mutation in cancer risk was not statistically significant. The findings suggest that inheritance of a p53 mutation dramatically increases the risk of SAC, and that the risk is further increased by cigarette smoking.

Program Nr: 702 from the 1999 ASHG Annual Meeting

Molecular analysis of chromosome 6p rearrangement in Retinoblastoma. *I.M. IMBERT[1,2], O. JAFER[2], L.J. COIGNET[2], F. PELLESTOR[1]*. 1) Institute of Human Genetics, CNRS UPR 1142, Montpellier, France; 2) Institute of Cancer Research,Royal Marsden Hospital, Sutton, UK.

Recurrent cytogenetic abnormalities are the hallmark of all malignant tumors. Classification of malignancies depends on the location of the chromosomic disruption/deletion, which relates to prognosis of the disease and therapeutic choices. Molecular genetics and cytogenetics techniques are used to identify oncogenes localized near the chromosomic breakpoints, and oncogenes activation seem to be dependent on translocation mechanism. Recurrent atypical cytogenetic abnormalities of chromosome 6p have been reported in a few cases of translocations implicated in Retinoblastoma. The translocation t(4;6)(p15;p21.2) was studied in the Y79 cell line established from the primary tumor (right eye) of a 2-year-old caucasian girl in 1971. To determine the site of the breakpoint on 6p, yeast artificial chromosome (YAC) clones from p21 to p22 bands were used. The breakpoint has been localised by FISH on 6p21.3 and the TNF-alpha gene has been shown to be involved in this rearrangement. TNF-alpha is a cytokine, a specialized hormone-like protein that can influence cellular development and function. To measure the expression of TNF-alpha gene in retinoblastoma cells, flow cytometric analysis and cytospins were performed using an anti-TNF-alpha antibody. This study has shown an enhancement of the expression of TNF-alpha gene in Y79 cells. Further cloning, sequencing and characterization of the gene(s) involved in this rearrangement from patient samples with this recurrent breakpoint will allow us to study the possible consequences of disruption/deletion of this gene in the development or progression of the disease.

Program Nr: 703 from the 1999 ASHG Annual Meeting

HER2/neu and cMYC alterations in breast lesions from women with and without a family history of breast cancer. *R.B. Jenkins, C.A. Reynolds, C.A. Soderberg, D.C. Melder, F.J. Couch, L.C. Hartmann.* Mayo Clinic, Rochester, MN.

The biology of breast cancer initiation and progression is poorly understood. Germline mutations in BRCA1, BRCA2, and other susceptibility loci are involved in the initiation of hereditary breast cancer. However, the somatic events that lead to progression of hereditary cancers are not known. In addition, it is not known whether somatic progression pathways differ in hereditary versus sporadic disease. In order to evaluate these questions, we have developed a registry of >500 women who underwent both therapeutic mastectomy to remove a cancer as well as a contralateral prophylactic mastectomy. At present, we have studied 22 hereditary cases and 29 matched sporadic cases from this cohort, with and without a strong family history of breast and/or ovarian cancer, respectively. For each case, paraffin blocks were available for both mastectomy specimens. Among these blocks, 46 in situ carcinomas and 51 invasive carcinomas were identified. These lesions as well as 32 regions of apparently benign epithelium (for control purposes) were subjected to fluorescent in situ hybridization (FISH) analysis using the HER2/neu/CEN17 and cMYC/CEN8 dual-probe mixtures. The incidences of oncogene amplification in hereditary and sporadic cases, respectively, were 28% (6 of 21) and 4% (1 of 27) for HER2/neu (p=0.04) and 19% (4 of 21) and 4% (1 of 27) for cMYC (p=0.09). The incidences of chromosomal gain in hereditary and sporadic cases, respectively, were 48% (10 of 21) and 11% (3 of 27) for +CEN17 (p=0.009) and 52% (11 of 21) and 26% (7 of 27) for +CEN8 (p=0.06). The incidences of any anomaly in hereditary and sporadic cases, respectively, were 67% (14 of 21) and 27% (7 of 26) (p=0.008). Our data show that chromosomal alterations, as measured by CEN8 and CEN17 gain and HER2/neu and cMYC gene amplification, are more frequent within breast cancers of women with a strong family history of cancer, consistent with an increased underlying chromosomal instability. Ongoing studies are directed toward the elucidation of separate pathways of carcinogenesis in hereditary versus sporadic disease.

Program Nr: 704 from the 1999 ASHG Annual Meeting

Genomic alterations in six bladder cancer cell lines studied by DNA arrays, comparative genomic hybridization, and flourescence in situ hybridization. *J.P. Johnson, H. Maruyama, S. DeVries, E. Gum, K. Golden, F.M. Waldman.*
Cancer Center, UC San Francisco, San Francisco, CA.

Comparative genomic hybridization has been able to identify many common sites of altered copy number in human cancers. In this study we used chromosome CGH to define chromosomal gains and losses in six commonly studied bladder cancer cell lines (J82, TCCSUP, HT1197, HT1376, 5637, and T24). In addition, FISH and array-based CGH were compared with chromosome-based CGH for utility in characterizing chromosome 20 gains at high resolution. The mean number of abnormalities seen by chromosome based CGH was 13.5 (range 4-25). All cell lines showed a gain involving chromosome twenty. Since gains in chromosome twenty have been associated with immortalization of urothelial cell lines, and with progression of primary tumors, the substructure of the chromosome 20 gain was further studied by fluorescence in situ hybridization (FISH) with a set of chromosome 20 probes, and by array-based CGH. These approaches yielded higher resolution than chromosomal CGH, showing the substructure of the 20q amplicon. Array CGH showed that 20q11 and 20q13.2 were consistently gained in all 20q amplified cell lines. Also, combining FISH and CGH approaches allowed for determination of absolute copy number by scaling of array-based ratios. Analysis of a series of oncogenes and tumor suppressor genes in these cell lines showed that array-based CGH was consistently able to detect deletions as well as DNA copy number gains. 20q gains were detected by chromosomal CGH in five of the six cell lines tested, while high level amplification of 20p was seen in the sixth, HT1197. Regions of chromosomes 6 and 11 were gained in five of the cell lines. 11p was consistently gained in all five, and amplification involving 6p22 was observed in four of the cell lines. Also, regions of chromosomes 4 and 8p were lost in five cell lines. Region 8p21-pter was the smallest common region of 8p loss, present alone in two of the cell lines. These data show that array based CGH analysis of chromosomal gains and losses are validated by alternative approaches, and are useful in defining alterations at high resolution.

Program Nr: 705 from the 1999 ASHG Annual Meeting

Characterization of a novel 17q25 GTPase gene suggests evidence for its role as a breast tumor suppressor gene.
L.M. Kalikin, H.L. Sims, C.K. Neeley, E.M. Petty. Departments of Internal Medicine and Human Genetics, The University of Michigan, Ann Arbor, MI.

We have previously defined a 300 kb minimal region of allelic imbalance on 17q25 by loss of heterozygosity studies in breast and ovarian tumors (Kalikin, LM et al., 1996, 1997). We hypothesize that this interval harbors a novel tumor suppressor gene. Toward identification of this gene, transcripts were isolate by solution hybrid capture from BACs and P1s spanning the candidate region. A novel EST with strong homology to a GTPase family of genes involved in cytokinesis was isolated. This gene showed variable expression of 3.5 and 4.0 kb transcripts in most tissues tested. Preliminary results from breast tumor cell line Northern and Southern blots revealed potentially altered bands in some samples. Recently, this same gene was reported as part of a fusion protein in an acute myeloid leukemia patient with a t(11;17)(q23;q25) rearrangement (Osaka, M et al., 1999). As these observations suggest that the normal cellular role of this gene may be altered by both gain of function and loss of function mutations, further structural and expression characterization is important to understanding its potential role in tumorigenesis and leukemogenesis. Toward this end, we have more precisely defined the genomic structure of this gene including exon/intron boundaries and transcript variabilities at the 5' end. Mutational analysis is ongoing in breast tumor samples exhibiting distinct 17q25 minimal regions of allelic imbalance or altered bands on Northern or Southern blots.

Program Nr: 706 from the 1999 ASHG Annual Meeting

Familial medullary thyroid carcinoma and prominent corneal nerves associated with a codon 804 germline mutation of the *RET* gene. *L. Kasprzak[1], S. Nolet[2], L. Gaboury[2], W. Gregory[1], C. Pavía[4], C. Villabona[5], F. Rivera-Fillat[3], J. Oriola[3], W.D. Foulkes[1]*. 1) Department of Medicine, McGill University, Montreal, PQ, Canada; 2) Département de Pathologie, Laboratoire d'Oncologie et de Pathologie Moléculaire, Université de Montréal, PQ, Canada; 3) Servei d'Hormonologia, (IDIBAPS), Hospital Clínic, Barcelona, Spain; 4) Secció de Endocrinologia, Hospital Universitari de Sant Joan de Deu, Barcelona, Spain; 5) Servei d'Endocrinologia, CSU Bellvitge, Hospital Principes de España, Barcelona, Spain.

Germline mutations in the *RET* protooncogene are associated with Multiple Endocrine Neoplasia (MEN) type 2A, 2B and familial medullary thyroid carcinoma (FMTC). MEN2A is characterised primarily by medullary thyroid carcinoma (MTC) and pheochromocytoma. MEN2B has additional stigmata including a marfanoid habitus, mucosal neuromas and corneal nerve thickening. In FMTC, the only lesion present is MTC. Although characteristic of MEN2B, prominent corneal nerves have been noted in individuals with MEN2A.

We report a unique, four generation kindred in which three individuals had MTC. The proband and his mother had visible corneal nerves without other features of MEN2. The family was initially thought to represent a phenotype consistent with MEN2B. However, subsequent assessment at two centers (Canada and Spain) confirmed prominent corneal nerves in three family members and no other symptoms of MEN2B. Molecular genetic studies were performed on the two affected and six unaffected family members. Germline mutation in exon 14, codon 804 of the *RET* was identified in four individuals. Furthermore, all of the mutation carriers but none of the non-carriers were found to carry a previously unreported variant at codon 778 in exon 13.

The relatively rare mutation at codon 804 (exon 14) has previously only been seen in FMTC families. V778I variant cosegregates with the disease allele and perhaps could be contributing to the distinct phenotype present in this family.

Program Nr: 707 from the 1999 ASHG Annual Meeting

FISH studies of c-myc, cyclin-D1, p53 and chromosome 8, 11 and 17 centromeres in Barrett's, dysplasia and adenocarcinoma of the esophagus. *N. KATAOKA[1], S.R. Young[1], Z. Wang[1], J.W. Jakub[2]*. 1) 1Department of Obstetrics and Gynecology, University of South Carolina School of Medicine, Columbia, SC; 2) 2Department of Surgery, University of South Carolina School of Medicine, Columbia, SC.

Most esophageal adenocarcinomas are thought to arise from the metaplastic columnar epithelium (Barrett's esophagus) through dysplastic changes and a series of genetic alterations. It is perhaps generally accepted that early diagnosis of carcinoma is needed for optimal treatment and good prognosis. Recent studies have described tp53 overexpression and Her2/neu amplification as potential markers of esophageal carcinoma and its precursor. The oncogene c-myc is known to have an important role in early embryogenesis, cell-growth control, cell differentiation and the tissue-repair process. Cyclin-D1 is known to have a very important role in regulating the cell cycle. One of the most common tumor suppressor genes in human cancer is p53. The purpose of this study was to evaluate possible molecular cytogenetic changes in c-myc, cyclin D1 and p53 in esophageal disease. Eleven specimens of paraffin-embedded, formalin-fixed esophageal disease (three Barrett's esophagus, five mild dysplasia, one severe dysplasia, two adenocarcinoma) were obtained and studied for quantification of the oncogene c-myc relative to the centromere of chromosome 8, cyclin D1 relative to the centromere of chromosome 11 and p53 relative to the centromere of chromosome 17 using a combination of dual color FISH. All eleven samples showed normal findings of c-myc/#8 and p53/#17. However, one of the two adenocarcinoma specimens exhibited amplification of cyclin D1. In this limited study, it appears that p53 and c-myc are not associated with esophageal carcinoma progression, but cyclin D1 amplification may be involved in this progression.

Program Nr: 708 from the 1999 ASHG Annual Meeting

The inheritance of missense mutations in Ataxia-Telangiectasia (A-T) families. *N. Khanlou, R.A. Gatti.* Department of Pathology, UCLA School of Medicine, Los Angeles, CA.

Increased cancer susceptibility is one of the major characteristics of A-T, an autosomal recessive disorder. A-T heterozygotes are estimated to constitute 5% of all cancer patients before the age of 46 in the USA. Several studies have shown somatic loss of heterozygosity in the ATM region and there is conflicting evidence as to whether ATM can function as a tumor suppressor. Recent studies suggest a role for ATM missense mutations in cancer susceptibility, especially with regard to breast cancer. In one study, the standard incidence ratio of breast cancer in relatives of Scandinavian A-T patients was estimated at 7.7 for mothers, 1.6 for grandmothers and 1.7 for great-grandmothers. We were impressed by the unexpected high ratio in great-grandmothers and, considering the major role of ATM in meiosis and gametogenesis, we hypothesized that perhaps ATM missense mutations might be more frequently inherited from one parent or the other. The segregation of eight missense mutations was investigated by single strand conformation polymorphism. None of these mutations involved a splice site. None of the families had a history of breast cancer. Five mutations were inherited from the father; three were inherited from the mother. These results suggest that ATM missense mutations are randomly inherited from father or mother, with no sex bias.

Program Nr: 709 from the 1999 ASHG Annual Meeting

The expression of the PAX2 in human prostate cancer. *B. Khoubehi[1,2], C.W. Ogden[2], J.M. Adshead[1,2], A.M. Kessling[1]*. 1) Medical and Community genetics, Imperial College, London, Harrow, England; 2) Department of Urology, Northwick Park Hospital, Watford Road, London, HA1 3UJ.

Prostate cancer is the most common solid tumour in American men and is the second most common cause of cancer death. Despite high incidence and mortality rate, the molecular mechanisms underlying the oncogenesis and progression of the prostate cancer are still unclear.

PAX genes encode nine nuclear transcription factors, which are essential for embryogenesis and are proto-oncogenes in mice. The class III PAX genes (PAX2,5&8) are the most likely candidates for a role in oncogenesis due to the salient feature of their expression in highly mitotic, undifferentiated cells during development and their inappropriate expression in a number of human tumours. PAX2 is expressed at high levels in the developing undifferentiated cells of the urogenital system and is downregulated upon terminal differentiation with no expression in normal adult cells. We studied PAX2 expression in prostate cancer using reverse transcriptase PCR and found no expression in histopathologically confirmed benign prostatic hypertrophy specimens (0/10), whereas PAX2 was expressed in 3/3 established cancer cell lines and 10/27 (37%) primary prostate cancers. Expression of PAX2 in the cell lines was confirmed using immunofluorescence.

The Fishers exact test for comparison of PAX2 expression in prostatic specimens gave p= 0.024. These data suggest PAX2 expression in prostate cancer cells may contribute to pathogenesis by supporting cellular proliferation in the de-differentiated state.

Program Nr: 710 from the 1999 ASHG Annual Meeting

Gene Expression Profiles of Esophageal Cancer Patients Using cDNA Microarray Technology. *C. Kihara[1,2], T. Tanaka[1], Y. Furukawa[1], K. Ono[1], O. Kitahara[1], N. Shiraishi[1], R. Yanagawa[1], H. Ogasawara[1], T. Seki[1], H. Yamana[3], T. Tsunoda[4], K. Hirata[2], T. Takagi[4], Y. Nakamura[1].* 1) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science University of Tokyo Japan; 2) 1st Dept.of Surg., Sappro Med. Univ., Japan; 3) Dept.of Surg., Kurume Univ.,Japan; 4) Laboratory of Genome Database, Human Genome Center, Institute of Medical Science University of Tokyo Japan.

cDNA microarray technology enables us to analyze expression of thousands genes at one time and will revolutionize the method to characterize individual properties of cancer cells. It is obvious that biological properties of cancer cell (potential of invasion and metastasis, sensitivity to chemo-radiotherapy) must reflect expression levels of genes in individual cancer cells. By means of systematic analysis of gene expression profiles, we attempted to examine in detail properties of each cancer and to establish novel diagnostic and therapeutic methods for cancer patients. We prepared microarray containing 4476 genes including ESTs and analyzed the gene expression profile of 60 esophageal cancers. We labeled RNA extracted from cancer tissues of patients with Cye 3 and the other from normal esophageal tissues with Cye 5, and compared gene expressions in cancer and its corresponding normal tissues. By a combination of T7 based RNA amplification method and the microarray system, we examined the relation between gene expression profile and clinicopathological features of each patients (TNM stage, resistance to adjuvant-therapy, prognosis) to find predictive marker genes for malignancy or sensitivity to adjuvant-therapy. Gene expression profile showed various pattern in each patient, but focused on several genes and conbine their expression pattern, we found the correlation between their pattern and some clinical features. We suggest that these results can contribute to the more precise diagnosis of cancer and the selection of optimal therapy to an individual patient.

Program Nr: 711 from the 1999 ASHG Annual Meeting

Biological characteristics of the breast in women with a genetic predisposition to breast cancer. *J.A. Kirk[1], K. Applebee[1,2], J. Leary[1], C. Clarke[2].* 1) Familial Cancer Service, Westmead Hospital, NSW, Australia; 2) Westmead Institute For Cancer Research, University of Sydney, Westmead Hospital, Westmead, NSW, Australia.

Other than the presence of a germline mutation in BRCA1/2/X, there is little known about the subsequent morphological, genetic and hormonal changes that may account for tumour development in the normal breast of a woman genetically predisposed to breast cancer. We have hypothesized that a mutation in a breast cancer susceptibility gene results in an alteration of the biology of the breast tissue of such women. We examined the breast tissue removed at prophylactic mastectomy from women who had previous unilateral breast cancer, and were known or suspected to carry a germline mutation in BRCA1 /2 (test cases, n=12) and compared the findings to those in normal breast (control cohort, n=28) removed for other reasons. We examined the expression of markers of hormone responsiveness (oestrogen receptor [ER], progesterone receptor [PR] and pS2), proliferation (Ki-67, Cyclin D1), tumour suppressor genes (p53, BRCA1) and molecules often overexpressed in breast cancers (erbB-2), using immunohistochemistry and image analysis. Cyclin D1 and erbB-2 were not detected in test cases or controls. BRCA1, Ki-67 and p53 were low in all samples. ER and pS2 were detected at the same levels in test cases and controls. By contrast, PR expression was significantly lower in the breast tissue of women with a genetic predisposition ($p<0.001$; t-test, assuming unequal variance). BRCA-associated breast tumours are generally less likely than sporadic tumours to express the hormone receptors, ER and PR. We have shown that the expression of PR is reduced in breast tissue of women with a genetic predisposition to breast cancer. PR is a marker of a functional oestrogen pathway in breast cancers, as oestrogen is one of the factors that regulate PR expression in breast tissue. One of the important roles of progesterone and PR may be to inhibit the proliferative action of oestrogen in normal tissue. Loss of PR may provide the opportunity for unopposed oestrogen action, increasing the risk of invasive breast cancer.

Program Nr: 712 from the 1999 ASHG Annual Meeting

***FGF4* and *INT2* oncogenes are amplified and expressed in Kaposi's sarcoma.** *S. Kiuru-Kuhlefelt[1], M. Sarlomo-Rikala[2], M.L. Larramendy[1], M. Söderlund[3], K. Hedman[3], M. Miettinen[4], S. Knuutila[1]*. 1) Department of Medical Genetics, University of Helsinki, Finland; 2) Department of Pathology, University of Helsinki, Finland; 3) Department of Virology, University of Helsinki, Finland; 4) Armed Forces Institute of Pathology, Department of Soft Tissue Pathology, Washington, DC.

Kaposi's sarcoma (KS) is a vascular tumor, the pathogenesis of which has been suggested to include human herpesvirus 8 (HHV-8), as well as various cytokines and growth factors. Very little is known about cytogenetic and molecular genetic changes in KS. We studied DNA copy number changes in KS and found a recurrent gain at 11q13. We then analyzed the amplification and expression status of two known oncogenes, *FGF4* and *INT2* residing at 11q13. Comparative genomic hybridization, interphase fluorescence in situ hybridization with *FGF4* and *INT2* containing YAC probes, and immunoperoxidase immunostaining with anti-FGF4 and -INT2 antibodies were used on twelve KS samples. All samples tested were shown by PCR to be HHV-8 positive. A recurrent gain at 11q13 was shown by CGH in four out of ten cases studied. Out of six cases studied by interphase fluorescence in situ hybridization, four showed a 3- to 4-fold amplification with the *FGF4* and *INT2* containing probes. Expression of *FGF4* and *INT2* was found in nine and three cases, respectively, out of nine studied. Amplification and expression of these genes is particularly interesting in the context of oncovirus involvement, since *INT2* is a homolog of mouse int2, which causes mammary carcinoma in mice when activated by integration of retrovirus MMTV, mouse mammary tumor virus. This rises the question whether HHV-8 represents an integrating oncovirus that causes amplification and activation of genomic oncogenes in man.

Program Nr: 713 from the 1999 ASHG Annual Meeting

Genotype-Phenotype Analysis of Gemistocytic Astrocytomas. *S. Kosel[1], B.W. Scheithauer[2], M.B. Graeber[3].* 1) Institute of Neuropathology, University of Munich, Munich, Germany; 2) Division of Surgical Pathology, Mayo Clinic, Rochester, MN, USA; 3) Department of Neuromorphology, Max-Planck-Institute of Neurobiology, Martinsried, Germany.

Among diffuse astrocytomas, the gemistocytic variant carries the least favorable prognosis. Such tumors are composed mainly of cells with large eosinophilic cell bodies and often eccentric, rather spherical nuclei. We selected 31 examples from among 201 gemistocytic astrocytomas operated at Mayo Clinic between 1985 and 1998. Typical cytologic appearance and relative abundance of gemistocytic cells were the selection criteria. Tumors representing WHO grades 2 (n=8), 3 (n=12) and 4 (n=11) were included in the study. Genomic sequencing of exons 5-8 was performed using an automated ABI377 DNA sequencer. In addition, morphometric analysis of individual tumor cells and tumor cell nuclei was undertaken using the Optimas image analysis program. In 21 cases analyzed for p53 sequence changes, 15 tumors, including 3 grade 2, 7 grade 3 and 5 grade 4 lesions were found to carry mutations. Specifically, 3 mutations were detected in exon 5, 2 in exon 6, 1 in exon 7, and 9 in exon 8 of the p53 gene with 5 patients carrying the C14486T/Arg273Cys variant; 5 mutations were novel. Thus, p53 mutations were present in 71% of the tumors. Patients whose tumors carried a p53 mutation were significantly younger (p=0.002). Furthermore, mutations were present in 7 of 8 anaplastic tumors. Regarding histologic phenotype, the sizes of tumor cell nuclei and of entire tumor cells were positively correlated (p=0.003). There was also a tendency for smaller tumor cell nuclei to be more atypical or less circular (high value of the Optimas circularity function)(p=0.01). Furthermore, there was a weak positive correlation between loss of circularity of tumor cell nuclei and diminished cell size (p=0.045). In summary, our data confirm that the frequency of p53 mutations is significantly higher in gemistocytic astrocytomas as compared to other astrocytoma subtypes. At present it is unclear whether their high frequency of p53 mutations contributes to the more malignant behavior of gemistocytic tumors.

Program Nr: 714 from the 1999 ASHG Annual Meeting

Association between the GSTM1, GSTP1 and GSTT1 gene polymorphisms and young onset prostate cancer in the UK. *Z. Kote-Jarai[1], S. Edwards[1], D. Easton[3], R. Jackson[1], A. Ardern-Jones[2], A. Murkin[2], D. Dearnaley[1,2], CRC/BPG UK Familial Prostate Cancer Collaborators[1], R. Eeles[1,2]*. 1) Cancer Genetics, Institute of Cancer Research, Sutton, UK; 2) Royal Marsden NHS Trust, Sutton, UK; 3) CRC Genetic Epidemiology Unit, Cambridge, UK.

There is an increasing amount of evidence suggesting that polymorphisms in the glutathion S-transferases (GST) are associated with cancer susceptibility and that some of these polymorphisms may have a modifier effect on tumour suppressor genes. The GST supergene family includes several loci with well characterised polymorphisms. Approximately 50% of Caucasian populations are homozygous for deletions in GSTM1 and about 20% are homozygous for deletions in GSTT1, resulting in conjugation deficiency of mutagenic electrophiles to glutathione. Both GSTM1 and GSTT1 null genotypes have been associated with an increased risk of various cancers. The GSTP1 gene has a polymorphism at nucleotide 313 resulting in an Ile to Val substitution which consequently lowers the enzymatic activity of the protein and this has also been suggested as a high risk genotype. We investigated the association between genetic polymorphisms in GST genes and young onset prostate cancer (age of onset £55 years) in a case-control study. GSTM1, GSTT1 and GSTP1 genotypes were determined for 275 young prostate cancer patients and for 280 control subjects by PCR and RFLP. The associations between specific genotypes and the development of prostate cancer were examined by use of logistic regression to calculate odds ratios (OR) and confidence intervals. We found no significant difference between the control group and the prostate cancer cases in the frequency of GSTM1 and GSTT1 genotypes (OR for GSTM1 null 0.86 95%CI 0.62-1.21, for GSTT1 null 0.86 95%CI 0.59-1.26). The GSTP1 genotype had however a significant effect on prostate cancer risk: the Ile/Ile homozygotes had the lowest risk, and there was a trend in risk with the number of Val alleles (Ile/Val OR:1.3 95%CI 0.91-1.87, Val/Val OR:1.75 95%CI 1.03-2.99; $p_{(trend)}$=0.026). These results suggest that the GSTP1 polymorphism is likely to be important in predisposition to young onset prostate cancer.

Program Nr: 715 from the 1999 ASHG Annual Meeting

Detection of BRCA1 and BRCA2 mutations in Saxonian families with a multi-tumor sectrum. *H. Kraus, K. Engelmann, B. Thamm, UG. Froster.* Institute of Human Genetics, University of Leipzig,Germany.

Abstract **Objective:**Alterations in the cancer susceptibility genes BRCA1 and BRCA2 seem to be responsible for most cases of inherited breast and ovarian cancer. Presently, an involvement of these genes in tumorgenesis of other kinds of cancer is unclear. In order to find clues of the putative influence of BRCA1 and BRCA2, breast cancer patients with a family history of breast and/or ovarian cancer, as well as breast cancer patients with a multi- tumor spectrum in the family, were screened for inherited predisposition in the both genes. **Methods:**Nine patients from nine unrelated Saxonian families were investigated to detect germline mutations in the BRCA1 and BRCA2 genes. The cancer spectrum of the members of these families involves leukemia, breast-, bladder-, stomach-, renal-, cervix-, laryngeal-, uterine-, and colon carcinoma. The entire coding regions including exon/intron junctions of BRCA1 and BRCA2 were amplified by PCR. The transcribed exons of BRCA1 were amplified with 28 PCR`s, for BRCA2 41 PCRs were necessary. Both, forward and reverse strands of each PCR product were analysed by direct sequencing using fluorescent dye terminators on an ABI 377 Sequencer. **Results:**Missense and nonsense mutations in both cancer susceptibility genes were detected in four out of nine patients (two BRCA1- associated, and two BRCA2-associated alterations). Three out of four mutation carriers showed a multi-tumor background in the family history. Unclassified variants are not included, but have been found in all patients. **Conclusion:**Alterations in the tumor suppressor genes BRCA1 and BRCA2 seem to play a role also in other cancers than breast and ovarian cancer. The involvement of these genes in tumorgenesis should be clarifed by investigations of tissues of different tumors.

Program Nr: 716 from the 1999 ASHG Annual Meeting

Candidates for the AML tumor suppressor gene mapped to a minimal deletion interval at 5q31. *J. Kravarusic[1], Z.H. Arbieva[1], H. Xie[1], S.K. Horrigan[2], T.T. Le[1], C.A. Westbrook[1].* 1) Section of Hematology/Oncology,Department of Medicine, Univ.Illinois at Chicago, Chicago, IL; 2) Department of Pediatrics, Lombardi Cancer Center, Georgetown University Medical Center, Washington, DC.

Interstitial deletions of chromosome 5 are frequent in malignant myeloid disorders such as acute myeloid leukemia, and are associated with a poor prognosis. The consistent occurrence of deletions at 5q31 suggests that it is the site of a tumor suppressor gene (TSG). We have attempted to further narrow this interval and identify genes within it as candidates for the TSG. To specify a narrower interval, we selected polymorphic markers from a high resolution physical, genetic, and radiation hybrid (RH) breakpoint map of 5q31, and used them to allelotype a case of AML with a sub-cytogenetic del(5q), comparing DNA from leukemic cells to buccal mucosa from the same patient. Loss of heterozygosity was observed for markers D5S476 and D5S1372, with retention of flanking markers D5S500 to D5S594, thus specifying a deletion interval of about 700 kb in size. The resolution of the RH breakpoint map of the interval was improved by additional typing of selected hybrids, and was then used to identify genes and ESTs from the Radiation Hybrid Database (Rhdb). As a result of the study, we have localized to the target interval four unknown ESTs and three known genes, including HSPA9 (a cellular immortalization protein or mortalin), CTNNA1 (alpha catenin), and EGR1. Additional ESTs in flanking RH bins are also under consideration. Appropriate expression of the candidate sequences in CD34+ cells and leukemic cell lines has been confirmed, and assembly of full-length cDNA and mutational evaluation in AML is underway.

Program Nr: 717 from the 1999 ASHG Annual Meeting

PTEN transcription in mouse development. *H. Kremer[1], M. Nelen[2], J. Schepens[3], W. Hendriks[3], G. Padberg[2]*. 1) Human Genetics, Univ Hospital, Nijmegen, Netherlands; 2) Neurology, Univ Hospital, Nijmegen, Netherlands; 3) Cell Biol and Histol, Univ Nijmegen, Nijmegen, Netherlands.

The PTEN gene is one of the most commonly mutated tumor suppressor genes in human cancer.The PTEN protein is a phosphatase and influences the activity of PI-3-kinase signaling pathways by regulating the levels of PIP3. Germline mutations in the gene can cause Cowden disease (CD). Characteristic for CD are hamartomatous features of several tissues and an increased risk to develop multiple neoplasias. The presence of developmental defects in CD, mainly macrocephaly, suggests a role of PTEN in development which is underlined by the death of PTEN-knockout mice before E10.

To provide more insight into the function of PTEN in development we have performed RNA in situ hybridization using the PTEN coding region as a probe on cryosections of mouse embryos and on brain sections of stages in postnatal development. The PTEN gene is ubiquitously transcribed. In stage E12.5 the highest transcript level is seen in the dorsal root ganglia and high levels are seen in the developing liver, thymus and in the primordia of the follicles of the vibrissae. Also several epithelia e.g. of the tongue and the stomach show an elevated level of transtripts. Transcription of PTEN in brain is homogeneous with the highest levels in the forebrain. At the stages E14.5 and E16.5 the above mentioned high transcript levels are even more prominent. Remarkably, several of the mentioned tissues are symptomatic in CD. During postnatal brain development both in the cerebral cortex and the cerebellum a general PTEN transcription changes into a more differentiated pattern and into a general expression again at postnatal day 20. The highest expression of PTEN in brain is seen in the hippocampus from postnatal day 4 up to adulthood.

Our results do not give evidence for a specific function of PTEN in development either in growth, differentiation or developmental apoptosis but suggest a versatile role of PTEN throughout development.

Program Nr: 718 from the 1999 ASHG Annual Meeting

Molecular But Not Cytogenetic Evidence Of t(11;22)(q24;q12) Translocation In A Patient With Ewing's Sarcoma(EWS)/Primitive Neuroectodermal Tumor(PNET): Immunohistochemical, Histological, Cytogenetic, And Molecular Studies And A Review Of The Literature. *M. Krishna[1], G.K. Turi[1], M. Ladanyi[2], J.J. Ding[1], D.M. Iancu[1], G. Nuggehalli[1], D.P. Bartok[1], V.C. Angadi[1], C.B. Cunha[1]*. 1) Department Of Pathology, Cytogenetics Laboratory, Winthrop-University Hospital, Mineola, NY; 2) Department Of Pathology, MEM Sloan-Kettering Cancer Center, New York, NY.

The t(11;22)(q24;q12) translocation is a characteristic chromosomal marker of Ewing's sarcoma(EWS) and is important in the differential diagnosis of EWS with respect to other mixed round cell tumors, such as rhabdomyosarcomas or lymphomas. Accurate diagnosis is therefore essential for prognosis and clinical management of the EWS disease. Here we describe a clinical case in which the cytogenetic analysis of extraskeletal tumor of a 40-year-old male, diagnosed as EWS on the basis of immunohistochemical and histologic profile, revealed a 45,X,-Y,t(2;4)(q37.1;q13.2), t(14;21) (q22;q21.2)[28]/46,idem,+8[2] karyotype with no evidence of the t(11;22) translocation. In view of this unexpected cytogenetically negative result, molecular studies, using reverse transcriptase-polymerase chain reaction (RT-PCR) test, were performed, and the results yielded EWS/FLi1 fusion transcripts, demonstrating the presence of t(11;22) rearrangement at the molecular level in the tumor. From the clinical point, this case demonstrates the importance of using more than one diagnostic modality to reach an accurate diagnosis. If the diagnosis was based on cytogenetic results alone, the case would have been false-negative, and would have resulted in improper clinical management of the disease. The results of this study will be reviewed along with other similar cases reported in the literature.

Program Nr: 719 from the 1999 ASHG Annual Meeting

Infrequent *MSH2* and *MLH1* gene carriers among newly diagnosed colon cancer patients of Eastern Ontario.

A.E. Lagarde[1,2], E. Baumann[1], D. Dewar[1], M. Guindi[3], S. Viertelhausen[2], H.S. Stern[1,2]. 1) Loeb Health research Institute; 2) Department of Surgery; 3) Laboratory of Medicine and Pathology, Ottawa Hospital and University of Ottawa,Ontario K1Y 4E9, Canada.

Mutations in *MSH2* and *MLH1* account for 50% of the families meeting the Amsterdam criteria for HNPCC, and for ~10% of the families that do not. Individuals considered at risk of being predisposed in the non-familial group include ~30% of patients younger than 30-35 yr of age, and 10% of patients having tumors expressing overt microsatellite instability (MSI). However, most common cancers and an appreciable proportion of HNPCC cases are diagnosed beyond the age of 40; the predictive values of the MIS markers are modest. This sudy was undertaken to provide an appreciation of the incidence of *MSH2* and *MLH1* mutations in a series of n= 72 newly diagnosed but otherwise unselected colon cancer patients.

Collateral MIS/familial/clinical and pathological information was available. The mutational analysis of tumor/mucosal DNAs investigated the entire coding regions, 70% by SSCP and 30% by direct sequencing. A total of four germline mutations were characterized, giving an uncorrected frequency of 5.6% (*95%CI*= 1.6-13%). The causality of two missense (Ser269Thr, Val326Ala) and one intronic (exon 11, -11 T/A) *MLH1* mutation could not be established, leading to a more conservative estimate of 1.4% (*95% CI*= .04-7%). The single pathogenic mutation found out of 72 tested cases was the recurrent G(exon5, +3nt)A donor splice *MSH2* mutation, present in an MIS-positive and HNPCC patient. Several polymorphisms but no mutations were identified in other age, familial colorectal, familial extracolonic, sporadic or MSI stratified subgroups. These findings corroborate the Finnish study by Aaltonen et al. and suggest that the *de novo* rate of *MSH2* and *MLH1* mutation contributes minimally to the burden of colon cancer. Thus, predictive testing targeting the colon cancer population has limited advantage over the prior ascertainment of cancer-prone families through genetic clinics and registries, and the inclusion of other genetic loci (*MSH6, TGFBR2* in the molecular assessment.

Program Nr: 720 from the 1999 ASHG Annual Meeting

Founder mutations in BRCA1 in the North West of England. *F. Lalloo[1], E. Redmond[1], C-L. Wu[1], D. Bourne[2], F. Macdonald[2], E. Maher[2], DGR. Evans[1]*. 1) University Department of Medical Genetics and Regional Genetics Service, St Mary's Hospital, Manchester, UK; 2) Regional Genetics Service, Birmingham Womans Hospital, Birmingham, UK.

Mutations within BRCA1 are spread throughout the coding exons of the gene. Within certain populations, founder mutations occur with increasing frequency. For example, two mutations, 185delAG, and 5382insC account for the majority of the mutations in BRCA1 amongst the Ashkenazim. Within the UK a strong founder effect has not been reported. The population covered by the Clinical Genetic departments of Manchester and Birmingham covers the North West of England and consists of 9.7 million. To date, 389 samples from affected women have been screened for mutations in all or part of BRCA1. A total of 80 mutations have been detected of which 11 have been detected more than once. The Jewish mutations account for two of these and have only been found in families with a Jewish background. The remaining 9 mutations account for 27 of the other 66 mutations detected. In particular, the 4182delAATC mutation has been detected in 5 samples. The pedigrees suggest that these families are unrelated. I will present data on the haplotype analysis of these recurrent mutations. It may be possible to target BRCA1 screening in the North West initially to a small number of specific mutations.

.

Program Nr: 721 from the 1999 ASHG Annual Meeting

Analysis of PAX-FKHR fusion positive vs. fusion negative alveolar rhabdomyosarcomas reveals distinct chromosomal patterns and novel genomic changes. *V.S. Lestou[1,2], E.R. Lawlor[1,2], P.H.B. Sorensen[1,2].* 1) Dept Pathology Lab Med, Univ BC, Vancouver, BC, Canada; 2) BCs Childrens Hospital, Vancouver, BC, Canada.

In this study, 17 alveolar rhabdomyosarcoma (ARMS) cases were analyzed for PAX3- or PAX7-FKHR gene fusion status by RT-PCR. Eight PAX3-FKHR fusion positive and nine PAX3-FKHR fusion negative ARMS cases were identified. There were no PAX7-FKHR cases identified. To determine whether there are specific patterns of genomic alterations that can distinguish between PAX3-FKHR fusion positive vs. negative ARMS cases, comparative genomic hybridization (CGH) was performed on primary tumor tissue. Fusion positive ARMS demonstrated prominent chromosomal gains involving 1q (n=5), 2 (n=2), 2p23-p24 (n=3), 2q34-q35 (n=5), 12 or 12q12-14 (n=6), 13q13-qter (n=5), 14q12-q21 (n=3), and 17q22-qter (n=3), and prominent deletions of 1p34-p36 (n=4) and 13q21-qter (n=3). Gain of 13q13-qter (n=5) was always associated with gain of 2 or 2q34-q35. Fusion negative ARMS demonstrated prominent chromosomal gains of 2 (n=4), 8 (n=4), 11p (n=3), 17q22-qter (n=3), and 20 (n=4), and deletions involving 1p34-p36 (n=4), 9p (n=5), 11 (n=4) and 15q21-qter (n=4). Interestingly, two cases of fusion negative ARMS demonstrated genomic changes typical of fusion positive ARMS, i.e. gain of 2q35 associated with deletion of 13q21-qter and/or amplifications 2p23-24 and 17q22-qter. One of these cases showed a cryptic t(1;13)(p36;q14) PAX7-FKHR fusion which was detectable by FISH but not by RT-PCR. Moreover, the clinical features of this case are highly suggestive of a PAX7-FKHR gene fusion. The second case and the molecular characteristics of both cases are currently under evaluation. We suspect such cryptic PAX-FKHR fusions may represent a subset of fusion negative ARMS cases. In summary, a comparison of fusion positive vs. negative ARMS revealed common genomic gains involving parts or whole chromosomes 2 and 12 as well as deletions of 1p34-36. In contrast, amplification of chromosome 8 and losses or gains of 11 was found only in fusion negative ARMS, whereas gain of 2q34-q35, gain of 13q13-qter, and gain of 17q22-qter were restricted to fusion positive or cryptic fusion positive ARMS.

Program Nr: 722 from the 1999 ASHG Annual Meeting

Molecular Cytogenetic Analysis of Uterine Leiomyoma And Leiomyosarcoma by Comparative Genomic Hybridization. *B. Levy, T. Mukherjee, K. Hirschhorn.* Mt Sinai School of Medicine,New York, NY.

Uterine leiomyomata (ULM) are benign smooth muscle neoplasms associated with abnormal uterine bleeding, infertility and abdominal pain. They are also the leading indication for approximately 30% of all hysterectomies performed in the United States. ULM comprise the most common uterine tumors and occur in about 25-30% of women of reproductive age. Uterine leiomyosarcomata (LMS) are presumed to be the malignant counterpart to ULM with less than 1% of ULM cases progressing to ULMS. Transformation of ULM to ULMS is yet to be conclusively confirmed and it may well be that ULMS arise through independent events. Traditional cytogenetic studies have not demonstrated any characteristic chromosomal aberrations common to all ULM and ULMS. Comparative genomic hybridization (CGH) permits direct analysis of genomic DNA obtained from the specimen, thus obviating the need for cell culture. We used CGH to evaluate DNA sequence copy number changes in 12 ULM and 5 ULMS. CGH analysis of ULM demonstrated chromosomal imbalances in 8 of 12 (66.7%) specimens. Of the 8 ULM specimens that showed DNA copy number changes, all displayed an overrepresentaion of chromosomal material at 9q34, a novel finding. Seven of the 8 abnormal specimens showed gains on chromosome 19 with the minimal region of overlap mapped to 19p13.3 (in 5 cases) and 19q13.1-q13.2 (5 cases). Three of these 7 cases showed gains in both the long and short arm of chromosome 19. Other chromosomal anomalies observed in ULM specimens included gains and losses of chromosome 1p, losses on 7q and gains on 12q. All ULMS specimens demonstrated chromosomal aberrations. Chromosome 1 imbalances primarily included gains on the long arm and losses on the short arm. A loss of chromosome 14 long arm material was observed in three of five ULMS samples. Gains, particularly on the long arm, were concomitantly observed on chromosomes 8 and 12 in 3 of 5 cases. Although overlapping anomalies were observed in some cases of ULM and ULMS, no specific anomalies were evident for all ULM and ULMS. The absence of specific anomalies common to all ULM and ULMS therefore argues against them being benign/malignant counterparts.

Program Nr: 723 from the 1999 ASHG Annual Meeting

Differential ovarian cancer survival in Ashkenazi BRCA1/BRCA2 carriers. *E. Levy-Lahad[1], B. Kaufman[2], S. Eisenberg[1], O. Gottfeld[1], U. Beller[3], P. Renbaum[1], A. Lahad[4], R. Catane[2].* 1) Medical Genetics Unit; 2) Istitute of Oncology; 3) Division of Gynecologic Oncology, Shaare Zedek Medical Center; 4) Dept. of Family Medicine, Hebrew University Medical School, Jerusalem, Israel.

A high precentage of ovarian cancer (ovca) in Ashkenazi Jews (AJ) (~30%) is associated with founder BRCA1/2 mutations. To further characterize BRCA1/2-associated ovca we studied a group of 52 AJ women with epithelial ovca seen sequentially at our Gynecologic Oncology service. 32 of these women were consecutively diagnosed after 1/1994. All patients answered an epidemiological questionnaire and medical records were reviewed. Genomic DNA samples were tested for the AJ founder mutations (BRCA1- 185delAG and 5382insC, BRCA2-6174delT). Of the 52 women 28(54%) were non-carriers (NC), 15 (24%) were BRCA1 carriers and 9 (17%) were BRCA2 carriers. Of consecutively diagnosed women 8 (25%) were BRCA1 and 4 (12%) BRCA2 carriers. Mean age at diagnosis was significantly younger in BRCA1 carriers (50.5$\pm$9.1) compared to NC (58.7$\pm$11.2, p=0.02) and significantly older in BRCA2 carriers (65.3$\pm$7.9) compared to BRCA1 carriers (p=0.001). There were no significant differences in pathology or stage at diagnosis: 4 stage IV (3 NC, 1 carrier), 39 (21 NC and 18 carriers) stage III, and 9 stage I (4 NC, 5 carriers). Survival was analyzed by Cox regression controlled for age-at-diagnosis. BRCA2 carriers had significantly better survival than NC, (all cases: HR 0.14, p=0.012, consecutive only: HR 0.15, p=0.08). Median survival in consecutive cases was 35$\pm$13.4 mos in NC and 52$\pm$23 mos.in BRCA1 carriers. In BRCA2 carriers the median was not reached. Our results suggest that BRCA2-related ovca in AJ is more benign, with an older age-at-diagnosis and improved survival. Older age at diagnosis is consistent with lower penetrance of BRCA2 vs. BRCA1 in AJ. Improved survival was found even though older age at diagnosis is generally an adverse prognostic feature in ovca. Older age at diagnosis and improved survival could be a feature of BRCA2-related ovca, or represent an allelic effect of the 6174delT mutation. Differential ovca survival in BRCA1 and BRCA2 carriers may have confounded previous survival analyses in the AJ population.

Program Nr: 724 from the 1999 ASHG Annual Meeting

Genomic characterization of a region commonly deleted in sporadic breast cancer. *T.B. Lewis[1], C. Wu[2], G. Gloeckner[3], P. deJong[2], A. Rosenthal[3], J. Tischfield[4].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Roswell Park Cancer Institute, Buffalo, NY; 3) Department of Genome Analysis, Institute for Molecular Biotechnology, Jena Germany; 4) Department of Genetics, Rutgers University, Piscataway, NJ.

The occurrence of nonrandom allele loss in sporadic cancer implies the functional inactivation of a tumor suppressor gene at, or near, the tested loci. One of the most common aberrations in sporadic breast cancer involves the long arm of chromosome 16. Deletion mapping of chromosome 16q has suggested 2 distinct regions harboring tumor suppressor genes involved in breast cancer, 16q22.1 and 16q24.3. Loss of these regions has been reported to occur in 23-67% of the cases examined.

A deletion map of the chromosome 16q24.3 region was derived by typing 16 polymorphic markers through 57 sets of DNA from sporadic breast tumors. Loss of heterozygosity was observed for at least one chromosome 16q24.3 marker in 36.8% (21/59) of our patient samples. Analysis of the loss of heterozygosity results allowed identification of the critical region of deletion as between markers D16S3028 and D16S3048, a distance of less than one centimorgan based on genetic maps.

We have assembled and sequenced a PAC contig spanning the region identified by markers D16S3028 and D16S3048. Through exon trapping we isolated 17 clones, direct selection provided 9 clones, and database searches identified 11 Unigene collections. These ESTs merge into 13 separate transcript groupings. One of these transcripts is a gene with high homology to the ribosomal L39 gene; 96% similarity and 92% identity for the length of the L39 gene plus an additional 24 amino acids. We are currently expanding these transcripts to full-length cDNAs through RACE and library screening. These transcripts are considered positional candidates for the putative tumor suppressor gene involved in sporadic breast cancer.

Program Nr: 725 from the 1999 ASHG Annual Meeting

Fractionated but not single dose X-rays influence mechanisms of *in vivo* loss of heterozygosity. *L. Liang[1], M.S. Mendonca[2], C. Shao[1], L. Deng[1], P.J. Stambrook[3], J.A. Tischfield[1]*. 1) Dept Medical/Molecular Gen, Indiana Univ Sch Medicine, Indianapolis, IN; 2) Dept Radiat Oncol, Indiana Univ sch Medicine, Indianapolis, IN; 3) Dept cell Biol, Neurobiol, and Anatomy, Univ Cincinnati, Cincinnati, OH.

To investigate the effect of radiation on *in vivo* LOH, B6C3F1 mice, which were heterozygous at *Aprt* (adenine phosphoribosyltransferase), were whole-body irradiated with single doses of 1, 2, or 4 Gy, or 1 Gy/week X 4 weeks doses of 250 Kvp X-rays. APRT-deficient T cells, a consequence of *in vivo* LOH, were selected in medium containing 2,6-diaminopurine (DAP), an adenine analog that is toxic only to cells with APRT enzyme activity. No significant increase of the median frequency of DAP-resistant (DAP^r) T cell variants was observed in mice exposed to either single doses of 1, or 2 Gy, or fractionated doses of irradiation. Only the 4 Gy single dose of X-rays increased the median frequency of DAP^r variants (~2 fold). Allele-specific PCR of *Aprt* demonstrated that 60-70% of DAP^r variants lost the $Aprt^+$ allele in both unirradiated and irradiated mice. The DAP^r variants exhibiting loss of $Aprt^+$ were genotyped with chromosome 8 linked polymorphic microsatellite repeat markers. In the unirradiated mice and the mice exposed to single dose of X-rays, 95% of the variants exhibiting loss of $Aprt^+$ showed LOH at the most telomeric marker (73 cM) and 50% also showed LOH at the most centromeric marker (8 cM), suggesting that mitotic recombination or/and chromosome loss are the predominant mechanisms for generation of these T cell variants. However, in mice exposed to fractionated doses of irradiation, 70% of DAP^r variants exhibiting loss of $Aprt^+$ did not show LOH at any other markers, suggesting interstitial deletion or gene conversion as the predominant mechanisms leading to loss of $Aprt^+$. Our results suggest that the mechanisms causing *in vivo Aprt* LOH in the mouse may differ according to the way in which X-irradiation is delivered.

Program Nr: 726 from the 1999 ASHG Annual Meeting

Evidence of a Founder *BRCA1* Mutation in Scotland. *A. Liede[1], B. Cohen[2], D.M. Black[3], R.H. Davidson[3], A. Renwick[3], E. Hoodfar[1], O.I. Olopade[1], M. Micek[1], V. Anderson[2], R. DeMey[2], A. Fordyce[2], E. Warner[1], J.L. Dann[5], M.-C. King[5], B. Weber[4], S.A. Narod[1], C.M. Steel[2]*. 1) University of Toronto, Toronto, ON, Canada; 2) University of St. Andrews, Scotland, UK; 3) University of Glasgow, Scotland, UK; 4) University of Pennsylvania, Philadelphia, PA, USA; 5) University of Washington, Seattle, WA, USA.

BRCA1 mutations have been identified in breast and ovarian cancer families from diverse ethnic backgrounds. We studied 17 different families with the *BRCA1* 2800delAA mutation; seven were ascertained in Scotland (Dundee, Edinburgh, Glasgow, St. Andrews), five in Canada (Toronto, Victoria) and five in the United States (Chicago, Philadelphia, Seattle). Overall there was a clear preponderance of Scottish ancestry. Genotype analysis performed on key members from 17 families was consistent with a common haplotype, strongly suggesting a single ancestral origin. A possible link was established between two families by tracing their genealogies through the records of the Registrar General for Scotland. This is the first example of a *BRCA1* mutation likely to be derived from a common founder in Scotland. Further studies will be necessary to estimate more accurately the population frequency of the *BRCA1* 2800delAA mutation among unselected cases of breast and ovarian cancer in Scotland and the United Kingdom.

Program Nr: 727 from the 1999 ASHG Annual Meeting

Augment the Incomplete LOH Data Using Expectation-Maximization Algorithm. *X. Liu[1,2], Z. Luo[2], G. Wang[1], Y. Zhao[1,2], C. Wu[1], W. Zhang[1,2], W. Huang[1], Z. Chen[1]*. 1) Chinese National Human Genome Center at Shanghai, Shanghai 201203, China; 2) Institute of Genetics, Fudan University, Shanghai 200433, China.

Scanning LOH (loss of heterozygosity or called allelic imbalance) is a powerful method in cancer genetics of searching candidate tumor suppressor genes. One big weakness of LOH data is the existence of quite large proportion of non-informative data, that is, the homozygotes. Here we suggest a new method to estimate the probability of allelic imbalance for homozygote. The principle is to use the Expectation-Maximization algorithm to recover the homozygote's hidden state given the information of other loci, whose LOH states are associated with the locus studied. The performance of the method is evaluated by applying it to computer simulation data sets. The results showed our method was much more efficient than the simple estimation using the locus' LOH ratio information. With sufficient sample size, our method can typically gave out 90% accuracy for recovering the LOH states of homozygotes of a locus which had five or more associated loci. So it should be very useful for fine-scale LOH mapping, which has quite some associated loci because of the short distance between loci. We also apply our method to the previous published fine LOH mapping data of chromosome 4q in hepatocellular carcinoma. The augmented data showed some narrower candidate regions of tumor suppressor genes. Finally we suggest that a higher accuracy could be achieved if iteratively using association analysis, clustering analysis and our augmentation method.

Program Nr: 728 from the 1999 ASHG Annual Meeting

Cosegregation of familial multiple lipomatosis and hereditary retinoblastoma in a large pedigree. *D.R. Lohmann[1], M. Genuardi[2], M. Klutz[1], M. Freistuehler[1], G. Neri[2], T. Wienker[3], B. Horsthemke[1]*. 1) Dept Humangenetik, Universitatsklinikum Essen, Essen, Germany; 2) Instituto di Genetica Medica, Rome, Italy; 3) Institut fuer Medizinische Statistik, Bonn, Germany.

Predisposition to retinoblastoma (RB, OMIM 180200) is caused by mutations in the RB1-gene. Patients with hereditary RB also have an increased risk for second tumors, notab-ly osteogenic and soft tissue sarcomata. In addition, recent data indicate that the incidence of multiple lipoma (ML, OMIM 151900) is higher in these patients. The majority of predisposing mutations result in premature termination codons. Patients that have inherited such mutant alleles almost invariably develop bilateral RB. However, some rare mutations are associated with a "low penetrance" phenotype mar-ked by reduced expressivity (unilateral RB) and incomplete penetrance. Up to now there are no data indicating that distinct RB1 mutations are associated with an increased risk for specific second tumors. Here we report on a 4 generation pedigree with ML and RB. Genotyping of RB1 linked loci showed that all 7 patients with ML, 3 patients with ML and RB, and 2 patients with RB only share the identical haplotype, which is also present in 6 family members without ML or RB. Five of the 6 carriers without ML are under age of 35 years and, therefore, ML may occur later. We also noted a significant segregation distortion in favor of the ML/RB linked haplotype. Mutation analysis of the RB1 gene showed a novel single base substitution in exon 13 that is in phase with the ML/RB phenotype. RT-PCR analysis of RNA from lymphoblastoid cell lines shows that exon 13 is skipped in transcripts from mutant alleles. Although some patients with hereditary RB also develop ML, cosegregation of RB and ML has not been reported before. Within the spectrum of RB1 alleles with low penetrance, the mutation identified here is atypical as it results in loss of a significant part of pocket domain A. At present, we cannot decide if this mutation causes both RB (with low penetrance) and ML (with almost complete penetrance) or if another mutation at a distinct but linked locus causes ML in this family.

Program Nr: 729 from the 1999 ASHG Annual Meeting

An unusual pericentric inversion of chromosome 16 in acute monocytic leukemia [M5b] with primary cutaneous manifestation. *J. Lo Ngeo[1], P. Chandra[1,2], M.A. Bertoni[1], M.J. Macera[1,3], R.S. Verma[1,2,3]*. 1) Wyckoff Heights Medical Center, Brooklyn/New York Hospital-Weill Medical College of Cornell University, New York, NY; 2) SUNY Health Science Center at Brooklyn, NY; 3) Institute of Molecular Biology and Genetics at InterScience, Brooklyn, NY.

An eighty three year old Caucasian male was admitted for dyspnea. Eight months prior to this admission, he was hospitalized for syncope. At that time he had pruritic maculo-papular rash over his body and an enlarged left inguinal node. Hemogram done at this time revealed WBC 2.55 X 10^3/ul, Hb. 14.2g/dl, platelet count 86,000/ul and a normal WBC differential. No blasts were noted in the peripheral blood smear (PBS) on admission. Skin biopsy revealed leukemic blasts infiltrating the skin. He was treated symptomatically as the patient refused chemotherapy. The patient remained well for the next 8 months when he was re-hospitalized for pneumonia. The skin rash got worse. Hemogram revealed WBC 70.9 X 10^3ul Hb.13.2 g/dl and platelets 10.2 X 10^3/ul. The PBS showed 40% blasts. The BM was hypoplastic and islands of promonocytes and monoblasts formed 50% of the cellular elements of BM. The blast cells were positive for muramidase. A clinical diagnosis of acute monocytic leukemia (M5b) was established. Using GTG- and FISH techniques with a probe specific for the 16p arm which detects the 16p13q22 inversion specific for AMMoL(M4) revealed an abnormal karyotype 46,XY .ish inv(16)(p13.3q23) in 50% of his dividing BM cells, while the remaining metaphases were apparently normal. At that time, he was treated with cytarabine and doxorubicin. The skin infiltrates cleared completely and the blasts in the peripheral blood disappeared. Pericentric inversion of chromosome 16 with typical breakpoints(p13q22) have been noted in 2 earlier cases of AML (M5b). However, our case has different breakpoints on the inverted chromosome 16(i.e.p13.3q23). This is of great significance as it may be a bio-marker for indolent disease which is also sensitive to chemotherapy. The inv(16) is shown to be associated with a better prognosis in AML(M4).

Program Nr: 730 from the 1999 ASHG Annual Meeting

Molecular Genetic Profiling of Renal Cell Carcinoma as an Alternative to Current Histopathologic Classification Systems. *S.T. Lott[1], L. Rogers[1], R. Amato[1], L. Wood[1], T. Powdrill[2], D. Thakkar[2], A. El-Naggar[1], A.M. Killary[1]*. 1) MD Anderson Cancer Ctr, Houston, TX; 2) Genometrix, The Woodlands, TX.

The initiation and progression of human cancer is a multistep process involving genetic alterations of critical genes controlling the destiny of defined cell lineages with regard to cellular proliferation, differentiation or death. Elucidation of the genetic pathways underlying these growth control processes is crucial to our understanding of the origins of the malignant state. Furthermore, definition of genetic pathways intimately involved in particular cancer types should lead to the improved clinical treatment of cancer. Our laboratory has undertaken an extensive genetic, molecular biologic, pathologic, and statistical approach to generate a comprehensive molecular profile of renal cell carcinoma (RCC). Currently, classification of RCC tumors is largely based on histopathological parameters, which do not directly correlate with clinical outcome. Our approach has centered on the use of a commercially developed microarray consisting of oligonucleotides corresponding to 44 genes frequently involved in the initiation and development of human tumors (Genometrix, Inc., The Woodlands, TX). Pathways represented on this array include cell signaling, apoptosis, cell cycle control and drug resistance. To explore the involvement of these genes in the development of RCC, we made use of a panel of twenty RCC matched tumor/normal samples obtained from patients undergoing nephrectomy at the M. D. Anderson Cancer Center. Fluorescently labeled, reverse transcribed cDNA from matched tumor/normal samples were simultaneously hybridized to the array. Following posthybridization washes, arrays were scanned to determine the amounts of fluorescently labeled probe bound at each element of the array. Relative expression of each gene was determined by comparing the average intensity of the hybridized material at each element to that of b-actin and GAPDH. Together, these studies have greatly expanded our understanding of the basic genetic changes associated with renal tumorigenesis.

Program Nr: 731 from the 1999 ASHG Annual Meeting

Chromosomal clues to the development of metastatic prostate neoplasm. *C.A. Luhrs[1], G. Morel[1], M.J. Macera[2,3], R.S. Verma[2,3]*. 1) Brooklyn V.A. Medical Center, Brooklyn, NY; 2) Institute of Molecular Biology and Genetics, Brooklyn, NY; 3) Wyckoff Heights Medical Center, Brooklyn, NY/New York Hospital-Weill Medical College of Cornell University, New York, NY.

A 65 year old Caucasian male was diagnosed with metastatic carcinoma of the prostate on December 1997. He had been recently evaluated for increasing fatigue, peripheral lymphadenopathy, splenomegaly, increased LDH (2625) and worsening anemia. A peripheral smear showed leucocytosis with predominant immature lymphoid cells. (CD20+). Flow cytomerry showed B cell lymphoma and abdominal CT revealed bulky mesenteric LDP and retroperitoneal, pelvic lymph nodes. Enlarged spleen with peripheral infarcts was observed. Cytogenetic evaluation of bone marrow cultured for 48 hours was performed by GTG- and FISH- techniques. A total of 50 metaphases were analyzed and highly complex chromosomal abnormalities of varied nature were characterized by the FISH technique. Cytogenetic evaluation of bone marrow in patients with metastatic prostate cancer has been very rare. No common chromosomal abberations were found by comparing with earlier cases. The chromosomal abnoromalities found in those cases could be random, representing secondary events or caused by chromosomal instability due to the culture conditions of cancer cells. However, Li and associates [Li et al Genes Chromosomes & Cancer 24:175-182, 1999] suggested that 16q23-24 could be a frequent aberration in patients with matastasis of prostate cancer.

Program Nr: 732 from the 1999 ASHG Annual Meeting

Transcriptional Regulation of Cyclooxygenase-2 Gene Expression : Novel Effects of Non-Steroidal Antiinflammatory Drugs. *A. Mandal, C-J. Yuan, Z. Zhang, A. Mukherjee.* SDG/HDB, NICHD/NIH, Bethesda, MD.

The cyclooxygenase-2 (COX-2) gene overexpression is suggested to play important roles in colorectal tumorigenesis. Epidemiological studies revealed that non-steroidal antiinflammatory drugs (NSAIDs), such as aspirin and sulindac that inhibit COX activity, reduce colorectal cancer mortality. Current investigations have focused on delineating the molecular mechanisms that regulate the COX-2 gene expression and the roles of NSAIDs in cancer chemoprevention. COX-2 catalyzes the production of prostaglandins (PGs) from arachidonic acid (AA), generated by phospholipases A2 (PLA2s), a family of acyl esterases that cause the release of AA from cellular phospholipids. Pancreatic secretory PLA2 (sPLA2), via its receptor (sPLA2R), transcriptionally activates the COX-2 gene expression in several cell types, although a specific transcription factor mediating COX-2 expression has not yet been identified. Here, we report that transcription factor, C/EBPb, plays a critical role in sPLA2IB-induced, receptor-mediated, COX-2 gene expression in MC3T3E1 cells. Furthermore, treatment of these cells with NSAIDs stimulates COX-2 mRNA and COX-2 protein levels with concomitant elevation in PG production. Most importantly, NSAID treatment of the cells drastically suppresses the production of cytosolic PLA2 (cPLA2)-mRNA. The lack of sPLA2IB-, sPLA2IIA- and sPLA2V-mRNA expression in both NIH3T3 and MC3T3E1 cells suggests that cPLA2 is the most likely enzyme that catalyzes the release of AA, the rate-limiting substrate of COX for the production of PGs. Our results, in addition to defining a critical role of C/EBPb in the regulation of COX-2 gene expression, demonstrate that despite the apparent stimulation of COX-2-mRNA expression, NSAIDs may inhibit PG production by drastically suppressing cPLA2-mRNA. Since both AA and PGs regulate many biological functions that are characteristic of most cancer cells and have profound effects on cellular differentiation, we propose that the previously reported anti-metastatic and cancer chemopreventative effects of NSAIDs stem from their combined inhibitory effects on cPLA2-mRNA expression, and on COX-2 catalysis.

Program Nr: 733 from the 1999 ASHG Annual Meeting

Phenotype of CDKN2A Arg24Pro carriers and their non-carrier relatives in a large Australian melanoma kindred. *G. Mann[1], C. Ang[2], L. Fritschi[3], E. Holland[1], H. Schmid[1], R. Kefford[1], J. Kelly[2].* 1) Westmead Institute for Cancer Research, NSW 2145, Australia; 2) Victorian Melanoma Service, Alfred Hospital, Vic 3181, Australia; 3) Dept Epidemiology & Preventive Medicine, Monash University, Vic 3168, Australia.

Germline mutations in the CDKN2A gene are observed in some cutaneous melanoma kindreds. Such kindreds are typically ascertained by the presence of multiple cases; affected family members might therefore share risk factors other than the mutant CDKN2A allele. We have studied 64 individuals in the fourth and fifth generations of a familial melanoma kindred residing in Victoria, Australia (lat. 38°S), in which 15 carriers of the Arg24Pro mutation, but no non-carriers, have developed melanoma. The number, size and distribution of melanocytic nevi and lentigines, and a variety of other melanoma risk factors was determined in 21 carriers, 24 non-carrier relatives descended from the same founders, and 19 spouses.

All nevus metrics (mean total nevus number [ANOVA $p=0.003$], mean total nevus density [$p<0.003$], and mean number of dysplastic nevi [$p=0.001$]) were highest in mutation carriers (695, 761, 13.5 respectively), lowest in spouses (302, 194, 0.8), and at intermediate levels in non-carrier relatives (422, 329, 3.5). The Arg24Pro carrier state therefore causes increased formation of both common and dysplastic nevi. Differences between non-carrier relatives and spouses, though not statistically significant, suggested that family members share risk factors for nevus formation other than the Arg24Pro mutant allele. Mutation carriers also reported more non-melanoma skin cancers ($p=0.02$) and severe sunburns ($p=0.02$) than non-carriers and spouses, and exhibited the highest numbers of shoulder lentigines ($p=0.02$), a correlate of prior sunburns. Germline Arg24Pro mutation of CDKN2A, which affects p16INK4A but not p14ARF, might therefore also confer increased sensitivity to solar UV radiation.

Program Nr: 734 from the 1999 ASHG Annual Meeting

Fluorescent in situ hybridization study of c-myc oncogene copy number in prostate cancer. *H.F.L. Mark[1,2,4], M. Samy[3], K. Santoro[4], A. Ashraf[2], S. Mark[1], D. Feldman[5]*. 1) KRAM Corporation, Barrington, RI; 2) Brown University School of Medicine, Providence, RI; 3) Women & Infants Hospital, Providence, RI; 4) Rhode Island Hospital, Providence, RI; 5) Yale University School of Medicine, New Haven, CT.

We previously conducted a study of 88 cases of prostate cancer in an attempt to identify potential prognostic biomarkers that can distinguish aggressive cases that must be treated immediately. Prostate cancer is a serious disease affecting men worldwide and compromises the quality of life of prostate cancer patients. Biomarkers studied included chromosome 7 trisomy, chromosome 8 trisomy, and HER-2/neu oncogene amplification. These biomarkers were initially studied because trisomy 8 and oncogene amplification of the HER-2/neu gene have been reported in many other cancers, including those studied in this laboratory. In view of the fact that HER-2/neu amplification was not found to play a prominent role in the group of prostate cancer specimens that we studied, an exploration of other biomarkers was felt to be warranted. Thus, we began a pilot study of c-myc oncogene copy number in prostate cancer using the same protocol for fluorescent in situ hybridization and a directly-labeled SpectrumOrange LSI c-myc probe (Vysis, Inc., Downers Grove, IL) on formalin-fixed paraffin-embedded tissue. Out of a total of 36 cases of prostate cancers successfully analyzed thus far, we found 11 (31%) of the tumors exhibiting three or more positive signals for c-myc in 15% or more of the cells. Of these, only 7 tumors (19% of the total cases studied) had 3 or more signals in 20% or more of the cells. No case had 3 or more signals in greater than 25% of the cells. Compared to other molecular probes tested, the c-myc signals were more faint and the quality of the preparation was less optimal than other tumor specimens that we previously studied. Based on the information available thus far, we conclude that an increase in c-myc oncogene copy number was not a prominent finding in our cohort of prostate cancer patients.

Program Nr: 735 from the 1999 ASHG Annual Meeting

LACK OF RECIPROCAL FUSION IN VARIANT PHILADELPHIA CHROMOSOME TRANSLOCATIONS: A Use of Double Fusion Signal FISH and Spectral Karyotyping. *V.D. Markovic[3], D. Bouman[3], J. Bayani[4], S. Kamel-Reid[1,2,3,4], J.A. Squire[1,2,3,4].* 1) Department of Laboratory Medicine and Pathobiology; 2) Department of Medical Biophysics, University of Toronto; 3) Cancer Cytogenetics Laboratory, Toronto General Hospital; 4) Ontario Cancer Institute, Toronto, ON, Canada.

Chromosomal rearrangements other than the classic reciprocal (9;22) translocation are present in about 5-10% of Philadelphia chromosome (Ph) positive Chronic Myeloid Leukemia (CML) patients and are called variant Ph translocations. It is unclear whether they occur subsequent to the classic Ph translocation, or whether they are caused by a single somatic recombinational event. The molecular genetic consequences of Ph producing translocations in CML result in a p210, p190, or occasionally p230 BCR/ABL fusion gene product and the molecular breakpoints in both classic and variant Ph translocations appear to cluster to the same molecular regions. We have used a sequential analysis of G-banding, spectral karyotyping (SKY) and double fusion signal (D) fluorescence in situ hybridization (FISH) on metaphases derived from ten variant Ph translocations to look for the chromosomal location of BCR and ABL genes. Nine patients had a translocation and one had a translocation and an associated insertion. All nine patients with a translocation had the typical Ph chromosome, and had the BCR/ABL fusion gene present on derivative 22. Reciprocal counterparts of ABL and BCR are usually seen as a second fusion signal in the classic Ph translocation. In the subset of CML patients with variant Ph translocations presented here, reciprocal FISH signals were either retained on separate chromosomes, or they were deleted from the karyotype. The patient with an associated insertion had an atypical Ph chromosome, and the fusion FISH signal indicated the BCR/ABL fusion was present on the derivative 9. We believe the BCR/ABL fusion in this case was produced by a chromosomal insertion. This study provides a more comprehensive description of the molecular events associated with chromosomal rearrangements involving the BCR/ABL fusion gene and has implications for cytogenetic laboratories utilizing interphase FISH analysis in CML.

Program Nr: 736 from the 1999 ASHG Annual Meeting

Germline p53 mutations in women with multiple primary cancers. *A-M. Martin[1], B. Amirimani[1], R.M. Howard[1], H.A. Shih[1], T.R. Rebbeck[2,3], B.L. Weber[1,3].* 1) Department of Medicine; 2) Center for Clinical Epidemiology and Biostatistics; 3) Cancer Center, University of Pennsylvania, Philadelphia, PA 19104.

Background: Women with multiple primary cancers, in which one is breast cancer, may be at an increased risk of germline mutations in tumor suppressor genes. In a cohort of women whose germline mutation status for BRCA1 and BRCA2 is negative, mutations in p53 may be identified.

Methods: To address this issue, 173 women were ascertained through a Breast Cancer Risk Evaluation Program. Eighty-nine women with breast cancer and at least one other primary cancer were screened along with 84 control women who had breast cancer alone and no family history of multiple primary cancers. There was no significant difference in the number of breast cancers per family. Genomic DNA, from each of the 173 women, was screened for allelic variants in the entire p53 gene using conformation sensitive gel electrophoresis (CSGE). Heteroduplex formation was detected on conformation sensitive gels. In addition, a high throughput screen using a modified, automated fluorescent detection system using the ABI 377 Sequencer^{TM}(Ganguly *et al.,* 1998)was conducted. Mutations were confirmed by direct sequncing.

Results: Eight variants were identified among the cases. Of those, 6 occurred at a frequency of >1% in our cohort, suggesting they may be polymorphisms. The remaining 2 variants may be disease-associated mutations. The frequency of variants in the control set is currently under investigation. The association of variants with the presence of multiple primary cancers will be determined.

Program Nr: 737 from the 1999 ASHG Annual Meeting

Role of Chromosome 3p12-p21 Tumor Suppressor Genes in Clear Cell Renal Cell Carcinoma: Analysis of *VHL*-dependent and *VHL*-independent Pathways of Tumorigenesis. *A. Martinez[1], P. Fullwood[1], K. Kondo[2], T. Kishida[2], M. Yao[2], E.R. Maher[1], F. Latif[1]*. 1) Section of Medical and Molecular Genetics, Department of Paediatrics and Child Health, University of Birmingham, Birmingham, UK; 2) Department of Urology, Yokohama City University School of Medicine, Yokohama, Japan.

Deletions on the short arm of chromosome 3 (3p) are a frequent finding in many common cancers including lung, breast, cervical, ovarian, head and neck, and kidney cancer and it is clear that several tumor suppressor genes (TSGs) map to 3p. Cytogenetic analysis and molecular genetics studies have shown that chromosome 3p deletions and loss of heterozygosity (LOH) for 3p markers are features of Clear Cell Renal Cell Carcinoma (CCRCC) but are rare in non-CCRCC. The von Hippel Lindau (*VHL*) TSG, which maps to 3p25, is a major gatekeeper gene for CCRCC and is inactivated in most sporadic CCRCC. However, we have previously suggested that inactivation of other 3p TSGs may be critical for CCRCC tumorigenesis in CCRCC with (VHL^-) and without (VHL^+) inactivation of the *VHL* TSG. To investigate the role of non-*VHL* TSGs in VHL^- and VHL^+ CCRCC, we analysed 82 CCRCC, of known *VHL* inactivation status, for LOH at polymorphic loci within the candidate critical regions for chromosome 3p TSGs (LCTSGR1 at 3p21.3, LCTSGR2 at 3p12 and at 3p14.2). Chromosome 3p12-p21 LOH was frequent in both VHL^- and VHL^+ CCRCC. However, while the frequency of 3p25 LOH in VHL^- CCRCC was similar to that at 3p12-p21, VHL^+ CCRCC demonstrated significantly less LOH at 3p25 than at 3p12-p21. Although there was LOH evidence for CCRCC TSGs at 3p21, 3p14.2 and 3p12, in both VHL^- and VHL^+ CCRCC, the major CCRCC LOH region mapped to 3p21.3 close to the lung cancer TSG region 1 (LCTSGR1). There was no association between tumor *VHL* status and tumor grade and stage. These findings suggest that *VHL* inactivation alone, is not sufficient to initiate CCRCC and that loss of a gatekeeper 3p21 TSG is a critical event for RCC development in both VHL^- and VHL^+ CCRCC.

Program Nr: 738 from the 1999 ASHG Annual Meeting

Correlation between expression of the matrix metalloprotease-1 (MMP-1) gene in ovarian cancers and an insertion/deletion polymorphism in its promoter region. *M. Matsushima[1], Y. Kanamori[1], T. Minaguchi[1], K. Kobayashi[2], S. Sagae[2], R. Kudo[2], Y. Nakamura[1]*. 1) Human Genome Center, University of Tokyo, Tokyo, Japan; 2) Department of Obstetrics and Gynecology, Sapporo Medical University School of Medicine, Sapporo, Japan.

Matrix metalloproteinases (MMPs), a family of closely related enzymes that degrade the extra-cellular matrix, are likely to be involved in invasion and metastasis of tumor cells. A guanine (G) insertion/deletion polymorphism within the promoter region of MMP-1 influences the transcription of this gene; i.e., the 2G (insertion type) promoter possesses greater transcriptional activity than the 1G (deletion type) promoter. To investigate whether the insertion/deletion polymorphism in the MMP-1 promoter has any correlation with development or progression of ovarian cancer, we compared the frequency of each allele in DNAs from 163 ovarian-cancer patients with control samples from 150 healthy women. The frequency of heterozygotes and homozygotes for the 2G allele was significantly higher among women with ovarian cancers (89%) than in individuals without cancer (80%; $p = 0.028$), indicating that individuals who carry even one 2G allele are more susceptible to ovarian cancer than women with a constitutional 1G/1G genotype. To further investigate whether this insertion/deletion polymorphism influences expression of the MMP-1 gene in ovarian cancers, we performed semi-quantitative RT-PCR experiments using tumor tissues whose genotype had been determined. In tumors carrying 2G alleles (1G/2G heterozygotes or 2G homozygotes), the median expression levels of MMP-1 were more than seven times the median level of tumors having no 2G alleles. The intensities of the MMP-1 bands calculated as a ratio against intensities of corresponding beta-2 microglobulin bands were 1.5 versus 0.2, respectively ($p=0.0038$). Since the 2G type of promoter possesses a binding site for the Ets transcription factor, such binding is likely to lead to higher transcription of MMP-1. An excess of MMP-1 production may contribute to enhance degradation of the extra-cellular matrix, and thereby promote invasion and metastasis of tumor cells.

Program Nr: 739 from the 1999 ASHG Annual Meeting

DNA repair gene polymorphisms and DNA-adduct levels in bladder cancer. *G. Matullo[1], S. Guarrera[1], L. Davico[2], S. Carturan[1], M. Peluso[3], A. Piazza[1], P. Vineis[2].* 1) Dip. di Genetica Biologia e Biochimica, Univ. di Torino; 2) Dip. di Scienze Biomediche e Oncologia Umana, Univ. di Torino; 3) IST, Dipartimento di Oncologia Sperimentale, Univ. di Genova; Italy.

The repair of DNA damage has a key role in protecting the genome of the cell from the insults of cancer-causing agents. Although development of bladder cancer is associated with exposure to tobacco (about 50%) and occupational exposure (about 20%), only a proportion of exposed individuals will develop cancer, suggesting that there is a genetic predisposition. Polymorphisms in several DNA repair genes have been identified; however the impact on repair phenotype has not been elucidated. We analyzed the relationship between the following polymorphisms in two repair genes XRCC1-R399H (exon 10) and XPD-K751G (exon 23) and DNA damage as measured by 32-P DNA-adduct in 123 individuals with bladder cancer and 85 controls. Work is in progress on other genetic polymorphisms (XRCC1-R194W exon 6, XPD-D312N exon 10, and XRCC3-T241M exon 7) of different repair systems. No significant difference has been observed in the genotype distribution between cases and controls for XRCC1-R399H and XPD-K751G, neither stratifying by class of age, or smoking habit, nor considering the possible combined effect of the two genotypes. Significant differences exist between cases and controls for DNA-adduct levels (0.47±0.04 vs 0.20±0.03, $p<0.001$) and smoking (110/123=89.4% vs 47/85=55.3%, $p<0.00001$). Notwithstanding we have not observed a significant difference in genotype distributions and DNA-adduct levels between smokers and non-smokers, even considering separately cases and controls, we have found an interesting higher DNA-adduct level (although not significantly) in individuals with XRCC1-R399H GG-AG vs AA genotypes (0.49±0.05 vs 0.34±0.07, $p=0.15$; maximum values are 2.5 and 0.9, respectively) in smoker cases but not in non-smoker cases. No difference in DNA-adduct levels has been observed among genotypes in smokers and non-smokers controls. These results suggest to further investigate the possible interaction between XRCC1 polymorphisms, smoking and other genetic or not risk factors.

Program Nr: 740 from the 1999 ASHG Annual Meeting

Mosaicism in neurofibromatosis 2. *V.F. Mautner[1], M.E. Baser[2], L. Kluwe[3].* 1) Neurology Department, Klinikum Nord Ochsenzoll, Hamburg, DEU; 2) Los Angeles, USA; 3) Laboratory of Brain Tumor Biology, University of Hamburg, Hamburg, DEU.

It is estimated that 10-15% of neurofibromatosis 2 (NF2) patients are mosaic, but few patients have been reported and the clinical spectrum is poorly characterized. From a large series of adult NF2 patients, we identified 11 mosaic patients by analyzing vestibular schwannomas (VSs), cloned fragments, or leukocytes using heteroduplex analysis. These patients had eight nonsense and three frameshift mutations that occurred throughout the *NF2* coding sequence. The age at onset ranged from 16-39 yrs (median, 21 yrs) and the presenting symptoms were hearing loss (one patient), tinnitus (three patients), skin tumor (two patients), gait disorder (one patient), tongue atrophy (one patient), impaired coordination (one patient), and asymptomatic (two patients). The current age ranged from 29-68 yrs (median, 41 yrs). Eight patients had a severe course and three had a mild course. Seven patients had bilateral VSs and four had unilateral VSs. Ten patients had spinal tumors, seven had intracranial meningiomas, six had skin tumors, six had non-VS cranial nerve tumors, and four had lenticular opacities. When compared to the prevalence of these abnormalities in the classically-defined NF2 patients in this series, the largest difference was in the prevalence of unilateral VSs: 36.4% in mosaic NF2 patients versus 6.2% in classical NF2 patients. These results suggest that the mosaic NF2 phenotype may differ from the classical NF2 phenotype, but require confirmation in a larger number of mosaic patients.

Program Nr: 741 from the 1999 ASHG Annual Meeting

The exon 13 duplication in the *BRCA1* gene is a founder mutation found in geographically diverse populations. *S. Mazoyer, G.M. Lenoir, the Duplication Screening Group.* Laboratoire de Génétique UMR 5641, Faculté de Médecine, Lyon, France.

Most mutation screening methods focus on genomic DNA and, being PCR-based, they do not allow the detection of large DNA rearrangements. Therefore, only 14 large germline insertions or deletions have been described in the *BRCA1* gene as compared to more than 500 point mutations or small insertions and deletions scattered over the whole coding sequence and the splice junctions. Rearrangements, however, were found to represent 25% and 15% of all mutations in 2 independent studies performed on Dutch and American breast/ovarian cancer families respectively.

Recently, we identified a 6 kb duplication comprising exon 13 in the *BRCA1* gene, which creates a frameshift at the mRNA level. It was found in 3 apparently unrelated American families of European ancestry and in 1 Portuguese family. A founder effect was very likely based on haplotype data.

In order to better estimate the frequency and geographic diversity of this duplication, which is difficult to identify if not specifically searched for, we have set up a collaborative screen for this mutation by providing specific primers and a positive control to laboratories from 20 different countries (Australia, Austria, Belgium, Canada, Finland, France, Germany, Great Britain, Hungary, Ireland, Israel, Italy, Netherlands, New Zealand, Norway, Spain, Sweden, Switzerland, Turkey, USA). To date, 37 groups have completed the screening of a total of ~3700 breast and/or ovarian cancer patients (~1/2 Anglo-Saxons) with a family history of either or both cancers (representing the diversity in patients who attend high-risk cancer clinics). Of this set, 13 additional independent patients from Australia (3), Belgium (1), Canada (1), Great Britain (6), New Zealand (1), and USA (1) were found to carry the duplication. Haplotype analyses are being performed to confirm a single origin and to estimate the age of this rearrangement. *(The names and affiliations of all individuals involved in this work will be presented on the poster)..*

Program Nr: 742 from the 1999 ASHG Annual Meeting

Clinical Effects of *WT1* Mutations in a Study of 118 Wilms Tumor Patients. *J.M. McDonald, V. Huff.* Department of Experimental Pediatrics, University of Texas MD Anderson Cancer Center, Houston, TX.

Wilms tumor (WT) is a childhood kidney neoplasm that has a genetically heterogeneous etiology. The one cloned WT gene, *WT1*, located at 11p13, has been reported to be mutated in 6-20% of Wilms tumors. To assess the effect of *WT1* mutations, we compared 44 WT patients whose tumors carried germline or somatic *WT1* mutations with 74 WT patients in whose tumors no *WT1* mutations were detected. The average age at diagnosis for patients with somatic *WT1* mutations and patients with no *WT1* mutations were comparable (44.7 and 42.8 months, respectively). As expected, WT patients with germline *WT1* mutations had an earlier average age at diagnosis (18.3 months) and a higher probability of having bilateral disease (0.591) than the patients with somatic or no *WT1* mutations (0.077 and 0.175, respectively). There was little difference between the two subsets of Wilms tumors in regard to favorable and unfavorable histologies. Anaplasia was noted in one of 32 *WT1* mutant tumors and in three of 43 tumors without *WT1* mutations. Because anaplastic tumor histology does not predict all WT relapses, we also assessed relapse status with respect to *WT1* mutations. There was no statistically significant difference in the frequency of relapse between the patients whose tumors did or did not carry *WT1* mutations. With comparable length of followup for both groups (~48 months), five of 26 (0.192) patients with *WT1* mutant tumors relapsed, while 12 of 51 (0.235) patients whose tumors had no detectable *WT1* mutation relapsed. These data on *WT1* mutations in a large cohort of WT patients suggest that *WT1* mutations do not confer a unique clinical phenotype with respect to age at diagnosis or prognosis.

Program Nr: 743 from the 1999 ASHG Annual Meeting

Cytogenetic and molecular evidence of constitutional mosaic trisomy 8 and hematologic abnormalities in a phenotypically normal woman. *J. Meck, T.J. Chen, L-J. Wong, J. Imholte, K. Perry, N. Qin, S. Baidas.* Georgetown Univ Med Ctr, Wash, DC.

Trisomy 8 has clinical significance as both a constitutional and an acquired abnormality. As a constitutional abnormality the phenotype ranges from normal to severe. Trisomy 8 is also an acquired chromosome abnormality common in myeloid disorders. Individuals with constitutional mosaic trisomy 8 regardless of phenotype are predisposed to develop cancer, most often myelodysplastic syndrome. Our report is significant because genotype analysis was used to show that the trisomy was constitutional in our patient and because she presented with hematologic abnormalities, but not cancer. Our patient is a phenotypically normal 34 year old woman with recurrent oral aphtous ulcers since childhood and increased MCV in the last several years. Bone marrow biopsy was slightly hypocellular with mild megaloblastic changes, but otherwise normal morphologically. Unexpectedly, the bone marrow karyotype revealed trisomy 8 in all 20 metaphases analyzed. A 72 hour PHA stimulated peripheral blood culture had 14/20 trisomy 8 cells; the 24 hour culture had no metaphases. None of the 50 skin fibroblast metaphases were trisomic. Constitutional trisomy 8 mosaicism with the abnormal cells confined to blood/bone marrow would explain the lack of phenotypic abnormalities with the exception of hematologic problems. It is unclear whether her bone marrow findings represent an increased risk for development of myelodysplastic syndrome. To confirm the trisomy as constitutional, we performed genotype analysis using six chromosome 8 genetic markers (heterozygosity 0.73 -0.87). Fluorescent labeled PCR primers were used to amplify microsatellite loci. Allele number and size were determined by GeneScan analysis on an ABI 377. All 6 markers suggested the presence of 3 alleles. Three markers showed 3 different sized alleles, while the other 3 markers showed 2 different sized alleles with a ratio clearly indicative of a trisomy. These results are consistent with our patient having a constitutional trisomy mosaicism resulting from a meiotic error with trisomy rescue. Parental genotyping will be performed for confirmation.

Program Nr: 744 from the 1999 ASHG Annual Meeting

The relationship between blood serotonin and depression in first-degree relatives of individuals with autistic disorder. *R.K. Abramson[1], S.A. Ravan[1], E.H. Cook[2], K.M. Wieduwilt[1], M.L. Cuccaro[1], H.H. Wright[1]*. 1) Dept Neuropsychiatry & Behav, Univ S Carolina Sch Medicine, Wm S Hall Psychiatric Inst, Columbia, SC; 2) University of Chicago School of Medicine.

The purpose of this study was to examine the relationship between whole blood serotonin (5HT) and depression in first degree relatives of children with autistic disorder (AD). Elevated blood serotonin may be inherited. It occurs in 30-40% of individuals with (AD), and is also present in unaffected first and second-degree relatives (Abramson, 1989, Cook, 1992, Kuperman, 1985, Perry, 1991). An increased prevalence of depression has also been reported in first degree relative of individuals with AD (Abramson, 1992, Piven, 1991, Smalley, 1993). In the general population, patients with depression have been found to have significantly lower blood 5HT levels (Banki, 1978, Aberg-Wistedt. 1981). In this pilot study, 77 parents and siblings of children with AD completed the Beck Depression Inventory (BDI) or the Child Depression Inventory (CDI). At the time blood was drawn for 5HT levels, current medication usage was recorded since antidepressant and certain over-the-counter medications affect 5HT levels. A bivariate multiple regression model was used with 5HT as the outcome variable and age, gender, ethnicity and depression score as independent variables in the final model. The overall F-test for the final model was significant ($F=8.83$, $p=0.0001$) and the variables in the model accounted for 59% of the variance in 5HT level. Partial t-tests indicate, after controlling for all other covariates, parents and siblings whose BDI or CDI scores indicated depression had significantly lower 5HT ($t=-2.4$, $p=0.023$). In addition, as previously found, participants who had reported taking serotonin inhibiting medications had significantly lower blood serotonin levels ($t=-4.07$, $p=0.0003$). This study indicates first degree relatives with elevated 5HT may be less likely to meet criteria for depression, and elevated 5HT may be a protective factor in family members of a child with AD.

Program Nr: 745 from the 1999 ASHG Annual Meeting

Familial Robin sequence with Wolff-Parkinson White syndrome. *D.N. Abuelo.* Genetic Counseling Center, Rhode Island Hospital, and Brown University School of Medicine, Providence, RI.

The Robin sequence (micrognathia, cleft soft palate, glossoptosis) can occur in otherwise normal individuals, but frequently occurs as part of multiple malformation syndromes such as Stickler syndrome and trisomy 18. Less commonly, it can be seen in some bony dysplasias and neuromuscular disorders. It has not been reported to occur together with the Wolff-Parkinson-White (WPW) type of cardiac arrhythmia. I have observed a family in which the father had Robin sequence and his two sons were born with both Robin sequence and WPW.

The proband was diagnosed with Robin sequence at birth and had cleft palate repair at 10 months. An episode of supraventricular tachycardia in the newborn period was found to be caused by WPW syndrome. He has downslanting palpebral fissures and joint hyperextensibility. Chromosomes, including FISH for 22q- were normal. Chest X-ray showed no rib gaps. The father had a history of micrognathia and cleft soft palate, which was repaired at age 1, with good catch-up growth of the mandible. He developed scoliosis, which was repaired in his teens. He has very mild downslanting palpebral fissures, but is otherwise not dysmorphic. He does not have facies suggestive of Sticker syndrome and has normal intelligence and a normal EKG. His next son was born with WPW, cleft soft palate, severe micrognathia with glossoptosis and required tracheostomy.

When the Robin sequence occurs without other abnormalities, it is considered to have a low recurrence risk. In this family, there is apparent autosomal dominant inheritance. The WPW syndrome in the siblings could be part of the same unique disorder or could have been inherited separately.

Program Nr: 746 from the 1999 ASHG Annual Meeting

Epilepsy with a particular EEG pattern in one patient with Pitt-Rogers-Danks syndrome. *M.-C. Addor[1], M. Maeder-Ingvar[2], T. Deonna[3], D.F. Schorderet[1]*. 1) Medical Genetics, CHUV, Lausanne, Switzerland; 2) Department of Neurology, CHUV, Lausanne, Switzerland; 3) Department of Pediatric Neurology, CHUV, Lausanne, Switzerland.

Partial deletion of the short arm of chromosome 4 is found in patients with Wolf-Hirschhorn syndrome (WHS). This contiguous gene syndrome is characterized by severe pre- and postnatal growth deficiency, mental retardation, a typical dysmorphic face associated with various malformations and midline defects, and seizures. Pitt-Rogers-Danks syndrome (PRDS) was formerly considered as a different clinical phenotype with intrauterine growth retardation, subsequent dwarfism, unusual facies, mental retardation and epilepsy. FISH and DNA analysis have recently shown that PRDS is caused by a deletion overlapping the critical region of WHS; thus the two syndromes are part of the same clinical spectrum associated with deletion near the terminus of 4p; the phenotypic variation observed is accounted for by allelic variation. A particular electroclinical picture has been reported in a few patients with WHS; this EEG pattern is very similar to the one described in Angelman syndrome.

We report on a clinical, cytogenetic, neurological and electroencephalographical study of a 3-year-old female patient with PRDS. She developped clusters of myoclonic seizures from the age of 18 months, and we could record a clinical-electroencephalographic EEG pattern similar to that described by Sgro et al. in four patients with WHS (Epilepsia 1995, 36 : 1206-1214). Valproate markedly reduced the seizure frequency and had a positive effect on development. As PRDS patients have a less severe phenotype and are recognized later than WHS patients, EEG study could facilitate an earlier diagnosis.

Program Nr: 747 from the 1999 ASHG Annual Meeting

Distinctive facial dysmorphism, abnormal wound healing and global developmental delay. A rare Ehlers-Danlos syndrome variant, or a new syndrome? *L.C. Ades[1,2], D. Little[3], A. Colige[4], J. Chaitow[5]*. 1) Dept of Clinical Genetics, Royal Alexandra Hosp Children, Westmead, NSW , N.S.W., Australia; 2) University of Sydney Dept of Paediatrics and Child Health, Royal Alexandra Hosp Children, Westmead, N.S.W., Australia; 3) Dept of Orthopaedics, Royal Alexandra Hosp Children, Westmead, N.S.W., Australia; 4) Laboratory of Connective Tissue Biology, Liege, Belgium; 5) Visiting Paediatric Rheumatologist, Royal Alexandra Hosp Children, Westmead, N.S.W., Australia.

We report the clinical findings in a 3 year-old girl with distinctive facial dysmorphism, extreme ligamentous laxity and joint hypermobility, abnormal skin fragility, poor wound healing and mild global developmental delay. Her features are similar to the Ehlers-Danlos syndrome (EDS) group of disorders, particularly those of the rare disorder EDS type VIIC (human dermatosparaxis). However, histological study of the skin, and molecular genetic studies do not support this diagnosis. Classically, in human dermatosparaxis, electron microscopy (EM)of reticular collagen in longitudinal sections shows branched, twisted ribbons of banded collagen fibrils and cross sections show a characteristic "hieroglyphic" profile. These findings were absent on EM study of the proband's skin. Contrary to the findings in human dermatosparaxis, procollagen I N-proteinase cDNA sequence was normal in this girl. The synthesis and processing of collagens types I, III and V in skin fibroblasts were also normal. Abnormal skin fragility is demonstrable in decorin knockout mice, and this was considered as another potential candidate gene. However, the decorin cDNA sequence in our patient was normal.

Program Nr: 748 from the 1999 ASHG Annual Meeting

Autosomal dominant inheritance of conductive deafness, external ear malformations and congenital facial palsy: second description. *M.A. Aguirre[1], C. Perandones[1], E.L. Furforo[1,2], M. Perez[1], H.A. Rodriguez[3], L. Alba[1].* 1) Genetica Medica, Centro Nac. Genetica Medica, Buenos Aires, Buenos Aires, Argentina; 2) Genetica Medica, Hosp. Mat. Inf. R Sarda, Buenos Aires, Argentina; 3) Hosp. Pediatr. Prof. J. P. Garrahan, Buenos Aires, Argentina.

In 1983 Sellars and Beighton described for the first time the association of conductive deafness due to stapedial anomalies, external ear malformations and congenital facial palsy, in three siblings and their mother. The transmission of these associated malformations in this family suggested autosomal dominant inheritance. We report on the association of congenital bilateral deafness and congenital unilateral facial palsy in a 2-year-old male child and his mother. The boy was the first child of a young non-consanguineous couple. The pregnancy was uneventful and there was no reported exposure to teratogenic agents. At birth the child was hypotonic and presented umbilical hernia. Physical examination revealed bilateral ear malformations, congenital unilateral facial palsy, abnormal palmar creases and a left undescended testis. Congenital unilateral facial palsy and conductive deafness were also observed in the mother. The karyotype was 46,XY for the child and 46,XX for the mother. To our knowledge the combination of auricular, meatal anomalies plus facial palsy has only been reported once before. The aim of this report is to contribute to the delineation of this rare condition and to provide further evidence for an autosomal dominant pattern of inheritance.

Program Nr: 749 from the 1999 ASHG Annual Meeting

Floating- Harbor syndrome - further characterization of the phenotype. *S. Ala-Mello[1], M. Peippo[2].* 1) Dept Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Dept Medical Genetics, The Family Federation of Helsinki, Helsinki, Finland.

The Floating-Harbor syndrome (F-HS) is a rare syndrome first described in 1973. Since then about twenty cases have been reported. The F-HS is characterised by disturbance in speech development, especially in expressive sppech, characteristic dysmorphic faces and short stature.

We report a second Finnish patient, a 6-year old girl, with the F-HS. Cleft palate was detected at birth. Speech development has been slow, and she spoke single words at 1 year and 8 months of age and sentences of a couple of words at 2 years of age. Her voice has been hypernasal. She walked unaided at 1 year and 10 months of age. Her height has been -2.5SD and at the time of investigation at 6 years of age it was -1.8SD. Her facial features are characteristic to the F-HS, and we represent photographs showing them and give more detailed data. All etiologic studies have been normal.

None of the earlier patients with the F-HS have had cleft palate. Five of them, including our first patient, have been described to have immobile palate, nasal speech, palatal insufficiency or hypernasality. We suggest that cleft palate represents one end of the wide spectrum of palatal insufficiency in the F-HS. Thus, the F-HS can be seen as one of the orofacial clefting syndromes.

Program Nr: 750 from the 1999 ASHG Annual Meeting

Al Aqeel-Sewairi Syndrome: An autosomal recessive syndrome with nodular arthropathy and acrolysis. *A.I. Al-Aqeel, W. Al-Sewairy.* Dept Pediatrics, Riyadh Military Hosp, Riyadh, Saudi Arabia.

Inherited genetic disorders are quite common in Saudi Arabia because of the high degree of consanguinous marriages which accounts for almost 60-80% of all marriages. We describe a new syndrome in a very highly inbred family, with all parents of affected children are first degree cousins, inferring an autosomal recessive mode of inheritance. The syndrome is characterized by mild dysmorphic features with proptosis, maxillary hypoplastic and a small jaw. Distal arthropathy starting in the first few months of life which is progressively increasing and involving more proximal joints with characteristic painful nodules involving palms and soles with bone destruction involving mainly tarsal and carpal bones as well as metacarpal, metarsal and phalanges with generalized osteoporosis. All studies including bone marrow aspirate, nodule biopsy and joint biopsy were negative. In conclusion, we describe a new autosomal recessive syndrome, with dysmorphic features, arthropathy, acrolysis. Molecular genetic studies are in progress to find the causitive gene of this new syndrome.

Program Nr: 751 from the 1999 ASHG Annual Meeting

Carpenter syndrome in eight Arab patients,dominant inheritance suspected. *S.S. Al Arrayed.* Genetic department Salmaniya Medical Ctr, Manama, Bahrain.

Carpenter syndrome is rare autosomal recessive syndrome. The diagnostic criteria are acrocephaly, poly dactyly and syndactyly of fingers and toes. Some patients have congenital heart disease hypogonadism, mild obesity and frequent mental retardation. Thirty-five cases had been reported worldwide, since 1961. We are reporting eight cases with carpenter syndrome, four alive and four diseased from two families. In both families parents are consanguineous. All patients have typical features of carpenter syndrome. All the patients have mild mental retardation. None of the patients have congenital heart disease. The karyotypes in all of them are normal. The father in one family has some of the syndrome features such as, hepertelerism, acrocephaly, epicanthus folds, but without polysyndactyly, and with normal intelligence. Conclusion: In this family the consanguinity supports autosomal recessive inheritance. The fact that the father shows some of the syndrome features may indicate either codominant inheritance or dominant inheritance.

Program Nr: 752 from the 1999 ASHG Annual Meeting

Familial cylindromatosis. *Y. Alembik, C. Stoll.* Serv de Genetique Med, Hopital de Hautepierre, Strasbourg, France.

Familial cylindromatose is an entity characterised by a striking clinical picture of multiple disfiguring tumours located on the face and scalp, which rapidly reccured after excision, had a distinctive histology, and showed familial occurence. A rare subtype of dermal eccrine cylindroma is called turban tumour, a highly descriptive label for the classical total involvement of the scalp with tumours covering the head and causing gross disfigurement. We report a family with dermal eccrine cylindromatosis. A mother 65 years old and her daughter 38 years old were examined. In both the tumors became apparent during late adolescence and initially grow slowly. They continue to develop and grow during life. The lesions are localised on the face and scalp, on the back, the chest, the extremities, the abdomen, the ears and the external genitalia. Individual tumors vary in size from a few millimeters to more than 5 centimeters. The mother had a turban tumour. A sister and a brother of the mother are also affected. A genome search using two families with this disease, provided strong evidence for linkage of cylindromatosis to loci on chromosome 16q12-q13. The gene is likely to be a tumor suppressor gene. This family is under study. Several genes including a retinoblastoma-related gene has been mapped to chromosome 16q12.2.

Program Nr: 753 from the 1999 ASHG Annual Meeting

Severe micrognathia, large ears, atrioventricular, septal defect, symmetrical cutaneous syndactyly of hands and multiple café-au-lait spots: A new syndrome? *N. Al-Sannaa, A.S. Teebi.* Clinical Genetics, Hospital for Sick Children, Toronto, ON, Canada.

An infant of nonconsanguineous phenotypically normal parents presented with unique constellation of craniofacial, cardiac, acral anomalies and multiple café-au-lait spots. Craniofacial manifestations include severe asymmetric micrognathia with strikingly large ears but without maxillary or malar hypoplasia or cleft palate. Cardiac defects include atriventricular septal defect and small patent ductus arteriosus. Acral anomalies are symmetrical and include long fingers and toes with complete cutaneous syndactyly between the third and fourth finger; and second and third toe. Skeletal survey revealed asymmetry of mandible and 11 pairs of ribs. Chromosomal analysis was normal. Psychomotor development in the first 3 months of life was normal. Various acrofacial dysostosis syndromes, mandibuloacral dysplasia, hypomandibular faciocranial dysostosis and the syndrome associating large ears with cleft palate and micrognathia (Say syndrome) were all considered in the differential diagnosis and were excluded. Also, no similar cases have been found in POSSUM and London Dysmorphology databases.

Program Nr: 754 from the 1999 ASHG Annual Meeting

Prenatal ascertainment of a novel Osteosclerotic Skeletal Dysplasia following an abnormal Maternal Serum Analyte Screen. *C.C. Apodaca[1], R.F. Hume[1,3], M.J. Stephan[2], R.K. Wagner[1], B.C. Calhoun[1], L.S. Martin[1,2,3]*. 1) Maternal Fetal Medicine; 2) Developmental Pediatrics; 3) Medical Genetics, Madigan Army Medical Center,Tacoma,WA.

Skeletal dysplasias occur in approximately 1:10,000 live births.Currently lethal skeletal dysplasias can be identified prenatally utilizing advanced sonographic methods.Our patient presented following aberrant maternal serum analyte screening.She is a 28 year old East Timoran who presented at 16 weeks for an ultrasound and genetic counseling after her maternal serum analyte screen results indicated an increased fetal risk of Trisomy 18(MSAFP:0.64 MoM,uE3:0.49 MoM,HCG:0.18 MoM).Pedigree analysis revealed advanced paternal age.Fetal anatomic survey demonstrated slightly bowed femurs. Amniocentesis revealed a normal karyotype,46,XY. Subsequent ultrasounds demonstrated bowing of the femurs, a left femur fracture, and a scalloped contour of the cranial outline.Fetal echocardiography demonstrated mitral and tricuspid valve regurgitation.Neonatal skeletal survey demonstrated basilar skull and cortical thickening of the femurs with no evidence of fractures. Sclerosing bone diseases, e.g.osteopetrosis, pycnodysostosis and dysosteosclerosis were considered in the differential diagnosis.Associated neonatal findings include hypothyroidism and exocrine pancreatic insufficiency.The definitive diagnosis has not yet been elucidated.The pleiotropism of this case is highly unusual.The unique constellation of findings:low maternal serum analytes, cardiac valvular anomalies, fetal fractures progressing to neonatal osteosclerosis, and exocrine and endocrine abnormalities remain to be explained.The association between low maternal serum analytes and the neonatal exocrine and endocrine abnormalities can not be ignored. This case demonstrates that while skeletal dysplasias may be identified prenatally, accurate, definitive diagnosis requires a comprehensive postnatal evaluation, to include clinical exam, radiographic survey, autopsy if indicated and appropriate molecular and biochemical testing. This prenatally identified sclerosing bone disease with multi-organ involvement may represent a new syndrome.

Program Nr: 755 from the 1999 ASHG Annual Meeting

Gorlin syndrome. A rare but recognizable cause of mental retardation. *M. Artigas, E. Ortega, G. Pintos.* Dept Pediatrics, Hosp Germans Trias i Pujol, Badalona, Spain.

Gorlin syndrome is an autosomal dominant condition which comprises mild phenotypic changes, skeletal abnormalities, development of nevoid basal cell carcinomas and, occasionally, other tumors. Mental retardation occurs in 5% of cases. We present a boy who was first seen in the outpatient clinic at thirteen years of age due to mild mental retardation. He was a slow learner with a low level of general language, needing multiple sessions of speech therapy. He developed multiple cavities at an early age for which he underwent several operations.. At present he is following special education. On physical examination he had frontal bossing, broad nasal bridge, prognathism, macrotia, scoliosis, flexion contraction at the elbows and short fifth metacarpal. He also showed three caf au lait spots and multiple nevi over the trunk.. The neurological evaluation was normal. A skeletal survey showed a throraco-lumbar scoliosis, a pseudocystic lytic lesion on the first metacarpal of the right hand and calcification of the falx cerebri. Gorlin syndrome seems more common than previously described and may be difficult to diagnose. The gene responsible for this condition is located on the long arm of chromosome 9, and probably acts as a tumour supressor gene.This needs to be taken into account in the follow up of this patients because they can develop other tumors.

Program Nr: 756 from the 1999 ASHG Annual Meeting

Genetic heterogeneity and therapy potential in hypochondroplasia (HCH): preliminary observations and proposal for an international collaborative study. *A.S. Aylsworth[1], T.E. Kelly[2], S.H. Blanton[2], E. Spector[3], L.A. Fordham[1], R.E. Stevenson[4], J. Sollenberger[3], C.A. Francomano[5], G.A. Bellus[3].* 1) Univ. North Carolina at Chapel Hill; 2) Univ. Virginia, Charlottesville; 3) Univ. Colorado Health Sciences Center, Denver; 4) Greenwood Genetic Center, Greenwood, SC; 5) National Human Genome Research Inst., Bethesda, MD.

BACKGROUND: HCH is characterized by short-limbed dwarfism and typical radiographic changes in the skull, spine, and pelvis that may be mild. Less than 75% of patients with a clinical diagnosis of HCH have a typical fibroblast growth factor receptor 3 (FGFR3) N540K mutation. METHODS: We have begun an international collaborative project to study genotype-phenotype correlation in 300 HCH patients and to measure responses to growth hormone (hGH) treatment in a smaller subgroup. Each patient will have clinical data submitted (measurements, craniofacies, development, etc.), molecular analysis for known FGFR3 mutations, and skeletal radiographs. Radiographic measurements for comparison are being made on patients with achondroplasia (ACH) and controls without skeletal dysplasia. So far, we have molecular and limited clinical data on 142 patients and radiographs from 85 individuals. PRELIMINARY OBSERVATIONS: FGFR3 HCH tends to have more severe short stature, lumbar lordosis, disproportion, macrocephaly, and other craniofacial changes than non-FGFR3 HCH. Developmental delay/learning disability is increased in both groups. Iliac proportions measured from radiographs may be helpful in refining phenotypic definitions; a ratio between two vertical measurements (iliac base/wing height) separates controls (avg=0.48), HCH (avg=0.33), and ACH (avg=0.16); but each group has a broad range and there is overlap. DISCUSSION/PLAN: We will enroll more HCH subjects so that analyses can be performed on data stratified by age and molecular diagnosis, treat a group of 50 children (25 with and 25 without FGFR3 mutations) with hGH to measure growth response, and perform linkage studies using families not linked to FGFR3. Study enrollment information will be available at the meeting for clinical geneticists who follow patients with HCH and wish to participate.

Program Nr: 757 from the 1999 ASHG Annual Meeting

Terminal osseous dysplasia and pigmentary defects: Clinical characterization of a novel X-linked dominant syndrome. *C.A. Bacino[1], R. Amir[1], H. Heilstedt[1], R.A. Sierra[2], R. Lewandowski[2].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Center for Genetic Services, Corpus Christi, TX.

We describe a four generation pedigree with a total of 10 affected females presenting with limb deformities and pigmentary anomalies over the face and scalp. There were no affected males in the pedigree. Furthermore, some of the affected females had a history of multiples miscarriages, strongly suggesting an X-linked pattern of inheritance with male lethality. There was variability in the clinical expression of the phenotype among the affected individuals, which correlated with skewing of X-inactivation detected using a methylation assay at the androgen receptor locus. The family was initially ascertained through a four month old female with multiple congenital anomalies. She presented with dysmorphic features including hypertelorism, iris colobomas, low set ears, midface hypoplasia, pigmentary abnormalities over the face and scalp and limb anomalies. The limb abnormalities consisted of brachydactyly, more marked on the first and second digits, and widening of the fingertips with bumpy, hard, tumor-like lesions, more prominent on the third and fourth fingers (digital fibromas). The hand creases were markedly abnormal. The toes showed internal deviation of the second through fifth toes and generalized toe hypoplasia. In addition she was diagnosed with an atrial septal defect and a liver hamartoma. The proband's mother, female cousins via the maternal side, maternal aunts, and great grandmother were all similarly affected, some with very severe limb deformities. The bumpy digital lesions regressed with age as no digital fibromas were seen in the adult females. Other physical findings include multiple frenulae, abundant vermillion border of the lower lip, and other skeletal anomalies. This syndrome was previously described in the literature in sporadic cases by Bloem et al. (J Bone Joint Surg, 56-B(4):746-751, 1974) and Horii et al.(Am J Med Gen, 80:1-5, 1998). The family presented here shows a novel X-linked dominant condition with male lethality. Current efforts are underway to characterize the disease at the molecular level.

Program Nr: 758 from the 1999 ASHG Annual Meeting

CLINIC AND GENETIC ANALYSIS OF TWENTY SEVEN CASES OF RECURRENT / FAMILIAL HIDATIDIFORM MOLE. *R. Baez-Reyes, R. García Cavazos.* Dept de Genetica, Instituto Nacional de Perinatologia SSa. Mexico, City.

Hidatiform mole (HM) is a challenge regarding its etiopathology. The incidence of HM in our country ranges from 1:44 to 1:552 pregnancies. The risk of recurrence is about 1%. Twenty seven couples with a background of recurrent HM were received in the Genetics Deparment from 1994 to 1998. Clinical history, pedigree and cytogenetic studies were achieved. Families were dividided into three groups: I) couples with recurrent mole (17) II) couples with recurrent mole whose sisters had the same event (7) III) couples with recurrent mole whose sisters and mothers had the same alteration (3). The analysis of the data suggests and atypical inheritance pattern nontraditional from the mother, since all men of these families did not show any pattern of transmission; the recurrence of HM remained, even with either the programs of attended reproduction. All of the mentioned above has interesting etiological implications upon the cellular behaviour during meiosis in a woman's eggs; howewer, it has been difficult to explain this. Consecuently, we can suggest that our patients followed a pattern of atypical inheritance. Conclusions: Hidatidiform mole has a pattern of genetic inheritance wich follows a familial pattern; this leads us make molecular studies aimed to determine the meiotic origin of the alteration and to figure out the ratio of recurrence in these cases due to risk of long-lasting coriocarcinoma.

Program Nr: 759 from the 1999 ASHG Annual Meeting

Rubinstein-Taybi syndrome: deletions by FISH associated with mispatterning of the visceral left-right axis and death in infancy. *O. Bartsch[1], A. Wagner[1], G.K. Hinkel[1], P. Krebs[2], M. Stumm[2], B. Schmalenberger[3], S. Balci[4], F. Majewski[5]*. 1) Inst of Clinical Genetics, Technical University, Dresden, Germany; 2) Inst of Human Genetics, Otto-von-Guericke-University, Magdeburg, Germany; 3) Practice Dr Sigmund, Passau, Germany; 4) Dept of Pediatrics, Hacettepe University, Ankara, Turkey; 5) Inst of Human Genetics, Heinrich Heine University, Düsseldorf, Germany.

The Rubinstein-Taybi syndrome (RTS, OMIM 180849) is an autosomal dominant disorder of characteristic facial features, broad thumbs, short stature and mental retardation. Previous studies indicated that 4 - 25 % of patients have a chromosomal microdeletion on 16p13.3 of the CBP gene. Using FISH and cosmid probes RT100 (CBP exons 14-31), RT191(exons 3-13) and RT203 (intron 2) we studied 45 RTS patients and found 4 deletions (8.9 %). All deletions were interstitial; 3 spanned the CBP gene (RT100-RT203) and 1 was smaller (RT100 only). Previous studies failed to detect a phenotype-genotype correlation between RTS patients with vs. without a deletion. Our findings suggest a more severe phenotype. Mean age at presentation was .96 yrs vs. 11.12 yrs in patients with vs. without a deletion. Patients A and B with a deletion died in infancy which is rare in RTS and was not observed among the other patients. Patients A and D had accessory spleens, Patient A with hypoplastic left heart, abnormal pulmonary lobulation and agenesis of the right kidney and the right uterine horn. This is the first report of polysplenia and the second report of hypoplastic left heart in RTS. The signs represent defects of blastogenesis (defective left-right patterning of the unpaired internal organs). Drosophila *cbp* was recently shown to function as a co-activator of transcription factor *ci (cubitus interruptus)* in *hedgehog* signalling: a molecular pathway establishing left-right asymmetry during blastogenesis. Thus the signs of Patients A and D may possibly represent a newly recognized pattern of RTS, or alternatively a novel contiguous gene syndrome.

Program Nr: 760 from the 1999 ASHG Annual Meeting

The recombinant 4 syndrome due to an unbalanced pericentric inversion of chromesome 4. *A. Battaglia*[1], *A.R. Brothman*[2], *J.C. Carey*[2]. 1) Inst Child Neurology & Psych, Stella Maris nst/Univ Pisa, Pisa, Italy; 2) Dept Peds/Div Med Genet, Univ of Utah Health Science Ctr, Salt Lake City, UT.

We have evaluated an informative patient with an MCA/MR syndrome consisting of global developmental delay, short stature, microcephaly, distinctive face, abnormal ears, iris coloboma and a congenital heart defect. His karotype shows 46,XY,rec(4) dup(4p) inv(4) (p14q35.1) mat, i.e. he has a partial 4p trisomy/distal 4q deletion due to an unbalanced pericentric inversion inherited from his mother. The 4p trisomy syndrome was originally described in 1970 [Wilson et al., Am J Hum Genet 22:679] in a very similar case with the same chromosome 4 inversion. Since then there have been over 75 cases published, mostly due to unbalanced translocations. Recent reviews suggest that the phenotype is hard to recognize clinically because the features are non-specific and the pattern is not as reproducible as in many chromosome syndromes. In contrast, 4p trisomy due to an unbalanced pericentric inversion of chromosome 4(p14q35); i.e. the recombinant 4 syndrome seen here, appears to be a discreet entity with relatively consistent features. This is similar to the rec 8 syndrome due to an unbalanced 8 pericentric inversion. Our patient is very similar to the original one of Wilson et al. In total there are 4 other kindreds described in the literature with this inversion, and the phenotype seems recognizable. Thus, we suggest that recombinant 4 syndrome is a discreet entity among 4p trisomy patients.

Program Nr: 761 from the 1999 ASHG Annual Meeting

Mitochondrial Diseases: A Recognizable Pattern of Systemic Disease. *C.A. Bay[1,2], M.A. Del Vecchio[1], G.L. Matika[1]*. 1) Div Medical Genetics, Children's Hosp of Pittsburgh, Pittsburgh, PA; 2) Dept. of Pediatrics, University of Pittsburgh, Pittsburgh, PA.

Symptoms of mitochondrial diseases are a consequence of abnormalities of the general function of mitochondria: to generate energy in the form of ATP, and to act as an effector of apoptosis. Despite the popular notion that mitochondrial diseases are always maternally inherited, they can be inherited as mendelian traits. The majority of mitochondrial genes are encoded in nuclear DNA, thus, they should be considered in diseases consistent with mendelian inheritance patterns. Previously recognized diseases with symptomatology typical of a mitochondrial disorder should be reevaluated to determine if they have a mitochondrial basis. By summing all symptoms present in individual family members, and considering the symptoms as if in one individual, we have been more effective in recognizing the typical systemic pattern of illness. Rarely does one individual demonstrate all the classical features present in the literature. A complete review of systems of family members is necessary to truly exclude this class of disorders. Symptoms to consider include: short stature, seizures, neuropathy, ataxia, apnea, progressive neurodegeneration, myoclonus, dementia, migraines, strokes, hemiparesis, cerebral palsy, dystonia, deafness, pseudoobstruction, cyclic vomiting, hepatopathy, increased liver function enzymes, chronic diarrhea, vague abdominal pain, irritable bowel syndrome, food intolerances, myopathy, diabetes, retinitis pigmentosa or degeneration, optic atrophy, lipomas and exercise intolerance. Frequent laboratory findings include lactic acidosis, abnormalities of electron transport chain, hyperalaninemia, ragged red fibers, mitochondrial proliferation, iron deposition, and hyper/hypothyroidism. However, the absence of these features does not preclude a mitochondrial disease. Examples of disorders which probably have a mitochondrial etiology are: OMIM # 165490: Optic Atrophy, Deafness, Ophthalmoplegia and Myopathy, and OMIM#234200: Hallervorden-Spatz Disease.

Program Nr: 762 from the 1999 ASHG Annual Meeting

The neurocognitive and psychosocial profile in children with a 22q11.2 deletion. *C.E. Bearden[1], M. Woodin[2], E. Moss[2], P. Wang[3], D. Driscoll[4], B.S. Emanuel[4], D.M. McDonald-McGinn[4], T.D. Cannon[1], E.H. Zackai[4].* 1) Dept of Psychology, University of Pennsylvania, Philadelphia, PA; 2) Dept of Child Psychology, Children's Seashore House, Philadelphia, PA; 3) Dept of Child Development, Children's Seashore House, Philadelphia, PA; 4) Div of Human Genet and Mol Bio, The Children's Hospital of Philadelphia, Philadelphia, PA.

Previous work has demonstrated that verbal skills are typically better preserved than non-verbal skills on both IQ and academic achievement testing in children with the 22q11.2 deletion (Moss et al., 1999). However, such measures are not sufficiently specific to determine a selective cognitive deficit in these children. In addition, the psychosocial profile of these children has not been well characterized. Here we present the first study to systematically evaluate these two issues in a cohort of children with 22q11.2 deletions. The psychosocial profiles of 58 children aged 5-17 with 22q11.2 deletions were assessed using parent ratings on the Child Behavior Checklist (CBCL). Internalizing problems and attention problems were significantly elevated in this cohort, regardless of IQ level or variance between verbal and performance IQ. A subset of these children (N=28) was evaluated with matched tasks of verbal memory (WRAML Verbal Learning) and visuospatial memory (CMS Dot Locations task). Regardless of IQ level or verbal-performance IQ split, all subjects displayed a selective deficit in visuospatial memory. These results indicate that children with a 22q11.2 deletion display a specific cognitive and psychosocial profile that is not adequately characterized by IQ tests. Findings will be instrumental in developing specific remediation strategies and are a first step towards localizing the CNS pathology in this syndrome.

Program Nr: 763 from the 1999 ASHG Annual Meeting

Third familial case report of the Ohdo syndrome in 2 Brothers. *B. Benzacken, B. Heron, J. Gaudelus, P. Bitoun.* *Embr-Cytogen & Biolog Reproduction, Neuro-Pediatrie, Pediatrie, Genet Medicale, CHU Paris-Nord, Hopital Verdier, BONDY, 93143cedex France.

Ohdo(1986) described 2 sisters and paternal cousin with mental retardation, heart defect, blepharophimosis & ptosis and hypoplastic teeth. 14 patients have been reported : Say & Barber 1987, Biesecker 1991, Maat-Kievit et al 1991, 1993, Clayton-Smith et al 1994, Melnick 1994, da Silva-Lopes&Guion-Dalmeida 1997, Rasmussen & Stromme 1998,Mhanni et al 1998; most of them sporadic.Some patients have deafness and all males have had cryptorchidism and/or scrotal hypoplasia.Dysmorphism includes broad flattened nasal tip & depressed bridge. Clayton-Smith et al found no evidence of microdeletion. Mhanni's patient and mother both have a balanced paracentric inversion of 9q, a common finding, suggestive of autosomal dominant inheritance with partial penetrance. We report 2 brothers, 5 and 3 years born to unrelated healthy parents presenting with mental retardation, blepharophimosis, blepharoptosis, ectopic testes in one and VSD in the other. Hypotonia and developmental delay were noted in the first year and only the older brother is starting with very few simple words. Both Patients have small ears and height near -1 s.d. They both have had an enlarged spleen resolved in the eldest and lymphocyte enzyme studies for storage disease which have been normal. The older boy has lighter hair on forehead concentrically darker from blond to dark brown towards vertex unrelated to sun exposure.They have had normal brain CT scan & MRI ,one has epilepsy with EEG anomalies responsive to valproate.Complete ophthalmologic examination is planned as well as hearing testing. Secondary amblyopia is a major risk of this blepharoptosis and should be detected and treated early. Both sibs have a 46XY high resolution karyotype without evidence of microdeletion. Parents are without any signs of blepharophimosis, ptosis, cardiac or genital anomalies but mother does have an unusually broad and prominent nasal tip. Both parents have normal high resolution karyotype. The mother consulted for genetic counseling with a new partner. The genetic counseling dilemma of recurrent Ohdo syndrome is approached.

Program Nr: 764 from the 1999 ASHG Annual Meeting

Isochromosome 20q mosaicism: extraembryonic or fetal in origin. *J. Bergoffen[1], D. Thibodeau[1], D. Edwards[2], L. Bros[1], B. Saxon[1], K. Nguyen[1], S. Owen[1], D. Sipos[1], X. Li[1].* 1) Genetics Dept, Kaiser Permanente Medical Grp, San Jose, CA; 2) Perinatology, KPMG, Hayward,CA.

Most reported cases of isochromosome 20q mosaicism (21/23) have resulted in normal pregnancy outcomes without confirming the i20q in fetal tissues. We present the second case of i20q mosaicism prenatally detected by amniocentesis but confirmed postnatally by interphase fluorescence in situ hybridization (FISH) in a baby with multiple congenital anomalies.

JH was a 3.4 kg (50%) product of a 38-week gestation delivered by NSVD to a 33 yo mother. Serial prenatal ultrasonography showed echogenic bowel, cardiac defects, and ventriculomegaly. Amniocentesis revealed 46,XX,i(20)(q10)[38 colonies]/46,XX[1]. Newborn exam was remarkable for length 5-10%, HC at 75%, micro/anophthalmia, and distal digit anomalies. Imagining studies revealed coarctation of the aorta with valve anomalies, anomalous ribs and vertebrae, and brain malformations. Support was withdrawn on day 3 of life and the infant died.

Standard cytogenetic analysis of 50 cells each from cultured blood and placental tissues failed to reveal i20q cells. However, interphase FISH using telomeric probes specific for 20pter and 20qter (Cytocell Limited) detected i20q in 15% of cells (30/200) in a direct preparation of the placental tissue but only 2% (4/202) in the cultured placental tissue and none in the blood culture (0/500). Interphase FISH analysis of a direct urine sample detected i20q in 27% of cells (54/200), confirming a true fetal mosaicism of i20q.

We suggest that true fetal mosaicism for i20q can have syndromic features such as ocular, skeletal, cardiac, and CNS anomalies. While most prenatally detected cases have been associated with normal outcome and suspected extraembryonic origin, the possibility of true fetal mosaicism for i20q must be carefully investigated. We caution that PUBS may not be helpful in prenatal cases. Our findings suggest that i20q cells may be selectively lost in culture. We propose that interphase FISH on directly prepared tissues is the method of choice for the confirmation of i20q.

Program Nr: 765 from the 1999 ASHG Annual Meeting

Noonan syndrome: a clinical and genetic study of 31 patients. *D. Bertola[1], C.A. Kim[1], S.M.M. Sugayama[1], L.M.J. Albano[1], J.D.A. Carneiro[1,2], E.A. D'Amico[2], C.H. Gonzalez[1].* 1) Dept. of Pediatrics, Instituto da Crianca, University of Sao Paulo, Sao Paulo, Brazil; 2) Dept. of Hematology, Hospital das Clinicas, University of Sao Paulo, Sao Paulo, Brazil.

Noonan syndrome is an autosomal dominant disorder comprising short stature, facial dysmorphisms, webbed neck, heart defect, cryptorchidism in the males, skeletal defects and abnormal hematological indices. In the present study, 31 affected patients, belonging to 26 families, were studied regarding their clinical and genetic characteristics. The isolated and familial propositus were separately analyzed from the affected relatives. Short stature was present in 69% of the propositus. The most common craniofacial dysmorphisms were ocular hypertelorism (62%), ptosis (58%) and downslanting of the palpebral fissures (42%), as well as high-arched palate and dental malocclusion. A webbed neck occurred in 42% of the propositus. The most frequent cardiac lesions, presented in 73% of the cases, were pulmonary valvar stenosis and hypertrophic cardiomyopathy. The eletrocardiogram frequently showed a superior QRS axis deviation. The abdominal ultrasound indicated the presence of hepatomegaly, splenomegaly or renal anomalies in less than 10% of the cases. Cryptorchidism occurred in 50% of the male propositus. The most common limb anomalies were prominent fetal pads on the fingers and toes and short and wide nails. The sternal deformity occurred in 54% of the propositus and the vertebral anomalies were observed in 23%. Abnormal hematological indices were present in 31% of our propositus, especially factor XI deficiency. The relatives showed less signs of the condition when compared to the propositus. In the 24 families in which the propositus' parents and sibs were evaluated, three (12.5%) had more than one affected, and so were considered familial cases. Therefore, the majority of the cases were sporadic.

Program Nr: 766 from the 1999 ASHG Annual Meeting

Congenital heart disease in Goldberg-Shprintzen syndrome. *M.G. Bialer, S.B. Ritz, M.E. Olson.* Dept Pediatrics, North Shore Univ. Hospital/NYU School of Medicine, Manhasset, NY.

A 5 wk old Guyanese male of mainly Asian Indian ancestry was seen because of Hirschsprung disease (HSCR) and congenital heart disease (CHD). He was the 3860g product of a 40 wk gestation born by primary C-section for transverse lie to a 35 yr old non-consanguineous mother who had normal amniocentesis. Baby was cyanotic at birth and was found to have a PFO and high muscular VSD resulting in congestive heart failure. At 11 days he developed vomiting, lethargy and abdominal distention and passed a bloody stool. Rectal biopsy revealed HSCR. He was hospitalized 3 times for pneumonia. His weight and OFC fell off the normal curve and follow-up visits identified a number of new problems including hypotonia, developmental delay and strabismus. Dysmorphology exams have revealed wide flat nasal bridge, epicanthal folds, broad bulbous nasal tip, pre-auricular pit, large ears, 5th finger clinodactyly, full lower lip, high arched palate, mild micrognathia with somewhat pointed chin, undescended testis, mild joint laxity, and somewhat hyperextensible skin. MRI scan of brain was normal. Sleep disturbance is a continuing problem and he will often stay awake all night. Blood chromosomes and FISH for Williams and Smith-Magenis syndrome deletions revealed no abnormalities. Findings are suggestive of Goldberg-Shprintzen syndrome (GSS). GSS is a rare autosomal recessive condition initially described in siblings with HSCR, submucous cleft palate, microcephaly, short stature, dysmorphic features and developmental delay. At least 23 cases with similar features have subsequently been described. Syndrome nosology may evolve. Although earlier cases of GSS had submucous cleft palate and iris coloboma, few subsequent cases have. CHD was not described in the earlier cases, but this is the 8th subsequent case with CHD. Other cases have had ASD, ASD/PDA, VSD, PS, PA/VSD, ASD/TOF, and PDA/PPS. Only 3 cases have lacked HSCR, and 2 were the sibs of an affected child with HSCR. Since all the other features, except developmental delay, have been variable, it seems probable that HSCR may also be, and the condition may be more common than previously thought.

Program Nr: 767 from the 1999 ASHG Annual Meeting

Variability in the behavior phenotype of the de Lange syndrome. *G.M. Bibat, G.V. Raymond.* Div Neurology & Dev Medicine, Kennedy Krieger Inst, Baltimore, MD.

The de Lange syndrome (dLS) is a developmental malformation syndrome characterized by mental retardation, growth delay, distinctive facial features, and limb reduction defects. A behavior profile described includes poor social relatedness, aggressive, disruptive, and self- injurious behavior. While a well-recognized condition, there may be considerable variability in its phenotypic expression and the full range of behavioral abnormalities has not been delineated. A retrospective review from 1994-1999 was conducted. Six patients with dLS were identified. They all had the characteristic facial features which included microbrachycephaly, synophrys, anteverted nares, triangular nasal tip, crescent-shaped mouth, and micrognathia. In addition, all had postnatal growth deficiency (4 of the 6 patients had prenatal growth retardation) and limb anomalies ranging from brachydactyly, camptodactyly, syndactyly, clinodactyly, to phocomelia of the upper extremity. Four of the six had karyotypes which did not reveal any abnormalities. All six had cognitive and behavioral abnormalities. Mental retardation ranged from mild to profound. One patient had mild articulation disorder while another was nonverbal (used sign language). Three of the 6 had some degree of hearing loss. Behavioral diagnosis included ADHD, oppositional defiant disorder, obsessive compulsive disorder, aggressive and disruptive behavior, stereotypies, and self-injurious behavior. Treatment included in most cases stimulant medications for inattention, mood stabilizers, and neuroleptic agents for aggression when appropriate. Response to medication was variable. Two of the 6 required admission to a psychiatric behavioral unit for aggressive and self-injurious behavior. Their behavior was described as explosive physical outbursts; destructive head banging episodes; and life threatening elopement. Both had severe to profound mental retardation. One patient had severe pica involving inedible objects (screws, lids, and coins) requiring surgical removal. The behavioral profile of dLS appears to correlate with the severity of their clinical features and cognitive potential, but additional study is necessary to determine the full range of behavior and most effective therapeutic approach.

Program Nr: 768 from the 1999 ASHG Annual Meeting

Diphallia: Case Report and Discussion of Etiologic Mechanisms. *R.D. Blackston.* Div Med Gen, Dept Pediatrics, Emory Univ Sch Medicine, Atlanta, GA.

Penile duplication (PD) is a very rare congenital anomaly with an estimated occurrence of 1 per 5 million live births in the United States. PD is rarely seen in isolation but as part of a cluster of congenital anomalies: spina bifida, vertebral, renal, anorectal and hindgut duplication. It is thought that these clusters of anomalies may be the result of an insult to caudal cell mass at approximately day 23 to 25 of gestation. We report a 6 week old Mexican-American male with diphallia seen in one of our genetic outreach clinics. He was an alert, handsome infant who had two complete penises with two crura on each penis. The anus was proximal and to left of the midline. There was a mass on the right buttocks consistent with meningocoele, confirmed by MRI scan. Plain films showed abnormalities of the lumbar spine with some tethering of the cord. There were two kidneys each with a urethra draining into separate bladders. The mechanism of PD and the associated anomalies in our patient may be explained by duplication of the caudal body elements of mesodermal origin. Between 21 and 35 days of gestation mesoderm migrates caudally separating the urogenital sinus from the rectum and the genital tubercle, later the phallus results from merging of the paired columns of mesoderm. The diphallia could also be the result of defect in migration of mesoderm through the cloacal membrane early in embryogenesis. Some initial work on Drosophila suggests a defect in homeobox genes as the mechanism of diphallia. We report another case of the rare anomaly diphallia. Significant emotional trauma can be spared frightened, confused parents by careful and continued support that their sons will have full productive lives.

Program Nr: 769 from the 1999 ASHG Annual Meeting

Microcephaly-Micromelia Syndrome in the Cree Indians of Northern Saskatchewan. *P.M. Blakley[1, 2], L.B. Holmes[1], R.E. Casey[2]*. 1) Genetics & Teratology Unit, Massachusetts General Hosp, Boston, MA; 2) Dept Pediatrics, Royal University Hosp, Saskatoon, Saskatchewan, Canada.

Microcephaly-Micromelia Syndrome (MMS) is a constellation of lethal, congenital malformations observed in the offspring of the Cree First Nation people living in LaRonge, Saskatchewan. It was first recognized in the 1950's and at that time was responsible for 20% of neonatal deaths among the Cree people. It has not been observed in the Caucasian population of LaRonge or in the offspring on other First Nation reserves. MMS is inherited in an autosomal recessive manner.

Twenty-two infants with MMS were identified through medical records at Royal University Hospital, Saskatoon. All infants were noted to be severely growth retarded with birth weights, lengths and head circumferences <3rd%. Microcephaly and cerebral dysgenesis were observed in all infants. Characteristic facial features, including prominent nose, micrognathia, microstomia, microphthalmia and craniosynostosis, were reported in 63% of infants. All infants had evidence of limb reduction deformity, manifested as aplasia/hypoplasia of the radius/ulna and absent digits. 29% of affected infants had three or less digits per hand. The arms were more severely affected than the legs. Other defects included congenital heart (58% of infants), renal (42%), musculoskeletal (33%), endocrine (33%), gastrointestinal(25%), respiratory (25%) and genital defects (17%).

The differential diagnosis of MMS includes Microcephaly Osteodysplastic Primordial Dwarfism I and III, Seckel Syndrome and Cerebro-Oculo-Facial-Skeletal Syndrome. While the facial features are similar to MMS, limb reduction deformities and lethality are not characteristic of these syndromes.

Molecular DNA studies, utilizing homozygosity testing of markers associated with microcephaly and limb defects, are currently in progress to define the chromosomal locus associated with MMS.

The present study describes a unique syndrome observed in the Cree people. Delineation of the molecular basis for MMS will allow for carrier testing and prenatal diagnosis.

Program Nr: 770 from the 1999 ASHG Annual Meeting

RNASEH1 gene in 17p11.2 deleted in Smith-Magenis syndrome (SMS). *J.K. Blancato[1], T. Lin[1], G. Veytsman[1], R.J. Crouch[2], S.M. Cerritelli[2], A. Gropman[3], A.C.M. Smith[1,3].* 1) Institute Molec. & Human Genetics, Georgetown Univ Medical Ctr, Washington, DC; 2) Laboratory of Molec. Genetics, NICHD/NIH, Bethesda, MD; 3) Med. Genetics Branch, NHGRI/NIH, Bethesda, MD.

Smith-Magenis syndrome (SMS) is a contiguous gene deletion syndrome of 17 p11.2 associated with a complex phenotype of characteristic physical features, clinical signs of peripheral neuropathy, developmental delay, and neurobehavioral problems, including sleep disturbance and self-injurious behaviors. Estimated to occur in 1/25,000 births, more than 150 cases have been identified worldwide from a diversity of ethnic groups. While most patients have a common SMS deletion interval spanning 4-5Mb, deletions have ranged from <2 to >9. Recently, the RNASEH1 gene was mapped to 17p11.2 region (Cerritelli & Crouch, 1998). Subsequent sequencing data, including lack of intron sequences, suggest this is a putative pseudogene. Although the RNASEH1 gene is in the region, it does not appear to be within the critical SMS interval. It is deleted in 2 of 10 SMS patients studied by FISH with a plasmid probe for the RNASEH1 gene. Clinically, these two females appear to have more severe involvement of the peripheral nervous system than classical SMS. Molecular studies confirm they have larger deletions extending distally, including deletion of the PMP22 gene and D17S122 and D17S261. Case 1, a female previously described as Patient #118-484 by Zori et al.(1993), now demonstrates progressive nerve conduction abnormalities consistent with bilateral peroneal (ankle) and median nerve (wrist) compression neuropathy. While Case 1 represents the only known case of an inherited deletion from a mosaic carrier mother, Case 2 has a de novo deletion of paternal origin based on DNA marker analysis. This is the first report of a possible pseudogene in the SMS region in the growing literature describing low copy repeat sequences and their association with chromosomal rearrangements, and specifically, microdeletion syndromes. Fiber FISH with known SMS markers is currently being used to better order the RNASEH1 gene and further define the breakpoints in these two children. *Cerritelli SM and RJ Crouch (1998) Genomics 53(3):300-307.*.

Program Nr: 771 from the 1999 ASHG Annual Meeting

Male to male transmission of Costello syndrome consistent with autosomal dominant inheritance. *N.M. Bodkin[1], E.S. Mortimer[2], L.A. Demmer[1]*. 1) Department of Pediatrics, Univ of Massachusetts Memorial Health Care, Worcester, MA; 2) Department of Orthopedics, Univ of Massachusetts Memorial Health Care, Worcester, MA.

Costello syndrome is a rare disorder involving mental retardation and multiple congenital anomalies. At least 52 patients have been reported with almost all cases presenting as isolated incidents in a family. Therefore the inheritance pattern has not yet been identified. Here we present the case of a 12 year old male with classic Costello syndrome whose father has many of the features of this disorder in an asymmetric pattern on his body suggestive of mosaicism.

Consistent with the marasmic phase of Costello syndrome, our patient's father has a history of feeding problems and failure to thrive in early childhood. Hyperkeratosis, seen in 88% of reported cases of Costello syndrome, was noted on both of his hands and was extreme on his left foot but absent on his right. Also remarkable was the asymmetrical presentation of anal papillomata which were present on the right but not left perianal region. Nasal papillomata had previously been removed. His affable personality, history of low normal intelligence scores, hyperpigmentation, thick ear lobes, increased AP diameter in the chest and patches of curly in his otherwise straight hair are all features consistent with Costello syndrome.

This apparent father to son transmission suggests that Costello syndrome is inherited as an autosomal dominant disorder. We predict that the father of our patient is a mosaic for Costello syndrome, probably the result of a post-zygotic mutation. Many of the previously reported affected males have a history of undescended testes and several of the females have a history of delayed puberty or amenorrhea. This suggests that infertility may be a feature of Costello syndrome and may account for the fact that there have been no other reported cases of vertical transmission of the disorder. Careful examination of the parents of all affected individuals is recommended when considering recurrence risk for Costello syndrome.

Program Nr: 772 from the 1999 ASHG Annual Meeting

Shprintzen-Goldberg syndrome (SGS): Report of 2 affected half siblings. *A. Bogdanow[1], P. Levy[1], A. Shanske[1], R.J. Shprintzen[2], R. Marion[1]*. 1) Ctr for Congenital Disorders, Montefiore Medical Ctr, Bronx, NY; 2) Communications Disorders Unit, Health Science Center at Syracuse, Syracuse, NY.

First described by our group in 1982, SGS combines craniosynostosis, MR, characteristic facial features, and other skeletal and connective tissue defects. Although AD inheritance is supported by a mutation in FBN1 in at least one of the clinical subtypes of this disorder, SGS has occurred in 3 sibs born to unaffected, non-consanguineous parents (Ades et al., AJMG , 1995). This has raised the possibility of either AR inheritance or AD with germinal mosaicism in one of the parents. We describe affected half sibs, an observation supporting the latter hypothesis.

Patient 1, the 3.86 kg product of an uncomplicated pregnancy born to a 20 yo primigravida, was admitted to the ICU at 6 weeks because of obstructive apnea (requiring tracheostomy) and FTT (necessitating a gastrostomy).. The infant had brachyturricephaly, ocular proptosis with downward obliquity and hypertelorism, low-set posteriorly rotated ears, high arched palate, pectus excavatum, and arachnodactyly of fingers and toes. A 3D CT scan revealed partial closure of the sagittal, lambdoidal and coronal sutures and ventriculomegaly. A diagnosis of SGS was made. Patient 2, his half sib, was the 3.64 kg product of his mother's second pregnancy. He had many of the same craniofacial and digital anomalies. In addition, he had malrotation of the intestines and an aberrant right subclavian artery. Examination of the mother and both fathers revealed no features of SGS or of a connective tissue dysplasia.

The occurrence of SGS in 2 half sibs born to unaffected, non-consanguineous parents provides further support for the conclusion that SGS has AD inheritance with germinal mosaicism. Five of the 21 patients described to date are the result of germinal mosaicism indicating the frequency of this occurrence in SGS. This must be kept in mind when these families are counselled.

Program Nr: 773 from the 1999 ASHG Annual Meeting

PAX3 missense mutations (G99S and R270C) in the original patient described with Klein-Waardenburg (WS3) syndrome. *A. Bottani, S.E. Antonarakis, J.L. Blouin.* Division of Medical Genetics, Geneva University Hospital, Geneva, Switzerland.

In 1947, David Klein in Geneva described (Arch Jul Klaus Stiftg 1947; 22: 336) a 10 year-old female with a previously unreported condition consisting of "partial albinism, deaf-mutism, osteomyodysplasia, multiple congenital joint contractures, and other congenital malformations". Parents were non consanguineous and phenotypically normal. This condition has since been called Klein-Waardenburg or Waardenburg type 3 (WS3) syndrome.We reexamined the 62 year-old proposita at her home, where she lives independently despite her striking physical handicaps. Sequence analysis of PCR-amplified genomic DNA from this patient revealed two PAX3 gene missense mutations which occured in conserved aminoacids of important PAX3 domains: G99S in exon 2 (encoding the paired box) and R270C in exon 6 (encoding the homeobox). Mutations of the same residues have previously been described in classical Waardenburg syndrome type 1 (WS1) heterozygotes. The origin (de novo vs inherited?) of the patient's mutations cannot be determined, as parents are deceased. This study confirms that WS3 is due to PAX3 mutation(s) and is thus allelic to WS1. It also shows that compound heterozygosity and, as previously reported, homozygosity for PAX3 mutations can lead to a severe, but compatible with long term survival, Waardenburg syndrome phenotype.

Program Nr: 774 from the 1999 ASHG Annual Meeting

Split cognitive function in an intelligent adult with Joubert syndrome despite dramatically hypometabolic cerebellum. *D.G. Brooks[1,2], M.M. Kurtz[3], J. Farmer[1], G. Liu[4], L. Harper Mozley[3], R.C. Gur[3], C.A. Friedrich[1]*. 1) Div. Medical Genetics; 2) Dept Genetics; 3) Neuropsychiatry Program; 4) Depts of Neurology and Ophthalmology, Hosp Univ Pennsylvania, Philadelphia, PA 19104.

Hypoplasia of the cerebellar vermis and adjacent brainstem/midbrain are characteristic of Joubert syndrome (JS). These anatomic deficiencies underlie the clinical features of JS: hypopnea, hypotonia, ataxia, developmental delay and abnormal eye movements. In a rare, high functioning adult with JS we investigated cerebellar metabolic activity as well as visual and cognitive function. The proband is a 25 year old female with coarse features, macrocephaly, synophrys and mandibular prognathism. She had generalized hypotonia, dysmetria, ataxic/shuffling gait and slow, dysarthric speech. By history there was apnea, hypotonia, delayed motor development, ataxia, tongue thrusting, dysconjugate gaze and preaxial polydactyly. She completed 1 year of college. MRI revealed hypoplastic superior cerebellar vermis, an enlarged 4th ventricle and mild cortical volume loss. PET scan revealed marked, uniform cerebellar hypometabolism. Fundoscopic examination was normal and an ERG was attenuated with compromised rod and slightly impaired cone responses. Corrected visual acuity was 20/400 OD and 20/80 OS; visual fields were constricted peripherally OU. There was ptosis, diffuse ophthalmoparesis and supranuclear gaze palsy. In contrast to severe MR in JS children, selective cognitive difficulties were apparent on neuropsychological testing. Strengths included general knowledge, expressive vocabulary, verbal comprehension/retention. Weaknesses included problem solving, visual memory and sensory-motor testing. Overall borderline intellectual function was evident by the following IQs: full scale 77, verbal 88 and performance 68. Although the cerebellar deficit seen on MRI is restricted to vermian hypoplasia this first ever PET scan of a JS patient shows hypometabolism of the entire cerebellum. The resulting severe motor dysfunction as well as visual/perceptual difficulties can mask considerable intelligence in JS. This case has implications for prognosis, genetic counseling and education of JS patients and families.

Program Nr: 775 from the 1999 ASHG Annual Meeting

Mild clinical features of 18q deletion and trisomy 19q seen in a child with a novel 18;19 translocation. *T.C. Brown[1], C. Kozma[2], J. Meck[3].* 1) Genetic Studies Section/LSB, NIAMS/NIH, Bethesda, MD; 2) Department of Pediatrics, Georgetown University Medical Center, Washington, D.C; 3) Department of OB-GYN, Georgetown University Medical Center, Washington, D.C.

Monosomy 18q first described in 1964, is well defined clinically. Patients with 18q- syndrome have been reported with the following: growth and mental retardation, facial dysmorphism, and multiple congential anomalies (MCA). The phenotypes are highly variable with a general correlation between the size of the deletion and the phenotypic severity. Cytogenetically the deletions appeared to include 18q21.2-18qter. Molecular analysis showed that some deletions were complex interstitial rearrangements. The critical region has been reported to be 18q23. Fewer chromosome 19q duplications have been reported in the literature. Along with cardiac anomalies, the phenotypic anomalies are similar to 18q- syndrome. 19q13 terminal duplications have been reported. No genes identified in these two regions are the primary cause of the phenotypic abnormalities. We describe a unique case involving a 4 year old girl with both partial monosomy 18q and partial trisomy 19q [46,XX,der(18)t(18;19)(q21.3;q13.42)mat]. We are not aware of similar cases in the literature. She presents with growth retardation, repaired ASD, repaired abdominal wall defect, repaired anteriorly placed anus, partial hearing loss, and delayed myelination documented on MRI. She has mild midface hypoplasia, upslanted palpebral fissures, bilateral nystagmus, and borderline low set ears. In addition, she has bilateral clinodactyly, small hands and feet, altered palmar creases, and hypotonia. She is currently receiving growth hormone injections for growth hormone deficiency and delayed bone age. She is independent in feeding and ambulation and communicates verbally by using one-two word sentences. These mild phenotypic features are surprising since the 18q monosomy is rather large and is coupled with 19q trisomy. This novel case should provide more information for recurrence risks and allow for refinement of the phenotypic map of these chromosomal regions.

Program Nr: 776 from the 1999 ASHG Annual Meeting

Human HOX-A1 gene and hindbrain malformations. *V. Capra[1], A. Moroni[1], P. De Marco[1], A. Faiella[2], E. Boncinelli[2], A. Cama[1]*. 1) Lab Servizio Di Neurochirurgia, Inst Scientifico G Gaslini, Genova, Italy; 2) DIBIT,Ospedale San Raffaele, Milano,Italy.

During hindbrain development, Hox genes provide regional specification and morphogenetic identity to the rhombomeric segments. Functional inactivation of Hox-a1 gene results in complete or near complete deletion of rhombomere 5 (r5) and severe reduction of r4 suggesting that Hoxa1 is acting in maintenance and/or generation of hindbrain segments. Hox-b1 instead is restrictly expressed in rhombomere 4 and its role is to give segmental identity to this region, that will give rise to the rhomboencephalon. The Hox-b1 and Hox-a1 double mutant phenotype seems to confirm functional interaction of these genes in determining hindbrain structure, cranial nerves and second pharingeal arch derivatives patterning. Furthermore Hox-a1-/- homozygotes have malformations of the basioccipital and exoccipital bones of the skull and of the external, middle and inner ear. Our patients present variable complex phenotypes including deafness, cranio-facial and vertebral anomalies (like Chiari I and Dandy-Walker malformation) that closely resemble Hox-a1 and/or Hox-b1 mutants mice. We assessed the presence of genomic mutations HOXA1 genes by means of the Single Strand Conformation Polymorphism (SSCP) technique in 30 sporadic cases of hindbrain malformations. We failed to find any mutated fragment on the coding region of the gene. Different paralogous homeobox genes expressed in the hindbrain will be analyzed. Acknowledgement: This project has been supported by Comitato Promotore Telethon E. 795.

Program Nr: 777 from the 1999 ASHG Annual Meeting

A NOVEL N114D TWIST MUTATION IN A CROUZON-LIKE PATIENT. *C. Carbonara[1], L. Sbaiz[2], L. Genitori[3], P. Peretta[3], F. Mussa[3], C. Nurisso[3], G. Restagno[2], S. Belli[4], G.B. Ferrero[1]*. 1) Dept Pediatrics, Univ di Torino, Torino, Italy; 2) Medical Genetic Lab., OIRM, Torino; 3) Pediatric Neurosurgery, OIRM, Torino; 4) Genetic Counselling Service, Trento.

Craniosynostosis, the premature closure of one or more cranial suture occur in about 1/2500 infants and represent an heterogeneous group of disorders. Recently mutations in the TWIST gene, a helix-loop-helix transcription factor, have been reported in patients presenting with Saethre-Chotzen syndrome, characterized by facial asymmetry, ptosis, hypertelorism, brachydactyly and cutaneous syndactylies. Here we report a novel mutation of the TWIST gene in a patient presenting with brachycephaly, severe ocular proptosis and no limb anomalies, features not typical of Saethre-Chotzen syndrome, rather of Crouzon syndromes phenotype. The A to G transition at position 340 leads to the aminoacid change N114D in the DNA binding domain and presumably alters the affinity of the mutated TWIST protein for its DNA target sequence. The presence of the mutation has been confirmed both by direct sequencing and by digestion with the MscI restriction enzyme. The phenotypically normal parents have been investigated both by sequencing and by MscI digestion and found normal. The patient has been also screened for mutation in the FGFR2 gene (exons IIIa and IIIc) and FGFR3 (exon 7) and found normal. This newly described mutation is likely to be pathological for the following reasons. 1) it represents a de novo mutation; 2) missense mutation of nearby codons have been already reported in Saehtre-Chotzen patients; 3) asparagine at position 114 is highly conserved in other species. The description of this patient shows that heterogenous conditions might be associated with TWIST mutations, as it has been already observed with FGFR2 and FGFR3 mutations.

Program Nr: 778 from the 1999 ASHG Annual Meeting

Molecular analysis of a hermaphrodite patient with triploid-diploid mosaicism. *A.K.J. Chan[1], T.L. Stockley[2], I. Teshima[2], P.N. Ray[2], D. Chitayat[3]*. 1) Clinical Genetics, The Hospital for Sick Children, Toronto, ON; 2) Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON; 3) The Prenatal Diagnosis Program, University of Toronto, Toronto, ON, Canada.

Triploid-diploid mosacisim is an uncommon condition and its association with hermphroditism has rarely been described. We present a triploid-diploid mosaic patient with hermaphroditism who was investigated using molecular microsatellite analysis. The patient presented at birth with ambiguous genitalia and was found to have a left-sided ovotestis and a right-sided ovary, each associated with a fallopian tube. A normal uterus and vagina were present. Cytogenetic analysis indicated a normal 46XX female karyotype in blood (n=50), and interphase nuclei (n=200) were negative by FISH for the Yp11.2 probe (Oncor). A 46XX/69XXY mosaic karyotype was found in the ovotestis and skin fibroblasts. Cytogenetic analysis estimated the percentage of triploid cells to be 36% in ovotestis and 33% in skin.

Molecular STR analysis was used to determine the formation of the diploid-triploid mosaicism. DNA was extracted from the patient's blood and ovary tissues and from the triploid-diploid mosaic ovotestis and skin tissues, as well as from parental blood samples. Analysis of microsatellite polymorphisms from nine different chromosomes indicated that the triploid-diploid mosaic tissues contained two paternal markers at certain loci, suggesting that the triploid cells were diandric in origin. The triploid cells likely originated from dispermy as indicated by random assortment of paternal microsatellite markers to the triploid-diploid mosaic tissues. Possible mechanisms for triploid-diploid mixoploidy include fusion of a diploid and a triploid zygote to produce a chimera, or alternatively mosaicism resulting from loss or gain of a haploid genome. Molecular results suggest that the most likely mechanism for triploid-diploid mixoploidy in this patient is not chimerism but is mosacisim resulting from gain or loss of a paternal genome.

Program Nr: 779 from the 1999 ASHG Annual Meeting

Mapping of the Translocation Breakpoint in a Patient Displaying Morbid Obesity and Features of the Coffin-Siris Syndrome. *F.F. Chehab[1], M. Golabi[1], J. Qiu[1], G. Magrane[1], P. Cotter[2].* 1) Departments of Laboratory Medicine and Pediatrics, University of California, San Francisco, CA; 2) Division of Medical Genetics, Children's Hospital, Oakland, CA.

The search for genes that underlie predisposition to obesity will improve understanding of body weight regulation and increase our ability to treat obesity-associated disorders. Coffin-Siris syndrome (CSS) is a multiple malformation syndrome with growth deficiency, undetermined mode of inheritance and an unknown molecular basis. We report an 11 year-old female who presented initially with features resembling those seen in Coffin-Siris syndrome. Hypertrichosis, sparse scalp hair, coarse facial features, hypoplastic fifth fingernails and mental retardation were observed in early infancy. Karyotype revealed 46, XX and a de novo translocation between 7q32 and 22q12. At 11 years, she developed severe obesity, which has never been reported to be associated with CSS. An individual diagnosed with CSS was previously found to carry a translocation at 1q21 and 7q34. Therefore, it is likely that the region around 7q32-34 might underlie the gene for CSS. Interestingly, the same chromosomal region includes the leptin gene, which is mutated in few morbidly obese individuals. Although it is possible that her obesity may be distinct and separate from her multiple malformation syndrome and be due to disrupted genes on both derivative chromosomes, it is also conceivable that both features could represent disruption of a gene on chromosome 7. Structural rearrangement of the leptin gene was ruled out based on a normal genomic Southern blot probed with leptin cDNA and a leptin level of 32 ng/ml, which correlated, with her BMI of 34.4. Yeast artificial chromosomes (YACs) which bracket the translocation breakpoint were assembled from chromosome 7 and spanned approximately 12 cM. Fluorescent in situ hybridization (FISH) with YACs from the contig and chromosome spreads from this patient allowed us to narrow down the critical region to 500 kb. Current efforts aimed at molecular cloning of the breakpoint region will yield genomic fragments from chromosomes 7 and 22 and reveal insights into the nature of interrupted genes.

Program Nr: 780 from the 1999 ASHG Annual Meeting

Neurological and dysmorphic features in a family with brachial plexus neuropathy. *A. Chen, M. Kovach, V. Kimonis.* Div. of Genetics & Metabolism, Dept Pediatrics, Southern Illinois Univ, Springfield, IL.

Hereditary neuralgic amyotrophy (MIM 162100) or familial plexus neuropathy is an autosomal dominant disorder characterized by the onset of recurring episodes of back pain and muscle weakness early in childhood. Affected individuals also have hypotelorism or closely spaced eyes. Although the molecular basis for this disorder remains unknown, genetic linkage has been established to chromosome 17q24-q25 (Pellegrino et al. 1997; Stogbauer et al. 1997). We report a four-generation family presenting with autosomal dominant brachial plexus neuropathy. The proband a 16 y. old male presented with pain and atrophy of his left deltoid, suprascapular, rhomboid muscles (causing winging of his scapular) and abductor pollicis brevis muscle. A further episode of pain in his right arm did not lead to permanent loss of function. Dysmorphic evaluation in him revealed hypotelorism and small palpebral fissures. His father age 47 y. was asymptomatic, however had hypotelorism. His paternal uncle age 49 y. has had a history of recurrent episodes of pain preceding weakness in his arms since the age of 17 y. He has marked wasting of the muscles in his hands and similar facies. The paternal grandmother developed recurrent paralysis in both arms since a pregnancy at the age of 24 y. She also developed weakness of her legs, became bedbound this leading to her death at the age of 54 y. Genetic linkage analysis with chromosome 17q24-q25 markers was performed in six family members (2 affected, 1 carrier, 2 unaffected, and 1 spouse). The power of the pedigree was not sufficient to generate significant LOD scores (maximum LOD score 0.109 at a recombination fraction = 0.00 for marker D17S802), however haplotype analysis with markers D17S802, D17S939 and D17S1603 revealed a shared haplotype among affected individuals. This study further confirms the lack of heterogeneity of this interesting familial disorder causing facial dysmorphisms and recurrent episodes of neuropathy.

Program Nr: 781 from the 1999 ASHG Annual Meeting

Fragile X Premutation Status in a Male with Mental Retardation. *E.J. Chernoff[1], M. Nunes[2], B. White[3], J. McClellan[2], E. Coll[4], K. Maggio[5], S. Levin[4].* 1) Heritable Disorders Branch, NICHD, National Institutes of Health, Bethesda, MD; 2) USAF Medical Genetics Center, 81st Medical Group, Keesler AFB,MS; 3) Quest Diagnostics, Nichols Institute, San Juan Capistrano, CA; 4) Department of Pediatrics &; 5) Dept of Dermatology, Walter Reed Army Medical Ctr, Wash. D.C.

Fragile X syndrome(FXS) is the most common form of inherited mental retardation(MR). It is caused by expansion of CGG repeats in the 5' exon of the FMR1 gene, known as full mutation(FM), and subsequent methylation of the CpG island. Mosaicism of gene repeat length or methylation has been documented and tissue heterogeneity has been demonstrated(AJMG 84:233,1999).

We report a 8 yr old male with moderate MR, the product of a term pregnancy complicated by oligohydramnios, growth retardation and placental calcifications. History is notable for bilateral cryptorchidism, recurrent otitis media, gastroesophageal reflux and strabismus. His nonconsanguineous parents had two prior first trimester pregnancy losses; there was no family history of MR. Exam noted rocker bottom feet with valgus deformity, right simian crease and hyperpigmentation on the abdomen and thighs. Our blood karyotype was found to be 46,XY (550 band level). Our analysis of fibroblasts from biopsies of hyperpigmented and normally pigmented skin was also 46,XY. However, fragile X analysis from blood and the 2 fibroblast sites showed a premutation(PM) of 100-165 repeats compared to a maternal PM in blood of 70-90 repeats by Southern blot. Methylation was normal .

Although our patient had MR and other features consistent with FXS and not due to a cytogenetic abnormality, a cell population with FM could not be demonstrated in blood or skin. While MR in this case may be caused by factors other than fragile X status, the finding of a PM expansion beyond that of his mother suggests the two findings may be related. Expansion to a FM could have occurred in the brain or other tissues not studied. Even though a FM was not detected in our patient, similar studies of skin fibroblasts should be considered to rule out this possibility in dysmorphic males with unexplained MR who have a PM and normal karyotype in peripheral blood.

Program Nr: 782 from the 1999 ASHG Annual Meeting

Rubinstein-Taybi syndrome with hepatoblastoma. *J. Claus, B. Kousseff, J. Ranells.* USF Regional Genetics Program, Tampa, FL.

We report a two-year old male patient, with Rubinstein-Taybi syndrome, phenylketonuria and hepatoblastoma. The patient, GP, was the first child of a 35-year old gravida 2 para 0-0-1-0 mother. The mother has mitral valve prolapse and left conductive hearing loss secondary to abnormal ossicles. Prenatal triple marker screen indicated an increased risk for Down syndrome. Amniocentesis was declined. Fetal sonograms suspected a Dandy-Walker variant with no hydrocephalus and severe IUGR. Delivery was at thirty-two weeks gestation by emergency Cesarean section for pre-term labor and vaginal bleeding secondary to subchorionic hematoma. Apgar scores were 6/8; birth weight was 1282 g (75th centile; corrected for gestation), birth length was 38 cm (5th centile; corrected), and OFC was 27 centimeters (5th centile; corrected). The umbilical cord had three vessels and was thick. A large PDA was diagnosed. He required a ventilator and phototherapy. EKG was abnormal with right axis deviation. Genetics consult revealed a prominent nose, pencil-like eyebrows, low-set ears, hypoplastic nipples, undescended testes, broad first digits and angulated thumbs. Hypotonia was noted. The impression was Rubinstein-Taybi syndrome. Indomethacin reduced the PDA. Newborn metabolic screening at 6 days of age showed a phenylalanine level of 8 mg/dl. Follow up level was 62.2 mg/dl at 15 days of age. He was diagnosed with classic PKU. Neopterin, biopterin and dihydropteridine reductase levels were normal. Karyotype was 46,XY. Ophthalmalogic evaluation was normal. Cranial sonograms showed no posterior fossa abnormality. MRI scan showed increased signal on the periventricular and subcortical white matter. The finding was considered nonspecific and possibly consistent with prematurity. Renal sonogram showed slightly small kidneys with mild left hydronephrosis. At two years of age GP presented with chronic constipation and feeding difficulties as well as low grade fevers and an enlarged liver. A surgical biopsy showed hepatoblastoma. Although a variety of rare tumors have been reported in individuals with Rubinstein-Taybi syndrome, this is the first report of hepatoblastoma in this condition.

Program Nr: 783 from the 1999 ASHG Annual Meeting

A novel WT1 mutation in Frasier syndrome: Support for the concept of the "WT1 spectrum disorder". *C.L. Clericuzio[1], F. Byrn[1], V. Huff[2]*. 1) Univ New Mexico Sch Medicine, Albuquerque, NM; 2) UT MD Anderson Cancer Center, Houston, TX.

The WT1 gene acts as both a regulator of normal genitourinary development and a tumor suppressor gene. Germline mutations of WT1 have been found in individuals with a wide range of genitourinary malformations and Wilms tumor (WT) risk. The clinical triad of male genital ambiguity, early onset nephropathy and high WT risk has been identified as the Denys-Drash syndrome (DDS). Greater than 95% of DDS patients have germline WT1 mutations, which are often missense mutations in the zinc finger coding regions. A somewhat distinct pattern of genitourinary malformation, characterized by complete sex reversal in XY individuals, later onset nephropathy and low WT risk has been termed the Frasier syndrome (FS). Approximately 20 FS individuals have been reported to have WT1 donor splice site mutations in intron 9, predicted to produce an altered ratio of alternative splice products.

We report a FS patient with a novel WT1 point mutation at the 5' splice junction of exon 10, which is also predicted to alter WT1 splicing. Our patient's genitourinary phenotype is atypical for FS in that she had clitorimegaly and a rudimentary testis.

This patient illustrates blurring of the distinction between DDS and FS genitourinary phenotypes. Likewise, while DDS and FS have been historically distinguished from one another by high WT risk in the former, and nil risk in the latter, Barbosa (1999) report a FS patient with WT and a typical mutation. Further compounding the question of WT risk in individuals with genitourinary anomalies, is the identification of protein truncating WT1 mutations in boys with WT and cryptorchidism/hypospadias (CH), who have no nephropathy.

In light of the lack of clear distinction between DDS/FS/CH phenotypes associated with WT1 mutations, we suggest that the term "WT1 spectrum disorder" be adopted to encompass the range of disorders which can arise from alterations in the WT1 gene. Within the spectrum, there remain general phenotype-genotype correlations.

Program Nr: 784 from the 1999 ASHG Annual Meeting

PROP1 gene analysis in familial and sporadic CPHD. *J.D. Cogan[1], J.A. Phillips[1], J.L. Carneal[1], L.K. Hedges[1], D.A. Doyle[2]*. 1) Dept Pediatrics/Genetics, Vanderbilt Univ, Nashville, TN; 2) Temple University, School of Medicine, Philadelphia PA.

Combined pituitary hormone deficiency (CPHD) has an incidence of ~1/8,000 births with ~10% of cases having an affected first degree relative. Affected individuals have growth failure, delayed or incomplete sexual development with infertility, features associated with combined deficiencies of anterior pituitary hormones including growth hormone, TSH, LH, FSH, PrL, and ACTH. There are now two genes known to cause CPHD in humans - PIT1 and PROP1. While the number of families with reported PIT1 defects is small, preliminary studies indicate that the proportion of familial cases with PROP1 defects is significant. In this study we screened a series of affected individuals for mutations in the PROP1 gene. Here we report three new mutations found in the PROP1 genes of affected individuals but not in normal controls. Two of the mutations were identified in a pair of affected sibs who were both found to be compound heterozyotes with the maternal allele containing a C®T transition in the 16th codon and the paternal allele containing a G®A transition in codon 120. The C®T transition converts a CGA(Arg)® TGA(stop) codon terminating protein synthesis after amino acid 15. The G®A transition converts a CGC(Arg)®CAC(His) which corresponds to amino acid 52 in the third helix of the highly conserved homeodomain of PROP1. The third mutation was a heterozygous G®C transversion in codon 51 identified in two sporadic cases. This substitution converts a GGG(Gly)®GCG(Ala) and was not found in normal controls (0/30). From this study we conclude that heterogeneous defects in the PROP1 gene contribute to the ideology and spectrum of the CPHD phenotype observed in familial and sporadic CPHD subjects.

Program Nr: 785 from the 1999 ASHG Annual Meeting

Okihiro Syndrome, 3 new cases - is this an under diagnosed cause of deafness and 'squint'? *L.A. Colvin, M.I. Van Allen.* University of British Columbia, Vancouver, BC, Canada.

Okihiro (DR, MIM 126800) syndrome is a reportedly rare AD disorder with variable expression of sensorineural hearing loss, Duane's anomaly and thenar eminence hypoplasia. Only a half-dozen families and as many case reports are in the literature. Due to lack of awareness and subtle presentation of radial ray anomalies, we think Okihiro syndrome is an under diagnosed cause of deafness and 'squint'. Case A: 7 year old with Duane's anomaly, thenar hypoplasia and proximal placement of the thumb, conductive hearing loss, a submucous cleft and C3 and C4 fusion of lateral masses. She has a 46,XX, 22q.ish negative karyotype and a family history of a maternal grandfather with Duane's anomaly, and palatal cleft in a cousin. Case B: 3 and 6/12 year old with Duane's anomaly, thenar hypoplasia, truncal hypotonia, and plagiocephaly, normal development. She has 46,XX, karyotype and positive family history of 'squint' and lazy eyes. Case C: 7 year old female with Duane's anomaly, thenar hypoplasia, moderate hearing loss bilaterally, cleft palate, malar hypoplasia, mild micrognathia, microcephaly, developmental delay and vertebral abnormalities, but normal kidneys. She has a 46,XX, karyotype and family history mental retardation and isolated cleft lip. The variable presentation includes radial ray anomalies, ranging from thenar eminence hypoplasia with or without abnormally positioned thumbs, to absent thumbs and radius. Deafness is congenital and usually sensorineural. Less frequently reported anomalies are cervical vertebral anomalies, palatal clefts and renal anomalies. Okihiro syndrome overlaps with acro-renal-ocular syndrome. It is distinct from Fanconi syndrome, Holt-Oram syndrome, Wildervanck syndrome and 22q partial duplication and 22q11.2 deletion syndrome.

Program Nr: 786 from the 1999 ASHG Annual Meeting

BONE DYSPLASIAS AND IMPLICATIONS FOR GENETIC COUNSELING. *H.A. Cooper, J. Crowe, M.G. Butler*. Section of Medical Genetics and Molecular Medicine, The Children's Mercy Hospitals and Clinics, Kansas City, MO.

We report an 11-year-old male with a rare short stature syndrome. His height was 106.1 cm (-4 SD). He had a coarse appearing face with a depressed nasal bridge, short upturned nose, and mid-face hypoplasia. His intelligence was normal. Based on clinical evaluation at six years of age, the diagnosis of spondyloepiphyseal dysplasia (SED) was suspected. However, repeat genetic evaluation with radiologic studies at 11 years of age revealed delayed carpal ossification (-4 to 5 SD), striations of the metaphyses most notably in the distal femurs and the proximal tibias, lumbar lordosis, narrow interpedicular distance of the lumbar spine, and pear-shaped vertebral bodies with increased calcification of the concave surfaces. These findings are consistent with the diagnosis of SPONASTRIME (SPOndylar and NAsal changes, with STRiations of the MEtaphyses) dysplasia, and not SED.

SPONASTRIME dysplasia is a rare, autosomal recessive bone disorder first described by Fanconi et al. in 1983. Radiographic findings include abnormal vertebral bodies with age dependent changes, striations of the metaphyses, lumbar lordosis, scoliosis, and retarded ossification of the carpal bones. Physical features include severe short stature, midface hypoplasia, frontal bossing, and a saddle shaped nose. To date, 13 patients from seven families have been reported. Four additional patients have been reported with a variant of this condition, which includes mental retardation. Radiographic findings of SPONASTRIME dysplasia are distinguishable from SED, even though the physical appearance may be similar. The diagnosis of bone dysplasias can be difficult, as exemplified by this patient. Many bone dysplasias have overlapping radiographic findings and clinical presentation, but with different recurrence risks making genetic counseling a challenge.

.

Program Nr: 787 from the 1999 ASHG Annual Meeting

Congenital diaphragmatic hernia in genetics. *K.P. Cusmano[1], B.G. Kousseff[2]*. 1) Pediatrics/Genetics, University of South Florida, Tampa, FL; 2) same.

Between 1-2-82 and 4-15-99 through the USF Genetic Clinics there were 93 probands with suspected or confirmed congenital diaphragmatic hernia (CDH) of the 35,414 probands/families evaluated. 50 were seen through the prenatal clinics. Among them were 5 in whom CDH was subsequently excluded; 3 had congenital cystic adenomatoid malformation of the lung, 1 had bronchogenic cyst, and 1 had trisomy 18. 24 survived and 26 expired including 3 miscarriages, 2 stillbirths, and 4 terminations. 34 had associated anomalies. Among these were 8 probands with Pentalogy of Cantrell, all deceased and previously reported [BDOAS 30:189-202, 1996]. The remaining 26 probands had in addition to CDH, a single defect, constellations of anomalies that were non-syndromic or syndromic CDH. The remaining 16 patients in the prenatal group had solitary CDH. 43 probands were evaluated through the pediatric genetic clinic. 17 survived and 26 died. 28 had associated abnormalities, 13 had solitary CDH. In this group there were 3 families each with first degree relatives having CDH. In one, sisters were affected; one of them had total anomalous pulmonary vein return. In the other, mother and daughter had solitary CDH. In the third, 2 brothers had CDH. This family most likely had autosomal dominant private syndrome with short stature, cleft palate, blepharophimosis, MVP, cryptorchidism, hypotonia and cardiomyopathy. Apart from the syndromic CDH there was no predilection towards a particular constellation of anomalies. Unique malformations included cyclopia, arhinia, proboscis, aphallia and blepharophimosis, all were with normal karyotypes. The syndromic CDH included 3 probands with Fryns syndrome and 1 each with Marfan, Saethre-Chotzen, Brachmann-DeLange, Ivemark, hypomelanosis of Ito, HARD, and limb-body wall syndromes. 9 patients had Pentalogy of Cantrell. CDH was found in 2 probands with trisomy 21 and in 1 each with trisomy 22 secondary to maternal translocation [11; 22], del 8p, mono 9p, del 15q and partial trisomy 1q. There were 3 maternal translocations, t [1; 9], t [11; 22] and t [7;13]. Despite having ECMO since 1993, in our experience CDH is still a high mortality genetically very heterogeneous condition without causative clues in solitary CDH.

Program Nr: 788 from the 1999 ASHG Annual Meeting

Christians Spondylo- digital syndrome: First sporadic male case.. *N.O. Dávalos[1,2], I.P. Dávalos[1,2], M.O. García-Cruz[3], Z. Nazará[4], D. García-Cruz[1,2]*. 1) Div. Genética, CIBO-IMSS, Guadalajara, México; 2) Doctorado en Genética Humana, CUCS-UdeG, Guadalajara, México; 3) Servicio de Labio y Paladar Hendido, HGR #46, IMSS, Guadalajara, México; 4) Servicio de Radiología, HE-CMNO, IMSS, Guadalajara, México.

The Christians spondylo-digital syndrome has been previously delineated in two familial cases (mother and daughter affected in both), it is characterized by metacarpal and metatarsal asymmetry, tarsal and carpal fusions, syndactyly, articular dysplasia and platyspondyly. The purpose of this paper is to describe the first sporadic male case in the literature. CASE REPORT: The propositus was 16 years old. Since birth unilateral cryptorchidism and digital malformations were detected. He also showed psychomotor delayed. Clinically he showed on the left hand: distal flexion contractures of 2nd 5th fingers with wide knucles and radial deviation of the distal phalanx of the 5th finger; radial deviation of 4th and 5th fingers, ulnar deviation of 2nd finger and prominent metacarpophalangeal joints. On the right hand: distal flexion contractures of 2nd, 4th and 5th fingers, wide knucles of 2nd, 4th and 5th fingers, ulnar deviation of 2nd and 3rd fingers, prominent metacarpophalangeal joints, bilateral cutaneous syndactyly, absence of distal interphalangeal creases, and thenar and hypothenar hypoplasia. Bilateral hallux valgus and shortened 2nd-5th fingers in both feet. He also presented oral anomalies: mandibular prognathism, permanent dentition with dental malposition and crowding, and a high-arched V-shaped palate. The routine laboratory examination, and karyotype yielded normal or negative results.The cardiologic and EKG evaluation were normal. Since the 2 previous familial reported cases were females, an autosomal dominant inheritance could be more feasible than a dominant X-linked inheritance, mainly by the presence of moderate clinical features noticed in the present case. On the other hand, the fact that female cases are more severely affected than the present male case, probably could be explained by maternal genomic imprinting. Althougth more cases must be studied to confirm this hypothesis.

Program Nr: 789 from the 1999 ASHG Annual Meeting

New families referred for confirmation of diagnosis of Marfan syndrome: the experience of a multidisciplinary approach in Wales. *S.J. Davies[1], M. Nicol[1], V. Booker[2], D. Wilson[2], A.G. Stuart[2].* 1) Inst Medical Genetics, Univ Hosp Wales, Cardiff, Wales; 2) Congenital Heart Unit, University Hospital of Wales, Cardiff, Wales.

New referrals to a multidisciplinary team for confirmation of diagnosis of Marfan syndrome (MFS) were reviewed for the three years from 1st of March 1995. Investigation included a full family history, reviewing clinical notes with consent, clinical examination, cardiological evaluation and ophthalmologic assessment. Eighty-eight new families were referred. The probands were 58 males and 30 females aged between 1 and 75 years. 162 individuals were evaluated according to the criteria of the Ghent nosology. Seventeen families had been referred with a definite diagnosis of Marfan syndrome (MFS), ten families had a family history of a first degree relative with diagnosed MFS and sixty-one families were referred with a queried diagnosis of MFS. Following investigation, three of the seventeen families with a definite diagnosis were reassigned as unaffected as they did not fulfil the diagnostic requirements. The ten probands referred with a 50% risk were all unaffected and in one family the diagnosis was incorrect on the supposed affected parent. Five families were diagnosed as having a condition other than MFS, namely contractural arachnodactyly, annulo aortic ectasia, Ehlers- Danlos Type IV, Stickler syndrome and dominant ectopia lentis. Eight new families were diagnosed as having MFS. These included 14 affected individuals, 7 adults and 7 children. Three probands had other affected family members whilst five were sporadic. Only one of these newly diagnosed families had a history of MFS cardiac related deaths. Overall 22 families were confirmed or newly diagnosed as MFS (25%). In 17 families the diagnosis was changed (19%). In 57 families the diagnosis could be refuted following careful assessment (64%). This review emphasises the importance of a multidisciplinary approach to the diagnosis of Marfan syndrome where a correct diagnosis is essential to prevent major complications. Furthermore, an incorrect diagnosis leads to unnecessary screening and anxiety about health, insurance etc.

Program Nr: 790 from the 1999 ASHG Annual Meeting

First report of two siblings with apparently isolated odontohypophosphatasia: Dominant or recessive inheritance? *A.B. Decker*[1], *C.T. Coccia*[2], *G.L. Feldman*[1]. 1) Medical Genetics, Henry Ford Hospital, Detroit, MI; 2) Pediatric Dentistry, Henry Ford Hospital, Detroit, MI.

Hypophosphatasia is characterized by reduced activity of tissue non-specific alkaline phosphatase (TNSALP), elevated serum pyridoxal 5'-phosphate (PLP) concentration, and increased urinary phosphoethanolamine (PEA) levels. Hypophosphatasia is heterogeneous, ranging from neonatal death caused by profound skeletal hypomineralization, to premature loss of primary teeth. Odontohypophosphatasia describes dental abnormalities and biochemical evidence of hypophosphatasia, with no evidence of bone involvement. Odontohypophosphatasia is often considered within the spectrum of hypophophatasia. Dominant and recessive inheritance have been described for odontohypophosphatasia. We report two siblings with premature loosening and loss of primary incisors (ages 24 and 26 months), low TNSALP levels and elevated PLP levels. PEA analysis has not yet been performed. Radiographic studies of the hands and knees of both sibs were normal, and there is no history of fractures, bowing or joint pain. The parents have no history of premature loss of teeth, other dental, bone or joint symptoms. However, the father has decreased TNSALP levels and elevated PLP levels, suggestive of biochemical evidence of TNSALP gene expression. The mother has serum TNSALP levels in the lower normal range, and normal PLP levels. Hypophosphatasia may result from two abnormal alleles which alone or in combination may cause the disease. One abnormal allele may function in an autosomal dominant manner, resulting in a mild phenotype. If two abnormal alleles are present, a more severe phenotype may result. The TSNALP gene has been localized to chromosome 1 (1p34-36.1), and over 70 mutations have been described. This family may represent autosomal dominant inheritance, with variable expressivity in the father, or autosomal recessive inheritance. Mutation analysis is in progress for this family. Although studies have found specific mutations and deletions associated with the various forms of this condition, genotype-phenotype studies are needed to learn more about the changes in the TNSALP gene and the mode of inheritance.

Program Nr: 791 from the 1999 ASHG Annual Meeting

A novel disorder of Pena-Shokeir phenotype and pachygyria due to autosomal recessive inheritance. *K.M. Dent[1], C.E. Miller[2], J.C. Carey[1], C.O. Leonard[1]*. 1) Pediatrics, University of Utah, Salt Lake City, UT; 2) Ob/Gyn, University of Utah, Salt Lake City, UT.

The Pena-Shokeir phenotype or fetal akinesia/hypokinesia sequence is a rare, lethal disorder characterized by multiple joint contractures, pulmonary hypoplasia, CNS dysfunction and distinctive facial anomalies including hypertelorism, low-set malformed ears, micrognathia, and depressed nasal tip. The etiology of the Pena-Shokeir phenotype is heterogeneous and no specific cause or pathogenesis has been identified in a substantial portion of cases. This is due, in part, to the difficulty of defining discrete subsets of children with the Pena-Shokeir phenotype that are etiologically related to one another. For example, severe joint contractures are characteristic of many disorders (e.g., cerebro-oculo-facio skeletal syndrome, lethal multiple pterygium syndrome, and Neu-Laxova syndrome) that result in diminished fetal movement. We describe a single family with three female siblings born to non-consanguineous parents sharing a unique constellation of features that define a discrete subset of children with the Pena-Shokeir phenotype. In addition to multiple congenital contractures and pulmonary hypoplasia, these infants had varying combinations of pachygyria, adrenal hypoplasia, hypertelorism, cleft palate, short neck, overlapping fingers, and varus deformities with rocker bottom foot. Polyhydramnios was observed in all three pregnancies. The third pregnancy was diagnosed prenatally due to polyhydramnios, contractures, clubfoot, and decreased fetal movement. All died shortly after birth due to respiratory insufficiency. Chromosome analysis (including FISH for 17p in one patient) was normal in all three cases. While pachygyria has been described in cases with congenital contractures, the phenotype of these children is different. This condition likely represents a new, probably autosomal recessive disorder.

Program Nr: 792 from the 1999 ASHG Annual Meeting

A new disorder or a variant form of Chanarin-Dorfman syndrome in twin sisters. *V.M. Der Kaloustian[1], J. Davignon[2], C. McCuaig[3], T. Babineau[1], B. Moroz[4], J.P. Roman[5], S. Melançon[5].* 1) The F. Clarke Fraser Clinical Genetics Unit, Departments of Pediatrics and Human Genetics, Montreal Children's Hospital and McGill University, Montreal, Quebec, Canada;; 2) Clinical Research Institute of Montreal, Montreal, Quebec, Canada;; 3) Department of Dermatology, Ste-Justine Hospital and Université de Montréal, Québec, Canada;; 4) Department of Dermatology, Montreal Children's Hospital and McGill University, Montreal, Quebec, Canada;; 5) Department of Medicine, CHUM, Université de Montréal, Montréal, Québec, Canada and Procréa, Services Génétiques, Montréal, Québec, Canada.

We present identical twin sisters with thick, yellow-brown, greasy and hyperkeratotic lesions of the face, scalp, and various parts of the trunk and extremities. The onset of the condition was at the age of 16 years in one of them and 27 years in the other. The clinical picture also includes Raynaud phenomenon and autoimmune thyroid disease. Mitral regurgitation is present in one of the sisters and scoliosis in the other. The eyes and intelligence are normal.

Histology of the skin reveals hyperkeratosis and a marked hypertrophy of the sebaceous glands, with small lipid vacuoles in the cytoplasms of the epidermal basal cells. Electron microscopy confirmed the intracytoplasmic location of the lipid vacuoles, without a surroundiing membrane, in the cells of the basal cell layer. These findings favour the diagnosis of the Chanarin-Dorfman syndrome.

Lipoprotein electrophoresis reveals a more rapid migration towards the anode. Cholesterol esters are found in the tears. The blood levels of retinol are very low. An excess of oxoproline (pyroglutamic acid) is present in the cutaneous lipid exudate with normal urine levels of all organic acids.

In spite of a strong suggestion of the Chanarin-Dorfman syndrome by skin biopsy, we believe that our patients have many clinical and laboratory differences, pointing to a variant form of this syndrome or a completely new entity.

Program Nr: 793 from the 1999 ASHG Annual Meeting

Macrocephaly in autism pedigrees. *C.K. Deutsch[1,2], S. Folstein[1,3], H. Tager-Flusberg[1,4], K.G. Gordon-Vaughn[1,3].* 1) Psychobiology Program, Eunice Kennedy Shriver Ctr, Waltham, MA; 2) Harvard Medical School, Boston, MA; 3) New England Medical Center, Boston, MA; 4) University of Massachusetts, Boston, MA.

A number of laboratories have found increased brain volume and macrocephaly to be statistically overrepresented in autism. Is this cranial enlargement uniform, or during development are some brain and cranial vault regions disproportionately affected? We have used objective, quantitative measures of craniofacial dysmorphology to assess cranial dimensions in a sample of 108 autistic probands. We have confirmed a statistical excess of increased head circumference in autism (25.0%; macrocephaly defined as a z-score greater than 1.5), exceeding the population baserate of 6.7% ($p < .01$). Goodness-of-fit tests reveal that the circumference scores in the autistic group are shifted in the direction of higher scores relative to the general population, yet a Gaussian distribution is still maintained. There was a marked increase in cranial width measured between the left and right eurion ($p < .01$). In contrast, the cranial length (the anterior-posterior linear distance between the glabella and opisthocranion) was normal, creating a brachycephalic pattern. Further, the presence of macrocephaly and increased biparietal width are predictive of the autistic probands' behavioral phenotype. The subgroup of patients with enlarged cranial dimensions is particularly intellectually impaired in comparison to autistic individuals with normal head size, with a specific impact on language skills. The dysmorphic phenotype described above for autistic probands was also seen among their first-degree relatives, even among those who did not meet criteria for autism ($N = 50$). The rate of macrocephaly among parents ($N = 39$) was 15.8% ($p < .05$) and among non-autistic siblings ($N = 11$) was 36.4% ($p < .01$). The pattern of excessive cranial width but not length was maintained among relatives ($p < .05$ and n.s., respectively). These data imply a specificity of brain growth patterns in autistic macrocephaly that is conserved among relatives. The implications of these findings for models of brain maldevelopment are also discussed. (This research was supported by NIH PO1 DC03610, R01 MH55135, and P30 HD04147.).

Program Nr: 794 from the 1999 ASHG Annual Meeting

Hypothyroidism in an infant with ectodermal dysplasia and cleft lip and palate. *J. DiMartino-Nardi[1], A. Palomba[2], A. Shanske[1]*. 1) Pediatrics, Montefiore Medical Center, Bronx, NY; 2) Pediatrics, Bronx Municipal Hospital Center, Bronx, NY.

The association of ectodermal dysplasia (ED) and clefting deformity is well known and has been reported in patients with a variety of disorders.A combination of oral clefting, ectropion and ED are the cardinal features of the blepharocheilodontic syndrome.Reports of ED and hypothyroidism are rare.We recently evaluated an infant with ED, cleft lip and palate and primary hypothyroidism.

AK was the 3.8 kg product of an uneventful pregnancy born to consanguineous Pakistani parents with a left-sided cleft lip and palate,ectropion,and dermoid cysts on the face and scalp.He was admitted at 4 months of age to our hospital because of respiratory distress.His physical examination at that time revealed a malnourished hypotonic infant with the additional findings of ankyloglossia, a large fontanelle, sparse lashes, absent eyebrows and normal nails. His length was 59 cm, weight 4 kg, and HC was 38.5 cm.The anterior fontanelle measured 5 by 4.5 cm and the primary dentition had not yet erupted. Imaging studies revealed a pericardial effusion, dilated loops of bowel, the bone age of a newborn, the absence of tooth follicles, and a normal MRI of the head.Laboratory investigation revealed a normal male karyotype,a TSH greater than 700mU/ml,a barely detectable level of T_4,and a normal cortisol.He was begun on synthroid therapy with resolution of the pericardial effusion and slow weight gain.

The association of ED and clefting is a rare event and when reported usually includes nail dysplasia.Our patient has normal nails,dermoid cysts,ectropion,and anodontia as well as hypothyroidism.It is difficult to implicate the action of a teratogen because of the variability of the critical times of origin and the involvement of derivatives of 2 germ layers.However, consanguinity suggests homozygosity for a single pleiotropic recessive gene.In fact, Zadik (Clin Dysmorph 1:24-27, 1983) reported a case with dermoid cysts,hyothyroidism,cleft palate and hypodontia.We propose that this and our case represent a discrete disorder.

Program Nr: 795 from the 1999 ASHG Annual Meeting

Female with autistic disorder and monosomy X (Turner syndrome): parent-of-origin effect of the X chromosome.

S.L. Donnelly[1], C.M. Wolpert[1], M.M. Menold[1], J.R. Gilbert[1], M.L. Cuccaro[2], G.R. DeLong[3], M.A. Pericak-Vance[1]. 1) Center for Human Genetics, Department of Medicine, Duke University Medical Center, Durham, NC; 2) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC; 3) Division of Neurology, Pediatrics, Duke University Medical Center, Durham, NC.

Skuse et al. (*Nature*, 1997) had previously reported three patients with the co-occurrence of Autistic Disorder (AD) and monosomy X (Turner syndrome) as part of a study examining social cognition and parent-of-origin effect of the X chromosome. They concluded that monosomy X individuals with a maternally-derived X chromosome exhibited more deficits in social cognition and verbal I.Q. than individuals with a paternally-derived X chromosome. We have independently ascertained and examined a fourth documented patient with idiopathic AD and monosomy X. The patient met DSM-IV/ICD-10 criteria for AD verified by the Autism Diagnostic Interview Revised (ADI-R) and exhibited both social and verbal deficits. Based on the findings of Skuse et al., we conducted parent-of-origin studies in our proband by genotyping X chromosome markers in the patient and her parents. We found that the patient's X chromosome was of maternal origin. These findings provide further support for the hypothesis that parent-of-origin of the X chromosome influences social cognition and could provide insight into the preponderance of males with AD.

Program Nr: 796 from the 1999 ASHG Annual Meeting

A new association comprising congenital hydrocephalus, albinism, megalocornea, retinal coloboma, and cryptorchidism. *P. Dubé[1], V.M. Der Kaloustian[2], R.K. Koenekoop[1]*. 1) Department of Ophthalmology; 2) Departments of Pediatrics and Human Genetics, McGill University, Montréal, Québec, Canada.

We present a 5 year-old-boy with congenital hydrocephalus, prominent metopic ridge with trigonocephaly, albinism, megalocornea, retinal coloboma, bilateral epicanthic folds, depressed nasal bridge, micrognathia, low-set ears, cryptorchidism, developmental retardation and generalized hypotonia. The clinical presentation resembles the deletion 9p syndrome. However, the karyotype is normal 46,XY. Certain features such as congenital hydrocephalus, albinism, megalocornea, and retinal coloboma have not been reported as part of the deletion 9p syndrome. We therefore suggest that this is a new association that has not been described previously in the literature.

Program Nr: 797 from the 1999 ASHG Annual Meeting

Acrocallosal syndrome with MRI findings of perisylvian syndrome: expansion of the phenotype. *S.A.K. Durrani*[1], *C.J. Tifft*[2]. 1) Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 2) Department of Medical Genetics, Childrens National Medical Center, Washington D.C.

Acrocallosal syndrome is an autosomal recessive disorder featuring postaxial polydactyly, limb anomalies and an absent corpus callosum. Here we describe a patient with the additional features of perisylvian changes on MRI, median cleft lip and bronchial anomalies.

The patient is a 13 year old 46,XY male who presented at birth with a midline cleft lip and multiple limb anomalies. The past medical history is also notable for multiple bronchial stenoses and tracheomalacia, and a slipped capital femoral epiphysis. He has cognitive deficits and significant motor and language delays. The family history is significant for a distant maternal relative with syndactyly of hands and toes.

The child is macrocephalic and brachycephalic with a short narrow forehead and palpable metopic ridge. There is synophrys and bilateral epicanthal folds. The nose has a broad alar base and bulbous tip. The major helices are incomplete and the lobules large. A repaired midline cleft lip with linear striae along both nasolabial folds and preauricular regions are noted. The left thumb is broad, short and medially deviated. The right hand has medial deviation of the third and lateral deviation of the fourth fingers. The fifth finger is hypoplastic and duplicated. The radii are long bilaterally preventing full extension and pronation. The child is moderately obsese. An MRI demonstrates bilateral perisylvian hypoplasia, a hypoplastic corpus callosum and a posterior fossa arachnoid cyst.

Acrocallosal syndrome has a broad clinical presentation including macrocephaly, hypertelorism, polydactyly, limb anomalies, arachnoid cyst, occipital prominence and dysplastic corpus callosum as seen in our patient. MRI changes suggestive of the perisylvian syndrome have not been previously reported. This case may represent a widened clinical spectrum for the disorder.

Program Nr: 798 from the 1999 ASHG Annual Meeting

Craniosynostosis in Prader-Willi syndrome: association or coincidence? *S. Dyack[1], M. Sgro[2], I. Teshima[3], P. Ray[3], L. Steele[3], A. Lowinsky[2], D. Chitayat[1,4].* 1) Div. Clinical & Metabolic Genetics, Hosp for Sick Children, University of Toronto, Toronto, ON, Canada; 2) Dept. Obstetrics/Gynecology, University Health Network, UofT, Toronto, ON, Canada; 3) Pediatric Lab Medicine, Hosp for Sick Children, UofT, Toronto, ON, Canada; 4) The Prenatal Diagnosis Program, UofT, Toronto, ON, Canada.

Prader-Willi syndrome (PWS) is a genetic condition most commonly associated with a deletion of 15q11-13 on the paternal chromosome. Affected patients present in the neonatal period with hypotonia, feeding difficulties, failure to thrive, and characteristic facial features. Craniosynostosis has not been reported in association with this condition. We report a patient with Prader-Willi syndrome and craniosynostosis. The patient was born to a healty 34 year-old G5P4SA1L4 woman of Pakistani descent, and a 36 year-old healthy father of the same descent. The parents were nonconsanguineous. There was very little antenatal care prior to the third trimester. Ultrasounds performed at approximately 32 and 36 weeks gestation revealed a breech position, and no fetal anomalies. The mother reported poor fetal movements throughout the pregnancy. The baby was delivered vaginally at term after induction of labor. Her birth weight was 3180 grams and the Apgar scores were 7 and 8 at 1 and 5 minutes respectively. Severe hypotonia and dysmorphic features were noted at birth, including an abnormal head shape. A skull x-ray and a 3D CT scan showed bicoronal suture craniosynostosis. Chromosome analysis was 46,XX and FISH analysis using probes for SNRPN and D15S10 showed a deletion of 15q11-13. DNA analysis for FGFR2 and 3 was performed and no mutation was detected. Review of the literature revealed 1 case of PWS with craniosynostosis; however, neither x-rays nor CT scan were done to confirm the craniosynostosis.

In summary, this is the first case of PWS and confirmed craniosynostosis. We speculate that the deletion of 15q11-13 resulted in a deletion of a dominant gene or genes associated with craniosynostosis.

Program Nr: 799 from the 1999 ASHG Annual Meeting

Progressive erosive arthropathy, characteristic non-coarse facies, malar erythema, facial telangiectasia, and multiple Nevi: A new syndrome. *A.M. Elliott[1], E.M. Azouz[2], A.S. Teebi[1]*. 1) Depts Peds & Human Genetics, MCH & McGill Univ, Montreal, PQ, Canada; 2) Deptartment of Diagnostic Imaging, MCH & McGill Univ, Montreal, PQ, Canada.

Syndromic forms of progressive arthropathy are extremely rare. They are either associated with significant epiphyseal and/or vertebral involvement suggestive of a skeletal dysplasia or with multisystem involvement suggestive of a storage disorder or a disorder of proteins of the extracellular matrix. We report a 27-year-old man with an apparently new syndromic form of progressive erosive arthropathy and contractures of small and large joints associated with mild epiphyseal changes, normal vertebrae and generalized osteopenia. The patient has a characteristic craniofacial appearance, dermatological abnormalities, and normal intelligence. The head is large with frontal bossing; the face is elongated with malar hypoplasia, thin upper lip, prominent lower jaw, high arched palate, dental malocclusion, and prominent ears with absent ear lobules. Dermatological abnormalities include malar erythema and facial telangiectasia together with multiple nevi and lentigens all over the body. Pseudorheumatoid arthropathy, spondyloathropathy, and Borrone dermatocardioskeletal syndrome (Am J Med Genet 46: 228-234, 1993) were considered in the differential diagnosis and were excluded. Also, no similar cases have been found in POSSUM or London Dysmorphology databases.

Program Nr: 800 from the 1999 ASHG Annual Meeting

Progressive Encephalopathy-Edema-Hypsarrhythmia-Optic atrophy (PEHO) syndrome. *G.M. Enns[1], A. Plump[2], C.S. Hoyt[3], E. Sherr[4], V.A. Cox[2], M. Golabi[2]*. 1) Div. Med. Genet., Stanford Univ.,CA; 2) Div. Med. Genet., U.C.S.F., CA; 3) Dept. Ophthal., U.C.S.F., CA; 4) Div. Ped. Neurol., U.C.S.F., CA.

PEHO syndrome is an autosomal recessive infantile encephalopathy of unknown origin. Typical findings start at age 2 weeks to 3 months and include postnatal microcephaly, severe hypotonia, hyperreflexia, infantile spasms, and extremity edema. Facial features are characterized by a narrow forehead, epicanthic folds, puffy cheeks, midface hypoplasia, protruding earlobes, high-arched palate, and open mouth. A small cerebellum and/or brainstem are often present. PEHO syndrome has been primarily described in the Finnish population, aside from two case reports in single Japanese and French Canadian families. We present two patients with different ethnic backgrounds with PEHO syndrome. Patient 1 is a 17 month old boy of mixed European descent born to non-consanguineous parents. A lack of visual tracking, hypotonia, and hypsarrhythmia were noted in infancy. Postnatal microcephaly, optic atrophy, characteristic facial features, tapering digits, and peripheral edema were also present. A head MRI at 9 months showed gray matter heterotopias and hypoplasia of the corpus callosum, pituitary, and pons. Metabolic labs and karyotype were normal. Patient 2 is a 3 year old Hispanic girl born to consanguineous parents. Clinical findings similar to patient 1 were present in infancy. A head MRI at 4 months showed delayed myelination. Metabolic labs, including lymphocyte EM studies, and karyotype were normal. A muscle biopsy showed fiber type disproportion with atrophy of type I fibers and hypertrophy of type II fibers. Muscle mitochondrial respiratory chain analysis was normal. The clinical course has been progressive with loss of all milestones. We conclude that PEHO syndrome may be present in diverse ethnic groups. Furthermore, gray matter heterotopias, pituitary hypoplasia, and muscle fiber type disproportion may occur in PEHO syndrome. Because of the significant implications for prognostic and genetic counseling, patients with infantile spasms and progressive loss of milestones should be evaluated for the characteristic features of PEHO syndrome.

Program Nr: 801 from the 1999 ASHG Annual Meeting

Liver fibrocystic disease and polydactyly in two unrelated patients: New syndromatic entity? *C. Esmer[1], E. Lieberman[1], A. Alvarez[2], F. Zarate[3], V. Del Castillo[1]*. 1) Department of Research in Human Genetics; 2) Patology Department; 3) Gastroenterology Department. National Institute of Pediatrics, DF, Mexico.

Liver fibrocystic disease (LFCD) consisting on dilatation of the intrahepatic bile ducts accompanied by variable degrees of fibrosis can be present alone or be found as part of many syndromes. There are at least 37 conditions, among which are metabolic disorders, bone dysplasias and other mendelian and sporadic diseases. We present two unrelated patients with LFCD and polydactyly. Both abnormalities have been described for four genetic conditions: Bardet-Biedl syndrome, Meckel syndrome, Jeune's asphyxiating thoracic dysplasia and Fraser-Jaquier-Chen syndrome. Bardet-Biedl Syndrome (BBS) is characterized by autosomal recessive inheritance, pigmentary retinopathy, obesity, polydactyly, mental retardation and hypogonadism. The existence of BBS and liver abnormalities has been previously described. Case 1 is a mentally retarded boy 18 months of age, he has hands and feet hexadactyly, kidney failure, convergent strabismus and liver fibrosis, as criteria for suspecting BBS. Case 2 is a 1 year-old child of consanguineous parents, with liver fibrosis and polydactyly in both hands and feet without any other cardinal data supporting BBS. Difficulties in the early diagnosis of BBS have been previously reported for the disease and this is explained by the clinical heterogeneity of manifestations and by the variability at the ages that they appear. Definitively, our patients didn't meet all the criteria to conclude BBS as diagnosis and a new genetic syndrome with an autosomal recessive inheritance must be considered as the cause of their abnormalities.

Program Nr: 802 from the 1999 ASHG Annual Meeting

Hydranencephaly and severe rib anomalies: an unusual presentation of Seckel syndrome. *J.A. Evans[1,2], B.N. Chodirker[1,2], S.R. Sanders[1,2], C.R. Greenberg[1,2]*. 1) University of Manitoba, Winnipeg, MB; 2) Children's Hospital, Winnipeg, MB, Canada.

Seckel syndrome, characterized by severe intrauterine and postnatal growth retardation, marked microcephaly, a "bird-headed" facial appearance and mental retardation has proved to be much rarer than initially thought. We report an infant with classic Seckel syndrome in whom hydranencephaly, severe rib defects and other anomalies were also present.

The female proband was stillborn at term to a 21-year-old G2P1 woman. Delivery was by cesarean section for abruptio placentae. The mother had been followed since 17 weeks gestation when growth retardation and an unusual skull shape were first noted on ultrasonographic examination. Growth parameters at birth were: weight 1.1kg, length 36cm and head circumference 24cm (all <<5th centile). Additional anomalies suggesting Seckel syndrome were sloping forehead, convex beaked nose, marked micrognathia, dysplastic ears, high-arched palate with a central membraneous defect, bilateral fifth finger clinodactyly with a single digital crease, delayed dyssynchronous ossification and fibular hypoplasia. Hydranencephaly, corneal clouding, non-fixation of the colon and dysplastic cartilagineous renal foci were also seen. The right clavicle, sternum, all ribs other than those at T8-11, the pubic rami and the tali were unossified. A subsequent pregnancy of the mother was terminated because of severe microcephaly, suggesting a recurrence.

Although hydranencephaly has not been reported previously in Seckel syndrome, Sugio et al. (1993) described a boy with cerebral and cerebellar hypoplasia leading to an essentially empty intracranial space on CT scan, and several other cases have had less severe dysgenetic anomalies such as lissencephaly, pachygyria and cerebral cysts. Brain defects also occur in other primordial dwarfisms. However, the lack of a more generalized osteodysplasia and the occasional occurrence of visceral anomalies (e.g. renal defects, tracheoesophageal fistula) in Seckel syndrome are further evidence that it is a pathogenetically distinct entity.

Program Nr: 803 from the 1999 ASHG Annual Meeting

Queen Of Punt Syndrome? *T.I. Farag[1], M.A. Sabry[2], A. Iskandar[3]*. 1) Dalhousie University, Halifax, NS, Canada; 2) Harvard University, Boston, Massachusetts, USA; 3) Purdue University, Hammond, Indiana, USA.

Critical bioanthropological and medico-genetic dissection of ancient art and mummies is a fascinating emerging discipline. In Cairo Museum, a relief (#11465) from Queen Hatshepsut's tomb (c.1479-1457 B.C.) in Deir el-Bahari shows the Queen of Punt(Somalia) with a lined face, hyperlordosis, corpulent body, gluteofemoral obesity and apparent symmetrically distributed hamarto-neoplastic swellings on the trunk, arms and thighs, sparing her face, neck, hands and feet. The portrait of her daughter, on the same relief, shows a similar posture. In the absence of the Queen's mummy (died nearly 34 centuries ago), there is insufficient substance, too much speculation and too few facts to decide the precise diagnosis.

Here we review different hypotheses regarding the Queen's characteristic phenotype including artistic pseudopathology, racial steatopygy, filariasis, myxodema, rickets, bilateral congenital hip dislocations in addition to the following 8 monogenic disorders: Achondroplasia, Dercum disease, lipodystrophy, Launois-Bensaude syndrome, Neurofibromatosis, familial obesity, Proteus syndrome and X-linked dominant hypophosphatemic rickets (MIM 100800, 103200, 151660, 151800, 162200, 164160, 176920, 307800).

It seems that the Queen's portrait represents a truly unique phenotype which, if accepted as a new entity, can be coined as Queen of Punt Syndrome. Syndromologists are invited to contribute their expertise to solve the puzzle and help in the precise delineation of the Queen' s alleged pathological obesity and lumbar hyperlordosis.

Acknowledgments: Thanks to Prof. John M. Opitz and Prof. R.Neil Schimke for their valuable comments and contributions.

Program Nr: 804 from the 1999 ASHG Annual Meeting

A Locus for Brooke-Spiegler Syndrome assigned to 16q12-q13. *C.D Fenske[1], P. Banerjee[2], C.A. Holden[2], N.D. Carter[1]*. 1) Medical Genetics Unit, St. George's Hospital Medical School , London, UK; 2) St. Helier's Hospital, Carshalton, Surrey, UK.

Brooke-Spiegler syndrome (BSS) is an autosomal dominantly inherited disease, characterised by the development of multiple trichoepitheliomas and cylindromas. Spiradenomas and basal cell carcinomas have also been observed in this disease. The gene for familial cylindromatosis has been localised to chromosome 16q12-q13 and loss of heterozygosity suggests that the gene involved is a tumour suppressor. The gene for multiple familial trichoepithelioma has been localised to chromosome 9p21 with a second form associated with cylindromas, determined by a gene on 16q. Heterogeneity of symptoms and tumour phenotype are found in families affected with BSS; however, familial cylindromas are invariably accompanied by trichoepitheliomas. DNA extracted from individuals of a family with three members affected with BSS was amplified using primer pairs in the regions of chromosomes 16 and 9 (candidate regions for familial cylindromatosis and trichoepithelioma respectively). Results identifying the segregation of haplotypes through the family eliminated 9p21 as a candidate region for a BSS locus. However, there was strong segregation with BSS affected members of the family of genotypes obtained with the markers on 16q12-q13. We conclude, therefore, that this area of the genome contains a locus for Brooke-Spiegler Syndrome. No obvious candidate genes lie within this region, but cDNA has been characterised at one locus (Cda01g10) where the base sequence is highly similar to a negative regulator of transcription subunit 1 in Saccharomyces cerevisiae. Given the frequent heterogeneity within families, other loci may be involved.

Program Nr: 805 from the 1999 ASHG Annual Meeting

A Clinical Genetic Study of Children Attending Special Schools (for Learning Disability) in Edinburgh. *D.R. FitzPatrick[1], P. Pearson[1], S. Halpin[2], P. Jackson[2].* 1) Human Genetics Unit, Edinburgh University, Edinburgh, Scotland; 2) Community Child Health, Sick Childrens Hospital, Edinburgh.

We wished to assess the completeness of genetic investigation in a community-based population of children with mild to moderate learning disability (LD). We performed a clinical genetic study of children attending two state-funded special schools in Edinburgh, one educates children of ages 5-12 years and the other 13-18 years. Permission was obtained from parents or guardians to review the records (school medical, community pediatric, laboratory and hospital) and clinically examine 105 (82%) children within the school setting. The sex ratio of the group was 1.62 (m:f 65:40). 20 children (19%) had previously identified causes for their disability (5 autosomal dominant disorders, 2 autosomal recessive, 2 X-linked recessive, 7 chromosomal, 3 neonatal infections and 1 malformation syndrome). Of the remaining 85 children (termed learning disability-cause unknown LDCU), chromosome analysis had been performed in 18/85 (21.2%) cases and fragile X status in 19/85 (22.4%), only 5/85 (5.9%) had both investigations recorded. Among the LDCU group 43/85 (50.6%) had a positive family history. 30 (35.3%) had at least one first degree relative with LD (15 with affected sibling(s), 11with affected parent(s), 4 with affected parent(s) and sibling(s)) and a further 13 had a second or third degree relative with LD. There is a highly significant genetic contribution to the etiology of LDCU in this population with relatively poor levels of genetic investigation. It is likely that much of difficulty in achieving adequate levels of care for these family relate to social circumstances rather than failure of referral to specialist services. The need for a community-based approach to investigation of LD is obvious.

Program Nr: 806 from the 1999 ASHG Annual Meeting

Clinical Features of Four Males and an Obligate Carrier in a Family with Lenz Syndrome. *S. Forrester[1], S. Rothert[1], R. Urban[2], M. Kovach[1], V. Kimonis[1]*. 1) Department of Pediatrics, SIU School of Medicine, Springfield, IL; 2) Department of Ophthalmology, Tampa General Hospital, Tampa, FL.

Lenz syndrome is a rare X-linked recessive syndrome first described by Lenz in 1955. Clinical features include anophthalmos or microphthalmos, microcephaly, mental retardation, external ear, digital, cardiac, skeletal, and urogenital anomalies (Traboulsi, et al 1988). Graham, et al (1991) localized the gene to Xq27-Xq28 in a Northern Ireland family with X-linked anophthalmos. However, the affected members in this family lacked digital, cardiac, and urogenital anomalies typically seen in Lenz syndrome. We present three brothers (ages 15 years, 9 years, and 18 months) and a maternal uncle (age 27 years) with Lenz syndrome. All four males have congenital anophthalmos with absence of the globes, optic nerve, and optic chiasm, and the youngest male has unilateral microphthalmos with corneal sclerosis. Delayed milestones and moderate to severe mental retardation were evident in the four males, and three of them have behavior problems. On physical examination, a high arched palate, pectus excavatum, finger and toe syndactyly and clinodactyly, fetal pads on all fingers and toes, and decreased muscle tone were noted in all four males. Scoliosis and outer ear anomalies were noted in three of the four males. The oldest brother has dilated left atrium of the heart and duplicated renal system, and the maternal uncle has right ventricular hypertrophy. An obligate carrier was noted to have syndactyly of the 2-3rdtoes bilaterally and dysplastic ears. We believe this family will add to the spectrum of clinical features of Lenz syndrome. Many of the cases published to date for Lenz syndrome are isolated reports. Linkage analysis in this family is in progress to identify the gene responsible for Lenz syndrome.

Program Nr: 807 from the 1999 ASHG Annual Meeting

Novel presentation of Goldenhar syndrome associated with tracheobronchial cartilaginous nodules in a premature neonate. *B.C. Freitag[1], H. Milczuk[1,2], M. Grompe[1,3], D.M. Pillers[1,3].* 1) Pediatrics, Oregon Health Sciences Univ., Portland, OR; 2) Otolaryngology and Head and Neck Surgery, Oregon Health Sciences Univ., Portland, OR; 3) Molecular and Medical Genetics, Oregon Health Sciences Univ., Portland, OR.

Goldenhar syndrome represents one end of a spectrum of disorders known as Oculoauriculovertebral syndrome (OAVS). While there is no agreement on minimal diagnostic criteria, most patients have abnormalities of the first and second branchial arch derivatives, including but not limited to microtia, mandibular hypoplasia, hemifacial microsomia, and ocular anomalies such as epibulbar dermoids and microphthalmia, as well as vertebral anomalies. Other manifestations include renal, cardiac, and radial limb defects, and rarely tracheoesophageal (TE) anomalies. Previously described tracheoesophageal malformations include TE fistula with or without esophageal atresia, tracheal cleft, and one report of vertically fused tracheobronchial cartilage. We report a patient with clinical features consistent with Goldenhar syndrome. The proband was a 28 week EGA premature male infant transferred to OHSU for tracheostomy placement secondary to inability to protect his airway. Diagnostic laryngobronchoscopy identified cartilaginous nodules of the trachea and right mainstem bronchus, a novel finding associated with this disorder. Other physical findings included low-set malformed auricles, micrognathia, epibulbar dermoids, and bilateral radial limb anomalies. Karyotype analysis revealed normal 46,XY with no evidence for Fanconi anemia. **Conclusion:** Tracheobronchial cartilaginous nodules are a novel finding expanding the clinical phenotype of OAVS. Morphogenesis of branchial arch and tracheoesophageal structures is dependent on proper interaction between mesenchymal and surrounding epithelial tissues during the fourth week of embryogenesis. We propose that this patient's anomalies illustrate a disruption of communication at the level of the cellular interface during this critical developmental stage. Tracheoesophageal anomalies and other malformations of mesenchymal derivatives may provide a clue to the etiology of this heterogenous disorder.

Program Nr: 808 from the 1999 ASHG Annual Meeting

Patent ductus arteriosus with a distinctive facial phenotype: Intrafamilial variability of the Char syndrome in a family with twins. *B.D. Friedman, L.A. Workman.* Perinatal and Pediatric Specialists Medical Group, Inc., Sacramento, CA.

We report on a family with patent ductus arteriosus and a distinctive facial phenotype in a mother and three of her four children. The findings in this family are similar to a rarely published syndrome first reported by Char (Birth Defects: Original Article Series XIV;6B:303-305, 1978), who described a family with patent ductus arteriosus and an unusual facial phenotype which included a short philtrum, duck-bill lips, ptosis, strabismus, and low set ears.

The affected individuals in this family include a 36 year-old mother, her 9 year-old son, and twin 5 year-old girls. All of the affected individuals required surgical repair of a patent ductus arteriosus in childhood; none was pre-term. In addition, a distinctive facial phenotype is present which includes a prominent forehead, upslanting palpebral fissures, a broad nasal bridge, a short, broad, flat nasal tip with anteverted nares, a short but prominent philtrum, and full lips with loss of the cupid's bow. The children have bifrontal narrowing with a prominent metopic area, and incurved fifth fingers. Short fifth fingers are present in one of the twins, her brother, and their mother. There is variable widening of the toes, which is most pronounced in the mother, and most commonly of the fifth toe. Other findings include a history of mild mixed hearing loss requiring hearing aids in the twins, who have severe receptive language, expressive language and articulation deficits. The mother had surgery for strabismus.

The findings in this family are consistent with previous reports of the Char syndrome, which includes autosomal dominantly inherited patent ductus arteriosus with a distinctive facial phenotype and variable other features, including hearing impairment, fifth finger clinodactyly, broad toes, and strabismus. Individuals presenting with a patent ductus arteriosus should be evaluated for similar phenotypic findings. Consideration should be given to audiologic and ophthalmologic testing in affected children and appropriate recurrence risk counseling should be offered.

Program Nr: 809 from the 1999 ASHG Annual Meeting

Metacarpophalangeal pattern profile (MCPP) analysis of Noonan syndrome. *D.D. Gale[1], G.A. Dahir[2], F.J. Meaney[3], R. Kumar[4], M.G. Butler[4].* 1) Col Allied Health & Nursing, Eastern Kentucky Univ, Richmond, KY; 2) University of Virginia, Charlottesville; 3) University of Arizona, Tucson; 4) The Children's Mercy Hospitals and Clinics, Kansas City, MO.

Metacarpophalangeal pattern profile (MCPP) analysis is an application of an anthropometric technique which provides a quantitative assessment of the amount and direction of abnormality in the hand skeleton. MCPP analysis was undertaken on 15 individuals (9 males; 6 females) with Noonan syndrome ranging in age from 0.1 to 36 years with a mean age of 11.6 years. This syndrome is associated with neck webbing, pectus excavatum, cryptorchidism, pulmonic stenosis, low posterior hairline, short stature and a particular facial appearance. The overall average Z score for the MCPP variables in individuals with Noonan syndrome was -2.1 and the range was -2.5 (metacarpal 2) to -1.5 (middle phalanx 5). The average pattern variability index, a measure of hand dysmorphogenesis, was 1.0. A value above 0.7 is considered abnormal. A Pearsonian correlation analysis was used to assess similarity between the mean pattern and each of the 19 individual patterns. Nine of 15 individuals with Noonan syndrome had significant positive correlations ($p < 0.05$) indicating homogeneity or similarity in hand patterns among Noonan syndrome subjects. A stepwise discriminant analysis was performed on 12 subjects with Noonan syndrome (8 males, 4 females; mean age = 7.3 years with age range of 0.1 to 13.5 years) and 41 controls (24 females, 17 males; mean age = 13.1 years with age range of 9.6 to 18 years). This analysis produced a discriminant function with age and one MCPP variable (middle phalanx 5) entered into the function. Although the hand pattern variability index indicated an abnormal MCPP, the multivariant analysis identified only one MCPP variable contributing to the overall difference between individuals with Noonan syndrome and the normative sample. The discriminant function will require testing with additional Noonan syndrome subjects for interpretation of its rate of correct classification of all individuals with Noonan syndrome.

Program Nr: 810 from the 1999 ASHG Annual Meeting

Three families with Perrault syndrome: Phenotypic variability versus genetic heterogeneity. *C.A. Gardiner[1], C.E. Chu[1], L. Al-Gazali[2], C.G. Woods[1], R.F. Mueller[1].* 1) Department Clinical Genetics, St James's University Hospital, Leeds, England; 2) Department of Paediatrics, United Arab Emirates University, United Arab Emirates.

The Perrault syndrome is an autosomal recessive condition. The diagnostic criteria are gonadal dysgenesis in the females and sensorineural hearing loss in both males and females. Other features reported include mental retardation and neurological abnormalities. It is unclear whether the Perrault syndrome is a single clinical entity. We report three families with female and male family members who are affected. The parents of the affected individuals are either first or second cousins. In the first family the affected female also has moderate mental retardation and a height greater than the 95th centile. Two of her brothers have sensorineural hearing loss but only one of the affected brothers has a height greater than the 95th centile and the probands mother has adult onset sensorineural hearing loss. In the second family the affected female has moderate mental retardation, as does her affected brother. In the third family, the affected female has a height below the third centile, but the height of her affected brothers is normal and all have normal intelligence. Twelve families have been previously reported in the literature. It has been suggested that the Perrault syndrome is either genetically heterogeneous or there is marked phenotypic variability but a third possible explanation of the features in the reported families is the occurrence of separate Perrault syndrome features occurring by chance in the same individual. In the families we report, chromosome analysis was normal and we did not find any mutations on sequencing Connexin 26 in affected family members. We conclude that the phenotypic spectrum of Perrault syndrome is not yet defined and it will await gene analysis and further family studies before the question of phenotypic variability versus genetic heterogeneity is answered.

.

Program Nr: 811 from the 1999 ASHG Annual Meeting

Agenesis of the corpus callosum and spastic paraparesis. Observations in a mother and her two daughters. *R.J.M. Gardner[1], E. Storey[2], A.M. Walker[3], J. Heywood[4], K.J. Collins[5]*. 1) Victorian Clinical Genetics Services, Royal Children's Hospital, Melbourne; 2) Dept Neurosciences, Alfred Hospital, Melbourne; 3) Dept Paediatrics, Monash Medical Centre, Melbourne; 4) Dept Neurosciences, St Vincent's Hospital, Melbourne; 5) Dept Neurology, Royal Children's Hospital, Melbourne, Australia.

We have studied a family in which the mother and her two children have structural and/or functional white matter disease. The mother presented with clumsiness since childhood, proceeding to a spastic paraparesis in adult life, along with a bladder disturbance and an asymptomatic peripheral neuropathy. Her MRI scan was interpreted as normal. Both children have agenesis of the corpus callosum. The elder daughter had significant learning difficulties, and was held back for 1 year at school. At age 13, there were subtle signs to suggest an early spastic paraparesis. The younger daughter, had a diagnosis of hydrocephalus in infancy, and was shunted at 18 months. In spite of this, early milestones were reportedly normal, but subsequently her academic progress was poor. Gait and lower limb reflexes, at age 11, were normal. The family history is otherwise unremarkable. On the parsimonious assumption that the three phenotypes reflect the same genotype, we would propose that this may represent a previously undescribed neurogenetic condition, involving in particular a structural and functional white matter defect.

Program Nr: 812 from the 1999 ASHG Annual Meeting

Autosomal Dominant Gillespie syndrome in 4 generations with highly variable expressivity and incomplete penetrance. *J. Gaudelus, B. Heron, P. Bitoun.* Dept Pediatrie, NeuroPediatrie & Genet Med,CHU Paris-Nord, BONDY,93143cedex France.

Gillespie (1965) described 2 sibs with aniridia, cerebellar ataxia and mental retardation. A total of 21 patients have been described including 9 sporadic and 12 in 5 families; 3 including the princeps case have described affected sibs and 2 have described vertical maternal transmission. Etiology and transmission remains unclear and has generally been reported as autosomal recessive although no consanguinity has ever been reported. Most case reports mention aniridia but indeed description is that of iris hypoplasia since most patients have a minimal iris collarette. All patients have been reported with cerebellar ataxia and some with cerebellar hypoplasia , mental retardation and one with pulmonic stenosis. We report a case of iris hypoplasia in a 3 year old girl with hypotonia, psychomotor and speech delay and cerebellar ataxia with a normal M.R.I. and normal high resolution chromosomes all compatible with the diagnosis of Gillespie syndrome(GS). Family history is significant for a 30 year old paternal second cousin with identical irides without mental retardation or ataxia. A paternal great aunt with polycoria, and a paternal great grandmother with a narrow anterior chamber. A paternal first cousin has mental retardation but his eye examination is not known and his status is unclear. This family thus shows a dominant transmission of GS with at least 4 affected members in 4 generations all having isolated iris anomalies including polycoria, narrow anterior chamber except the proband who is the only affected with both iris and cerebellar and mental symptoms. It seems that there are 2 unaffected transmitting males who are obligate carriers and incomplete penetrance in the affected. All reported familial cases are compatible with dominant transmission, the affected sibships could possibly be due to either minimal or non penetrance in one parent or germline mosaicism. Glaser et al 1994 have searched for mutation in the PAX6 gene in 3 families with GS with negative results while Dollfus et al (1998) have reported a patient with GS and a t(X;11)(p22.32;P12) de novo translocation without detectable anomaly in the PAX6 coding sequence.

Program Nr: 813 from the 1999 ASHG Annual Meeting

Unusual distribution of acanthosis nigricans in the Crouzonodermoskeletal syndrome. *J.T. Goodrich[1], S. Orlow[2], D. Staffenberg[1], R. Marion[1], S. Eisig[1], A. Shanske[1].* 1) Depts. of Neurological Surgery, Pediatics, Plastic Surgery, and Dentistry, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; 2) Dept. of Dermatology, NYU Medical Center, New York, NY.

Acanthosis nigricans (AN) consists of thickening and hyperpigmentation of the skin usually confined to the flexural areas of the body and rarely the entire body. The oral mucosa is affected in 25% of cases and involvement of the esophagus has been reported. It may occur as part of the Crouzondermaoskeletal syndrome due to a mutation in FGFR3, ala391glu. In this disorder, the Crouzonoid phenotype is combined with AN, jaw cementomas, vertebral alterations and hydrocephalus. We have observed AN in the meninges of a girl with Crouzon syndrome (CS).

KS is an 11 year old who has already undergone a number of procedures because of her Crouzon syndrome including a tracheostomy and VP shunt placement. Her physical examination prior to her recent surgery revealed a stigmatized youngster whose height was 132 cm(10%), weight 40 kg(50-75%), and HC was 51.5 cm(25%). She had turricephaly with deep depressions above the supraorbital ridges, hypertelorism, a downward obliqity of the palpebral fissures and severe midfacial hypolplasia. The intraoral examination revealed an underbite, byzantine arch and bifid uvula. AN involved the chin, the commisures of the mouth, median canthi, upper lids, neck, chest and axillary areas. She also had a number of macular nevi. She underwent a LeForte III with distraction in conjunction with a calvarial bone graft and bilateral canthoplasties. At surgery, striking thickening of the dura and difficulty elevating the forehead flap was noted. The tissue around the eyes was friable and thin. A number of pigmented areas of the meninges were visible through the craniotomy holes.

AN is associated with several congenital disorders including CS. The AN associated with CS is atypical in several ways. Histochemical analyses using in situ hybridization has shown that the FGFR3 gene is expressed in many areas of the brain. Our observation confirms it is also expressed in the meninges.

Program Nr: 814 from the 1999 ASHG Annual Meeting

Two cases of partial trisomy 8 and 14 (8q24.1®qter and 14pter®q22) with semilobar holoprosencephaly and comparisons to Seckel syndrome. *G.C. Gowans[1,3], S. Goncalves[5], A.M.V. Duncan[2,3], P. Eydoux[4], A.S. Teebi[5]*. 1) F. Clarke Fraser Clinical Genetics Unit, Division of Medical Genetics, Montreal Children's Hospital, McGill University, Montreal, QC, Canada; 2) Department of Pathology, Montreal Children's Hospital, McGill University, Montreal, QC, Canada; 3) Department of Human Genetics, McGill University, Montreal, QC, Canada; 4) Biologie du Developpement, Hopital Roberte-Debre, Paris, France; 5) Department of Genetics, The Hospital for Sick Children, Toronto, ON, Canada.

We report sibs with +der(14)t(8;14)(q24.1;q22)mat . The anomaly arose from a 3:1 meiotic segregation of a maternal balanced reciprocal translocation. The patient's sister, mother and maternal grandmother are known to be balanced translocation carriers. Their karyotypes are 46, XX, t(8;14)(q24.1;q22). The first unbalanced case was detected through amniocentesis with a karyotype of 47, XY, +der(14)t(8;14)(q24.1;q22)mat. This male neonate had many congenital abnormalities including microcephaly, low set ears, large beaked nose, micrognathia, cleft palate, cryptorchidism, camplodactyly, bilateral club feet and semilobar holoprosencephaly on MRI. He died at 27 days of respiratory failure. The second case, a female, also has tertiary trisomy 8 and 14 and has a very similar phenotype with microcephaly, lowset ears, a beaked nose with a wide malar region, retrognathia with cleft hard palate, camplodactyly, bilateral club feet and semilobar holoprosencephaly. Comparisons are made with other cases of partial duplications of 8 and 14 and the relation of these cases to Seckel and Seckel-like syndromes is discussed. The phenotypes of these infants have much in common with the autosomal recessive Seckel type dwarfism that is characterized by severe short stature, microcephaly, prominent beaked nose, and receding lower jaw. We also suggest that holoprosencephaly could be an additional feature of trisomy 8q24®ter and/or 14pter®q22.

Program Nr: 815 from the 1999 ASHG Annual Meeting

AN AUSTRALIAN CADASIL PATIENT WITH A NOVEL NOTCH3 MUTATION. *R.F Grigg[1], A.A. Sullivan[2], R.P. Curtain[1], L.R. Griffiths[1]*. 1) Genomics Rsc Ctr, Sch Hlth Sci, Griffith University-Gold Coast, Southport QLD, Australia; 2) Department of Medicine, Royal Brisbane Hospital, Herston, Qld.

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is a dominantly inherited disease of the small vessels of the brain. Recent studies by Joutel et al1 have indicated that mutations within the Notch3 gene are involved in families with this disorder. Here we describe the clinical features of a patient from a previously reported Australian CADASIL kindred with a novel mutation of the Notch3 gene. Using PCR techniques to amplify the Notch3 gene, we performed direct mutation analysis via sequencing. A base substitution mutation involving a G to T transition was identified. The mutation results in an amino acid change from a Cysteine to a Phenylalanine and is found in exon 4. A recent study by Joutel et al 2 found a clustering of mutations in this region, all resulting in the loss or gain of a cysteine residue. These typesof mutation, within the EGF-like domain, are thought to be involved in aberrant intramolecular disulphide bonds, resulting in abnormal folding of Notch3 or inappropriate bond formation with other cysteine-containing proteins.DNA from a sibling of this patient, who has also been diagnosed with CADASIL is also currently being used for mutation analysis. Other members of the family are undergoing genetic counselling before considering testing. (1) Joutel et al 1997 Ann N Y Sci826:213-217 (2) Joutel et al 1997 Lancet350:1511-1515.

Program Nr: 816 from the 1999 ASHG Annual Meeting

Neurodevelopmental Assessment and Functioning in Five Young Children with Smith-Magenis syndrome (SMS).

A.L. Gropman[1], P. Wolters[2], B. Solomon[3], A.C.M. Smith[1,4]. 1) Dept Genetics, Medical Gen Br, NHGRI/NIH, Bethesda, MD; 2) HIV and AIDS Malignancy Branch, NCI and Medical Illness Counseling Center NIH, Bethesda, MD; 3) Clinical Center NIH, Bethesda, MD; 4) Georgetown University Washington, DC.

Smith-Magenis syndrome (SMS), a probable contiguous gene syndrome due to del 17p11.2, is associated with a distinctive phenotype of characteristic physical features, developmental and neurobehavioral abnormalities, and speech & language delay. Limited studies have been reported on young children. We developed a comprehensive test battery to assess the early cognitive and behavioral phenotype of SMS. A neurologic, developmental, language, and oral motor assessment was administered to five children with SMS ages 21- 28 months. All children had neurologic abnormalities including hypotonia, motor delays, at least one feature of peripheral neuropathy (decreased DTRs, pes planus/cavus, decreased pain sensitivity, 6-8 Hz upper extremity tremor, distal muscle weakness), and sleep disturbance. Psychometric testing revealed cognitive functioning in the moderately delayed to low average range. Expressive verbal language was more delayed than receptive language in all children. All exhibited limited vocalizations and poor vocal sound production but had begun to use simple signs and gestural communication. Oral motor findings were consistently found: all had open mouth posturing, exaggerated lingual papilla, anterior tongue carriage, & decreased lingual movements; 3/5 had downward slanting cupid bow mouth and palatal abnormalities. Orientation/engagement and emotional regulation scores were within normal limits in all cases, yet mild-moderate autistic-like behaviors also were seen in four. Videotaped samples will be shown to illustrate the salient features of SMS behavior. Due to decreased verbal skills, maladaptive behavior, and developmental delays, a comprehensive battery is useful to assess the range of cognitive and neurobehavioral abnormalities in SMS to facilitate early identification and appropriate educational, behavioral, and speech interventions.

Program Nr: 817 from the 1999 ASHG Annual Meeting

47,XXX with Mullerian Agenesis. *C. Guze, R. Hassan, A. Adeniji, F. Hodges, D. Estrada-Smith.* Obstetrics and Gynecology, King Drew Medical Center, Los Angeles, CA.

We report on a 27-year-old, white Hispanic female referred from the fertility clinic because of primary amenorrhea. Physical examination revealed a blind 3 cm vaginal pouch with no cervix, Tanner stage 3 breasts, and scant pubic and axillary hair. She has a flat facies, short fingers and toes, and her toes are widely separated. Our patient weighs 207 lbs and is 5 ft 5 in which is several inches taller than her 3 sisters. Her IVP showed normal urinary anatomy. An MRI of the abdomen and pelvis showed an absence of the uterus and hypoplasia of the vagina. The ovaries are present bilaterally. The left ovary, 2.5 cm x 2.0 cm, is located anteriorly in the pelvis and the right, 4.5 cm x 4.9 cm, is posteriorly located. Both contained normal appearing follicles. The patient experiences monthly pelvic pain. The MRI showed no evidence of any abnormality of the liver, spleen, kidneys, pancreas or adrenal glands. TSH was normal (1.77 IU); FSH (3.3 mIU/ml) and LH (8.2 mIU/ml) were normal for follicular and luteal phases. PRL (21.7 ng/ml), E2 (112 pg/ml) and T (31 ng/dl) levels were within normal limits. In both blood and fibroblast chromosome studies, a 47,XXX karyotype was observed.

The patient stopped going to school when she was 16 years old and still in the 6th grade. She reports that she has a speech problem and difficulty expressing herself. She describes herself as shy and often depressed. She feels she is different from her siblings in social skills and ability to retain information. She expressed relief at finding there was an explanation for her differences.

Our patient manifests several clinical features often associated with the 47,XXX condition. These include learning and language problems, depression, shyness, increased height relative to female sibs, and fertility problems. However, her infertility is unique because it is due solely to mullerian agenesis without ovarian dysgenesis. She has complete absence of the fallopian tubes, uterus, and the internal portion of the vagina along with functional ovaries. Unlike other triple-X patients reported to have mullerian anomalies, there is no evidence of urinary tract malformation.

Program Nr: 818 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of trisomy 8 mosaicism. *J. Habecker-Green, R. Naeem, S. Pflueger, J.P. O'Grady, G. Markenson, G.M. Cohn.* Baystate Medical Ctr, Springfield, MA 01199.

Trisomy 8 mosaicism is a variable condition that may include multiple anomalies and mental retardation. Prenatal diagnosis for this condition has rarely been reported. We present two cases of prenatal diagnosis for trisomy 8 mosaicism.

Case 1: A 16-year-old Puerto Rican female presented for routine prenatal ultrasound. The fetus had Dandy-Walker malformation, choroid plexus cysts, absence of the inferior vermis, hydrocephalus, mild pyelectasis, and possibly a small abdominal wall defect. Amniocentesis was performed, but cellular culture failed. Repeat amniocentesis or PUBS was declined. At 36 weeks gestation, a 2.2 kg female infant was delivered. She had cleft palate and microcephaly with brain anomalies including Dandy-Walker malformation, hydrocephalus, schizencephaly, lissencephaly, and intraparenchymal calcifications. Renal ultrasounds and spine films were normal Peripheral blood karyotyping was significant for 47,XX,+8[2]/46,XX[121] mosaicism confirmed by FISH. Cerebrospinal fluid cultures for karyotypic analysis were attempted and were unsuccessful. Additional karyotypic studies were declined.

Case 2: A 29-year-old female of northern European ethnicity presented for routine prenatal ultrasound. The fetus was noted to have unilateral ventriculomegaly, unilateral hydronephrosis, a disorganized spinal colums (possibly secondary to a hemivertebra), and single umbilical artery. Amniocentesis was performed and was significant for 47,XY,+8[5]/46,XY[20] mosaicism. The parents were counseled about the variable nature of trisomy 8 mosaicism and chose to end the pregnancy. Post mortem evaluation was notable for a wide head and dysmorphic face, low set ears, large nuchal fold, micrognathia, abnormal rotation of the heart, a 9th thoracic hemivertebra, and deep palmar and plantar creases. Trisomy 8 was seen in all studied thymus cells, in 70% of skin cells, in 20% of villi, and was not seen in brain cells.

Program Nr: 819 from the 1999 ASHG Annual Meeting

New x-linked MR/MCA syndrome associated with cleft lip/palate, upslanted/short palpebral fissures, high nasal bridge, prominent nasal tip, inguinal hernia and minor digital defects. *B.D. Hall, J.M. Robl.* Dept Pediatrics/Genetics, Univ Kentucky Medical Ctr, Lexington, KY.

There are approximately 178 recognized disorders with x-linked mental retardation (Am J Med Genet 83:237, 99). Seventy-five (42%) of these are associated with multiple congenital anomalies (MR/MCA) which allows for more rapid, specific syndrome identification. Only 9% of these x-linked MR/MCA syndromes are associated with cleft lip and/or cleft palate. We report a new x-linked MR/MCA syndrome in three males of a single family. Two of the males, ages 10 years and 16 months, are brothers and the third male is a maternal first cousin through normal female carriers. All three affected males share moderately severe mental retardation, normal prenatal growth parameters, upslanted eyes, short palpebral fissures, prominent nasal tip, and marked delay in speech. Two of the three males have clefts (cleft lip in one/cleft palate in the other), increased inner canthal distance, high-wide nasal bridge, short 5th fingers, low set ears, and inguinal hernias. The following features are found in one of each of the males: postnatal growth deficiency, left helical pit, kyphosis, cubitus valgus, small thumbs, left club foot, multicystic left kidney, and undescended testes. Chromosomes were normal and a brain MRI in one male revealed asymmetric white matter. We could not find a similar phenotype in any of the reported x-linked MR/MCA syndromes. These three males have a distinct recognizable facial gestalt associated with oral clefts. Further studies to include gene localization are planned.

Program Nr: 820 from the 1999 ASHG Annual Meeting

FGFR2 mutations in patients with Pfeiffer syndrome type III. *K. Hedrich, H. Thiele, A. Rühl, I. Hansmann, U. Hehr*. Humangenetik, Martin-Luther-Universität, Halle, Germany.

Craniosynostosis, the premature fusion of one or several cranial sutures, is with a prevalence of appr. 1 in 3,000 one of the most common craniofacial anomalies at birth. Recently, mutations in three of the four human fibroblast growth factor receptor genes (FGFRs) have been shown to account for appr. 15-20% of all cases with craniosynostosis. Here we report the results of a screening for FGFR mutations in 5 familial cases and 10 sporadic patients with craniosynostosis, referred to our department for genetic counseling. Two of the patients were identified as Pfeiffer syndrome Type III. In addition to bilateral coronal craniosynostosis with short anterior cranial base and ocular proptosis, both patients presented with developmental delay, hydrocephalus internus, hearing deficit and short stature. In both patients previously reported mutations affecting exon IgIIIc of FGFR2 were identified. The first patient died at the age of 34 months following repeated craniosurgery, the clinical course was complicated by dyspnoe resulting from choanal stenosis and stenosis of the bronchi. She was found to carry the common FGFR2 mutation Cys342Arg within exon IgIIIc, which had previously been reported in more than 20 patients with CS, PS or JWS. The second patient presented with localized tracheostenosis and multiple orthopedic problems including hip dysplasia, severe scoliosis and limited extension of the elbows. Mutation analysis confirmed an A(-2)G substitution at the acceptor splice site of exon IgIIIc. Comparison of the clinical features of both patients with the previously reported cases further underlines the wide phenotypic spectrum of identical FGFR2 nucleotide substitutions, most notably in exon IgIIIc, and supports the idea of additional genetic and/or environmental factors modifying the extend of the initial mutation effect.

Program Nr: 821 from the 1999 ASHG Annual Meeting

Silver-Russell syndrome and cystic fibrosis caused by maternal uniparental disomy 7. *U. Hehr[1], S. Brömme[2], S. Dörr[1], M. Hagemann[1], U. Preiss[2], I. Hansmann[1].* 1) Humangenetik, Martin-Luther-Universität, Halle, Germany; 2) Kinderklinik, Martin-Luther-Universität, Halle, Germany.

Maternal uniparental disomy 7 (mUPD7) has been reported so far in two patients with cystic fibrosis (CF; Spence et al., 1988, Voss et al., 1989). Prenatal and postnatal growth retardation in both patients were more severe than expected in patients with CF alone. This marked growth retardation, typically combined with asymmetry and a distinct small triangular face, is recognized today as a significant feature of Silver-Russell syndrome (SRS). About 10% of SRS patients are identified to result from mUPD7, which prompted the search for differentially imprinted growth related genes on chromosome 7. Here we describe a third patient with mUPD 7 causing the combination of SRS and CF. He presented with intrauterine growth retardation, postnatal failure to thrive and distinct craniofacial features. No asymmetry was noted. Two weeks post partum an exocrine pancreas insufficiency was diagnosed. Weight gain resumed under pancreas enzyme substitution, although the patient at the age of 2 years still remains under the third percentile for both weight and height. Mutational screening of the CFTR gene revealed homozygosity of the patient for the common CFTR mutation DF508, while only his mother was found to be heterozygous for DF508. Microsatellite analysis confirmed maternal uniparental isodisomy 7 and was consistent with paternity for other chromosomes. With this report we want to emphasize the importance of screening for UPD 7 in patients with CF and severe growth retardation. Additional features of SRS might not be present at the time of examination. Finally, the diagnosis of UPD 7 in patients with CF confirms a novel epigenetic mechanism for the inheritance of CF, which provides the affected parents with a much better perspective for subsequent pregnancies when compared to the common recurrence risk for CF of 25%.

Program Nr: 822 from the 1999 ASHG Annual Meeting

A second family linked to spinocerebellar ataxia 5. *A. Herman[1], G. Stevanin[1], G. Cancel[1], O. Didierjean[1], A-S. Lebre[1], Y. Agid[1,2], A. Brice[1,2], A. Durr[1,2]*. 1) INSERM U289, Hopital de la Salpetriere, Paris, France; 2) Federation de Neurologie, Hopital de la Salpetriere, Paris, France.

Spinocerebellar ataxia type 5 (SCA5), one of the genetically heterogeneous autosomal dominant cerebellar ataxias, was assigned to chromosome 11 in a single family descending from the grand parents of President Lincoln. We report a second, apparently unrelated, SCA5 family, of French origin. Although the clinical pictures of the two families are similar, we show that the slowly progressive cerebellar ataxia that characterizes the phenotype in SCA5 patients can be associated with other signs such as nystagmus, myokimia and decreased vibration sense, thus indicating that the clinical picture of these patients can overlap with those carrying SCA1-7 mutations. Furthermore, the age at onset (mean of 27 years), that varies from the second to the fourth decade, is discordant with the late onset that was thought to characterize pure cerebellar ataxias. Magnetic resonance imaging showed a marked global cerebellar atrophy, even after a short disease duration, similar to SCA6. Finally, we did not find evidence of maternal anticipation, as previously described (Ranum et al, 1994), and no CAG repeat expansions or polyglutamine-containing-protein were detected in patients using RED or 1C2-western-blot techniques.

Program Nr: 823 from the 1999 ASHG Annual Meeting

Resolution of hematologic abnormalities not due to somatic mosaicism in a male with Fanconi anemia. *J.H. Hersh[1], A.D. Auerbach[2]*. 1) Dept Pediatrics/CEC, Univ Louisville, Louisville, KY; 2) Laboratory of Human Genetics & Hematology, The Rockefeller University, New York, N.Y.

Fanconi Anemia (FA) is an autosomal recessive disorder characterized by various congenital malformations and a predisposition to bone marrow failure and leukemia. At least 8 complementation groups have been identified, and both clinical and genetic heterogeneity exist in affected individuals. Hypersensitivity of FA cells to the clastogenic effect of diepoxybutane (DEB) serves as a cellular marker for the disorder. In a portion of FA patients, hematologic mosaicism may lead to normal hematopoiesis and improvement in hematologic status. We present a male with FA who was suspected of being affected at 8 years of age based on the presence of hypoplastic thumbs, microcephaly, short stature, cryptorchidism, hyperpigmentation, mild intellectual deficits, vesicoureteral reflux and evidence of bone marrow suppression. At that time, WBC was 3100, Hgb 10 & platelet count 42,000. At 19 years, his hematologic status had normalized with a WBC 7600, Hgb14.3 and platelet count 172,000. Exposure of peripheral blood lymphocytes to DEB at 8 and 19 years of age resulted in 7.6 and 8.5 mean breaks/cell, and 92% and 100% aberrant cells respectively. A variant in *FANCG* was discovered in this patient (IV12 -38 -(-28)del); the pathogenicity of this variant is not determined as yet. Normalization of hematologic findings in an FA patient without somatic mosaicism has yet to be described. Additional complementation studies and mutation analysis are reviewed in order to elucidate the mechanism for natural gene therapy in this FA patient.

Program Nr: 824 from the 1999 ASHG Annual Meeting

Dysmorphic features, multiple congenital anomalies, and preaxial polydactyly of feet: Diabetic embryopathy or a malformation syndrome? *T. Heshka[1,2], K. Chorneyko[1,2], B. Brennan[1,2], M.J.M. Nowaczyk[1,2]*. 1) Hamilton Health Sciences Corporation; 2) Faculty of Health Sciences, McMaster University, Hamilton, ON, Canada.

This male infant was born at 28 weeks gestation to a 23 y.o G1 with poorly controlled IDDM. Severe oligohydramnios and fetal anomalies were noted antenatally. The baby had micrognathia, low set ears, high, broad and flat forehead, flat-appearing face, hypoplastic nose with anteverted nares. There was a cleft of the lower alveolar ridge, a bifid uvula, and a normal tongue. There was severe bowing of the legs, severe equinovarus deformities of both ankles and metatarsus adductus of both feet. There was pre-axial polydactyly of both feet with proximally placed great toes. The hands and upper limbs were normal. External genitalia were male with hypospadias and undescended testes. Radiographs showed 11 pairs of ribs, two hemivertebra with associated bifid ribs, and bilateral parietal foramina. There was a single bowed bone in the left lower leg and two bowed bones in the right lower leg. Autopsy showed hypoplasia of the pulmonary valve and pulmonic trunk, right aortic arch with mirror image branching, an aorto-pulmonary window with incomplete truncus arteriosus, and a type C T-E fistula. Kidneys and ureters were absent and bladder was hypoplastic. Pancreas showed islet cell hyperplasia. Neuropathologic examination showed a 3.0 x 4.0 mm hamartoma in the septum pellucidum. There was placentomegaly and focal amnion nodosum. Karyotype was normal male; DNA analysis for SOX9 mutations was negative.

The features presented here are suggestive of VACTERL association, however, the facial dysmorphism and polydactyly is against this diagnosis. Preaxial toe polydactyly is a recognized feature of diabetic embryopathy as are renal agenesis and vertebral and cardiac malformations. However, this infant had a number of other malformations and dysmorphic features that suggested an underlying syndrome. The differential diagnosis includes acrocallosal syndrome, oral-facial-digital spectrum, camptomelic syndrome, Pallister-Hall syndrome, diabetic embryopathy, and a newly recognized syndrome.

Program Nr: 825 from the 1999 ASHG Annual Meeting

Familial Charcot-Marie-Tooth with spasticity and additional features. *F.M. Hisama, D.S. Russell, E. Auld, J.M. Goldstein.* Dept of Neurology, Yale Univ Medical School, New Haven, CT.

Charcot-Marie-Tooth (CMT) is a genetically heterogenous group of peripheral nerve disorders characterized by pes cavus, hammer toes, and distal atrophy. CMT is usually inherited an an autosomal trait. Mutations in connexin-32 cause an X-linked dominant form of CMT, with milder clinical and electrophysiological features in females compared with their male relatives. We present a family with 5 affected individuals (age 10-55 years, 3 females and 2 males) in 3 generations. Each has clinical features of CMT, however, both clinically and by nerve conduction velocity, males are more severely affected than females. CMT is rarely associated with upper motor neuron signs, yet the 4 subjects examined have significant spasticity and hyperreflexia. Additional features in more than one family member include dysarthria and strabismus. The most severely affected male has mental retardation, low set ears,severe scoliosis, and multiple contractures. Brain MRI of the proband showed mild, diffuse increased white matter signal with normal corpus callosum. Evoked potentials showed combined peripheral and central neuropathy. Electromyography/nerve conduction studies of multiple family members showed demyelinating and axonal sensorimotor neuropathy, more severe in the males. DNA testing for PMP-22 duplication in CMT-1A and mutations in connexin-32 was negative. Very long chain fatty acids and phytanic acid were normal. Because of overlap with spinocerebellar ataxias, DNA testing for SCA1,2 and 3 was performed and was negative. This family differs from others with hereditary motor and sensory neuropathies by the presence of spasticity, hyperreflexia, and additional features. The inheritance pattern is suggestive of X-linked dominant inheritance or autosomal dominant inheritance with sex-influenced expression.

.

Program Nr: 826 from the 1999 ASHG Annual Meeting

Robin sequence with distichiasis: a new dominant syndrome. *R.J. Hopkin[1,2], C.E. West[3]*. 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) Craniofacial Center, Children's Hosp Medical Ctr, Cincinnati, OH; 3) Div Ophthamology, Children's Hosp Medical Ctr, Cincinnati, OH.

The triad of micrognathia, glossoptosis and cleft palate define Robin sequence. Distichiasis, two rows of eyelashes, is a rare congenital malformation that has been reported as an isolated malformation, in association with congenital lymphedema, and as a part of several rare genetic syndromes. We have recently evaluated a family with Robin sequence and distichiasis inherited as a dominant condition. This combination has been reported in only one previous patient. **Case report:** The proband is a 2 year old female with micrognathia, cleft palate, and distinct facial features including a flat profile, down slanting palpebral fissures, and epicanthic folds. Growth and development have been normal. An ophthalmologic evaluation revealed bilateral distichiasis with no evidence of myopia. **Family history:** The patient's father was born with micrognathia, cleft palate, distichiasis, and sensory neural hearing loss (SNHL). The paternal grandmother has micrognathia, cleft palate, and distichiasis. A paternal uncle has micrognathia, cleft palate and SNHL. He is not known to have distichiasis. The paternal grand father has SNHL, but is otherwise without congenital malformations. There is no history of lymphedema or high myopia in any family member. **Discussion:** We report on a family with a previously undescribed syndrome characterized by Robin sequence, distichiasis, and distinct facial features that are inherited as a dominant trait. Important negatives include the absence of lymphedema, high myopia, or other major malformations. There is a great deal of overlap with non-occular Stickler syndrome, however, distichiasis is not seen in that condition. It is possible that some individuals previously diagnosed with non-occular Stickler syndrome had the condition reported in this family. It is also interesting to note that, with the exception of isolated distichiasis, all of the syndromes associated with distichiasis have cleft palate as an occasional feature. This syndrome may reveal insights into the genetic and developmental factors that lead to cleft palate and facial dysmorphogenesis.

Program Nr: 827 from the 1999 ASHG Annual Meeting

Trisomy 21 and Ebstein Anomaly. *M.J. Huggins, J. Mernagh, J. Xu, M.J.M. Nowaczyk.* Hamilton Health Sci Corp, Hamilton, ON, Canada.

Ebstein anomaly (EA) consists of downward displacement of an abnormal tricuspid valve into the right ventricle with resultant enlargement of the right atrium and tricuspid valve incompetence. Although there are reports of EA following fetal exposure to lithium, EA malformation is sporadic and rare. Approximately 40 per cent of fetuses and children with Down syndrome (DS) have a cardiac anomaly; there are two cases of EA and DS reported in the literature. We report a fetus with trisomy 21 who had EA diagnosed during a prenatal sonographic evaluation at 25 weeks of gestation. This finding was confirmed by fetal echocardiography.

A 42 year old G1 was referred for a genetic amniocentesis because of advanced maternal age and triple screen positive for DS. The fetal karyotype was 47,XY,+21. Sonographic examination at 25 weeks of gestation showed thickening of the nuchal fold measuring 10.5 mm (normal <6 mm), and cerebral ventriculomegaly [posterior horns of the cerebral ventricles measured 11 mm in maximum diameter (normal<10 mm)]. The fetal heart circumference was 106 mm corresponding to an estimated gestation of 29 weeks. The right atrium was enlarged with an apically displaced tricuspid valve. The interventricular septum was intact. Fetal echocardiogram confirmed the finding of EA. Bilateral pleural effusion was also noted. The pregnancy ended at 33 weeks of gestation following the ultrasound finding of intrauterine fetal demise. Autopsy was not performed.

To our knowledge, EA has previously been reported in association with DS in two patients; in both cases EA was an incidental finding and had no clinical sequelae. These three cases suggest that DS should be considered in the differential diagnosis of EA detected antenatally.

Program Nr: 828 from the 1999 ASHG Annual Meeting

Skewed X-chromosome inactivation in 47,XXY and 48,XXYY patients: potential explanation for phenotypic variation among Klinefelter individuals. *Y. Iitsuka[1, 2], A. Bock[1], D.D. Nguyen[1], J.L. Simpson[1], F.Z. Bischoff[1]*. 1) OB/GYN, Baylor College of Medicine, Houston, TX; 2) OB/GYN, Chiba University School of Medicine, Chiba, Japan.

Klinefelter syndrome occurs in approximately 1:800 male births, and accounts for about 10-20% of males attending infertility clinics. Most studies have shown no obvious phenotypic differences between Klinefelter syndrome patients in which the extra X-chromosome is of paternal or maternal origin, but a minority of 47,XXY patients are adversely affected clinically and intellectually. The explanation for this phenotypic variation is not apparent. We hypothesize random or skewed X-inactivation in correlation to parental origin of the X-chromosomes. EXPERIMENTAL RATIONALE- We determined the parental origin and inactivation status of the X-chromosomes in 16 cytogenetically confirmed 47,XXY cases, two 48,XXYY cases and one 46,XY/47,XXY case. Parental origin of X-chromosomes was determined using fluorescent-based PCR for nine highly polymorphic markers specific to the X-chromosome. The human androgen-receptor methylation assay was then used to measure quantitatively X-inactivation status in subjects and their parents (controls). RESULTS- In 10 (53%) of 19 cases, both X-chromosomes were of maternal origin; in the remaining 9 (47%), one X was of maternal and one was of paternal origin. Of the 19 cases, 15 were informative at the androgen-receptor locus; in 4 (27%) of the 15, nonrandom X-inactivation was observed as defined by greater than 80% preferential inactivation involving one of the two X-chromosomes. The two 48,XXYY cases each showed one X of maternal origin (X^m) and one as paternal origin (X^p); in both cases preferential paternal X-chromosome inactivation existed. Two 47,X^mX^mY also showed preferential inactivation in one of the two X's, based on polymorphic marker analysis. CONCLUSION- Our results provide novel evidence for skewed X-inactivation in Klinefelter syndrome. This mechanism could explain the wide range of mental deficiency and phenotypic abnormalities observed in the disorder. Further studies correlating clinical features with parental origin and X inactivation status are in progress.

Program Nr: 829 from the 1999 ASHG Annual Meeting

Overlapping features of Prader-Willi syndrome and trisomy 18 during infancy. *H.A. Ishmael[1], L.M. Pasztor[1], P.G. Rothberg[1], J. Pfotenhauer[2], V. Hannig[2], M. Summar[2], M.G. Butler[1].* 1) Section of Medical Genetics and Molecular Medicine, The Children's Mercy Hospitals and Clinics, Kansas City, MO; 2) Division of Medical Genetics, Department of Pediatrics, Vanderbilt University, Nashville, TN.

Prader-Willi syndrome (PWS) and trisomy 18 share a number of features in the neonatal period. We recently evaluated three hypotonic infants with dysmorphic features who demonstrate common characteristics. The first, a 20-month-old female, who was born at term, was referred due to developmental delay and growth retardation. Decreased fetal movement and a choroid plexus cyst was identified by routine prenatal ultrasound. She was hypotonic with significant neonatal feeding difficulties. She had a narrow bifrontal diameter, dolicocephaly with mild ridging of the sagittal and metopic sutures, almond shaped eyes, a small mouth with a thin upper lip, a short nose, narrow hands, a small VSD, hypotonia, and developmental delay. Chromosome testing with FISH analysis was performed because of the clinical impression of PWS. Surprisingly, trisomy 18 mosaicism [47,XX, +18(23 cells)/46,XX(27 cells)] was found with no evidence of a 15q11-13 deletion. DNA methylation analysis with the SNRPN probe was normal. The second patient was thought initially to have trisomy 18 during the newborn period. He was severely hypotonic and presented at birth with a narrow bifrontal diameter, a small mouth, a prominent occiput, dorsiflexion of great toes, low set ears, bilateral cryptorchidism, and a high arched palate. He was found to have a deletion of 15q11-13, which was confirmed by FISH. A third hyptonic newborn with maternal disomy 15 was also initially thought to have trisomy 18. This female was hypotonic and had a narrow bifrontal diameter, a down turned mouth, almond shaped eyes, narrow hands, and a weak cry. These subjects illustrate the clinical similarities between PWS and trisomy 18 during infancy. One must proceed cautiously with the initial counseling and management of these infants. The prognosis and etiology behind these two conditions are markedly different.

Program Nr: 830 from the 1999 ASHG Annual Meeting

Phenotypic features of a patient with mosaic trisomy 18 and 45,X; comparison with three previous cases. *K.E. Jackson[1], M. Prieto-Carrasquero[1], S. Li[1,2], M. Marble[1]*. 1) Human Genetics Program, Tulane Univ Medical Sch, New Orleans, LA; 2) Department of Medical Genetics, University of South Alabama, Mobile, AL.

We report a 15-month-old female who was initially referred to genetics at six months of age because of developmental delay, and slightly abnormal urine organic acids at an outside laboratory. Growth parameters were in the 25th-50th percentile. She had micrognathia, narrow palate, downslanting palpebral fissures, cutis marmorata, hypotonia, and mild developmental delay. We analyzed urine organic acids, plasma amino acids, biotinidase enzyme analysis, and ammonia, which were non-diagnostic. The developmental delay persisted, and at 14 months, a karyotype surprisingly revealed 47,XX,+18, in 50 out of 50 cells analyzed. Echocardiogram, renal and abdominal ultrasounds were all normal. Since her phenotype was not indicative of trisomy 18, we repeated the karyotype in peripheral blood and skin fibroblasts. A repeat peripheral blood karyotype showed mosaicism for trisomy 18 and 45,X. Of 121 cells analyzed, 100 cells had trisomy 18, while 21 cells had 45,X. Interphase and metaphase fluorescent *in-situ* hybridization (FISH) are being performed for further analysis. The FISH results and the fibroblast cytogenetic analysis result will be presented.

In conclusion, we report a patient with a rare chromosomal abnormality. There are three previous case reports with mosaic 45,X and trisomy 18 in distinct cell lines. However, these individuals had a phenotype similar to Turner syndrome, while our patient has developmental delay, without stigmata of Turner syndrome. The percentage of cells with 45,X was higher in these reports than in our patient.

Program Nr: 831 from the 1999 ASHG Annual Meeting

A novel method for quantifying facial asymmetry. *P.L. Jamison[1], R.E. Ward[2], E.T. Everett[2].* 1) Anthropology, Indiana University, Bloomington, IN; 2) Oral Facial Genetics, Indiana School of Dentistry, Indianapolis, IN.

Assessment of facial asymmetry may be useful in exploring dysmorphogenesis. We hypothesize that disruptions in developmental stability may be evidenced by abnormal degrees of facial (fluctuating)asymmetry. Few studies have used direct measurements of the face to assess asymmetry because normal ranges of variation in facial asymmetry were unknown. In this study we describe two measures of overall asymmetry: a measure of total asymmetry (TA) based on summed differences for fourteen paired craniofacial anthropometric measurements and a weighted summed asymmetry, (WA) based on the absolute (nonsigned) differences but adjusted for the size of the measure. Using a large (N = 1312) reference data set of normal individuals, we calculated asymmetry values (TA and WA) for every individual in this sample. For TA the resultant distribution was non-skewed (S=.075; SE=.068) but was kurtotic (K=1.247; SE=.135) while the distribution for WA was both skewed (S=.942; SE=.068) and kurtotic (K=2.300; SE=.135). Following accepted statistical conventions for such nonnormal distributions, we utilized the 3rd and 97th percentiles of these distributions to define normal ranges of variation for each value. We also calculated TA and WA for 24 individuals with recognized syndromes manifesting various degrees of craniofacial dysmorphology and compared the results to our reference base asymmetry norms. Nineteen (79.2%) of the syndromic individuals fell outside the normal range on one or both of the asymmetry measures. Furthermore the ability to detect abnormal degrees of facial asymmetry may be useful in testing the theory that conditions with significant facial asymmetry, such as OAVS have a familial component. To this end we examined thirty-eight first degree relatives of individuals with OAVS. Thirteen (34.2%) had abnormally high asymmetry values based on one or both of the summary measures described above. These individuals were concentrated in just six of the twelve families comprising this preliminary study. These findings are consistent with other studies and support the theory that a genetic component exists in some cases of OAVS.

Program Nr: 832 from the 1999 ASHG Annual Meeting

Trisomy 7 mosaicism associated with carbohydrate-deficient glycoprotein syndrome and incontinentia pigmenti phenotype. *R. Jayoussi[1], R. Brill[1], H. Mandel[1,2], O. Lobel[1], I. Laeveski[1], Z. Galperin[1], R. Gershoni-Baruch[1,2]*. 1) Human Genetics, Rambam Medical Ctr, Haifa, Israel; 2) The Bruce Rappaport Faculty of Medicine, Technion, Institute of Technology, Haifa, Israel.

A girl with dysmorphic features, severe mental retardation and anomalous skin pigmentation associated with trisomy 7 and an unusual pattern of carbohydrate glycoprotein deficiency is described. Born at term to young, unrelated couple of Jewish Ashkenazi origin, following normal gestation and delivery. Birth weight was 2650g. (< 3rd centile) and OFC 34cm. (3rd centile). At two years of age she was referred for investigation because of slow psychomotor development. On clinical examination the following features were noted: high forehead, antimongolian slant, deep set eyes, a depressed nasal bridge, dysplastic low set ears, widely spaced inverted nipples, widespread irregular streaks and punctate lesions of depigmentation on trunk and all four limbs. Her lymphocyte karyotype was normal and she was given the diagnosis of incontinentia pigmenti. Anomalous pigmentation known to be correlated to chromosomal mosaicism or chimerism induced further evaluation and a skin fibroblast which was performed showed trisomy 7 mosaicism (46,XX/47,XX+7). FISH using a centromeric direct probe (Cytocell) confirmed the diagnosis. Extensive biochemical evaluation revealed an abnormal serum transferrin isoelectro-focusing pattern, consisting of an increased amount of disialotransferrin, reduced amounts of tetra, penta and hexasialotransferrin and a small amount of monosialotransferrin. Normal phosphomanomutase and phosphomanose isomerase activities in fibroblasts are consistent with the diagnosis of a previously undescribed variant of a carbohydrate-deficient glycoprotein syndrome. The association of the clinical biochemical and chromosomal abnormalities remains to be defined and clarified.

Program Nr: 833 from the 1999 ASHG Annual Meeting

Familial inheritance of a 5p14 deletion that results in a variable phenotype. *E.I. Johnson[1], R.C. Marinescu[1], H.H. Punnett[2], B. Tenenholz[3], J. Overhauser[1]*. 1) Dept. of Biochem/Mol Pharm, Thomas Jefferson University, Philadelphia, PA; 2) St. Christopher's Hospital for Children, Philadelphia, PA; 3) Penn State Geisinger Medical Center, Danville PA.

Deletions of 5p are normally associated with a diagnosis of cri-du-chat syndrome. Clinical features of this syndrome include a cat-like cry at birth, microcephaly, mental and developmental delay, growth delay and craniofacial features that include microcephaly, hypertelorism, and micrognathia. In 1986, a 3 generation family with 6 individuals having an interstitial deletion of 5p14 was described. All of the 6 individuals were completely asymptomatic. This suggested that a deletion of 5p14 is not associated with a clinical phenotype and does not contribute to the cri-du-chat syndrome phenotype. We report on a father and son who have an identical interstitial deletion of 5p14. Although the father is clinically and mentally normal, the son has significant clinical involvement including microcephaly, seizures, and global developmental delay. The location of the 5p14 deletion in the father and son was determined using fluorescent in situ hybridization and YAC clones that had been precisely mapped along 5p. Cells from a skin biopsy as well as blood were investigated in the father to rule out mosaicism. The extent of the deletion was compared with the deletion in the 3 generation family. The deletion in our father-son pair is smaller and entirely contained within the deletion previously described in a multigenerational family that lacks any clinical phenotype. This report demonstrates that the clinical outcome of a 5p14 deletion can vary even within the same family.

Program Nr: 834 from the 1999 ASHG Annual Meeting

Graves disease in patients with microdeletion 22q11.2: Possible predisposition to autoimmune disorders. *H. Kawame[1], M. Adachi[2], K. Tachibana[2], M. Masuno[3], K. Kurosawa[4], Y. Ochiai[1], F. Ito[4], Y. Eto[4]*. 1) Dep of Pediatrics, Tokyo Metropolitan Kita Med & Rehabilitation Ctr, Tokyo; 2) Dep of Endocrinology, Kanagawa Children's Med Ctr, Yokohama; 3) Div of Medical Genetics, Kanagawa Children's Med Ctr, Yokohama; 4) Dep of Pediatrics, Jikei Univ. Schl of Med, Tokyo, Japan.

Phenotypes associated with the microdeletion 22q11.2 chromosme involve many systems. The list of clinical findings are quite long, including some endocrine findings, but etiological mechanism of those entire features have not been understood. Graves disease, the most common cause of thyrotoxicosis in childhood and adolescence, is an autoimmune disorder characterized by the production of stimulating antibodies to the thyrotrophic receptor. These antibodies lead diffuse goiter and hyperthyroidism.

We present three female patients with a microdeletion 22q11.2 and Graves disease. Graves disease was diagnosed at age 7, 10, and 17 years, respectively. Clinical presentation was typical for hyperthyroidism, such as weight loss, palpitations, polyuria, excessive sweating, and exophthalmos. All patients showed elevated serum levels of thyroid hormones in association of suppressed level of TSH. TSH-receptor antibodies were positive in all patients. Noteworthy all patients had thrombocytepenia and two showed elevated platelet-associated IgG (PA-IgG). All of them had hypocalcemia, two presented as late-onset hypoparathyroidism.

Recently, juvenile rheumatoid arthritis, autoimmune hemolytic anemia, and immune thrombocytepenia have been described in patients with a microdeletion 22q11.2. Our observation suggest that Graves disease may be part of the clinical spectrum associated with the 22q11.2 microdeletion syndrome. We also suggest that this syndrome is associated with predisposition to autoimmune disorders which explain some of the extremely variable phenotypes of this syndrome.

Program Nr: 835 from the 1999 ASHG Annual Meeting

Fryns Syndrome or Pallister-Killian (Tetrasomy 12p) Syndrome? The Importance of Delineation. *S.J. Kennedy, A. Chan, N. Al-Sannaa, I. Teshima, A.S. Teebi.* Clinical Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

Phenotypic overlap exists between autosomal recessive Fryns syndrome and Pallister-Killian syndrome (PKS). A definitive diagnosis of PKS can be made via detection of tetrasomy 12p on fibroblast culture. Two patients, who presented with eventration of the diaphragm, or diaphragmatic hernia, wide mouth, nail hypoplasia and other anomalies, were diagnosed initially as having Fryns syndrome. In patient 1, the presence of slightly coarse facies with bitemporal narrowing and upward slanting eyes along with a bifid left thumb and relatively large body size prompted us to request chromosome analysis on fibroblast culture. Tetrasomy 12p was confirmed on 24/25 metaphases examined. The patient's development was only slightly delayed and she did not show skin pigmentation problems which are unusual for patients with PKS. In patient 2, maternal serum screening was positive for trisomy 21, but amniocentesis was declined. The patient had profound hyotonia and the facies were coarse but not typical of PKS or any classical chromosomal syndrome. The patient's condition deteriorated rapidly and an early post mortem fibroblast culture confirmed the diagnosis of tetrasomy 12p. One of the patients originated from an ethnic group known to have high frequencies of autosomal recessive disorders, lending to the initial diagnosis of Fryns syndrome. This illustrates the importance of considering other diagnoses such as chromosomal disorders that may have lower recurrence risks. This also suggests that PKS should be considered in any case suspected to have Fryns syndrome for counselling purposes.

Program Nr: 836 from the 1999 ASHG Annual Meeting

Clinical features in a unique family with Autosomal Dominant Limb-Girdle Muscular Dystrophy and Paget Disease of Bone. *V.E. Kimonis, M. Kovach, R. Khardori, D.A Gelber.* Southern Illinois Univ Sch Med, Springfield, IL.

We have identified a large family with a unique phenotype: Autosomal Dominant Limb-Girdle-Muscular-Dystrophy (LGMD) associated with early onset Paget Disease of Bone (PDB). A large family with autosomal dominant amyotrophic lateral sclerosis and PDB first reported by Tucker et al. in 1982 (MIM 167320) bears some resemblance to this family. Clinical evaluation in eight affected individuals (5M, 3F), mean age 49 y. indicated that 6/8 had both LGMD/PDB with evidence of only PDB in the youngest individual age 34 y. The onset of bone pain leading to a diagnosis of PDB begins early at a mean age of 39.5 y. Muscle weakness and pain begins at a mean age of 41.5 y. Clinical findings include tenderness of the hip, shoulder and spine, muscular weakness and pain, wasting of the shoulder and pelvic girdle muscles, and reduced/absent deep-tendon reflexes. Muscle biopsy in 4 individuals revealed abnormal muscle with evidence of atrophic fibers, fibrosis and mild regeneration and degeneration. Consistent with PDB, X-rays show coarse trabeculation, and sclerosis, particularly of the pelvis, shoulder and skull bones. Bone biopsy in 1 female for suspected neoplasia confirmed PDB. Laboratory evaluation revealed elevated alkaline phosphatase (mean 250 U/L, normal 30-130) in all individuals except one male age 46 y. who only had LGMD. Interestingly this male had the highest creatine kinase level of 264 IU/L (mean of group 121.6, normal 20-260). High resolution karyotype was normal. A male died at age 50 y from muscular dystrophy and cardiomypathy. He also had insulin dependant diabetes mellitus and coronary artery disease. Affected individuals eventually become bedbound; several ancestors died prematurely in their fifties from LGMD/cardiomyopathy. The association of LGMD with Paget disease of bone appears to also be genetically unusual. Linkage analysis excluded the loci for dominant and recessive forms of LGMD, PDB and cardiomyopathy in the family. A genome search is in progress to identify the gene causing these two apparently unrelated disorders. The clinical and molecular data in this unique family will be presented.

Program Nr: 837 from the 1999 ASHG Annual Meeting

A mutation in the 5' non-HMG box region of the SRY gene in two patients with Turner syndrome and Y mosaicism. *S. Kofman-Alfaro[1], P. Canto[2], E. de la Chesnaye[2], A. Cervantes[1], M. Lopez[1], B. Chavez[3], F. Vilchis[3], E. Reyes[3], A. Ulloa[3], J.P. Mendez[2].* 1) Genetica, Hosp General de Mexico, Mexico, DF, Mexico; 2) UIM en Biologia del Desarrollo, CMN SXXI, IMSS, Mexico DF, Mexico; 3) Depto. de Biologia de la Reproduccion, INNSZ, Mexico, DF, Mexico.

Mutations of the SRY gene are the cause of sex reversal in approximately 10-15% of XY females with Y pure gonadal dysgenesis. Most of these mutations are located on the HMG box coding region of the gene. However, several mutations outside this region have also been reported. We performed molecular studies of the SRY gene in 3 subjects with Turner syndrome and mosaic karyotypes; patients 1 and 2 were 45,X/46,XY, while patient 3 was 45,X/46,X,+der(Y). In cases 1 and 3 a missense mutation, S18N, was identified in the 5'non-HMG box encoding region of the SRY gene in DNA extracted from peripheral blood and both gonadal streaks. This abnormality was not identified in the father and brother of patient 3 and it was not found in 75 normal males, excluding a common polymorphism. Recently, the same mutation was observed in a brazilian 46,XY female with partial gonadal dysgenesis, suggesting the existance of a hot spot in this region of the SRY gene. We consider that in our two patients the predominance of the 45,X cell line besides the existing mutation, prevented the development of testicular tissue. The magnitude in which the 45,X cell line or the SRY mutation affected the phenotype can not be ascertained.

Program Nr: 838 from the 1999 ASHG Annual Meeting

A new X-linked lissencephaly syndrome, Barry-Kravis and Israel syndrome: Lissencephaly with agenesis of corpus calloum in a Japanese family. *I. Kondo[1], J. Tohyama[2], T. Fukuda[1], K. Obata[1], H. Yamagata[1]*. 1) Dept of Hygiene, Ehime Univ. School of Medicine, Ehime 791-0295, Japan; 2) Dept. of Pediarics, Okinawa Child Development Center, Okinawa 904-2174, Japan.

Lissencephaly is one of the most severe brain malformations characterized by a smooth cerebral surface and agyria with or without pachygyria. More than 25 syndromes with lissencephaly have been described and divided into two distinct groups, type 1 (generalized lissencephaly), including the Miller-Dieker syndrome (MDS), and isolated lissencephaly sequence (LIS), and type II (hydrocephalic lissencephaly), involving the Fukuyama congenital muscular dystrophy. Most cases with lissencephaly are sporadic, and patients with MDS or LIS have a deletion within chromosome band 17p13.3. Some forms of lissencephaly, however, are familial, and one of the gene responsible for X-linked lissencephaly has been isolated and named as doublecortin. Lissencephaly is sometimes associated with agenesis of the corpus callosum. Almost all patients are sporadic, but two families with lissencephaly and agenesis of the corpus callosum have been reported, one family with X-linked and another one with autosomal recessive inheritance. We report a family that has two male infants with lissencephaly and agenesis of the corpus callosum. The clinical features in these patients were characterized by severe growth failure, psychomotor retardation and intractable seizures with the neonatal onset. No microdeletion of 17p13.3 was detected by FISH analysis. No DNA mutation was identified in the doublecortin gene (DCX1) in both patients and their mother by DNA sequencing. Magnetic resonance imaging (MRI) scan of the mother did not show a subcortical band heterotopia. On the basis of the clinical course and a family pedigree, our family seems to the second family with a X-linked lissencephaly syndrome described by Berry-Kravis and Israel. The main clinical characteristics of the Berry-Kravis syndrome are 1) intractable seizure, severe psychomotor retardation, and growth detraction, 2) agyria-pachygyria and agenesis of the corpus callosum in MRI scan, and 3) X-linked recessive inheritance.

Program Nr: 839 from the 1999 ASHG Annual Meeting

Caudal duplication sequence in a monozygotic twin. *H.Y. Kroes, J.C. Oosterwijk, A.J. van Essen.* Department of Medical Genetics, University of Groningen, Groningen, The Netherlands.

We present a girl with a spina bifida occulta, duplication of the distal spine including the sacrum, left double ureter, duplication of the vagina and cervix, and duplication of the distal colon with an ectopic anus and rudimentary perineal anus. She was one of a pair of monozygotic twins. Her sister had none of the above mentioned anomalies. This case is another example of the phenotype illustrated in the paper by Dominguez et al (1993), in which he presents six similar cases, and introduces the term caudal duplication syndrome. We propose the term caudal duplication sequence, as it is likely that one single event caused sequentially the duplications of the different involved organs. Monozygotic twinning is a known risk factor for anomalies in the caudal region like VATER association, caudal regression sequence, bladder exstrophy sequence, and sirenomelia. The occurrence of caudal duplication sequence in a monozygotic twin makes it very likely that the etiology is non-genetic, although a somatic mutation cannot be excluded.

Program Nr: 840 from the 1999 ASHG Annual Meeting

Identification of a novel common mutation in the connexin 26 gene (GJB2) among Japanese patients with childhood deafness. *T. Kudo[1,2], S. Kure[1], Y. Matsubara[1], K. Ikeda[2], T. Oshima[2], K. Watanabe[2], T. Kawase[2], T. Takasaka[2], K. Narisawa[1]*. 1) Department of Medical Genetics; 2) Department of Otorhinolaryngology-Head and Neck Surgery, Tohoku University School of Medicine, Sendai, Japan.

Mutations in the connexin 26 gene (GJB2), which encodes a gap-junction protein and is expressed in the inner ear, have been shown to be responsible for a major part of nonsyndromic hereditary prelingual (early-childhood) deafness in Caucasians. We have sequenced the GJB2 gene in 39 Japanese patients with childhood deafness (group 1), 39 Japanese patients with postlingual progressive bilateral sensorineural hearing loss (group 2) and 63 Japanese individuals with normal hearing (group 3). Three novel mutations were identified in group 1: a single nucleotide deletion (235delC), a 16 bp-deletion (176-191 del (16)) and a nonsense mutation (a408c) in five unrelated patients. The 235delC mutation was the most common, accounting for seven in ten mutant alleles. Screening of unrelated normal individuals for the three mutations indicated that the carrier frequency of the 235delC mutation was 2 in 203 in the Japanese population. No mutation was found in group 2 patients. We also identified two novel polymorphisms, a341g and t608c, as well as previously reported two polymorphisms (g79a and g109a). Genotyping with these four polymorphisms allowed normal Japanese alleles to be classified into seven haplotypes. All 235delC mutant alleles identified in four patients resided only on type 1 alleles, which would favor the hypothesis that the mutation has a single origin. The present study suggested that GJB2 mutations were responsible for approximately 13% (5 of 39) of prelingual deafness in Japan. The relatively high prevalence of the 235delC mutation and the availability of a simple DNA-diagnostic method would be useful in genetic counseling of prelingual deafness in Japan.

Program Nr: 841 from the 1999 ASHG Annual Meeting

Parental mosaicism of JAG1 mutations in families with Alagille syndrome. *A. Kujat, A. Röpke, I. Hansmann, I. Giannakudis.* Humangenetik, Martin-Luther-Universität, Halle, Germany.

The clinical features of the Alagille Syndrome (AGS) include chronic cholestasis, a typical face, heart, skeletal and ocular anomalies. The positionally cloned JAG1 gene within 20p12 has been found to be causally related to the disease. The analysis of pedigrees of AGS patients demonstrates highly variable expression. The clinical study of 33 AGS patients where mutations had been detected we found anomalies in liver 91%, heart 97%, face 97%, eye 87% and vertebrae 65%. Phenotypic differences between patients within same but also between different families carrying identical mutations were observed. In our screen (48 mutations were described) we observed mosaicism in four cases. In case 1, two sisters were affected by an insertion in exon 26 and was not observeable by sequencing the parent's DNA. By designing a primer that corresponds to the insertion the mutation was detected in the mother's DNA. In case 2 upon sequencing the father's DNA showed no signal corresponding to the mutation found in his offspring (R184H). Since this mutation creates a restriction site for PmlI we confirmed our observation by digestion, which resulted in mutation specific fragments in the patients and weaker in the father's DNA. In case 3 the clinically affected mother showed a mutation specific SSCP-shift of exon 5 with less than half of the intensity of the patient's band. Accordingly, sequence analysis of the respective exon of the mother disclosed a faint heterozygous signal representing a splice site substitution. In case 4 after microsatellite analysis using D20S1154 the patient's paternal allel showed a clear signal reduction appearing at less than half the dose as expected. The result was reproduceable with another pair of primer for the respective locus. We consider the signal reduction to be due to a deletion affecting about 25% of the lymphocytes, as judged from the signal intensity. Our results point to a possibly underestimated frequency of mosaicism in Alagille Syndrome occurring in up to 10% of the cases. Since mosaicism was detected in clinically mildly affected patients and in parents with no obvious anomaly, this has to be considered in genetic counselling.

Program Nr: 842 from the 1999 ASHG Annual Meeting

Intrafamilial correlation of clinical manifestations in neurofibromatosis 2 (NF2). *R.A. Kumar[1], M.E. Baser[2], D.G.R. Evans[3], A. Wallace[3], V.F. Mautner[4], L. Kluwe[5], H. Joe[1], J.M. Friedman[1], G. Rouleau[6].* 1) Dep't Medical Genetics, UBC, Canada; 2) L.A., USA; 3) St. Mary's Hosp, Manchester, UK; 4) Klin. Nord Ochsenzoll, Hamburg, Germany; 5) Univ Hamburg, Germany; 6) McGill Univ, Quebec, Canada.

Anecdotal evidence suggests that familial correlations exist in disease presentation in patients with neurofibromatosis 2 (NF2). We analyzed intrafamilial correlations in age at onset of first symptom, age at hearing loss and number of intracranial meningiomas in 223 patients from 55 families with NF2. The correlation coefficients and their corresponding 95% confidence intervals are shown in the table.

	Age at onset	Age at hearing loss	No of meningiomas
All patients	0.32 (0.19, 0.54)	0.37 (0.16, 0.59)	0.48 (0.33, 0.68)
Excluding probands	0.40 (0.22, 0.60)	0.58 (0.35, 0.77)	0.56 (0.39, 0.75)

Consideration of the mutation types separately was limited by small sample sizes, but the correlation coefficients were generally higher in 8 families with germ-line nonsense or frameshift mutations and in 9 families with missense mutations than in 10 families with with splice-site mutations. This is consistent with previous reports of phenotypic heterogeneity in patients with splice-site mutations. The most striking finding for a specific mutation type was the high intrafamilal correlation of age at hearing loss for patients with missense mutations (r = 0.83; 95% CI, 0.51-0.99). This may reflect the occurrence of a milder overall phenotype among patients with germ-line missense NF2 mutations and consequent larger family sizes. We conclude that some NF2 clinical manifestations exhibit significant intrafamilial correlations and that allelic heterogeneity is an important determinant of disease severity in NF2.

We thank the Acoustic Neuroma Association of Canada and the BC Medical Services Foundation for their support.

Program Nr: 843 from the 1999 ASHG Annual Meeting

Familial and Sporadic acromegaly: A distinct clinical entity. *W.W. Lam[1], S. Orme[3], G. Taylor[2], P. Belchetz[3], C.E. Chu[1]*. 1) Dept Clinical Genetics, St James's Hosp, Leeds; 2) Yorkshire Regional DNA Laboratory, St James University Hospital, Leeds; 3))Dept Endocrinology, The General Infirmary at Leeds.

Acromegaly is a chronic disorder resulting from excessive secretion of growth hormone. It may occur as an isolated phenomenon or as part of the Carney complex or Multiple Endocrine Neoplasia type 1(MEN1). Isolated acromegaly is a rare disorder with an incidence of around 1 in 30,000 and is usually considered to be sporadic but familial cases have been recognised. Some acromegalic families have been found to have mutations in the MENIN gene.The aim of the study was to investigate the incidence of familial isolated acromegaly in a population of acromegalics attending a regional endocrine clinic and the possibility of germline mutations in the MENIN gene in patients with isolated acromegaly and whether this is part of the MEN1 spectrum.30 kindreds (total of 257 subjects; including 32 patients with isolated acromegaly with 2 sib pairs, 60 parents, 93 siblings and 72 children) were studied for evidence of clinical features of acromegaly. This was performed by 2 experienced endocrinologist working independently, viewing serial photographs and biochemical investigations of suspected cases.22 acromegalic patients, including 3 sib pairs (one extra-regional), were then investigated for germline mutations by genomic sequencing of the coding region and all intron-exon boundaries of the MEN1 gene using Big-Dye terminators and the ABI 377 semi-automated sequencer.No new cases of acromegaly were identified but 2 sib pairs in such a cohort was highly significant (O/E ratio 396.8; $p<0.0001$). No mutations were detected in either familial or sporadic patients. This suggests that familial and sporadic isolated acromegaly are not part of the MEN1 phenotype. Combined with studies which link isolated acromegaly to chromosome 11, this would indicate that a possible second tumour suppressor gene may be present.

.

Program Nr: 844 from the 1999 ASHG Annual Meeting

Adverse phenotypes associated with gonosomal aneuploidy. *R.R. Lebel[1], R.L. Brown[2].* 1) Genetics Services, Glen Ellyn, IL; 2) Univ Colorado Health Sci Center, Grad Program in Genetic Counseling, Denver, CO.

Gonosomal aneuploidy (45,X; 47,XXX; 47,XYY; various mosaic states) may have a cumulative incidence greater than that of trisomy 21, and may pose a greater challenge to genetic counseling. Prospective studies generally show highly variable phenotypes, but seldom serious malformations or developmental delays (typical in 45,X or high-order multiples such as tetrasomy). We report 15 sex chromosome aneuploidies other than 45,X and 47,XXY: 7 cases of 47,XXX, 3 of 47,XYY and 5 mosaics. Eight were diagnosed prenatally for indications of maternal age (6), delayed fertility (1) or thick fetal nuchal skin fold (1); this last proved to be associated with 47,XXX and Tetralogy of Fallot. One woman referred for maternal age had ventriculomegaly found by ultrasound at time of amniocentesis, which revealed 47,XXX. Five postnatal diagnoses were made after referral for malformations (47,XXX with cleft palate; X aneuploid mosaicism with aniridia; 47,XYY with craniosynostosis and cryptorchidism), secondary amenorrhea, or recurrent miscarriages (1). One case of 47,XYY was made at autopsy of a 19 week miscarriage with urogenital anomalies. Mosaic 45,X/47,XYY was found in a miscarried twin pregnancy. Though the etiologic significance of these aneuploid states is indeterminate, and the association with a seriously abnormal phenotype might be coincidental, it is important to report these observations in view of what is known of the potential importance of other aneuploid states, including other gonosomal aneuploidies such as 45,X and 47,XXY. Genetic counseling is complex when findings such as these are at hand, either prenatally or postnatally.

Program Nr: 845 from the 1999 ASHG Annual Meeting

Febrile convulsions, ataxia, developmental delay and overgrowth-a new MR syndrome. *D. Lev[1,3], N. Watemberg[2,3], T. Lerman-Sagie[2,3]*. 1) Institute of Medical Genetics, Wolfson Medical Center, Holon, Israel; 2) Pediatric Neurology Unit; 3) Metabolic Neuro-Genetic Clinic.

We describe a new syndrome consisting of recurrent complicated febrile convulsions, developmental delay, ataxia and overgrowth in three unrelated girls. The three girls, aged 3 to 4 years were all born to healthy non-consanguineous parents and have normal siblings. Their birth weight was appropriate for gestational age. They are not dysmorphic and have normal head circumference. Development was delayed: they walked with ataxic gate after the age of 2 years and spoke at 3 years. Their growth charts are remarkably alike: they initially had a normal growth curve and around 24 months of age they started to gain weight excessively. They all continue to suffer from complicated febrile seizures, which started before 12 months of age and are resistant to anticonvulsive medications. Metabolic evaluation was normal. They have normal MRI and normal EEG. Fragile X syndrome and Prader-Willy syndrome was ruled out. We suggest this is a new MR/Overgrowth syndrome that should be considered in children with recurrent febrile convulsions, developmental delay and obesity.

Program Nr: 846 from the 1999 ASHG Annual Meeting

Eleven years old Arab girl with trisomy 13. *A.A. Abdulaal, Sr., S.S. Al Arrayed, F.A. Ali, H. Sanad.* Genetic Dep., Salmaniya Medical complex., Manama., Bahrain.

A case of trisomy 13,confirmed by G banded chromosome analysis, in an eleven years old Bahraini girl. There is no cytogenetic evidence for mosaicism in the propositus or her parents. banding analysis showed a complete extra chromosome 13.\parThis female baby was born on 7.5.88 by assisted breech to a 37-years old gravida 8 para 7 mother,who had uneventful pregnancy and delivery.\parBirth weight was 2.9kg,(10th centile)birth length47.5cm(3rd centile)head circumference 31.5cm(below 3rd centile)and apgar scores 9and 9 at 1 and 5 minutes respectively.\parThe following congenital abnormalities were noted at birth:Microcephaly,high arched palate, micophthalmia,scalpdefect with abnormal hair whorls, haemangiomata of the face, overlapping of fingersleft hnds simian crease,abnormal feet,all other system were normal.\par screening for congenital infection was done,which was negative.Skull Xrays and skull ultrasound were normal.Renal ultrasound ,echocardiogram were normal. ocular ultrasound confirmaed bilateral microphthalmia.\parAt two months of age,patients develop recurrent grand mal epilepsy for which she was hospitalized many times.EEG shows a diffues brain dysfunction with multiple epileptiform activity.\parShe suffered severe developmental and mental retardation and was bedridden all her life.\parAdmitted recently for convulsion at age of 11 years, all her growth parameter were below 3rd centile. .MRI brain show gross atrophic changes in the brain.

Program Nr: 847 from the 1999 ASHG Annual Meeting

Trisomy / monosomy of the N-MYC region in sibs arising from a unique maternal karyotype. *J. Ahmad[1], S. Herath[1], T. Barnhart[1], J. Andeweg[1], S. Baldinger[2], T.M. Sutton[3], E. Bendelstenzel[3], C.A. Curtis[1], R.R. Higgins[1]*. 1) Allina Cytogenetics Laboratory, Abbott Northwestern Hospital, Minneapolis, MN; 2) Genetic Counseling Director, Abbott Northwestern Hospital; 3) Children's Hospitals and Clinics, Minneapolis, MN.

Cytogenetic studies were requested on a one day-old infant with pulmonary atresia and ventricular septal wall defect. Other phenotypic findings included: patent ductus arteriosis, hypoplastic left ventricle and mitral valve, posteriorly rotated ears and hypoplastic nails. Chromosome analysis revealed a 46,XX karyotype with a small interstitial deletion in one chromosome 2 involving G-band region 2p24.1-2p25 that included the N-MYC proto-oncogene. Parental chromosomes were done. The father's karyotype was 46,XY. The mother's karyotype included the deleted chromosome 2 previously identified in the child but was balanced by the insertion of that chromosome 2 segment into one chromosome 1 at G-band region 1p34.2 [46,XX,ins(1;2)(p34.2;p24.1p25)]. Cytogenetic results were confirmed by FISH using probes specific for the 2p subtelomeric sequences and the N-MYC proto-oncogene. Cytogenetic analysis of the 3 year-old brother of the proband showed he inherited the der(1) from the mother, but not the der(2) [46,XY,der(1)ins(1;2)(p34.2;p24.1p25) mat]. This karyotype results in trisomy for the 2p24.1-2p25 region and N-MYC. The brother is noted as also having hypoplastic left heart syndrome with significant aortic arch obstruction. A recent chest x-ray has demonstrated pulmonary edema with significant cardiomegaly. He is developmentally delayed with an estimated developmental quotient of 2 and 2 1/2 years of age. His height is 86.4 cm (3rd percentile) with a weight of 13.8 kg (25th percentile). He has had a tracheostomy and was hospitalized for several episodes of pneumonia. He continues to be trached and is ventilated, has subglottic stenosis and left vocal cord paresis. Four patients with a deletion of the N-MYC region have been summarized by Saal et al. (1996), but this appears to be the first report of a patient trisomic for a small chromosomal segment encompassing the N-MYC proto-oncogene.

Program Nr: 848 from the 1999 ASHG Annual Meeting

Duplication Xq in a severely affected male with 46,XY,der(21) t(X, 21)(q26; p13) identified by chromosome microdissection. *M. Akiyama[1], H. Ohashi[2], T. Tohma[2], H. Ohata[1], A. Shishikura[1], I. Miyata[1], N. Usui[1], Y. Eto[1], H. Kawame[3]*. 1) Dept. of Pediatrics, Jikei Univ. School of Medicine, Tokyo; 2) Div. of Medical Genetics, Saitama Children's Med. Center, Saitama; 3) Dept. of Pediatrics, Tokyo Metropolitan Kita Med.& Rehabilitation Center, Tokyo, Japan.

Functional disomy of partial Xq chromosome with unbalanced X-autosome translocation is extremely rare. Male patients with functional X disomies usually have severe phenotypic outcome, although female patients show variable phenotypes. We report a male infant with MCA/MR and a duplication Xq26-qter on derivative chromosome 21 identified by chromosome microdissection. The proband was 9-month-old male infant. He was born at 33 weeks to a 30 years old, healthy mother. He had severe prenatal-onset growth retardation, microcephaly, dysmorphic facial features, cryptochidism, and left multidysplastic kidney. Neurologically, he had remarkable hypotonia, infantile spasms, severe developmental delay, and feeding difficulty. Brain CT revealed agenesis of corpus callosum. His blood chromosome analysis revealed 46, XY, add (21) (p13). Chromosome analysis of his parents was denied. In order to define the extra material on der (21), chromosome microdissection was performed. The dissected DNA was amplified and labelled using degenerated oligonucleotide primed polymerase chain reaction (DOP-PCR). The labelled DNA was reverse painted to the patient's cells and his karyotype was concluded as 46, XY, der (21) t (X; 21) (q26; p13). Functional Xq disomy was supported by the absence of XIST on der (21). Duplication Xq26-qter attached to Xp has been described in only one family previously. To our knowledge, this is the first case to be described with this cytogenetic abnormality due to unbalanced translocation defined by microdissection.

Program Nr: 849 from the 1999 ASHG Annual Meeting

Clinical, Endocrine and Cytogenetic study of 141 pediatric patients with ambiguous genitalia. *A. Al-Mutair, M.A. Iqbal, A. Ashwal, N. Sakati.* Cytogenetics/Molecular Genetic, King Faisal Specialist Hospita, Riyadh, Saudi Arabia.

In the present study, we report our data on 141 newborn patients referred for karyotyping with a primary indication of ambiguous genitalia. Chromosome analysis and hormonal evaluations were performed according to routine laboratory methods.

Out of 141 patients, 22 (15.7%) were excluded because the criteria for ambiguous genitalia did not fit in these patients. The remaining 119 patients with sexual ambiguity were due to: a) endocrine defects – 52.4%; b) non-endocrine defects – 47.8%. In the group with endocrine defects, congenital adrenal hyperplasia was the underlying cause in 41 patients; the karyotype of these patients was 46, XX (39 cases) and 46, XY (2 cases). The remaining 22 cases in this group showed 46, XY karyotype and consisted of vanishing testicular syndrome (6 cases); Leydig cell hypoplasia (5 cases); androgen insensitivity syndrome (5 cases); 5 alpha reductase deficiency (3 cases); gonadal dysgenesis (1 case); para hypopitutirism (one case) and true hermophrodite (1 case).

In the non-endocrine defect group, hypospiadias was seen in 11 cases all of these had a 46, XY karyotypes. Cloacal anomaly was present in 10 patients, six of these were 46, XY and 4 were 46, XX. Congenital local genital malformations were observed in ten cases (9 cases = 46, XY; 1 case = 46 XX). Nineteen cases were due to metabolic defects or associated with dysmorphic features. 7 cases were classified as idopathic (6 cases = 46, XY; 1 case = 46, XX).

Thirteen patients were wrongly referred as having ambiguous genitalia (most probably by a general pediatrician). All of these cases were later found to be normal by the pediatric endocrinologist.

Approximately 10% patients were raised phenotypically different than their chromosomal sex. Our data emphasizes the importance of rapid clinical and laboratory evaluation of newborns with ambiguous genitalia to eliminate life threatening medical and psychological problems.

Program Nr: 850 from the 1999 ASHG Annual Meeting

Phenotype of patient with pure partial trisomy 2p (p23®pter). *M. Al-Saffar[1,4], E. Lemyre[2,4], R. Koenekoop[3,4], A.M.V. Duncan[2,4], V.M. Der Kaloustian[1,4].* 1) F. Clarke Fraser Clinical Genetics Unit, Departments of Pediatrics and Human Genetics; 2) Department of Pathology; 3) Department of Ophthalmology; 4) Montreal Children's Hospital and McGill University, Montreal, Quebec, Canada.

We present a 7-month-old female with the karyotype 46,XX,der(13)(p23;p11.2).ish der(13)(wcp2+). Painting confirmed that the additional segment on 13p was of chromosome 2 origin, resulting in trisomy 2p23®2pter. Parental karyotypes were normal. The child had a prominent forehead with a flat hemangioma, depressed nasal bridge, protruding tongue, and posteriorly angulated ears.

Ophthalmological examination revealed esotropia with poor abduction of the right eye, bilateral high myopia (-5.50 D), retinal hypopigmentation, foveal hypoplasia and striking left optic nerve hypoplasia. Pectus excavatum and a protruding abdomen with diastasis recti were also observed. There was generalized hypotonia. Fine and gross motor developments were at the one-month age level. Abdominal U/S was normal. A voiding cystourethrogram indicated grade II reflux on the left and grade III-IV reflux on the right side. An EEG revealed epileptiform discharges. CT scan of the brain showed decreased white matter, but MRI was normal.

Twelve cases reported in the literature have partial trisomy of 2p23®2pter. These are inherited as unbalanced translocation and associated with partial deletion of various chromosomes (Bender et al., 1969; Carrier,1975; Magenis et al., 1975; Francke and Jones, 1976; Cassidy et al., 1977; Neu et al., 1979; Rosenfeld et al., 1982; Fineman et al., 1983; and Laurie et al., 1995). As a result of the associated partial monosomies of diverse chromosomes, these patients have different phenotypes. There are no reports of *de novo* direct duplication of 2p23®2pter. Our patient represents the only case of pure partial trisomy of this segment.

Program Nr: 851 from the 1999 ASHG Annual Meeting

The behavior of molecular cytogenetic parameters in parents of Down Syndrome offsprings. *A. Amiel, O. Reish, I. Kedar, M. Fejgin.* Genetics Unit, Meir General Hosp, Kfar-Saba, Israel.

We attempted to demonstrate a loss of replication control and thereby centromere dysfunction leading to predisposition to nondisjunction in 10 couples with a Down Syndrome (DS) offspring and in elderly women. One color FISH was applied to interphase nuclei (lymphocytes). Replication pattern of two pairs of allels, RB-1 and 21q22 were studied and the rate of aneuploidy was estimated using two alpha satellite probes of chromosomes 8 and 18.

	ASYNCRONOUS REPLICATION*		HYPER	PLOIDY *
patients	21q22	RB-1	8 alphasatel	18 alphasatel
DS mothers n=9	18+/- 1.3 **	17 +/- 1.1 **	3.7+/- 0.6 **	4+/-0.6 **
elderlies n=4	17+/-1.0 **	15+/-1.8 **	4+/-0.1 **	4.6+/-1.0 **
controls n=13	11+/-1.0	8+/-0.9	1.5+/-0.2	1.5+/-0.3

* mean 0f the proportion of cells with asynchrony or hyperploidy ** $p<0.01$ Asynchronous replication pattern (SD Pattern) was significantly higher in elderly women and in mothers of DS (both young and old mothers) compared to the control group($p<0.01$) in both loci studied. The rate of hyperploidy (three or more signals) with the two alpha sattelite loci was also significantly higher in these groups ($p<0.01$). Our results suggest the existence of an association between replication timing and the rate of non-disjunction. A higher rate of asynchronization and aneuploidy was found in older women and in mothers of DS offsprings irrespective of age. These findings may reflect a predisposition for neiotic non-disjunction in these women.

Program Nr: 852 from the 1999 ASHG Annual Meeting

Towards the clinical validation of Spectral Karyotyping (SKY). *A. Anguiano, V. Sulcova, M. Ayad, A. Sbeiti, A. Fraser, S. Wang, L. Edwards, K. Reddy, B. White.* Cytogenetics Dept, Quest Diag, Nichols Inst, San Juan Capist, CA.

Spectral Karyotyping (SKY) is an interferometer based method that allows the distinctive identification of all 24 human chromosomes by color after the hybridization with chromosomal DNA libraries that are each combinatorially labeled with as much as five fluorochromes. A number of reports have shown that SKY is useful to identify chromosomal exchanges and to characterize marker and ring chromosomes. In this study we aimed to test the performance of SKY in a cytogenetics reference laboratory. The vendor's protocol was followed. We studied cytogenetic preparations from peripheral blood of 20 normal subjects (10 males and 10 females). We also studied 30 cytogenetic preparations from selected abnormal cases having chromosomal abnormalities such as translocations, additional genetic material in certain chromosomes, and marker or ring chromosomes. The abnormal cases were representative of prenatal, pediatric, reproductive investigation, products of conception, and hematologic malignancy (peripheral blood or bone marrow) cases. The study of chromosomes from the peripheral blood of normal subjects yielded a 99.2% accuracy of automatic classification of chromosomes. All SKY results of constitutional abnormalities were confirmed with GTG banding and/or whole chromosome painting; some were also confirmed by locus specific FISH probes. One constitutional case and a significant number of hematologic malignancy cases revealed cryptic rearrangements. Confirmatory chromosome painting was not performed for cases with hematologic malignancies. While we were able to consistently identify origin of small markers and ring chromosomes, the lower limit of resolution of SKY has yet to be defined. However, our results demonstrate that the method was highly accurate and informative in the cases selected for analysis. Additional studies are now in progress to further evaluate and establish the role of SKY in our clinical laboratory practice.

Program Nr: 853 from the 1999 ASHG Annual Meeting

Significant hypotonia and developmental delay: Hallmarks of a terminal deletion of chromosome 2q. *H.H. Ardinger[1], D.L. Persons[1], R.E. Lutz[2], M.A. Beattie[2].* 1) Pediatrics, University of Kansas Medical Center, Kansas City, KS; 2) Pediatrics, University of Kansas School of Medicine-Wichita, Wichita, KS.

Patients with a terminal deletion of the long arm of chromosome 2 have been rarely reported. We present the clinical findings of a 5 year old girl whose deletion was not initially detected on a high resolution analysis. A second analysis coupled with a FISH test using a 2q telomere probe confirmed the deletion of 2q37-qter.

The patient presented with a history of pronounced hypotonia that did not affect infant feeding, but which delayed ambulation until age 4 years. She has had surgery for coarctation of the aorta and eyelid ptosis. She is followed for bicuspid aortic valve and aortic stenosis, a seizure disorder and severe developmental and cognitive delay especially in the area of language. Growth has been normal. She has a number of minor dysmorphic facial features in addition to a narow thorax with low nipple placement, small labia majora, proximally placed thumbs, long slender fingers, flat narrow feet, thin lower legs and hyperextensible joints.

There are 4 patients reported in the literature with a terminal deletion of 2q involving band 2q37 in two, 2q36->qter in one and 2q35->qter in one. Comparing our patient to the previous reports, the 5 patients are all noted to have hypotonia and developmental delay. Dysmorphic features common to all are not particularly distinctive and include frontal bossing, long eyelashes and micrognathia. Our patient is the only one to have a heart defect.

Because of the lack of a specific facial phenotype or particular structural anomalies, and because the deletion may be difficult to detect, it is possible that this diagnosis is being missed. High resolution chromosome analysis with special attention to 2qter and FISH studies with a 2q telomere probe are recommended for any undiagnosed patient presenting with significant hypotonia (walking delayed beyond 2 years) and developmental delay even if unaccompanied by other anomalies.

Program Nr: 854 from the 1999 ASHG Annual Meeting

Microarray based Detection of Single Copy Sequence Changes in Genomic DNA. *Y. Bao, D. Che, N. Lermer, J. Shi, A. Prokhorova, U. Müller.* Advanced Technology, Vysis, Inc., Downers Grove, IL.

The Vysis GenoSensor microarray system consists in a unique chromium coated chip surface, multi-color fluorescent hybridization chemistry, and a wide-field non-scanning CCD based imaging system. This system has been successfully applied to the detection of sequence amplifications in tumor tissues, whereby genomic DNA was extracted from tumor cells and labeled with a green fluorophor, then hybridized to a microarray in the presence of normal human reference DNA (labeled red) and Cot-1 DNA (to suppress repeat sequences). The microarray contains 3 spots for each genetic locus, which for this application consisted mostly in oncogenes that have been shown to be potentially amplified in tumor tissues. A mixture of tumor DNAs with known amplifications has been used to measure the performance of this system, and to demonstrate reproducible detection of 2 fold amplifications with >95% confidence on each chip. For applications to prenatal diagnosis the reliable detection of single copy gene deletions or additions is essential. As proof of principle we have carried out hybridizations with normal female (green) and normal male (red) total human DNA. Target spots containing the androgen receptor (X chromosome) revealed a Green/Red ratio significantly higher than the ratios of all other loci (>99% confidence level), suggesting sufficient sensitivity for detection of single copy deletions. Using the DNA from three patients with various cytogenetic abnormalities (deletions and/or unbalanced translocations) we have been equally successful in detecting trisomic or monosomic regions. Supported by the National Institute of Standards and Technology ATP Award 94-05-0021.

Program Nr: 855 from the 1999 ASHG Annual Meeting

Molecular cytogenetic characterization of a familial translocation (1;4) with a breakpoint telomeric to the most distal subtelomeric single copy probe known on chromosome 4. *I. Bartels[1], S.K. Bohlander[1], Y. Mehraein[2], M.R. Speicher[3], S. Uhrig[3], B. Zoll[1].* 1) Institute of Human Genetics, University of Goettingen, Goettingen, Ger; 2) Institute of Human Genetics, Medical University of Hannover, Germany; 3) Institute of Anthropology and Human Genetics, Muenchen, Germany.

A 28 year old pregnant woman presented in our genetic counselling unit. She had two pregnancies: one was terminated because the male fetus had a hydrocephalus, the other was a missed abortion at 8 weeks of gestation. Her lymphocyte karyotype revealed additional G-band negative material at band 4p16.3. Hybridization with a probe for 4p16.3 (Wolf-Hirschhorn) showed that the breakpoint was distal to this locus. 24-colour multiplex-FISH analysis demonstrated material not originating from chromosome 4, but the additional segment was too small to be identified by this method. A subtelomeric probe from 4p also hybridized to the der(4) chromosome. The most likely region of origin of additional material was thought to be the short arm of chromosome 1. A subtelomeric PAC clone from 1p hybridized only to one 1p, the other signal was present on the der(4)p. Thus the additional material at 4p originated from 1p. This was not visible on the 500-band level. The fetus was shown to carry both derivative chromosomes. In this family, applying molecular cytogenetic methods is essential to differentiate balanced and unbalanced carriers of the translocation. To our knowledge this is the first example of an apparently balanced but non-reciprocal translocation.

.

Program Nr: 856 from the 1999 ASHG Annual Meeting

Primary ovarian failure associated to a 46,XX,t(6;18)(p23;q22) balanced reciprocal translocation. Possible new autosomal genes involved in ovarian development. *E.F. Bastos[1,3], J.C. Llerena Jr.[1,2], J.C. Cabral de Almeida[1,2]*. 1) Instituto de Biofísica CCF, Univ. Fed. do Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil; 2) Centro de Genética Medica - Instituto Fernandes Figueira - FIOCRUZ - Rio de Janeiro, Brazil; 3) Instituto de Biociências - Universidade do Grande Rio - Prof. José de Souza Herdy - Rio de Janeiro, Brazil.

Primary ovarian failure has heterogeneous causes. Among genetic causes, X monosomy and Xp11/Xq13 deletions are among the principal causes associated with primary or premature ovarian failure. We describe a 22 year old woman with primary amenorrhea, no dysmorphies or neuro-developmental anomalies, absence of secundary sexual development, hypergonadotrophic hypogonadism and biopsy of both streak gonads with scarcity of primordial follicles. The cytogenetic analysis by G- band in lymphocytes showed a translocation between chromosomes 6 and 18 with breakpoints at 6p23 and 18q22. The investigation using FISH with a whole chromosome painting probe for chromosome 18 (wcp18)confirmed the reciprocity of this translocation characterizing the karyotype as 46,XX,t(6;18)(p23;q22).ish(6;18)(wcp18+;wcp18+). The parents were not available for investigation. The presence of an autosomal balanced translocation in this case points to new autosomal sites in the search for genes associated to ovarian development.

Program Nr: 857 from the 1999 ASHG Annual Meeting

Duplication 1q32->q44 and Multiple Congenital Anomalies. *J. Bayani[1], J. Xu[2,3], V. Freeman[2,3], J. Watts[4], P.A. Smith[5], J. Squire[1], M.J.M. Nowaczyk[2,3,4].* 1) Cellular and Molecular Biology, Princess Margaret Hospital, Toronto, Ontario, Canada; 2) Department of Pathology and Molecular Medicine, McMaster University, Hamilton, Canada; 3) Hamilton Regional Laboratory Medicine Program, Hamilton, Canada; 4) Department of Pediatrics , McMaster University, Hamilton, Canada; 5) Department of Obstetrics & Gynecology, McMaster University, Hamilton, Canada.

We report a prenatal detection of de novo direct 1q duplication. A prenatal referral was made because of abnormal ultrasound findings of cerebral ventriculomegaly and bilateral choroid plexus cysts 24 weeks gestation. The amniocentesis showed an abnormal male karyotype with a duplication of the long arm of chromosome 1, 46,XY,dup(1)(q32q44). Duplication of this segment was subsequently confirmed by G-banding of peripheral blood lymphocytes and comparative genomic hybridization using DNA extracted from blood. Parental karyotypes were apparently normal. The baby was born at 37 weeks of gestation with dysmorphic features. His head circumference was 35.5 cm (90 centile), weight was 2600 g (10-25th centile), and length was 47 cm (25th centile). The anterior fontanel measured 6 x 5.5 cm (> +2SD), and there was a posteriorly sloping forehead. The ears were round in shape with unfolded helices. He had hypertelorism, short, downward-slanting palpebral fissures and a high-arched and narrow palate. Both of his feet were large with overriding second and third toes. Head CT scan showed prominent posterior horns of the lateral ventricles but normal third and fourth ventricles. The radiographic skeletal survey showed 11 pair of ribs. Sonographic evaluation of the abdomen showed left hydronephrosis. He also had a medium sized patent duct arteriosus, pre-ductal shelf of the aortic arch and tricuspid regurgitation. This is the 2nd report of 'pure' duplication of 1q32-q44. Flatz and Fintasch (1979) reported the first case in a 6 week old boy with pointed chin, beaked nose, midface hypoplasia, enlarged skull and fontanelles, unilateral cryptorchidism and hypospadias. Our case will help establish the correlation of this chromosome region and the clinical features.

Program Nr: 858 from the 1999 ASHG Annual Meeting

Chromosome 8p23.1 duplication: is there an association with a clinical phenotype? *M.L. Begleiter, H.A. Cooper, L.M. Pasztor, M.G. Butler.* Sect Medical Gen/Molec Med, The Children's Mercy Hospitals & Clinics, Kansas City, MO.

A 5 8/12 year old boy was referred for evaluation of developmental delay and mild dysmorphic features. The family history was significant for clinical depression in the mother and bipolar illness in the father. The child had attention deficit hyperactivity disorder, bipolar illness, myopia, a coarse facial appearance, an abnormally placed hair whorl and prominent ears with a malformed low-set left ear. He had significant speech delay and late acquisition of motor skills. His karyotype was 46,XY,dup(8)(p23.lp23.1). By FISH analysis whole chromosome 8 painting probes hybridized to both chromosome 8s in their entirety. There was no evidence for the fragile X DNA mutation. Studies of other family members identified the dup(8p) in the child's mother, both his half siblings (through his mother) and in his maternal grandfather. None of these individuals had developmental delay or dysmorphia.

Duplication of 8p23.1 has been previously documented in 14 families. In only three of these families were any clinical stigmata described. In one family, a girl was identified with short stature (her mother, who was of normal height also had the duplication). In another family, an eighteen-month-old boy with developmental delay was found to have a de novo duplication. In a third family, two sisters with minor dysmorphia and normal development and their nondysmorphic mother were shown to have the 8p duplication. Thus, most individuals with the same euchromatic duplication seen in our patient have been described as phenotypically normal. It has been suggested that duplication 8p23.1 is a cytogenetic anomaly of no known established clinical significance and that the few cases of phenotypically abnormal individuals who carry this duplication represent bias of ascertainment. Our family adds additional evidence to support this impression.

.

Program Nr: 859 from the 1999 ASHG Annual Meeting

Gene expression profile analyses in Roberts Syndrome. *J.W. Belmont[1], A. VanHooser[2], L.R. Adam[2], L.G. Shaffer[1], B.R. Brinkley[2], O.A. Cabello[2].* 1) Dept Mol & Human Genetics, Baylor Col Med, Houston, TX; 2) Dept Cell Biology, Baylor Col Med, Houston, TX.

Roberts syndrome (RS) is a rare AR disorder with variable phenotype. Clinical features include tetraphocomelia, growth and mental retardation, genitourinary abnormalities, and increased rate of malignancy. Cell from the RS+ complementation group exhibit premature centromere separation in metaphase. We probed the integrity of chromatin remodeling pathways in RS+ cells. Posttranslational modifications of histones associated with mitotic condensation were assessed by immunofluorescence. In mitotic RS fibroblasts, chromosomes stained intensely with antibody against tetraacetylated H4, indicating lack of deacetylation compared to control. These results suggest a defect in mitosis-specific deacetylation of histone H4. HDAC has been shown to interact with MeCP2 and deacetylation may cooperatively mediate transcriptional repression. However, we detected no disturbance in methylation of *SNRPN*, a locus known to be regulated by methylation status, in RS+ cells. We used a filter cDNA array with approximately 18,000 known cDNAs and ESTs (GDA1.3) to analyze the transcription profile of mutant and normal lymphoblast cell lines. In two independent replicates, we detected asymmetric global distribution of expressed loci in control cells vs RS+. We restricted quantitative analysis to transcripts in the 90%ile for signal intensity i.e. correlating with standard analytical methods like Northern blot. After correction for global mean signal there was excellent concordance of most individual transcript hybridization intensities. However, we found that the distribution of the log(Control/Roberts) signal intensity was significantly skewed toward the Control (skewness 0.83±.05). 71% of transcripts (175/245) exhibiting discordant expression (>10-fold) were under-expressed in the Roberts cells. There is not yet extensive experience with expression array data in mammalian mutants and a broader interpretation of these data will depend on the specific mRNAs affected by the RS+ mutation. Evaluation of the repressed transcripts may advance understanding of RS as a model of chromatin structure disorders.

Program Nr: 860 from the 1999 ASHG Annual Meeting

Another cause for an extra marker chromosome: unequal segregation of the products of a maternal fission chromosome 19. *C. Booth, L. Jazmines, D. Rita.* Pediatrics, Lutheran General Hosp, Park Ridge, IL.

Chromosome studies were performed on the products of conception from a first trimester loss of a 30-year-old woman with a history of repeated miscarriages. 47 chromosomes were found, including an extra unsatellited marker. Parental chromosomes were studied. The father's were normal. The mother had 47 chromosomes with centric fission of one chromosome 19 [47,XX,-19,+fis(19p)(p10),+fis(19q)(q10)]. The fetal marker was identified as the fission chromosome 19p. Centric fusion produces Robertsonian translocations, some of the most common rearrangements in man. Centric fission is rare but, when present, often leads to reproductive wastage and/or failure. Parental chromosome studies should always be performed when a marker chromosome is found in fetal material.

Program Nr: 861 from the 1999 ASHG Annual Meeting

Two distinctively different phenotypes of 2q37 terminal deletion: Location of a gene on telomeric 2q37 mimicking Albright hereditary osteodystrophy/ pseudohypoparathyroidism. *B.R. Braddock[1], A.E. Shrimpton[2], C.S. Stein[1,2], J.J. Hoo[1]*. 1) Dept. of Pediatrics, Div. of Genetics, SUNY Health Science Center, Syracuse, NY; 2) Dept. of Pathology, SUNY Health Science Center, Syracuse, NY.

We report a 17 year old male with clinical features suggestive of Albright hereditary osteodystrophy (AHO)/pseudohypoparathyroidism (PHPT). He has mild to moderate mental retardation, stature below the 5th percentile, a round face with mildly upslanting palpebral fissures, myopia, multiple nevi on his upper trunk, abdominal obesity and delayed puberty with Tanner stage 1 external genitalia. He also presents with hypoplastic 3rd and 4th metacarpals and a short 4th metatarsal, bilaterally, and flat feet. He has a history of focal seizures up until age 7. Cytogenetic studies revealed an apparently terminal deletion of the long arm of chromosome 2 [46,XY,del(2)(q37.1)]. The break appears to occur distally in q37.1 since a portion of the band is still clearly detectable at the end of the chromosome. Molecular delineation will be carried out to clarify the breakpoint.

Terminal 2q37 deletion has been frequently reported. Review of the literature revealed that there are two distinctively different phenotypes. The majority of cases are associated with moderate to severe mental retardation, nonspecific dysmorphic features, and moderate to severe growth retardation. It is postulated that most of these cases are due to an interstitial deletion of the proximal portion of the 2q37 band. The second recognized phenotype from at least 7 cases in the literature (Wilson, L.C. et al., 1995; Power, M.M. et al., 1997) is characterized by milder mental retardation and a phenotype resembling AHO/PHPT. While classic AHO/PHPT is caused by a mutation in the alpha subunit of a G protein gene (GNAS1 gene) on 20q13.2, Power et al. suggested that a vasoactive intestinal peptide receptor gene on the telomeric 2q37 band is likely a candidate gene for 2q37 deletion cases resembling AHO/PHPT. The phenotypic and cytogenetic findings in our patient are consistent with this hypothesis and molecular delineation will provide further verification.

Program Nr: 862 from the 1999 ASHG Annual Meeting

The human homolog of the rat phospholipase C beta1 gene (PLCB1) maps at 20p12. *G. Calabrese[1], E. Morizio[1], D. Peruzzi[2], L. Stuppia[1], D. Fantasia[1], V. Gatta[1], G. Sabatino[1], L. Cocco[2], G. Palka[1], F.A. Manzoli[2].* 1) Dip Scienze Biomediche/sez Genetica Medica, Univ G. d'Annunzio, Chieti; Italy; 2) Cellular Signalling Lab, Ist Anatomia UN, Universita' di Bologna, Italy.

The hydrolysis of inositol lipid by specific phospholipase C (PLC) constitutes a key step of a signal transduction pathway that ultimately regulates a number of cellular processes such as proliferation, secretion, and neural activity. Among the 3 groups of PLC characterized in mammalians (beta, gamma, and delta), PLC beta consists of at least 4 isoforms of which type beta1 is of interest because of its localization within the nucleus as well as at the plasma membrane. We previously reported the mapping of the Plc beta1 in rat at chromosome band 3q34-35. With the aim of identifying its human homolog, we selected a clone, named plc1, from a human fetal brain cDNA library using the rat cDNA as a probe. The alignement of the 5.1 kb plc1 probe sequence with the 3.5 kb rat full length cDNA showed a 89% homology. Northern blotting experiments on human and rat total brain RNA displayed two similar transcripts of 7.2 kb and 5.4 kb with clone plc1 and rat full length clone, respectively. The human cDNA clone was then used in FISH experiments on human metaphases. In 50 cells signals were observed on chromosome 20 at band p12 in one or both homologs. This localization confirmed the synteny between rat chromosome 3 and human chromosome 20 and provided a novel homolog locus between bands q35 in rat and p12 in man. Such a synteny is also supported by co-localization of another PLC beta isoform, i.e. beta4, mapped at 20p12 which showed a 11% homology with clone plc1. Band 20p12 has been recently reported amplified and/or deleted in different solid tumors such as head and neck, lung, duodenal, and bladder cancers. Thus, the observation of activation of the nuclear Plc beta1 during cellular proliferation and its down-regulation during differentiation in normal and neoplastic cells in vitro further suggests the involvement of PLC beta1 in neoplasms. These evidences are also supported by the frequent rearrangement in rat tumors of band 3q34-35 where the rat Plcb1 maps.

Program Nr: 863 from the 1999 ASHG Annual Meeting

Delayed membranous ossification of the cranium associated with familial translocation (2;3)(p15;q12). *C.B. Cargile[1, 4], I. McIntosh[2], M. Clough[2], R. Yaghmai[1], B.K. Goodman[3, 4], G.H. Thomas[1, 4], M.T Geraghty[1]*. 1) Department of Pediatrics; 2) Medicine; 3) Obstetrics and Gynecology, Johns Hopkins School of Medicine, Baltimore, MD; 4) Kennedy Krieger Institute, Baltimore, MD.

The relationship of delayed membranous cranial ossification to cranium bifidum and parietal foramina syndromes is unclear. We now report a family with delayed cranial membranous ossification that segregates with a reciprocal translocation between chromosomes 2 and 3. The proband was born at 38 weeks by cesarian section with vacuum suction due to fetal brachycardia. The baby was noted to have low set ears, proptosis and the skull was not palpable. A radiographic survey of the skeleton showed markedly decreased ossification of the cranial bones and no other skeletal abnormalities. Serum calcium, phosphorous, alkaline phosphatase and thyroid function tests were normal. The mother and maternal grandmother have brachycephaly, hypertelorism and history of a soft skull. Chromosome analysis of peripheral blood from the proband showed 46,XY,t(2;3)(p15;q12). The proband, mother and grandmother carry the same reciprocal translocation, while the mothers normal siblings have a normal karyotype. The gene for the a1 chain of type VIII collagen, COL8A1, which maps to chromosomal region 3q12 and is expressed in the calvarial bones of newborn mice, was investigated as a candidate gene for delayed membranous cranial ossification. FISH analysis with COL8A1 phage clone showed signal close to, but not disrupted by, the familial translocation breakpoint. Southern blot analysis of COL8A1 showed no evidence of altered gene structure. We identified BAC clones from chromosomes 2 and 3 that map proximally and distally to the translocation breakpoint. This is the second report of familial delayed membranous cranial ossification and the first time it has been associated with a familial reciprocal translocation.

Program Nr: 864 from the 1999 ASHG Annual Meeting

Chromosome constitution studies in buccal smear samples by fluorescent in situ hybridization (FISH). *V. Catala[1], E. Cuatrecasas[1], T. Vendrell[2], M. Crespo[1], J. Colomer[1], A. Plaja[2], C. Mediano[2], A. Seres-Santamaria[1].* 1) Prenatal Genetics. Casanova 153 08036 Barcelona, Spain; 2) Unitat Gentica Hospital Materno-Infantil Vall d'Hebron. Barcelona.

Buccal smear analysis have been used for interphase analysis of X and Y chromosomes for over 30 years using the Barr body test for determination of X chromatin and the fluorescent Y-chromatin test. These methotds are not specific and sensitive enough for detection of mosaicism, because the X-chromatin can be identifies in the 20-40% of the cells in normal females, and the Y-chromatin is only observed in about the 50% of the normal male cells. The study of autosomes had not been possible at that moment. The introduction of non-isotopic fluorescent in situ hybridization (FISH) technology using specific probes for each chromosome allows interphase analysis of aneuploidies and sex determination. We have analyzed the exfoliated epithelial cells in 3 controls and 5 clinical cases (2 newborn infants cytogenetically normals with suspected Pallister-Killian S., 2 dismorphic newborn infants with c-anaphases in the cytogenetic study, and a 19-years-old female cytogenetically XY after blood culture due to a bone marrow transplantation from a male donnor with suspected Turner Syndrome.

Program Nr: 865 from the 1999 ASHG Annual Meeting

PCR-FISH-PRINS analysis of marker chromosomes in 8 patients with Turner phenotype. *A. Cervantes[1], M. Lopez[1,2], R. Guevara Yanez[3], N. Monroy[1], M. Aguinaga[1], H. Valdez[4], C. Sierra[4], S. Canun[4], J. Guizar[3], C. Navarrete[3], G. Zafra[5], F. Salamanca[3], S. Kofman[1].* 1) Genetica, Hospital General Mexico SSa, F Medicina UNAN, Mexico DF; 2) S Biologicos UAM-X, Mexico DF; 3) UIMGH Hospital Pediatria CMNSXXI IMSS, Mexico DF; 4) S Genetica Hospital Gea Gonzalez SSa, Mexico DF; 5) S Genetica Hospital Espanol,Mexico DF.

The presence of Y-derived material in patients with Turner phenotype is correlated with a high risk of developing gonadoblastoma and dysgerminoma, requiring preventive removal of the dysgenetic gonads. Therefore, it is clinically relevant to determine the chromosomal origin of marker chromosomes that cannot be identified by conventional banding techniques. Also, their identification is important for establishing phenotype-karyotype correlations. We describe the identification of marker chromosomes in 8 patients with Turner phenotype by a combination of PCR, FISH and PRINS methodology in DNA and cell cultures from blood lymphocytes. In all cases, initial karyotypes were 45,X/46,X,+mar; six of the marker chromosomes were rings of different sizes, 3 being particularly small. PCR analysis for Y-sequences (PABY, SRY, ZFY, Ycen and Yqh) were negative for the 6 patients with ring chromosomes and positive in the rest. PRINS were done with Xcen and Ycen primers in all patients, demonstrating the X origin of all the ring chromosomes and the Y origin of the remaining 2 marker chromosomes, one being dicentric. FISH with Xcen and Yqh probes was performed in the patients with Y material, showing that one has very little heterochromatine while the other marker has signals on both sides. Taken together, data shows that the latter chromosome is pseudodicentric with a breakpoint in Yp11.3. Phenotype-karyotype correlations could not be establish since mosaicism of highly variable nature can exhibit an unpredictable outcome. None of the patients had mental retardation, including those with tiny X-chromosomes. Replication studies demonstrated the inactivation of all the X-derived ring chromosomes, suggesting the presence of XIC. We discuss the advantages of the combined use of PCR, PRINS and FISH over the use of single or conventional techniques.

Program Nr: 866 from the 1999 ASHG Annual Meeting

Ring chromosome 16 in a normal female. *K.E. Chandler, K. Turnbull, K.L. Gaunt.* University Department of Medical Genetics and Regional Genetics Service, St Mary's Hospital, Manchester, UK.

Ring chromosome 16 in a normal female. Chandler, KE (1); Turnbull, K (1); Gaunt, KL (1) (1) University Department of Medical Genetics and Regional Genetics Service, St Marys Hospital, Hathersage Road, Manchester, M13 0JH A 34 year old woman was referred for genetic counseling after an in utero death at 28 weeks following 7 years of infertility. Cytogenetic investigations revealed her karyotype to be 46,XX, r(16)(p13;p3q24) in 186/200 cells examined. 8/200 cells had a 45,XX,-16,karyotype, 4/200 cells had a double ring 16 and 1/200 had a small ring 16. Only 1/200 cells had a normal 46,XX karyotype. Skin chromosomes showed ring 16 karyotype with a similar low level of mosaicism. Fetal material was not available for karyotyping and post mortem was unremarkable save for growth retardation. A subsequent spontaneous miscarriage at 8 weeks gestation was found to have a mosaic ring 16 karyotype with a large number of abnormal ring derivatives. To date, only 7 cases of ring (16) have been reported in the literature. Normal cell lines and 45,XX,-16 cell lines were found in most of these, unlike our case where a low level of mosaicism was found. In all cases the patient had significant learning difficulties and mild dysmorphic features. Most of them had growth retardation.Our patient was of above average intellect and of normal appearance and stature. Apart from infertility, she has had no health problems. Ring formation by means of telomere/telomere fusion is proposed as no loss of genetic material could be seen on cytogenetic analysis. This may explain our patients normal appearance and intelligence. The structural instability of a ring chromosome gives rise to continuous generation of aneuploid cells. Such cells are likely to be lost at subsequent cell divisions. This could explain her recurrent fetal loss and infertility. Several complex counseling issues have been raised by this case.The couple have opted to be assessed for pre-implantation genetic diagnosis.

.

Program Nr: 867 from the 1999 ASHG Annual Meeting

X CHROMOSOME ABNORMALITIES : REPORT OF 14 CASES. *V. CHARPENEL[1], L. TELVI[1], R. ION[1], J.L. CHAUSSAIN[2]*. 1) LABORATOIRE DE CYTOGENETIQUE, HOPITAL ST VINCENT DE PAUL, PARIS, FRANCE; 2) SERVICE D'ENDOCRINOLOGIE PEDIATRIQUE, HOPITAL ST VINCENT DE PAUL, PARIS, FRANCE.

We describe 14 cases with X chromosome abnormalities as Xp- (3 cases), Xp+ (1 case), Xq- (2 cases), Xq+ (1 case), X-Y translocation (1 case) X-Autosome translocations (3 cases) and complex X chromosome abnormalities (3 cases). Chromosome analysis required RHG, CBG, QFQ, RTBG bandings, and completed in some cases by FISH analysis of the X chromosome, Y chromosome, XIST gene or translocated autosomal chromosomes. The inactivation of normal or abnormal X chromosome was analyzed by RTBG banding. The growth retardation, mental retardation, dysmorphia, Turner syndrome features and the presence or absence of gonadal dysgenesis were analyzed and discussed. The growth retardation is variable from the average to -8SD and depending of the chromosomal breakpoints. The mental retardation is present in all 3 cases with X-Autosome translocations. In other cases mental retardation is rare and found only in 2 patients. The expression of dysmorphia and Turner syndrome features depend on the localisation of the breakpoints and the percentage of cells with inactivated abnormal X chromosome.The presence or absence of gonadal dysgenesis depend also of the localisation of the breakpoints. The gonadal dysgenesis was found in the majority of cases (11 out 14 cases). These findings should be helpfull in genetic counselling.

Program Nr: 868 from the 1999 ASHG Annual Meeting

Nonrandom rearrangements of 6p in malignant hematological disorders. *Z. Chen, B. Issa, L.J. Brothman, M. Hendrickson, D. Button, A.R. Brothman.* Dept Pediatrics/Cytogenetics, Univ Utah Sch Med, Salt Lake City, UT.

Anomalies of chromosome 6, often present as 6q-, have been associated with lymphoid disorders, especially acute lymphocytic leukemia and lymphoma. However, it is very uncommon to observe anomalies of 6p in malignant hematological disorders (MHD). A literature review shows 6p anomalies as a sole change in only three cases and as an evolutionary anomaly in 36 cases of MHD. By using conventional cytogenetics and FISH with chromosome-microdissection probes specific for 6p21 and 6p25, we observed five patients with myeloid malignancies and two patients with lymphoid malignancies to have 6p anomalies. Possible biologic characteristics of such aberrations in MHD can be divided into three groups: The first group presents with 6p anomalies as a sole change in myeloid malignancies with only two cases reported, including one case with del(6)(p23) and one present case with ins(6)(q23p23p25)identified by FISH only; both cases have the same breakpoint (p23) involved, suggesting a nonrandom relationship between the 6p23 breakpoint and myeloid malignancies. The second group presents with 6p anomalies as a sole change in lymphoid malignancies with three cases reported, including one with del(6)(p21p23), one with del(6)(p21), and one present case with del(6)(p21). A potential tumor suppressor gene, located in 6p21-p23, may be specifically associated with the pathogenesis of some lymphoid malignancies. The third group has 6p anomalies, in addition to other known primary changes, present in 36 cases of myeloid or lymphoid disorders, including five cases from our series. Deletions involving 6p21, 6p22, or 6p23 have been observed in both myeloid and lymphoid disorders. The primary changes often present with the 6p anomalies include t(9;22), 5q-, 20q-, 7q-, -7, +8 and 11q23-related changes in myeloid disorders and 9p-, +3, +7, t(8;14), and other 14q32-related abnormalities in lymphoid disorders. It appears that 6p anomalies may be breakpoint-specific disease-related when presented solely, or may represent an evolutionary event when appearing with other primary changes. The present data provide cogent information for further molecular characterization of 6p anomalies in MHD.

Program Nr: 869 from the 1999 ASHG Annual Meeting

HC Forum ® : an international database and a Web site dedicated to structural abnormalities of chromosomes;.
O. Cohen, M.A. Mermet, J. Demongeot. Genetic Lab/TIMC/UMR CNRS 5525, Grenoble Univ Medical Sch,La Tronche, France.

Structural abnormalities represent many difficulties for risk assessment. On the other hand, they represent a powerful tool for research on the genome.

Since 1988, we have developed an international database, which now includes familial data from 3.500 reciprocal translocations and 1.000 pericentric inversions carriers. From this database, we have developed a Web site, named HC Forum® (Human Cytogenetics Forum)° , which offers different tools for medical genetics and to research workers:

- Assistance for diagnosis whith a schematic view of rearranged chromosomes, according to the ISCN
- Assistance for genetic counselling with risk assessment specific to each abnormality for guiding the strategy of prenatal diagnosis or assisted procreation and many other usefull information: pachyten diagram, list of the potential imbalances with a prediction of their viability, retrospective data, references.
- Cartographic applications that show the distribution of the chromosomal breakpoints and of the viable partial trisomic and monosomic regions of the genome. Interactive screens allow finding information specific to breakpoints or imbalances such as references or contacts to find biological material.
- A data submission process with an interactive pedigree drawing and an availability to send an image of the karyotype.
- A forum for discussion about the submitted cases.
- A link to other Human genetic Web sites.

More than 200 geneticists from more than 25 different worldwide countries are already users. Finally, this Web site, which needs a preliminary registration, represents a link between the diagnosis centers where many biological of interest exist, and the research teams which need specific biological materials but don't know where they are available.

Program Nr: 870 from the 1999 ASHG Annual Meeting

Mild learning disabilities and anomalies associated with monosomy/trisomy of 11q in a 3-generation family carrying an insertional translocation. *L.A. Correia[1], A. Nadel[1,2], W.A. Miller[3], B.R. Braddock[3], A. Milunsky[4], H.E. Wyandt[4], M. Sandstrom[5]*. 1) Maternal Fetal Medicine, The Women's Health Center of the North Shore, Danvers, MA; 2) Obstetrics and Gynecology, Brigham and Women's Hospital, Boston, MA; 3) Perinatal Diagnosis Center, Inc., Lexington, MA; 4) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 5) Pathology, Brigham and Women's Hospital, Boston, MA.

The index case, a 39-year-old G5P1SAB2TAB2 female, has a deletion of 11q, i.e. 46,XX,del(11)(q14q21)pat. She presented at 6 weeks gestation with a history of being a slow learner and having a third toe curled under the fourth unilaterally. She graduated from high school and attended college for a short time. She was diagnosed with ADD as an adult, although formal IQ testing was not performed. The family history is significant. A brother with learning disabilities has the same deletion. His daughter reportedly has speech delay but has not been karyotyped. A second brother with learning disabilities and behavioral problems has not been karyotyped. A paternal first cousin has a karyotype of 46,XX,der(20)ins(20;11)(q12;q14q21). She has learning disabilities, low set ears and a missing incisor. She had two prior pregnancies studied by amniocentesis at ages 29 and 30. Both pregnancies showed karyotypes identical to her own; the first, a female, was therapeutically aborted; the second, a male, is now three years old. The karyotype of the father of the index patient is apparently balanced with an insertion of a piece of the long arm of chromosome 11 into the long arm of chromosome 20, i.e. 46,XY,ins(20;11)(q13.1;q14q21). Fluorescent in situ hybridization using a whole chromosome paint (WCP11, Oncor) confirmed this translocation in the father and the cousin. Probes for Cyclin D at 11q13 and MLL at 11q23 indicate that the breakpoints on chromosome 11 are telomeric to Cyclin D and centromeric to MLL. An amniocentesis of the patient's current pregnancy yields a normal, 46,XX, fetal karyotype. Discussion will include the segregation of the familial translocation and unbalanced products through three generations.

Program Nr: 871 from the 1999 ASHG Annual Meeting

Mosaic tetraploidy in a healthy woman with recurrent pregnancy loss. *J.M. Cowan, M.S. Murray, P.G. Wheeler, D.W. Bianchi.* Division of Genetics,Department of Pediatrics, Tufts University School of Medicine, Boston, MA.

Background: There are relatively few case reports in the literature of individuals with mosaic tetraploidy. In all cases, patients have been ascertained by mental retardation, abnormal phenotype, or congenital anomalies. Our patient (TC), a 37 yo G9P3Sab4Tab1 healthy employed woman, presented for genetic evaluation following the loss of triploid conceptus (68,XXY).

Methods: Standard peripheral blood karyotype analysis was performed on two occasions. A skin biopsy was obtained for fibroblast karyotype analysis. Interphase FISH using the alphoid probe for chromosome 7 was used to determine ploidy in the samples. The frequency of tetraploid cells in TC's blood samples was compared with the frequency in blood samples from 3 controls who presented with a history of infertility or pregnancy loss.

Results: Tetraploid cells were observed in preparations of TC's first peripheral blood sample, and were also present in the repeat blood specimen and the skin fibroblast cultures. TC had 1-2% tetraploid cells in her 2 blood samples, while the control patients had 0% in each of 4 cultures per patient. The frequency of tetraploid cells in the skin sample was 6% by FISH analysis.

Conclusions: There are 2 interpretations of the results in this case: either the patient has a diploid karyotype and error-prone cell division or she is a mosaic 92,XXXX/46,XX. There are problems with both conclusions. FISH demonstrated division of the tetraploid cells and it might be expected that failure of cell division would result in octaploid cells. No octaploid cells were seen. If the patient is a mosaic for tetraploidy, she is much more mildly affected than the previously reported cases. The loss of the conceptus with triploidy, however, suggests that a percentage of TC's oocytes are tetraploid, and become diploid during meiosis.

Program Nr: 872 from the 1999 ASHG Annual Meeting

Search for a gene disrupted in a patient with acrodysostosis and a t(4;6)(q12;p23). *J.G. Dauwerse[1], B. de Vries[2], C.H. Wouters[2], D.J.M. Peters[1], M.H. Breuning[1].* 1) Dept of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Clinical Genetics Center Rotterdam, Rotterdam, The Netherlands.

The index patient is a mentally normal 31 year-old male with height 1.40m (-6SD), arm span 1.26m and normal head circumference (54.5 cm = 25th centile) with a flat face, depressed nasal bridge, broad nasal root and anteverted nostrils. He had extreme brachydactyly of both hands and, to a lesser degree, of the feet. The aorta was sclerotic with insufficiency of the aortic valves. X-ray investigation showed acrodysostosis with relatively short ulna suggesting either acrodysostosis (MIM 101800) or a mild form of acromesomelic dysplasia. Both non-consanguineous parents and 5 sibs had normal postures. A de-novo 46,XY,t(4;6)(q12;p23) was found.
In order to find the gene(s) disrupted by the t(4;6) we began by mapping the chromosome 4 breakpoint more precisely. FISH with YAC clones selected from the SHGC chromosome 4 YAC map was performed on metaphase slides of the patient. Out of 40 YACs tested, five YACs turned out to span the chromosome 4 breakpoint. Using Alu-PCR fragments from the smallest YAC (330Kb) two PAC clones were isolated, which FISH signals were split by the translocation. Using the PACs, cosmids could be isolated and a restriction map of the region was constructed; however, cosmids spanning the breakpoint could not be isolated. Using the same FISH mapping approach a YAC (1.5Mb) spanning the chromosome 6 translocation breakpoint has also been identified. Currently various techniques are applied to identify genes in the cloned chromosome 4 region. Within the cosmid contig mapping distal to the translocation breakpoint we could place the PDGFRA-KIT genecluster. A fragment close to the breakpoint, showing cross-species conservation is currently being evaluated.

Program Nr: 873 from the 1999 ASHG Annual Meeting

An unusual case of a mosaic Turner syndrome variant with a tiny r(X) and a rare partial proximal duplication of 1q. *A.J. Dawson[1,2], D.E. Wickstrom[1], D. Riordan[1], S. Cardwell[3], R. Casey[3].* 1) Cytogenetics Laboratory, HSC, Winnipeg, MB, Canada; 2) Depts. Human Genetics and Pediatrics, University of Manitoba, Winnipeg, MB, Canada; 3) Division of Medical Genetics, Royal University Hospital, Sakatoon, SK, Canada.

A 7 yr old female with global cognitive impairment and delayed motor and mental development as well as significant hyperactivity and impulsivity was referred to the Genetics clinic. Height and weight were at the 5th% while head circumference was at the 50th%. Dysmorphic features included bluish sclera, low set and slightly posteriorly rotated auricles and a narrow palate with marked overbite. There was no significant family history. Chromosome analysis showed an unbalanced, mosaic female karyotype consisting of three cell lines: 46,X,+r[46]/45,X[37]/45,X,dup(1)(q11q21.3)[17].ish r(X)(DXZ1+,XIST+). The first cell line, present in 46% of cells, was missing a normal X chromosome and had a small ring chromosome which was identified as an active pericentromeric derivative of the X chromosome containing the XIST locus. The second cell line, present in 37% of cells, had a classic Turner karyotype with a missing X chromosome. The third cell line, present in the remaining 17% of cells, was also missing an X chromosome and, in addition, had a direct duplication of chromosome 1 from bands q11 to q21.3. The tiny r(X) syndrome with the karyotype 46,X,r(X)/45,X is known to have functional X disomy for the region encompassed by the r(X) and is generally associated with a severe phenotype of physical and mental handicap. The presence of the XIST gene is consistent with an active X chromosome. The clinical phenotype of the tiny r(X) syndrome in our patient is obviously further influenced by mosaicism for the dup(1). Few cases of duplication of the proximal portion of chromosome 1 have been reported. Of these, the duplication either was present in all cells or involved different band regions so that a direct comparison is difficult. However, the lower percentage of mosaicism for the dup(1) in our patient would suggest a milder influence on the clinical phenotype. The parental karyotypes are normal.

Program Nr: 874 from the 1999 ASHG Annual Meeting

Case of supernumerary der22,T(11/22), born to a mother mosaic for the 11/22 translocation. *M. Descartes, A. Carroll.* Department of Pedicatris, Uviv. of AL. at Birmingham, AL.

Our patient was the first child born to a 21 year old female at term by SVD. Her birth weight was 3.2kg (50th), her length was 53cm (50th), and her FOC measured 34cm (25th). She was noted at birth to have dysmorphic features and CHD(coartation of the aorta and AV canal). Her physical examination was pertinent for: malformed ears with preauricular pits and tags, fronto orbital hypoplasia, scarce eyebrows, flat nasal bridge, epicanthic folds, micrognathia, facial asymmetry, hypoplasia of the labia majora, anteriorly placed anus. Peripheral blood cytogenetic analysis revealed a 47,XX,+der(22)t(11;22)(q23;q11.2) karyotype. Maternal chromosome analysis of peripheral blood on 2 different occasions revealed that she was a mosaic carrier of the 11;22 translocation, mos46,XX,t(11;22)(q23;q11.2)/46,xx. Chromosome studies of the maternal grandparents revealed normal karyotypes for both. The t(11;22) is thought to be one of the most common reciprocal translocations in man. While most reported cases have been familial, at least 3 instances are known where the balanced t(11;22) occurred "de novo" in a carrier parent. Mosaicism for any balanced translocation is very rare and we are unaware of any previous report of mosaicism for the balanced t(11;22). We presume that our proband's mother's cells were initially normal, and that a very early somatic event led to the translocation that was present in approximately 50% of her PHA stimulated leukocytes. Chimerism seems unlikely, but has not been ruled out. The recurrence risk we quoted the mother was the same (2-6%) as that listed in the literature for non-mosaic carrier females.

Program Nr: 875 from the 1999 ASHG Annual Meeting

Tetrasomy Y by structural rearrangement: A patient with two isodicentric Y chromosomes and global psychomotor delay. *M. DesGroseilliers[1,3], E. Lemyre[2,3], L. Dallaire[2,3], N. Lemieux[1,3].* 1) Department of Pathology and Cell Biology, University of Montreal, Montreal; 2) Service of Medical Genetics, Ste-Justine Hospital, Montreal; 3) Research Center, Ste-Justine Hospital, Montreal, Quebec, Canada.

Poly-Y karyotypes -except for 47,XYY- are rare events in humans. Y chromosome tetrasomy, for instance, has only been reported 9 times - one of which was by structural rearrangement. We present a 2-year-and-4-month-old boy who was referred for cytogenetic assessment because of global psychomotor delay. The GTG and CBG banded karyotypes on PHA-stimulated lymphocytes showed two cell populations, one of which contained two identical isodicentric Y chromosomes in 93% of metaphases analyzed and a 45,X cell line (7%). This was confirmed by FISH with probes DYZ3 (specific for the centromeric region of Y chromosome), 91H4.5 (recognizing Yp11.2) and DYZ1 (recognizing Y heterochromatin in Yq12). The breakpoint is near the end of the heterochromatic region. Therefore, the karyotype is mos 47,X,idic(Y)(q12)x2[123]/45,X[9]. This is the second time that such a karyotype is reported. Clinical features included speech delay, short stature, brachycephaly, large ears, bilateral epicanthal folds, hypertelorism, delayed teeth eruption, bilateral radio-ulnar synostosis, normal external genitalia and impulsive behavior. The father had normal phenotype and karyotype. A review of the poly-Y karyotypes is presented, as well as the most likely mechanism by which these two isodicentric Y chromosomes occurred. Most patients with Y chromosome tetrasomy exhibit some degree of mental retardation, various skeletal abnormalities and facial dysmorphism. Nevertheless, the correlation between the karyotype and the phenotype is not yet well defined since few cases have been reported. This case report will be helpful in defining the phenotypic range of the tetrasomy Y patients. (*This research was supported by grants from Réseau de Médecine Génétique Appliquée-FRSQ).*

Program Nr: 876 from the 1999 ASHG Annual Meeting

CYTOGENETIC EXPRESSION OF FRAXA AND IT'S RELATIONSHIP WITH SPEECH DELAY. *M. Diaz Garcia, G. Garca Sanchez, F. Huesca Hernandez, J.E. Dominguez-Aburto L.* Instituto Nacional de la Comunicacion Humana SSa. Mexico, City.

In Mexico the studies in the Fragile X-Syndrome or FRAXA has been realized in people with mental retardation and not in individuals with normal intelligence (IQ) or boderline (70-80) and speech delay. For this reason we decide to search the presence cytogenetic of FRAXA in a population of 50 individuals with speech delay and IQ >70 to determine if the presence of FRAXA associates with one or more speech delay. The 50 patients were selected through the consultation of Genetics, to them realized their clinical history and diagnosis of psychologicaaal, speech, audiologic, etc. For the cytogenetic study the chromosomal preparations was realized from lymphocyte culture, using 3 media for the induction of FRAXA, 300 metaphases was analyzed per patient. All patients were diagnosed with speech delay: perserveration, echolalia and articulation and omissio errors. The most patients, presented characteristics of common behabior: emotional lability, short lapses of attetion and low tolerance to the frustration, 17 patients presented alterations in one or both ears, 34 presented other alterations phenotypic common to the syndrome. All the patients had antecedent hereditary of speech delay. In the cytogenetic study 45 patients were negative FRAXA and 5 positive FRAXA with different percentages in the expression. However, with the application of the citogenetic techniques, we cannot identify the carrier FRAXA and possibly in some patients the alteration it is masked, whereby is requieres the use of methodology applied in Molecular Biology to detect carrier though of number CGG repeat, that are in Xq27.3.

Program Nr: 877 from the 1999 ASHG Annual Meeting

Hydrocephalus and microcephalus associated with a satellited 6q in a family segregating a t(6;21) and a paracentric inversion in 9q. *T.C. Drumheller, J. Low, S. Katz, R. Vandergon, T. Treisman, C.J. Curry.* Dept Cytogenetics, Genetic Medicine, Valley Children's Hosp/UCSF, Madera, CA.

X-linked hydrocephalus was suspected in a male proband and his sister's male child, both diagnosed with hydrocephalus and moderate mental retardation. However, mutational analysis of L1CAM was negative. Following the birth of the sister's second child, a daughter with severe microcephaly, chromosome studies were repeated.

Chromosome analysis of all three severely-affected family members revealed a chromosome 6 with a satellited long arm and deletion of 6q25.3®qter. A balanced translocation between the long arm of chromosome 6 and the short arm of chromosome 21 was found in the proband's father and twin sisters. Another sister, who is short and obese with borderline normal intelligence, was found to have the unbalanced derivative chromosome 21 with trisomy for 6q25.3®qter. A subtle paracentric inversion in the long arm of chromosome 9, seen in both affected and non-affected family members, appears to be a familial variant having no clinical significance. The findings in this family suggest that genes critical for normal brain development lie within the region of 6q25.3®qter and that haploinsufficiency of these genes causes severe abnormalities with significant mental impairment. This case further underscores the importance of repeating cytogenetic studies when the clinical geneticist suspects a chromosome abnormality. FISH analysis as well as high-resolution cytogenetic analysis were required to characterize both rearrangements segregating in this interesting family.

.

Program Nr: 878 from the 1999 ASHG Annual Meeting

Pachygyria and polymicrogyria, cranio-facial dysmorphism and atrio-ventricular canal resulting from a duplication of the proximal region of chromosome 11q (11q11-11q12). *O. Dupuy[1], I. Husson[2], J. Wirth[3], J. Wiss[1], C. Nessmann[1], P. Evrard[2], P. Eydoux[1]*. 1) Cytogenetics, Hopital Robert Debre, Paris, France; 2) Neurology, Hopital Robert Debre, Paris, France; 3) Max Planck Institute for Molecular Genetics, Berlin, Germany.

Very few cases of imbalance of the paracentromeric region of chromosome 11 have been described. We report a patient with delayed development, seizures, cranio-facial dysmorphism, and a congenital heart disease, with a duplication of the centromere and paracentromeric region of chromosome 11. This male patient was born at 41 weeks; oligohydramnios, intra-uterine growth retardation and a small biparietal diameter were noted during the pregancy. An amniocentesis was performed and did not demonstrate any chromosomal aberration. Clinical abnormalities included unusual cranio-facial features (microcephaly, facial asymetry, upslanted palpebral fissures, dysplasia of the right ear, high arched palate), seizures, sleep disturbance, axial hypotonia with limb hypertonia. An atrio-ventricular canal was associated with an auricular septal defect. Polymicrogyria and pachygyria were seen at MRI examination. Cytogenetic investigation from blood and skin samples demonstrated mosaicism for a dicentric chromosome 11, as seen with G- and R-banding. C-banding demonstrated the presence of 2 centromeres, with a small interposed euchromatic extra-band. Parental karyotypes were normal. Using a whole chromosome painting probe, we demonstrated an intra-chromosomal rearrangement. With YAC probes, we were able to further characterize this rearrangement as a duplication of the proximal part of the long arm of chromosome 11q (band q12-q13). To our knowledge, this is the first report on trisomy of this part of the genome resulting in an abnormal phenotype.

Program Nr: 879 from the 1999 ASHG Annual Meeting

Isolated Growth Hormone Deficiency Associated with de Novo Balanced 46,XX, t(3;20)(q24;p13). *C. Duran[2], R. Romero[1], JC. Prieto[1,2], P. Sanchez[1], OL. Gutierrez[1], L. Jimenez[3].* 1) Departamento de Genetica Clinica Hospital la Victoria. Secretaria Distrital de Salud Bogota, Colombia; 2) Instituto de Genetica Humana. Universidad Javeriana, Bogota, Colombia; 3) Servicio de Endocrinologia Hospital San Ignacio. Bogota, Colombia.

The growth hormone deficiency is a cause of proportionate short stature, and represents a heterogeneous group of disorders secondary to a variety of genetic and acquired defects in human growth hormone (hGH) secretion or action. The frequency of hGH deficiency is estimated to range from 1:4000 to 1:10000. The hGH deficiency has been described with 18p- and 20p- chromosomal deletions, and rarely associated with 47XXY, 49XXXXY, and ring 5. We report on 10 year-old girl with proportionate short stature, high-pitched, retardation of growth and skeletal maturation; skeletal radiographs, thyroid hormone/thyroid-stimulating hormone were normal, basal Serum hGH levels <10 ng/ml, and the provocative tests of hGH secretory with clonidine suggests hGH deficiency. Chromosomal analysis performed using high-resolution R banding showed that the patient had a balanced translocation between the long arm of chromosome 3 and the short arm of chromosome 20. The parents were chromosomally normal. Thus, the karyotype of the patient was interpreted as 46,XX,t(3;20)(q24;p13), de Novo. The break at 3q24 or at 20p13 may have disrupted a gene responsible for the growth hormone deficiency locus. In a screen of the human genome for hGH and GNRH genes. One of these, designated Gonadotropin-releasing hormone 2(GNRH2) has been mapped to 20p13 and expression of GNRH2 suggests it may have multiple functions. In the band 3q25-q26.1 has been confirmed the localization of Short Stature Homeo Box 2 (SHOX2). The SHOX genes are implicated in craniofacial, brain, heart, and limb development. The new case further supports the assignment of the gene(s) responsible for hGH deficiency to 3q24 or 20p13. To our knowledge there are no similar reports involving translocations in hGH deficiency. A possible assignment of a new locus is discussed.

Program Nr: 880 from the 1999 ASHG Annual Meeting

Phenotypic effects of a 7p13p21 interchromosomal duplication including GLI3, TWIST and HOXA genes. *H. ELGHEZAL[1], A. MEGARBANE[2], P. GOSSET[1], G. JOLY[1], M. LE LORC'H[1], M. PRIEUR[1], M. VEKEMANS[1], C. TURLEAU[1], S.P. ROMANA[1]*. 1) Department of Genetics, Hopital Necker-Enfants Malades, Paris, FRANCE; 2) Department of Genetics, Saint Joseph University, Beyrouth, LEBANON.

Here we report on the phenotype of a man with a de novo insertion into 8p. HRB did not allow us to identify the chromosome material of this insertion. Spectral karyotype and CGH were performed and showed an 7p13-7p21 insertion in 8p23.1. FISH with probes corresponding to GLI3, TWIST and HOXA genes demonstrated that these genes were included in the rearrangement. The GLI3 (7p13), the HOX A (7p15) cluster and the TWIST (7p21) genes are of particular importance for their implications in dysmorphic syndromes. Haploinsufficiency of GLI3 and TWIST are responsible for two dominantly inherited malformative diseases, respectively the Greig cephalopolysyndactyly and the Saethre-Chotzen acrocephalosyndactyly syndromes. However the phenotype associated with triple dose of these two genes is not well documented. The HOXA cluster, contains 11 genes and, as the 3 others HOX genes clusters, is involved mainly in the determination of the body axis and in the limbs patterning. In human, except for the sympolydactyly and the hand-foot-genital syndrome due respectively to HOXA13 and HOX D13 dominant negative mutations, no homeotic transformation has been reported. Also the human phenotype associated with triple dose of the HOXA cluster genes has not been well documented. A detailed analysis of our patient's phenotype showed that he was only moderately mentally retarded, mildly dysmorphic but did not present gross skull, limbs or vertebral abnormalities except for a kyphoscoliosis. Particularly no homeotic transformation was noted. Firstly, this observation illustrates the value of spectral karyotype, FISH and CGH experiments in allowing a precise definition of a complex chromosome rearrangement and refinement of phenotype-genotype correlations. Secondly, it shows that triple gene dosage for the GLI3 and TWIST genes is not associated with gross phenotypic features. Thirdly, the absence of homeotic transformation in this patient indicates that triple dose of the HOXA cluster has few phenotypic consequences.

Program Nr: 881 from the 1999 ASHG Annual Meeting

Mosaic tetrasomy 9p in a 12 year old boy with Hypomelanosis of Ito. *C. Espiritu[2], J. Leonard[1], A. Shanske[2].* 1) Coriel Institute for Medical Research, Camden, NJ; 2) Dept. of Pediatrics, Montefiore Medical Center, Albert Einstein College of Medicine.

Hypomelanosis of Ito(HI) is a heterogeneous disorder characterized by patterns of hypopigmented whorls, streaks and patches typically distributed along Blaschko's lines associated with CNS abnormalities.It is felt to result from somatic mosaicism for a gene defect lethal to ectodermal dreivatives.The majority of patients have been found to have a chromosome abnormality (J Invest Derm 103:141S-143S, 1994). About 40% of these have chromosome mosaicism usually involving the X chromosome.Tetrasomy 9p is associated with a specific phenotype with craniofacial abnormalities, congenital heart defects, genital abnormalities and moderate to severe mental retaardation in survivors.We have evaluated a 12 year old boy with mosaic 9p tetrasomy and HI.

GL was the product of a term uneventful pregnancy.His physical examination at 12 years revealed a stigmatized youngster whose height was 130 cm(<5%), weight 33 kg(<<5%), and HC was 51.5(<2%). He had microbrachycephaly with occipital flattening, downslanting palpebral fissures, a lop ear deformity, synophrys, a unilateral simian crease, bilateral cryptorchidism, and linear streaks and whorls of depigmented skin following Blaschko's lines.He was ambulatory and was able to communicate in 2 word phrases but required assistance with activities of daily living. Laboratory investigation revealed a normal male karyotype in cultured fibroblasts.However, tetrasomy 9p was observed in in 98% of lymphocytes: 46,XY{2}/47,XY,psu dic(9)(9pter>9q12::9q12>9pter).ish psu dic(9)(wcp9+){98}.

Chromosomal abnormalities have been reported in association with HI since 1985 (Neurology 35:607-610).Since then, many chromosomal abnormalities have been reported including ring chromosome mosaicism, mosaic tetraploidy and chimeras.There have been only 17 cases of tetrasomy 9p reported to date (Am J Med Genet 63:434-437 1996). Our patient has many of the phenotypic features of this disorder as well as pigmentary dysplasia. We feel that he represents the first case of HI caused by mosaic tetrasomy 9p.

Program Nr: 882 from the 1999 ASHG Annual Meeting

Prenatal Interphase FISH Using the AneuVysion Probe Set in over 10,000 samples. *L.L. Estabrooks, M. Sapeta, C. Lytle, P. Challinor, H. Dietrich-Cook, D. Crenshaw, P. Norvell, P. Shadoan, R. McKnight, N. Hunter, B. Ravnan, P. Mowery-Rushton, V. Suri, A.N. Lamb.* Genzyme Genetics, Inc, Santa Fe, NM.

We report on our experience with over 8500 prenatal interphase FISH cases (to be updated to over 10,000 cases by October) using the AneuVysion probe set which was FDA approved in the Fall of 1997. This probe set detects the centromeric regions of chromosomes 18, X, and Y and unique sequence regions at 13q14 and 21q22.2. To date, experience with these probes shows the following: False negative rate (<1%), false positive rate (0%), detection rate (99%), and false sex results (<1%). The uninformative rate (4%) and rehybridization rate (6%) are low. The most common reason for an uninformative result is the risk for maternal cell contamination in a bloody sample (48%). Our abnormality rate is 9%, but varies considerably when correlated with indication, from a low of 3% with AMA and abnormal serum screen to a high of 18% with abnormal ultrasound. The probe set detects approximately 80% of all clinically significant chromosome abnormalities found in this prenatal population. Although the informative and detection rates decrease slightly in samples from pregnancies greater than 30 weeks, this appears to be reflective of a lower rejection rate of suboptimal samples in this population. A few unique cases will be presented as well as other adjunct uses of prenatal interphase FISH that can be advantageous in prenatal diagnosis.

Program Nr: 883 from the 1999 ASHG Annual Meeting

MOLECULAR STUDIES ON A SMALL RING X CHROMOSOME IN A FEMALE WITH A SEVERE PHENOTYPE. *W. Fang[1], H.C. Lu[1], W.L. Chen[1], Y.M. Wang[1], W.T. Chaou[2], C.C. Hwang[1], L. Estabrooks[3], B.T. Wang[3].* 1) Medical Research, Changhua Christian Hospital, Changhua, Taiwan, ROC; 2) Pediatrics, Changhua Christian Hospital, Changhua, Taiwan, ROC; 3) Genzyme Genetics, Santa Fe, NM.

Mosaic 45,X/46,X,r(X) can be associated with Turner syndrome or a more severe phenotype including MR, growth retardation, cardiac defects and dysmorphic features. The difference is thought to reflect size of the ring, distribution of the cell lines, and whether or not a functional XIST (X chromosome inactivation specific transcript) gene is present on the r(X). A functional XIST gene is necessary for appropriate r(X) inactivation and often predicts a Turner syndrome phenotype where absence of the gene or presence of a dysfunctional XIST gene is associated with a more severe phenotype. We report molecular findings of a small r(X) in a baby girl who manifests a severe phenotype. Clinical features in the propositus include an atrial septal defect, growth retardation, dysmorphic facial features. The differential diagnosis included Kabuki syndrome. Chromosome analysis revealed mos46,X,r(X)[39]/45,X[11]. FISH studies confirmed that the ring originated from an X chromosome and appeared to have an XIST gene locus. To determine if the XIST gene on the r(X) is fully expressed, RT-PCR analysis was performed and the amplified products were subjected to automated sequencing testing for mutations in the XIST and androgen receptor (AR) transcripts. Both XIST and AR products were generated from this patient, supporting that the XIST gene is transcribing. Sequencing did not reveal any mutations. Determination of methylation status and thus expression of the XIST gene were attempted using the AR assay described by Allen et al. (1992). Our initial data suggest that XIST and AR genes are expressed; however, the AR assay did not support full inactivation of the r(X). We suggest that although transcription of an XIST gene is required for X inactivation, it may not be sufficient for successful X inactivation. There could be other factors affecting normal function of the XIST gene transcript acting in cis or trans. Alternatively, the non-random X inactivation could be uncovering an X-linked recessive disorder.

Program Nr: 884 from the 1999 ASHG Annual Meeting

Recombinant Down syndrome: A case report and literature review. *S.A. Farrell, S.J. Lazzaro, V. Zimmer, A. Clough, G. Chow, M.D. Speevak.* Dept Lab Medicine, Credit Valley Hosp, Mississauga, ON, Canada.

We report a case of a female identified at birth to have features of Down syndrome (DS) with an atypical karyotype. Chromosome analysis initially revealed a 46,XX,dup(21q).ish21(wcp21+). The father's chromosomes were normal. However, the mother was found to have mosaicism for a pericentric inversion of chromosome 21 (19/30 cells). The revised karyotype of the child was 46,XX,rec(21)dup(21q)inv(21)(p12q21.1)mat. We performed a literature review to aid in counselling the family about recurrence risks as well as the developmental outlook for this child. Ten comparable probands from four previous publications were identified. All cases of rec dup(21q) were secondary to a maternal pericentric inversion. Male carriers did not seem to be at risk of having offspring with the rec dup(21q), although the number of male carriers was limited. In those with rec dup(21q), the risk of congenital heart disease was similar to that of trisomy 21. As well, their facial appearance was suggestive of Down syndrome but perhaps less striking. Although the data are limited, there is an indication the developmental disabilities as well as the short stature are milder in these individuals than noted for trisomy 21. This observation suggests the region proximal to the duplication must contain genes contributing to the severity of these features in Down syndrome.

Program Nr: 885 from the 1999 ASHG Annual Meeting

Development of FISH for Human Heart Tissue. *O. Faye-Petersen[1], I.J. Barrett[2], D.K. Kalousek[2], K.D. Wenstrom[1].* 1) Depts. of Pathology, and Obstetrics and Gynecology, University of Alabama at Birmingham, Birmingham, AL; 2) Dept. of Pathology, University of British Columbia, Vancouver, BC, Canada.

Congenital cardiovascular malformations (CCVM) affect approximately 8/1000 live born infants annually, and many have high rates of associated morbidity and mortality. However, despite their frequency, and rates of complication and death, the precise causes and/or mechanisms involved in their pathogeneses remain largely unknown. To date, archived samples from congenitally diseased hearts, submitted for diagnostic purposes at the time of autopsy or surgical palliative or corrective procedures, have been unavailable for research, because of the lack of methodology for cytogenetic analysis of formaldehyde fixed, paraffin embedded myocardium. Moreover, studies which have employed fresh tissue have been largely limited to the use of animal model myocardium. We report a novel method successfully permitting fluorescence in situ hybridization (FISH) to be used to detect genomic abnormalities in human, nondividing myocardial cells. Method: Parallel samples of fresh myocardium from routine autopsy were either frozen, formalin fixed, or formalin-fixed, paraffin embedded. Frozen samples were pepsin HCl digested to yield a single cell suspension, then hybridized with a DIG labeled centromeric probe for Chromosome 2 or 7 and the Di George/VCFS region probe. Formalin fixed material was sequentially digested with pepsin HCl and trypsin EDTA. Paraffin sections (4) were treated with sodium bisulfite and pepsin HCl prior to hybridization with centomeric probe for 16 and Di George probe. Findings: Discrete signals were obtained from all cell preparations. Conclusions: FISH analysis can now be utilized to study the potential roles of recently identified genomic aberrations in the occurrence of syndromic and nonsyndromic CCVM. Fresh frozen tissue is preferable for FISH analysis. Cytogenetic study of CCVM will be less restricted to kindred analysis; institutional surgical and autopsy pathology reservoirs of stored heart tissues can now be accessed and/or prospectively built for investigations of common and uncommon forms of CCVM.

Program Nr: 886 from the 1999 ASHG Annual Meeting

Unbalanced familial cryptic translocation t(8;11) in two fetuses with Beckwith-Wiedemann features. *S. FERT-FERRER[1], A. GUICHET[2], J. TANTAU[1], A.L. DELEZOIDE[1], C. OZILOU[1], S.P. ROMANA[1], P. GOSSET[1], G. VIOT[1], S. LOISON[1], C. MORAINE[2], N. MORICHON-DELVALLEZ[1], C. TURLEAU[1], M. VEKEMANS[1], M. PRIEUR[1].* 1) Department of Genetics, Hopital Necker-Enfants Malades, PARIS, FRANCE; 2) Genetics Unit, CHR Bretonneau, TOURS, FRANCE.

We describe a cryptic translocation ascertained after two induced abortions in the same family. Both fetuses had similar abnormal findings on ultrasound examination. Previous cytogenetic studies performed on cultured amniotic fluid cells were considered as normal in both fetuses. However, high resolution banding analysis and FISH studies performed on the parents revealed a paternal translocation t(8;11)(p23.2;p15.5). Retrospective FISH analysis on both fetuses showed that they carried a derivative chromosome 8, resulting in a partial deletion of 8pter and a partial trisomy of 11pter. Also a detailed examination of the fetuses phenotype revealed some features suggestive of BWS. Indeed FISH analysis using a IGF2 probe demonstrated the presence of three copies of the IGF2 gene. This study highlights the importance of cryptic subtelomeric rearrangements in pregnancies with recurrent unexplained multiple malformations syndromes discovered prenatally and contributes to a better delineation of the prenatal phenotype of BWS.

Program Nr: 887 from the 1999 ASHG Annual Meeting

First report of an unstable marker chromosome in a child with attention deficit disorder. *D.B. Flannery[1], H.B. Radtke[2], K.N. Norris[1], A.S. Kulharya[1]*. 1) Dept Pediatrics, Sect Genetics, Medical Col Georgia, Augusta, GA; 2) Dept Genetics, Children's Hospital of Wisconsin, Milwaukee, WI.

We present a first report of the observation of an unstable marker chromosome. While occurring with a variable incidence in different tissues of an individual, marker chromosomes are usually stable in size and morphology. Exceptions are seen in neoplasms. Review of the literature failed to identify any previous reports of an unstable marker chromosome.

This 10 year old boy was referred for Fragile-X testing because of speech delay, learning disabilities, sensitivity to noise, and attention deficit disorder. His prenatal and perinatal histories were benign. Physical examination was normal, except for numerous nevi. EEG and CT were normal. Peripheral blood chromosome analysis demonstrated mosaicism for a marker chromosome in 2 of 50 cells. The marker was not found in fibroblasts. Parental karyotypes were normal. On a repeat peripheral blood chromosome analysis the marker was seen in 6 of 150 cells. The size and morphology of the marker was variable in each metaphase. Rod-shaped morphology of the larger marker indicated that it is not a ring. FISH with whole chromosome painting robes demonstrated that the marker chromosome was derived solely from chromosome 12. While the phenotype is not consistent with previously reported partial trisomy of 12, it seems likely that his developmental and behavioral problems are related to the chromosomal anomaly.

Program Nr: 888 from the 1999 ASHG Annual Meeting

Influence of CYP2E1 and GSTM1 polymorphism on the frequency of chromosome aberrations in lymphocytes of former alcoholics. *G.J.F. Gattas, M.C.T. Calabrez.* Dept. of Legal Medicine, Ethics and Occupational Health, Medical School, Sao Paulo University, Sao Paulo, SP, Brazil.

Epidemiological data have identified chronic alcohol intake as a significant risk factor for alimentary tract cancer including liver. Although the exact mechanisms are not known, experimental studies support that ethanol is a cocarcinogen and or a tumor promoter. Genetic polymorphism of xenobiotic enzymes as CYP (cytochrome P450) and GST (glutathione-S-transferase) have been implicated in inter-individual variations in susceptibility to cancer related to environmental exposure. Ethanol is in part metabolized by CYP2E1 that has been implicated as a mediator in alcohol-induced liver damage. GSTM1 detoxify a wide range of reactive metabolites produced from CYP-mediated activation. We investigated the frequency of structural chromosome aberrations (CA) in lymphocytes of 26 ex-alcoholics individuals with no tumors and 29 control subjects not screened for alcohol intake from Sao Paulo, Brazil (Gattas & Saldanha, 1997). A PCR-based method was used to determine polymorphism of the CYP2E1 (at the RsaI site) and GSTM1 enzymes and the amplified products were evaluated in 2% agarose gel. Cytogenetic analyses revealed a significant increase ($p < 0.001$) of the frequencies of cells with CA in the abstinent alcoholics (8.5%) compared with controls (3.5%). Association with CA and enzymes polymorphism was not observed in control subjects. Only among ex-alcoholics a statistically significant (Fisher's exact test / $p=0.04$) increase in baseline CA frequencies was detected in subjects with GSTM1 null genotype (30%). The same association was not observed ($p=0.9$) for CYP2E1 mutant genotype in alcoholics (11.5%). Despite the limited number of subjects genotyped, the results seem to indicate an association between CA and GSTM1 polymorphism in alcoholic individuals. (This work was partially supported by LIM-HC-FMUSP).

Program Nr: 889 from the 1999 ASHG Annual Meeting

Alternate centromere inactivation in a dicentric (Y;14) (q12;p11) associated with azoospermia. *M. Gentile, P. Losavio, F. Cariola, A.L. Buonadonna, E. Caroppo, G. D'Amato, A. Di Carlo.* Medical Genetics, IRCCS, Castellana (BA), Italy.

Balanced reciprocal Y/A translocations have been reported in association with male infertility. A correlation between Y breakpoint within the spermatogenesis AZF genes region and azoospermia and/or hypogonadism have been postulated. Such correlation could be either confirmed or negated by molecular studies which identify precise breakpoints involving Yq11 or Yq12. We had the opportunity to evaluate a 28-year-old azoospermic patient. All metaphases showed a translocation t(Y;14). A 14/22 (p14.1) centromere probe and a Y centromere (pZYA) both showed a signal on the translocation chromosome confirming it was dicentric. Every copy of the translocation chromosome had only one primary constriction; in most (90%) the Y centromere has been inactivated, but in some (10%) the 14 centromere has been inactivated. FISH with a YAC contig and PCR amplification of 27 Y specific sequences (STS) spanning the Y chromosome short arm and the euchromatic portion of the long arm allowed assignment of the breakpoint in the Yq12 region. The paternal karyotype was normal. In our patient FISH and molecular deletion mapping analysis allowed acute assignment of the Yq breakpoint at the junction of euchromatin and heterochromatin, distal to the AZF genes location (Yq11), supporting the hypothesis that in Y/A translocations the infertility might be explained by other factors. No clear correlations have been found between alternate centromere inactivation and phenotype. An epigenetic mechanism seems regulate centromeric activity. Peripheral blood and germ cells patients alphoid DNA deletions analysis could contribute to identify an association between azoospermia and translocation chromosome centromeric inactivation. Contributions from Project 126-5-98, Ministero della sanit.

Program Nr: 890 from the 1999 ASHG Annual Meeting

Endoreduplication in oral squamous cell carcinoma (OSCC). *B.M. Gharaibeh[1], X. Huang[1], W.S. Saunders[2,3], I. Petersen[4], S.M. Gollin[1,3]*. 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Department of Biological Sciences, University of Pittsburgh; 3) University of Pittsburgh Cancer Institute, Pittsburgh, PA; 4) Institute of Pathology, University-Hospital Charité, Berlin, FRG.

Endoreduplication, a common form of polyploidization in a variety of tissues, is rarely reported in cancer [Li et al. (1996) Cancer Genet. Cytogenet. 87:7-10]. Chromosomes are thought to duplicate inside of the nucleus in an endomitotic division without spindle formation, resulting in the appearance of diplochromosomes. We and others have observed that OSCC are characterized by complex, near-triploid karyotypes with multiple numerical and structural abnormalities, including deletions, duplications, and translocations. In addition to these alterations, we observed metaphases comprised of diplochromosomes that most likely resulted from endoreduplication. Schmid demonstrated that diplochromosomes can lead to the formation of atypical metaphase plates composed of tri- or tetrapolar spindles [Exp. Cell Res. 42:201-204 (1965)]. Consistent with this interpretation, our study revealed multipolar spindles in our OSCC cell lines by immunostaining and abnormal mitoses in sections of paraffin-embedded tumors. We also saw defects in expression of key cytoskeletal proteins that may have contributed to the observed abnormal spindle structures. This study suggests that endoreduplication and multipolar spindles may lead to chromosomal instability in OSCC.

Program Nr: 891 from the 1999 ASHG Annual Meeting

DETECTION OF SOMATIC GENETIC CHANGES IN HUMAN ENDOMETRIOSIS DERIVED CELL LINE (FbEM-1) BY COMPARATIVE GENOMIC HYBRIDIZATION AND FISH ANALYSIS. *J. GOGUSEV[1], L. TELVI[2], M. DOUSSAU[1], S. DU MANOIR[3], M. LEVARDON[4], J. BOUQUET DE LA JOLINIERE[4]*. 1) INSERM U507, NECKER HOSPITAL, PARIS, FRANCE; 2) LABORATOIRE DE CYTOGENETIQUE, HOPITAL ST VINCENT DE PAUL, PARIS, FRANCE; 3) INSERM U184, IGBCM, ILLKIRCH, FRANCE; 4) SERVICE DE GYNECOLOGIE OBSTETRIQUE HOPITAL BEAUJON, CLICHY, FRANCE.

Endometriosis is a cause of infertility and pelvic pain in 10-15%; of women of reproductive age. The molecular basis of this condition includes defects in oncogenes (c-myc, c-fms, Ki-ras, e-erbB1), aromatases, metalloproteinases and growth factor expression, but is in large part unknown. Comparative genomic hybridization (CGH), FISH and conventional cytogenetic analysis were used to perform wide genome survey in recently established human endometriosis derived permanent cell line FbEM-1 (Hum.Reprod. Update, 3,117, 1997). Genomic DNA from FbEM-1 cells labelled with biotin-16-dUTP and normal genomic DNA digoxigenin-11-dUTP labeled, were hybridized to metaphase spreads from blood of a healthy donor. Labeled sequences were detected using avidin-FITC and antidigoxigenin-TRITC. Images from metaphase cells were captured and the ratios of the FITC/TRITC intensities calculated. The cytogenetic analysis showed a hypotriploid karyotype and multiple marker chromosomes including a der(1) complement with homogeneous staining region (HSR). A clonal aberration interpreted as der(5)t(5q34;6p11) was found in more than 70%;; of the nuclei. CGH demonstrated gain of chromosome 1,3,5,6,7 and 17, while chromosomes 9,11,12,13,18 and X were underrepresented. Distinct amplicons were detected on 1q, 5p, 6p and 17q. FISH with paints for chromosome 1 confirmed chromosome 1 trisomy. The translocation der(5) was confirmed by double-color FISH. According to the CGH profile showing DNA sequences increase at 17q, FISH with single locus probe confirmed amplification of HER-2/neu protooncogene in 16.2%; of the FbEM-1 nuclei. These results reveal that FbEM-1 is characterized by several molecular genetic alterations. Thus, FbEM-1 cells may be an useful model to investigate the role of tumor suppressor genes and/or oncogenes in development of endometriosis.

Program Nr: 892 from the 1999 ASHG Annual Meeting

Cryptic terminal rearrangements detected using 24-color karyotyping (M-FISH). *B.K. Goodman[1,2], V. Praphanphoj[1,2], G.H. Thomas[1,2], G. Stetten[1].* 1) Johns Hopkins University School of Medicine, Baltimore, MD; 2) The Kennedy Krieger Institute, Baltimore, MD.

Subtle abnormalities at chromosome ends are sometimes detected using high-resolution G-band analysis. Chromosome-specific subtelomeric probes now permit testing for the possibility of a very distal deletion when such an abnormality is suspected. The question remains, whether or not material from another chromosome is involved. We tested the ability of 24-color fluorescence in situ hybridization (M-FISH) to detect and identify subtle or cryptic rearrangements at chromosome ends. Four techniques were used for each suspected terminal rearrangement: 1) high-resolution banding (650 bands or greater), 2) individual sub-telomeric FISH probes, 3) multi-telomere FISH (Cytocell, Inc.), 4) SpectraVysion 24-color FISH (Vysis, Inc.). Thus far we have examined two cases of 22q13 deletion and a deletion (18)(q21.3) for the presence of translocated material. In both 22q deletions, M-FISH results were in agreement with the other FISH assays. One case was found to be an unbalanced terminal rearrangement [der(22)t(19;22)(q13.42;q13.31)mat]. The M-FISH analysis consistently detected the presence of chromosome 19 material on the end of the deleted 22. The second case appeared to be a simple terminal deletion by all methods. No evidence of a translocation was found. While the del(18q) was cytogenetically obvious, the identity of the terminal G-light band was in question. M-FISH analysis detected the presence of material from another chromosome at the very end of the deleted 18 in all but one very short metaphase spread. In 33% (5/15) of the cells, the Quips SpectraVysion software (Vysis, Inc.) suggested chromosome 21 as the source of the extra material. The material was inconsistently identified in the remaining 10 cells. Viewing separate color planes confirmed the presence on the der(18) of the chromosome 21-specific fluors, and FISH with a 21qtel probe confirmed the rearrangement. Our experience indicates concordance among high resolution G-banding, multi-telomere FISH, individual sub-telomeric probes and M-FISH in identification of the origin of small rearrangements at chromosome ends.

Program Nr: 893 from the 1999 ASHG Annual Meeting

Tetrasomy(13)(q32-qter) due to a neocentromere at 13q32 in a mentally retarded boy with progressive loss of function. *L.P. Govaerts[1], I.F.M. de Coo[2], M. van der Blij-Philipsen[3], C.H. Wouters[1], H.J.F.M.M. Eussen[1], Chih-yu Yu[4], D. Warburton[4], J.O. Van Hemel[1]*. 1) Dept. Clinical Genetics, University Hospital Dijkzigt, Rotterdam, Netherlands; 2) Dept of Child Neurology, Sophia Childrens Hospital, Rotterdam, The Netherlands; 3) Dept of Molecular Cell Biology and Genetics, P.O. Box 108, 5500 AC Veldhoven, The Netherlands; 4) Clinical Genetics and Development, Columbia University, New York, NY, USA.

Statement of purpose: We report on the clinical and cytogenetic findings in a developmentally retarded hypotonic boy with tetrasomy (13)(q32-qter) due to a neocentromere at 13q32. At the age of 5 he developed behavioral changes, epilepsy, progressive loss of function and hypertonia. He died at home at the age of ten. Cytogenetic methods and results: The standard karyotype (GTG banding) showed non-mosaic 47,XY,+M with euchromatine. Parental chromosomes were normal. Additional chromosome staining technics (CBG, NOR and DA/DAPI) were all negative. Centromere identification by FISH with pTRA.20 probe (# 15), L1.26 probe(# 13, 21), 237(# 14, 22) and r521 (ribosomal DNA) failed. Spectral karyotype analysis suggested the marker to be a der(13). With CGH a duplication of the 13qter region from q32 was obvious. Subsequent FISH with WCP #13 (Cambio) and TH13qter probe confirmed the idea of an invdup(13q). The double signals from the telomere probe TH13qter on both ends of the marker proved the #13 marker to be an invdup13q32 with a neocentromere formation. Further analysis on metaphase and interphase chromosomes with cosmid 2G4 localised at the ZIC2 gene (13q32) showed two very closely opposed signals on the invdup(13).

Program Nr: 894 from the 1999 ASHG Annual Meeting

Design of modified oligonucleotide probes to detect telomere repeat sequences in FISH assays. *J.G. Hacia[1], E.A. Novotny[1], R.A. Mayer[1], S.A. Woski[2], M.A. Ashlock[1], F.S. Collins[1]*. 1) GMMB, NHGI/NIH, Bethesda, MD; 2) Dept. of Chemistry, U of Alabama, Tuscaloosa, AL.

Much current interest surrounds the structure of mammalian telomeres, and consequently, a robust and inexpensive fluorescent in situ (FISH) assay for telomere detection would be of considerable utility in both the research and clinical area. FISH probes based on unmodified oligonucleotides of peptide nucleic acid (PNA) homologs, complementary to one strand or the other of the hexamer repeat have certain disadvantages that caused us to examine alternative substrates for telomere hybridization. A series of dye-labeled oligonucleotide probes containing base and sugar modifications were tested for the ability to detect telomeric repeat sequences in FISH assays. These modified oligonucleotides, all 18-nt in length, were complementary to either the cytidine-rich $(C_3TA_2)_n$ or guanosine-rich $(T_2AG_3)_n$ telomere target sequences. Oligonucleotides were modified to either increase target affinity by enhancing duplex stability (2'-OMe ribose sugars and 5-(1-propynyl)-pyrimidine residues) or inhibit the formation of inter- or intramolecular structures (7-deazaguanosine and 6-thioguanosine residues) which might interfere with binding to target. Several dye-labeled oligonucleotide probes were found that could effectively stain the telomeric repeat sequences of either cytidine- or guanosine-rich strands in a specific manner. Such probes could be used as an attractive alternative to PNAs for investigating the dynamics of telomere length and maintenance. In principle, these relatively inexpensive and readily synthesized modified oligonucleotides could be used for other FISH-related assays such as triplet repeat expansions.

Program Nr: 895 from the 1999 ASHG Annual Meeting

Interstitial deletions of chromosome 5 and 16 without phenotypic abnormalities: further confirmation. *J.L. Hand[2], V.V. Michels[2], R.P. Ketterling[1], M.J. Marinello[3], S.M. Jalal[1]*. 1) Cytogenetics Laboratory, Department of Laboratory Medicine and Pathology; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN; 3) Genetic Diagnostic Laboratories, Inc., Buffalo, NY.

We describe two cases of euchromatic interstitial deletions without detectable phenotypic abnormalities. Patient one was a 19-year-old male who presented with progressive encephalopathy, progressive blindness, deafness, and spastic quadriparesis and was subsequently diagnosed with a peroxisomal disorder. Despite extensive evaluation, the specific peroxisomal disorder was not identified. We hypothesize that the son's phenotype may represent unmasking of a new autosomal recessive peroxisomal disorder in the deleted region. High-resolution chromosome analysis was interpreted as 46,XY,del(5)(p14.1p14.3). The asymptomatic mother had the same interstitial deletion. Use of wcp5 and SKY analysis confirmed that the abnormal chromosome 5 was not involved in a translocation. Chromosome 5p14 deletion has been reported previously in a family for three generations without phenotypic anomaly that included female to male and female to female transmissions. In the second case, an amniocentesis for advanced maternal age revealed an interstitial deletion in the long arm of chromosome 16. The karyotype of the fetus was 46,XX,del(16)(q13q22). The wcp16 painted the abnormal and the normal 16 entirely and there was no evidence of the presence of chromosome 16 DNA on any other chromosome. The pregnancy was carried to term and resulted in the birth of a normal daughter. The same deletion was observed in the phenotypically normal mother and a normal first child who is a 2-year-old son. Interstitial deletion of 16q21 has been reported previously to have a normal phenotype in a two generational family. These deletions do not seem to be associated with an abnormal phenotype due to imprinting. Interstitial euchromatic deletions without an apparent phenotypic anomaly include: Xq26,5p14,11p12, 13q21 and 16q21, a list that is growing.

Program Nr: 896 from the 1999 ASHG Annual Meeting

Y-Autosome Translocations characterized by classical banding techniques and molecular cytogenetic studies. *D. Hansmann[1], Z. Storm[1], R. Raff[2], G. Schwanitz[2].* 1) Institute Prenatal Diagnosis, Meckenheim, Germany; 2) Institute of Human Genetics, University of Bonn, Bonn, Germany.

Y-Autosome translocations are rare events of chromosome rearrangements. In our own investigation group of about 30000 chromosome analyses from lymphocyte culture we diagnosed ten cases. 5 of them had breakpoints in euchromatic regions and showed a phenotype in agreement with the unbalanced karyotype. The other 5 cases were rearrangements with chromosome 15 and breakpoints in the constitutive heterochromatin. In chromosome 15 the breakpoints were located between 15p11.2 and p12/13, in the Y-chromosome between Yq11.23 and Yq12. In these 5 cases, where we investigated the probands and their relatives, each person was carrying only one of the translocation chromosomes, this means that the rearrangement had occurred in earlier generations. The translocations could be delineated by a combination of different banding techniques and FiSH. The way of genetic counselling is given, 2 of the pedigrees are demonstrated in detail.

Program Nr: 897 from the 1999 ASHG Annual Meeting

Generation of repetitive sequence-depleted microdissected chromosome arm painting probe. *H. He[1], W. Huang[1], XY. Guan[2]*. 1) American Lab Technologies, Inc, Rockville, MD; 2) Department of Clinical Oncology, University of Hong Kong, Hong Kong, China.

The application of fluorescence in situ hybridization (FISH) with whole chromosome painting probes, chromosome arm painting probes, and chromosome band-specific painting probes has greatly facilitated to detect chromosome rearrangements in both hereditary diseases and cancers. To meet the increasing demand for the high quality FISH painting probes, a subtraction strategy has been applied in our company to remove repetitive sequences from microdissected DNA probes before hybridization. Chromosome arm 5p has been chosen to test our new method. Briefly, 10 copies of 5p were microdissected and amplified using a degenerate oligo primer (UN1) by PCR. UN1 primer was then replaced by a unique sequence primer (R1) by PCR. These PCR products were then hybridized with biotin-labeled human repetitive sequences derived from a 120 kb BAC containing various human repetitive sequences. After hybridization, avidin was added into the reaction and phenol/chloroform subtraction was performed to remove proteins in the reaction solution including all avidin-bound biotin-labeled repetitive sequences and their specifically hybridized repetitive sequences in the microdissected DNA. The remaining unique DNA fragments were recovered by PCR with R1 primer. The intensity and specificity of the repeat-depleted 5p arm painting probe have been characterized by FISH without adding block DNA Cot-1. The intensity and hybridization specificity of the fluorescence signal was similar between a regular 5p arm painting probe with Cot-1 block and our repeat-deplete 5p painting probe. This repeat-depleted painting probe which no longer require adding block DNA will be used for FISH and will provide cheaper and quicker resource for the increasing demand of the high quality FISH painting probes.

Program Nr: 898 from the 1999 ASHG Annual Meeting

Comparison of secondary cytogenetic abnormalities in pediatric T-cell versus B-cell lymphomas. *C.M. Higgins, M.M. Hess, B. Gordon, W.G. Sanger.* Human Genetics Laboratory, Univ Nebraska Med Ctr, Omaha, NE.

Cytogenetics of non-Hodgkin's lymphoma (NHL) have not been as intensively studied in children compared to adults. In childhood NHL, the majority of cases are neoplasms of B-lymphocyte origin (70%). Fewer lymphomas are of T-cell origin and most of these fall into a group of large cell lymphomas (LCL) known as anaplastic large cell lymphomas (ALCL). We present the cytogenetic and histologic results of eight t(2;5)-positive T-cell ALCL and compare the secondary clonal abnormalities with those of eleven pediatric B-cell neoplasms. Recurrent chromosome abnormalities in ALCL include t(2;5)(p23;q35) which leads to fusion of the nucleophosmin (NPM) gene on 5q to the anaplastic protein kinase (ALK) gene on 2p. This and other cryptic rearrangements may be important in the deregulation of ALK causing the pathogenesis of ALCL. The most frequent secondary cytogenetic features of ALCL from this analysis include the following disruptions, listed in decreasing frequency: 1q21, 10q24, 1q10, 3p23, 11q13, and 10q22. Loss of chromosome 4 and gain of the X chromosome were the most frequent numeric aberrations. Numerous breakpoints were noted on the long arms of chromosomes 1, 10, 11, and the entire length of chromosome 17. Most karyotypes were hyperdiploid followed by near-tetraploidy. Secondary to disruptions of 14q32 and 8q24, the B-cell lymphomas had a much more diverse pattern of additional abnormalities than the ALCLs. In decreasing frequency, repeated disruptions were at band 1q21, 1q42, and 15q26. The loss of Y and chromosomes 3, 4, and 15, in addition to extra copies of 8 and 18 were recurrent numeric abnormalities. Only chromosome 1 revealed a pattern of breakpoints along its entire length. Most of the pediatric B-cell cases were diploid and hyperdiploid. Similarities between the two groups of lymphomas were restricted to breakpoints clustered at 1q21 and the repeated loss of chromosome 4. The ALCL group had a much more consistent pattern of secondary abnormalities than did the B-cell tumors. Continuing studies may help elucidate the pathogenesis and progression of these pediatric lymphomas. Supported in part by the National Childhood Cancer Foundation.

Program Nr: 899 from the 1999 ASHG Annual Meeting

Aneuploidy for chromosomes 12, 13, 17, 18, X and Y and deletions on the Y chromosome in sperm from twenty oligoasthenoteratozoospermic (OAT) patients undergoing ICSI. *S.F. Hoegerman[1], M.G. Pang[2], M.K. Rudd[1], N.K. Dahiya[1], M. Stacey[1], L. Lunsford[1], G. Doncel[3], A.A. Acosta[3], W.G. Kearns[1,3,4].* 1) Cent for Ped Res, EVMS, Norfolk, VA; 2) Biomedical Res Cent, Korea Adv Inst of Science and Tech, Taejon, Korea; 3) Jones Inst, East VA Med Sch, Norfolk, VA; 4) Inst of Genet Med, Johns Hopkins Univ School of Med, Baltimore, MD.

Objective: To determine aneuploidy frequencies and Y chromosome deletions from twenty OAT patients and six proven fertile donors. **Study Design:**Multi-probe, multi-color fluorescence *in situ* hybridization (FISH) and STS-PCR was performed on sperm to determine aneuploidy and Y chromosome deletions. **Materials and Methods:**Aneuploidy frequencies were determined in sperm from twenty OAT patients and six controls. Three-probe, three-color FISH was performed using direct labeled DNA specific for chrom. 12,13 and 17 (probe set I) and chrom. 18,X and Y (probe set II). Over 104,000 sperm were scored in this study. STS-PCR was performed to determine genomic deletions within the Y chrom. **Results:** In OAT patients, the per chrom. disomy for chrom. 12 ranged from 0.3 to 4.3%, for chrom. 13 from 0.2 to 3.5%, and per chrom. disomy for chrom. 17 ranged between 0.09 and 2.4%. In controls, the mean per chrom. disomy frequency was 0.8% for chrom. 12, 0.2% for chrom. 13, and 0.2% for chrom. 17. The per chrom. disomy for the sex chrom. ranged between 1.8 and 5.3% and the per chrom. disomy for chrom. 18 ranged between 0 and 1.5%. In controls, the mean disomy frequency for the sex chrom. was 0.4% and the mean disomy frequency for chrom. 18 was 0.2%. Diploidy ranged between 0.1 and 2.6% in OAT patients, with a control mean of 0.3%. Total aneuploidy ranged from 31 to 70% for OAT patients. Total aneuploidy in controls ranged between 4.1 and 7%. STS-PCR studies from 20 OAT patients identified one Y chromosome deletion, from both sperm and somatic cells of one patient. From this same patient, a significant increase ($p<0.05$) in autosomal and sex chromosome aneuploidy was found in his gametes. **Conclusions:**These findings showed significant increases of genetic abnormalities in sperm of all OAT patients studied.

Program Nr: 900 from the 1999 ASHG Annual Meeting

Identification of a human autoimmune serum containing antibodies against the inactive X-chromosome. *B. Hong[1], M.S. Swanson[2,3], T.P. Yang[1,3,4].* 1) Department of Biochemistry and Molecular Biology; 2) Department of Molecular Genetics and Microbiology; 3) Center for Mammalian Genetics; 4) Division of Pediatric Genetics, University of Florida College of Medicine, Gainesville, FL.

Dosage compensation of X-linked genes in female mammals is achieved by transcriptional silencing of one of the two X-chromosomes. Structurally, the inactive X chromosome appears as a distinct heterochromatic nuclear inclusion, or Barr body. XIST RNA, a large non-coding nuclear RNA, is associated with the Barr body and is essential for X inactivation. However, it has been shown that XIST RNA is not directly bound to the X chromosomal DNA, suggesting that protein components of the Barr body may bind XIST RNA to the DNA by forming protein-RNA complexes. So far, such protein components have not been identified. Autoantibodies have been used as research tools for elucidation of intracellular structure and function. To identify antibodies that recognize components of the Barr body, we screened a total of 255 human autoimmune sera by indirect immunofluorescence microscopy. A variety of staining patterns by these autoimmune sera was observed. One serum sample recognized a Barr body-like heterochromatic structure. Further immunofluorescence studies with cultured human fibroblasts carrying different numbers of X-chromosomes demonstrated that the number of Barr body-like structures stained by this serum corresponded to that expected from the "n-1" rule of X inactivation. These results indicate that we have identified an autoimmune serum that contains antibodies against one or more molecular components of the Barr body. Identification of the antigen(s) is currently under way.

Program Nr: 901 from the 1999 ASHG Annual Meeting

The Neocentromere and Centromere Protein A (CENP-A). *E.V Howman, P. Kalitsis, K. Fowler, A. Newson, S. Redward, A. MacDonald, K.H.A Choo.* Chromosome Research, The Murdoch Institute, Royal Children's Hospital, Melbourne, VIC, Australia.

We previously identified a marker chromosome, mar del (10), in a patient who presented with mild developmental delay. A latent centromere was activated at the 10q25 region. This neocentromere lacks alpha-satellite and CENP-B. Using positional cloning, an 80kb region spanning this neocentromere was obtained and subsequently sequenced. A comparison between this region and the corresponding region of the normal 10 proved unremarkable. The activation of the neocentromere is therefore due to an epigenetic mechanism that has yet to be elucidated. An ideal candidate for this epigenetic role is CENP-A. This 17kD protein is restricted to active centromeres and its expression is synchronous with the late replication of centromeric DNA. CENP-A is a histone H3-like protein and a nucleosomal component. To determine the biological function of Cenpa, we generated mouse mutants by homologous recombination. Exon 2 of the Cenpa gene (amino acids 29-64) was deleted. This corresponds to the N-helix domain and a partial deletion of the helix 1 domain which are essential for centromere targeting. Heterozygous mice were produced and appear healthy. Current studies are focused on the production of null mice and the elucidation of the corresponding phenotype.

Program Nr: 902 from the 1999 ASHG Annual Meeting

Aneuploidy, chromosomal instability, and cytoskeletal defects in oral squamous cell carcinoma (OSCC) cells. *X. Huang[1], W.S. Saunders[2,3], B. Gharaibeh[1], M. Shuster[2], A.H. Enyenihi[2], S.M. Gollin[1,3].* 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Department of Biological Sciences, University of Pittsburgh; 3) University of Pittsburgh Cancer Institute, Pittsburgh, PA.

OSCC are characterized by complex, often near-triploid karyotypes with structural and numerical variations superimposed on the initial clonal chromosomal alterations. The most likely reasons for the chromosomal instability in the OSCC cells are: 1) defects in the mitotic machinery of the cell, preventing normal mitotic chromosome segregation; 2) loss of function of the gatekeeper genes in the cell, preventing detection of DNA damage and cell cycle arrest; and 3) defects in cell cycle regulation, preventing the recognition and correction of segregational errors. We used immunohistochemistry and spectral karyotyping to study the chromosomal segregation and cytoskeletal defects and the relationship between them in cultured OSCC cells. In metaphase and anaphase cells, multipolar spindles and lagging chromosomes are detected frequently, suggesting the presence of defects in the mitotic apparatus and resulting chromosomal instability. Dicentric anaphase chromatin bridges and gene amplification suggest the occurrence of breakage-fusion-bridge (BFB) cycles. Some anaphase bridges persist into telophase, resulting in aberrant chromosomes that are excluded from the reforming nucleus, presumably leading to the micronuclei often observed in OSCC cells. Furthermore, half of the micronuclei are kinetochore-negative, suggesting chromosome breakage into acentric fragments. Our results suggest that cytoskeletal defects and BFB cycles may be responsible for some of the genetic instability in OSCC.

Program Nr: 903 from the 1999 ASHG Annual Meeting

Great Plains Cytogenetic Laboratory Trends between 1986-1996. *P.S. Ing[1], C. Johnson[2], S.R. Patil[2], W.G. Sanger[3].* 1) Boys Town Nat'l Research Hosp, Omaha, NE; 2) University of Iowa Hospitals and Clinics, Iowa City; 3) University of Nebraska Medical Center, Omaha.

Pooled data can be used as benchmarks for assessing laboratory quality assurance. Since 1986, the Great Plains Genetics Service Network Cytogenetics Committee has collected data on laboratory volume, failure rates, abnormality rates & turnaround times for different tissues: peripheral blood (PB), amniotic fluid (AF), chorionic villus (CVS), bone marrow (BM), tissue culture (TC), etc. from cytogenetic laboratories within the eight states of the region. In 1977, data items were modified. Not all labs provided all data on all items on all tissues in all years. As many as 20 different labs participated, from 9 labs in 1986 to 18 labs in 1991.

Laboratory volume across the region slowly increased from 12,000 samples total (14 labs) in 1987 to ~22,000 samples (16 labs) in 1996. PB & TC samples remained steady between 4,500 - 5,000 and 1,000 cases per year, respectively. AF samples rose steadily from >5,000 studies in 1987 to >8,000 in 1996. BM studies showed the greatest growth from ~1,400 studies in 1987 to ~6,000 in 1996. CVS studies peaked in 1991.

For **peripheral bloods:** failure rates dropped from 2.2% in 1986 to 1% in 1996; turnaround times were at 15 days in 1986, rose to 21 days in 1989, & dropped to 12.5 days for the last three years; abnormality rates remained fairly constant at ~15%.

For **bone marrows:** abnormality rates declined from 40% in 1986 to 22% in 1996 while failure rates remained steady at 8%; data were insufficient to calculate turnaround times.

For **amniotic fluids:** failure rates remained low (0.16% to 0.39%) while abnormality rates rose slightly from 2.5% in 1986 to 4% in 1996; data were insufficient to calculate turnaround times.

Supported in part by grant MCJ-191002, "Great Plains Genetic Service Network.".

Program Nr: 904 from the 1999 ASHG Annual Meeting

Cytogenetic Diagnosis of Fragile X Syndrome A study of 305 suspected cases in Saudi Arabia. *M.A. Iqbal, N. Sakati, A. Nester, P. Ozand.* King Faisal Specialist Hosp&RC, Riyadh, Saudi Arabia.

Background: Fragile X syndrome is the most common cause of inherited mental retardation. Patients with fragile X syndrome show variable mental disability, typical long and narrow facial appearance with large ears and prominent fontanel and frequent macro-orchidism. It is generally associated with a fragile site at Xq 27.3, which can be observed in the metaphase chromosome following selective culture conditions. At the molecular level, the fragile X syndrome is associated with an amplification of CGG repeat sequence of the FMR1 gene. The prevalence estimates are reported as one per 1500 males and one per 2500 females. Estimated prevalence rates of fragile X syndrome in different ethnic groups range from 0.4 - 0.8 per 1000 in males and 0.2 - 0.6 per 1000 in females. In this study, we have determined the frequency of fragile X positive cases in 305 preselected patients. Materials and Methods: 305 Saudi patients with mental retardation/developmental delay/clinical suspicion of fragile X syndrome were screened for fragile X chromosome by cytogenetic methods. Results: The majority of patients (95.59%) screened were under the age of 20 years. Two-hundred and ninety nine patients (98.03%) were in the category of mild to moderate mental retardation group. The frequency of fragile X positive cells in males ranged between 7% to 58% (mean 26 + 13.11), while in the females it was between 14% to 21% (mean 12.5 + 3.5) respectively. 24 males (7.86%) and two females (0.65%) were found to express fragile X site at q27.3. In this study 8.52% fragile X positive cases were found among 305 mentally retarded Saudi patients. Our findings are similar to the reports of frequency of fragile X cases observed in selected mentally retarded patients in other parts of the world. Molecular studies are currently in progress, and a correlation with cytogenetic and molecular fragile X analysis should give more insight into the etiology of this disorder.

Program Nr: 905 from the 1999 ASHG Annual Meeting

A high degree of mosaicism in preimplantation embryos from a carrier of a reciprocal translocation t(11;22)(q23;q11). *E. Iwarsson[1], H. Malmgren[1], J. Inzunza[2], L. Ährlund-Richter[2], B. Rosenlund[3], M. Fridström[3], P. Sjöblom[3], M. Nordenskjöld[1], E. Blennow[1]*. 1) Dept of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Department of Bioscience at Novum, Karolinska Institutet; 3) Department of Obstetrics and Gynaecology, Huddinge Hospital.

Introduction: Carriers of reciprocal translocations are at risk of having unbalanced offspring. Therefore, preimplantation genetic diagnosis (PGD) was performed on a woman carrying a reciprocal translocation t(11;22)(q23;q11). It is known that normal developing human preimplantation embryos show a high degree of aneuploidy/mosaicism. This prompted us to analyze all cells from 26 biopsied embryos in three treatment cycles for presence of unbalance and mosaicism. **Material and Methods:** Using three color fluorescence in situ hybridization (FISH) with two probes from chromosome 22 (22q11.2 and 22q13) in combination with a centromere-specific probe from chromosome 11, we examined the majority of cells from each embryo. **Results:** Three PGD treatment cycles were performed and one balanced embryo was transferred in cycle two and three. However, no pregnancy was established. In total, 26 biopsied, normal developing embryos were analyzed and a successful FISH analysis was achieved in 189 of 230 nuclei (82%). Twenty-three out of 26 embryos (88%) were mosaic and only 3 out of 26 embryos (12%) were balanced. For the two balanced embryos that were transferred, only the two biopsied cells were analyzed and a possibility of mosaicism remains. In the third balanced embryo there was no mosaicism. There were different degrees of mosaicism in the embryos. Some showed only two cell types (regarding the chromosomal content) while others displayed a different chromosomal content in every cell (chaotic chromosomal content). No embryo with homogeneously unbalanced chromosomal content was found.**Conclusion:** Compared to our own results and others, the number of abnormal embryos was higher (88%) than earlier studies (up to 75%) on normal developing preimplantation embryos from IVF patients without known chromosomal abnormality. These findings ought to be considered in the clinical preimplantation genetic diagnosis situation.

Program Nr: 906 from the 1999 ASHG Annual Meeting

Application of M-FISH for Identification of Markers and Derivative Chromosomes in Congenital Cases. *S.M. Jalal[1], M.E. Law[1], N.M. Lindor[2], G.S. Sekhon[3].* 1) Cytogenetics Lab, Mayo Clinic, Rochester, MN; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN; 3) Division of Clinical Genetics, University of Wisconsin, Madison, WI.

We have tested multicolor FISH (M-FISH), that became commercially available in 1998, in a series of normal and abnormal cases from blood, amniotic fluid, fibroblast culture, and bone marrow. We present the result of M-FISH analysis on a series of abnormal congenital cases. An extra ring was identified to be from chromosome 8 and confirmed by centromere-specific probe. In a family carrying a subtle t(4;8)(p16.1;p23.1) the der(4) and der(8) were detected in two members and confirmed by the chromosome-specific paint probes. However, the translocated segment of der(8) was detected by M-FISH with difficulty and had to be confirmed by 4p16.3 locus-specific probe. An add(4)(p16.1) was entirely from chromosome 4. Locus-specific probes for 4q16.3 and 4p12 were present once in this complex duplication. An add(7)(q26) was from 12 and confirmed by paint and telomere-specific probes. A suspected inv(18) was confirmed. An add(3) was entirely from 3. Telomere-specific probes indicated it to be a cryptic translocation involving dup(3qter) and del(3pter). A complex karyotype with an insertional translocation and balanced t(4;9) turned out to have the insertion but the translocation was complex t(8;10;12). M-FISH requires optimal hybridization for a distinct discrimination of classification colors, and the acrocentric fluorophores sometimes cross-hybridize to the acrocentric short arms. However, we find M-FISH to be an invaluable tool for resolution of markers, derivative chromosomes, and complex karyotypes.

Program Nr: 907 from the 1999 ASHG Annual Meeting

del(18p)SYNDROME WITH GH DEFICIENCY : REPORT OF 6 CASES AND REVIEW OF THE LITERATURE. *O. JARAMILLO LINES*[1], *C. SEVIN*[1], *L. TELVI*[2], *J.L. CHAUSSAIN*[1]. 1) ENDOCRINOLOGIE PEDIATRIQUE, HOPITAL ST VINCENT DE PAUL, PARIS, FRANCE; 2) LABORATOIRE DE CYTOGENETIQUE, HOPITAL ST VINCENT DE PAUL, PARIS, FRANCE.

More than 100 cases with 18p- have been reported until recently. Clinical features of these patients are variable. Patients presented caracteristic dysmorphia with mild to severe mental retardation. A short stature was found constantly. The etiology of the growth retardation is unknown. We described 6 patients with short stature (1,8SD to -6SD) and 18p monosomy (5 cases with del(18p) and 1 case with der18,t(13;18)(q11;p11.2)). Four patients had a partial and isolated GH deficiency, and 2 of them showed an abnormal pituitary gland after MRI examination. Two patients, out of 6, (one with GH deficiency and one with normal GH secretion) received GH treatment (0,8-0,9 IU/kg/wk) for 5 years. Height went up from -4SD to-2SD for the GH deficient patient and from -2SD to average for the normal GH patient. To date, 8 cases of 18p monosomy associated with short stature and GH deficiency was described. Three of them showed abnormalities of the development of pituitary gland. Four patients had GH treatment with a satisfactory growth rate. The 2 cases reported in this data, in addition to the 4 of the literature, showed that the patients with 18p monosomy and short stature should be considered for the GH treatment.

Program Nr: 908 from the 1999 ASHG Annual Meeting

Marker chromosomes are present at higher frequencies in older individuals with Down syndrome. *E.C. Jenkins, L. Ye, H. Gu, M. Genovese, C. Duncan, S. Brooks, N. Schupf, W.T. Brown.* NYS Inst Basic Res Dev Disab, Staten Island, NY.

Recently, we reported increased low-level chromosome 21 mosaicism in short-term whole blood cultures from older individuals with Down Syndrome (DS)(Am J Med Genet 1997;68:147-151). We observed a marker or acentric chromosome in 5% of the cells studied from a 45-year-old female subject. A number of deletions and age-associated losses of chromosomes 15, 17, 21 and X were also observed. We have now studied additional older individuals with DS and have observed marker chromosomes in 1 to 100% of cells examined from 5 older (40 years or older) individuals with DS, ranging in age from 43 to 61 years. Among a total of 324 individuals with DS studied, 5 or 1.5% have exhibited marker chromosomes. Among 148 individuals with DS who were under 40, none exhibited a marker chromosome, while 5 or 2.8% of 176 individuals with DS, 40 years or older, had marker chromosomes ($P<.05$, one-tailed), as compared to 1 or 0.4% marker chromosomes observed in 243 non-DS individuals with an otherwise normal karyotype ($P<.05$, one-tailed), who ranged in age from 40-88 years. It was possible to study two such marker chromosomes with M-FISH (multitarget fluorescence in situ hybridizaiton) followed up by whole chromosome painting via single DNA probe FISH analysis. One marker chromosome, from a 45-year-old female with DS, was present in 14 of 30 cells and was found to be derived from chromosome 6. The other marker, from a 54-year-old female with a 21q;21q translocation (trisomy 21), was a small metacentric chromosome that appeared to have been derived from chromosome 21 material, likely a result of Robertsonian fusion between two No. 21 chromosomes. This marker was present in 100% of 36 cells studied. To our knowledge, this is the first example of a mosaic marker chromosome 6 from an individual with DS. With this additional information, we now hypothesize that there is increased chromosome instability in cultures from older individuals with DS resulting in the formation of marker chromosomes, deletions, and selective, low-level non-disjunction. This work was supported in part by the NYS Office of Ment. Ret. and Devel. Disabil.; NIH: P01 HD35897-12, AG 14673; Alzheim. Assoc. RG3-96-077.

Program Nr: 909 from the 1999 ASHG Annual Meeting

A Ring Chromosome Derived From An Interstitial Deletion of The Short Arm of Chromosome 5. *M.T. Jodah[1], B.G. Kousseff[1], C.S. Kalter[2].* 1) USF Regional Genetics Program, Tampa, FL; 2) Florida Perinatal Associates, Tampa, FL.

Marker chromosomes are seen in 0.65-1.5 per 1,000 fetuses; 45% are familial. De novo markers have a risk of 10-15% risk for abnormalities. The size, staining properties and the presence of mosaicism are often useful in predicting their consequences. Ring chromosomes account for about 10% of all markers. On amniocytes, we encountered a de novo, ring chromosome derived from an interstitial deletion of the short arm of one chromosome 5. FISH analysis using an all-human centromere probe and a chromosome 5 painting probe confirmed there was an interstitial deletion of 5p. The ring represented the deleted segment of 5p with a centromere; the karyotype was 47, XY, del(5)(p13), +mar.de novo.ish (5)(p11p15.1). The genetic counseling for this patient was complicated. The initial concern was about cri-du-chat syndrome. Fortunately, FISH determination of the origin of the marker resulted in an improved prognosis. The patient was counseled regarding at least a 10% risk for phenotypic abnormalities and/or developmental delay. Clinical genetics evaluation is pending. Ring chromosomes are formed when there is a break in both arms of a chromosome with the resulting terminal segments lost and formation of a ring from the remaining segment or due to telomere-to-telomere fusion. Frequently they are unstable leading to varying levels of mosaicism. Interstitial deletions leading to ring chromosome are rare and have only been described involving chromosomes 2, 5, 9, 10, 16, and 17 (Petit & Fryns, 1997; Schuffenhauer, 1996). At least three mechanisms have been proposed to explain the occurrence of ring chromosomes.
.

Program Nr: 910 from the 1999 ASHG Annual Meeting

SRY in XX males and XY females: Demonstration by primed in situ labeling. *J.S. Kadandale[1], Y. Tunca[1], R.S. Wilroy[1], P.R. Martens[1], S.S. Wachtel[2], A.T. Tharapel[1].* 1) Clinical and Molecular Cytogenetics Laboratory, Dept Pediatrics, Univ Tennessee, Memphis, TN; 2) Reproductive Genetics Laboratory, Dept Obstetrics & Gynecology, Univ Tennessee, Memphis, TN.

Primed in situ labeling (PRINS) is a sensitive and specific method that can be used to localize DNA segments too small to be detected by conventional FISH. We used the PRINS method to localize the SRY gene to the short arm of the Y-chromosome. We also demonstrated its presence on the Y chromosome in women with 46,XY gonadal dysgenesis, and identified an SRY domain on the der(X) in men with t(Xp;Yp). In addition, we performed PCR with conventional primers to amplify SRY in genomic DNA from the same subjects. The PRINS method that we employed involved significant modification of the existing methodology (which is used to identify repetitive sequences). Annealing of primers and extension were accomplished on chromosome preparations on microscope slides in the presence of labeled nucleotides and Taq DNA polymerase. SRY signals were detected at band Yp11.31p11.32 (ISCN 1995) in 95% of metaphase spreads. About 90-95% of interphase nuclei showed the SRY signal in the male controls. SRY signals were observed on the short arm of the der(X) from the 46,XX male and the male with 46,der(X),t(Xp;Yp),+mar, confirming Xp-Yp interchange. The signals were not detected in female controls. In view of our experience with SRY and five other genes, we conclude that PRINS is useful for routine localization of single copy genes and small DNA segments, in general.

Program Nr: 911 from the 1999 ASHG Annual Meeting

A rare terminal deletion involving the distal short arm of chromosome 12. *K.A. Kaiser-Rogers[1], K.W. Rao[1], M.I. Roche[1], C.M. Lese[2], C.M. Powell[1]*. 1) Dept Pediatrics, Univ North Carolina, Chapel Hill, NC; 2) Ctr Medical Genetics, Univ Chicago, Chicago, IL.

We are studying a 9 4/12 year old male with what appears to be the smallest cytogenetically detected terminal short arm deletion of chromosome 12 reported to date [46,XY,del(12)(p13.33)]. This deletion was so subtle that many of the examined cells looked normal by G-band analysis. A FISH study using a unique telomere probe for the short arm of chromosome 12 (BAC 124K20) was used to exclude the possibility that mosaicism was present in this patient. Additional FISH studies are currently in progress to further characterize this rearrangement.

J.D. presented as a small, thin child with a marfanoid habitus, mental retardation, behavior problems and involuntary movements involving his face, body and extremities. His height was 131.5cm (25th percentile), his weight was 20 kg (<5th percentile) and his head circumference was 47 cm (< 5th percentile). Several minor dysmorphic features were noted including small ears (3rd percentile), periorbital fullness, a narrow palate, and a small mandible. On the left hand, a single transverse palmer crease and an extra digital crease on the fourth finger were noted. Dermatoglyphics were also unusual with a predominance of whorls. His joints were mildly hyperextensible.

Comparison of our patient with those previously reported suggests that the most consistent clinical findings reported in terminal 12p deletion patients include growth retardation, microcephaly and micrognathia. Mental retardation was the only feature common to all patients. The involuntary movements observed in our patient have not been previously reported. At this time we do not know whether this dyskinesia is related to his medication(s) or is secondary to his deletion. Interestingly the gene for dentatorubral-pallidolysian atrophy (DRPLA), a progressive neurological disorder also known as Haw River syndrome, has been mapped to the distal long arm of chromosome 12.

Program Nr: 912 from the 1999 ASHG Annual Meeting

Double and Triple Aneuploidy In Products of Conception. *N.B. Kardon[1,2], T.M. Dunn[1], K. Hirschhorn[1,2]*. 1) Dept Human Genetics, Mount Sinai Medical Center, New York, NY; 2) Dept Pediatrics, Mount Sinai Medical Center, New York, NY.

Reports of double aneuploidy observed in products of conception as well as liveborns are infrequent. The occurrence of triple aneuploidy in cases of spontaneous abortions are extremely rare. From January 1998 through May 1999 our laboratory processed 320 products of conception (POC). Approximately 60% of these cases were diagnosed with an abnormality. In total there were 23 cases of complex aneuploidy. The 23 cases consisted of 17 cases of double aneuploidy; 2 cases of triple aneuploidy; one case each of five extra chromosomes and six extra chromosomes; trisomy mosaicism for two different chromosomes and a jumping translocation with aneuploidy. This represented 7% of the total POC specimens and 12% of the observed abnormalities. Only 4 cases had double aneuploidy involving sex chromosomes. None of the triple or greater aneuploid cases involved the sex chromosomes. The extra autosomes included various combinations of 2, 4, 5, 7, 8, 9, 10, 12, 13, 15, 16, 18, 19, 20, 21 and 22. The predominance of complex aneuploidy in POC specimens has not been previously reported. Most reports are of single cases without any indication of the frequency of the abnormality. While cases that survive to term include extra sex chromosomes, this the significance of various other combinations of chromosomes and recurrence risks have not been established. Our data identify a significant number of multiple aneuploidies in these specimens. It appears that multiple errors in a single conceptus are more common than is indicated in the literature. These errors appear to be random events with no significant prevalence. The consequences of not reporting complex aneuploidies due to the inability to correlate a specific phenotype with the SAB is that no true indication of frequency, follow up on future pregnancies or histories of current pregnancies are available. We will compare the frequencies of complex aneuploidy in the products of conception from our laboratory to those previously reported cases found in the literature.

Program Nr: 913 from the 1999 ASHG Annual Meeting

Double recombinant chromosome 22's in a family with an inherited pericentric inversion through 3 generations.
J.C. Kelly, S.M. Zneimer. Cytogenetics Laboratory, SmithKline Beecham Clinical Laboratories, Van Nuys, CA.

We report a rare family study of 3 generations with an inherited chromosome abnormality. A proband presented for amniocentesis due to abnormal ultrasound findings. Chromosome analysis of the amniocentesis showed a bisatellited chromosome 22. Fluorescence in situ hybridization (FISH) showed loss of the arylsulfatase (ARSA) locus (Vysis, Inc.) at 22q13.3 and duplication of the rRNA on the long and short arms of chromosome 22. Outcome of the pregnancy is pending. Parental blood chromosome analysis revealed a pericentric inversion of chromosome 22 in the father of the fetus. The father's karyotype was 46,XY,inv(22)(p11.2q13.3). The subsequent karyotype of the fetus was 46,XY,rec(22)dup(22p)inv(22)(p11.2q13.3)pat. Genetic counseling with the family revealed that the father of the fetus had a 21 year old brother with mental retardation. Subsequent chromosome analysis of the brother and their parents showed the brothers' 47 year old mother as a carrier for the inversion. The brother's chromosome analysis revealed the other type of recombinant chromosome 22. FISH studies confirmed the presence of separate, duplicated ARSA loci on the long and short arms of chromosome 22. His karyotype was 46,XY,rec(22)dup(22q)inv(22)(p11.2q13.3)mat. The phenotypic features of del(22)(q13.3) which was seen in the fetus with ultrasound abnormalities have been described in the literature. Major features include developmental delay, hypotonia, speech delay and mild facial dysmorphic features. Phenotypic features of the brother with the duplicated 22q13.3-ter bands include mild dysmorphic features and mental retardation. It is unusual to find both recombinant versions of an inherited pericentric inversion with viable offspring in a single family. Since chromosome 22 is small, one might expect both recombinant versions to be viable, however, the region of crossover during meiosis is small enough to give a low probability that both events would occur. Further clinical workup of the brother with mental retardation is underway as is a detailed pedigree analysis of relatives and their pregnancy histories.

Program Nr: 914 from the 1999 ASHG Annual Meeting

de novo Acute myelogenous leukemia(AML)-associated cytogenetic abnormalities in patients with acquired severe aplastic anemia. *S.H. Kim[1], K.A. Lee[1], H.R. Yoon[2]*. 1) Dept of Clinical Pathology, Samsung Medical Center, Sungkyunkwan Univ School of Medicine, Seoul, Korea; 2) Seoul Clinical Laboratories, Seoul, Korea.

There may be some of acquired severe aplastic anemia(SAA) that may have chromosomal abnormalities such as +8, -7 and 22q-, which are frequently associated with clonal disorders of multipotent stem cells, e.g. myelodysplastic syndrome(MDS) or secondary leukemia. These findings suggest that some SAA could be preleukemic clonal disorders, however, the clonal nature of SAA is still in debate. The cytogenetic studies could be helpful in the clonal study of SAA. Twenty-nine patients with acquired SAA underwent cytogenetic studies on bone marrow cells at the time of diagnosis. Of the 29 patients, 8 patients(27.6%) had chromosomal abnormalities at the time of diagnosis, which were trisomy 8 in two cases, t(8;21), inv(16), t(4;14), t(X;19), del(10) and monosomy 10, in one case each. Six patients underwent follow-up examination after immunosuppressive therapy(IS) and/or bone marrow transplantation. One patient with trisomy 8 showed persistent chromosomal abnormality after IS. Interestingly, two patients had t(8;21)(q22;q22) and inv(16)(p13.1q22), which are strongly associated with de novo AML(M2 and M4e), however these two patients did not evolve to MDS or acute leukemia after 16 and 28 months. The incidence of aplastic anemia appears to be relatively higher in Korea and the frequency of chromosomal abnormalities of SAA in this study seem to be higher than those of other previous studies. Our data suggest that a proportion of SAA might be associated with lineage commitment progenitor cell defect and has potentials for a myeloid specific leukemic evolution.

Program Nr: 915 from the 1999 ASHG Annual Meeting

De novo translocation between chromosomes 15 and 18 in prenatal diagnosis. *Y.M. Kim[1], S.Y. Park[1], M.Y. Kim[2], J.M. Kim[1], S.A. Nam[1], H.M. Ryu[2], I.S. Park[2]*. 1) Genetic Reserch Laboratory, Samsung Cheil Hospital, Seoul, Korea; 2) Obstetrics and Gynecology, Samsung Cheil Hospital, Sungkyunkwan University, School of Medicine, Seoul, Korea.

We report de novo t(15;18) in prenatal diagnosis. The patient was referred to us for nuchal fold thickness 5mm at 13.6wks of gestation. Amniocentesis revealed 45,XX,der(15)t(15;18)?(p11.2;p11.2),-18 by conventional GTG-banding. The level II sonography at 20wks didn't show any special physical abnormality other than right unilateral ventriculomegaly and nuchal fold thickeness 6.4mm without cystic hygroma. In the parental study, they showed normal karyotypes and had 1 healthy child and 3 spontaneous abortion, one due to 22 trisomy. To confirm the result of amniocentesis, the cordocentesis was performed at 21.4wks, and high resolution and RBG-banding showed same result as that of amniocentesis. Using comparative genomic hybridization(CGH) and local specific FISH we found out the partial monosomy of chromosome 18p.

Program Nr: 916 from the 1999 ASHG Annual Meeting

Interstitial deletion (1)(qter®p21::p22®pter) in a 22 month old boy. *E.P.E. Kirk[1], A. Daniel[2], Z. Wu[2], P.J. Grattan-Smith[3], M-Y. Yip[4].* 1) Dept of Medical Genetics, Sydney Children's Hospital, Randwick, NSW, Australia; 2) Department of Cytogenetics, Western Sydney Genetics Program, Westmead, NSW, Australia; 3) Department of Neurology, New Children's Hospital, Westmead, NSW, Australia; 4) Molecular and Cytogenetics Unit, South Eastern Area Laboratory Services, Randwick, NSW, Australia.

We report a 22 month old boy with an interstitial deletion of chromosome 1p. His clinical features include moderate global developmental delay, submucus cleft palate and craniofacial dysmorphism. He has marked brachycephaly, a flat facial profile with midface hypoplasia, small, cupped, lowset ears and a small, down-turned mouth. Cranial MRI at 14 months revealed mild global cerebral atrophy but was otherwise normal. The deletion was not detected on the initial study on blood lymphocytes. Subsequently, a karyotype was performed on cultured skin fibroblasts, because of the possibility of chromosomal mosaicism not detectable in lymphocytes. This was abnormal, with the karyotype 46,XY, del (1)(qter®p21::p22®pter). This finding was confirmed on review of the lymphocyte chromosomes. There have been eight previous patients with interstitial deletions of 1p reported, of whom two were identical twins. Both of the other reported interstitial deletions involving 1p21 were larger than that observed in our patient. The only clinical feature our patient has in common with these cases is developmental delay.

Program Nr: 917 from the 1999 ASHG Annual Meeting

Parental Origin and replication timing studies in a 70,XXXX liveborn. *J.H.M. Knoll[1,2], H. Baker[1], G. Cox[1], M.L. Begleiter[2], L.M. Pasztor[2].* 1) Division of Genetics, Children's Hospital, Harvard Medical School, Boston, MA; 2) Section of Medical Genetics and Molecular Medicine, Children's Mercy Hospital, Department of Pediatrics, University of Missouri School of Medicine, Kansas City, MO.

We describe the clinical, cytogenetic and molecular findings in a female with a 70,XXXX karyotype. Triploidy, while infrequent in liveborns, is even more rare when combined with X chromosome aneuploidy. E.G., a 32 3/7 week child born to a 27 y.o. G2P2 woman, exhibited severe growth retardation, facial dysmorphology, cardiac anomalies and Dandy Walker malformation. E.G. died on day 4 and an autopsy confirmed the physical findings and identified streak ovaries. The placental was small and immature. Cytogenetic analysis revealed 70,XXXX in all metaphases from blood (n=20) and four autopsy tissues. BrdU replication studies showed that three of the X chromosomes were late replicating. Consistent with the placental morphology, the extra haploid chromosome set was of maternal origin. Two distinct maternal alleles (heterodisomy) at D1S249, D15S817, D15S1043, DXS8043, DXS991 and one distinct maternal allele (isodisomy) at D4S402, D5S639, D13S170, DXS987, DXS1001 were observed. Methylation at SNRPN confirmed that the third chromosome 15 was maternally derived; however, the maternal chromosomes replicated sequentially rather than synchronously. It will be important to investigate whether the sequential replication observed in this case is characteristic of other tirploid and trisomic cell lines and whether it has a role in phenotypic outcome.

Program Nr: 918 from the 1999 ASHG Annual Meeting

Familial Mental Retardation Syndrome ATR-16 Due to an Inherited Cryptic Subtelomeric Translocation t(3;16)(q29;p13.3). *R.F. Kooy[1], E. Reyniers[1], S. Uhrig[2], I. Schoepen[1], A. Golla[2], J. Wauters[1], P. Kroisel[3], P. Bossuyt[1], I. Rost[2], K. Jedele[2], H. Zierler[3], S. Schwab[4], D. Wildenauer[4], M. Speicher[5], P.J. Willems[1], T. Meitinger[2], E. Holinkski-Feder[2].* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Department of Medical Genetics, University of Munich, Munich, Germany; 3) Department of Human Genetics, University of Graz, Graz, Austria; 4) Department of Human Genetics, University of Bonn, Bonn, Germany; 5) Department of Human Genetics, University of Munich, Munich, Germany.

The etiology of mental retardation can be established in less than 50% of all cases. Especially in the category of patients with mild to moderate mental retardation (IQ 50-70) the molecular cause is only determined in a minority of cases. These cases are rarely caused by metabolic disorders or teratogenic effects, and the combination of standard karyotyping and molecular analysis of the FMR1 gene leads to a diagnosis in less than 10% of the patients. Recently, chromosomal translocation and deletions that could not be detected by standard cytogenetic analysis have been identified in some of these patients. These cryptic (cytogenetically invisible) translocations of chromosome ends have been estimated to be implicated in 6% of cases of mental retardation that are otherwise karyotypically normal. Here we present a five-generation family including ten patients in generations IV and V affected with mild to moderate mental retardation and nonspecific dysmorphic features. Standard DNA and cytogenetic analysis was unable to determine the cause of the mental retardation. Only after linkage of the phenotype to chromosome 16p13.3 was FISH analysis able to detect an unbalanced subtelomeric translocation resulting in partial monosomy 16ptel and partial trisomy of 3qtel in all affected patients. Reevaluation of the dysmorphic features and red blood cell parameters indicated that the affected patients had clinical features compatible with ATR16 syndrome. Investigation with FISH then revealed a balanced translocation between telomeric 16p and 3q in obligate carriers. This case supports the role of subtelomeric chromosomal aberrations in familial mental retardation.

Program Nr: 919 from the 1999 ASHG Annual Meeting

Quantitative fluorescent PCR in the prenatal and postnatal detection of aneuploidies, loss of heterozygosity, interstitial deletions and of their parental origin. *A. Krebsova[1,3], I. Horka[1], S. Jobert[1], O.A. Haas[2], D. Chudoba[1], M. Koudova[1], J. Diblik[1], M. Macek Jr.[1], K. Sperling[3], M. Macek[1].* 1) Inst. Biol & Med. Genetics, 2.Sch. Med., Charles Univ. , Prague, Czech Rep; 2) CCRI, St. Anna Kinderspital, Vienna, Austria; 3) Inst. Hum. Genetics, Humboldt Univ., Berlin, Germany.

The aim of the study was to assess reliability of quantitative fluorescent PCR (QFPCR) in rapid detection of aneuploidies, interstitial deletions, loss of heterozygosity (LOH) and parental origin of chromosomes (13, 18, 21, X, Y) from micro-quantities of uncultivated cells. STR markers-D13S258, D13S631, MBP, D18S51, D18S535, D21S11, D21S1414, D21S1411, D21S1412, D21S167, XHPRT and AMX, AMY were examined on ABI 310 Prizm. QFPCR was tested in 369 cases on DNA from non-cultivated/cultivated amniocytes, non-cultivated placenta, mola hydatidosa, solid tumors and peripheral blood cells. The results of QFPCR were in 100% identical with prenatal cytogenetic diagnosis. Prenatal diagnosis was not possible in 8/200 cases, because QFPCR characteristic was inconclusive, according to our statistical analysis of normal peak height, size variability and diagnostically significant quantitative criteria for diallelic (2:1) trisomy. QFPCR was successful also in amniocytes from 0.1 ml of amniotic fluid and persisting in suspension. Parental origin of fetal aneuploidies was disclosed in 7 detected fetal aneuploidies and in 27/29 families with trisomy 21. The determination of meiotic origin of aneuploidy was possible in 21/27 cases. QFPCR of solid tumors and mola hydatidosa enabled rapid detection of aneuploidy and LOH, interstitial deletions invisible by the current cytogenetic methods. Analysis of control and tumor cells is necessary to discriminate monoallelic STR markers from LOH. Differentiation between total or partial monosomies, interstitial deletions, determination of their size requires more STR markes from centromeric-telomeric regions. QFPCR complements cytogenetic diagnosis, assures it even if it is impossible due to cultivation failure and contributes to the improvement oncogenetic studies. Supported by IGA 2899-5, 3526-3, 4124-3, OK 192.

Program Nr: 920 from the 1999 ASHG Annual Meeting

Duchenne muscular dystrophy in a girl with a balanced translocation [46,X,t(4;X)(q31.1;p21.1)]. *R.W. Kula[1,2], S.M. Kleyman[3], M.J. Macera[3,4], R.S. Verma[2,3,4].* 1) Long Island College Hospital, Brooklyn, NY; 2) SUNY Health Science Center at Brooklyn, NY; 3) Institute of Molecular Biology and Genetics at InterScience, Brooklyn, NY; 4) Wyckoff Heights Medical Center, Brooklyn, NY/New York Hospital-Weill Medical College of Cornell University, NY, NY.

An 11 year old African-American girl had a slight speech developmental delay and was noted to have large calves at age 21/2-3 years. At age 8, she was noted to have frequent falls. For the past few months, she has been using a wheelchair. On neurological examination, she walked with increased lordosis and had a tendency to toe walk. She has a positive Gower's maneuver and is unable to lift her head while lying flat. She has more prominent proximal, but significant gereralized weakness graded 4/5 in the upper extremities at worst and 3/5 in the lower estremities at worst. Her deep tendon reflexes were absent except 2+ at the ankles with flexor plantar responses. Clinical presentation was consistent with Duchenne muscular dystrophy. Cytogenetic findings with GTG- and FISH- techniques revealed an abnormal 46,X ish.t(4;X)(q31.1;p21.1)(wcpX+.wcp4+). Although the patient has an apparently balanced translocation, the breakpoint is located at Xp21.1 by high relolution banding technique. This observation suggests that a gene involved in muscular dystrophy must be at or around Xp21.1. Although the exchange points were not the same in earlier affected cases and the disruption region extends from Xp21.1 to Xp21.3, this finding clearly raises a sereious issue concerning inactivation, balanced translocations and obviously a critical region for this disease.

Program Nr: 921 from the 1999 ASHG Annual Meeting

Does anticipation exist for some familial chromosome abnormalities? *A.S. Kulharya, K.N. Norris, E.A. Sekul.*
Pediatrics, Medical College of Georgia, , Augusta, GA.

Unbalanced familial chromosome abnormalities have been occasionally reported in literature. Some of these abnormalities are without any significant phenotypic effect, while others show a more pronounced phenotype in the proband as compared to the carrier parent. It is unclear whether this is due to better awareness and availability of genetic services, or a phenomenon similar to anticipation exists for some of these unbalanced chromosome abnormalities. Wilson et.al. (1993)have suggested that for familial 22q deletions the phenotype is more severe in the child as compared to the carrier parent.

We report a familial interstitial duplication of 7(q32->36.1). The family history is significant for bipolar disorder. Mother has history of depression and manic behavior. She is mildly retarded and has difficulty in reading although she can write. The proband's maternal aunt and all four of her children are developmentally delayed. Great grandmother also had a nerve problem of unknown etiology. At 20 months the child did not walk or crawl. He did not have any dysmorphic features. The CT and EEG exams were normal. No organomegaly was noted. He has behavioral problems.

Chromosome analysis demonstrated interstitial duplication at the distal end of the long arm of a chromosome 7. Maternal blood chromosome analysis also showed the same abnormal chromosome 7. Father was unavailable for testing. FISH with a whole chromosome paint demonstrated that the extra material was derived from chromosome 7 itself. The karyotype of the proband is 46,XY,dup(7)(q32q36.1). Several cases have been reported with duplication of various regions of 7q. This patient does not have any dysmorphic features or skeletal abnormaities associated with similar duplications of 7q. However, there is a pronounced progression in the severity of developmental and neurological charecteristics as opposed to the carrier mother.

Program Nr: 922 from the 1999 ASHG Annual Meeting

Chromosome Abnormalities in a Consanguinous Couple with "Double Trouble". *G.S. Kupchik[1, 2], S.K. Barrett[1, 2], A. Babu[3], M.J. Macera[4], R.S. Verma[4].* 1) Dept Pediatrics, Maimonides Medical Center, Brooklyn, NY; 2) SUNY Health Sciences Center at Brooklyn, NY; 3) Beth Israel Medical Center, New York, NY; 4) Institute of Molecular Biology and Genetics at InterScience and Wyckoff Heights Medical Center, Brooklyn, NY.

In certain cultures, first cousin marriages are favored, while in others such unions are discouraged. We report a case of first cousin mating where both partners have the same balanced translocation involving chromosomes 16 and 18; i.e. t(16;18)(p13.2;p11.2). Consanguineous matings in such situations may produce progeny with balanced and unbalanced genotypes. By 29 years of age, our proband had two first trimester spontaneous abortions, a phenotypically normal daughter, and a son with multiple congenital anomalies and an unbalanced karyotype 46,XY, t(16;18)(p13.2;p11.2),der(18)t(16;18)(p13.2; p11.2).ish(wcp16+,18+;16-,18+)(wcp16-,18+). Now, at 36, she is again pregnant and GTG-banding and FISH-technique chromosome analysis on her amniocytes showed an apparently balanced rearrangement: 46,XX,t(16;18)(p13.2;p11.2). Couples in which both members carry similar balanced translocations are at very high risk for pregnancy loss and potentially high risk to have unbalanced offspring with malformations. There have been a few reported cases where progeny have inherited an apparently balanced translocation from a parent, yet they are mentally retarded or have malformations. The concept of imprinting has been hypothesized as a plausible explanation. For clinical purposes, it will be useful to be able to distinguish these functional differences of parental genome to avoid erroneous genetic counseling.

Program Nr: 923 from the 1999 ASHG Annual Meeting

Cytogenetic and molecular studies of an unusual presentation of Turner syndrome with 45,X/46,X,t(X;7) mosaicism. *T.W. Kurczynski[1,2], T. Durliat[2], M.A. Micale[1,2], A. Hampton[2], B. French[1], C. Gaba[1], S. Schwartz[3]*. 1) Dept of Pediatrics and; 2) Dept of Pathology, Medical College of Ohio, Toledo, OH; 3) Center for Human Genetics, Case Western Reserve University, Cleveland, OH.

A number of different karyotypes have been associated with Turner syndrome. The vast majority of these are observed in patients with a classical phenotype. In this study, we report an individual with a clinically severe presentation of Turner syndrome and an unusual karyotype. The 4lb 7oz female was the product of a 35 week gestation. At birth, a variety of dysmorphic features including downward slanting palpebral fissures, low-set ears, pectus excavatum, and bilateral simian creases were noted; however, neck webbing was not present. At age 15, this patient's medical history is remarkable for severe language delay and mental retardation, hypotonia, abnormal EEG, seizures, attention deficit disorder, thoracic scoliosis, and cerebral palsy. Initial chromosome studies in 1987 revealed a 45,X[13]/46,X,Xq+[37] karyotype. A recent peripheral blood chromosome study, including FISH analysis, more accurately defined the child's karyotype to be 45,X[7]/46,X,der(X)t(X;7)(q28;q31.1)[13]. Peripheral blood analysis of both parents revealed normal karyotypes. X inactivation studies were performed utilizing a PCR-based analysis of methylation-sensitive restriction endonuclease sites within the triplet repeat array of the androgen receptor gene. These studies revealed a skewed pattern of X-inactivation. Females with an unbalanced X autosome translocation generally demonstrate inactivation of the abnormal X, which eliminates the autosomal imbalance. If preferential inactivation of the der(X) in the 46,X,der(X) cell line occurred in this patient, one might expect that she should present a typical Turner syndrome phenotype; however, the observation of seizures, mental retardation, and other severe clinical features not typical of Turner syndrome suggests that the abnormal X may be preferentially active in at least some cells. In addition, some phenotypic features observed in this patient are consistent with partial trisomy 7 (specifically of the region 7q32®qter), but are not typical features of Turner Syndrome.

Program Nr: 924 from the 1999 ASHG Annual Meeting

Low proportion of subtelomeric rearrangements in a population of patients with mental retardation and dysmorphic features. *A.N. Lamb[1], C.H. Lytle[1], A.S. Aylsworth[2], C.M. Powell[2], K.W. Rao[2], M. Hendrickson[3], J.C. Carey[3], J.M. Opitz[3], D.H. Viskochil[3], C.O. Leonard[3], A.R. Brothman[3], M. Stephan[4], J.A. Bartley[6], M. Hackbarth[5], D. McCarthy[5], J. Proffitt[5]*. 1) Genzyme Genetics, Santa Fe, NM; 2) Univ of North Carolina Sch of Medicine, Chapel Hill, NC; 3) Univ of Utah Sch of Medicine, Salt Lake City, UT; 4) Madigan Army Med Ctr, Tacoma,WA; 5) Vysis, Inc., Downers Grove, IL; 6) Genzyme Genetics, Orange, CA.

Several recent studies have suggested that subtelomeric rearrangements in previously karyotyped individuals with mental retardation and dysmorphic features may be found in 5 - 18% of such individuals. In an attempt to verify these studies and further define the phenotypic features of the individuals that should be screened, we are undertaking a multicenter project with patients with mental retardation and dysmorphic features selected by clinical geneticists. The analysis is being performed with unique sequence subtelomeric FISH probes. All patients selected have had previous karyotype analysis, usually with high resolution banding (HRB). Currently, 43 patients have been screened by FISH and one rearrangement has been detected, for a detection rate of 2.3%. The one rearrangement is a derivative chromosome 18 that is the result of an unbalanced cryptic translocation between the distal short arm of chromosome 2 and the distal long arm of chromosome 18. Phenotyptic details and a further characterization of the size of the segments involved will be presented. A reciprocal 2;18 translocation was detected in one of the parents by FISH analysis with the relevant subtelomeric probes. The low detection rate in this study may be due to the fact that most all patients have had HRB analysis. Published studies have indicated that many of the rearrangements detected should have been detectable by HRB. Therefore, the rate of 2% in this study could reflect the rate associated with truly cryptic rearrangements and higher rates may be expected from a population of patients receiving only routine banding, in the 450 - 500 band range.

Program Nr: 925 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of a familial complex chromosomal rearrangements on four chromosomes 5, 10, 16 and 18.

M.H. Lee[1], S.Y. Park[1], Y.M. Kim[1], J.M. Kim[1], H.M. Ryu[2], J.Y. Han[2], M.Y. Kim[2]. 1) Genetic Reserch Laboratory, Samsung Cheil Hospital, Seoul, Korea; 2) Obstetrics and Gynecology, Samsung Cheil Hospital, Sung Kyunkwan University, School of Medicine, Seoul, Korea.

We report one case of a familial complex chromosomal rearrangements (CCR) involving four different chromosomes 5, 10, 16 and 18. The CCR was detected prenatally in a fetus who was suspected of Down's syndrome by the triple test using maternal serum. Cytogenetic analysis of cultured amniotic fluid cells with GTG banding showed a 46,XX,t(5;16;10;18)(q13;q22;q11.2;q21) karyotype. Parental cytogenetic study revealed that the mother has the same CCR. RBG banding, high-resolution banding and FISH were performed to better characterize the rearranged chromosomes. No physical abnormalities were showed in the Level II ultrasonography examination at 28wks. The pregnancy is still going on.

Program Nr: 926 from the 1999 ASHG Annual Meeting

Stable dicentric duplication - deficiency chromosome 14 in a girl resulting from crossing-over within a maternal paracentric inversion. *G.F. Lefort[1], P. Blanchet[2], F. Rivier[3], A.M. Chaze[1], P. Sarda[2], J. Demaille[1, 4], F. Pellestor[4].* 1) Cytogenetics Laboratory, Hopital Arnaud de Villeneuve, Montpellier; 2) Department of Clinical Genetics, Hopital Arnaud de Villeneuve, Montpellier; 3) Department of Neuropediatrics, Hopital Arnaud de Villeneuve, Montpellier; 4) CNRS UPR 1142, Montpellier, France.

The proposita is a mentally retarded girl with dysmorphic features and multiple malformation syndrome who was presented to our Genetics Center for evaluation at the age of 32 months. She is the second child of healthy unrelated parents. Pregnancy was complicated during the second trimester by intrauterine growth retardation. No prenatal chromosome studies were done, and a 1970g baby girl (<3rd centile) was delivered at 38 weeks' gestation. On evaluation at the age of 32 months the proposita presents growth retardation, severe developmental delay, generalised hypotonia, dystonic movements, microcephaly, craniofacial dysmorphism and tapered fingers, corpus callosum hypoplasia and gastro-oesophageal reflux. The proposita's karyotype showed an elongated chromosome 14 long arm with atypical RHG-banding pattern. Subsequent studies in the parents suggested a paracentric inversion in the mother : inv(14)(q13q32.3). Characterisation of the proposita's abnormal chromosome 14 (RHG and C-banding, FISH and PRINS labeling) identified a stable dicentric duplication-deficiency chromosome 14. The occurrence of this stable dicentric chromosome 14 and the clinical duplication-deficiency features are discussed.

Program Nr: 927 from the 1999 ASHG Annual Meeting

Stable dicentric chromosomes: Four new cases and a review of the literature. *E. Lemyre[1], V.M. Der Kaloustian[2], A.M.V. Duncan[1].* 1) Dept of Pathology, Montreal Children's Hospital, McGill University, Montreal, Canada; 2) F. Clarke Fraser Clinical Genetics Unit, Montreal Children's Hospital, McGill University, Montreal, Canada.

Cytogenetically recognizable dicentric autosomes are rarely encountered as stable constitutional chromosomes in humans because of the high risk of breakage during anaphase bridge formation. However, stabilisation of the dicentric can exceptionally occur when the two centromeres are very close together (eg Robertsonian translocations) or by inactivation of one of them. We report four cases of stable dicentric chromosomes. Two of them were inherited from asymptomatic carriers: 45,XX,dic(14;18)(p11.2;p11.3) and 45,XY,dic(16;22)(p24;p11.2). The other two occured de novo in children with phenotypic manifestations of 18p deletion syndrome: 45,XY,dic(13;18)(p12;p11.2) and 45,XX,dic(13;18)(p11.2;p11.2). In our series, all cases involved an acrocentric chromosome. Only one primary constriction was seen, even though the presence of two centromeric sequences was demonstrated either by FISH studies or C-banding.This primary constriction was always on the non-acrocentric chromosome. Only 22 cytogenetically recognizable dicentrics of non homologous autosomes were reported previously. A literature review also showed a predominance of acrocentric chromosomes in stable dicentric autosomes (22/26). Only one primary constriction was found in all cells of 15/18 cases for whom this information was available. Of those, the primary constriction was the centromere of the non-acrocentric in 13/15 cases. Non-acrocentric chromosome was chromosome 18 in almost half of cases (10/22). Apart from our two patients, the dicentric was transmitted over at least two generations in only 2 families. In conclusion, our cases demonstrate further the predominance of acrocentric chromosomes in stable dicentric autosomes. Most of them will reach stability by inactivating one centromere and will be functionally monocentric. If an acrocentric is involved, its centromere is most often the inactivated one.

Program Nr: 928 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of holoprosencephaly in a fetus with a recombinant 18 dup(18q)inv(18)(p11.31q11.2) mat. *N.J. Leonard[1,2], D.J. Tomkins[1,3], N. Demianczuk[4].* 1) Dept Medical Genetics, Univ Alberta; 2) Medical Genetics Clinic, UA Hosp; 3) Cytogenetics, UA Hosp; 4) Dept Obstetrics and Gynecology, Univ Alberta and Royal Alexandra Hosp, Edmonton, AB, Canada.

Holoprosencephaly was identified by ultrasonography at 18 weeks' gestation in a fetus of a G2P0A1 woman. Amniocentesis was performed and a rearrangement of chromosome 18 resembling an isochromosome for the long arm of chromosome 18 was found in all 11 colonies examined. Parental karyotypes were requested for interpretation of the rearrangement. The mother was found to have a pericentric inversion of chromosome 18 with breakpoints at p11.31 and q11.2. The karyotype of the fetus was interpreted as 46,XX, rec(18)dup(18q)inv(18) (p11.31q11.2)mat. This is the first case of a parental inversion leading to a deficiency of 18p associated with holoprosencephaly. Holoprosencephaly is a malformation complex of abnormal forebrain and midface development. It is genetically heterogeneous with associated genes localized to chromosome 21q22.3 (*HPE*1), 2p21 (*HPE*2), 7q36 (*HPE*3), 18p11.3 (*HPE*4) and 13q3.2 (*HPE*5). The critical region for holoprosencephaly on chromosome 18 has been mapped using lymphoblastoid cell lines from patients with deletions of 18p due to *de novo* anomalies or a deficiency of 18p due to segregation of a balanced translocation (Overhauer *et al*., 1995. Am. J. Hum. Genet. 57:1080). Holoprosencephaly has been described in five cases of isochromosome (18q) with additional features of the trisomy 18 phenotype (van Essen *et al*., 1993. Am. J. Med. Genet. 47:85). The presence of holoprosencephaly in these cases would be consistent with deletion of the entire 18p arm including the critical region in 18p11.3. The deficiency of the recombinant chromosome reported here represents the smallest deficiency of 18p associated with duplication of 18q. The possibility of using a FISH approach to characterize the inversion 18 is being explored.

Program Nr: 929 from the 1999 ASHG Annual Meeting

TELOMERIC ASSOCIATION IN SMOKERS EXPOSED TO LOW LEVEL OF X-RAYS. *P.E. Leone[1,2], J.C. Pérez[1], R. Burgos[1], V. Dávalos[1], M.E. Sánchez[1,2], J.C. Santos[1], C. Paz-y-Mino[1,2]*. 1) Hum Mol Genet & Cytogen Lab., Ecuadorian Catholic Univ, Quito, Ecuador; 2) Medicine Faculty, Ecuadorian Catholic University.

Deregulation of the enzyme to catalyze the telomeres replication -telomerase- could be involved in cellular immortality and oncogenesis. Alterations in telomerase activity could lead to chromosome instability, such as an increased propensity for chromosome fusions, phenomena known as telomeric association (TA). TA probably could be a chromosomal marker in populations exposed to genotoxic agents. In this study we analyzed the frequency of TA in peripheral blood of 10 smokers occupationally exposed to low levels of x-rays (1,7mSv)(SG), 10 smokers (SxRG) and 10 individuals non-smokers occupationally exposed to low levels of x-rays (1,7mSv) (xRG). These data are compared with a control group (CG). One hundred metaphases were analyzed per individual and chi-square test was used for statistical analysis. The percentage of TA in each group was 0.1% in CG, 6.0% in xRG, 9.1% in SG and 12.6% in SxRG. These results indicates that the three exposed groups show a greater percentage of TA in contrast with the CG ($p<0.001$). Also, it were observed statistical differences ($p<0.05$) to compare the three exposed groups. Because of high proportion of metaphases with TA could be considered as an indicator of malignant process, these results confirm that both x-rays and cigarette chemicals are carcinogenic agents. However, cigarette smoking might mean a greater risk for developing oncogenesis process rather than x-rays. Probably, this is a consequence of that chemical agents, such as substances present in the cigarettes smoke, are per se more closely related with malignant processes, while the action mechanism of the physic agents, such as the x-rays, not always lead to development of cancer. In addition, it suggests that there is a synergistic effect between these two agents, because of the exposed group to both agents present a greater frequency of TA. This study suggests the possibility of evaluating populations exposed to mutagens through cytogenetic analysis of peripheral blood, adding TA analysis as part of genetic instability phenomena. This work was supported by BID-111 project.

Program Nr: 930 from the 1999 ASHG Annual Meeting

Extended survey of cases with a positive diagnostic yield on second cytogenetic studies for suspected constitutional chromosome abnormalities . *K.A. Leppig[1], K.E. Opheim[1], E. Keitges[2], F. Luthardt[2], M. Lloyd[3], J. Hanna[3], S. Olson[4], E.R. Magenis[4], C.M. Disteche[5]*. 1) Children's Hosp/Reg Med Ctr, Seattle, WA; 2) Dynacare Northwest Inc., Seattle, WA; 3) Sacred Heart Medical Center, Spokane, WA; 4) Oregon Health Sciences University, Portland, OR; 5) University of Washington, Seattle, WA.

This is an extension of a preliminary study to define factors favoring a diagnostic yield for patients with a suspected constitutional chromosome abnormality (AJHG 61:A30, 1997). Over 20,000 cases from 6 cytogenetic laboratories in Washington and Oregon states completed from 1977-1998 were reviewed. Among 369 cases performed on patients with an abnormal phenotype and a normal first cytogenetic study, 49 had a "positive" diagnostic yield with an abnormal second cytogenetic study and 320 had a "negative" yield with a normal second study. Of cases with a positive diagnostic yield, 37 were non-mosaic while 12 were mosaic chromosome abnormalities. Of the non-mosaic cases, 10 were repeated within 2 years while 25 were repeated ³10 years after the initial study. All but 2 cases had structural chromosome abnormalities. The chromosome band level was ³650 in 22 cases. FISH analysis was used solely in 6 or in conjunction with G-banding in 10 cases. Seven cases had a positive family history. The repeat study was directed in 21 cases, 19 of which were correctly directed. A clinical geneticist requested the repeated study for 20 cases. Among the 12 mosaic cases, 11 were repeated within 1 year of the initial study. The mosaic abnormality was numerical in 11 cases. Most were performed on fibroblasts accounting for < 650 band level. FISH was used in conjunction with G-banding in 2 cases. Of the 7 directed cased, 6 were correctly directed. A clinical geneticist requested 5 of the repeated studies.

In this survey 49/369 (13%) cases had a positive diagnostic yield on a repeated cytogenetic study. Factors influencing the diagnostic yield included careful clinical re-evaluation, a positive family history, improved cytogenetic techniques, and evaluation of a second tissue for the detection of clinically significant mosaicism.

Program Nr: 931 from the 1999 ASHG Annual Meeting

Partial and random correction of probably familial and apparently balanced complex chromosomal rearrangements. *J.J-Y Lespinasse[1], B. Sele[2], M.R. Guichaoua[3].* 1) Laboratory of cytogenetics, General Hospital, Chambery, France; 2) Biology of reproduction laboratory, A. Bonniot Institute, Univ. of Med. La Tronche, France; 3) Biology of reproduction laboratory, Conception hospital, Marseille, France.

The authors report the case of a 38-year-old, G6, nulliparous woman. The blood karyotype showed a homogeneous complex chromosomal anomaly involving chromosomes 13, 14, 22. this anomaly corresponded to a Robertsonian translocation between one chromosome 13 and one chromosome 14. This Robertsonian translocation was in turn the subject of a reciprocal translocation with breakpoints situated between the subtelomeric extremity of 14q and the juxta centromeric part of 22q. Analysis of the siblings revealed various particularly surprising chromosomal. One of the patients sisters (G1;P0) presented a complex chromosomal anomaly perfectly identical to that presented by patient. Another sister (G4;P2) presented part of the complex chromosomal anomaly corresponding to the Robertsonian translocation between one chromosome 13 and one chromosome 14. A brother, in childless relationship, carried the other part of the complex chromosomal anomaly corresponding to a reciprocal translocation between 14q and 22q and a monosomy of the centromere of 22 and the subtelomeric extremity of 14q. This subject inherited the unbalanced form of the reciprocal translocation according to a 3:1 alternating mode. Minor psychological disorders were observed in this subject and in a paternal uncle. The family history did not reveal any other abnormalities. The mothers (G9;P6) blood karyotype was normal. The father, deceased, and two other bothers of the proband could not be studied. The chromosomes and telomeres were studied by chromosomal and molecular genetic techniques according to standard protocols. The chromosomal genetic study of this Lebanese patient and her family raises several points. Was this apparently balanced complex chromosomal anomaly inherited from the father or was there a parental germ cell mosaic? Can a spontaneous correction mechanism explain the partial and random correction of this anomaly?

Program Nr: 932 from the 1999 ASHG Annual Meeting

Detection of human sex chromosome aneuploid mosaicism by interphase FISH in noninvasively obtained and directly prepared tissues. *X. Li, J. Kobori, L. Tuttle, S. Owen, T. Tse, K. Nguyen.* Genetics Department, Kaiser Permanente Northern California, San Jose, CA.

Individuals with a mosaic sex chromosome aneuploidy may have few recognizable phenotypes and are often undetected. A cytogenetic finding of mosaic sex chromosome aneuploidy in a blood culture in those individuals poses a dilemma in genotype-phenotype correlation and for genetic counseling. Further study usually requires invasive procedures such as skin biopsy. We report here two cases who were found to have mosaic X-chromosome aneuploidies in blood lymphocytes without Turner syndrome phenotypes. Case 1 is a 35-year-old G4P1Sab2Tab1 woman who is 5'3". Case 2 is a 36-year-old G5P1Sab3 woman who is 5'7". Neither woman has a significant medical history and each has a healthy child. They were both referred for karyotyping due to a history of multiple miscarriages. Cytogenetic studies on bloods showed a 45,X[48]/47,XXX[1]/46,XX[1] karyotype in case 1 and 45,X[3]/47,XXX[1]/49,XXXXX[1]/46,XX[45] in case 2. To study the distribution of these cell lines in different tissues, cells were collected noninvasively from buccal smear and urine. Slides were directly prepared for interphase fluorescence in situ hybridization (FISH) analysis using an alpha satellite DNA probe specific for the X chromosome (DXZ1, Vysis, Inc.). Examination of 200 nuclei in total revealed different levels of X-chromosome aneuploid mosaicism in alimentary and urinary tracts in comparison with the bloods in both cases. FISH analysis in case 1 showed a much lower proportion of the X cell line but a much higher percentage of the XXX and XX cell lines in buccal smear (X=42%, XXX=47%, XX=11%) and urine (X=50%, XXX=38%, XX=12%). In case 2, FISH analysis revealed a similar proportion in buccal smear except for a higher proportion of the XXX cell line (X=6%, XXX=7%, XX=87%), but a lower percentage of the XX cell line and a higher proportion of the X and XXX cell lines in urine (X=16%, XXX=10%, XX=74%). Our findings demonstrate the direct evidence of uneven distribution of mosaic chromosome aneuploidy in vivo. Our method provides a simple, effective, and reliable tool for the study of chromosome aneuploid mosaicisms.

Program Nr: 933 from the 1999 ASHG Annual Meeting

Direct visulaization of genomic orgnization of mammalian centromeric satellite DNA families. *Y.C Li[1], C. Lee[2], S.Y. Li[1], C.C. Lin[1,3].* 1) Dept. Life Sciences, Chung Shan Medical/Dental Col., Taichung, Taiwan; 2) Dept. Obstetrics and Gynecology, Brigham and Women's Hospital, Harvard Medical School, Boston, USA; 3) Dept Laboratory Medicine and Pathology, University of Alberta, Edmonton, Canada.

The physical organization of human satellite DNAs has recently been investigated on a few centromeres at the molecular level. Multiple color FISH study with different satellite DNA probes on metaphase chromosome and extended chromatin fiber could also provide a direct visualization of genomic organization of those satellite families. Toward this approach, we have identified two mammalian centromeric satellite families (cervid satellite I and II) in caribou and Indian muntjac and performed FISH with following findings: 1. In the caribou, satellite I DNA is located on the centromeric regions of all acrocentric chromosomes. No hybridization signal was observed in a pair of submetacentric autosomes and the sex chromosomes. Satellite II DNA is located on the centromeric regions of all the chromosomes except the Y chromosome. In most acrocentric chromosomes, the satellite I signal appeared to locate more proximately to the primary constriction whereas the satellite II appeared to orient toward the short arm as two separated dots. Fiber FISH showed that satellite I and satellite II are organized in juxtaposition. The length of "beads on a string"; hybridization signals of each two satellite DNA arrays in a centromere can also be estimated. 2. In the Indian muntjac, satellite I signals were observed in the centromeric regions as well as along the chromosome arms of all chromosomes with the exception of Y chromosome. Whereas, satellite II signals were found in the centromeric region of all chromosomes. Usually, interstitial satellite I signal and satellite II signal were co-localized with some exceptions which only satellite I or satellite II signals were observed. Striking hybridization pattern was observed in the centromeric region of X+3 chromosome. A large block of green fluorescent signal of satellite II is centrally located and flanked by two blocks of red signal of satellite I DNA. This also indicates that the satellite II is ordered more toward to terminal in relation with satellite I DNA.

Program Nr: 934 from the 1999 ASHG Annual Meeting

FISH detection of low copy number HER-2/*neu* amplification in prostate cancer is more sensitive than IHC. *H.L Liu[1], R. Gandour-Edwards[3,5], R. deVere White[4,5], J.M. LaSalle[2,1]*. 1) UC Davis School of Medicine, Davis, CA; 2) Med Microbiol & Immunol Dept and Rowe Program in Hum Genetics; 3) Pathology Dept; 4) Urology Dept; 5) UC Davis Cancer Center, UCDMC, Sacramento, CA.

HER-2/*neu* oncogene amplification and overexpression occurs in 25-30% of human breast cancers and is associated with poor clinical outcome. In prostate cancers, HER-2/*neu* amplification has also been correlated with tumor progression, but detection of overexpression by immunohistochemistry (IHC) has been somewhat inconclusive in these tissues. The identification of patients with HER-2/*neu*amplification in prostate tumors is of clinical importance for identifying candidates for the drug Herceptin which blocks the HER-2/*neu* growth factor receptor. To identify HER-2/*neu*amplification in prostate cancer, paraffin-embedded archived tumor samples were tested by both IHC and fluorescence in situ hybridization (FISH). Thirty samples were selected, 15 from patients which had since shown progressed cancer and 15 from patients in stable condition. All samples were negative for HER-2/*neu* amplification by IHC performed with the DAKO kit which has been FDA approved for Herceptin® trials. In contrast, low copy number gene amplifications (3-8 signals/nucleus) were detected in 11 of 25 samples (44%) by FISH performed with Vysis HER-2/*neu* and CEP 17 probes. Cells were heterogeneous in number of FISH signals per nucleus, but most cells showing HER-2/*neu* amplification were diploid for CEP 17. In addition, a greater percentage of cells with HER-2/*neu* amplification without aneuploidy were found in progressed compared to stable patient samples, suggesting that HER-2/*neu* amplification may be an early indicator of poor prognosis in prostate cancer. Based on these results, we conclude that FISH is more sensitive than IHC for detecting low copy number amplifications of HER-2/*neu* in heterogeneous cells in prostate cancer. These results may be of significance in identifying prostate cancer patients for Herceptin® treatment in clinical trials.

Program Nr: 935 from the 1999 ASHG Annual Meeting

45,XY,der(22)t(15;22)(q13;q13.3) de novo karyotype in a child with Prader Willi syndrome. *J.C. Llerena[1,2], R.B. da Silva[3], H. Ramos[1], E. Bastos[2], V.E. Ferraz[4], J.M. Pina Neto[4], J.C. Cabral de Almeida[1,2].* 1) Dept de Gen(é)tica M(é)dica, IFF/FIOCRUZ, Rio de Janeiro, Rio de Janeiro, Brazil; 2) Unidade de Citogen(é)tica Humana/IBCCF/UFRJ; 3) Servi(ç)o de Gen(é)tica/HUPE; 4) Dept. Gen(é)tica/Faculdade de Medicina Ribeir(ã)o Preto/USP.

Rare chromosomal rearrangements associated to Prader Willi syndrome (PWS) have been reported in 5% of patients frequently associated to unbalanced translocations involving the critical 15q11-q13 PWS/AS region. As a result, loss of non-imprinted paternal genes has been identified through SNRPN molecular studies. We report the case of a 2 years old infant with severe hypotonia, poor sucking reflexes at birth, and a G- band karyotype 45,XY, der (22)t(15;22) (q12~13;q13.3),-15 de novo. FISH investigation using probes (ONCOR) SNRPN, GABRB3, 22q11.2 (D22S75) and 22q13.3 (D22S39) showed that the derivative chromosome was composed of chromosome 22 (two copies of 22q11.2 and 22q13.3 probes) and no hybridization signal was observed with both SNRPN and GABRB3, however chromosome 15 distal control probes were detected. The investigation for intercalary telomeric sequences on the der22 by FISH did not yield reliable results. Thus, the patients karyotype by FISH was defined as 45,XY.ish der(22)t(15;22)(q13;q13.3) de novo.(SNPRN-, GABRB3-)(D22S75x2, D22S39x2). Clinical examination of the propositus at 2 years showed heigth and weigth below 25th centile, normal cephalometric measures, triangularly shaped face, supracilliary hemangiomas, almond shaped eyes, convergent strabism, high and narrow palate, normal male external genitalia, acromicria and motor and mental retardation. To our knowledge 28 cases of PWS and unbalanced translocation have been reported and in 25 of them the abnormality was de novo and paternal in origin, as also demonstrated in our case by molecular studies (D15S113,D15S11,GABRB3), as expected.

Program Nr: 936 from the 1999 ASHG Annual Meeting

De novo bisatellited chromosome 22 in a patient with mild mental retardation. *L.A. Lopez Miranda, P. Barbero, M. Mollica, A. Rebechi, I. Aranda, L. Alba.* Centro Nacional de Genetica Medica, Buenos Aires, Argentina.

We described a 7 year old girl with a karyotype 46,XX,22qs who was referred to our center because of mild mental retardation. The proband is the fourth child of healthy, non-consanguineous parents. She was delivered at 40 weeks of gestation from a 36-year-old mother and a 44-year-old father. There is no relevant genealogical background. Weight and height were at the 75th centile, and head circumference at the +1SD for her age. She showed downslated palpebral fisures, hypermetrophy, cup shaped and prominenet ears. Echocardiography and brain CT scan were normal. Cytogenetic studies using G; C and NOR banding techniques were performed. An abnormal bisatellited chromosome 22 was detected. DA/DAPI did not showed bright fluorescence on the long arm of this derivative chromosome. FISH using chromosome 22 painting probe(WCP22) revelead that the euchromatic material was 22 on the abnormal chromosome and with a centromeric 14/22 probe (D14Z1/D22Z1) showed only one 14/22 centromeric region on this chromosome. FISH analysis using centromeric 13/21 probe (D13Z1/D21Z1) are in progress. Parental karyotypes were normal. The abnormal bisatellited chromosome must have been originated by a reciprocal translocation between the long arms of a chromosom 22 and the short arms of an acrocentric chromosome leading to a terminal deletion 22q. The clinical findings in our patient are similar to those previously described for 22q deletions.

Program Nr: 937 from the 1999 ASHG Annual Meeting

Multiple second trimester maternal serum markers as predictors of preeclamptic pregnancies. *D.A. Aitken[1], S. Bergh[2], J.A. Crossley[1], S. Lahiff[1], R. Arngrimsson[2], J.M. Connor[1].* 1) Biochemical Genetics Div, Inst Medical Genetics, Glasgow, Scotland; 2) University and National Hospital, 101 Reykjavik, Iceland.

Preeclampsia is a condition associated with the third trimester of pregnancy when it may seriously threaten the well-being of mother and fetus. Recognition of preeclampsia is usually delayed until onset of the symptoms and a predictive test in early pregnancy would be valuable. We have investigated the levels of seven feto-placental markers in second trimester maternal serum from 75 women who subsequently developed preeclampsia at later gestations. All had screening for neural tube defects and Downs syndrome between 15 and 20 weeks gestation when alphafetoprotein (AFP) and human chorionic gonadotrophin (ihCG) were analysed. Serum samples from cases and controls (n = 250) were recovered from frozen storage and assayed retrospectively for dimeric inhibin A (InhA), free beta hCG (FbhCG), pregnancy specific 1 glycoprotein (SP-1), pregnancy associated plasma protein A (PAPP-A) and cancer antigen 125 (CA125) using specific immunoassays. Analyte levels for each marker were converted to multiples of the appropriate gestational median (MOM) derived from the control series. Significantly elevated median MOM levels (Mann whitney $p<0.01$) were found for AFP (1.19 MOM), ihCG (1.31 MOM), and InhA (1.36 MOM) in the preeclamptic pregnancies. PAPP-A levels were reduced (0.76 MOM) but this did not reach statistical significance ($p = 0.56$) and there was no significant difference in levels of SP-1 (1.06 MOM) or FbhCG (1.09 MOM). In this study the increase in InhA level in preeclampsia was less marked than that reported in two previous studies (Muttukrishna et al, Lancet 1997, 349:1285; Cuckle et al, BJOG 1998, 105:1101). However, identification of women at risk may be improved by the use of additional markers (eg. AFP and ihCG) allowing clinical monitoring to be started early which, in turn, may lead to improved management of pregnancies and the development of effective treatment.

Program Nr: 938 from the 1999 ASHG Annual Meeting

A unique mosaic marker chromosome resulting from a familial Robertsonian translocation (21;22). *S. Arab[1], D. Chitayat[2,5], A. Gardner[3], E. Winsor[4,5].* 1) pathology and laboratory Medic, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of clinical Genetics, Hospital for sick children; 3) Genetic services, Likeridge Health Oshawa, Ontario; 4) Toronto General Hospital, Depat. Laboratory Medicine and pathobiology; 5) The prenatal diagnosis program University of Toronto, Canada.

A mosaic marker chromosome found in amniotic fluid was shown to be the result of deletion of a segment of a maternally inherited Robertsonian 21;22 translocation. Using a DiGeorge/velocardiofacial FISH probe (Vysis), it was demonstrated that in metaphases with the marker present there was a probe signal on the marker, but no signal on the translocation chromosome. However, in the absence of the marker there was a probe signal on the translocation chromosome. The karyotype was 45,XY,der(21;22)(q10;q10)/46,XY,der(21)(pter->21q10::22q11.2->qter),der(22)(22q10->22q11.2). Centromeric fission of the dicentric translocation chromosome resulted in two separate functional centromeres. Although the location of the second breakpoint for this marker is not known precisely, we speculate that the break may have occurred in the same "hot spot" which results in deletion of the DiGeorge/velocardiofacial region. Since no marker was found in maternal cells, it is suggested that the deletion and marker formation probably occurred post zygotically in the fetus. Fetal ultrasound at 19.5 weeks revealed a single fetus with measurements consisted with gestational age. Autopsy revealed a male fetus with no detectable abnormalities except for a small thymus. This case illustrates the difficulty in estimating risk of fetal abnormalities associated with de novo marker chromosomes. Marker chromosomes are usually assumed to contain "extra" material and the risk of associated fetal abnormalities is usually related to the amount of euchromatin present in the marker. This unique example illustrates that a marker chromosome which was initially assumed to be extra may be part of a balanced karyotype.

Program Nr: 939 from the 1999 ASHG Annual Meeting

Sex chromosome complement of placental trophoblast in X chromosome aneuploid pregnancies. *I.J. Barrett[1], W.P. Robinson[2], D.K. Kalousek[1]*. 1) Dept of Pathology,; 2) Dept of Medical Genetics, Univ of BC, Vancouver, Canada.

Monosomy X is seen in approximately 11% of spontaneous abortions. The fetal phenotype of 45,X consists of cystic hygroma, hydrops, pulmonary hypoplasia, horseshoe kidney, congenital heart defects. Less than 1% of 45,X conceptuses survive intrauterine development. It has been shown that approximately 5% of trisomy 13 and 18 conceptuses survive to third trimester and in these a significant level of disomy 13 or 18 has been shown to occur specifically in the trophoblast of the placenta. The role of chromosomal diploidy in placental trophoblast in gestations with 45,X fetuses has not been studied. The present study determines the distribution of disomy X in trophoblast and various tissues of conceptuses with prenatally diagnosed mosaicism for X chromosome aneuploidy or non-mosaic 45,X pregnancies. Eighteen pregnancies with X chromosome aneuploidy were analysed for presence of disomy X in the trophoblast. The gestational ages ranged from 14 to 40 weeks. Prenatal diagnosis using traditional cytogenetic methods had been performed in 15 of them; 5 involved X chromosome mosaicism and 10 non-mosaic 45,X. In addition 3 were terminated following identification of cystic hygroma with post-termination cytogenetic analysis demonstrating non-mosaic fetal aneuploidy 45,X. Cytogenetic analysis (direct, FISH or culture) was performed on trophoblast, chorionic stroma and fetal tissues if available. In all 5 cases with fetal mosaicism for X chromosome the trophoblast showed high levels of disomy X by FISH with varying levels in other tissues studied. Disomy X was observed in the trophoblast in only 3 out of 13 pregnancies with non-mosaic 45,X fetuses. The presence of high levels of disomy X in trophoblast in cases with fetal mosaicism suggests that these pregnancies originated as a diploid conceptus and the loss of an X chromosome occurred after trophoblast differentiation. Intrauterine survival of non-mosaic 45,X fetuses does not appear to be dependent upon the presence of disomy X in the trophoblast. DNA analysis of the parental origin of disomy X in the trophoblast of mosaic and non-mosaic 45,X pregnancies is in progress. ¥.

Program Nr: 940 from the 1999 ASHG Annual Meeting

A novel *SOX* gene expressed in the developing dermomyotome and neural crest. *K.M. Bell, A.H. Sinclair.* Department of Paediatrics, University of Melbourne, Centre for Hormone Research, Royal Children's Hospital Melbourne, Victoria, Australia.

SOX genes are members of a large and highly conserved family encoding putative transcription factors related by a common DNA binding domain, the HMG box. Twenty seven mammalian *SOX* genes have been identified to date. *SOX* genes have a restricted spatial and temporal expression profile in the developing embryo. Three members of the *SOX* gene family have been implicated in human diseases. Mutations in *SRY, SOX9* and *SOX10* cause XY sex reversal, Campomelic Dysplasia and Hirschsprung-Waardenburg syndrome respectively. Further study of *SOX* genes will elucidate their role in normal development and human disease.

In order to isolate novel *SOX* genes we screened a day 5 and 6 chick urogenital embryonic cDNA library with known *SOX* genes. We identified a novel *SOX* gene with highest sequence homology to the *SOX* subgroup which includes *SOX9* and *SOX10*. Using whole mount *in situ* hybridisation we first detected expression in early day two embryos. The temporal and spatial expression profile suggests a role in the development of the dermomyotome and neural crest cells, as well as some of the derivatives of these tissues. Expression is also seen in discrete bands in the ventricular zone of the neural tube.

Further studies mapping the human orthologue will help to identify possible congenital defects involving this gene. It might be expected that mutations in this gene will disrupt normal muscle and neural crest development.

Program Nr: 941 from the 1999 ASHG Annual Meeting

Abnormal maternal serum inhibin-A levels in trisomy 16 mosaic pregnancies. *P.A. Benn, R. Collins.* Div Genetics, Dept Pediatrics, Univ Connecticut Hlth Ctr, Farmington, CT.

Prenatal diagnosis of trisomy 16 mosaicism is associated with fetal death, IUGR, preterm delivery, and diverse congenital anomalies. Second trimester maternal serum alpha-fetoprotein (MS-AFP) levels are often high and, in addition, human chorionic gonadotropin (hCG) concentrations (and therefore Down syndrome (DS) risk) can be substantially elevated (Benn, AJMG,79,121;1998).

We analyzed Inhibin-A (Inh-A) levels in thawed maternal serum specimens from three previously reported cases with confirmed trisomy 16 mosaicism. Each pregnancy was associated with IUGR, preterm delivery and/or fetal anomalies. Case 1 (with triple test results MS-AFP= 2.80 MoM, hCG= 12.02 MoM, uE3= 0.81 M0M, and DS risk of 1:55) had Inh-A= 11.40 MoM and a DS risk based on all four analytes of 1:15. Case 2 (MS-AFP= 1.64 MoM, hCG= 21.41 MoM, uE3=0.59 MoM, and triple test DS risk 1:24) had Inh-A =13.32 MoM with a quad DS risk of 1:5. Case 3 (MS-AFP= 4.98 MoM, hCG= 8.62 MoM, uE3= 0.75 MoM, triple test DS risk of 1:106) had Inh-A= 9.90 MoM and a quad DS risk of 1:34. Inh-A was also measured in a fourth specimen from a pregnancy with IUGR, preterm delivery and fetal anomalies consistent with trisomy 16 mosaicism but normal amniotic fluid cytogenetic analysis (occult mosaicism). This case (with triple test results MS-AFP= 2.13 MoM, hCG= 13.32 MoM, uE3= 0.66 MoM, and DS risk 1:16) had Inh-A= 8.48 MoM and a quad DS risk of 1:2.

This preliminary data therefore indicates that very high Inh-A levels are often present. Based on simulation using published means, standard deviations and correlation coefficients, less than 1 in 100,000 normal and less than 0.14% of DS pregnancies will have MS-AFP>1.00 MoM, hCG>5.00 MoM and Inh-A>5.00 MoM. This pattern would therefore appear to be useful in identifying trisomy 16 mosaicism (and possibly other disorders with similar placental disturbance). We hypothesize that the degree of elevation of the analytes will reflect the relative proportion of abnormal cells present in the placenta and that the most extreme values will be associated with the greatest risk for poor pregnancy outcome.

Program Nr: 942 from the 1999 ASHG Annual Meeting

Declining termination rates for chromosome abnormalities identified prenatally by amniocentesis in southeast United States. *R.G. Best[1], A.M. Sanders[1], K.C. Phelan[2], V.A. Vincent[1]*. 1) Dept Obstetrics/Gynecology, Univ South Carolina Sch Med, Columbia, SC; 2) Greenwood Genetic Center, Greenwood, SC.

We report the study of pregnancy termination decisions following the prenatal diagnosis of cytogenetic abnormalities by amniocentesis among women tested in the southeast United States from 1987 through 1998. A total of 679 chromosome abnormalities were identified from 28,690 pregnancies (2.4%) at six centers. This includes 269 cases of trisomy 21, 126 sex chromosome abnormalities, 113 cases of trisomy 18, 38 cases of trisomy 13, 35 balanced de novo rearrangements, 24 unbalanced structural rearrangements, and 74 others. Outcome data were obtained from 419 cases excluding spontaneous losses and cases identified after the limits for termination. The overall termination rate was 57% with higher rates of termination associated with greater phenotypic severity. Termination rates were highest for trisomy 13 (86%), followed by trisomy 18 (74%), trisomy 21 (68%), unbalanced rearrangements (65%), sex chromosome abnormalities (25%), and balanced de novo rearrangements (8%). Termination rates also correlated with race (p=.0353). A trend was apparent between termination rates and maternal age (p=0.26) with rates of 44%, 54%, and 62% in women aged <25, 25-34, and >35 respectively. The most common indications for testing among all abnormalities identified include advanced maternal age (32%), abnormalities on ultrasound (27%), positive serum screening (22%), and combined AMA/ positive screen test (10%).Our findings represent a higher frequency of chromosome abnormalities, and an overall lower termination rate compared with an earlier study of termination rates among prenatally diagnosed cytogenetic abnormalities in the southeast US (Vincent et. al, 1991). The previous study revealed 416 cytogenetic abnormalities among 26,950 pregnancies (1.5%) studied during the period from 1969-1986. The overall termination rate of 73% included 95% of trisomy 13 and 18 pregnancies, 92% of trisomy 21, and 42% of sex chromosome abnormalities. The distribution of indications revealed 75% referred for AMA, 7% with abnormal ultrasound, 4% for abnormal serum screening in that study.

Program Nr: 943 from the 1999 ASHG Annual Meeting

Isolating fetal cells from maternal blood: Strategies to increase sensitivity for fetal aneuploidy detection. *F.Z. Bischoff[1], D. Lewis[2], J.L. Simpson[1,3], D.D. Nguyen[1], D. Marquez-Do[1], A. Bryson[2], J. Scott[2], K. Leonard[1], S. Elias[4]*. 1) Depts OB/GYN; 2) Immunology/Microbiology; 3) and Molecular/Human Genetics, Baylor College of Medicine, Houston, TX; 4) Dept OB/GYN, Univ of Illinois, Chicago.

Increasing numbers of investigators are pursuing strategies for isolation and analysis of fetal cells in maternal blood as a method of non-invasive prenatal diagnosis. We have previously described methods for enrichment (Cytometry 23:218 1996) and aneuploid detection (Am J Obstet Gynecol 179:203 1998). Our efforts have focused on obtaining consistency in flow-sorting methodologies and optimizing FISH analysis for aneuploidy detection. POPULATION-Blood samples were obtained from women seen for prenatal genetic diagnosis at Baylor (n=389) and Wayne State (n=42) (14 wks mean gestational age). Of 431 samples, 354 were enrolled in a multicenter NICHD study; 77 non-enrolled cases were analyzed similarly. METHODS-A variety of enrichment strategies have been employed, namely positive selection for glycophorin A (gly A), CD71 (transferrin receptor) or gamma globin (HbF) and negative selection for CD45. Following enrichment, antibody-stained cells are fixed in formaldehyde and permeabilized with 0.1% Triton-X prior to sorting. RESULTS-Each of five gly A antibodies produced agglutination, resulting in our abandoning gly A for positive selection. Positive selection by flow-sorting for either $CD71^+$ or gamma-$globin^+$ cells seems equally successful. Specific modification of cellular permeabilization strategies have now maximized accessibility of DNA to probes; cellular fixation after enrichment and storage conditions also affect cellular integrity for subsequent FISH. ANEUPLOID DETECTION (1999)-Overall, we detect 42% of fetal aneuploid cases with a very low false-positive rate - 0.5% for trisomies 13, 18 and 21, respectively. CONCLUSION-Our goal of greater aneuploid detection, at least that of maternal serum screening and nuchal translucency, is not yet achieved. Alternative methods of enrichment (i.e. MACS or density gradient separation) are being investigated to improve efficiency in fetal cell recovery. NICHD N01HD43203.

Program Nr: 944 from the 1999 ASHG Annual Meeting

Isolation of fetal nucleated red blood cells (FNRBCs) from maternal blood cultures: Optimization of culture conditions for flow sorting based on correlated cellular HbF and HbA contents. *R.M. Bohmer, D.K. Zhen, D.W. Bianchi.* Division of Genetics, Dept Pediatrics, Tufts University School of Medicine, Boston, MA.

Background: Using flow cytometric measurement of correlated cellular HbF and HbA contents, we have shown previously that FNRBCs in culture develop a hemoglobin profile that makes them distinguishable from most adult erythroid cells, so that FNRBCs can be detected and highly enriched from maternal blood cultures (Br J Haematol 1198;103:351). However, some adult cells make HbF (F+ cells) like fetal cells, which limits the purity of fetal cell isolation by flow cytometry.

Methods: In peripheral blood cultures from pregnant women, we tested a variety of drugs and culture conditions for their ability to selectively suppress the growth of adult F+ cells. Analysis was performed using two-color flow cytometry, FACS and FISH.

Results: The following cytokines or drugs had no effect on the proportions of adult F+ cells: TNFalpha, Mip1alpha, Activin A, SDF-1alpha, PGE2, dexamethasone, IFNgamma, IGFI and IGFII. The proportions of adult F+ cells were strongly increased by TGFbeta. Two modifications of standard culture conditions were found to suppress the growth of adult F+ cells dramatically while having little effect on fetal F+ cells: the use of charcoal-treated human umbilical cord serum at low concentrations, and the omission of IL-3 from the standard cytokine cocktail. Under these conditions, the enrichment of FNRBCs in co-cultures of fetal and adult blood cells was estimated to approach 1000 fold.

Conclusions: The biology of fetal and adult erythroid cells in culture is complex. However, culture conditions can be designed to suppress the growth of adult F+ cells selectively, permitting a dramatic enrichment of fetal nucleated red cells in erythroid cultures from maternal blood. We will test this procedure on blood samples obtained from pregnant women carrying normal and abnormal fetuses.

Program Nr: 945 from the 1999 ASHG Annual Meeting

Normal twin pregnancy following ICSI of ejaculate spermatozoa from a patient with Klinefelter's syndrome. *N. Bolduc, M.M. Bielanska, S.L. Tan, A. Ao, V. Desilets.* McGill University Health Centre, Royal Victoria Hospital, Montreal, Quebec, Canada.

Klinefelter's syndrome is usually associated with azoospermia or severe oligospermia. Recent evidence suggests that 47,XXY germ cells are able to complete meiosis and produce sperm nuclei. In recent years, pregnancies and births have been reported following intracytoplasmic sperm injection (ICSI) using spermatozoa collected through testicular biopsy.

We report a twin pregnancy in a couple in which the man has Klinefelter's syndrome. Motile spermatozoa were present occasionally in the ejaculate of this man. His blood karyotype, done twice in different laboratories, was 46,XY(1)/47,XXY(59) and 47,XXY(50). FISH analysis of his sperm revealed a normal number of sex chromosomes in 94.4% of the cells. They underwent ICSI without testicular sperm extraction. Due to technical difficulties, preimplantation genetic diagnosis failed. Three embryos were transferred resulting in a dichorionic, diamniotic twin pregnancy. At 12 weeks, normal nuchal translucency measurements were obtained in both twins. At 16 weeks, amniocentesis showed a 46,XX karyotype in each twin. No fetal anomalies were seen at the 18 week ultrasound.

To our knowledge, this is the second report of a successful pregnancy using spontaneous spermatozoa from ejaculate of a man with Klinefelter's syndrome. Patients with Klinefelter's may achieve pregnancy through reproductive technology without having testicular biopsy. Preimplantation diagnosis and/or prenatal diagnosis should be considered. It is likely that this patient has 46,XY/47,XXY gonadal mosaicism. We are in the process of completing further cytogenetic analysis in him.

Program Nr: 946 from the 1999 ASHG Annual Meeting

Mouse Sry requires a CAG repeat domain for male sex determination. *J. Bowles, L. Cooper, J. Berkman, P. Koopman.* CMCB, University of Queensland, Brisbane, Queensland, Country.

SRY, the mammalian Y-chromosomal sex-determining gene, encodes a protein characterized by a DNA-binding and bending domain referred to as the HMG box. Despite the pivotal role of this gene, only the HMG box region has been conserved through evolution, suggesting that function depends solely on the HMG box and therefore that SRY acts as an architectural transcription factor. In mice (genus Mus), Sry also includes a large CAG trinucleotide repeat region encoding a C-terminal glutamine-rich domain that can act as a transcriptional trans-activator in vitro. However the absence of this or any other potential trans-activating domain in other mammals has raised doubts as to its biological relevance. To test directly whether the glutamine-rich region is required for SRY function in vivo, we created truncation mutations of the Mus musculus musculus Sry gene and tested their ability to induce testis formation in XX embryos using a transgenic mouse assay. Sry constructs that encode proteins lacking the glutamine-rich region were unable to effect male sex determination, in contrast to wild-type counterparts. We conclude that the glutamine-rich repeat domain of the mouse SRY protein plays an essential role in sex determination in vivo, and that SRY may act via a fundamentally different biochemical mechanism in mice compared to other mammals.

Program Nr: 947 from the 1999 ASHG Annual Meeting

Tissue specific involvement in fetal trisomy 16. *H. Bruyere[1,2], I.J. Barrett[2], D.K. Kalousek[2], W.P. Robinson[1]*. 1) Dept. of Medical Genetics; 2) Dept. of Pathology, University of British Columbia, Vancouver, Canada.

Placental mosaicism is found in 1-2% of viable pregnancies diagnosed by chorionic villous sampling and is typically confined to the placenta. However, in about 10% of these cases, follow-up amniocentesis reveals fetal involvement. The extent and tissue specific distribution of the trisomy in the fetus is expected to depend on the timing of the responsible event, the chromosome involved, the role of selection against the trisomy in different tissues or stochastic factors. To understand how mosaicism may be distributed in fetal tissues, we have performed fluorescence in situ hybridization and/or DNA marker analysis in fetal/neonatal tissues in 7 cases of mosaic trisomy 16. Four cases were terminated after a positive AF (13 to 50% trisomy). Case 1 was trisomy positive in skin but negative in brain, spleen, kidney. Case 2 was trisomy positive in lung but negative in skin, kidney, brain, spleen, liver, adrenal, thymus, gonad and amnion. Case 3 was trisomy positive in lung but negative in kidney. Case 4 was negative for trisomy in thymus, blood and amnion. Trisomy 16 was diagnosed in case 5 on CVS. Despite a normal AF result, in utero death occurred at 24 weeks and trisomy was confirmed in brain but not in lung. Case 6 (previously published) was terminated after a positive CVS result. Oocytes and amnion were positive for the trisomy but skin, lung, kidney, brain and blood were negative. In case 7, trisomy 16 mosaicism was identified in the placenta and in spleen after neonatal death of a phenotypically abnormal baby. Amnion and blood were diploid. These results suggest that 1) trisomy 16 detected by AF is frequently confined to a single or a few fetal tissues. The affected tissues can differ from case to case, possibly explaining the large phenotypic variability in liveborn infants with mosaic trisomy 16. 2) AF results do not reflect the level of trisomy in affected fetal organs. 3) AF may reflect the presence of trisomy in skin, lung, kidney or amnion, tissues which contribute to AF. However, involvement of other tissues cannot be predicted by AF analysis and "occult" fetal mosaicism may occur in some cases diagnosed as "confined placental mosaicism".

Program Nr: 948 from the 1999 ASHG Annual Meeting

Prenatal detection and follow-up of Renal Cystic Disease. *L. Carrillo[1], R. Sanchez[1], C. Llanusa[1], J. Oliva[1], L. Rodriguez[1], L. Heredero[2].* 1) Genetics, Gonzalez Coro Hospital, Havana City, Havana City, Cuba; 2) National Center of Genetics.

The prevalence at birth of urinary tract anomalies is 3 per 1000 liveborns. Since 1990 the genetics unit at the Gonzalez Coro hospital in Havana City conducts prenatal ultrasound diagnosis of renal anomalies with the goals of improving their prenatal detection, delineating their natural history and developing guidelines for their management after birth. Between 1990 and 1997, 34 cases of unilateral or bilateral renal cystic lesions were detected in the second trimester of gestation. In 9 of these, the parents decided the termination of pregnancy: these cases tended to be bilateral, progressive, and/or associated with oligohydramnios or additional malformations. In all cases the pathologic examination after termination confirmed the prenatal ultrasound diagnosis: single renal cyst (1), infantile polycystic kidney (4), multicystic kidneys (3) and obstructive cystic disease (1). Of the 25 cases born at term, postnatal ultrasound confirmed the same lesion detected prenatally: unilateral multicystic kidney (15), bilateral polycystic kidney (1) and single renal cyst (1). In 6 cases, the postnatal tests determined a renal lesion different from the one predicted prenatally and in 2 cases the postnatal studies failed to show any renal anomaly. Of the 23 patients born at term with a renal anomaly, only 2 required unilateral nephrectomy and 3 required occasional antibiotic treatment and the remaining did not require any treatment. In 13 of the 15 patients born with unilateral multicystic kidney, the affected kidney eventually atrophied. Overall, of the 34 cases detected prenatally, the diagnosis after termination or birth coincided exactly in 26 cases (76.5%), and partially (renal anomaly different from the one diagnosed prenatally) in 6 cases (17.6%). Only 2 cases representred true false positives.

Program Nr: 949 from the 1999 ASHG Annual Meeting

Cytogenetic and FISH analysis in two prenatal cases with half cryptic chromosome rearrangements involving a terminal 2q37 deletion. *S.W. Cheung[1], C.M. Lese[2], J.L. Smith[1], D.A. Kass[3], C.G. Hatjis[3], J.C. Sawyer[1], D.H. Ledbetter[2]*. 1) Laboratories Genetic Services, Houston, TX; 2) Dept.of Human Genetics, Univ.of Chicago, Chicago, Ill; 3) Perinatal Services, St. Agnes Healthcare, Baltimore, MD.

Terminal 2q37 deletion is a recognizable syndrome with growth retardation, developmental delay, microcephaly, dysmorphic features, cardiac defects, genital anomalies, and syndactyly/clinodactyly. We report two novel cases with subtle terminal deletions of 2q37 resulting from paternal chromosome rearrangements which became apparent with the aid of telomeric probes. Amniocentesis was performed in case 1 due to an abnormal trisomy screen (risk for Down syndrome 1 in 37). Chromosome analysis revealed 46,XX,add(2)(q37). The paternal karyotype was 46,XY,inv(2)(p25.1q37.2). FISH studies using both centromeric and 2p telomeric probes (ONCOR) were performed on fetal and paternal cells. The result confirmed the inversion in the father and showed that the fetus carried a rec(2) with a partial duplication of 2p at band 25.1 and monosomy for 2q at band q37. Pregnancy termination was elected and abnormalities were noted in the abortus. Amniocentesis was performed in case 2 for advanced maternal age and abnormal trisomy screen (risk for Down syndrome 1 in 213). Initial results were 46,XY,add(2)(q27), which was also found in the father. FISH analysis carried out with a probe specific for the 2q telomere (BAC 172113) revealed monosomy 2q in the amniotic fluid sample. FISH analysis using the same probe on the father identified a balanced translocation between 2q and 11p, a translocation which was only detectable by cytogenetics after the FISH result was available. These results verify paternal transmission of the unbalanced translocation in the amniotic fluid sample. Pregnancy termination was elected; no follow up studies are available. Detailed cytogenetic studies for chromosome rearrangements, FISH analysis and follow up studies will be presented.

Program Nr: 950 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of glutaric aciduria type II associated with cystic renal changes and elevated maternal serum alpha-fetoprotein. *C.A. Chisholm[1], F. Vavelidis[1], M.A. Lovell[1], D.S. Roe[2], C.R. Roe[2], L. Sweetman[2], W.G. Wilson[1]*. 1) Depts. of Obstetrics and Gynecology, Pathology, and Pediatrics, Univ of Virginia Health System, Charlottesville, VA; 2) The Institute of Metabolic Disease, Baylor Univ Medical Center, Dallas, TX.

We report the occurrence of glutaric aciduria type II (GA II) in two consecutive pregnancies in a young Caucasian non-consanguineous couple. In the first pregnancy, the maternal serum alpha-fetoprotein (MSAFP) value was elevated (2.62 MOM). Ultrasound showed a fetus two weeks smaller than menstrual dates with enlarged, echogenic, microcystic kidneys and oligohydramnios. The couple elected to terminate the pregnancy because of concerns about severe cystic renal disease. Post-mortem examination of the fetus showed glomerulocystic renal changes and hepatic steatosis. Fibroblast analysis confirmed electron transfer flavoprotein deficiency (GA II). In the second pregnancy, ultrasound at 15 weeks showed an early growth lag and kidneys that were normal in size and appearance. Results of testing included an elevated MSAFP (3.4 MOM), elevated amniotic fluid AFP (2.51 MOM), normal female karyotype, negative acetylcholinesterase, elevated amniotic fluid C4, C5, and C5-diCOOH acylcarnitines, and increased C5/C3 and C5-diCOOH/C3 acylcarnitine ratios by tandem mass spectroscopic analysis. Subsequent in vitro studies of fat oxidation in cultured amniocytes were consistent with GA II. Follow-up ultrasound showed enlarged, echogenic, microcystic kidneys. The couple elected to terminate the pregnancy, and the findings were confirmed on post-mortem examination. These cases provide additional information regarding the evolution of renal changes in fetuses affected with GA II, as well as showing a relationship with elevations in AFP, which may be useful in counseling the couple at risk. GA II should be considered in the differential diagnosis of elevated AFP and cystic renal disease in the fetus. Early fetal growth delay may be an additional finding.

Program Nr: 951 from the 1999 ASHG Annual Meeting

Short Tandem Repeats polymorphism Is Useful in Diagnosis of Trisomy 21. *D.C. Chu[1,3], L.R. Boots[2], C.L. Wu[3], K.C. Tsao[3], D.T.Y. Chiu[1], C.F. Sun[3].* 1) School of Medical Technology, Chang Gung University, Tao Yuan, Taiwan; 2) Department of OB/GYN, University of Alabama at Birmingham, USA; 3) Department of Clinical Pathology, Chang Gung Medical Center, Lin-Kou, Taiwan.

Human chromosome 21, the smallest human chromosome, constitues approximately 1.2% of the human genome. A large number of sequence-tagged sites (STS)and polymorphic DNA markers have been identified on the human chromosome 21 recently. Since quite a number of trisomy 21 cases result from nondisjunction during meiosis I, it was hypothesized that the 3 chromosome 21s of different parental origins could be differentiated by their DNA polymorphism.

Forty-eight amniotic fluid samples from pregnancies complicated with fetal Down syndrome were analyzed for D21S11 and interferon-a receptor (IFNAR)- intervening sequences. These loci contain tetranucleotide repeat sequences. The heterogeneity rates of these 2 markers were reported to be 0.90 and 0.83, respectively. Polymerase chain reaction (PCR) was performed to amplify the sequences and the band patterns were resolved by polyacrylamide electrophoresis with ABI Prism 377.

The preliminary data revealed that 35 of 40 (87.5%) fetal Down syndrome cases analyzed for IFNAR showed 3 distinctive bands, each band represents one individual chromosome 21, while 24 of 30 (80%) fetal Down syndrome cases analyzed for D21S11 showed 3 distinctive bands. Altogether 39 of 40 (97.5%) of the fetal Down syndrome cases studied showed 3 distinctive bands.

In conclusion, polymorphic DNA markers are useful in determining the number of chromosome 21 present in the fetal cells. The high sensitivity of the preliminary data suggested possible clinical application of this technique for prenatal diagnosis of chromosome aneuploidy.

Program Nr: 952 from the 1999 ASHG Annual Meeting

Carnitine Acylcarnitine Translocase Deficiency : First prenatal genetic analysis on crude chorionic villus biopsy.

C. Costa[1], J.M. Costa[2], F. Daffos[3], M.P. Beaujard[3], A. Boutron[1], D. Mitanchez[4], A. Legrand[1], M. Brivet[1]. 1) Laboratoire de Biochimie, AP-HP Hopital de Bicetre, Bicetre, France; 2) Centre de Diagnostic Prenatal, Hopital Americain de Paris; 3) Service de Medecine Foetale, Institut de Puericulture de Paris; 4) Service de Pediatrie, Institut de Puericulture de Paris.

Carnitine acyl carnitine translocase (CACT) deficiency is a severe disorder of long-chain fatty acid oxidation with a bad prognosis. For the last five years, we performed 8 prenatal diagnosis in 6 families by biochemical investigations on cultured trophoblasts or amniotic cells (fatty acid oxidation assays and CACT activity measurements). These methods are accurate but the diagnosis was only obtained in 30 to 40 days. Cloning and sequencing of human CACT cDNA have allowed the beginning of mutation recognition in patients. The recent determination of the exon-intron structure of the human CACT gene has opened the way to direct analysis of fetal DNA for a faster prenatal diagnosis of CACT deficiency. We have identified CACT mutations in 9 unrelated families by directly sequencing the entire cDNA and confirming the mutational status on genomic DNA. In one of these families, two different mutations, a C-G transversion in exon 7 leading to a P751R missense mutation inherited from the father, and a G-A transition in the splice acceptor site in intron 6 inherited from the mother were found, before initiation of a second pregnancy by the mother. Fetal genomic DNA was extracted from a chorionic villus biopsy sampled at the 12th week of gestation. Paternal and maternal contribution were checked with highly polymorphic microsatellite markers. Intronic oligonucleotides primers were used to amplify both the exon 7 and the associated splice donor and acceptor sites. Fetal DNA sequence analysis indicated that the fetus had received both normal CACT alleles. With this approach, the diagnosis was obtained within 2 days. Long chain fatty acid oxidation assays and CACT activity measurements, performed on cultured trophoblasts and amniocytes confirmed, one month later, that the fetus was not affected. Supported by Assistance Publique de Paris (CRC N 97010).

Program Nr: 953 from the 1999 ASHG Annual Meeting

Expression of *JAGGED1* gene in human embryos. *C. Crosnier[1], T. Attie-Bitach[2], S. Audollent[2], F. Encha-Razavi[2], F. Soudy[1], M. Hadchouel[1,3], M. Meunier-Rotival[1], M. Vekemans[2]*. 1) INSERM U347, Kremlin-Bicetre, France; 2) INSERM U393, Dept de Genetique, Hopital Necker, Paris, France; 3) Hopital de Bicetre, France.

Mutations of the *JAGGED1* gene encoding a NOTCH receptor ligand, cause Alagille syndrome (AGS), a malformative disorder affecting mainly liver, heart, vertebrae, eye, face. To study its role during human development and in the AGS phenotype, we performed in situ hybridization on paraffin-embedded 24- to 56-day old human embryos and on fetal tissues (liver and kidney at 11, 13 and 20 weeks, brain and heart at 20 weeks of gestation).

We showed that *JAGGED1* was expressed in the developing central nervous system (CNS), eye, ear, kidney, heart and blood vessels. In the CNS, it was strongly expressed in 2 stripes in the ventral neuroepithelium of the mesencephalon and rhombencephalon, and on either side of the roof plate. In the developing ear, *JAGGED1* was first seen in the ventral half of the otic vesicle, then in the developing sensory epithelium of the endolymphatic canal and the cochlea. In the eye, it was first detected in the lens placode, then in the lens and was finally restricted to posterior epithelial cells. A strong signal was observed in the ciliary body, hyaloid plexus and choroid. *JAGGED1* was strongly expressed early in the foregut mesenchyme, and later in the stomach and duodenum. In the kidney, it was first detected in the wolffian duct and mesonephric tubules, then in metanephric tubules. Finally, it was weakly expressed in the developing atria, but strongly in the conotruncus. *JAGGED1* was observed in all the developing vessels including the hepatic arteries of the liver at 20 weeks.

These observations are consistent with the features observed in various tissues in AGS patients, including minor features of the syndrome such as renal and forelimb abnormalities. Blood vessels were the structures which were most frequently labelled in human embryos, suggesting that abnormal angiogenesis/vasculogenesis might be involved in the pathogenesis of AGS features, including the paucity of interlobular bile ducts.

Program Nr: 954 from the 1999 ASHG Annual Meeting

Maternal smoking: age distribution, analyte levels and effect on detection of Downs syndrome pregnancies in second trimester screening. *J.A. Crossley[1], D.A. Aitken[1], S. Waugh[1], T. Kelly[2], J.M. Connor[1]*. 1) Biochemical Genetics Div, Inst Medical Genetics, Glasgow, Scotland; 2) Glasgow Royal Maternity Hospital, Glasgow, Scotland.

Information on maternal smoking was obtained by case-note searches in 101 Down's syndrome pregnancies and 2272 normal pregnancies which had been screened in the second trimester using AFP and hCG. In the affected pregnancies there were 75 non-smokers, 24 smokers and 2 who had recently stopped. In the unaffected pregnancies there were 1514 non-smokers, 671 (30%) smokers and 87 recently stopped. The median ages for the non-smokers and smokers were, respectively, in the Down's syndrome group 33 years and 31 years, and in the unaffected pregnancies 28 years and 25 years. The proportion of pregnant women who smoked decreased with increasing maternal age, from 52% in those aged under 20 years to 19% in those 35 years and over. Using maternal age risks in individual years the expected rate of Down's syndrome at term was calculated from the age distribution of smokers and non-smokers and found to be 1.1/1000 in the smokers and 1.4/1000 in the non-smokers. In the unaffected singleton pregnancies the median MOM (multiple of the median) for AFP was 1.00 overall: 0.98 in non-smokers and 1.04 in smokers, and for hCG, 1.00 overall: 1.13 in non-smokers and 0.80 in smokers. This reduction in hCG levels in smokers did not vary with the number of cigarettes smoked per day. In the Down's syndrome pregnancies the median MOM for AFP was 0.69 overall: 0.69 in the non-smokers and 0.70 in the current smokers, and for hCG 2.13 overall: 2.49 in the non-smokers and 1.53 in current smokers. The detection rate for Down's syndrome was 67% overall: 76% in the non-smokers and 38% in the smokers. Correcting the analyte levels for smoking status makes little difference to the overall detection rate (68%), but gives a more equal distribution of detection with 69% in the non-smokers and 63% in the smokers. Use of uncorrected medians therefore leads to loss of detection of Down's syndrome cases amongst smokers and an increase in the false positive rate amongst non-smokers.

Program Nr: 955 from the 1999 ASHG Annual Meeting

Early prenatal diagnosis of XLR centronuclear myopathy using mutation analysis and early histopathological changes in an affected fetus. *D. Cushing[1], S. Liechti-Gallati[2], A. Chan[1], V. Jay[3], D. Chitayat[1]*. 1) Prenatal Diagnosis Program, University of Toronto, Toronto, Ontario, Canada; 2) Department of Human Molecular Genetics, Children's Hospital, Inselspital, Bern, Switzerland; 3) Department of Pathology, University of Toronto, Toronto, Ontario, Canada.

X-linked centronuclear myopathy (XLR-CNM, OMIM #310400) is a myopathy resulting in severe hypotonia and respiratory failure. The disease is caused by a mutation in the MTM1 gene mapped to Xq28. We report early prenatal diagnosis in a family with XLR-CNM due to a 340insA mutation in exon 5 of the MTM1 gene and the fetal histopathological findings at 14 weeks gestation. The patient was a 34 year old woman whose first son was delivered at 28 weeks gestation with hypotonia and respiratory difficulties and died at 6 months of age. Muscle biopsy was consistent with CNM. Muscle biopsy on the patient demonstrated muscle fibres with increased central nuclei consistent with a carrier state for XLR-CNM. In her subsequent pregnancy the patient decided to pursue early prenatal diagnosis. Mutation analysis on the patient demonstrated she is a carrier of the 340insA mutation in exon 5 of the MTM1 gene(previously reported in XLR-CNM) and analysis of fetal DNA extracted from CVS showed the fetus to be an affected male. The pregnancy was terminated at 15 weeks gestation and histopathology confirmed prominent central nuclei and type 1 predominance consistent with CNM. Review of the family history showed that the patient had a brother and two maternal uncles who died in infancy of unknown etiology. To the best of our knowledge this is the first reported case of prenatal diagnosis of XLR-CNM by mutation analysis and the earliest fetal muscle histopathology showing that the muscle changes present very early in pregnancy. Since similar histological changes can be detected in normal fetuses, prenatal diagnosis is most reliable by mutation analysis.

Program Nr: 956 from the 1999 ASHG Annual Meeting

Two dimensional ultrasound detection of coronal synostosis at 19 weeks gestation leading to the prenatal diagnosis of Apert syndrome. *D. Day-Salvatore[1], E. Guzman[2], T. Cimaroli[1], J. Pellegrino[1], F. Schaefer[3], A. Vintzileos[2]*. 1) Division of Clinical Genetics, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 2) Division of Maternal-Fetal Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 3) H.A. Chapman Institute of Medical Genetics, Tulsa, OK.

The prenatal ultrasound detection of sporadic Apert syndrome has been previously described in eight cases. In these cases, presenting sonographic findings included ventriculomegaly, cloverleaf or other bizarre skull shape, abnormal facial profile with frontal bossing, and polyhydramnios; the diagnosis was ultimately made between 26 and 34 weeks of gestation. We report on a healthy 32-year-old prima gravida referred at 18 weeks 6 days gestation for strawberry-shaped cranium to rule out trisomy 18. Fetal ultrasound biometry was consistent with gestational age based on intrauterine insemination. Axial views of the cranium revealed frontal-parietal notching with fusion of the coronal sutures inferiorly. The superior aspect of the coronal sutures and the metopic, sagittal, and lambdoidal sutures at all levels were noted to be echolucent and patent. Ultrasound examination of healthy fetuses of similar gestational age demonstrated sutural patency at all levels. The fetal profile, intracranial anatomy, and amniotic fluid index in this case were normal. The hands appeared clenched bilaterally with no visible separation of the digits and both feet were abnormally shaped. Amniocentesis revealed a 46,XX karyotype. Molecular analysis of cultured amniocytes demonstrated an alteration of the FGFR2 gene in exon 7 at codon 253 leading to a proline-to-arginine substitution, one of two mutations previously described in Apert syndrome. Autopsy revealed complete syndactyly of all fingers and toes, partial coronal synostosis, and unremarkable facial appearance. This case supports the utility of standard prenatal sonography in identifying fetuses with coronal suture synostosis prior to the third trimester and the development of secondary craniofacial abnormalities.

Program Nr: 957 from the 1999 ASHG Annual Meeting

A report of the diagnostic and pronostic accuracy of prenatal sonographic diagnosis of skeletal dysplasias. *B. Doray[1], R. Favre[2], B. Viville[2], B. Langer[2], C. Stoll[2].* 1) INSERM U393, Inst Necker/IFREM, Paris, France; 2) Service de Genetique Medicale, Hopital de Hautepierre, Strasbourg, France.

As ultrasonographic assessment of the skeleton is now routine part of fetal anomaly scanning, the objective of this study was to examine the accuracy of prenatal diagnosis of skeletal dysplasias and ways to refine this ability. We report a series of 47 cases seen during a 6-year interval in which a skeletal dysplasia was suspected prenatally. Diagnosis was performed between 16 and 24 weeks of gestational age in 28 cases (59.6 per cent). Follow up was incomplete in two cases. In 45 (96.0 per cent) of the 47 cases, prenatal sonographic examination correctly predicted the prognosis, although in only 29 (67.7 per cent) of the 47 cases was the suggested prenatal diagnosis proven to be correct. In 9 cases (19.1 per cent) the prenatal diagnosis was inaccurate and in 10 cases (21.3 per cent) the prenatal diagnosis was false. In ten (21.3 per cent) of the 47 cases, a specific diagnosis could not to be made either pre-or postnatally. The most common final diagnosis were achondroplasia (7 cases), osteogenesis imperfecta (13 cases), thanatrophoric dwarfism (4 cases), achondrogenesis (5 cases) and Ellis van Creveld syndrom (3 cases). The diagnosis of achondroplasia was never made before 24 weeks of gestational age. In two cases (5.5 per cent) the fetus did not appear to have a skeletal dysplasia or an obvious dysmorphic syndrom. Termination of pregnancy was performed in 36 cases (76.6 per cent). Our study showed the difficulty of making an accurate prenatal sonographic diagnosis in fetuses with suspected skeletal dysplasias throughout gestation, especially in the third trimester, and the importance of comprehensive multidisciplinary assessment in these cases.

Program Nr: 958 from the 1999 ASHG Annual Meeting

A Spinal Muscular Atrophy Conundrum. *D. du Sart[1], I. Biros[1], S. Forrest[2], A. Bankier[1], M. Smith[1]*. 1) Victorian Clinical Genetics Services , Murdoch Institute, Melbourne, Victoria, Australia; 2) Gene Discovery Group, Murdoch Institute, Melbourne, Victoria, Australia.

Spinal muscular atrophy (SMA) is a common autosomal recessive disease affecting the motor neurones of the spinal cord. The critical SMA region on chromosome 5q13 shows a complex genomic structure, including a 500-kb duplication and inversion encompassing four genes, which are present in at least two copies each, the telomeric (t) and centromeric (c) counterparts. Homozygous deletions of the telomeric copies of these genes are found in SMA patients, with the survival motor neuron (SMN) gene showing the highest frequency, deleted in 95% of SMA patients. The diagnostic test for SMA linked to chromosome 5 has been analysis for homozygous deletion of the SMNt. Prenatal testing for SMA involves the direct deletion gene test of SMN and linkage analysis with polymorphic markers close to the critical SMA region. There have been suggestions that the linkage analysis is not necessary for a prenatal exclusion if a previously affected sibling was genotyped to be homozygously deleted for SMNt. We tested a CVS sample using the deletion test and JK53 and EF1/2a linkage markers. The previously affected sibling was homozygously deleted for SMNt. The CVS was found to have at least one copy of SMNt and the semi-informative linkage result indicated that the CVS sample was at least a carrier of SMA. The pregnancy was continued. The child was born and started displaying symptoms of SMA at 6 weeks. SMA gene testing was repeated and the second result showed homozygous deletion for SMNt. Maternal cell contamination was ruled out. The SMA gene test was repeated on all samples, including 10 different placental tissue biopsies (the parents kept the placenta for personal reasons). All placental tissue samples confirmed the CVS results. New closer linkage markers, D5S1414 and D5S1408, indicated that the CVS and placental samples had inherited the high-risk chromosomes from both parents and therefore should have been homozygously deleted for SMNt. How do we explain this conundrum? We therefore propose, that prenatal diagnosis should include both the direct deletion gene test and linkage analysis.

Program Nr: 959 from the 1999 ASHG Annual Meeting

PRENATALLY DIAGNOSED BALANCED ROBERTSONIAN OR RECIPROCAL TRANSLOCATIONS AND FREQUENCY OF UPD. *J.R. Exeler[1], D. Meschede[1], M. Lemmens[2], B. Dworniczak[1], J. Horst[1]*. 1) Universitaet Muenster, Humangenetik, D-48149 Muenster, NRW, Germany; 2) Humangenetik, Eisenhuette 23, D-52076 Aachen, NRW, Germany.

The term uniparental disomy was originally used by Engel in 1980 and implies the inheritance of both homologous chromosomes from one parent. UPD may adversely affect development if homozygosity for recessive gene mutations occurs or imprinting effects are present. An increased risk for UPD has been identified in several groups including carriers of mosaic trisomies, fetuses after prenatal diagnosis of confined placental mosaicism, and carriers of balanced Robertsonian or reciprocal translocations. In this study we investigated the frequency of UPD after the incidental prenatal diagnosis of a balanced Robertsonian translocation in a total of 25 cases and a balanced reciprocal translocation in 10 cases, respectively. In all cases the fetal translocation had originated from an analogous maternal or paternal translocation. To establish the parental origin of the involved chromosomes highly polymorphic dinucleotide repeats were analysed. Informative results were obtained without exception. UPD of the affected chromosomes could be excluded in all 35 cases. We conclude that UPD has a low prevalence among carriers of balanced Robertsonian or reciprocal translocations who are diagnosed incidentally in the setting of prenatal diagnosis.

Program Nr: 960 from the 1999 ASHG Annual Meeting

Chromosome 8p rearrangements are a cause of prenatal conotruncal cardiopathies. *P.L. Eydoux[1], O. Dupuy[1], J. Wirth[2], N. Collot[1], A. Azancot[3], C. Baumann[3], S. Magnier[4], E. Vuillard[3], J.F. Oury[3], P. Blot[3], C. Nessmann[1]*. 1) Lab De Biol du Development, Hosp Robert-Debre, Paris, France; 2) Max-Planck Institute for Molecular Genetics, Berlin, Germany; 3) Obstetrics-Gynecology, Hosp Robert-Debre, Paris, France; 4) Cardiology, Hosp Robert-Debre, Paris, France.

Conotruncal malformations are a frequent clinical feature of chromosome 22q11.2 microdeletion and other anomalies such as chromosome 10p13 microdeletion. Chromosome 8p rearrangements have also been reported as a possible cause of these cardiopathies. We report two patients with a conotruncal malformation detected through ultrasound examination, and a rearrangement of chromosome 8p. In one case, an amniocentesis was performed because of a thickened nuchal fold at 15 weeks of gestation. The karyotype was normal, and an echocardiography showed a regular form of tetralogy of Fallot. No microdeletion of chromosome 22q11.2 was detected. After birth, the cardiac malformation was confirmed, and developmental delay and a cranio-facial dysmorphism were noted. Blood karyotyping showed an excess of the short arm of chromosome 8; whole chromosome painting indicated an intrachromosomal rearrangement. Parental karyotypes were normal. Using YAC probes, a deletion was detected in band 8q23. Clinical and cytogenetic findings are thus compatible with the recombinant chromosome 8 syndrome. In the other patient, intra-uterine growth retardation and a cardiac malformation were detected at 22 weeks. Prenatal echocardiographic diagnosis was a double outlet right ventricle. Amniotic fluid cells karyotyping showed an excess of the short arm of chromosome 8; parental karyotypes revealed a translocation in the mother (46,XX,t(2;8)(q34;p22)). Thus, the fetus had the der(8) of maternal origin, with partial trisomy of chromosome 2q and partial monosomy of chromosome 8p. Termination of pregnancy was denied by the parents, and the pregnancy is still ongoing. Chromosome 8p deletions should be emphasized as a possible cause for conotruncal cardiac malformations. Molecular cytogenetic studies will be useful for prenatal diagnosis of this condition, and for delineation of the critical region of chromosome 8 involved in conotruncal malformations.

Program Nr: 961 from the 1999 ASHG Annual Meeting

Familial Lethal X-linked Arthrogryposis Syndrome in an Extended Mexican Kindred: Results from Fetal Ultrasound, Autopsy and Molecular Investigations. *J.C. Ferreira[1], P. Dar[1], N. Tenney[2], S.M. Carter[1], L.L. Baumbach Reardon[3], S.J. Gross[1]*. 1) Montefiore Med Ctr, Bronx, NY; 2) Woodside FHC, Woodside, NY; 3) Univ Miami School Med, Miami, FL.

Background: Pena-Shokeir syndrome is a lethal arthrogryposis syndrome that seems to be secondary to a motor neuron disorder (MIM 208150) or to developmental brain anomalies (MIM 214150). Inheritance is consistent with autosomal recessive transmission. However, some cases suggesting X-linked transmission have also been described, most have been related to a motor neuron disorder (MIM 301830) with possible linkage to Xp11-Xq11(Hum Mol Genet.,4(7):1213-6,1995). Additionally, a few families have been reported in which only males were affected with an arthrogryposis secondary to brain anomalies, suggesting yet another X-linked syndrome(MIM 300073). We describe a family with males presenting with a lethal arthrogryposis syndrome, secondary to brain anomalies. X-linked transmission is strongly suggested.

Case:: The proband, a 27 yo, G6P4 of Mexican descent had two sons who died perinataly. Both were affected with an arthrogryposis syndrome and brain anomalies. Family history is significant for two stillborn siblings, one with clubbed feet. In the current pregnancy the fetus,46XY, was found sonographically at 19 weeks to be growth restricted with clubbed feet, clenched hands and cerebellar hypoplasia. Based on these findings, the pregnancy was terminated. Fetal autopsy revealed severe growth restriction and multiple digit and limb contractures. The spinal cord was normal but adequate evaluation of the brain was not possible. Blood samples from the entire family are being collected and being used to examine potential linkage to Xp11.1-3 region referenced above.

Conclusion: This family reinforces the hypothesis that X-linked form of arthrogryposis exists. The possible allelic nature of this syndrome with previously reported cases is being examined, and our findings will be reported.

Program Nr: 962 from the 1999 ASHG Annual Meeting

Multiple congenital anomalies in a fetus with male and female cell lines: a chimera? *K. Filkins[1], N. Rao[2], W. Robinson[3], L. Chen[1], T. Markuson[1], S. Poggi[1], F. Kaselonis[4], S. Cederbaum[4].* 1) Dept OB/GYN, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Pathology, Univ California, Los Angeles, CA; 3) B.C. Research Institute for Children's & Women's Health, Univ British Columbia, Vancouver, BC, Canada; 4) Dept Pediatrics, Univ California, Los Angeles, CA.

Prenatal expanded MSAFP screening done in a 31 year old G1 P1 A6 yielded a screen positive result for Trisomy 18. The patient was referred for genetic counseling but she declined amniocentesis because she would not consider termination of the pregnancy even for a lethal condition. Ultrasound evaluation at 22 weeks revealed growth consistent with dates except for a week lag of the abdominal circumference. Severe oligohydramnios along with limb posturing (possibly secondary to the oligohydramnios) was noted. The nuchal fold was increased to 7-10 mm. The fetal stomach and bladder were eventually visualized but the cardiac and facial evaluations were hampered due to lack of fluid. At 28 weeks gestation the abdominal circumference lagged 3 weeks and the femur length 4 weeks.

Chromosome analysis revealed two cell lines (approximately 50:50): 46,XY, der(16) 16ps and 46,XX. It was initially thought that the 46,XX line might represent maternal cell contamination, but the der(16)line was of maternal original and was not in the female cell line. Therefore, the likelihood of a chimeric 46,XY/46,XX could not be ruled out. At 38 weeks gestation a 2000 gm fetus was delivered with ambiguous genitalia,very small eyes with down slanting palpebral fissures, short sternum and profound limb abnormalities. The infant expired within 24 hrs. Further studies are pending to determine parental origins of the two cell lines and these will be reported along with the possible mechanisms for this abnormality.

Program Nr: 963 from the 1999 ASHG Annual Meeting

An assembly mutation in cartilage oligomeric matrix protein causes delay in skeletal development. *K.G. Gaiser*[1,2], *W.A. Horton*[1,2]. 1) Research Unit, Shriner's Hosp for Children, Portland, OR; 2) Dept. of Molecular and Medical Genetics, OHSU, Portland, OR.

Cartilage oligomeric matrix protein (COMP) is a pentameric, non-collagenous glycoprotein found abundantly in cartilage, tendon, ligament and synovium. Each COMP pentamer is composed of five identical monomers, which are assembled by a coiled-coil domain. Mutations within the COMP gene have been found to cause two types of dominantly inherited chondrodysplasias, pseudoachondroplasia (PSACH) and multiple epiphyseal dysplasia (MED). These disorders are characterized by mild to severe short stature and early onset osteoarthritis. Cartilage samples of PSACH and MED patients show an accumulation of material in the chondrocyte rough endoplasmic reticulum (RER). The effects of COMP mutations in these patients suggest that COMP function is essential for normal bone growth. However, there is a limited understanding of how COMP is assembled, its functional role(s) and how it is involved in bone development. In an attempt to understand the function of COMP, transgenic mice have been generated, which have a mutation in COMP assembly. By overexpressing a truncated monomer containing the coiled-coil domain, a dominant negative mutation has been created. The transgenic F1 offspring appear slightly smaller in size compared to the wild-type. Affected mice seem to be less active, but otherwise healthy and fertile. Further studies to characterize this phenotype are underway.

Program Nr: 964 from the 1999 ASHG Annual Meeting

Assessment of the genetic influence on human sperm morphology: A twin study. *N. Gursoy[1], J. Winters[1, 3], C. Clark[2], H. Maes[1], C. Jackson-Cook[1]*. 1) Dept. of Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Department of OB/GYN, Virginia Commonwealth University; 3) Case Western University and University Hospitals of Cleveland, Ohio.

Spermatogenesis is a very complex process involving multiple mitotic divisions, genetic recombination, two meiotic divisions and extreme morphologic changes. This unique process of differentiation is believed to be under genetic regulation by "unknown" genes. To assess the genetic influence on human sperm morphology and its possible association with sperm aneuploidy levels we evaluated sperm morphology and aneuploidy frequencies in 23 monozygotic (MZ) and 5 dizygotic (DZ) twin pairs (a total of 56 males). The ages of the donors ranged from 26 to 59 years. The zygosity of the twin pairs was confirmed using a panel of six highly polymorphic markers. Morphology of spermatozoa was assessed according to WHO guidelines. Aneuploidy levels for chromosomes X, Y, 3, 7, 8, 9, 15, 17, and 18 were determined using tri-color FISH. The analyses were performed blindly. There was no significant correlation between the proportion of morphologically abnormal spermatozoa and the proportion of aneuploidy in a male. However, a very significant correlation was found between genetically identical MZ co-twins for sperm morphology ($r = 0.931$). To determine the variation between two ejaculates within a male, sperm morphology analyses were repeated in a subset of 28 individuals (with > a 2 months interval). No significant differences in sperm morphology were noted between the first and second ejaculates in these men. To quantify the contribution of genetic and/or environmental factors to morphology, model fitting was performed using the structural equation modeling program Mx. This path analysis showed highly significant family resemblance for sperm morphology, most likely due to additive genetic factors. The very significant correlation between genetically identical twins as well as the results of path analysis suggests a strong genetic influence on sperm morphology. Studies of additional twins will allow us to better quantify the contribution of the genetic and/or shared environmental factors influencing sperm morphology.

Program Nr: 965 from the 1999 ASHG Annual Meeting

The Effect of Gravidity and Maternal Age on The First Trimester Down Syndrome Biochemical Markers Free-b **hCG and PAPP-A.** *T.W. Hallahan[1], D.A. Krantz[1], P.D. Buchanan[2], J.W. Larsen, Jr.[3], J.N. Macri[1].* 1) NTD Laboratories, Huntington Stat, NY; 2) GeneCare Medical Genetics Center, Chapel Hill, N.C; 3) The George Washington Univ. Medical Center, Washington, D.C.

Historically, maternal factors such as weight, ethnicity and diabetic status have been used to adjust second-trimester biochemical markers to refine the screening process and improve false positive and detection rates. The effects of maternal age and gravidity on second-trimester biochemical markers are small and generally do not need to be taken into account. To determine the effect of gravidity and maternal age on first-trimester biochemical markers, dried blood specimens from 1884 patients between 8w2d and 13w6d gestation were analyzed for free-b hCG and PAPP-A. The table shows median weight adjusted MoM levels of free-b hCG and PAPP-A vs. gravida and maternal age.

	Gravida				Age		
	1	2	3	>=4	<=30	30-34	>=35
free-b	0.97	0.99	1.08	1.04	0.95	1.00	1.04
PAPP-A	0.99	0.99	1.02	1.03	0.95	0.99	1.07

The rank correlation coefficient of free-b with gravidity and age was 0.05 and 0.04 respectively, while for PAPP-A they were 0.04 and 0.10, respectively. Only the correlation of PAPP-A and age was statistically significant (P<.001), however this association was quite small, especially in light of the association of gravida and age. In conclusion, although maternal age plays a significant role in Down syndrome screening as a major factor in determining prior risk, maternal age and gravidity have little or no effect on the serum levels of first trimester biochemical Down syndrome screening markers.

Program Nr: 966 from the 1999 ASHG Annual Meeting

High level *SOX9* expression during development of the human embryonic pancreas is associated with abnormal islet formation in a case of Campomelic Dyplasia. *N.A. Hanley[1], K. Piper[1], S.G. Ball[2], M. Clement-Jones[1], T. Strachan[1], J.W. Keeling[3], D.I. Wilson[1,2].* 1) School of Biochemistry & Genetics; 2) Dept. of Medicine, University of Newcastle, Newcastle upon Tyne, UK; 3) Department of Pathology, Royal Hospital for Sick Children, Edinburgh, UK.

SOX9 is a high mobility group (HMG) domain transcription factor that is important for chondrogenesis and testicular determination. Human mutations in the *SOX9* gene result in the haploinsufficiency disorder, Campomelic Dysplasia, characterised by severe skeletal malformations and male-to-female sex reversal. Although not uniformly fatal *in utero*, death due to respiratory problems almost always occurs prior to 5 years.

The pancreas develops as ventral and dorsal outgrowths of the foregut endoderm. During human embryogenesis, we show that *SOX9* is expressed from the inception of pancreas development (26 days post-conception) at levels comparable to the developing skeleton and testis. This expression throughout the entire organ decreases during the second trimester and, in particular, is seemingly extinguished within cells that have differentiated towards an endocrine lineage.

Analysis of the pancreas from a neonatal case of classical Campomelic Dysplasia shows that gross morphology is intact, however, despite the presence of all major cell types, immunocytochemistry reveals an abnormal histological appearance with disordered islet structure. In the absence of glucose intolerance, the insulin-glucagon core of islets appears smaller than those of normal controls, with a preponderance of outlying cells positive for pancreatic polypeptide.

The pancreatic phenotype of this neonate and the high level of pancreatic *SOX9* expression during normal human embryogenesis suggest a hitherto unrealised and potentially important role for this transcription factor during human pancreas development. High mortality during early life makes it difficult to interpret a clinical lack of glucose intolerance. A role for *SOX9* in determining beta cell mass, in addition to islet formation, therefore cannot be excluded and warrants further investigation.

Program Nr: 967 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of cutis laxa by fetal echocardiography. *P. Himes[1], L. Linck[2], P. Silberberg[3], M.J. Rice[4], L. Hankenson[5]*. 1) Dept Mol & Medical Genetics, Oregon Health Sci Univ, Portland, OR; 2) Kaiser Permanente, Clackamas, OR; 3) Dept Radiology, Oregon Health Sciences Univ, Portland, OR; 4) Dept Cardiology, Oregon Health Sciences Univ, Portland, OR; 5) Portland, OR.

Cutis laxa is a heterogeneous condition associated with lax skin and, frequently, systemic abnormalities involving the lungs, arteries and urinary tract. Cutis laxa has been associated with lysyl oxidase deficiency and elastin mutations. Autosomal dominant, autosomal recessive and X-linked recessive inheritance have been reported, but it may also be an acquired condition. When present in the newborn period, the condition is usually due to autosomal recessive inheritance. In the absence of a positive family history or a known mutation in the elastin gene, definitive prenatal diagnosis may not be possible. We report a case of prenatal diagnosis of cutis laxa by fetal echocardiography at 23 weeks gestation in a pregnancy known to be at risk. The couple's first child had been diagnosed with cutis laxa at birth. Associated findings included an atrial septal defect and pulmonary artery stenosis, a markedly tortuous aorta, diverticuli of the esophagus and bladder, bilateral inguinal hernias, and bronchomalacia. Laboratory studies included normal serum copper and ceruloplasmin levels; a urine pyridinoline assay of collagen cross-links showed a marked increase in pyridinoline relative to deoxy-pyridinoline. She died when seven months old. In the subsequent pregnancy, fetal echocardiography was performed at 23 weeks' gestation which showed an atrial septal aneurysm, mild tricuspid regurgitation and a tortuous aortic arch. Lax skin with excessive folds was noted at birth and the child was diagnosed with cutis laxa. Elevated right ventricular pressure, tricuspid insufficiency, branch pulmonary stenosis and tracheobronchomalacia were present. Interestingly, a urine pyridinoline assay was normal. He developed severe pulmonary emphysema and died when three months old. This case demonstrates the usefulness of fetal echocardiography for prenatal diagnosis of some cases of cutis laxa.

Program Nr: 968 from the 1999 ASHG Annual Meeting

Expression of the Rieger syndrome Pitx2 protein in mouse development. *T. Hjalt[1], E.S. Semina[1], B.A. Amendt[2], J.C. Murray[1]*. 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept Physiology, Univ Iowa, Iowa City, IA.

The Rieger syndrome, an autosomal dominant disorder involving ocular, dental, and umbilical defects is caused by mutations in PITX2, a Bicoid type homeobox protein. Moreover, Pitx2 is involved in the Nodal/Sonic hedgehog pathway that determines left/right polarity. Mouse Pitx2 mRNA is expressed in eye, tooth and umbilicus consistent with the human Riegers phenotype. It is also asymmetrically expressed on the left side in the early lateral plate mesoderm, and later to the left in structures of the gut and the heart. In this report we demonstrate a 32 kDa polypeptide on western blots of nuclear extracts from a rat pituitary cell line, using a Pitx2 specific antibody (designated P2R10). The rabbit anti human P2R10 was specific for a region in the N-terminus, preceding the homeodomain. The epitope is conserved between human, mouse, and Xenopus Pitx2. We describe also expression of the Pitx2 protein in mouse. Pitx2 protein immunostaining was detectable during the development of the eye, tooth, umbilicus, and also in the pituitary, heart, gut, and limb. In the developing eye, Pitx2 protein was expressed in the corneal ectoderm, and in late stages in the iris. We detected asymmetric expression of Pitx2 protein in the early heart and gut. Pitx2 was also expressed in the septum primum of the heart. We further show nuclear localization for transiently transfected PITX2, as well as for endogenously expressed PITX2 in a pituitary cell line. The Rieger syndrome mutation T68P was also shown to be nuclear localized. These localizations are consistent with the Rieger phenotype and support a role for PITX2 in cardiac development as well.

Program Nr: 969 from the 1999 ASHG Annual Meeting

Prenatal Diagnosis of Desbuquois Syndrome. *W.A. Hogge[1,2], T. Prosen[1,2], E. McPherson[1], L. Hill[2], K. Lain[2].* 1) Dept Genetics, Magee Womens Hosp, Pittsburgh, PA; 2) Dept OB/GYN, Magee Womens Hosp, Pittsburgh, PA.

We present a case of Desbuquois Syndrome diagnosed prenatally in a family without a prior history of the disorder. A 29 year old Middle Eastern G2 P1 was referred for evaluation after a routine dating ultrasound at 21 weeks was suspicious for skeletal dysplasia. Long bones measured <5%ile. The ultrasound was also notable for bilateral clubbed feet. Family history was unremarkable without a history of skeletal dysplasia. Consanguinity was denied. A detailed ultrasound at our institution revealed shortening of all long bones (<5%ile) as well as shortening of the fetal foot. The ribs measured at the 50%ile for gestational age and the chest circumference was at the 10th to 25th percentile. Bilateral syndactyly of the third, fourth, and fifth digits of the hands was suspected. The hands also had a significant separation of the second and third digits. Bilateral clubbed feet with a rocker bottom appearance were noted. The right foot was thought to have polydactyly and the toes of both feet appeared unusually long, except for the great toes which appeared shortened. The fetal eyes protruded from the orbits. Fetal echo was normal. Karyotype was 46,XX. Cytogenetic studies for Robert's Syndrome were negative. A repeat ultrasound 13 days later had additional findings of polydactyly of both feet. The couple opted to terminate the pregnancy and underwent labor induction at 23 weeks gestation. Autopsy findings included short long bones of both the upper and lower extremities; short, stubby, tapered fingers; clinodactyly of the 5th fingers bilaterally; short, stubby, great toes bilaterally with wide space between 1st and 2nd toes; abnormal palmar creases; short, broad neck; micrognathia & hypoplastic lungs. X-rays revealed supernumerary ossification center between the proximal phalanx and second metacarpal of the index finger. Conclusion: We suspected the diagnosis based on the extreme shortening of the long bones coupled with the abnormal positioning of the fetal hands. The polydactyly, in retrospect, likely reflected the presence of supernumerary ossification centers. These may be clues to the prenatal diagnosis of this rare autosomal recessive skeletal dysplasia.

Program Nr: 970 from the 1999 ASHG Annual Meeting

Are there better antibodies than CD71 for the detection of fetal nucleated cells out of maternal blood? *H. Hohmann[1], S. Michel[1], W. Reiber[2], M. Günther[3], T. Graf[4], U. Claussen[1], F. von Eggeling[1]*. 1) Institute of Human Genetics and Anthropology, University of Jena, Jena, Germany; 2) Private Gynecologist, Jena, Germany; 3) Department of Obstetrics, University of Jena, Germany; 4) Albert Einstein College of Medicine, New York, USA.

The availability of fetal cells from the maternal peripheral blood opens up the possibility for a non-invasive prenatal diagnosis. Up to now this prospect is hampered by the fact that there are no highly fetal specific antibodies. Various studies have been done concerning the identification of specific cell surface antigen markers to facilitate the specific isolation of fetal nucleated erythrocytes (e. g. CD71, glycophorin A, CD36). In the present study four up to now untested monoclonal antibodies 2G5, 3F9, EPO-R and Flk1 were analysed in view of their effectiveness to stain fetal nucleated cells. 2G5 and 3F9 are avian cell specific antibodies, which seem to be suitable in human because they can differentiate between fetal and adult nucleated erythrocytes. EPO-R is a monoclonal antibody against the erythropoeitin receptor. Flk1 is a monoclonal antibody against the fetal liver kinase 1 and is required for the embryonic development of vascular endothelial and hematopoietic cells. As reference the commonly used antibody against the transferrin receptor CD71 was constituted. 20 ml of peripheral blood from 40 women carrying a male fetus were collected in the 16th to 28th week of pregnancy. Mononucleated cells, enriched by density gradient, were stained with one of the four antibodies and isolated with magnetic activated cell sorting (MACS). Succeeding fluorescence in situ hybridisation (FISH) with chromosome X and Y centromere probes allowed to analyse the origin of the cells. For evaluation 500 nuclei per case (n) were examined. The antibody 3F9 detected 0.2 cells on average (n=5), 2G5 1.2 (n=11), EPO-R 1.6 (n=10) and Flk1 1.9 cells (n=8) on average with fetal specific Y-positive hybridisation signals. The antibody against CD71 (n=6) used as reference gave no Y-specific signals. Considering these results the tested antibodies, especially Flk1 seem to be more effective in detecting fetal cells than the CD71 antibody.

Program Nr: 971 from the 1999 ASHG Annual Meeting

Use of fetal cells in maternal blood for FISH - and PCR - based prenatal diagnosis . *W. Holzgreve[1], X.Y. Zhong[1], C. Troeger[1], P. Miny[2], S. Tercanli[1], S. Hahn[1]*. 1) Dept. OB/GYN, University of Basel, Basel, Switzerland; 2) Dept. Human Genetics, University of Basel, Basel, Switzerland.

Aim: Our laboratory has pioneered the use of Magnetic Cell Separation (MACS) for the enrichment of fetal cells from the blood of pregnant women. As participants of the NICHD Fetal cell isolation study (NIFTY), we are currently testing the efficacy of using such cells for the prenatal diagnosis of fetal aneuploidies. We have further extended upon this study by examining single enriched fetal cells isolated by micromanipulation by single cell PCR for Mendelean disorders.

Methods: Fetal cells are enriched from peripheral blood samples (15 ml) obtained from pregnant women (12 - 16 weeks gestation) by the use of miniMacs columns and either anti-CD71 or anti-glycophorin A. Fetal cells are identified either by multicolor FISH or by single cell PCR for fetal specific loci such as rhesus D or the SRY gene.

Results: In an examination of 520 samples by XY FISH, we were able to correctly determine fetal cells in 57 percent of the cases. When two or more XY positive cells were used as being indicative of male fetal sex, specificities of over 95 percent could be attained. In an examination of 14 samples obtained from rhesus D negative women, both the fetal sex and rhesus D genotype were correctly determined in all instances by the use of multiplex PCR on single isolated fetal erythroblasts.

Conclusion: We have shown that fetal cells can be reliably enriched from maternal blood, and that they can be used for the detection of specific chromosomes by FISH and for the analysis of fetal genetic loci by single cell PCR with specificities superior to current non-invasive means.

Program Nr: 972 from the 1999 ASHG Annual Meeting

Successful pregnancy in a patient with severe deforming osteogenesis imperfecta (O.I.). *L. Hudon[1], G.N. Willey[2], V. Enciso[3], S. Longmire[2], I.B. Van den Veyver[1,3]*. 1) Dept of Obstetrics and Gynecology; 2) Dept of Anesthesiology; 3) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

There are few reports of successful pregnancy in severe deforming O.I. We describe here the pregnancy outcome of a wheelchair-bound patient with severe O.I. and extreme short stature, and make recommendations for a multidisciplinary approach in these cases. The proband was born with fractures and was diagnosed with severe O.I., likely type III. She sustained multiple fractures requiring surgical intervention throughout childhood. The patient presented at 12 weeks gestation. Her height and weight were 117 cm and 19 kg and she had severe scoliosis and long bone deformities. Prenatal diagnosis was declined. The following specific risks were anticipated: cardiopulmonary compromise with advancing gestation due to short stature and thoracic deformities; preterm labor and delivery; poor maternal and fetal weight gain and defective nutrition; increased anaesthetic risk at delivery. A baseline echocardiogram and pulmonary function tests were normal for her stature. Optimal nutrition resulted in a 15 kg weight gain. Weekly steroids for fetal lung maturation were started at 24 weeks. Delivery by cesarean section was planned. Based on the results of a CT scan with 3 dimensional reconstruction of the lumbar spine regional anesthesia was found to be technically impossible. Baseline and pre-operative chest X-ray, arterial blood gas and echocardiogram were obtained and were normal. The patient presented at 30 4/7 weeks gestation in active labor. Elective fiberoptic awake intubation was performed because of difficult airway passage. A healthy male infant weighing 1120 g with no apparent fractures was delivered by classical cesarean section. The patient was discharged after 3 days in good condition. The newborn was discharged with no apparent sequelae and no clinical and radiological evidence of OI. Adult female patients severely affected with genetic conditions often desire pregnancy. This report illustrates that this is possible despite significant risks if potential complications are anticipated and managed in a tertiary care center by a team approach.

Program Nr: 973 from the 1999 ASHG Annual Meeting

Prenatally diagnosed isolated Dandy-Walker variant associated with 4p- and 6p- karyotypes. *L. Hunnisett[1,5], A. Toi[1,2,5], E. Winsor[1,3,5], S. Blaser[4,5], D. Chitayat[1,5]*. 1) Prenatal Diagnosis Program, The University Health Network; 2) Department of Diagnostic Imaging, The University Health Network; 3) Department of Laboratory Medicine, University Health Network; 4) Department of Radiology, Hospital for Sick Children; 5) University of Toronto, Toronto, Ontario, Canada.

Dandy-Walker Variant (DWV) is a posterior fossa anomaly with partial agenesis of the cerebellar vermis. The etiology is heterogenous and the prognosis is difficult to predict. In the largest reported series (Estroff, et.al., 1992) an abnormal karyotype was found in 5/17; however, other sonographic abnormalities were detected in all of them. We report two fetuses, with isolated partial agenesis of the cerebellar vermis who were found to have abnormal karyotypes: 4p- and 6p-. Case 1: A 31-year-old G1P0 woman of Fillipino descent presented at 18.7 weeks gestation with query isolated DWV. Fetal brain MRI at 24 weeks gestation confirmed partial hypoplasia of the cerebellar vermis. Fetal karyotype was 46,XX,del(4)(p16.1). The pregnancy was terminated and vermian hypoplasia was confirmed at autopsy. In addition, autopsy revealed persistent left superior vena cava, abnormal thyroid gland and facial features consistent with Wolf-Hirschhorn syndrome. Parental karyotypes were normal. Case 2: A 26-year-old G1P0 woman of German descent presented at 18 weeks gestation with query isolated DWV. Subsequent ultrasound examinations confirmed isolated partial agenesis of the vermis and a small posterior fossa cyst. Fetal karyotype was 46,XY, del(6)(p25). The pregnancy was terminated and the autopsy report is pending. Parental karyotypes were normal. DWV is not a rare finding on fetal ultrasound, however not much is known about the etiology and prognosis. Although fetuses with isolated DWV usually have normal karyotypes and a good prognosis, our cases suggest that chromosome analysis should be considered even in the absence of other ultrasound abnormalities.

Program Nr: 974 from the 1999 ASHG Annual Meeting

Embryonic Alphafetoprotein Expression: Significant Human and Mouse Differences. *E.A. Jones[1,2], M. Clement-Jones[1], S. Lindsay[1], T. Strachan[1], S. Robson[1], D.I. Wilson[1,2].* 1) School of Biochemistry and Genetics, University of Newcastle upon Tyne, Newcastle upon Tyne, Tyne and Wear, UK; 2) School of Clinical Medical Sciences, University of Newcastle upon Tyne, Newcastle upon Tyne, Tyne and Wear, UK.

PURPOSE : Alphafetoprotein (AFP) is a major serum protein in early fetal and embryonic life. It is initially produced by the yolk sac and later by hepatocytes. Expression is down regulated at birth but can be re-expressed in tumors such as hepatocellular carcinoma. However, despite extensive investigation, its function is still unknown. In order to define when and where AFP is produced during the embryonic period we have investigated the expression of AFP in mouse and human embryos.

METHODS : We have used human embryos (26-52 days post ovulation - dpo) from the Newcastle Human Embryo Collection and mouse embryos (9ed-13ed) for tissue in situ hybridisation using ^{35}S labelled riboprobes for AFP.

SUMMARY OF RESULTS : AFP is expressed in the hepatic diverticulum in mice and humans as it differentiates from the foregut endoderm and continues in hepatocytes throughout the embryonic period. AFP is also expressed in the yolk sac and gastrointestinal tract throughout the embryonic period. There is weak pancreatic expression in 41 dpo human embyos and 12ed mouse. However, in human embryos there were addditional sites of expression not observed in murine embryos. At 32 dpo the mesonephric duct expressed AFP and later the mesonephric tubules also expressed AFP. Expression was not seen in the human metanephros.

CONCLUSION : The major sites of AFP expression in man and mouse are hepatocytes, yolk sac, gastrointestinal tract and pancreas. Significantly, AFP is expressed in the mesonephric duct and tubules in humans but not in the mouse.

Program Nr: 975 from the 1999 ASHG Annual Meeting

Results of cytogenetic analysis of 560 amniotic fluid cell cultures (amniocenteses) performed in Iran. *M.H. Karimi-Nejad, A. Karimi-Nejad, N. Lashgarian.* Pathology & Genetics Ctr, Tehran, Iran.

From Nov. 1989 until 20 June 1999, more than 900 prenatal tests have been performed in this center for the following purposes: 598 cases for chromosomal abberation, 245 for Hemoglobinopathy, 41 for Inborn Errors of Metabolism, 11 cases for Tri- Nucleotide repeats, 7 for Muscular disorders, 5 for Skin lesions.

The indication and results of cytogenetic analysis of 560 amniotic cell cultures performed mostly at 13-16 wks of gestation are being reported. 546 (97.5%) fetuses were cytogenetically normal, or had balanced karyotypes. 14 (2.5%) had unbalanced karyotypes, and 2 fetuses were found to have major abnormalities, one with anencephaly detected by measurement of Alpha feto protein levels in amniotic fluid and ultrasonography, and the other with a full mutation at the FMR1 locus detected by molecular techniques. The unbalanced karyotypes include 2 cases each of trisomy 21, trisomy 18, Triple X, 47,XXY, and mosaicisms; and 4 cases of various chromosomal abnormalities.

245 tests were performed for women 35 years of age or over; 6(2.45%) abnormal karyotypes were detected, which shows a 6 fold increase over the general population. This risk was even much higher 2/27 (7.4%) for those parous aged>35 y with previous history of offspring with chromosomal aberrations.

5 of 34 (14.7%) fetuses whose parent was carrier of a balanced chromosomal translocation or a small chromosomal marker (in one case), had unbalanced chromosomal aberrations. 15 and 14 of the remainder revealed normal and balanced Karyotypes similar to their parents respectively.

There were 7 cases of spontaneous abortion within 4 wks after amniocentesis, one of which was a case of 46,XY,t(14;21),+18. Excluding this case, the rate of abortion 6/560 (1.07%) was quite below the expected rate of 2.1% for spontaneous abortion in the 2nd trimester of pregnancy. To the best of our knowledge the first chromosomal study of amniotic fluid cells in Iran was in November 1989, and at our center.

Program Nr: 976 from the 1999 ASHG Annual Meeting

Numerical abnormalities for chromosomes 1, 13, 16, 18, 21, 22, X and Y from 59 preimplantation embryos using mulit-color fluorescence *in situ* hybridization. *W.G. Kearns[1,2,3], M. Franzitta[1], S. Gitlin[2], M.W. Stacey[1], S. Phillips[2], W.E. Gibbons[2]*. 1) Center for Pediatric Research; 2) Jones Inst for Reproductive Med, EVMS, Norfolk, VA; 3) Inst. Med Genet. Johns Hopkins University School of Medicine, Baltimore, Maryland.

Objective: This study determined aneuploidy in blastomeres from 59 cleaving preimplantation embryos in which two pronuclei were observed 1 day after insemination. With IRB approval, embryos were donated by patients after informed consent was obtained. **Study Design:**Multi-probe, multi-color FISH was performed on blastomeres to diagnose aneuploidy for chromosomes 1,13,16,18,21,22,X and Y. Materials and **Methods:**Blastomeres from 6-8 cell preimplantation embryos were isolated. Individual blastomeres were dropped onto microscope slides and fixed. For all embryos, all available blastomeres were studied. First, simultaneous five-probe, four-color FISH was performed for chromosomes 13,18,21, X and Y using direct labelled chromosome specific alpha satellite or contig DNA using a 2 hour hybridization protocol. Second, three-probe, three-color FISH was performed for chromosomes 1, 16, and 22 using direct labelled alpha satellite DNA. Images were captured using a cooled CCD camera controlled by a MacIntosh computer using Image and FISH analysis software. **Results:**Twenty-six of 59 (44%) embryos were diploid. Four of 59 (6.8%) embryos were mosaic. Two trisomy 18's, one trisomy 13 or 21, and one XXY mosaic were observed. Three of 59 (5.1%) embryos were classified as chaotic. Tweny-four of 59 (40.7%) embryos, diagnosed by the analysis of just one blastomere, were either aneuploid or mosaic. Five trisomy 13 or 21's, three trisomy 18's, three Turner syndrome, one Klinefelter syndrome, two monosomy 13 or 21's, five trisomy 16's, one trisomy 1, and four trisomy 22's were observed. One embryo (1.7%) was triploid and one mis-diagnosis for a gonosome occurred (1.7%). **Conclusions:**Of the 59 embryos evaluated for preimplantation diagnosis, 54% were aneuploid, mosaic, chaotic or triploid. FISH analysis for chromosomes 1, 16, and 22 identified an additional 12.5% aneuploid embryos not detected when analyzed for chromosomes 13,18,21,X and Y.

Program Nr: 977 from the 1999 ASHG Annual Meeting

The C. elegans homologues of Ataxin-2 and Ataxin-2-Binding-Protein are essential genes in early development.
T.R. Kiehl, H. Shibata, S.M. Pulst. Div. of Neurology Cedars-Sinai Medical Center, Los Angeles, CA.

Ataxin-2 , the gene product of the autosomal dominant Spinocerebellar Ataxia Type 2 (SCA2), is a protein of unknown function. Ataxin-2 interacts with a A2BP1, a member of a novel family of putative RNA-binding proteins. Since Ataxin-2 as well as A2BP1 are evolutionarily conserved we investigated the expression pattern and function in C. elegans. The human SCA2 gene has a 19.3 % amino acid identity to its homologue in C.elegans (CeAtaxin-2). Likewise, Ataxin-2-Binding Protein 1 (A2BP1) is 29.8 % identical to the homologous C.elegans protein (CeA2BP1). We studied the expression pattern of CeAtaxin-2 using the CeAtaxin-2 promotor coupled with a GFP expression vector. CeAtaxin-2 was widely expressed in the adult worm with strong expression in muscle. It was also heavily expressed in worm eggs. In order to elucidate the function of CeAtaxin-2 and CeA2BP1, we conducted RNA interference (RNAi) studies. RNAi leads to an effective knockout of the targeted gene, presumably by specific degradation of native mRNA. The interfering double-stranded RNA was introduced into larval L4 stage worms of the N2 strain by microinjection or soaking. Microinjection was carried out as a two-gonad injection. Soaking involved leaving the worms in in dsRNA-solution for 24 hours. In line with previous RNAi studies, microinjection was more effective than soaking. DsRNA representing the full length CeAtaxin-2 gene resulted in an early lethal phenotype in the offspring of all 40 microinjected worms. RNAi for the full length CeA2BP1 showed a similar arrest in development when 40 worms were injected. However, no effect was observed with either construct on the parental animals. We conclude that both CeAtaxin-2 and CeA2BP1 are essential cellular genes in the early development of C.elegans. Both are highly conserved in mammals. The fact that both genes give an early lethal phenotype when targeted by RNAi underlines previous findings regarding the interaction of Ataxin-2 and A2BP1.

Program Nr: 978 from the 1999 ASHG Annual Meeting

RHD/CE genotyping by polymerase chain reaction using sequence-specific primer in RHD negative Korean donors. *Y.T. Kim[1,4], S.B. Kim[4], Y.H. Lee[1], S.H. Park[3], Y.S. Whang[5], D.H. Seo[5], Y.J. Cho[2].* 1) Dept. of Obstetrics and Gynecology, College of Medicine, Korea Univ., Anam Hospital, Seoul, Korea; 2) Dept. of Clinical Pathology, College of Medicine, Korea Univ., Anam Hospital, Seoul, Korea; 3) Department of Pediatrics, College of Medicine, Korea Univ., Anam Hospital, Seoul, Korea; 4) Graduate School of Biotechnology, Korea Univ., Seoul, Korea; 5) Research Institute for Blood Transfusion, The Republic of Korea National Red Cross, Seoul, Korea.

Antigens of Rh blood group system are considered to be encoded on chromosome 1p34-36 by 2 genes, RHD and RHCE. In Caucasians, almost all RhD negative people have deletion in RHD gene, but in Orientals, such as the Japanese, up to 27.7% of RhD negative donors retained the RHD gene.This study was to confirm the incidence of RHD gene deletion in RhD negative Korean donors. After phenotyping 250 RhD positive and 116 negative Korean donors using polyclonal anti-C,c,E,e,D, we performed RCR-SSP to determine the deletion in exon 3,4,5,6,7,9,10, intron4, and intron4-exon5 boundary.

Phenotypes of 250 RhD positive consisted of 107 CCee(42.4%), 93 CcEe(37.2%), 26 ccEE(10.4%), 21 Ccee(8.4%), 3 ccEe(1.2%) and 1 ccee(0.4%). In 116 RhD negative donors, the frequency of phenotypes was 62 ccee(53.5%), 35 Ccee(30.2%), 9 ccEe(7.8%), 6 CcEe(5.2%), 3 CCEE(1.7%), and 3 CCee(1.7%). After genotyping, 22 samples (22%: 22/101) from RhD negative donors revealed intact RHD gene. Deletion was 76(75.3%) in intron4-exon5 boundary, 74(73.3%) in intron 4, 72(71.3%) in exon 4, 67(66.3%) in exon 7, 63(62.4%) in exon 10, and 9 (8.9%) in exon 5, but no deletion was found in exon 3,6,9.

We also compared the deletion frequency in various RHCE phenotypes of RhD negative donors. Over 90% in ccee showed deletion in exon 4,7,10, and inton 4 except for exon 5(9.4%). About 70% was deleted in ccEe; about 45% in Ccee; about 40% in CcEe. In conclusion, our result could provide useful data for prenatal diagnosis in RhD negative Korean pregnant women.

Program Nr: 979 from the 1999 ASHG Annual Meeting

Genetic Susceptibility to Preeclampsia: Roles of Factor V Leiden and Lipoprotein Lipase mutations. *Y.J. Kim[1], J. Andrews[1], P. Peraud[1], R.A. Williamson[1], J.C. Murray[1], D.C. Merrill[2].* 1) University of Iowa, Iowa City, IA; 2) Wake Forest University, Winston-Salem, NC.

Previous studies have suggested an association of preeclampsia(PRE) with several genes involved in cardiovascular control. The objective of this study was to evaluate the association between PRE and the Factor V Arg506Gln (Factor V Leiden) and the lipoprotein lipase(LPL) Asp9Asn and -93G promoter mutations. DNA was extracted from whole blood or cheek swab of 320 preeclamptic patients and 260 controls (All Caucasians). Controls consisted of women who had undergone at least two term pregnancies unaffected by PRE. All samples were genotyped for all the polymorphisms using PCR of known allelic varients. Sequences were confirmed on an Applied Biosystems 373 DNA Sequencer. Results were analyzed with a X^2 contingency table. Seventeen of 310 women with PRE (5.5%) and 5 of 139 with severe PRE(3.6%) were heterozygous for the Leiden mutation compared with 12 of 254 controls (4.7%)(P=NS). Nine of 314 women with PRE (2.9%) and 5 of 141 with severe PRE (3.5%) were heterozygous for the lipoprotein lipase Asp9Asn mutation compared with 9 of 249 controls (3.6%). 15 of 306 women with PRE (4.9%) and 5 of 131 with severe PRE (3.7%)were heterozygous for the lipoprotein lipase -93G promoter mutation compared with 13 of 254 controls (5.1%). There were no significant differences between the groups for the lipoprotein lipase Asp9Asn mutation and -93G promoter mutation. No patients were homozygous for the Leiden mutation or the lipoprotein lipase mutations. There were also no significant differences identified when the genotype of the infant from the affected pregnancy was considered the case. Combining the rare variants for LPL Asp9Asn, LPL -93G promoter mutation, and Factor V Leiden (12.1% cases vs 11.3% controls) or stratifying the cases by severity did not affect significance. Our data suggest that carriers of the Factor V Leiden mutation, lipoprotein lipase Asp9Asn mutation, and -93G promoter mutation are not associated with an increased risk for preeclampsia. Additional analysis is being extended to family based controls, sib pairs, and new loci.

Program Nr: 980 from the 1999 ASHG Annual Meeting

Delineation of the paternal disomy 14 syndrome: Identification of a case by prenatal diagnosis. *J. Klein[1], L.G. Shaffer[2], C. McCaskill[2], L. Scheerer[1], C. Otto[1], D. Main[1], M. Thangaveul[3], J. Goldberg[1]*. 1) Prenatal Diagnosis, California Pacific Medical Ctr, San Francisco, CA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Genzyme Genetics, Orange, CA.

Uniparental disomy (UPD) may lead to a disease phenotype due to the effects of genomic imprinting or homozygosity of recessive alleles. We report a case of paternal isodisomy 14, the fifth reported to date. A G1P0 30 yo woman was referred for a positive maternal serum triple screen which predicted a 1/60 risk for Down syndrome. Ultrasound showed polyhydramnios, bilateral pyelectasis and hand contractures. An echocardiogram revealed an aortic arch anomaly. Cytogenetic analysis of cultured amniotic fluid revealed a 45,XX,der(14;14)(q10;q10)de novo karyotype. The pregnancy was terminated based on the ultrasound findings. DNA analysis of the fetus revealed homozygosity for 5 polymorphic markers on chromosome 14, with all alleles paternally inherited. There was no evidence of trisomy 14 mosaicism by cytogenetic or DNA analysis. Based on the molecular findings, the likely mechanism was a nullisomy 14 ovum fertilized by a normal haploid sperm. A postzygotic mitotic duplication, or monosomy rescue, resulted in formation of an isochromosome 14 and paternal UPD. The consistent prenatal features seen in our patient, as compared to others, appear to be polyhydramnios and hand contractures. Other features seen with this syndrome include skeletal anomalies and dysmorphic features. Our case is unique because of the heart anomalies and positive prenatal screen and thus should be considered in future cases. The severe phenotype in paternal disomy 14 is likely due to imprinted genes on chromosome 14 and the variability of some features may be due to homozygosity of mutant recessive alleles. Paternal disomy 14 should be considered in the presence of polyhydramnios and contractures, and in apparently balanced Robertsonian translocations involving chromosome 14. The prognosis of paternal UPD 14 appears to be uniformly poor. This case provides further evidence of a clinically relevant and consistent paternal UPD 14 syndrome.

Program Nr: 981 from the 1999 ASHG Annual Meeting

Determination of the absolute number of fetal cells in maternal blood using molecular cytogenetic techniques. *K. Krabchi, F. Gros-Louis, J. Yan, M. Bronsard, P. De Grandpre, J. Masse, J.-C. Forest, R. Drouin.* Pav Saint-Francois d'Assise, CHUQ, Dept Medical Biology, Laval University, Quebec, Quebec, CANADA.

The presence of fetal cells in maternal blood was first shown almost a century ago. Even though, many investigators have attempted to estimate the number of fetal cells present in maternal blood, there is still much controversy concerning the exact number of these cells. Therefore, the purpose of our project was to determine the absolute number of all the different types of fetal cells per unit volume of maternal blood. Peripheral blood samples were obtained from pregnant women between 18th to 22nd weeks of gestation. The selection of women known to be carrying male fetuses was necessary to recognize fetal cells (XY) among maternal cells (XX). Identification of fetal cells was carried out by fluorescent in situ hybridization (FISH) and by primed in situ labeling (PRINS) techniques. FISH using specific sex chromosome probes and PRINS using specific oligonucleotide primers and subsequent primer extension by Taq DNA polymerase were performed and fetal cells were identified and scored by fluorescent microscopy screening. Both techniques are highly specific and sensitive. However, the cheaper PRINS technique allows a more rapid detection compared to FISH. So far, six maternal blood samples have been analyzed without any enrichment procedures. The results showed that the range of fetal cells in maternal circulation fluctuates between 3 to 5 cells per ml of blood. Thus, we can conclude that it is possible to identify an extremely low number of fetal cells among millions of maternal cells. Moreover, these findings will allow the study of various factors that influence the number of fetal cells in maternal blood such as gestational age, status of mothers health (eg: diabetus, preeclampsia), smoking and drinking habits, ultrasound and chromosome constitution of the fetus. It is likely that the complex enrichment procedures actually under investigation for prenatal diagnosis of trisomy 21 cause the loss of fetal cells. Therefore, the estimation of absolute number of fetal cells constitutes critical information to obtain in order to assess the efficiency of an enrichment procedure.

Program Nr: 982 from the 1999 ASHG Annual Meeting

Use of Chorionicity to Refine the Risk of Chromosomal Abnormalities in Twin Pregnancy. *D.A. Krantz[1], T.W. Hallahan[1], J.W. Larsen, Jr.[2], P.D. Buchanan[3], R.J.M. Snijders[4], V. Klein[5], J.N. Macri[1].* 1) NTD Laboratories,Huntington Stat, NY; 2) The George Washington Univ., Washington, DC; 3) GeneCare Medical Genetics Center, Chapel Hill, NC; 4) Cedar Sinai Medical Center, Los Angeles CA; 5) Norh Shore Univ. Hospital, Manhasset, NY.

Information regarding the risk of chromosomal abnormality in one or both fetuses in a twin pregnancy assists patients in making decisions regarding invasive diagnostic procedures. Risks can be determined based on the percentage of twins that are dizygotic (Rodi et al 1990). However, zygosity can not easily be determined at this stage of pregnancy. Chorionicity is not synonymous with but can be used to give an indication of zygosity. A 10-14 week scan can determine dichorionicity (lambda-sign or twin peak) or monochorionicity (T-sign) by paying specific attention to the junction of the intertwin membrane and placenta. It is estimated that about 2/3 of twins are dizygotic and 1/3 are monozygotic. All dizygotic twins are dichorionic. Of monozygotic twins, about 2/3 are monochorionic and 1/3 are dichorionic. These figures may vary depending on other factors such as ethnicity or if twinning is spontaneous or induced. Bayes' rule can be used to determine the likelihood of zygosity based on chorionicity. Using the above percentages, all monochorionic pregnancies are monozygotic while 86% of dichorionic pregnancies are dizygotic. The table below gives an example of how chorionicity determined from U/S can refine the risk of Down syndrome for a 32 year old patient:

	Singleton	Twins	Monochorionic	Dichorionic
At least 1 Affected	1/659	1/395	1/659	1/355
Both Affected	-----	1/1991	1/659	1/4571

This approach could be developed for Down syndrome screening based on biochemistry and NT as well as maternal age.

Program Nr: 983 from the 1999 ASHG Annual Meeting

Preimplantation diagnosis for patients with homozygous beta-thalassemias. *A. Kuliev[1], S. Rechitsky[1], O. Verlinsky[1], V. Ivakhnenko[1], M. Angastiniotis[2], G. Kalakoutis[2], A. Kalnakou[2], N. Ginsberg[1], C. Strom[1], Y. Verlinsky[1]*. 1) Reproductive Genetics Inst, Chicago, IL; 2) Cyprus Thalassemia Center, Cyprus.

Preimplantation genetic diagnosis (PGD) is an important option for couples with one of the partners homozygous for beta-thalassemia, because of their 50% risk of having affected child. We performed PGD for two such couples, in one of whom female partner was homozygous for IVS1-110, and in the other - double heterozygous, IVS1-6/IVS1-110. In the latter couple, who attempted two subsequent PGD cycles, husband was a carrier of IVSII-745 mutation while in the former, paternal mutation was similar to the maternal one. As half of the resulting embryos from such couples were expected to have a normal paternal allele of the beta-globin gene, our strategy was to pre-select heterozygous embryos, using blastomere biopsy at the cleavage stage, coupled with nested PCR analysis and restriction digestion. To avoid a possible misdiagnosis due to contamination with extraneous DNA, or allele drop out, two highly polymorphic linked markers, STR at the 5' end of the globin gene and HUMTH01, which is a syntenic STR, were amplified simultaneously with beta-globin gene. This also required a single sperm typing to reveal the haplotypes of the affected and unaffected paternal chromosomes, prior to blastomere testing. Of a total of 10 embryos studied from both of these couples, 6 contained a normal allele, and transferred back to patients (3 embryos in one couple and 3 in the other), while the rest were used for a followed up study, which confirmed the affected status of these embryos. Overall, we performed 37 PGD cycles for different beta-globin gene mutations, resulting in pre-selection and transfer of unaffected embryos in each of these cycles. This resulted in establishment of 11 unaffected pregnancies, and birth of 6 healthy children. The follow up study of a total of 116 affected embryos rejected from transfer showed 98% accuracy of PGD.

Program Nr: 984 from the 1999 ASHG Annual Meeting

Prenatal detection of Charcot-Marie-Tooth disease type 1A duplication resulting from a rare recombination event. *V. Labelle[1], R.B. Bernard[1], S. Tardieu[2], J.P.. Azulay[3], P. Malzac[1], E. Leguern[2], N. Philip[1,4], N. Lévy[1,4]*. 1) Département de Génétique Médicale, Hôpital d'enfants de la Timone, Marseille; 2) Clinique des maladies neuromusculaires, Hôpital Timone, Marseille; 3) Inserm U289, Hôpital Pitié-Salpétrière, Paris; 4) Inserm U491 "Génétique Médicale et Développement, Marseille. FRANCE.

CMT1A is caused in most cases by a 1.5 Mb duplication arising after unequal crossing-over between repeated sequences (*CMT1A-REPs*), flanking the 1.5 Mb unit. Reiter et al. and Lopes et al. (1996), described a recombination "hotspot" within a 3.2 Kb junction fragment between *Eco*RI (distal *CMT1A-REP*) and *Sac*I (proximal *CMT1A-REP*), then reduced to 1.7 Kb between EcoRI and NsiI (Reiter et al.,1996) and recently to a 731 bp "hotspot" region within the *Eco*RI/*Nsi*I fragment (Lopes et al., 1998). We report a 28-year-old woman requesting prenatal diagnosis because of CMT1A familial history in her husband's family. The duplication was initially evidenced in the father's family by Southern blot analysis showing a 3.2 Kb *Eco*RI/*Sac*I junction fragment segregating with the duplication. Here we used a *CMT1A-REPs* based PCR strategy to characterize the foetus's status, since this approach detects the entire set of duplications occuring after recombination within the "hotspot". Surprisingly, the expected 1.7 kb (*Eco*RI/*Nsi*I) junction fragment was absent from the father's and foetus's DNAs. After *Eco*RI/*Sac*I digestion of the PCR product, a 3.2 Kb fragment was observed in their DNAs but not in mother and controls, indicating the duplication originated from a 1.5 Kb rare recombination zone. Although the karyotype was normal in the foetus, parents decided to interrupt the pregnancy because of a possible severe phenotype. Indeed, a large clinical heterogeneity was observed in this family. We report the interest of the *CMT1A-REPs* based PCR assay for use on trophoblastic tissues with obtention of results within 6 days. Opportunity and feasibility of preimplantation diagnosis will be compared to the ability of early prenatal diagnosis, to limit psychological distress due to pregnancy termination, particularly in diseases with unpredictible phenotype's severity.

Program Nr: 985 from the 1999 ASHG Annual Meeting

Influence of VPA and CBZ Monotherapy on Homocysteine Metabolism and Copper Levels in Premenopausal Epileptic Women. *D.M. Lambert[1,5], G.E. Graham[1,5], R. Rozen[2,5], B. Gilfix[3,5], H. Seni[4,5], E. Andermann[4,5], E.P. Treacy[1,5]*. 1) F Clarke Fraser Clinical Genetics Unit, CR Scriver Biochemical Genetics Unit and DeBelle Laboratory, Montreal Children's Hospital; 2) Montreal Children's Hospital Research Institute; 3) Royal Victoria Hospital; 4) Montreal Neurological Institute; 5) McGill University, Montreal, Canada.

Remethylation of homocysteine (hcys) to methionine (met) is essential for the production of s-adenosyl methionine and for other methylation reactions likely to be critical in embryogenesis. We postulated that anticonvulsants might exert their known teratogenic action by an effect on the hcys-met axis, influenced by folate/B12 status and MTHFR genotype. To establish whether the met/hcys (M/H) ratio was altered by VPA or CBZ monotherapy, we measured levels of met, hcys, RBC folate, B12, copper, zinc and anticonvulsants in 24 premenopausal epileptic women on long-term VPA or CBZ monotherapy and compared them to a control group of 11 healthy premenopausal women. All measurements were performed at midday following a minimum 3 hour fast to control for diurnal variation, and all participants were genotyped for the MTHFR thermolabile polymorphism C677T. We did not detect any homozygotes for the C677T polymorphism, and the prevalence of heterozygosity was similar between cases and controls (p=0.96). We did not detect a significant difference in M/H ratio between cases and controls, and methionine was significantly higher in cases (20.4 vs.16.2; F^1_{32}; p=0.005). The M/H ratio was independent of the dose of anticonvulsant (F^2_{20}; p=0.86). However, among CBZ cases, heterozygotes for the MTHFR polymorphism had significantly lower M/H ratios (p=0.03). No such relationship was observed in the VPA or control groups. Multivariate analysis indicated that M/H ratio was best predicted by the presence and type of medication, and the presence or absence of MTHFR polymorphism (F^2_{30}; p=0.04; R^2=0.19). Maternal copper deficiency has been associated with birth defects; thus of particular interest, serum copper was found to be significantly lower in both the VPA and CBZ groups compared to controls (F^1_{32}; p=0.0004) and was inversely correlated with M/H ratio (p=0.05).

Program Nr: 986 from the 1999 ASHG Annual Meeting

Hyperechogenic fetal bowel: an ultrasonographic marker associated with low risk of cystic fibrosis. *S.F. Langlois[1], F. Tessier[2], F. Sizmur[2], L.C. Kwong[1], C.R. Siemens[1], R.D. Wilson[1,2]*. 1) Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada; 2) Dept Obstetrics and Gynecology, Univ British Columbia, Vancouver.

Ultrasonographic detection of fetal hyperechogenic bowel is associated with an increased risk of cystic fibrosis (CF), aneuploidy and gastrointestinal malformation. The incidence of CF in this patient population varies from 0-20% in published studies. To determine the risk of CF in our population, we reviewed all cases referred to the Molecular Diagnostic Laboratory for CF testing because of an ultrasound finding suggestive of an increased risk of CF in the fetus.

129 pregnant patients were studied. In 116 cases, the partner was also tested. 208 individuals were of European descent. Of the 129 cases, 94 patients were referred for hyperechogenic bowel (echogenecity less than bone in 11, equal or greater than bone in 68 and no grade indicated in 15 cases). In 17 cases, echogenic calcifications were seen suggestive of meconium peritonitis. In an additional 10 cases, associated dilated bowel loop(s)were seen. Finally 8 cases were tested because of an echogenic mass or echogenic cyst.

Mutation analysis for 12 common CFTR mutation detected 5 carrier parents. In all 5 cases, the partner was negative. Four cases were referred for echogenic bowel and one case, for echogenic bowel with dilated bowel loop. In one case, testing of amniocytes showed that the fetus had not inherited the parental mutation; in three cases the fetus did inherit the parental mutation but investigations in the newborn period excluded the diagnosis of CF. The last case (echogenic bowel with dilated bowel loop) did not have testing of amniocytes and was lost to follow up.

In summary, no case of cystic fibrosis was diagnosed amongst the 94 cases referred for isolated hyperechogenic bowel. Amongst this group, three fetuses were found to be CF carriers, an incidence consistent with the population frequency of CF. A review of neonatal outcomes will be discussed.

Program Nr: 987 from the 1999 ASHG Annual Meeting

Abnormal multiple marker screen and ultrasound findings of fetal edema secondary to Congenital Erythropoietic Porphyria. *N. Lazebnik[1,2], C. Tsai[1].* 1) Dept Genetics, Henry Ford Hosp, Detroit, MI; 2) Dept OB/GYN, Henry Ford Hosp, Detroit, MI.

A Caucasian couple of western European decent, a 22-year-old G1P0 female and her 27-year-old husband were initially referred for genetic consolation due to an abnormal multiple marker screen at 16 weeks (MSAFP 2.87 MoM, hCG 1.5 MoM, and uE3 0.39). A level II ultrasound study was remarkable for a 9.7 mm nuchal fold, skin edema, mild ascites, and pericardial effusion. Amniocentesis documented a normal female karyotype, 46, XX, and normal AFAFP. TORCH studies were negative. Follow up ultrasound study at 31 weeks documented adequate fetal growth, mild ascites, pericardial effusion, skin edema and a mildly larger than expected heart. The liver dimensions were >90%. The placenta was thicker than normal (5.9 cm). The patient was induced to labor at 34 weeks gestation, due to decreased amniotic fluid volume and fetal heart rate decelerations. The Apgar scores were 6 and 7 at 1 and 5 minutes respectively. Birth weight was 2089 g (31st percentile). The newborn physical examination was remarkable for generalized hydrops, cloudy corneas, glaucoma, bilateral semian crease, and small hypoplastic nails. In addition severe hemolytic anemia, pancytopenia, massive hepatosplenomegaly, and skin blistering in areas exposed to light were noted. Due to severe respiratory distress the newborn was started on ECHMO. Comprehensive hematology work up documented Congenital Erythropoietic Porphyria secondary to Uroporphyinogen III Synthase deficiency. Molecular study documented homozygosity for the C73R mutation, a severe transfusion-dependent phenotype. The results were confirmed by showing that each parent has one copy of the C73R mutation. Recently the patient underwent bone marrow transplantation.

Program Nr: 988 from the 1999 ASHG Annual Meeting

The N terminal sequence of PMP70 is sufficient for targeting to peroxisomal membrane in CHO cells but not in S. cerevisiae. *S. Almashanu*[1,2], *D. Valle*[1,2]. 1) Howard Hughes Medical Institute; 2) Johns Hopkins University School of Medicine, Baltimore, MD.

The 70 kD peroxisomal membrane protein, PMP70, is one of four (PMP70, P70R, ALDP, ALDR) half ATP binding cassette (ABC) transporters targeted to human peroxisomal membranes by a poorly understood pathway. All of these have six transmembrane domains (TMD) in their N-terminal half with a hydrophobic C-terminal half containing an ATP binding domain. To identify targeting motifs, we generated a series of N-terminal and C-terminal deletions of PMP70 tagged with a C-terminal green fluorescent protein (GFP) and expressed them in Chinese hamster ovary (CHO) cells. We localized a peroxisomal membrane targeting signal to the 80 N-terminal amino acids, preceding the first TMD. We made a chimeric protein with the N-terminal 183 residues of PMP70 followed by the C-terminal 428 residues of its E. coli homolog (YDDA) tagged with GFP. In contrast to YDDA-GFP alone which showed a nonperoxisomal pattern, the chimeric PMP70/YDDA-GFP localizes to peroxisomes. Thus the N-terminus of PMP70 is both necessary and sufficient for peroxisomal targeting. To study targeting in a more malleable system, we expressed each of the four human peroxisomal membrane half ABC transporters in S. cerevisiae with high levels of the corresponding mRNA but no detectable protein. Similarly, when we expressed the truncated PMP70 GFP fusions that localize to peroxisomes in CHO cells, we observed a diffuse cytosolic GFP pattern in yeast. These results suggest some difference in the targeting pathway of peroxisomal half ABC transporters between humans and yeast. Recently, several human peroxins (PEX19, PEX16, PEX3) and yeast peroxins (PEX19 and PEX3) have been suggested to play a crucial role in the targeting of PMPs. One difference is an apparent absence of a PEX16 homolog in S. cerevisiae. We are currently attempting to reconstitute the human targeting pathway in S. cerevisiae by introducing all human genes potentially involved in this pathway (PEX19, PEX16, PEX3) and determining their effect on PMP70 targeting.

Program Nr: 989 from the 1999 ASHG Annual Meeting

The Identification of Twenty-One SNPs in Xq and Candidate Gene Analysis in Rett Syndrome. *R. Amir[1], E.J. Roth Dahle[3], H.Y. Zoghbi[1,2,3].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; 2) Pediatrics, Baylor College of Medicine, Houston, Texas; 3) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, Texas.

Rett syndrome (RTT) is a neurodevelopmental disorder primarily affecting females. Most cases are sporadic but, several reports about familial recurrence support X-linked dominant inheritance with male lethality. RTT families were used for mapping studies and resulted in the exclusion of large portions of the X chromosome except for a small region on Xp22.31 and the distal Xq from Xq25-Xqter. Recently, exclusion mapping studies using a new family defined Xq28 as the candidate region for the RTT gene. Accordingly, six candidate genes were selected for mutation analysis based on their established expression patterns and known functions in the CNS. These are: Glutamate receptor subunit 3 (*GLUR3*), GABA receptor subunit alpha 3 (*GABRA3*), GABA receptor subunit e1 (*GABRE1*), Vacuolar ATPase subunit 1 (*VATPS1*, *XAP3*), the human homologue of plexin 3-"*SEX*" (*XAP6*) and the Synaptobrevin-like protein (*SYBL1*). Major rearrangements involving these genes were excluded by Southern analysis. The genomic structures of *GLUR3* and *GABRA3* were established. Genomic DNA from 30-50 RTT patients were screened for mutations by PCR amplification of all coding exons as well as the 5' and 3' untranslated regions, followed by Conformation Sensitive Gel Electrophoresis (CSGE) analysis and direct sequencing. The "*SEX*" gene was analyzed by direct sequencing of RT-PCR products amplified from RNA derived from RTT patients. No disease-causing mutations were found but twenty one Single-Nucleotide Polymorphisms (SNPs) were detected in the six genes studied. The SNPs identified will be useful in future linkage analysis and whole-genome association studies for other diseases. The genomic characterization of *GLUR3* and *GABRA3* will allow mutational analysis of these genes as candidates for other X-linked neurological disorders mapping to Xq25-Xq26 and Xq28. As the candidate region harboring the RTT gene is now localized to the most distal band of Xq28, our future efforts will focus on the analysis of additional candidate genes in this region.

Program Nr: 990 from the 1999 ASHG Annual Meeting

Effect of a *CYP3A4* Promoter Variant on a Reporter Gene. *B. Amirimani[1,2], A.H. Walker[2], B.L. Weber[1,3], T.R. Rebbeck[2]*. 1) Department of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Clinical Epidemiology and Biostatistics, University of Pennsylvania, Philadelphia, PA; 3) Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Of the P450 cytochromes, CYP3A4 is the major metabolizer of carcinogens, drugs, and steroid hormones in adult liver. We have previously identified a variant in the promoter region of *CYP3A4*, and reported that it may be associated with cancer susceptibility. To evaluate the functional significance of this variant, we generated two transfection vector contructs, each containing 1 kb of the *CYP3A4* promoter, an SV40 enhancer element, and a luciferase reporter gene. One construct contained the wild-type (*W*) *CYP3A4* promoter sequence, and the other contained the variant (*V*) *CYP3A4* promoter sequence. The expression of these promoter constructs was studied in HepG2 and MCF7 cell lines. In HepG2, luciferase expression was 1.6 fold higher in *V* compared with *W* promoter ($p<.0001$). In MCF7, luciferase expression was 2 fold higher in *V* compared with *W* promoter ($p<.0005$). These results suggest that *CYP3A4* transcriptional expression may be higher in the presence of a *V* promoter than a *W* promoter. Since CYP3A4 is an important metabolizer of numerous human carcinogens and steroid hormones, this genetic variant may explain interindividual variability to cancer susceptibility and drug metabolism.

Program Nr: 991 from the 1999 ASHG Annual Meeting

Analysis of variable TIMP1 expression from the inactive X chromosome. *C. Anderson, C. Brown.* Dept Medical Genetics, Univ British Columbia, Vancouver, Canada.

X inactivation silences most of the genes on one of the two Xs in females. We have shown that the human TIMP1 gene has polymorphic X inactivation - being expressed from the inactive X in some females but not others. As methylation is generally correlated with X inactivation, we examined methylation of 3 sites at the 5 end of TIMP1. Methylation was detected in females, presumably due to the presence of an inactive X but not in males who have only one active copy. However, methylation was still observed in females with TIMP1 expression from the inactive X, suggesting methylation is not sufficient to inactivate TIMP1. To analyze the factors involved in TIMP1 inactivation, we used somatic cell hybrids where TIMP1 expression from the inactive X has also been observed. Expression from the inactive X was limited to the TIMP1 gene as flanking genes remained silent. Two of three inactive X hybrids expressing TIMP1 showed methylation. This may have reflected a heterogeneous population of cells so single cell clones from all of the inactive X hybrids expressing TIMP1 were analyzed. In the hybrids unmethylated at the 5 end of TIMP1, all 13 clones were unmethylated and expressing TIMP1, indicating stable expression. The levels of TIMP1 expression were similar to the expression levels seen in active X hybrids. However, in the hybrids that had retained methylation at the 5 end of TIMP1, 8 of 25 clones expressed TIMP1 and remained methylated with a level of expression below that of active X hybrids. Therefore, it seems that methylation is not sufficient for silencing but still has a suppressive effect. To further examine the role of methylation, we demethylated inactive X hybrids that originally did not express TIMP1. Seven clones reactivated TIMP1 and surrounding genes were also expressed, in contrast to the gene-specific expression observed for spontaneous TIMP1 expression from the inactive X. Since methylation does not seem to be the only factor affecting TIMP1 expression from the inactive X, we are currently analyzing the contribution of expression levels to stability and examining the role of regional chromatin configuration in maintaining TIMP1 inactivation.

Program Nr: 992 from the 1999 ASHG Annual Meeting

Identification of *Barhl1*, a novel homeobox gene of the *Bar* family highly expressed in the primordia of the cerebellum. *S. Banfi, E. Menguzzato, V. Broccoli, A. Marchitiello, C. Gattuso, A. Ballabio, A. Bulfone.* Telethon Institute of Genetics and Medicine (TIGEM), San Raffaele Biomedical Science Park, Milan, Italy.

The *Drosophila* dual *Bar* genes (*BarH1* and *BarH2*) encode two homeodomain-containing proteins which play an important role in the development of the external sensory organs in the fly. In the course of a project aimed at the systematic identification of human and/or murine cDNAs similar to *Drosophila* mutant genes in dbEST, we identified *Dres115*, a murine EST showing a very high sequence homology to the *Drosophila Bar* genes. By cDNA library screening, we isolated and sequenced the full-length *Dres115* cDNA, subsequently renamed *Barh-like1 (Barhl1)*. We also identified and mapped the corresponding human *BARHL1* gene. The murine transcript is predicted to encode a 327-amino acid homeodomain protein which shows the highest sequence similarity with the BarH1 and BarH2 *Drosophila* proteins and the recently identified rat mBH1 protein. To study the expression pattern of the Barhl1 gene in detail, we decided to carry out RNA *in situ* hybridization experiments in mouse, on both whole embryos and tissue sections. These studies showed that *Barhl1* is expressed at remarkable levels and at very early stages in the developing central nervous system (CNS). The main domains of expression are represented by the pretectum in the diencephalon, the primordia of the cerebellum and the most dorsal portion of the alar plate in the rhombencephalon, and in the spinal cord. In postnatal stages, *Barhl1* is only detected in the cerebellar cortex, specifically in the external granular layer. This intriguing expression pattern suggests that *Barhl1* might play a role in the development of the vertebrate CNS in both normal and pathological conditions.

Program Nr: 993 from the 1999 ASHG Annual Meeting

CASTing for genes regulated by PAX3 during embryonic development and cancer epigenesis. *T.D. Barber[1,2], T.B. Friedman[1]*. 1) NIDCD, NIH, Rockville, MD; 2) Genetics Program, MSU, East Lansing, MI.

PAX3 is a transcription factor important for neural, muscle, facial and auditory development in vertebrates. Mutations in PAX3 cause Waardenburg syndrome (WS) types 1 and 3 and Craniofacial-deafness-hand syndrome in humans and the Splotch phenotype in mice. A translocation t(2;13)(q35;q14) gives rise to a chimeric fusion protein, PAX3/FKHR, and results in alveolar rhabdomyosarcoma (ARMS). In order to identify genes regulated by PAX3 during embryogenesis and tumor formation, we have used a Cyclic Amplification and Selection of Targets (CASTing) strategy to isolate genes whose cis-regulatory elements are bound by PAX3. A library of mouse genomic fragments that bind Pax3 protein in vitro was generated, and additional libraries of human DNA fragments which interact with PAX3 and PAX3/FKHR are being constructed. Over 1000 clones from the mouse library have been sequenced, and approximately 100 genes have been identified thus far. We are beginning to screen these genes for Pax3-dependent expression patterns in Splotch mice and other model systems using northern, in situ and microarray hybridization analyses. Early results suggest that many of these putative Pax3 target genes have expression patterns and predicted functions consistent with regulation by Pax3. Two promising candidates include Itm2A and even-skipped 2. We have determined that Itm2A is abundantly expressed in developing murine skeletal muscle and is down-regulated in Splotch mutant embryos. Previous studies have shown that a Drosophila homolog of even-skipped 2 is regulated by paired (prd), a homolog of Pax3, suggesting that the regulation of even-skipped 2 by Pax3 has been conserved throughout evolution. Identification and characterization of genes regulated by PAX3 will provide a better understanding of the role of PAX3 in neural, muscle, auditory and craniofacial development, and how mutations in PAX3 perturb these processes in individuals with WS and ARMS.*Splotch, in vitro, in situ, Itm2A, even-skipped 2*.

Program Nr: 994 from the 1999 ASHG Annual Meeting

Heavy chain dynein DNAH9: cDNA sequence, genomic structure and exclusion as the gene responsible for one form of Primary Ciliary Dyskinesia. *L. Bartoloni[1], A. Maiti[1], J.L. Blouin[1], C. Rossier[1], M. Meeks[2], C. Gehrig[1], A.J. Sainsbury[1], C.D. DeLozier-Blanchet[1], M. Gardiner[2], H.S. Scott[1], S.E. Antonarakis[1].* 1) Division of Medical Genetics, University of Geneva Medical School, Switzerland; 2) Department of Pediatrics, University College London, UK.

Heavy chain dyneins are large proteins with ATPase activity involved in microtubule-mediated transport of organelles (cytoplasmic dyneins), and in motility of cilia and flagella (axonemal dyneins). We report the first complete cDNA sequence and genomic structure of a human axonemal dynein heavy chain gene, DNAH9, which maps to 17p12. The gene is divided into 69 exons over 400 Kb, with 14 Kb of coding sequence for a protein of 4488 predicted amino acids. The cDNA sequence of DNAH9 was determined using a combination of methods including: extension of previously determined partial sequences by 5'RACE, RT-PCR, and cDNA library screening. The predicted protein sequence is homologous to sea urchin axonemal heavy chain dyneins (67% identity). RT-PCR in nasal epithelium and testis revealed several alternatively-spliced transcripts. The genomic structure was determined using the publicly available sequences of 2 overlapping BACs produced by the Whitehead/MIT Genome Sequencing Center. These data provide tools for examining DNAH9 as a candidate gene for Primary Ciliary Dyskinesia (PCD), a recessive disorder with respiratory infections, bronchiectasis, male sterility and (dys)immotility of cilia; situs inversus is present in 50% of cases (Kartagener Syndrome). Ultrastructural defects of cilia are often found and they are related to the dynein complex in 50% of cases. Moreover a missense mutation in a heavy chain dynein gene was found in the iv/iv mouse, which has situs inversus. A highly informative dinucleotide polymorphism was found in intron 26. We used this polymorphism in 31 families with at least 2 siblings with PCD, and detected 2 families with co-segregation of both DNAH9 alleles in affecteds. Mutation search by direct sequence was performed in these 2 "candidate" families. We detected polymorphic variants but not a pathogenic mutation, thereby excluding DNAH9 as responsible for one form of PCD in our family sample.

Program Nr: 995 from the 1999 ASHG Annual Meeting

Characterization of the human *Talin* gene. *T. Ben-Yosef, C.A. Francomano.* Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

Talin is a high molecular weight cytoskeletal protein, localized at cell- extracellular matrix associations known as focal contacts. In these regions talin is thought to link integrin receptors to the actin cytoskeleton. Talin plays a key role in the assembly of actin filaments, and it is also essential for spreading and migration of various cell types.

Talin proteins are found in a wide variety of organisms, from slime molds to humans. The human gene was previously mapped to chromosome 9p, but little was known of its sequence and genomic structure. To further characterize human *Talin* we have isolated a single BAC clone, harboring the entire *Talin* gene. The gene extends over more than 23 Kb, and consists of 57 exons. Exon boundaries completely conform to the classical 5-donor and 3-acceptor consensus rules. We have localized *Talin* to human chromosome band 9p13 by both fluorescence in situ hybridization and Radiation Hybrid mapping. Northern blot analysis detected *Talin* expression in various human tissues, including peripheral blood leukocytes, lung, placenta, liver, kidney, spleen, thymus, colon, skeletal muscle and heart.

Based on its chromosomal location, expression pattern and protein function we considered *Talin* as a candidate gene for Cartilage-Hair Hypoplasia (CHH). CHH is an autosomal recessive metaphyseal chondrodysplasia characterized by short stature, hypoplastic hair growth and T-cell mediated immunodeficiency, which was previously mapped to 9p13. We sequenced the entire *Talin* coding sequence in several CHH patients, but no functional mutations were detected.

.

Program Nr: 996 from the 1999 ASHG Annual Meeting

Genomic Structure of Human Oligophrenin-1 and its implication in the axon and dendrite outgrowth. *P. BILLUART, J. CHELLY, A. CARRIE, M.C. VINET, N. McDONELL, F. FAUCHEREAU, P. COUVERT, C. BELDJORD, T. BIENVENU.* INSERM U129, ICGM, CHU Cochin, Paris, FRANCE.

We have recently shown that mutations in oligophrenin-1 (OPHN1) are responsible for nonspecific X-linked mental retardation. The structure of the gene encoding the OPHN1 protein was determined by isolation of genomic DNA clones from a human cosmid library. Genomic fragments containing exons were sequenced, and the sequences of the exons and flanking introns were defined. Knowledge of the genomic structure of OPHN1 gene, which spans at least 500 kb and consists of 25 exons, will facilitate the search for additional mutations in OPHN1. OPHN1 encodes a protein with a relative molecular mass of 91 KDa which contains a domain typical of rho-GTPase-activating proteins. Further investigations using polyclonal antibodies allowed us to define the cellular localisation in primary cultures of neuronal and glial cells. Interestingly, a cell type-dependant localisation of OPHN1 and a potential interaction with cytoskeletal proteins were pointed out. Also, a significant immunolabeling was observed in growth cones of cellular neurites. These data are coherent with our hypothesis that OPHN1 could be involved in the outgrowth of axons and dendrites in vivo. Therefore, a defect in neurite outgrowth and in the establishment of connections between neurones could be the cellular basis underlying cognitive impairment.

Program Nr: 997 from the 1999 ASHG Annual Meeting

Isolation, expression and mapping of mCul3, the mouse ortholog of human CUL3 a member of the cullin/Cdc53 family. *H. Boettger-Tong[1], A.I. Agulnik[1], N. Roeckel[2], C.E. Bishop[1], N. Lévy[1,2]*. 1) Department of Obstetrics/Gynecology, Department of Human and Molecular Genetics, Baylor College of Medicine, 77030 Houston, TX 2; 2) Inserm U491 "Génétique Médicale et Développement, Faculté de Médecine, 27, Bd. Jean Moulin, 13385 Marseille Cedex, France.

While constructing a genetic map from mouse proximal chromosome 1, we identified a novel mouse gene homologous to Human Cullin 3 (hCUL3) a member of the cullin/Cdc53 family. We named this gene mCul-3 for Mus musculus Cullin 3. The full length cDNA was cloned; it encodes a 768 amino-acid polypeptide and shows 95% nucleotide and 99% amino acid identity to hCUL3. Here we show that mCul3 is transcribed in a wide range of tissues by RT-PCR, with a particularly high expression in testis as evaluated by Northern blot analysis. Sequencing analysis and protein prediction indicated that the mouse Cul3 homolog contained several motifs conserved between C.elegans, mouse and human. One of them, located at the N terminal region of the protein, is 32 amino acids long including peptides 40 to 71 and is identical between the 3 species. Several differences exist between the mouse and human orthologs : (i) In human, hCUL3 has been found to be ubiquitously transcribed with a predominant expression in skeletal muscle and heart. In the mouse, Cul3 is predominantly expressed in the testis; expression in other tissues is detectable by RT-PCR, but not by Northern blot analysis. (ii) hCul3 shows two different transcripts, respectively 2.8 Kb and 4.3 Kb; only a 2.8 Kb transcript was found in mouse. Cullins/Cdc53 are a recently identified family of genes/proteins whose six members have been characterized in human (Kipreos et al., 1996). Several studies suggested a role for the Cullin proteins in cell cycle regulation. Based on structural homology, it is likely that Cul3 is also involved in cell cycle proliferation. Based on the predominant expression pattern of the mouse gene in testis, and its nearly absent expression in ovary, we speculate that mCul3 may have a function in spermatogenesis.

Program Nr: 998 from the 1999 ASHG Annual Meeting

Identification of AHCP, a human gene expressed during brain development and candidate for genetic predisposition to schizophrenia. *T. Bourgeron[1], S. Jamain[1], M. Clergues[1], H. Quach[1], R.H. Segman[2], K. Kanias[2], M. Fellous[1], B. Lerer[2]*. 1) Lab Human Genetics, Institut Pasteur, Paris, France; 2) Biological Psychiatry Laboratory, Dept of Psychiatry Hadassah - Hebrew University Medical Center Ein Karem Jerusalem 91120, Israel.

We have isolated a human gene AHCP (Autosomal Highly Conserved Protein) localised on the human chromosome 6p. Analysis of the protein sequence indicates that AHCP is a putative membrane protein with no known consensus motifs. The genomic structure of the gene is conserved in mice and C.elegans. but D. melanogaster seems to have lost the introns. In human and mice, the gene is expressed ubiquitously in the adult with a smaller transcript specific to the testis. In mice, during development, the expression seems to be restricted to the forebrain. AHCP transcripts are found at the boundaries of the telencephalon and the diencephalon closed to the zona limitans intrathalamica (ZLI). In human, there are several retro-transcribed pseudo-genes including one copy on the Y chromosome. The localisation of the transcribed gene is between D6S274 and D6S285 on human chromosome 6p23. This region was found by different studies to contain a locus for predisposition to schizophrenia. In order to test the gene as a candidate, we have screened 73 schizophrenic patients for base substitution in the coding region. Three polymorphisms were found and the transmission disequilibrium test is under way.

Program Nr: 999 from the 1999 ASHG Annual Meeting

Role of human mitochondrial translocators in the import of nuclear encoded proteins. *A.M. Brown, W.T. Garvey, G. Argyropoulos.* Medicine, Medical Univ South Carolina, Charleston, SC.

Transfer of cytosolic preproteins into the mitochondria requires components of the Translocase machinery of the Outer mitochondrial Membrane (TOM) and immediate transient interaction with the Translocase machinery of the Inner mitochondrial Membrane (TIM). Initially, preproteins bind to receptors of the TOM complex and they are inserted into the intermembrane space via further binding to receptors of the General Import Pore. Final insertion of preproteins into the matrix is mediated by the various translocators of the inner membrane and the matrix heat shock protein 70. Over 20 protein members belonging to the TIM and TOM complexes have been identified in yeast but limited research has been done in mammalian systems and only a handful of TIM/TOM cDNAs have been cloned in humans (hTOM34, hTOM20, hTIM17, hTIM23, hTIM44, hTOM40, and hTIM8). The binding affinities and the requirement of hTIMs and hTOMs for the importation of human nuclear encoded mitochondrial proteins (NEMPs) (hUCP2, hUCP3, hBCL-XL, hBAK1, and hVDAC1) is being investigated and reported here. In vitro binding assays show that hTOM20 has binding affinities for hUCP2 and hUCP3 and hVDAC1. ELISA assays also indicate that a native mutant isoform of hUCP3 (R70W) has a significantly stronger binding affinity for hTOM20 than the wild type protein does. In addition, a novel translocator of the outer mitochondrial membrane has been identified and characterized. In organello experiments involving isolated mitochondria, in vitro purified hTIMs and hTOMs, and fluorescent-labeled NEMPs are also presented. The significance of mitochondrial translocators in metabolic diseases (obesity, diabetes) and their possible involvement in apoptotic events due to their interactions with NEMPs, are also discussed.*In organelloin vitro.*

Program Nr: 1000 from the 1999 ASHG Annual Meeting

Overexpression of a FANCD-EGFP fusion protein leads to accumulation in the nucleus and rapid cell death.*FANCD*. *D.A. Bruun, J.A. Hejna, C.D. Timmers, M. Grompe, R.E. Moses.* Department of Molecular & Medical Genetics, Oregon Health Sciences University, Portland, OR.

The Fanconi anemia complementation group D (FANCD) gene has recently been cloned. The full-length cDNA contains a 4413 bp open reading frame. Like the other cloned Fanconi anemia genes, the sequence reveals few identifiable features; however, the N-terminal region of the translated open reading frame is rich in Arg and Lys, suggesting a nuclear localization signal (NLS). Despite the absence of a consensus NLS motif, we decided to test whether this region could translocate an expressed green fluorescent protein fusion construct to the nucleus. A 2 kb fragment from the 5' end of the cDNA was ligated in-frame to pEGFP-N1 (ClonTech). Electroporation of the construct into GM639 fibroblasts resulted in a green fluorescent signal in only a small percentage (5%) of cells, compared to cells electroporated with pEGFP-N1. The cells expressing the fusion protein showed foci of green fluorescence in the nucleus. In addition, most of these cells appeared to be undergoing cell death, even within 16 hours after electroporation. In order to uncouple the cell-killing phenomenon from nuclear localization, a 200 bp fragment carrying the N-terminal 50 codons was ligated in-frame to pEGFP-N1. Electroporation of this construct into GM639 cells resulted in nuclear-localization of the fusion protein without cell death. The FANCD protein thus appears to carry a novel NLS and may function in an apoptotic pathway.*FANCD.*

Program Nr: 1001 from the 1999 ASHG Annual Meeting

From fish to human, structural and functional evolution of the p53 protein. *J. Cachot[1, 2, 3], F. Leboulenger[1, 3], T. Frebourg[2, 3]*. 1) Ecotoxicology Laboratory, University of Le Havre, Le Havre, FRANCE; 2) INSERM EPI 9906, Faculté de Médecine et de Pharmacie, Rouen, FRANCE; 3) IFRMP, Mont-St-Aignan, FRANCE.

Since its cloning in 1983, the p53 gene has been identified in about 35 vertebrates from fish to human. In mammals, this gene encodes a 53 kDa transcription factor implicated in cell cycle control, apoptosis and cellular responses to DNA damages and its inactivation plays a key role in tumorigenesis. The flounder (Teleostei, Pleuronectidae), a sentinel species for ecotoxicity, is one of the most phylogenetically distant species from human in which p53 has been cloned. The two p53 proteins display relatively low percentage of amino-acid identities within the transactivation (32%) and oligomerization (30%) domains, whereas the core DNA binding domain is much more conserved (57%). The functional assay developed in yeast to screen for p53 mutations in human tumors was used to test the biological activity of the flounder p53 protein. Preliminary results demonstrate that flounder p53 acts as a transcription factor which activates genes implicated in cell cycle control (p21) and apoptosis (Bax and PIG3). This transcriptional activity was highly dependent of temperature and flounder p53 optimal temperature was different from human p53, 20°C versus 30°C in human. These results are in complete agreement with biological data and reflect structural and functional adaptations of p53 proteins to physiological and environmental conditions of each species.

Program Nr: 1002 from the 1999 ASHG Annual Meeting

Evolution of the glucocerebrosidase pseudogene. *M. Callahan, R. Samimi, N. Tayebi, E. Sidransky.* DHHS/PHS, NIH/NIMH, Bethesda, MD.

Gaucher disease, the most common of the lysosomal storage disorders, is caused by mutations within the gene encoding for the enzyme glucocerebrosidase. Human glucocerebrosidase has a pseudogene located 16kb downstream on chromosome 1q21 that shares 96% homology with the functional gene. Many glucocerebrosidase mutations identified in patients with Gaucher disease are identical to pseudogene sequence, which suggests that the presence of the glucocerebrosidase pseudogene contributed to mutation introduction. Sequencing of the region surrounding the murine glucocerebrosidase gene demonstrated that this species does not have a nearby pseudogene. Two strategies were used to determine the presence or absence of a pseudogene in other species. After comparing the human and murine glucocerebrosidase and human pseudogene sequences, PCR primers were designed in conserved regions to enable the amplification of gene and pseudogene fragments whose size differs. Appropriate primers for two different glucocerebrosidase regions were identified, and the screening of DNA from nine different species indicated that the pseudogene was present in the human and rhesus monkey but absent from the mouse, rat, and chicken. Southern analysis using genomic DNA digested with SspI and Hind III confirmed the presence of the glucocerebrosidase gene and pseudogene in the human and monkey but not the other species. Further investigations using DNA sequencing are currently being performed.

.

Program Nr: 1003 from the 1999 ASHG Annual Meeting

Molecular cloning and mapping on human chromosome 21q22.1 of a new human metalloproteinase: ADAMTS-1. *C. Casas, M. Pritchard, M.L. Arbones, X. Estvill.* Medical and Molecular Genetics, IRO, Barcelona, Spain.

An initial step in understanding the pathogenesis and pathophysiology of Down syndrome and the monogenic disorders and traits associated to chromosome 21 (HC21) is the cloning and characterization of genes located on HC21. As a part of the effort to identify new HC21 genes, we used an in silico approach and searched for ESTs at the chromosome 21-specific UniGene database and found a cluster of partial cDNAs with high similarity to the mouse gene Adamts-1. The murine gene was isolated by differential display from the RNA extracted from tumours induced in mouse by the injection of a colon 26 cachexigenic cell line. It encodes for a secreted metalloproteinase with thrombospondin type I (TSP-1) repeats that anchors to the extracellular matrix and seems to be involved in inflammatory processes. We present the isolation, characterization, expression pattern and mapping of the human orthologue of the murine Adamts-1 gene. Expression analysis of ADAMTS-1 by Northern showed a weak signal in muscle tissues, lung, placenta, peripheral nervous system and in discrete regions of the central nervous system, such as cerebellum and putamen. Analysis in depth of ADAMTS-1 predicted protein primary structure and comparison to other recently discovered matrix degrading proteases; the aggrecanase-1 and the procollagen-I-N-proteinase, confined them into a novel subfamily of metalloproteinases with TSP-1 repeats, the ADAMTS (A Metalloproteinase And ThromboSpondin). Since adhesion and proteolysis of the extracellular matrix are vital processes for morphogenesis, cell migration, tissue repair and cell death, an abnormal expression of ADAMTS-1 could be detrimental in some of these processes leading to the development of pathological events that may result in the phenotypic manifestations in Down syndrome individuals or in those with HC21 monogenic disorders.

Program Nr: 1004 from the 1999 ASHG Annual Meeting

Cloning and characterization of the mouse and rat homologs of *MEFV*, the gene for familial Mediterranean fever. *J.J. Chae[1], M. Centola[1], I. Aksentijevich[1], A. Dutra[2], M. Tran[3], K. Nagaraju[1], D.W. Kingma[3], P.P. Liu[2], D.L. Kastner[1]*. 1) National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD; 2) National Human Genome Research Institute, Bethesda, MD; 3) National Cancer Institute, Bethesda, MD.

Familial Mediterranean fever (FMF) is a recessive disorder characterized by episodes of fever with serositis or synovitis. Recently the FMF gene (*MEFV*) was cloned; the protein product, pyrin, belongs to a family of nuclear factors homologous to the Ro52 autoantigen, and is thought to be a regulator of inflammation in myeloid cells. In this study we cloned and characterized the mouse and rat homologs of *MEFV*. The murine gene contains ten exons with a coding sequence of 2304 bp, while the rat homolog has nine exons with a coding sequence of 2253 bp. A considerable amino acid sequence homology was observed between the mouse and human (47.6% identity and 65.5% similarity) and between the mouse and rat genes (73.5% identity and 82.1% similarity). The predicted rodent proteins have several important domains and signals, such as the B-box zinc finger domain, Robbins-Dingwall nuclear localization signals, and coiled-coil domain, found in human pyrin. However, probably because of an ancient frame-shift mutation, neither the mouse nor the rat protein has an intact C-terminal B30.2 domain, in which most of the FMF-associated mutations have been found in humans. Nevertheless, like the human gene, mouse *Mefv* is expressed in peripheral blood granulocytes but not lymphocytes. The mouse *Mefv* is localized on mouse chromosome 16 region A3-B1, thus extending a region of synteny with human chromosome 16p13.3 where *MEFV* is located. Overall similarities between mouse and human genes suggests that the generation of the mouse models should not only provide insight into the precise role that *MEFV* plays in inflammation but also create valuable tools for studying the molecular pathogenesis for FMF.

Program Nr: 1005 from the 1999 ASHG Annual Meeting

Fine mapping and genomic organization of human filamin genes FLN2 and FLN3. *C.F. Chakarova[1], P.F.M. van der Ven[2], D.O. Frst[2], M. Wehnert[1].* 1) Institute of Human Genetics, University of Greifswald, Germany; 2) Department of Cell Biology, University of Potsdam, Germany.

Filamins are a group of ubiquitous, dimeric actin cross-linking phosphoproteins of the peripheral cytoplasm who promote orthogonal branching of actin filaments and link them to the membrane glycoproteins. So far, three human filamin cDNA sequences - termed alpha, beta and gamma-filamin - were described and found to be highly conserved. The precise chromosomal position and the genomic organization, however, were described only for alpha-filamin (FLN1). In the present study, we mapped beta-filamin/FLN3 on chromosome 3 and gamma-filamin/FLN2 on chromosome 7 by FISH and PCR. High-resolution mapping was achieved by PCR on the GeneBridge 4 Human/Hamster Radiation Hybrid Mapping Panel (Research Genetics). This positioned the FLN2 gene 2.12 cR (0.57 cM) off D7S530 on 7q32 and the FLN3 gene on 3p14 between WI-3771 (1.31 cR; 0.35 cM) and WI-6691 (1.71 cR; 0.46 cM). Taking the established structure of the FLN1 gene and assuming that the genomic organization of the three known filamin genes could be very similar, a PCR-based primer walking approach was used to define the intron-exon boundaries of FLN2 and FLN3. In contrast to FLN1, FLN2 consists of 45 exons and 44 introns and FLN3 consists of 44 exons and 43 introns. All intron-exon boundaries follow the GT-AG rule. The average intron size of FLN1 and FLN2 genes is almost identical (404 bp and 433 bp, respectively). Introns were significantly larger in FLN3 (average size 1584 bp). Thus the estimated sizes of FLN2 and FLN3 are 27 kb and 80 kb, respectively. The majority of the intron positions are identical in all three filamin genes. Five introns are either missing or inserted in one or two of the paralogous genes. Exon 30 is deleted in the FLN2 gene leading to the loss of one "hinge" at the protein level. Instead, a novel exon (38A) is inserted, which should result in distinct functional properties of the resulting protein. In summary, our study provides evidence that the three filamin paralogs share a highly conserved genomic structure. The observed differences hint at a hitherto unknown functional diversity of filamin isoforms.

Program Nr: 1006 from the 1999 ASHG Annual Meeting

Mechanisms of transcriptional repression of the human *HPRT* promoter by DNA methylation. *C. Chen[1], M.C.K. Yang[2], T.P. Yang[1]*. 1) Dept. of Biochem. and Mol. Biology,; 2) Dept. of Statistics, University of Florida, Gainesville, FL.

The correlation between promoter hypermethylation and transcriptional repression is well documented, particularly among the X-linked housekeeping genes. The 5' region of the X-linked human hypoxanthine phosphoribosyl transferase gene (*hHPRT*) is unmethylated on the active allele but almost completely methylated on the inactive allele. *hHPRT* can be reactivated on the inactive X chromosome (X_i) by treatment with the DNA demethylating agent 5-aza-deoxycytidine (5aCdr), further implicating methylation in its transcriptional repression. To identify methylation sites that may be critical for maintaining repression of *hHPRT*, we have treated a human/hamster hybrid containing a single human X_i with 5aCdr and then examined by LMPCR the high resolution methylation pattern of the *hHPRT* 5' region in single-cell-derived clonal lines. Both spontaneous and 5aCdr-induced reactivation of *hHPRT* correlate with global demethylation of its 5' region. However, in 61 non-reactivated 5aCdr-treated clones examined, sporadic demethylation was observed at all but three CpG methylation sites, which always remained methylated. These three methylated CpG's may be critical for transcriptional silencing of *hHPRT* on the X_i. DNase I *in vivo* footprinting suggests that on the X_i, all three sites fall within a single phased nucleosome encompassing the major transcription initiation sites of *hHPRT*. However, only one site falls within a potential transcription factor binding site as defined by dimethyl sulfate and DNase I *in vivo* footprinting. 5aCdr re-treatment of those partially demethylated clonal lines that failed to reactivate *hHPRT* reveals no correlation between the reactivation frequency of *hHPRT* and the pre-existing level of demethylation, a finding consistent with the existence of critical methylation sites. Treatment with trichostatin A, a potent histone deacetylase inhibitor, fails to reactivate *hHPRT* in either of two hybrid cell lines containing a X_i suggesting that repression by methylation involves more than just histone deacetylase recruitment. We also present evidence of *de novo* methylation secondary to 5aCdr treatment.

Program Nr: 1007 from the 1999 ASHG Annual Meeting

Cloning and sequence analysis of two distinct cDNAs encoding cystic fibrosis transmembrane conductance regulator from the Atlantic salmon, Salmo salar. *J.M. Chen[1], C. Jacques[1], C. Cutler[2], B. Mercier[1], G. Boeuf[3], C. Ferec[1]*. 1) Centre de Biogenetique, Universite, Hopital, ETSBO, Brest, France; 2) Molecular Physiology Group, Bute Medical Buildings, St Andrews, UK; 3) Direction des Ressources Vivantes, IFREMER, Brest, France.

The Atlantic salmon, Salmo salar, is capable of adapting rapidly to transfer from freshwater to seawater. Investigation into this unique phenomenon of osmoregulation, which is believed to be a function of the human cystic fibrosis transmembrane conductance regulator (CFTR) homologue, would provide insights into the structure and function of the human CFTR gene. As a first step, we isolated the CFTR cDNA from mRNA samples prepared from salmon gill by routine RT-PCR using degenerated primers and rapid amplification of cDNA ends. DNA sequence analysis of the overlapping cloned PCR products revealed two clearly distinct cDNAs, designated as sCFTR-I and sCFTR-II respectively. The nucleotide sequence of sCFTR-I cDNA is 5496 bp long, encoding 1519 amino acids, and that of sCFTR-II is 5413 bp long, encoding 1518 amino acids. At the nucleotide level these two types of cDNA show an identity of 93.2% in the coding region and at the amino acid level, they are 95.3% identical. When compared to human CFTR, sCFTR-I, which turns out to be the most divergent form of CFTR characterised to date showes a 1% less identity than sCFTR-II both at the nucleotide level (60.3% vs 61.3%) and at the amino acid level (58.1% vs 59.1%). The two nucleotide-binding domains are the most highly conserved domains and the R domain is the least highly conserved one. Despite the high sequence homology in the coding region, the 110 bp nucleotides upstream from the translation start site is only 64.0% identical and the 3' untranslated region is 71.8% identical between the two sCFTR cDNAs, suggesting that they are to be encoded by two different genes. Future experiments are to investigate their expression pattern in different tissues, in different developmental stages, and functional analysis of these two sCFTR genes.

Program Nr: 1008 from the 1999 ASHG Annual Meeting

A rapid method for elucidating exon-intron boundaries and genomic structure of genes. *S. Cheng, S.D. Pandit.* Human Genetics, Genome Therapeutics Corporation, Waltham, MA.

We have developed a rapid method to elucidate the genomic structure of candidate genes. Previous methods for elucidating exon-intron boundaries have relied on subcloning of YACs/BACs and extensive screening of sub-libraries with cDNA probes. Other methods have utilized ligation mediated PCR (Xu, G., et al., (1998), Genomics, 47: 171-179) or Vectorette PCR strategies (Roberts, R. G., (1992), Genomics, 13: 942-950) for genomic structure elucidation. These protocols either involve extensive subcloning, or are technically challenging. The method described here utilizes PCR to identify exon boundaries in cDNA segments followed by direct sequencing of BAC clones to obtain full or partial intronic sequences. PCR is performed against both cDNA (cDNA clone or pools) and genomic DNA (BAC clone) templates. Comparing the PCR product size from cDNA and genomic DNA templates allows the identification of potential existing introns in the genomic region. When a particular PCR primer pair produces the expected size product from the cDNA template but no product or a larger product from the genomic template, this region presumably contains one or more introns that interrupt the PCR. We modified the 33P-cycle sequencing method and used the PCR primers to perform direct sequencing of BAC DNA to obtain high quality genomic sequence. Aligning the cDNA and genomic DNA sequences using "Sequencher" software package allowed us to define exon-intron boundaries. This simple and rapid method has proven useful for rapidly defining exon-intron boundaries which will prove useful in detecting variants in large number of candidate genes identified in positional cloning projects.

Program Nr: 1009 from the 1999 ASHG Annual Meeting

Cloning and genomic characterization of the human *PREB* gene; a conserved WD-repeat protein expressed in the mature adult and during human development. *C.T. Clelland[1], B. Levy[2], E. Nomoto[1], K. Hirschhorn[2], C. Bancroft[1]*. 1) Dept Physiology & Biophysics, Mount Sinai Medical Ctr, New York, NY; 2) Dept Human Genetics, Mount Sinai Medical Ctr, New York, NY.

PREB (prolactin regulatory element binding), a novel rat protein, exhibits sequence-specific DNA binding to site 1P of the prolactin promoter. This WD-repeat protein accumulates in the nucleus of rat pituitary cells and can transactivate the prolactin promoter *in vivo*. Furthermore, PREB can mediate both basal and PKA stimulated transcriptional responses in pituitary cells. The murine *Preb* gene exhibits a stage-specific expression pattern during embryogenesis, with high levels of mRNA transcripts observed in the developing pituitary gland, the hepatic system, and the cartilaginous condensations of the craniofacial and axial skeleton.

We have cloned the human *PREB* gene. The full length sequence of the 2.1kb human fetal brain cDNA has over 83% nucleotide identity with the rat *Preb* cDNA. In addition there is 89% identity and >91% similarity between the PREB protein homologues. The three putative WD-repeat motifs are highly conserved. Northern analysis of fifty adult tissues indicates that, although human *PREB* mRNA is ubiquitously expressed, levels of these transcripts vary considerably between tissue types, with the highest levels of expression in the pituitary gland, skeletal muscle, liver, salivary gland, placenta and pancreas. *PREB* is expressed in all human embryonic tissues examined. We have determined the intron/exon boundary structure of *PREB*, and have FISH mapped the gene to human chromosome 2p23, a region associated with a developmentally abnormal phenotype characterized as 2p trisomy syndrome. Further investigations into the role of this putative transcription factor may elucidate the role of *PREB* in human development.

Program Nr: 1010 from the 1999 ASHG Annual Meeting

PLAC1, an X-linked unique marker gene for placenta. *M. Cocchia, R. Huber, S. Pantano, M. Ko, D. Schlessinger.* Laboratory of Genetics, National Institute on Aging, NIH, Baltimore MD, 21224.

A novel human X-linked gene identified through genomic sequence analysis shows placental-specific expression, and has been named PLAC1. The gene maps 65 Kb telomeric to HPRT in Xq26 and has an ortholog in mouse that maps to the syntenic region of the murine X chromosome. The putative human and murine PLAC1 proteins are 60% identical and 77% homologous. A low but significant level of homology was also detected with ZP3 (Zona Pellucida 3). ZP3 is an important protein involved in the fertilization process in several species of eutherian mammals.

In order to understand how PLAC1 may be functioning in the developing placenta, we are studying the murine homolog expression pattern. Preliminary experiments using a PLAC1-GFP fusion protein suggest a cytosolic localization; and from *in situ* hybridization studies with the antisense mRNA during mouse embryogenesis, PLAC1 is expressed from 7.5 dpc to 13.5 dpc (days after coitus) in the primary trophoblastic giant cells and in the trophoblast cells; that is, in specialized extra-embryonic cells present only in eutherian mammals and critical for the processes of implantation and placentation. The hints from its homology to ZP3 and specific localization make PLAC1 a marker with a potential role in the establishment of the indispensable mother-fetal interface.

Program Nr: 1011 from the 1999 ASHG Annual Meeting

Characterization of the mouse *rotated abdomen* homolog, *Pomt1*. Mapping to chromosome 2 and exclusion of *Pomt1* mutations in *mdm*. *A. Cortes*[1], *P. García Pavía*[1], *L.A. Pérez Jurado*[1,2], *J. Cruces*[1]. 1) Dept. Bioquímica, Universidad Autónoma, Madrid, Spain; 2) Servicio de Genética, Hosp. Univ. La Paz, Madrid, Spain.

Rotated abdomen, *rt*, is a poorly viable recessive mutation of *Drosophila melanogaster* causing a clockwise twisted abdomen in affected individuals due to defects in embryonic muscle development. A human gene highly homologous to *rt*, *POMT1*, has been recently cloned that encode a protein with high homology to key yeast mannosyltransferases, PMTs. We have now characterized the mouse ortholog, *Pomt1*. A full length 3.1 kb *Pomt1* cDNA has been obtained by RT-PCR from various sources and encodes a 724 aa protein with 95%, 68%, and 54% similarities to human POMT1, *Drosophila* rt, and yeast PMTs, respectively. Northern blot reveals that *Pomt1* is ubiquitously expressed with higher levels in testis. Computer prediction of protein sorting suggests that the Pomt1 product could be located at the ER or Golgi membranes. Like the human homolog, the *Pomt1* gene consists of 20 exons. The *Pomt1* locus has been assigned in the EUCIB backcross to cM 22 of mouse chromosome 2, in a region of conserved synteny with human chromosome 9q34.1 where the *POMT1* locus maps. Interestingly, the *mdm* mutation (muscular dystrophy whit myositis), a mouse model of congenital muscular dystrophy, had been previously located at cM 26+/-4 of mouse chromosome 2. We have then screened mdm DNA for mutations in *Pomt1* by PCR amplification and sequencing of all exons and exon-intron junctions. No mutations were found, suggesting that *Pomt1* is not the site of the mutation responsible for the *mdm* defect.

Program Nr: 1012 from the 1999 ASHG Annual Meeting

Tight regulation of a mammalian promoter by bacterial *lac* operon elements. *C.A. Cronin, L. Abramova, L.A. Ligon, H. Scrable.* Dept Neuroscience, Univ Virginia, Charlottesville, VA.

Experimental control of gene expression is a powerful tool that can be used to elucidate aspects of gene function. Regulatable viral promoters have been used extensively to control target gene expression in both the *tet* and *lac* systems. The use of viral promoters, however, sacrifices the tissue specificity and level of expression that a gene's endogenous promoter would provide.

With the aim of controlling gene expression in the mouse, we introduced *lac* operator sequences into the promoter of the murine tyrosinase gene. A primary operator was introduced just downstream of the start of transcription by changing 25bp of the endogenous sequence. This maintained the endogenous spacing of promoter elements in the tightly spaced tyrosinase minimal promoter. Additional operator sequences were inserted 176bp and 526bp upstream from the primary operator. The final structure closely resembles that of the promoter of the bacterial *lac* operon.

Potentially regulatable tyrosinase promoters were cloned in front of the coding sequence of the b-galactosidase reporter gene. When VMM12 cells were transiently transfected with the *lac* repressor in combination with the reporter constructs, expression of the reporter gene was significantly reduced. When a lactose analog was added to the culture medium, expression of the reporter gene was restored to non-repressed levels. The repressed and induced levels of expression differed by an order of magnitude. To test how tightly expression could be controlled by these *lac* elements, the b-galactosidase coding sequence was replaced by the coding sequence for diphtheria toxin-A (DT-A). It has been estimated that only a few molecules of DT-A are necessary to poison a cell irreversibly. Repression of toxin expression in transfected VMM12 cells was tight enough to rescue the cell death seen in the unrepressed state.

Program Nr: 1013 from the 1999 ASHG Annual Meeting

Genomic Organisation of the PPP1CC gene located within the Noonan syndrome critical interval. *A.H. Crosby[1], M. Salehpour[1], R. Dong[1], K. Kalidas[1], A. Ion[1], S. Jeffery[1], M. Patton[1], H. Kremer[2], M. van Reen[2], I. van der Burgt[2], H. Brunner[2], E. Mariman[2], R. Kucherlapati[3], K. Montgomery[3]*. 1) Dept Medical Genetics, St George Hosp Med Sch, London, England; 2) Dept Human Genetics, University Hosp Nijmegen, Nijmegen, The Netherlands; 3) Dept Molecular Genetics, Albert Einstein College Medicine, NY, USA.

Noonan syndrome (NS) is an autosomal dominant developmental disorder characterised by typical facial dysmorphology, congenital heart defects and short stature. Whilst we have shown that this condition is genetically heterogeneous, we have previously localised one gene for NS to a 5cM interval on the long arm of chromosome 12 at band 12q24.1. More recent work has involved the fine mapping and characterisation of a number of both novel and previously described transcripts within the interval. One of these transcripts, the PPP1CC gene, is a serine-threonine protein phosphatase. Due to their involvement in a variety of cellular functions from muscle contraction through to cell cycle progression, the protein phosphatases constitute potential candidates for NS. In order to examine this gene for mutations, we have determined its genomic organisation. PPP1CC comprises 7 exons which span approximately 17.5kb of genomic DNA. This gene is now being evaluated for disease-specific mutations in our large cohort of NS patients.

Program Nr: 1014 from the 1999 ASHG Annual Meeting

Isolation of two *DAZAP* genes encoding proteins that interact with both DAZ and DAZL. *T. Dai[1], S. Tsui[1], E. Salido[2], S. Roettger[3], W. Schempp[3], P. Yen[1]*. 1) Medical Genetics, Harbor-UCLA Medical Center, Torrance, CA; 2) Pathology, University of La Laguna, Spain; 3) Human Genetics and Anthropology, University of Freiburg, Germany.

The *DAZ* (Deleted in AZoospermia) gene family on the human Y chromosome and the *DAZL* (DAZ-Like) gene on chromosome 3 encode RNA-binding proteins that are expressed only in germ cells. The *DAZ* gene cluster is deleted in about 10% infertile males with azoospermia, and *Dazl* knock-out mice are sterile, supporting a role for *DAZ* and *DAZL* in spermatogenesis. DAZ and DAZL differ in that DAZ contains 8-24 copies of a DAZ repeat, whereas DAZL contains only a single copy of the repeat. In addition, these proteins have different C-terminal sequences due to a frame-shift after the DAZ repeats. In order to compare the two proteins and elucidate their function, we used the DAZ protein as the bait in the yeast two-hybrid system and isolated two *DAZAP* (DAZ Associated Protein) genes. Interactions between DAZ and the DAZAP proteins were confirmed by *in vitro* binding assays, in which labeled DAZ bound to immobilized GST-fusion proteins of the DAZAPs. Similar binding assays showed that DAZL also interacted with the two DAZAP proteins. *DAZAP1* represents a novel gene encoding a 45 kd protein with two RNP motifs in the N-terminal region , similar to those found in hnRNP A/B and a *Drosophila* hnRNP protein hrp48. However, the C-terminal region of DAZAP1 is rich in proline instead of glycine. *DAZAP2* is identical to an anonymous gene, KIAA0058, previously isolated from a human male myeloblast cell line, KG-1. It encodes a 19 kd protein with no recognizable functional domains. *DAZAP1* is expressed most abundantly in the testis, whereas *DAZAP2* is ubiquitously expressed. *DAZAP1* and *DAZAP2* were mapped to 19p13.3 and 2q33-34, respectively, by FISH. The significance of the interactions between DAZ, DAZL and the DAZAPs remains to be determined.

Program Nr: 1015 from the 1999 ASHG Annual Meeting

Cloning of two genes from the 22q11 deletion syndrome proximal critical region. *S. Demczuk[1], A. Aurias[2], B. Dion[1]*. 1) Research Inst, PT 239, Montreal Children's Hosp, Montreal, PQ, Canada; 2) INSERM U509, Institut Curie, Paris.

Microdeletions of chromosome 22q11.2 are associated with a wide range of clinical abnormalities, the most frequent of which are conotruncal cardiac defects, thymus and parathyroids hypoplasia, a typical facial dysmorphism and cleft palate. A number of genes have been isolated from the 22q11 deleted region, but definitive evidence to incriminate one gene, rather than another in this pathology are missing.

We have chosen exon trapping as a method to build a transcription map of the proximal critical region for this syndrome. Two of the exons retrieved were identical in sequence to ESTs, strongly suggesting that they corresponded to genes.

Exon 39-2A2 is 97 bp and the corresponding EST (R88591) was completely sequenced and is 774 bp-long. The EST has been isolated from an adult brain library and recognizes a 2.6 kb transcript in adult heart, muscle, kidney, brain and lung RNAs. It maps a few kilobases telomeric to *DGCR6*. This EST has a strong homology to the Drosophila proline oxidase gene and is actually part of the recently cloned human proline dehydrogenase gene. It has been linked to the hyperprolinemia phenotype displayed by some 22q11 deletion syndrome patients.

The second exon, Po-1B9, is 104 bp-long and the analogous EST, H08046, isolated from an infant brain library is 1424 bp. Clone H08046 recognizes an approximately 3 kb transcript in adult pancreas RNA. It maps a few kilobases centromeric to the 5' of *DGCR5*. The EST was completely sequenced and database search revealed weak homology to the human diaphanous gene and to synapsin genes from a variety of species. Further characterization of this gene will be done in order to elucidate its potential function.

Program Nr: 1016 from the 1999 ASHG Annual Meeting

Structure and function of the 5' flanking region of human very long chain acyl-CoA dehydrogenase: possible bi-directional promoter activity. *J.H. Ding, G. He, B.Z. Yang, C.R. Roe.* Inst Metabolic Disease, Baylor Univ Medical Ctr, Dallas, TX.

Very long chain acyl-CoA dehydrogenase (VLCAD) catalyzes the initial beta-oxidation step of long chain fatty acids in mitochondria. Mutations identified in the coding region of the gene were shown to cause enzyme deficiency resulting in recurrent hypoglycemia and/or cardiomyopathy. It was postulated that down regulation of enzymes involved in fatty acid oxidation in the mitochondria was associated with the development of cardiomyopathy and heart failure. In order to understand the regulation of VLCAD at the transcriptional level, an inverse nested PCR-based method was used to clone the 1 kb fragment immediately 5' upstream of VLCAD. Sequence analysis of the fragment revealed many structural similarities with the promoter region of medium chain acyl-CoA dehydrogenase. In addition, sequence search in the GenBank database identified an unusual overlap of sequence covering the 5' upstream region of both VLCAD and Postsynaptic Density-95 (PSD95) genes. To investigate this unique structure and its role in regulating the transcription of both VLCAD and PSD95 genes, the overlapping fragment was cloned into a green fluorescence protein (GFP) reporter vector in both orientations. Transfection of these constructs and subsquent expression of GFP in human fibroblast cells demonstrated that the region contained regulatory elements essential for the promoter activity of both VLCAD and PSD95 genes. We believe that the understanding of VLCAD as well as PSD95 gene expression and regulation should provide insight into the development of cardiomyopathy and heart failure.

Program Nr: 1017 from the 1999 ASHG Annual Meeting

Cloning of KCNE-2 and KCNE-3: two new putative voltage-dependent K+ channel subunits. *A. Domenech, M.L. Arbones, X. Estivill, S. de la Luna.* Medical and Molecular Genetics, IRO, Barcelona, Spain.

To identify new genes in human chromosome 21, we have used an in silico approach. BlastN search of the ESTs database was performed with a public genomic sequence (GB acc. no. AP000052). A human EST (GB acc. no. AI246239) was considered for further study due to its similarity to KCNE-1. A corresponding cDNA was isolated from human adult heart cDNA, and its sequence determined, showing the presence of an open reading frame of 123 amino acids. We have named this new human gene as KCNE-2. To identify another putative voltage-dependent K+ channel subunits, a tBlastX search of human dbESTs was performed with the nucleotide sequence of KCNE-2. The consensus sequence of eigth overlapping ESTs showed the presence of an ORF of 103 amino acids. The cDNA was isolated from human adult colon cDNA. We have named this new human gene as KCNE-3. At the amino acid level, KCNE-2 and KCNE-3 have high similarity to human Isk protein (also known as minK), a membrane protein which induces slowly activating, voltage-dependent K+ channels when it is complexed to KvLQT1 (KCNQ-1). Mutations in either KCNE-1 or KCNQ-1 are responsible for the Jerwell and Lange-Nielsen syndrome, characterized by syncopal attacks and high risk of sudden death due to ventricular tachyarrythmia and severe bilateral deafness. Northern blot analyses with a KCNE-2 probe showed a 1.35 kb transcript highly expressed in human adult heart and a lower level of expression in skeletal muscle. A 3.5 kb transcript highly expressed in colon, small intestine, ovary and peripheral blood was detected with a KCNE-3 probe. KCNE-2 and KCNE-3 subcellular location has been studied by immunofluorescence analysis of COS-7 transfected cells. KCNE-2 and KCNE-3 are glycosilated proteins which localised to the plasmatic membrane being its N-terminus extracellularly located. Considering the high degree of similarity with Isk, the tissue specific expression pattern and the subcellular localisation, we suggest that KCNE-2 may participate in a cardiac voltage-dependent K+ channel, and KCNE-3 may participate in a colon voltage-dependent K+ channel.

Program Nr: 1018 from the 1999 ASHG Annual Meeting

Characterization of an enhancer region of the X-linked anhidrotic ectodermal dysplasia (EDA) gene. *M.C. Durmowicz, D. Schlessinger.* Laboratory of Genetics, National Inst on Aging, Baltimore, MD, 21224.

Because individuals affected with anhidrotic ectodermal dysplasia (EDA) have sparse hair, rudimentary teeth, and few eccrine sweat glands, the gene is believed to function at an early stage in ectodermal development, possibly at a branch point. Regulation of gene expression occurs at transcription and at mRNA splicing, producing eight transcripts that are differentially expressed at low levels during development. In ongoing studies of the regulation of transcription, a hierarchical promoter structure is emerging. Moving 5' from the coding region, one encounters a segment containing two active Sp1 sites that determine basal transcription; a binding site for LEF-1, a transcription factor already implicated in ectodermal formation; and a region, further described here, that shows enhancer activity. The enhancer region is centered approximately 610 bp upstream of the transcription start site. In transient transfection assays with an enhancer reporter construct, the 125 bp enhancer region is defined by its capacity to boost transcription from an SV40 promoter 4- to 5- fold in an orientation-independent manner. Deletion of 40 bp from either end of this segment abolishes enhancer activity. Oligos within each of these 40 bp regions detect binding proteins in mobility shift assays. Further analysis has detected three distinct binding sequences, with two of them similar to GATA and Nkx-2 sites, in the segment from nt-673 to nt-633, and a third site at the other end of the enhancer region, extending from nt-590 to nt-550 and not corresponding to any known class of enhancer-binding protein binding sites. Mutations in any of these sites abolish their activity in gel shift assays. Thus, there are at least three putative transcription factors that bind within two distinct enhancer regions of the EDA gene to activate transcription; the binding affinities are sufficient to permit affinity purification, now in progress.

Program Nr: 1019 from the 1999 ASHG Annual Meeting

Characterization of xnp-1, a *Caenorhabditis elegans* gene similar to the human XNP/ATR-X gene. *J.J. Ewbank*[1], *M. Fontes*[2], *L. Villard*[2]. 1) CIML - Campus de Luminy, Marseille Cedex9, France; 2) INSERM U491. Faculté de Médecine La Timone. 27 Bd Jean Moulin 13385 Marseille Cedex 5. France.

We have characterized a new *Caenorhabditis elegans* gene, that we have called xnp-1, which encodes the closest known non-mammalian relative of the human XNP/ATR-X protein. Mutations in the corresponding gene lead to several mental retardation syndromes in humans (ATR-X and Juberg-Marsidi syndromes). The nematode gene is composed of 10 exons and we have shown that a 4,3 kb transcript is produced from the xnp-1 locus. The 1359 residues XNP-1 protein is 33,6 % identical and 52,2 % similar to the human XNP/ATR-X protein. Such a degree of similarity over more than a thousand amino acid residues is likely to reflect a conserved cellular function for the two proteins. In two regions of more than 250 amino acids, the proteins display 70% identity. The human and the nematode proteins are putative DNA-helicases as they contain the seven characteristic domains of this family of proteins, which is involved in various cellular processes such as DNA repair, chromosome segregation, recombination or transcriptional regulation. In addition to the fact that similar proteins are encoded by the nematode of the human genes, they both have a partially identical genomic structure. These data may indicate that xnp-1 and XNP/ATR-X may have diverged from the same ancestral DNA-helicase gene and may have conserved identical functions at the cellular level. RNA interference and xnp-1 promotor-mediated GFP expression experiments currently being performed using the nematode gene will allow an exploration of the cellular mechanisms in which it is involved and give potential clues as to the role of its human counterpart.

Program Nr: 1020 from the 1999 ASHG Annual Meeting

LINE1 element tails: a possible role in alternative splicing relevant for primates genome evolution? *A. Ferlini[1,2], T. Patarnello[3], M. Dunckley[2], F. Muntoni[2].* 1) Istituto di Genetica Medica, Universita' di Ferrara, Ferrara, Italy; 2) Neuromuscular Unit, Imperial College School of Medicine, Hammersmith Campus, London, UK; 3) Dipartimento di Biologia, Universita' di Padova, Italy.

We further studied an already reported family with X-linked dilated cardiomyopathy caused by a dystrophin mutation involving a sequence originally classified as an Alu-like element. This sequence is however part of the unconventional 5 tail of a novel LINE1 element, named LIPMA2 and deposited in the Repbase (http://charon.girinst.org/). We defined the mutation as a 11Kb deletion in intron 11. This deletion brought the 5 tail of a LIPMA2, normally present in intron 11, close to a cryptic splice site, inducing the shuffling of part of the 5 tail into the dystrophin transcript. The pathogenic mechanism of this mutation provides the first experimental evidence that, in addition to the demonstrated 3' transduction model, a 5'transduction of tails co-mobilised with LINE1 elements can occur. Since this splicing mutation also had a tissue specific expression, this also suggests that LIPMA2 is involved not only in exon shuffling, but also in splicing regulation. In order to identify specific regions of the 5 tail involved in splicing regulation we are producing constructs containing different part of this tail to perform "in vitro" transcription/splicing assay studies.In order to investigate when this element appeared in the course of evolution, we tested by PCR and Southern blot analysis the Alu-like sequence in genomic DNA of several primate species as well as in other mammals and birds.Our results suggest that this sequence is primate specific. Sequence comparison of this part of the LIPMA2 5' tail in different primates revealed diagnostic mutations and the phylogenetic relationships were as expected. On this base, we can assume that the 5 LIPMA2 tail appeared at least 25-45 million years ago.In conclusion the mechanism of disease in this family with XLDC support the 5' transduction model and suggest that the 5 tail of LIPMA2 does indeed have a role in RNA remodelling. The primate specific nature of this sequence makes this hypothesis extremely intriguing for its evolutionary implications.

Program Nr: 1021 from the 1999 ASHG Annual Meeting

Modelling mutational spectra using recursive partitioning. *B.A. Fijal[1], R.M. Idury[2], J.S. Witte[1].* 1) Epidemiology and Biostatistics, Case Western Reserve University Cleveland, OH; 2) Axys Pharmaceuticals, La Jolla, CA.

A mutational spectrum is the pattern of changes that have taken place in a gene that is thought to cause a specific disease. While it is well known that the positions of hotspots and clusters of mutations within a spectrum indicate where functional domains and other areas of the protein that are essential for its proper functioning are located, very few statistical methods exist that satisfactorily identify both hotspots and clusters for this type of data. We present a method of analyzing mutational spectra that allows one to identify both hotspots and clusters. As an example we analyze a p53 mutational spectrum taken from colorectal cancer patients. The hotspots and clusters identified by our method and their possible relevance are compared to what is known of p53's structure and function. We show that information gained by modelling spectra with this method can compliment information on a protein's structure/function gained by other methods, such as searching for conserved regions across species.

Program Nr: 1022 from the 1999 ASHG Annual Meeting

The human *GTX* gene maps to 10q26, a region often deleted in gliomas. *J.Y. Garbern[1, 2], H.H.Q. Heng[2], R.-P. Wu[1, 2], C.J. Ye[3], R. Awatramani[1], J. Kamholz[1, 2].* 1) Dept Neurology, UHC 8B, Wayne State Univ, Detroit, MI; 2) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI; 3) SeeDNA Biotech, Windsor, ON.

The murine *GTX* gene is an NKx-family homeobox gene that we have found is expressed in the central nervous system specifically in oligodendrocytes. The GTX protein is a sequence specific DNA binding protein and therefore is a potential regulator of gene expression in these cells.

We have now cloned and sequenced the human *GTX* gene from a brain cDNA library and a genomic library and mapped its chromosomal location by fluorescence in situ hybridization. The *GTX* gene is comprised of 3 exons separated by introns of 91 and 109 base pairs. The relative intron positions are identical between the human and murine genes, although the intron sizes differ between the species. The predicted human GTX protein is 97 % identical to its murine homolog across its 277 codon reading frame, with all variances lying outside of the homeodomain. A histidine at position 3 of the homeodomain is found in the NKx6.1 protein but is otherwise unique at that position among known homeodomain proteins, and may underlie its specific biological properties. We have mapped the human gene to 10q26.

Although the biological role(s) of GTX in the human brain have not been defined, its extremely high sequence similarity to the murine gene suggest common functions. The localization of *GTX* to a region of chromosome 10 that is often lost in gliomas raises the possibility that this gene may have tumor suppressor properties.

Supported in part by a Virtual discovery grant from the Karmanos Cancer Institute.

Program Nr: 1023 from the 1999 ASHG Annual Meeting

Genomic Structure and Localization of the IKBKAP gene to the Familial Dysautonomia Candidate Region on 9q31. *S.P. Gill[1], M. Leyne[1], J. Mull[1], C.B. Liebert[1], C.M. Robbins[2], H.W. Pinkett[2], I. Makalowska[2], C. Maayan[3], F.B. Axelrod[4], A. Blumenfeld[3], M. Brownstein[2], B.P. Chadwick[1], S.A. Slaugenhaupt[1]*. 1) Harvard Inst. Human Genetics, Massachusetts General Hospital, Boston, MA; 2) National Institute of Health, Bethesda, MD; 3) Hadassah University Hospital, Jerusalem, Israel; 4) New York University Medical Center, New York, NY.

Familial Dysautonomia (FD, Riley-Day Syndrome) is an autosomal recessive disorder characterized by the poor development and progressive degeneration of the sensory autonomic nervous system. The gene defect has a carrier frequency of 1:30 among people of Ashkenazi Jewish descent. Linkage studies have narrowed the candidate region for the gene (DYS) to a less than 0.5 cM area of chromosome 9q31. We have used positional cloning techniques to isolate transcripts from this region. Exon trapping identified 23 exons which were pooled and used to screen a cDNA library. Seven overlapping clones were isolated and sequenced to form 'CG-5', a 4390 base pair cDNA. Additionally, cDNA selection identified a clone which matched two groups of human ESTs through database searches. The sequences of these clones extended the 3' untranslated region of CG-5 to form a 6040 base pair cDNA. Database searches have shown this to be the IKappaBKinase(IKK)-complex Associated Protein (IKBKAP) gene. IKBKAP has been reported as an assembler and regulator of active kinase complexes and was originally mapped to 9q34. Southern and Northern analysis showed IKBKAP definitely maps to the Familial Dysautonomia candidate region in 9q31. We have determined the genomic structure of the gene and identified several single nucleotide polymorphisms and a single dinucleotide polymorphism during mutational screening of IKBKAP as a candidate gene for FD. No splicing or coding mutations have been found in the gene which are pathogenic in Familial Dysautonomia. However, until DYS is discovered, IKBKAP remains a candidate for FD, and may contain non-coding mutations.

Program Nr: 1024 from the 1999 ASHG Annual Meeting

Two functional copies of the *DGCR6*gene are present on 22q11 and lie within the low copy repeat, sc11.1. *R. Goldberg[1], L. Edelmann[1], E. Spiteri[1], R.K. Pandita[1], B. Funke[1], N. McCain[1], A. Skoultchi[2], R. Kucherlapati[1], B.E. Morrow[1]*. 1) Dept Molecular Genetics, Albert Einstein Col Medicine, Bronx, NY; 2) Dept of Cell Biology, Albert Einstein Col Medicine, Bronx, NY.

The *DGCR6*(DiGeorge Critical Region 6) gene encodes a putative protein with high sequence similarity to gonadal (gdl), a *Drosophila melanogaster*gene of unknown function (Demczuk et al., 1996). We mapped the *DGCR6*gene to chromosome 22q11 within a low copy repeat, sc11.1a, of which there are two members termed sc11.1a and b, originally identified by interphase FISH mapping with the cosmid, sc11.1. We identified a second copy of the gene, *DGCR6L*, within the sc11.1b locus. We sequenced genomic clones from both loci and determined that the putative initiator methionine is located further upstream than originally described in a position similar to the mouse and chicken homologs. *DGCR6L*encodes a highly homologous, functional copy with some base substitutions rendering amino acid changes. Expression studies of the two genes using multiple tissue cDNA panels indicates that both genes are widely expressed in fetal and adult tissues. Both sc11.1 repeats are deleted in most VCFS/DGS patients and map immediately adjacent to the low copy repeats, termed LCR22, that mediate the deletions associated with velo-cardio-facial syndrome/DiGeorge syndrome (VCFS/DGS). Interestingly, an intact HERVK retrovirus maps within sc11.1a, however, a second HERVK integration site is not present at the sc11.1b locus indicating that the integration of the retrovirus occurred after the sc11.1 duplication during evolution.

Program Nr: 1025 from the 1999 ASHG Annual Meeting

Identification and expression analysis of C21orf5, the ortholog of which leads to embryonic lethality in C. elegans using double-stranded RNA-mediated interference. *M. Guipponi[1], K. Brunschwig[2], Z. Chamoun[3], J. Kudoh[4], HS. Scott[1], S. Al Samadi[3], AL. Delezoide[5], Z. Chettouh[3], C. Rossier[1], N. Shimizu[4], F. Mueller[2], JM. Delabar[3], SE. Antonarakis[1].* 1) Div Med Genet, Geneva, Switzerland; 2) Inst Zool, Fribourg, Switzerland; 3) CNRS URA 1335, Paris, France; 4) Dept Mol Biol, Keio Univ, Sch Med, Tokyo, Japan; 5) Hop. Necker, Hop. Robert Debre, Paris, France.

Human chromosome 21 has been intensively studied, since trisomy 21 causes Down syndrome (DS). Molecular analyses of patients with partial trisomy 21 allowed the characterization of the Down Syndrome Critical Region (DSCR). To isolate genes from this region on 21q22.2, a pool of cosmids positive for D21S333/S334 was selected for cDNA selection. From the 27 transcription units identified, one, CER5-0, was found to be identical to several HC21 trapped exons. cDNA library screening and RACE were used to determine the cDNA sequence of 7288 bp with an ORF of 2298 aa, termed C21orf5 (chromosome 21 open reading frame 5). Analysis of the 21q22.2 genomic DNA sequence revealed that C21orf5 consists of 37 exons that extend over 130kb and maps between CBR and D21S334. Northern blot analyses revealed a major ubiquitously expressed transcript of 8.5kb. RNA in situ hybridization on human embryos revealed a weak and ubiquitous signal with strong labeling only in restricted areas. In the CNS, strong labeling might correspond to neuronal cells which have already migrated and which have started to differentiate. C21orf5 shared significant homology with the E. nidulans DopA protein, a potential novel component of tyrosine kinase signal transduction pathway and with D. melanogaster, S. cerevisiae and C. elegans predicted protein from the different genome sequencing projects. Double-stranded RNA-mediated interference in C. elegans were performed by injection of dsRNA derived from the ortholog gene in C.elegans into the gonads of adult wild-type worms. The major phenotype observed in the progeny generated by the injected animals was embryonic lethality. These results indicated that C21orf5 is essential for the survival of C. elegans, and may be involved in one of the DS phenotypes.

Program Nr: 1026 from the 1999 ASHG Annual Meeting

Functional characterization of the *PMP22* gene promoters. *M. Hai[1], S.I. Bidichandani[2], P.I. Patel[1,2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Neurology, Baylor College of Medicine, Houston, TX.

Overexpression of peripheral myelin protein-22 (PMP22) results in Charcot-Marie-Tooth Type 1A, one of the most common inherited peripheral neuropathies, while underexpression of PMP22 results in hereditary neuropathy with liability to pressure palsies. The dosage of PMP22 is therefore critical, and transcriptional control could be a mechanism of ensuring correct levels of gene expression. *PMP22* expression is driven by two alternative promoters (P1 and P2), that give rise to two different transcripts.The transcript from the P1 promoter is strongly associated with myelination by Schwann cells.Transient transfection of a deletion construct series of the P1 and P2 promoters into fibroblast and Schwann cell lines had provided preliminary evidence for the existence of transcriptional regulatory elements. Electrophoretic mobility shift assays (EMSA) detected regulatory factors that bind to these elements. Candidate regulatory regions of the P1 promoter were assayed for regulation of a heterologous promoter, in different Schwann cell and other cell type lines. A 43-bp region of the P1 promoter was able to regulate a heterologous promoter in a cell-type specific manner. EMSA competition experiments were used to localize the binding site of the putative regulatory factor. Mutation analysis of this 43-bp region has been designed to further confirm its role in the regulation of the *PMP22* gene. In order to develop a method of reducing expression of the *PMP22* gene, triplex forming oligonucleotides (TFOs) were developed that bind to regions of the P1 and P2 promoters. TFOs form triplex DNA with purine-rich regions, and reduce gene expression by interfering with the transcription factors. High-affinity TFOs binding to the P1 promoter competed with the binding of a protein factor, and may be good candidates for regulatory agents. The P2 promoter TFOs bind with high affinity to their target region, but are not able to compete with the simultaneous binding of a protein factor. Together, these two lines of study will further our understanding of transcriptional control of the *PMP22* gene.

Program Nr: 1027 from the 1999 ASHG Annual Meeting

_IS_-RT-PCR localisation of MMP gene expression in human breast biopsy material. *L.M. Haupt[1], M.G. Irving[2], R. Irving[1], L.R. Griffiths[1]*. 1) Genomics Research Centre, Griffith University Gold Coast, Australia; 2) Victoria University, Wellington, New Zealand.

The in situ-reverse transcription-polymerase chain reaction (IS-RT-PCR) was successfully adapted from a previously reported in vitro assay (1), for use in archival paraffin embedded human breast biopsy material. IS-RT-PCR allows the site of amplification and hence gene expression to be localised in situ, and was utilised to examine gene expression of several members of the matrix metalloproteinase (MMP) family. MT1-MMP (membrane-type1-MMP), the activator of MMP-2, MMP-1 (interstitial collagenase) and MMP-3 (stromelysin-1) were examined in progressive breast biopsy lesions from poorly invasive breast carcinomas to lymph node metastases. Critical to the success of the IS-RT-PCR technique in paraffin embedded tissue are primer design and specificity, along with protocol steps including tissue fixation, protease digestion, and the use of sufficient inter-assay negative and positive controls. Validation of gene expression was confirmed through the use of two negative controls, an RNase/DNase control and a no reverse transcription (RT) control. The ubiquitous gene beta-actin served as a positive control for gene expression, with tissue morphological integrity confirmed by the haematoxylin/eosin (H&E) stain. Through utilisation of the IS-RT-PCR technique, the three MMP genes examined were able to be loclised to both the epithelial tumour and stromal components within the paraffin embedded tissue. The expression patterns observed confirmed both the previously observed associations of MMP genes with breast carcinoma and the specificity of IS-RT-PCR. Results indicate distinctive roles for MT1-MMP, MMP-1 and MMP-3 throughout the progression of breast neoplasia toward lymph node metastasis. 1. Program Nr: 1028 from the 1999 ASHG Annual Meeting

An imprinted antisense transcript at the human *GNAS1* locus. *B.E. Hayward, D.T. Bonthron.* Human Genetics Unit, Univ Edinburgh Western Gen Hos, Edinburgh, Scotland.

The upstream region of the *GNAS1* gene contains two oppositely imprinted first exons, which encode two unrelated polypeptides and are separated by only 11kb of genomic sequence. The 5-most of these, encoding NESP55, is expressed from the maternal chromosome and methylated on the paternal allele; conversely the other exon, encoding XLas, is expressed from the paternal chromosome and methylated on the maternal one. The differentially methylated CpG-rich region associated with the XLas exon extends approximately 3kb upstream of its putative initiation codon and here we describe another transcript originating in this region. This transcript, which has an orientation antisense to XLas, has multiple alternative splice forms and terminates approximately 20kb 5 to the NESP55 exon. Although this RNA lacks coding potential, its sequence is very highly conserved. Nonetheless, the identification of one rare single-nucleotide polymorphism allowed us to establish that this antisense transcript is imprinted. Furthermore, this transcript is not detected by RT-PCR using RNA from the parthenogenetic lymphoblastoid cell line FD, although it is present in normal female lymphoblastoid cell RNA. Antisense transcripts have been described for other imprinted genes and suggested to play a role in regulating in cis the coding (sense) transcripts. Traversing as it does the maternally expressed NESP55 promoter, the paternally expressed *GNAS1* antisense transcript could play a major role in the regulation of this complex gene.

Program Nr: 1029 from the 1999 ASHG Annual Meeting

Identification of a novel gene expressed in human bone marrow stromal cells. *N. Ho, L. Jia, L. King, C. Driscoll, E. Gutter, M. Anderson, C. Francomano.* Medical Genetics Branch, NHGRI/NIH, Bethesda, MD.

To identify bone and cartilage-specific genes, to explore their functions and to study their relationship with normal skeletal growth and development as well as dysplasias, a project termed Skeletal Genome Anatomy Project SGAP (Jia et. al, 1997) involving cataloguing genes expressed in bone and cartilage and developing a tissue bank comprising bone, cartilage, tendon, synovium and ligament has been established. By high-throughput sequencing analysis from both human bone marrow stromal cells and normal human trabecular bone cells, 8666 ESTs were isolated. More than 100 ESTs with novel sequences, representing genes that are as yet uncharacterized, were identified. The clones containing the novel ESTs fragments were then sequenced and characterized.

One cDNA clone derived from bone marrow stromal cells carried an insert with novel human sequence of 4.7 kb in size. This gene is localized to the pericentromeric region (10p11.1-10q11.1) of chromosome 10 by radiation hybrid mapping using the Stanford 3 panel.Reaffirmation of the chromosome location by fluorescent-in-situ hybridization is in progress.By sequencing and BLAST searching against NCBI GenBank database, this 4.7 kb sequence shows no homology to any known gene. Part of the domain of the gene has a 63% amino acid identity to glutamate permease. To determine the expression pattern of this gene in different tissues, a probe containing 1.2 kb sequence of the gene is now being constructed and hybridized against multiple human tissue mRNA.

In conclusion, further characterization of novel genes expressed in human bone marrow stroma and trabecular bone will facilitate greater understanding into the pathophysiology of normal and abnormal processes of skeletal development.

Program Nr: 1030 from the 1999 ASHG Annual Meeting

Persistence of Foreign DNA in Mice after Oral or Parenteral Application. *U. Hohlweg[1], S. Dumrese[1], R. Schubbert[2], W. Doerfler[1].* 1) Institute for Genetics, Univ. Cologne, Cologne, NRW, Germany; 2) Medigenomix GmbH, Mnchen, Germany.

In previous work, we have demonstrated that orally administered foreign DNA as bacteriophage M13 DNA or plasmid pEGFP DNA with no homology to mouse DNA can persist in fragmented form in the gastrointestinal (GI) tract. These DNA fragments can penetrate the intestinal wall and reach the nuclei of leukocytes, spleen and liver cells. There is evidence that in spleen cells this foreign DNA can become covalently linked to genomic DNA with a high degree of homology to mouse DNA. We have now extended these studies to DNA which is enclosed in cells. To mimic the natural exposure of DNA to the GI-tract, we have fed mice with soybean leaves. From all segments of the gut, the complete small subunit of the ribulose-1,5-bisphosphate (RuBP) carboxylase gene could be retrieved and characterized by Southern blot hybridization analyses. These results suggest that DNA within cells is protected against the attack by nucleases and might have a better chance to penetrate the intestinal wall than naked plasmid DNA. Maximal fragment lengths of 337 bp from the RuBP carboxylase gene can be traced by PCR in some of the liver and spleen samples. The medical and evolutionary implications of these findings may be considerable. More recently, we have analyzed the fate of DNA (pRSVGFP) in mice upon intramuscular (i.m.) injection. The injected DNA (5 mg) can be retrieved by PCR (772 bp fragment length) in DNA from the injected muscle at least up to 4 weeks after injection and up to 24 h in DNA from organs remote from the injection site, like blood, liver and contralateral muscle. In order to investigate the uptake and expression of the injected DNA, we have analyzed the injected muscle and other organs for the expression of the green fluorescent protein (GFP) by fluorescence microscopy. Furthermore, the injected DNA with a length of 593 bp can be discovered by PCR in the contents of different segments of the intestine. These findings suggest that foreign DNA injected i.m. is not completely degraded in the organism and is eliminated via the liver-bile-intestinal pathway. (This research was supported by the Federal Ministry of Education and Research - BMBW - BEO 0311110).

Program Nr: 1031 from the 1999 ASHG Annual Meeting

Identification of Dyxin: A Novel Intracellular Binding Partner of a-**Dystroglycan.** *K.H. Holt, R.H. Crosbie, K.P. Campbell.* Howard Hughes Medical Institute, Dept. of Physiology & Biophysics and Dept. of Neurology, Univ. of Iowa College of Medicine, Iowa City, IA.

Dystroglycan functions as a component of the dystrophin-glycoprotein complex (DGC), to link the extracellular matrix via the a-dystroglycan-laminin-2 interaction, with the intracellular cytoskeleton via the b-dystroglycan-dystrophin interaction. The DGC stabilizes the muscle fiber against the constant forces of contraction. Although mutations in dystroglycan have yet to be identified in humans, mutations in various subunits of the DGC destabilize a- and b-dystroglycan at the sarcolemma. Furthermore, targeted deletion of the dystroglycan gene results in an early embryonic lethality in mice. In an attempt to learn more about the role of dystroglycan in muscle, we performed a yeast two-hybrid screen to search for novel intracellular binding partners of b-dystroglycan. We reasoned that this approach might identify proteins which interact transiently with b-dystroglycan, compared to integral components of the DGC, which for the most part have been discovered by biochemical purfication and cloning. We report here the identification of a novel human b-dystroglycan-binding partner, termed Dyxin, which contains two tandem LIM domains and is highly expressed in striated muscle in humans.

Program Nr: 1032 from the 1999 ASHG Annual Meeting

Characterization of the Lafora's Progressive Myoclonus Epilepsy (EPM2A) gene and protein. *L. Ianzano[1], B.A. Minassian[1], A.V. Delgado-Escuieta[2], G.A. Rouleau[3,4], S.W. Scherer[1].* 1) Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Dept. of Neurology,UCLA School of Medicine and DVA West LA DVA, West Los Angeles, CA; 3) Dept. of Human Genetics, McGill University, Montreal, Quebec, Canada; 4) Centre for Research in Neuroscience, Montreal General Hospital, Montreal, Quebec, Canada.

Lafora's disease is an autosomal recessive form of adolescent progressive myoclonus epilepsy (PME) characterized by myoclonus, decreasing mental function, and death within 10 years of onset. The definitive diagnosis of Lafora's disease is based on detection of characteristic periodic acid Schiff-positive polyglucosan inclusions (Lafora bodies). In 1998, using a positional cloning approach, was been identified a gene (EPM2A) at chromosome 6q24 that causes LD. In the course of this study it was determined that genetic hetereogeneity existed indicating another gene elsewhere in the genome can cause the same phenotype. Moreover, the gene encodes a protein (laforin) of 332 amino acids with a consensus amino acid sequence indicative of a protein tyrosine phosphatase (PTP). To understand the role of the protein in the pathology of the disease we have raised antibodies to two different 'unique' portions of the peptide and are studying its expression at the tissue and cellular level. We have so far identified 10 mutations in 16 families. Of those, 5 are nonesense or deletion mutations and the other 5 are missense mutations. Work is underway to identify more mutations and to study the effect of missense mutations on the structure and function of laforin. Moreover, we have initiated experiments to generate a knock-out mouse; model with germ line inactivation of EPM2A by homologous recombination in ES cells. Two BACs were identified containing the complete EPM2A murine gene. The genomic structure of the mouse gene was determined. Using a segment from the 5' region a targetting vector was constructed that upon proper integration would replace EPM2A exon 1 with a neomycin-resistance gene cassette. Experiments are now underway to electorporate the construct into R1 ES cells. Homologous recombinants will be screened by Southern blot-hybridization analysis.

Program Nr: 1033 from the 1999 ASHG Annual Meeting

The gene structure of *MJD*. *Y. Ichikawa[1], M. Hattori[2], A. Toyoda[2], K. Ishii[2], S.-Y. Jeong[3], H. Hashida[1,3], N. Masuda[1,3], K. Ogata[1], F. Kasai[4], M. Hirai[4], J. Goto[1,3], G.A. Rouleau[5], Y. Sakaki[2], I. Kanazawa[1,3].* 1) Dept. of Neurology, Univ. of Tokyo, Tokyo, Japan; 2) RIKEN Genomic Science Center, Kanagawa, Japan; 3) CREST, Japan Sci. and Tech. Corp., Tokyo, Japan; 4) Dept. of Biological Sciences, Univ. of Tokyo, Tokyo, Japan; 5) Dept. of Neurology, McGill Univ. Montreal, Quebec, Canada.

Machado-Joseph disease (MJD) is an autosomal dominant neurodegenerative disorder characterized by cerebellar ataxia and variable associated symptoms. The disease is caused by an unstable expansion of the CAG repeat in *MJD* that maps to chromosome 14q32.1. The original cDNA clone, MJD1a, consists of 1776bp and four exons. We present here the update results of the gene structure of *MJD*. Northern blot analysis showed that the size of mRNA is approximately 7.8kb which is larger than MJD1a. To obtain a cDNA clone for *MJD*, we screened four human cDNA libraries; whole brain, caudate, retina, and testis. Twenty seven clones were obtained, including 21 independent clones. Most of the clones have a new exon which we have previously reported. Two clones (#H4-1. #H13-2) have longer 3'UTR region than the one that has been reported. Until now, we identified two alternative splicing sites and four polyadenylation signals. Therefore, there are at least 6 transcription products of *MJD*. To determine the genomic structure, we obtained 13 cosmid clones from a human 14 chromosome library and four BAC clones from a human genomic BAC library. FISH analyses was performed to determine the chromosomal localization of these clones. Eight cosmid clones and all BAC clones were mapped on 14q32.1, and the other cosmids were localized on 14q21-22. Using PCR and fiber FISH analyses, we made a contig of 6 cosmid clones and a BAC clone which were localized on 14q32.1 The genome sequencing of *MJD* is currently underway using nested deletion method. We sequenced approximately 75kb of the contig and identified three new introns. Taken together, *MJD* is composed of at least 8 exons. The gene structure of *MJD* appears to be complicated than the one that has been first reported.

Program Nr: 1034 from the 1999 ASHG Annual Meeting

Identification of a splicing enhancer sequence within exons of the dystrophin gene using a chimeric dsx pre-mRNA. *T. Ito[1], Y. Takeshima[2], H. Sakamoto[3], H. Nakamura[2], M. Matsuo[1]*. 1) Division of Genetics, ICMR, Kobe Univ. School of medicine, Kobe, Hyogo, Japan; 2) Pediatrics, Kobe Univ. School of Medicine, Kobe, Hyogo, Japan; 3) Biology, Kobe Univ. Faculty of Science, Kobe, Hyogo, Japan.

Pre-mRNA splicing is an essential process in the expression of most eukaryotic protein-coding genes. Several factors comprise the splicing mechanism thus making it complicated. The splicing enhancer sequence (SES) is one of the cis-acting elements located within an exon sequence. It consists of a polypurine-rich stretch and enhances the splicing of upstream introns. The SES in exon19 of the dystrophin gene has been reported earlier. We,thus,investigated SES candidate regions between exons 40 and 60. The candidate SES region was determined by selecting the longest purine segment that does not include a T nucleotide and also,the same segment must include as many AAg repeats possible. Using this criteria, 3 candidate SES regions in exons 43,46,and 53 were selected. SES was examined in vitro by analyzing the splicing of heterogous introns of the doublesex gene pre-mRNA in HeLa cell nuclear extracts. In this in vitro system,the splicing of chimeric dsx pre-mRNA is dependent on the downstream sequence. To evaluate SES, the template plasmids for chimeric dsx pre-mRNA was cut with restriction enzymes and various artificial oligonucleotides were inserted in the recognition sites. The reaction products were then electrophoresed and quantified. An artificial oligonucleotide,mimicking SES in exons 43 and 53,enhanced active splicing of an upstream intron in this chimeric pre-mRNA while the SES in exon 46 was noted to possess weak splicing enhancer activity. Among the 3 selected SES regions,the SES in exon 43 was recognized as having the strongest splicing enhancer activity. We have identified novel splicing enhancer sequences in exons 43 and 53 of the dystrophin gene.These results of in vitro splicing experiments showed that some of exons of the dystrophin gene have splicing enhancer sequence within it.

Program Nr: 1035 from the 1999 ASHG Annual Meeting

Identification of new mouse ABC Transporter gene related to ABCP, Mapping to chromosome 5. *P.K. Jain[1], V. Koneti Rao[2], T. Fojo[2], S. Bates[2], M. Dean[1]*. 1) NCI-FCRDC, NIH, Frederick,MD; 2) NCI-DCS, NIH.

ATP binding cassette (ABC) transporters, or traffic ATPases comprise a superfamily of proteins that couple the hydrolysis of ATP to the translation of solutes across a biological membrane. These transporters are wide spread among all living organisms. They accomplish not only the uptake of nutrients in bacteria, but are involved in diverse cellular processes. Moreover, some hereditary human diseases are caused by defects in the ABC transport system such as Cystic Fibrosis, Adrenoleukodystrophy, Age-related Macular Degeneration, Stargarts disease, Dubin Johnson syndrome, and Sideroblastic anemia. Although of major significance, details of the molecular mechanism by which these systems exert their functions are still poorly understood. Within the ATP binding domain, the second motif, walker B, is immediately preceded by a highly conserved sequence motif, known as the linker peptide. This sequence has proven to be a useful tool in identifying putative family members. By these criteria, a few proteins have also been recognized as a typical ABC protein that clearly serve functions other than transport. A recently found novel human ABC protein, ABC 50, contains no transmembrane domains. We have identified a new mouse gene by employing BLAST search against a conserved sequence from TM domain. An EST AA 277174 was identified which did not have any sequence identity with known ABC genes. The mouse BAC clone was identified by PCR screening, using the primers from 3 sequence of the EST. The sequence data of the BAC clone confirmed the sequence of the EST. Additional sequencing of the clone showed similarity with other mouse and rat ESTs and clones. The contig was assembled; the clone was sequenced further, and intron/exon boundaries were identified. The FISH analysis showed signal on mouse chromosome 5, using the BAC clone as a probe on a normal metaphase spread. Further FISH experiments on a normal human metaphase spread identified a syntenic region on chromosome 8p. Subsequently we are attempting to identify the human homologue. These results will help in analyzing the disorders mapped in this syntenic region.

Program Nr: 1036 from the 1999 ASHG Annual Meeting

A DNA architecture prone to spontaneous mutagenesis in the ITGB genes may have contributed to the expansion of the integrins network of adhesion molecules. *T. Jamal, K. Dellagi, D.M. Fathallah.* Dept Molecular Genetics, Institut Pasteur de Tunis, Tunis, Tunisia.

The human integrins network mediates a wide range of essential adhesive functions. It is formed by the association between 8 b and 14 a subunits. The diversity of the repertoire of integrins mediated-interactions is based upon the various combinations between the two subunits. To investigate the contribution of spontaneous mutagenesis in the generation of integrins functional versatility, we have first analyzed in the ITGB 2, 3 and 4 genes , the regions affected by mutations causing three integrins-related genetic disorders respectively: Leukocyte Adhesion Deficiency, Glanzmann Thrombasthenia and Epidermolysis Bullosa with Pyloric Atresia, for specific sequences prone to spontaneous mutations. Single base substitutions occurred mostly in the CpG dinucleotide mutation hot spot or affected dinucleotides GG,GC and CC that have high relative mutability. Most of the deletions were associated with consensus sequences known to be prone to this type of DNA alteration. Some of the deletions observed occured through the deletional mechanism mediated by the presence of palindromic or quasipalindromic sequence. The study was extended to the eight b integrins coding sequences, to show that the DNA architecture of the b integrins coding sequences is characterized by the presence of high copy numbers of DNA motifs that are prone to spontaneous mutations such as palindromic sequences, the putative polymerases a and b arrest sites or the dinucleotides CG,GC,GG and CC. We have also observed that codon usage in the human b integrins genes does not fully comply with the rule of CG containing supression codons observed in other human or vertebrates genes. Furthermore, use of the mutability prediction software: MUTPRED showed that the human b integrins genes have high overall mutability coefficients and defined the codons that have elevated mutability indexes. We concluded that the occurrence of spontaneous mutations favored by the integrins genes specific DNA architecture may have contributed to the genesis of the various a/b associations and hence to the expansion of the integrins repertoire.

Program Nr: 1037 from the 1999 ASHG Annual Meeting

Human CCTb1 and CCTb2, two novel isoforms of Phosphocholine Cytidylyltransferase: Characterization of the cDNAs and Mapping of the Gene Locus to Human and Mouse Chromosome X. *M.A. Karim[1], A. Lykidis[1], S. Jackowski[1,2]*. 1) Dept of Biochemistry, St Jude Children's Res Hosp, Memphis, TN; 2) Dept of Biochemistry, University of Memphis, Memphis, TN.

CTP:phosphocholine cytidylyltransferase (CCT) is a key regulator of phosphatidylcholine biosynthesis. A single isoform, CCTa, has been studied extensively. We have recently identified two additional isoforms termed CCTb1 and CCTb2. Human CCTb1 and CCTb2 encode 330 and 369 amino acid proteins, respectively, that differ at their carboxy termini and arise from alternate splicing of the same gene. CCTb1 and CCTb2 mRNAs were expressed differentially in multiple human tissues, whereas CCTa was uniformly expressed as determined by Northern blot and RT-PCR. Both isoforms of CCTb were expressed in brain, with CCTb2 being dominant. Liver also expressed both isoforms, but CCTb1 gave a stronger signal. Placental tissue contained CCTb1 transcripts with no detectable signal for CCTb2. On the other hand, CCTb2 was the predominant isoform expressed in HeLa cells whereas a lower amount of CCTb1 was detected. Both CCTa and both CCTb isoforms were expressed in fetal lung whereas mRNA from adult lung did not yield a signal for CCTb and only CCTa was expressed. The novel gene encoding CCTb, named PCYT1B, was mapped by fluorescence in situ hybridization (FISH) to human chromosome Xp22 using a BAC containing human genomic DNA as a probe. The mouse CCTb gene also mapped to the conserved syntenic locus of mouse chromosome XC3 as determined by FISH using a 13 kb CCTb genomic clone from a l-phage mouse genomic library. In contrast, CCTa is encoded by PCYT1A located on mouse chromosome 16. The PCYT1B gene structure is currently being determined.

Program Nr: 1038 from the 1999 ASHG Annual Meeting

Illegitimate Splicing of 5 of 7 Investigated in-frame Exons of the Neurofibromatosis Type 1 Gene. *D. Kaufmann[1], W. Leistner[2], S. Hoffmeyer[3], W. Just[4], P. Kruse[1], B. Bartelt[1]*. 1) Department of Human Genetics , University of Ulm, Ulm, Germany; 2) Max Delbrueck Centre for Molecular Medicine, Berlin, Germany; 3) Epidauros AG, Bernried, Germany; 4) Department of Medical Genetics, University of Ulm, Ulm, Germany.

Mutations in the regulatory sequences of human genes necessary for splicing can lead to skipping of exons. Such a mutation was found recently in cells of a Neurofibromatosis type 1 (NF1) patient leading to the skip of exon 8 of the NF1 gene. Investigations on human cell lines, primary cell cultures and cells in vivo revealed that this in-frame exon was also skipped in all cells examined at a low frequency (about 0.6 %). It is not due to mutations in single cells as shown in clones of HeLa cells. Of seven in-frame exons of the NF1 gene investigated afterwards illegitimate exon skipping was found for exon 7, 9 and 10b at a low percentage but not for the exons 10a and 10c. The alternative exon 9br, expressed normally only in brain, was inserted at a low percentage in all cell types tested. Transfection of HeLa cells with hnRNP-A1 or SF2/ASF, two proteins belonging to the splice factors, does not influence the occurrence of this illegitimate splicing. According to simulations of the two-dimensional minimum-free-energy structures of hnRNA illegitimately spliced or not, we propose that the illegitimate splicing of in-frame exons is due to the rare occurrence of metastable structures of hnRNA after transcription. These would lead to misfolded splice donor site sequences which are not recognized by the splice machinery. We speculate that illegitimate splicing limits the maximal number of in-frame exons in human genes.

Program Nr: 1039 from the 1999 ASHG Annual Meeting

Cloning and genomic structure of a 9.5-kb transcription factor-like nuclear regulator (TFNR), closely localized to the survival motor neuron gene. *A.R. Kelter[1], J. Herchenbach[1], F. v. Deimling[1], T. Liehr[2], J.M. Scharf[3], L.M. Kunkel[3,4], W.F. Dietrich[4], B. Wirth[1].* 1) Inst. Human Genetics, Bonn, Germany; 2) Inst. Human Genetics and Anthropology, Jena, Germany; 3) Children's Hospital, Boston, MA, USA; 4) Harvard Medical School, Boston , MA, USA.

Spinal muscular atrophy (SMA) is caused by homozygous mutations in the survival motor neuron gene (SMN1). However, rare familiar and sporadic cases, so called atypical SMA forms have been described, where SMA patients show additional atypical features, such as axonal neuropathies, brain atrophy with homozygous absence of SMN1 and usually with larger deletions within 5q13. We postulated that atypical SMA forms might represent contiguous gene syndromes caused by additional deletions/mutations of genes adjacent to SMN1. The SMA region contains a 500-kb duplication and inversion including the H4F5, SMN, NAIP and BTF2p44 gene copies. The region between the H4F5 copies is still unknown.

We describe a novel gene, called TFNR (for transcription factor-like nuclear regulator), that maps close to H4F5/SMN gene copies. Fluorescence in situ hybridization analysis with a BAC that covers the TFNR gene shows a strong signal on 5q13 and a weaker signal on 5p14-p15.1. TFNR shows ubiquitous expression of a 9.5 kb transcript with the strongest expression in cerebellum and a second small transcript at 1.9 kb. TFNR encodes a protein of 2190 amino acids (aa) and a molecular weight of 245 kD of unknown function . The coding region is organized in 30 exons and contains within exon 16 a 9x repeated 55-aa fragment. The putative aa-sequence is highly hydrophilic and has two putative bipartite nuclear signaling domains, indicating that TFNR is a soluble nuclear protein. We also identified the first 544 aa of mouse Tfnr (11 exons) which reveals 79% similarity to TFNR. Amino acids 156-470 show significant homology ($1.5e^{-18}$) to the TFC5 protein, a subunit of the yeast transcription factor TFIIIB, suggesting that TFNR may function as a transcription factor. The establishment of TFNR-antibodies is in progress and should draw new light into the cellular location and function of the protein.

Program Nr: 1040 from the 1999 ASHG Annual Meeting

Characterization of a gene encoding an E-rich protein (ERP) expressed in human bone marrow stromal cells.
L.M. King, T. Iwata, C.A. Francomano. NHGRI/NIH, Bethesda, MD.

The identification and characterization of genes expressed in skeletal tissue is one goal of the Skeletal Genome Anatomy Project (SGAP). Bone marrow stromal cells (BMSC) are a population of pluripotent cells capable of differentiating into at least four types of connective tissues: bone, cartilage, hematopoiesis-supporting stroma, and adipocytes. Here we describe the structure, chromosomal location, composition, and expression of a novel gene encoding a glutamic acid (E) rich protein (ERP) isolated from a human BMSC cDNA library. We sequenced the 1.2 kb insert of the clone and extended the 5' and 3' cDNA ends by 5' RACE and by a homology search of 3' ESTs in GenBank. The 1865 bp cDNA sequence contains an 846 bp ORF and based on comparisons with genomic sequences, the gene lacks introns. Four potential poly(A)+ addition sites are present in the 3' UTR of the cDNA. Based on fluorescence *in situ* hybridization (FISH), the gene maps to the cytogenetic location Xq13. We performed Northern analysis to assess mRNA expression across several tissues. The major sites of expression are fetal and adult liver and kidney. Multiple transcripts occur in adult heart. Analysis of the 282 amino acid predicted protein shows that it is largely composed of charged residues: glutamic acid (n=73, 25.9%), lysine (n=51, 18.1%) and aspartic acid (n=29, 10.28%). The N-terminal region contains a consensus bipartite nuclear localization signal (NLS), which is composed of basic residues and has been shown in other proteins to be required for nuclear translocation. To further identify possible functions of ERP, we searched for a mouse homologue of ERP. We found the mouse GARP34 protein, which shows 56.7% similarity to ERP. It is similar in size (307 amino acids), possesses a bipartite NLS and a similar composition of charged residues. GARP34 is expressed in liver and kidney, similar to ERP. GARP34 is also expressed in thymus, small intestine and testis. RNA *in situ* hybridization experiments are in progress to evaluate further the patterns of gene expression in murine development.

Program Nr: 1041 from the 1999 ASHG Annual Meeting

Genomic structure and complete genomic sequences of the Fukuyama-type congenital muscular dystrophy (FCMD) gene, *fukutin*. *K. Kobayashi[1], J. Sasaki[1], E. Kondo-Iida[1], Y. Nakamura[2], T. Toda[1]*. 1) Laboratory of Genome Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Fukuyama-type congenital muscular dystrophy (FCMD), one of the most common autosomal recessive disorders in Japan, is characterized by severe muscular dystrophy in combination with cortical dysplasia. We have recently identified the *fukutin* gene responsible for FCMD by positional cloning, and found that the ancestral mutation is the insertion of a 3-kb retrotransposon element. The gene encodes a novel 461 amino-acid protein, fukutin, that is likely to be an extracellular matrix component. In this study, we determined complete genomic sequences that span more than 130 kb around the *fukutin* gene on 9q31, and obtained the complete structure of the gene. The *fukutin* gene extends over 100 kb and is organized into 10 exons ranging in size from 60 to 6,067 bp. The nine introns vary from 1,842 to 16,778 bp, and all splice acceptor and donor sites conform to the AG/GT rule. The flanking 5' region contains a predicted TATA box. More than ten minor transcripts were found that were produced by alternative splicing. We also found two EST clusters constructing two novel genes in the upstream of the *fukutin* gene. These data provide fundamental information for further studies including mutation search, expression regulation, and identification of new genes.

Program Nr: 1042 from the 1999 ASHG Annual Meeting

Genomic organization and chromosomal mapping of the human LALP70 gene. *C. Kosan[1], A. Biederbick[2], H.P. Elsässer[2], J. Kunz[1]*. 1) Institut fuer Humangenetik, Philipps-Universitaet Marburg, Marburg, Germany; 2) Institut fuer Zytobiologie und Zytopathologie,Philipps-Universitaet Marburg, Marburg, Germany.

LALP70 is a human lysosomal apyrase, highly similar to a human uridine diphosphatase (hUDPase), which is located in the Golgi complex. Here we report the analysis of the LALP70 gene structure using a genomic clone which was isolated from a human PAC library by hybridizing with PCR derived probe amplified with LALP70 cDNA specific primers. The LALP70 gene spanns a region of approximately 16 kb and contains 12 exons and 11 introns. All exon/intron boundaries were determined and obeyed the GT-AG paradigm. FISH analysis showed LALP70 to be located on human chromosome 8 in the region 8p21.1-p21.3. To map the gene more precisely the Genbridge G4 radiation hybrid panel (Research Genetics, Huntsville, AL) was used. We determined that the gene is located 0.4 cR distal to WI-961 (LOD > 3.1) which maps in the Genethon map between the genetic markers D8S1734 and D8S1820 (44.9 cM and 54.2 cM from the top of chromosome 8, respectively). Our results suggest that the uridine diphosphatase gene (hUDPase) is a splice variant of LALP70, lacking 24 basepairs. Possible roles of the resulting 8 amino acid stretch for intracellular localisation and enzyme substrate specificity are discussed.

Program Nr: 1043 from the 1999 ASHG Annual Meeting

Identification and Characterization of a brain-specific *APC* homologue, *APCL*(*APC*-like). *K. Koyama[1,4], H. Nakagawa[2], Y. Murata[3], T. Akiyama[3], Y. Nakamura[4].* 1) Department of Human Genome Analysis, Japanese Foundation for Cancer Recearch, Tokyo, Japan; 2) The 2nd Department of Surgery, Osaka University Medical School, Osaka, Japan; 3) Department of Oncogene Research, Institute of Microbial Disease, Osaka University, Osaka, Japan; 4) Laboratory Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

We isolated a novel gene, APCL, that showed significant homology to the adenomatous polyposis coli (APC) tumor suppressor gene. This novel gene, located on chromosome 19p13.3, encodes a protein of 2,303 amino acids that is expressed specifically in the brain. The heptad-repeat domain found in the APC protein is well conserved in APCL (45% of the amino acids are identical); therefore APCL is likely also to form homo- or hetero- dimers. Moreover, since the armadillo domain is also well conserved (76% identical), both proteins may interact with the same or similar molecular entities. The central portion of APCL consists of five copies of a 20-amino-acid motif (FXVEXTPXCFSRXSSLSSLS). Like APC, this domain of APCL was able to bind to b-catenin and deplete the intracellular b-catenin pool. A reporter-gene assay revealed that APCL could also regulate interaction of b-catenin with Tcf, although less actively than APC. These results suggest that the APCL protein may be involved in the Wnt/Wingless signal pathway and the identification of a novel relative of APC may provide new insights into the function of APC. However, APCL C-terminus bears only 13% identity in sequence to the carboxyl region of APC protein. To shed light on the functions of APCL, we have been using a yeast two-hybrid system to search for proteins that associate with its carboxyl region. Among 166 cDNA clones isolated from a human fetal-brain cDNA library as candidates for interaction with APCL, 32 encoded parts of p53-binding protein 2 (53BP2). In vivo studies confirmed that this association regulated the cytoplasmic localization of 53BP2 by concentrating it in the perinuclear region. Since 53BP2 also interacts with p53 and Bcl2 and regulates p53 function, our results suggest that APCL might be involved in the p53/Bcl2-linked pathway of cell-cycle progression and cell death.

Program Nr: 1044 from the 1999 ASHG Annual Meeting

Human transcription factor SLUG: genomic characterization and mutation analysis in patients with neural tube defects. *J. Kunz[1], K. Stegmann[1], J. Boecker[1], C. Kosan[1], A. Ermert[2], M.C. Koch[1]*. 1) Institut fuer Humangenetik, Philipps-Universitaet Marburg, Marburg, Germany; 2) Kinderneurologisches Zentrum des Landes Rheinland-Pfalz, Mainz, Germany.

Vertebrate Slug is a highly conserved member of the snail family encoding zinc finger transcription factors homologous to Drosophila snail and escargot. Slug is expressed in neural crest migrating cells during embryogenesis. Here we report the identification, characterisation and chromosomal fine localisation of the human Slug gene (SLUG). Using fluorescence in situ hybridisation (FISH) we determined that SLUG maps to chromosome 8q11.21-q11.23. The transcript is approximately 2.0 kb in length containing a 807 nt open reading frame organised in three exons encoding a protein of 268 amino acids. Human SLUG protein has five tandemly arrayed zinc fingers, four CCHH fingers and one variant CCHC finger, a structure typical for the vertebrate snail family. Alignment of human SLUG with homologs of other vertebrates (mouse, chicken and Xenopus) demonstrates strong conservation. Based on evidence from model systems SLUG appears to play a role during neural tube closure. Characterisation of the genomic structure including determination of the exon-intron boundaries provided the opportunity to test this hypothesis in humans. We screened the coding sequence of SLUG in 150 patients with neural tube defects (NTD) using single strand conformation analysis (SSCA). We identified a missense mutation (D119E) in one female patient. Thus, our data do not support a major role of SLUG in inducing NTD, even if SLUG may have acted as a predisposing factor in this patient.

Program Nr: 1045 from the 1999 ASHG Annual Meeting

Identification of FLRT1, 2 and 3: A family of novel leucine-rich repeat proteins. *S. Lacy, L.M. Kunkel.* Genetics, Boston Children's Hospital, Boston, MA.

A degenerate oligonucleotide screening assay was used to identify novel proteins which reside in the extracellular matrix, resulting in the isolation of three genes encoding related proteins termed FLRT1, FLRT2 and FLRT3. FLRT1 and FLRT2 are complete sequences, whereas FLRT3 at present is an incomplete clone representing only the 3' end of the complete cDNA. The FLRT1 and 2 open reading frames are each 2 kb in size and code for proteins of approximately 90 kDa. All three proteins are predicted to be transmembrane by hydropathy plot. FLRT1 and FLRT2 each contain 10 leucine rich repeats (LRRs) which constitute almost one half of their sequence; a putative signal sequence is also present at their amino termini. In addition, all three sequences contain fibronectin III and collagen XII-like repeats in the region between the leucine-rich repeats and the transmembrane domain. The LRRs of FLRT1 and FLRT2 are flanked by highly conserved cysteine-rich clusters which are presumed to give rise to intramolecular disulfide bonds and are believed to be present in portions of proteins which reside extracellularly. Potential N-linked glycosylation sites appear twice in the FLRT1 sequence (249N and 305N), 5 times in the FLRT2 sequence (203 N, 299N, 390N, 433N and 521N) and once in the partial FLRT3 clone (106N). The overall structure of the FLRT proteins is similar to several LRR proteins, including human garpin and GP1b-a, Drosophila tartan and gp150. On multi-tissue Northern blots, the 4.4 kb FLRT1 message is expressed in brain and kidney. The 7.5 kb FLRT2 message is highly abundant in pancreas and less prominent in skeletal muscle, brain and heart. The 4.4 kb FLRT3 message is present in kidney, skeletal muscle, lung and brain and lower levels appeared in pancreas, liver, placenta and heart. Overall, the FLRT family of proteins appears redundant. Following FISH and YAC mapping, the chromosomal localization of FLRT1 was determined to be 11q12-13, FLRT2 to 14q24-32 and FLRT3 to 20p11. In summary, the structural composition of the 3 FLRT family members classifies them as novel type I transmembrane proteins and suggests they may be involved in cell adhesion or function as receptors in the context of the extracellular matrix.

Program Nr: 1046 from the 1999 ASHG Annual Meeting

The effect of sequence heterology on recombination between human a**-globin genes.** *J. Lamb, A. Allen, J.B. Clegg.* Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK.

Meiotic recombination in the human genome is not randomly distributed and the factors affecting recombination are not well understood. Eukaryotic recombination has been extensively studied in yeast where it has been demonstrated that the introduction of a limited number of sequence heterologies reduces homologous crossovers while increasing aberrant recombinants, including unequal crossover, due to a second recombination event. The advent of sperm typing by PCR has allowed examination of large numbers of human meioses. We have studied the effect of sequence heterology on recombination at the human a-globin complex. The complex contains a duplicated pair of a-globin genes (aa); aberrant recombination due to misalignment of the a-globin genes and unequal crossing-over results in chromosomes with one (-a) or three (aaa) genes as reciprocal events. The a-globin genes are virtually identical at the sequence level but divergence beyond the genes has allowed us to develop a small pool PCR assay to specifically amplify the deletion gene (-a). The recombinant product is visualized by a second round of PCR. Nine polymorphic sites across the a-globin complex can be organized into haplotypes. We have determined the a-globin haplotype for three normal males (2 heterozygotes and 1 homozygote) as an indicator of sequence heterology. The equivalent of $3.8x10^5$ single sperm cells have been analyzed by small pool PCR. These initial experiments gave an estimated recombination rate of $1.4x10^{-3}$ for the homozygote while heterozygotes with 3/9 or 5/9 polymorphisms gave a rate of ~2 $x10^{-3}$. These data suggest that sequence heterology does not increase aberrant recombination at the a-globin locus. In fact, the highest rate was obtained with germ-line DNA from a homozygote. Recombination rates that we have measured in the male germ-line are lower than the frequency of the aaa chromosome in the extant Caucasian population (~1%). Whilst the -a chromosome is under selection in areas of malarial endemicity due to protection against infection it is unclear if selection can account for the aaa gene frequency or if stochastic processes may be acting at the population level.

Program Nr: 1047 from the 1999 ASHG Annual Meeting

Teaching professional ethics to science majors in an undergraduate human genetics course. *A.J. Ahern-Rindell.* Biology Department, University of Portland, Portland, OR.

Professional Ethics is a major area that is missing from many undergraduate science curriculums. Reasons for the lack of coverage are numerous and vary between universities. However, there is an academic ground swelling that recognizes the importance of educating students about the ethical situations that they may encounter in their future careers and professions. The hotly debated question is how professional ethics should be addressed in the classroom and by whom?

Helping students learn the skills for making sound judgements and decisions in their personal and professional lives is a facet of the university's role in educating students. Who is best trained to deal with discipline-specific ethical issues is controversial and therefore, a major impediment in introducing professional ethics into the science curriculum. Anything pertaining to ethical issues is seen as belonging to the realm of the philosophers and is expected to be taught as a humanities course. An other view emphasizes the discipline-specific nature of professional ethics and suggests additions be made to existing science courses on an individual basis.

The latter approach was tried in a science major's Human Genetics course. A part of the course deals with changes to the medical field such as the ability to perform genetic diagnostic testing. For certain diseases, one can determine if a healthy individual may succumb to a fatal, currently untreatable disease later in life. Thus the field of medical genetics and in particular, the genetic counseling profession deals with ethical issues and situations on a daily basis.

In the revised course curriculum, a discussion of the genetic counseling field was augmented by including coverage of ethical situations with case studies, small group and class discussions and a guest genetic counselor. Students responses to the professional ethics material were obtained through surveys and traditional student course evaluations. The students felt their awareness of professional ethics was increased by the course and that their ability to analyze and deal with ethical issues was improved.

Program Nr: 1048 from the 1999 ASHG Annual Meeting

Australian Jewish Women's Experiences with a Breast Cancer Gene Testing Program as Part of the Co-operative Family Registry for Breast Cancer Studies (CFRBCS). **.** *C. Apicella[1,4], L. Andrews[2], K. Tucker[2], A. Bankier[3], M. Friedlander[2], D. Venter[1], J. Hopper[4].* 1) Peter MacCallum Cancer Institute, East Melbourne, VIC, Australia; 2) Prince of Wales Hospital, Randwick, NSW, Australia; 3) Victorian Clinical Genetic Services, Parkville, VIC, Australia; 4) Genetic Epidemiology, University of Melbourne, Carlton, VIC, Australia.

Background and Aims: The Australian Jewish Breast Cancer Study offers testing for the three Jewish founder mutations in BRCA1 and BRCA2. Participants received counselling and results through one of three protocols: 1. Researcher only; 2. Researcher and genetic clinic; 3. Genetic clinic only. Our aim is to evaluate these protocols.

Methods: A questionnaire was mailed to participants excluding those known to be deceased. Genetic knowledge and participant satisfaction questions were modified from those used previously[1,2]. Anonymity of responses was ensured by removing all identifying details prior to access by anyone involved in the study.

Results: Response rate was 75% (156/207). Of respondents, 83% were 'very pleased' to have had the test, and none 'regretted' it. Average scores for genetic knowledge, and for satisfaction with provision of (a) information and (b) emotional support, were high and no different between the protocols. More than 8 in 10 respondents considered information provision as the 'most important' function of genetic counselling, while half considered emotional support as the 'least important'. 90% of respondents raised several other issues through optional qualitative information.

Conclusions: Jewish women viewed information provision as the most important function of counselling, and emotional support provision as the least important. There was no evidence that genetic knowledge gained, or satisfaction with the process, was different between the protocols.

Program Nr: 1049 from the 1999 ASHG Annual Meeting

Community education initiatives and the World Wide Web: Experience of the Genetics Education and Counseling Program. *M.G. Banke[1], W.S. Rubinstein[2], E. O'Rourke[1], J.A. Barranger[1]*. 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Cancer Genetics Program, Magee-Womens Hospital/UPMC Health Systems University of Pittsburgh Cancer Institute, Pittsburgh, PA.

The Genetics Education and Counseling Program (GECP), a joint effort of the University of Pittsburgh and UPMC Health System, is a community awareness and education initiative on genetics in Pittsburgh and Western Pennsylvania. The GECP extends the community education missions of the Center for the Study and Treatment of Jewish Genetic Diseases and the Cancer Genetics Program. The program is designed to improve awareness of genetics and genetic diseases for the community and for professionals and to provide easy access to clinical and testing services. The GECP offers educational workshops, referral information, brochures, a hotline number (800-640-GENE), and a comprehensive website (http://www.pitt.edu/~edugene). Voluntary workshop questionnaires have shown what the public understands about genetics and what areas require additional resources. Educational workshops in the community present major points regarding why different ethnic populations are at higher (and lower) risks to be carriers for certain genetic disorders, what those disorders are, what genetic counseling and testing involve, and what options people from those ethnic populations have. As a consequence of the educational workshops, new awareness of Tay-Sachs disease carrier frequency has been seen and a new Tay-Sachs disease screening program has been organized in the community. The World Wide Web has proven to serve as a tool for public and professional education. The main webpage of the GECP has received over 6600 visits and averages 10 visits per day. The online Genetics Resource Center (http://www.pitt.edu/~edugene/resource) has received over 8200 visits and averages 22 visits per day. As we reach the start of the new millenium, the World Wide Web and broad-ranging community education initiatives such as the GECP may represent the most advantageous and efficient ways of bringing the explosion of scientific knowledge to the public.

Program Nr: 1050 from the 1999 ASHG Annual Meeting

Counselling in Incontinentia Pigmenti (IP2) families: useful information from X-inactivation studies. *M.L. Bonduelle, W. Lissens, I. Rayen, L. De Raeve, I. Liebaers.* Dutch-speaking Brussels Free University, Brussels, Belgium.

Incontinentia Pigmenti (IP2) is an X-linked dominant neurocutaneous disorder with prenatal male lethality. Affected females display a progressive erythematous and vesicular skin eruption soon after birth evolving through different stages and frequently accompanied by dental and retinal abnormalities. Central nervous system is affected in a variable degree. Expression is highly variable even within families. Penetrance approaches 100%, but in families with minimal symptoms counselling remains sometimes difficult. Selection against mutant alleles in blood leukocytes is a consistent feature in IP2 families (98% in multigenerational IP2 and 85% in new mutations). In families with apparently de novo mutations and minimal symptoms such as dental anomalies in the mother, X inactivation studies can help to make the diagnosis and determine the parental origin of the mutation. In 4 IP2 families where the mother had minimal or no symptoms we determined the parental origin of the new mutation through X inactivation studies for the M27beta locus with restriction enzymes MspI and HpaII. Three new mutations had a maternal and 1 had a paternal origin. Complete skewing in the patients and random X-inactivation in the healthy mother could be used as an additional argument for considering the mother not being a carrier. Unless germline mosaicism would have occurred, these data could be used to reassure the couple and minimalise the recurrence risk for IP2.

Program Nr: 1051 from the 1999 ASHG Annual Meeting

Genetic support groups: Significant others in the conduct of human genetics research. *J.C. Carey[1], J.D. Cody[2], & the ad hoc Committee for Consumer Issues[1,2]*. 1) Dept Peds/Div Medical Genetic, Univ of Utah Medical Ctr, Salt Lake City, UT; 2) Chromosome 18 Registry & Research Society, San Antonio, TX.

The Boards of the ASHG & the Alliance of Genetic Support Groups established the ad hoc Committee for Consumer Issues with the purpose of opening a dialogue between the 2 communities. The first activity of the Committee involved a workshop designed to examine the current conduct of present & future genetics research. Several highly successful approaches to support group/researcher collaboration were identified. A new model of interaction was developed, the essence of which is summarized in the following consensus statement: Research in human genetics is a shared enterprise that involves investigators, participants, & ancillary agencies. The cultures of these groups often differ & these differences create a dynamic tension between shared & divergent interests. When divergent interests interfere with recruitment of participants to research & compromise mutual understanding of the goals of both parties, it is important to identify mechanisms to create or recognize shared goals. Genetic support groups are an important agency in this enterprise. These groups have diverse & differing objectives: support, education, & research. To the extent that successful support groups have created active involvement in research, their activities provide models for future collaborative relationships. The key activities at the level of the support group include education of members about expectations for research, elements of consent, & understanding the nature of research as well as education of investigators in many of the same elements. Support groups can best broker the successful relationships between investigators & participants when the cultural differences are clearly delineated. As the Human Genome Project reaches its objective of a complete sequence & the emphasis in human genetics research evolves from gene finding to identification of disease mechanisms & treatment, the role of support groups will be increasingly important. Active collaboration among investigators, participants, & support groups will be the catalyst for future research productivity in human genetic disorders.

Program Nr: 1052 from the 1999 ASHG Annual Meeting

Drama helps tell our tales. *M.E. Carlin[1], J.R. Redman[2], M.C. Aguilar[3], S.D. McLean[4], G.A. Glenn[5], TEXGENE Ethics and Education Subcommittees, San Antonio, TX[5]*. 1) Genetic & Developmental Ctr. of SW, Fort Worth, TX; 2) NIH, Washington, D.C; 3) CHRISTUS Santa Rosa Health Care, San Antonio, TX; 4) United States Army Corp, San Antonio, TX; 5) TEXGENE Ethics and Education Subcommittees, University of Texas Health Care Center, San Antonio, TX.

For their annual conference, Texas Genetics Network (TEXGENE) highlighted some of the dilemmas posed by the technological advances of genetic presympomatic testing by creating *Genetic Scenes*, a dramatic presentation with narrator and 3 vignettes - a father of teenagers and his wife consider presymptomatic testing for a progressive AD disorder; a single pregnant mom, whose brother died early of an X-linked disease, now carries a male fetus; and a young, chronically ill adult, who is contemplating marriage, learns she has an AR condition. Issues such as testing when there is no known cure, quality of life, longevity, confidentiality and insurability, disclosure to children, prenatal diagnosis costs, loss of income caring for an affected child, alternatives to abortion, revealing inheritability and suggesting testing to a potential mate, having children who could inherit a mutated gene are all brought from the theoretical to immediate personal life experiences by the live drama. The audience reactions and the extended post-presentation discussion, which included the 4 high school thespians, documented the effectiveness of this format in spotlighting the issues, clarifying some of the major questions such situations pose, and enhancing everyone's understanding of the difficult decisions facing those dealing with such dilemmas. *Gene Scenes* has also been presented at a TEXGENE conference for clergy and pastoral caregivers with a similar response. Drama seems to be well suited to assist in educational programs that address personal and family, as well as ethical, legal and social implications of genetic services. TEXGENE will be exploring future productions addressing these issues. (This project was supported by a Maternal and Child Health Grant #MCJ481005.).

Program Nr: 1053 from the 1999 ASHG Annual Meeting

From predictive genetic diagnosis to individually-tailored prevention: Ethical and psychosocial issues related to the identification and management of familial hypercholesterolemia. *L. Caron[1], L. Dallaire[2], G. Bourgeault[3]*. 1) Faculty of Medicine, University of Montreal, Montreal, Quebec, Canada; 2) Service of Medical Genetics Ste-Justine Hospital, Montreal, Quebec, Canada; 3) Faculty of Education, University of Montreal, Montreal, Quebec, Canada.

Objective: In contrast to DNA testing for hereditary breast or colon cancer the identification of individuals at high risk for coronary artery disease (CAD) due to heterozygous familial hypercholesterolemia (FH) has received very little attention even though there are relevant ethical and psychosocial issues to be addressed. **Method:** These issues were explored in a qualitative study using a Grounded Theory approach. Semi-structured interviews were conducted with 10 hereditary dyslipidemia specialists and 15 FH adults attending lipid clinics in the Province of Quebec. Specific themes and FH-CAD explanatory models were elicited to allow for comparative analysis. **Results:** This study shows that knowledge held by most FH individuals closely reflects expert knowledge especially with respect to a) the impact of FH on CAD risk assessment, b) ill-health perception that ensues from attributing a genetic condition c) the acknowledgement of individual responsibility for future health and d) the positive effects of the preventive measures. The treatment rationale still rests on lipid-lowering guidelines which do not account for this specific etiology. **Conclusions:** These results suggest that 1. Informed consent may be viewed as an engagement and nondirective counseling should be revisited; 2. There are negative psychological effects that may result from being unable to achieve "normal" cholesterol levels enlightening the risk of setting unrealistic treatment goals; 3. A major challenge is to define the extent of doctor-patient duties in the context of shared responsibilities for a life-long intervention with uncertain individual outcome and 4. There is a potential for non-caring when dealing with "difficult patients". Overall, the production, communication and use of genetic information is a central issue that should be analyzed more thoroughly from an ethical perspective.

Program Nr: 1054 from the 1999 ASHG Annual Meeting

46,XX males. Genetic Counseling in adults and prepuberal childs: five year follow-up. *G.B. Castyneira[1], S. Gottlieb[2], S. Copelli[2], C. Ruarte[2], C. Perandones[3], M. Mollica[3].* 1) Genes; 2) CEDIE, Hosp de Ninos R. Gutierrez; 3) CENAGEM.

Genetic counseling is not easy in sexual chromosome abnormalities.Patients in which there is not correlation between phenotype and karyotype is even more difficult. We present seven adult patients and three prepuberal childs followed up to postpuberal age. Clinical, hormonal , cytogenetic and molecular aspects were studied. All patients were phenotipic males. In adults hipogonadism was evident in seven patients. They were all azoospermic. In children prepuberal (age 8,9,13) and postpuberal (12,16,17) examinations revealed micropenis in one and gyanecomastia in all the cases. Stature was in the normal range. No other phenotypic abnormalities were found. Their WISC-RIQ were in the bordeline level(70). Hormonal findings showed normal tetosterone levels except in two adults, elevated FSH in four adults, normal LH levels with the exception of one child and three adults. Molecular analysis by PCR showed the presence of SRY gene in all cases. The authors would underline the difficulties of counseling these subjects. When the diagnosis was made in adults the phsycological stress of confirmed infertility and the unavoidably conflict of questioning their sexual identity occurs in all of them. Their process was followed by depression status. In the prepuberal cases the information was based in development, puberty, learning, sexual behavior and fertility. The main conflict was the development and the phenotypic stigmata. During their adolescence they showed poor self image, attentional deficit and emotional impairment. It was remarkable the need of emphathetic support from parents, counselors and pysichologists. Special care was taken to give and explanation that cast no ambiguity on patients social and phenotypic sexual identity. Molecular findings, were very useful in all cases. The aim of these report is to delineate some aspects of genetic counseling in sexual chromosomal abnormalities and highlight the need of a multidisciplinary team to be specially sensitive to the true sexual identity (phenotypic and psychosocial) that is more relevant than chromosomal sex.

Program Nr: 1055 from the 1999 ASHG Annual Meeting

Genetic counseling for azoospermic patients: with focus on reproductive decision in patients with Y chromosome abnormalities. *J.M Chen[1], Y.M Lin[2], P.L Kuo[3], S.J Lin[4].* 1) Department of Behavior Science,; 2) Department of Urology; 3) Department of OBS/GYN; 4) Department of Pediatrics,National Cheng Kung University, Tainan, Taiwan.

Genetic disorders are not infrequent causes of severe oligospermia and azoospermia in male. Treatment with assisted reproduction may result in transmission of the genetic abnormalities in their offspring. Thus genetic counseling is important whether a genetic etiology is known or suspected. Psychosocial counseling and in depth interview with focus on reproductive behavior were conducted in our male infertility clinic. Each azoospermic patient enrolled in the study underwent routine cytogenetic examination, microdeletion screening using Y-linked sequence tagged sites and/or testicular biopsy. Fourteen patients were found to have chromosomal abnormalities among 70 azoospermic patients. Six patients, two cases of 47,XXY and 4 cases of Yq microdeletion, showed strong desire to have children. When asking about any concern on passing genetic defects to offspring, 3 out of 4 patients with Yq deletion did not consider this as a problem and one decided to receive ICSI and two received Chinese herbs treatment. The one who did concern the genetic problem received AID. Two patients with 47XXY chose adoption.

Program Nr: 1056 from the 1999 ASHG Annual Meeting

Providers' knowledge of heritable breast cancer. *G.M. Cohn, D. Cardeiro, L.A. Correia, J. Habecker-Green.*
Ob/Gyn, Baystate Medical Center, Springfield, MA.

Health care providers are vital in determining access to genetic counseling and/or gene testing for individuals at risk for heritable breast cancer(HBC). We surveyed primary care providers and providers of cancer services to address baseline knowledge of and attitudes toward cancer genetics, and methods of risk assessment. Methods: A study group of 307 providers was ascertained through the Baystate Medical Center mailing list of OBGYNs, Oncologists, Internists, General Surgeons, and Psychiatrists. Providers were sent a cover letter, consent, and questionnaire. Upon return, the data was entabulated and evaluated. Results: Overall response rate was poor (15%). Of those responding, each provider reported an average of 52 patients seen at risk for HBC. Average number of patients with whom DNA testing was discussed was 10, and average number of patients referred for genetic services was 6. This indicates at least 70% of patients whom providers believed to be at risk for HBC, did not receive appropriate counseling for these risks. Risk assessment tools such as the Gail, Clause, and Mendelian models were poorly understood, and 65% of providers believed that family members with other cancers were not relevant to a risk assessment. Finally, the genetics of HBC were poorly understood with only 28%; of providers correctly identifying the inheritance of HBC as autosomal dominant and only 52%; believing that the DNA results of an affected relative would be important to their patient's test interpretation. Conclusions: These results suggest that many providers are not ready for the responsibility of providing risk assessment for HBC or informed consent for testing.

Program Nr: 1057 from the 1999 ASHG Annual Meeting

Genethics: Involving non-scientists in the gene technology debate. *F.J. Cunningham[1,2], S. Metcalfe[1,3], M. Aitken[1,2], I. Maccioca[1,2], J. Savulescu[1,3,4], L. Gillam[1,3,4], R. Williamson[1,2].* 1) Murdoch Institute, Melbourne, Australia; 2) CRC for Discovery of Genes for Common Human Diseases, Australia; 3) Dept of Paediatrics, University of Melbourne, Australia; 4) Centre for Study of Health and Society, Melbourne, Australia.

Applications of gene technology cause increasing concern to our community. The public is often exposed to information that is sensationalised or misleading. The Education and Ethics Units at the Murdoch Institute and the CRC have initiated programs that address this by providing a forum for discussion of ethical issues arising from applications of gene technology with 'experts' in the fields of biology, ethics and philosophy. Accurate information is also provided, aiming to improve scientific literacy of the public to facilitate a more informed debate of issues. Our schools program has focussed around a series of 'Ethics Colloquia' involving ethics, philosophy and biology students. Lectures providing background scientific information were followed by discussion of hypothetical scenarios of applications of gene technology, initially in small groups, then a larger forum. Public involvement has been achieved through three activities: 1)A public student debate in the Educational session of the Inaugural Meeting of the Australian Gene Therapy Society to over 200 students and scientists that was preceded by short lectures on gene therapy and its issues. 2) A "Genethics" competition for secondary schools where students expressed their views to a hypothetical scenario on genetic screening for deafness in a written essay. Six finalists presented their arguments to an audience of scientists, students and 'expert judges'. Noted television and radio personalities hosted the finals. 3) An "Ethics of the New Genetics" workshop has enhanced scientific knowledge through a series of lectures and discussion of genetic research scenarios to Institutional Ethics Committee members. Evaluation through analysis of responses to scenarios before and after the program indicated changes in students' attitudes and quality of arguments. Evaluation questionnaires reflect the success of using ethics to promote public interest in genetics.

Program Nr: 1058 from the 1999 ASHG Annual Meeting

Patient perspectives on the process of informed consent for DNA testing. *C.S. Cytrynbaum[1], R. Babul-Hirji[1], S. Kennedy[1], M. Rowell[2], K. Henderson[3], K. Australie[4], H. Druker[1], L. Dupuis[1], N. Quercia[1], C. Shuman[1].* 1) Clinical & Metabolic Genetics, Hosp Sick Children, University of Toronto, Toronto, ON, Canada; 2) Department of Bioethics, Hospital for Sick Children, Toronto, ON, Canada; 3) Division of Medical Genetics, Montreal General Hospital, Montreal QC, Canada; 4) Yale University School of Medicine, New Haven, CT.

The informed consent process (ICP) has long been recognized to be an important component of clinical practice and, more recently, of research as well. Yet limited information is available regarding the impact of ICP on patients and their families. We set out to evaluate patient perceptions of ICP which includes a newly devised DNA testing/banking consent form. In addition to addressing the issues currently recognized to be critical to informed consent, this form allowed individuals to choose between the options of closed consent (sample destroyed after requested testing completed) versus open consent (sample banked for use in ongoing research). Participants completed self-administered questionnaires pre and post ICP. Results are available from 50 completed questionnaires to date. Seventy-six percent of participants chose open consent and 24% chose closed consent. Seventy-two percent indicated an interest in a detailed discussion in the pre-counseling questionnaire and 76% responded that the ICP was helpful in the post-counseling questionnaire, although 83% indicated that they had decided to proceed with testing prior to ICP. Of note, 68% agreed with the statement "consent forms are mostly to provide legal protection for health care professionals". Anxiety levels ascertained by visual analog scale revvealed no significant change in anxiety levels pre and post ICP in half of the respondents. The remaining respondents reported incresed or decreased anxiety levels with approximately even distribution. Preliminary findings indicate a positive attitude towards ICP and provide justification for its implementation in clinical practice. More detailed data analysis, from a larger sample size, will be presented and this information will be utilized to develop guidelines to improve ICP to better meet patient needs.

Program Nr: 1059 from the 1999 ASHG Annual Meeting

Perception of genetic Diseases In a North African Population : Toward the Implementation of Genetic Screening of Hemoglobinopathies. *K. Dellagi, T. Sokraf, A. Ghriss, T. Bellaj, R. Hafsia, M. Bejaoui, A. Hafsia, D.M. Fathallah.* The Hemoglobinopathies Study Group, Institute Pasteur de Tunis-Tunisia. Institut Pasteur Tunis Tunisia.

Over the last decades, considerable progress in controlling communicable diseases has been made in North African countries while awareness of the high prevalence of genetic disorders was increasing. In Tunisia like in most Mediterranean countries, the population has a high frequency of hemoglobin morbid alleles. To identify and evaluate the social and psychological factors that would influence the success of a program to prevent hemoglobinopathies, we conducted a psychosocial survey in a sample of the Tunisian population. Three groups were studied: 82 patients with b-thalassemia major and sickle cell disease, 71 parents, 76 non affected siblings and a control group of 85 healthy individuals. A questionnaire was designed to address the following issues: Knowledge of the disease, prevention and psychological impact.Analysis of the data collected showed an overall poor level of information about the disease. This information was almost lacking in the control group. The majority of the persons surveyed were not informed about prevention however 87%; would be in favor of it, if informed. The remaining 13%; were reluctant because of religious believes. Interestingly the existence of a mandatory premarital testing for Hepatitis B,Syphilis,ABO typing but not screening for sickle cell or thalassemia traits, is approved by 96%; of the persons surveyed. It was striking that audio-visual information means would be best to convey informations on the disease and the prevention. The study also revealed that patients were not given satisfactory psychological support. Interestingly the psychological impact (Self esteem, projection in the future, attitude toward treatment..) varied sharply in patients with b-thalassemia and those with drepanocytosis, the latter being much more negatively affected by the disease.Our study will be helpful in designing effective guidelines for information, testing and counseling programs to control prevalent genetic disorders in other countries of this part of the world.

Program Nr: 1060 from the 1999 ASHG Annual Meeting

GENETIC COUNSELING FOR MITOCHONDRIAL DISORDERS. *M.A. Del Vecchio[1], G.L. Matika[1], C.A. Bay[1,2]*. 1) Division of Medical Genetics, Children's Hosp of Pittsburgh, Pittsburgh, PA; 2) University of Pittsburgh School of Medicine, Pittsburgh, PA.

Mitochondrial disorders are being diagnosed with increased frequency, and present clinicians and genetic counselors with many issues to address. Mitochondrial disorders generally result in deficient energy production or availability. Virtually all organs systems can be affected, but most commonly the central nervous, cardiac, muscular and ophthalmologic systems are involved. Mitochondrial disorders are typically thought of as maternally inherited, but all modes of inheritance have been described and need to be considered during the genetic evaluation. When suspicious of a mitochondrial disorder it is necessary to determine the most likely mode(s) of inheritance, explain difficult genetic concepts and provide psychological support. While these roles are typical for a genetic counselor, mitochondrial disorders present a unique set of challenges. The genetic counselor must obtain a very targeted pedigree with special attention paid to the soft signs in family members, such as migraines, seizures, mental retardation, gastrointestinal complaints, chronic fatigue and weakness. Explanations of difficult concepts such as heteroplasmy, oxidative phosphorylation, nuclear DNA, mitochondrial DNA, and nuclear-mitochondrial gene interactions are unique. Providing psychological support can be a daunting task, even to an experienced team. When one makes a diagnosis of a maternally inherited mitochondrial disease in a proband, one usually also makes the same diagnosis in the mother. In many cases prognosis can vary considerably, thus counseling must by necessity be vague as to prognosis. Frequently there is no reliable prognostic indicator. Like with other genetic disorders the diagnosis is often accompanied by feelings of grief, despair and guilt. While those feelings are not specific to maternal line inheritance, the high recurrence risk in maternal line disorders is specific. Reliable prenatal testing is not available for many mitochondrial disorders, and reproductive options are limited. In summary, mitochondrial disorders present unique and difficult issues for the genetic counselor.

Program Nr: 1061 from the 1999 ASHG Annual Meeting

Consanguinity and birth defects. *B. Dott[1], Y. Alembik[1], M-P. Roth[2], C. Stoll[1].* 1) Serv de Genetique Med, Hopital de Hautepierre, Strasbourg, France; 2) Centre Hospitalo-Universitaire, Strasbourg, France.

The risk for birth defects in the offspring of first-cousin matings has been estimated to increase sharply compared to non consanguineous marriages. As a general decline in the frequency of consanguineous marriages was observed in this century, one wonders whether consanguinity is still a factor in the appearance of birth defects in developed countries. Based on our registry of congenital anomalies we tried to answer to this question. In the population studied in North-Eastern France a consanguineaous mating was known in 1.21% of the cases with congenital anomalies, vs.0.27% in controls, ($p<0.001$). The frequency of the malformations recorded paralleled the degree of consanguinity : out of 89 malformed children, 51 were seen in first-cousins mating (10.3 times more frequent than in offspring of non consanguineaous couples), 17 in second-cousins marriages and 18 in more distant relatives mating. Three were uncle-niece marriage. Excluding known mendelian conditions these numbers were 73, 36, 17 and 17 respectively and the corresponding relative risk were 3.68, 3.01, 3.41 and 4.89 respectively. Therefore there is a negative dose-response effect between level of inbreeding and risk of congenital malformations. Consanguineous mothers were more often pregnant than non consanguineous mothers ($p<0.01$) and they had more stillbirths than non consanguineous mothers. These results show that consanguinity is still a factor of birth defects and they must be taken into account for genetic counseling of inbred marriages, in developed countries.

Program Nr: 1062 from the 1999 ASHG Annual Meeting

What is the status of medical genetics in graduate medical education and continued professional development?

S.A. Goldberg, S.V. Spilson, M.P. Short. Dept Sci, Research/Technology, American Medical Assoc, Chicago, IL.

Purpose: Following graduation from medical school, physicians enter residency training. The curricula are determined by the ACGME (Accreditation Council for Graduate Medical Education), represented by five member organizations: the American Board of Medical Specialties, the American Hospital Association, the AMA, the Association of Medical Colleges, and the Council of Medical Specialty Societies. Following residency, physicians are specialty board eligible. Upon completion of board exams, continuing medical education (CME) materials are available. This research looks at medical genetics in graduate education and professional development. The goal is to assess the opportunities for more effective genetic education on the eve of the completion of the Human Genome Project.

Methods: The ACGME directory was searched for the root word 'gene'. CME modules from 96 medical specialty societies' education conferences were reviewed for genetic medicine content. A survey of the same societies assessed current genetic activities and perceived needs in genetics. The content of review materials targeted to exam board applicants was reviewed.

Results: The ACGME directory reveals sporadic genetics within different residency specialties. The specialty society meeting materials reveals the majority of genetics education is research oriented. Little basic genetics, genetic counseling, or ethical issues raised by genetics is available. Specialty survey results reveal (92% response) 64% have no CME genetic modules, but 67% are interested in developing modules. The specialty board survey results are pending.

Conclusions: Genetics in graduate education is fragmented. It is difficult to be assured of its consistency despite occasional specific references, mainly in pediatric and obstetric/gynecology programs. The latter traditionally have recognized the importance of genetic medicine. There is a great need to fully assess the methods used to teach this 'new science' of medical genetics and particularly its appropriate integration into clinical practice.

Program Nr: 1063 from the 1999 ASHG Annual Meeting

Science for the Next Millenium: High School Cancer Genetics Project. *P.E. Gregory, S. Nolan.* Dept Human Cancer Genetics, Ohio State Univ, Columbus, OH.

The OSU Human Cancer Genetics Program developed a model educational program that provides high school students with both a basic background in cancer genetics and hands-on research experience using PCR. Using PCR kits which are designed specifically for the high school classroom, students isolated DNA samples from their own cheek cells an compared their genetic "fingerprint" to that of DNA from tumor cell lines. The partnership was with four high schools Columbus, Ohio and approximately 200 Advanced Placement biology students participated. This partnership represents an innovative effort to bridge the gap between OSU and the schools. The primary goal of this project was for students to begin to understand that there is a genetic component to all cancers and that some cancers are clearly hereditary. All participating schools were required to do a poster presentation of their research to OSU Comprehensive Cancer Center scientists on campus at the end of the school year. Student evaluations revealed that the students felt well-prepared for the activity (86%) and that the experiments were at the right level (93%). Interestingly, the students were more interested looking at their own DNA than in the DNA from the tumor (71%), this is a something to be considered when planning such a program. The students did well on knowledge questions, with two exceptions: 71% thought PCR could copy the entire genome and 68% incorrectly identified the percentage of cancer that is hereditary (80% overestimated). 80% of the students understood that 100% of cancer cells are genetically abnormal, an extremely important concept for them to grasp. This program was highly successful and will grow to include four more schools during the 1999-2000 school year. Our data strongly suggest that high school students are interested in cancer genetics and research. This is an excellent level to begin public cancer genetics education programs.

Program Nr: 1064 from the 1999 ASHG Annual Meeting

Genetic awareness of consanguinity in a Pakistani Community in the U.K. *H.S. Hasan[1], D. Craufurd[2].* 1) Ctr Medical Ethics, Univ Oslo, Oslo, Norway; 2) Clinical Genetics Dept, St Mary's Hospital, Manchester, UK.

Previous studies have shown children of Pakistani couples in the UK have higher rates of neonatal mortality, congenital malformations, non-specific autosomal recessive diseases and chronic illnesses. High rates of cousin marriages within this community are thought to explain this. This study assessed the attitudes of parents (by semi-structured interviews) to determine the awareness of genetic implications of consanguinity, acceptability of genetic counselling and views regarding second cousin marriages.

Parents of children with a congenital disorder (36 cases) and parents with healthy children (28 controls) were interviewed. The consanguinity rate was found to be 75% in the cases and 46% in the controls ($p<0.005$). Although the majority of the study group had a family tradition of cousin marriages, most were unaware of the congenital malformation risks associated with consanguinity. The majority of the study group thought genetic counselling should be available to all cousins wishing to marry, regardless of their own acceptability of the risk figures. Attitudes towards genetic knowledge and the prospect of community education are discussed as well as a educating young adults in a sensitive non-threatening (both towards community and cultural ties) manner. Views on marriage partners for the study groups' children are analysed as well as the paradoxical views regarding second cousin marriages.

Comments by mothers regarding the psychosocial dimension of their child's genetic disorder are focussed on by the use of specific case mother presentations.

Program Nr: 1065 from the 1999 ASHG Annual Meeting

Critical Predictive Factors in a Woman's Decision to Elect Genetic Testing for Breast and Ovarian Cancer. *G.D. Havens, D. Puñales-Morejon.* Department of Medical Genetics, Beth Israel Medical Center, New York, NY.

DNA testing for mutations in the BRCA1/2 genes is offered to an increasing number of women and families. A woman who knows her mutation status has a more accurate estimation of her risk for breast and ovarian cancer. This knowledge can be useful in devising an individual cancer screening program, altering diet, using medications to decrease the chance of certain cancers, or undergoing prophylactic removal of the breasts and/or ovaries. In addition, if an individual is identified as a mutation carrier, other family members may also be at risk for being mutation carriers and be able to make decisions regarding testing for themselves. However, little is known about the psychological, social and familial characteristics of the women that elect versus decline such testing. Several studies have described women considering mutation analysis, yet few have extended research to those that are actually accepting or declining testing.

Experience shows that not all women who are at risk of carrying a mutation in the BRCA1/2 genes elect DNA analysis. The reasons for declining testing are varied. Some women do not want to live with the knowledge that their risk of breast cancer may be as high as 85% and their risk of ovarian cancer may reach 60%. A woman may feel she is doing everything that she deems acceptable in an attempt to prevent or detect cancer. Others are distrustful of technology and fear harm such as a breach of confidentiality or insurance discrimination.

A group of more than 90 women who received genetic counseling and considered participation in a research protocol that provides free testing for three mutations in BRCA1 and BRCA2 were studied. Data analysis revealed that 65% of the women elected testing after receiving genetic counseling. These women are described according to demographic variables, family history, and primary reasons for electing or declining mutation analysis. Various predictive factors in this sample and recommendations for future research are explored. This information has practical value for genetic counselors as these professionals facilitate decision-making processes for patients.

Program Nr: 1066 from the 1999 ASHG Annual Meeting

Why Patients Don't Show for Their Appointments at a Genetics Clinic. *L. Humphreys[1], A. Hunter[2], A. Zimak[2], M. Cappelli[1]*. 1) Department of Psychology,Children's Hospital of Eastern Ontario Ottawa, Ontario, Canada; 2) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Cancellations and “no-shows” at outpatient medical clinics represent a significant problem in the delivery of health care services. The purpose of this study was to determine some of the variables associated with non-attendance at the Genetics clinic of the Children’s Hospital of Eastern Ontario (CHEO), in order to find ways to improve the dissemination of genetic risk information and reduce wasted preparation time. A 37-item telephone survey was administered to 62 patients who did not show up for their scheduled appointments and 75 patients who did attend their appointments (or who cancelled with greater than 12 hours notice). The survey was designed to assess a variety of information, including details about the referral source, issues of transportation and child care, beliefs and attitudes regarding genetic health services, and sociodemographic factors. Analyses revealed that patients who attended their appointments perceived more benefits and fewer disadvantages of attending the genetics clinic, and viewed their appointments as being more important than did nonattenders. Attenders also had a higher mean education level and were more likely to be planning on having more children in the future than nonattenders. Practical issues such as having to arrange for childcare and not being paid for time off work to attend clinic appointments were raised significantly more often by nonattenders. These results provide a variety of possible strategies for reducing the no-show rate at this and other genetics clinics. They also suggest ways of improving the quality of care and information provided to patients before, during and following clinic visits.

Program Nr: 1067 from the 1999 ASHG Annual Meeting

APOE genotype and response to galantamine treatment in Alzheimer's disease. *J. Aerssens, P. Raeymaekers, S. Lilienfeld, W. Parys.* Janssen Research Foundation, Beerse, Belgium.

It has been reported that APOE genotype might affect the response to treatment with the acetylcholinesterase inhibitor tacrine in Alzheimer's disease (AD). Our aim was to evaluate whether similar differential effects related to APOE genotype can be observed during treatment of AD patients with galantamine, a cholinesterase inhibitor and nicotinic receptor modulator. APOE genotype was determined in DNA samples from 835 Caucasian AD patients enrolled in two international clinical trials (cohorts of 310 and 525 subjects respectively). These trials were specifically designed to evaluate efficacy of galantamine treatment in AD patients (identified using NINCDS-ADRDA criteria) during periods of 3 and 6 months respectively. In addition to patient demographics, baseline scores for the mini mental state examination (MMSE) and disability assessment for dementia (DAD) were recorded. Scores on the cognitive AD assessment scale (ADAS-cog) were recorded at the start, periodically during and at the end of the clinical trials. APOE genotype and allele frequencies were similar to other AD patient populations. A higher copy number of APOE-e4 alleles was significantly associated with a decreased age of onset of cognitive problems and age of AD diagnosis. No significant associations were found between APOE genotype and baseline scores of MMSE, DAD, or ADAS-cog, nor was APOE genotype associated with the change in cognitive ADAS over 3 to 6 months in the subgroup of placebo treated patients. Overall, a highly significant positive effect of galantamine treatment was observed on the change of ADAS-cog (daily treatment dose: of 24-32 mg). However, no significant differential effect of galantamine treatment was identified after stratification of the AD patients according to APOE genotype or APOE e4 allele copy number. These results were observed in both of the independent trials. In conclusion, our results confirm a strong relationship between APOE and age of onset of AD, but do not support the hypothesis that APOE genotype may be a prognostic indicator of response rate to therapy with galantamine, as has been suggested for other cholinesterase inhibitors in AD patients.

Program Nr: 1068 from the 1999 ASHG Annual Meeting

Molecular evolutionary studies of *HLA-G* null allele suggest non-neutral evolution. *C. Aldrich[1], M.S. McPeek[2], A. Di Rienzo[1], C. Ober[1].* 1) Dept of Human Genetics; 2) Dept of Statistics, Univ Chicago, Chicago, IL.

HLA-G is an unusual class I gene that is primarily expressed in fetal tissues at the maternal-fetal interface, that has membrane and soluble splice forms, and limited and conservative polymorphism at both the amino acid and nucleotide level. A deletion of a single cytosine in exon 3(alpha 2 domain) results in a null phenotype for the full-length protein in homozygotes, and is a striking departure from the otherwise low level and conservative nature of polymorphism in *HLA-G*. Interestingly, this null allele occurs at similar frequencies (0.06-0.08) in distantly-related populations, such as the Spanish and Africans, suggesting that it may have been subjected to evolutionary forces other than random genetic drift. To test this hypothesis we examined variation in genomic regions around *HLA-G* to determine if the pattern of variation around the deletion allele differs from that of a conservative polymorphism in *HLA-G* (T31S), which occurs at a similar frequency in our study population. An African American sample (N=95) was genotyped for the *HLA-G* polymorphisms and for seven flanking STRPs. Age estimates were determined for each polymorphism based on the decay of linkage disequilibrium (LD) (Risch *et al., Nat. Genet.* 1995;9:152) and from allele frequencies assuming neutrality (Kimura and Ohta *Genetics* 1973;75:199). Haplotype frequency estimates were generated by a maximum likelihood algorithm implemented in the HAPLO program (Hawley and Kidd *J. Hered.* 1998;86:409). Based on allele frequencies, the age of the T31S and of the null mutation is approximately 9,500 generations (or about 200,000 years). Consistent with this age estimate, there is no significnat LD between T31S and an STRP at 40kb (D'=0.31,p>0.05). In contrast, significant LD was observed between the null allele and the same flanking STRP (D'=1.0,p=0.001), providing an allele age estimate of only 240 generations, or 5,000 years. These data suggest that these two polymorphisms in the *HLA-G* gene have had different evolutionary histories, and that natural selection may have increased the frequency of the null allele. (Supported by HD21244 and HD27686.).

Program Nr: 1069 from the 1999 ASHG Annual Meeting

Association of pyruvate kinase (ATT)n microsatellite polymorphism with Gaucher disease mutations. *O.M.O. Amaral, E.M. Pinto, M.C. Sa Miranda.* Enzymology Department, Instituto Genetica Medica Jacinto Magalhaes and Instituto Biologia Molecular e Celular, 4150-180 Porto, Portugal.

Gaucher Disease (GD is a lysosomal storage disorder (LSD) where the defective activity of the lysosomal glucocerebrosidase (GBA) leads to subsequent accumulation of glucosylceramide. In Portugal, GD is the most frequent LSD, GBA mutations N370S, G377S and N396T (which has only been found in the Portuguese) together account for about 72% of the alleles among unrelated patients. Previous reports have shown the existence of linkage disequilibrium between pyruvate kinase (PKLR) polymorphisms and GBA mutations (Beutler et al, 1994; Glenn et al, 1994; Rockah et al, 1998; Diaz et al, 1998). Given the relatively high frequency of the aforementioned mutations in the Portuguese patient population, and the fact that they always appeared in the context of the GBA Pv1.1- haplotype, their association with different forms of a polymorphic microsatellite in the PKLR gene was studied. Additionally, the association between this PKLR marker and other less frequent GBA mutations was also investigated. In accordance with the results of other groups, allelic association was verified between mutations in the GBA and PKLR genes. In contrast with findings in the Ashkenazim (Rockah et al, 1998), but in accordance with previous reports (Diaz et al, 1998), mutation N370S was found to be associated not only to 17 repeats but also to 18 repeats. Interestingly, founder effects seemed to exist in the case of two mutations of probable Iberian origin: G377S was always associated to (ATT)17 and N396T was found to be associated to (ATT)14. On the basis of the present study, other rare mutations are also likely to have common origins. The study of PKLR polymorphisms in patients described in the literature, who share uncommon GBA mutations with the Portuguese, could be relevant to investigate the possibility of common ancestors among patients with apparently different ethnic origins.

Program Nr: 1070 from the 1999 ASHG Annual Meeting

Molecular epidemiology of genetic mutations that predispose to thrombophilia in a Greek-Cypriot population. *K. Angelopoulou[1], C. Constantinou[1], A. Chrysanthou[2], A. Nicolaides[1], C. Deltas[1].* 1) The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) The Cyprus Institute of Reproductive Medicine, Nicosia, Cyprus.

Mutations in several genes have been shown to predispose to an increased risk for thrombophilia. The best studied are the R506Q factor V Leiden mutation, the C677T mutation in the methylenetetrahydrofolate reductase (MTHFR) gene and the G20210A mutation in the prothrombin gene. All three DNA variants have been documented to be significant risk factors for various cardiovascular conditions, including pregnancy complications. We investigated the prevalence of these mutations in the Greek-Cypriot population by screening 90 unrelated individuals. Eleven (12.2%) were heterozygous and one was homozygous (1.1%) for the 506G allele of factor V. In total, 12 subjects (13.3%) carried this mutation, and the mutant allele frequency was 7.2%. Heterozygosity for the MTHFR C677T mutation was detected in 40 subjects (44.4%), whereas 16 of them (17.8%) were homozygous. The mutant allele frequency reached 40%. The G20210A mutation in the prothrombin gene was found in 7 individuals (7.8%). No homozygotes were identified and the mutant allele frequency was 3.9%. Of the 90 subjects 50 (55.6%) had a mutation in either one of the three factors, 11 (12.2%) had a mutation in two of them, and 1 (1.1%) carried a mutation in all three. These data demonstrate that Greek-Cypriots have an increased mutant allele frequency for factor V Leiden compared to the rest of the Europeans (3.2%), and the frequency of the prothrombin mutation is up to 6.5-fold higher compared to the UK population (according to one report). Whether this reflects genetic or environmental factors, or both, is unknown, but these findings are important for alerting physicians in the direction of preventing venous thromboembolic disease and its complications. Assessment of risk factors can also help to decide who requires anticoagulation during surgery or pregnancy. This is the first study for the frequency of mutations in risk factors that predispose to thrombophilia on the island of Cyprus.

Program Nr: 1071 from the 1999 ASHG Annual Meeting

Dissecting inheritance pattern predisposing to vitiligo in Colombian pedigrees. *M. Arcos[1], E. Parodi.[2], E. Bedoya[2], D. Jaramillo[2], G. Ceballos[2], A. Uribe[2], M. Salgar[1], J.J. Builes[1].* 1) Dept Biol, Univ de Antioquia, Medellin, Colombia; 2) Dermatology Service, Internal Medicine Department, Hospital San Vicente de Paul, Medelln, Colombia.

The unified model of segregation was used to elucidate cohort, multifactorial and major gene components predisposing to vitiligo on extended and multigenerational pedigrees from Antioquia, Colombia. Fifteen hypothetical models were contrasted. The hypotheses of cohort effect, recessive major gene, non-polygenic component (against recessivity) in the mixed model and that of non- transmission of major effect were rejected. Multifactorial, major gene (dominant and codominant), no polygenic component (against dominant and codominant major gene in the mixed model) and that of recessive major gene (in the mixed model) hypotheses, could not be rejected. The most parsimonious model is that of a mixed model with strong environmental effects on the recessive genotype. Penetrance and risk corrected by onset age showed that affecteds belong to the codominant and recessive genotype in similar proportions. The affection of the aa unaffected genotype could be explained by the two step Knudson hypothesis.

Program Nr: 1072 from the 1999 ASHG Annual Meeting

Genetic association with human survival and aging at the KLOTHO locus. *D.E. Arking[1], M. Macek Jr.[2], A. Krebsova[2], M. Macek Sr.[2], A. Arking[3], I. McIntosh[1], H.C. Dietz[1].* 1) HHMI and Institute Genet Med, Johns Hopkins Sch Med, Baltimore, MD; 2) Institute Biol and Med Genet, Dept Mol Genet - CF Ctr, Univ Hospital Motol and 2nd Sch Med Charles Univ, Prague, Czech Republic; 3) Johns Hopkins Univ, Baltimore, MD.

Homozygosity for null mutations in the *Klotho* gene leads to a phenotype resembling human aging in mice, including atherosclerosis, osteoporosis, emphysema, and age-related skin changes. To determine whether variation in or around the human KLOTHO locus contributes to fitness and/or longevity, we applied two newly characterized microsatellite polymorphisms flanking the KLOTHO gene in population-based association studies. We compared marker allele frequencies of 429 elderly individuals (>75 years) from a stable Bohemian Czech population that survived high levels of infant and childhood mortality (20%) to 611 contemporary newborns drawn at random from the same population (Macek et al., Hum Genet, 1997). For Marker 1 (12 kb 3' of the last KLOTHO exon), we found an overall difference between the two groups ($p < .03$), with allele 17 more prevalent in newborns ($p < .0002$), suggesting a detrimental influence of this allele on human survival. Marker 2 (66 kb 5' of the first KLOTHO exon) allele frequencies also differ between the groups ($p < .11$), with allele 6 more prevalent in newborns ($p < .05$) and allele 9 more prevalent in the elderly ($p < .05$), suggesting both deleterious and protective roles for different alleles. These differences are not dependent on sex. Additional analysis was performed comparing marker allele frequencies in elderly individuals stratified into "SENIEUR - Apparently Healthy" (140 subjects) and "SENIEUR - Inpatient" (289 subjects) categories of the SENIEUR protocol. Marker 1 allele 13 frequencies were found to be significantly different ($p < .02$), with »0.3% frequency in the "SENIEUR - Apparently Healthy", and »3% in the "SENIEUR - Inpatient" groups. The frequency in newborns was also »3%, suggesting that this allele is a determinant of fitness in the elderly, rather than of early mortality. Ongoing studies will determine if and how klotho protein polymorphisms contribute to these observations.

Program Nr: 1073 from the 1999 ASHG Annual Meeting

Comparison of linkage using simple echocardiographic left ventricular (LV) mass versus factor analysis of LV mass in African Americans: The HyperGEN Study. *D.K. Arnett[1], R.B. Devereux[2], A. Oberman[3], D.W. Kitzman[4], M.A. Province[5], D.C. Rao[5]*. 1) Univ. of MN, Minneapolis, MN; 2) Cornell Univ., New York, NY; 3) Univ. of AL, Birmingham, AL; 4) Wake Forest Univ., Winston-Salem, NC; 5) Univ. of Washington, St. Louis, MO.

An increase in the mass of the LV (ie, LV hypertrophy) is a strong predictor of cardiovascular mortality. Animal studies indicate LV mass may be genetically determined (ie, chromosomal regions are linked to LV mass in rats). No linkage information for LV mass is reported in humans. We evaluated the utility of factor analysis scores compared to simple measures of echocardiographic LV mass for detection of linkage as part of the Hypertension Genetic Epidemiology Network (HyperGEN) study of hypertension genetics. Echocardiograms were collected and centrally read to derive estimates of LV mass in 247 African American hypertensive sibpairs. LV mass was defined by the cubic formula [(posterior wall+intraventricular septal wall+LV internal dimension)^3 - internal dimension^3]. Markers (n=387, CHLC8) were typed by the Mammalian Genotyping Service. Initially, a search for quantitative trait loci for LV mass was carried out using a multipoint model-free variance components method implemented in SEGPATH (Province, 1999), and identified regions on chromosomes 3 and 7 with suggestive linkage to LV mass. Using factor analysis, a factor with echocardiographic LV dimensional and functional measures and height, weight, and waist/hip ratio was created. LV mass was adjusted for the same anthropomorphic variables. Linkage analysis for the LV factor scores and LV mass was done only in regions with prior evidence for linkage to avoid multiple comparisons between the two methods. Results for the factor scores and adjusted LV mass at the two linked markers on Ch7 indicate the factor score provides stronger evidence than adjusted LV mass (LOD=2.49 versus 2.14 at 72.3 cM from the p telomere). However, linkage results were weaker on Ch3 for the factor score compared to adjusted LV mass (LOD=1.80 versus 2.53 at 52.3 cM from the p telomere). We conclude that factor analysis does not provide consistently better linkage results for LV mass phenotypes.

Program Nr: 1074 from the 1999 ASHG Annual Meeting

ATM Mutations in Iranian Patients with Ataxia-Telangiectasia. *M. Babaei, N. Khanlou, M. Mitsui, R. Gatti.* Department of Pathology, University of California at Los Angeles School of Medicine, Los Angeles, California 90095-1732 .

Ataxia-telangiectasia (A-T) is an autosomal recessive disorder with a broad range of clinical manifestations. Epidemiological studies have suggested that A-T heterozygotes are at an elevated risk for breast cancer. A-T occurs worldwide. ATM mutations cover the entire ATM gene, making it difficult to identify heterozygotes in large populations. Here, we report the 11q22-q23 haplotypes of 12 Iranian patients and 3 mutations. Two of these mutations occurred in Iranians of Turkish ethnicity. Although Iranians of Turkish ethnicity are generally considered to be distinct from the people of Turkey, the two mutations and haplotypes were similar to those found previously in A-T patients from Turkey. The third mutation is new. The haplotyping data predict that at least 10 Iranian mutations exist, with the most common mutation accounting for perhaps 40% of affected chromosomes. This would allow genetic screening of large Iranian cohorts for ATM heterozygote identification, similar to studies underway in Costa Rica and Norway.

Program Nr: 1075 from the 1999 ASHG Annual Meeting

Molecular basis of red cell genetic disorders in the Comorian population. *C. Badens[1], F. Martinez di Montemuros[2], M.D. Cappellini[2], D. Lena-Russo[1], J.F. Mattei[1].* 1) genetics, faculty of medicine, marseille, France; 2) Department of Internal Medicine, Ospedale Maggiore, Milano, IRCCS (Italie).

Hemoglobin diseases and G6PD deficiency are red cell genetic disorders which are widespread in various parts of the world. Their geographical distributions correlates well with past and actual malaria distribution because of a selective advantage conferred to heterozygotes against malarial infection. The Comoro archipelagos is located in the Indian ocean and groups 4 islands which have been mainly populated by Bantu Africans coming from Mozambican coasts and by immigrants from the Arabo-Persic gulf, specially from the Shiraz region in Iran. Both countries are areas endemic for hemoglobin diseases and G6PD deficiency but with different underlying molecular defects . For the last fifteen years, Marseilles (France) has been the main destination for Comoro's emigrants. Currently, about 40 000 people from Comoro are living in Marseille. From this population, 11 patients with Sickle Cell Anemia (SCA) and about 80 patients with G6PD deficiency attend the Pediatric Hematology Unit of the Hospital La Timone, Marseilles. In this study, we determine the origin (African or Mediterranean) of the various mutant alleles of the b-globin gene and the G6PD gene, by molecular analysis in a group of comorian patients with hemoglobin disorders and/or G6PD deficiency. The African alleles are predominant being present in all the subjects studied for SCA and G6PD deficiency. Mediterranean alleles have been found for all the b-thalassemia mutations and for two G6PD variants but they are always associated with an African allele in a state of compound heterozygozity. It is noteworthy that the b-thalassemia mutation identified are the most frequent mutation in the Shiraz region of Iran. Our results are consistent well with the mixed Arab-African population of Comoro Islands revealing the presence of unusual heterozygozities composed of East-african and Mediterranean mutations in cases of both hemoglobin diseases and G6PD deficiency.

Program Nr: 1076 from the 1999 ASHG Annual Meeting

Family history of breast/ovarian cancer as an indication of germline BRCA1 mutations. *C.D. Bajdik[1,2], J.M. Raboud[1,3], M.T. Schechter[1,3], B.C. McGillivray[4,5], R.P. Gallagher[1,2].* 1) Department of Health Care and Epidemiology, University of British Columbia; 2) Cancer Control Research, British Columbia Cancer Agency, Vancouver, British Columbia, Canada; 3) Canadian HIV Trials Network, Vancouver, British Columbia; 4) Department of Medical Genetics, University of British Columbia; 5) Women's Health Centre, BC Children's Hospital, Vancouver, British Columbia.

Background: A family history of female breast and ovarian cancer is associated with increased risks for both diseases. In some instances, the family history is due to a germline BRCA1 mutation. Genetic testing requires substantial laboratory resources and expertise, and it would be useful to determine if an individual has a BRCA1 mutation by assessing family history. The accuracy of predictions about BRCA1 will depend on how family history is measured, as well as the age of the proband and the size of the family. Methods: A simple measure of family history was defined by the presence of disease among the proband's close relatives. A second measure was defined by the ratio of observed and expected cases according to population disease rates. Using computer simulations, we estimated the sensitivity and specificity of each measure as a test of BRCA1 mutations. Results: For both measures, the sensitivity of family history depended on the proband's family size, and to a lesser extent on the proband's age. The specificity of the measures also varied with the proband's age and family size, but less so than sensitivity and not in any systematic manner. Tests based on the different measures of family history had similar sensitivity and specificity for probands of the same age and having the same family size. Conclusions: The similarity of results for the two measures is noteworthy because the simpler one's calculation is more practical for health care workers. Our results show that, even in large families and populations where roughly 1% carry a germline BRCA1 mutation, the chance that someone with a family history has a germline BRCA1 mutation is less than one in nine. Many carriers in the population will have no family history of breast/ovarian cancer.

Program Nr: 1077 from the 1999 ASHG Annual Meeting

Genetic evidence on the origins of Indian castes. *M. Bamshad[1], T. Kivisild[2], W.S. Watkins[1], M.E. Dixon[1], B.B. Rao[3], J.M. Naidu[3], B.V.R. Prasad[3], A. Rasanayagam[4], S.S. Papiha[5], R. Villems[2], L.B. Jorde[1]*. 1) Eccles Inst Human Genetics, Univ Utah, Salt Lake City, UT; 2) Inst of Mol and Cell Bio, Tartu Univ and Estonian Biocentre, Tartu, Estonia; 3) Dept of Anthro, Andhra Univ, Andhra Pradesh, India; 4) Lab of Mol Systematics and Evol, Univ of Arizona, Tucson, AZ; 5) Dept of Human Genetics, Univ of Newcastle-upon-Tyne, UK.

The origins and affinities of the 1 billion people living on the Indian sub-continent have long been contested. Shared Indo-European languages (i.e., Hindi and most European languages) suggested to linguists that contemporary Indians are descendants of Caucasians who migrated from Western Eurasia (Europe, the Near East, Anatolia, and the Caucasus) 3,000 to 4,000 years ago. However, archaeological evidence of the diffusion of material culture from Western Eurasia into India has been limited. To reconcile the origin of Indian castes, we analyzed mtDNA and Y chromosome markers to estimate the genetic affinities of castes of varied status to world-wide populations. For maternally inherited mtDNA, the majority of Indian mtDNA lineages belong to an Indian-specific haplogroup, all castes show highest similarity with East Asians, and the level of European admixture with Indians is proportionate to caste rank. This is consistent with either the hypothesis that proportionately more West Eurasians became members of the upper castes at the inception of the caste hierarchy or that social stratification preceded the West Eurasian incursion and that West Eurasians tended to insert themselves into higher-ranking positions. In contrast to the mtDNA distances, the Y chromosome data do not demonstrate a closer affinity to East Asians for each caste group. Upper castes are more similar to Europeans than to East Asians. This is consistent with sex-specific differences in levels of admixture, with males with European affinities contributing proportionately more than females to upper castes. We conclude that Indians are largely of proto-Asian origin, and admixture with West Eurasians was recent and limited in scope. Nevertheless this admixture resulted in rank-related and sex-specific differences in the genetic affinities of castes to East Asians and Europeans.

Program Nr: 1078 from the 1999 ASHG Annual Meeting

Examination of phylogenetic relationships among Siberian and Native American populations using pooled DNA samples. *P. Banerjee[1], J. McComb[2], A. Pfeffer[2], M.H. Crawford[2], J.A. Knowles[3,4]*. 1) Genetics and Development, Columbia University, New York, NY; 2) Department of Anthropology, University of Kansas, Lawrence, KS; 3) Dept. of Psychiatry,; 4) Columbia Genome Center, Columbia University, New York, NY.

A number of studies have attempted to elucidate the genetic origins of the Native Americans. Since the early 1990s, samples from the native populations of Siberia have been examined with polymorphic DNA markers (mtDNA, STRs, VNTRs) and yielded a conflicting picture of the peopling of the New World. One limitation of these studies was the small number of markers examined in each. In an attempt to construct a more accurate phylogenetic relationship of this migration we plan to screen the entire genome of multiple populations with 377 STRs spaced approximately 10 cM apart. To reduce the amount of genotyping required, we pooled equimolar amounts of DNA from each sample from three Siberian (Altai, Buryat and Chuvash), one Native American, one South African, and one Caucasian population and determined the allelic frequencies. In our preliminary analysis of 20 STRs spread across the genome, we have found that the frequency of each allele is accurately estimated by the proportion of height in each peak (r=0.9811). Furthermore, we have corrected for error in measurement using DNA pooling as compared to typing individual samples by linear regression. Using this model of prediction, we obtained 95% confidence limits for the proportions (heights) and compared populations. Populations were considered to be significantly different if at least one of the proportions was different and multiple such differences were observed. We plan to screen the rest of the genome and compare these populations and develop a weighted measure of genetic distance. This distance shall enable us to connect the various populations and establish phylogenetic relationships among them.

Program Nr: 1079 from the 1999 ASHG Annual Meeting

Multiplex heteroduplex generator strategy to genotype homocysteine related polymorphisms. *S. Barbaux, L.A.J. Kluijtmans, A.S. Whitehead.* Pharmacology, University of Pennsylvania, Philadelphia, PA.

A modest elevation of circulating levels of the amino acid homocysteine has been identified as a risk factor for some human pathologic conditions, including cardiovascular diseases and neural tubes defects. We have developed a rapid and simple method for genotyping the 4 most common polymorphisms in genes related to homocysteine/folate metabolism. These polymorphisms consist of 2 missense mutations in the methylenetetrahydrofolate reductase (MTHFR) gene (C677T and A1298C) and 1 in the methionine synthase (MS) gene (A2756G), and an insertion/deletion polymorphism of 68 bp in the cystathionine beta synthase (CBS) gene. The method is based on a multiplexed heteroduplex strategy: for each polymorphism, a fragment identical to the target region, except for a few base pairs deletion close to the mutated nucleotide, is added to genomic DNA prior to PCR amplification to produce heteroduplexes, that have different mobilities depending on the presence or absence of the polymorphic change. Synthetic heteroduplex generators have been generated for each of the above missense polymorphisms and cloned together into a single construct. Primers specific for each polymorphism were designed and reaction conditions optimized to produce heteroduplexes and homoduplexes of diagnostic sizes, that could be resolved on a 12% non denaturing polyacrylamide gel. Thus the above 4 genotypes can be determined by electrophoretic analysis of the products of a single PCR reaction. This method will facilitate further research on the role of genetic variants of genes involved in homocysteine/folate metabolism in various conditions and enable rapid genotyping of at-risk individuals to be undertaken: i) rapidly and at low cost and ii) without the failure and partialing problems inherent in the restriction enzyme based genotyping currently used to define MTHFR and MS variants.

Program Nr: 1080 from the 1999 ASHG Annual Meeting

The impact of racial admixture on traditional linkage analysis. *J.S. Barnholtz[1,2], M. de Andrade[1], R. Chakraborty[2].* 1) MD Anderson Cancer Center, Dept. of Epidemiology, Houston, TX; 2) UT School of Public Health, Houston, TX.

Racially admixed families are routinely excluded from traditional (LOD score) linkage analysis or analyzed as racially homogeneous using the proband's race. Through simulation, we investigated the effect of admixture on the LOD score of two racial groups under various conditions.

Four-generation racially homogeneous and admixed families were simulated with 27 markers and two linked, bi-allelic disease loci. One locus was linked to a marker with correct allele frequencies for both groups and the other was linked to a marker with correct information for only one group. Two different types of admixture were tested: admixture within a family unit and a mixture of homogeneous families within a data set. The mixing was done at the founder level in three different proportions: 30/70, 50/50 and 70/30.

We observed that the LOD scores under both models of admixture were closest to the homogeneous family scores of the racial group having the highest mixing proportion. In the 50/50 case, the LOD scores were in-between the homogeneous scores. Random sampling of families or ascertainment of families with disease affection status did not affect this observation, nor did the mode of inheritance (dominant/recessive) or disease/marker allele frequencies.

LOD scores in admixed family data were further affected due to departures from Hardy-Weinberg expectations of genotypic frequencies and presence of linkage disequilibrium in admixed populations. Subroutines performing these tasks with relaxed assumptions are being implemented in current LOD score analysis programs. (Research supported by NCI-R25CA57730-07 and NIH-GM41399.).

Program Nr: 1081 from the 1999 ASHG Annual Meeting

Large human panels for the study of genomic variation. *P.K. Bender, L.H. Toji, C.M. Beiswanger, J.C. Leonard, J.C. Beck, R.T. Johnson.* Coriell Cell Repositories, Coriell Inst. for Medical Research, Camden, NJ.

The Coriell Cell Repositories have compiled panels of cell lines and DNA samples from 90 donors representing 9 different ethnic origins or geographic regions. These panels of 10 individuals each have stimulated considerable research interest and requests for additional and larger panels of Caucasians and African Americans. Panels of 50 and 100 samples from African Americans have been assembled, and similar size panels of Caucasians will be available shortly. The African American samples were collected principally from the Northeast of the U.S. The samples are from unrelated individuals and most of the samples are from clinically unaffected donors. Approximately, 80% of the samples are female. Based on the geographic data, it is estimated that the European genetic contribution to these African American panels may range between 14-20% (Parra, E.J., *et al.*, *Am. J. Human Genet.*, **63**, 1839-1851, 1998). These data assure that these panels will provide a good control cohort for many linkage studies.

As part of the Repositories' routine quality assurance, each sample has been genotyped with six different microsatellites. This procedure assures sample identity from receipt of sample to shipping. As an introduction to the variation present in these panels, the allele frequencies for these six microsatellites have been determined and are available as histograms. These data allow comparison of the occurrence of low frequency alleles in the different size panels, and provide a basis for comparing representation between the different size panels. The availability of these panels provides a new and extended resource for the identification of polymorphisms that contribute to genetic variation, disease linkage, and anthropological studies. »»

Program Nr: 1082 from the 1999 ASHG Annual Meeting

Modelling Susceptibility to Bowel Cancer using Segregation Analysis. *D.T. Bishop[1], D.J.B. St John[2], G.P. Crockford[1], E.A. Debney[3], F.T. McDermott[3], E.S.R. Hughes[4].* 1) Gen Epid Lab,St James Univ Hos, Imperial Cancer Research Fund, Leeds, England; 2) Dept of Gastroenterology, The Royal Melbourne Hospital, Melbourne, Australia; 3) Monash University, Dept of Surgery, Alfred Hospital, Melbourne, Australia; 4) Deceased.

Segregation analyses of susceptibility to bowel cancer have uniformly identified a rare, dominantly inherited susceptibility with lifetime penetrance 0.5 or higher. However, it is now known that germline mutations in mismatch repair genes (notably hMSH2 and hMLH1) are associated with susceptibility in families with the syndrome, Hereditary Non-Polyposis Colorectal Cancer (HNPCC). Many of the families with multiple cases of colorectal cancer and especially those with early onset can be attributed to mismatch repair gene mutations while for others this is apparently not the case. We are interested in (i) estimating the contribution of mismatch repair genes to colorectal cancer incidence in the general population and (ii) evaluating the evidence for other genetic factors being involved in bowel cancer susceptibility in families without mismatch repair mutations. To investigate these issues, we obtained detailed and verified family histories from 525 bowel cancer patients of the late Sir Edward Hughes in Melbourne. Four of these families are known to have mismatch repair mutations. Segregation analysis of these remaining families again suggests a rare, high penetrance gene with lifetime penetrance 0.45. Reasoning that many other families may well have mismatch repair mutations but have not or will not be tested, we obtained from other studies (including our own), the contribution of MMR mutations to colorectal cancer incidence by extent of family history. Incorporating this information into the segregation analysis still suggests a dominantly inherited susceptibility but with decreased gene frequency suggesting that there are other genes involved in susceptibility to colorectal cancer.

Program Nr: 1083 from the 1999 ASHG Annual Meeting

Comparing odds ratios from family-based and case-control association studies: application to Alzheimer's disease. *D. Blacker[1,2], L.M. O'Brien[3], R.E. Tanzi[4], N.M. Laird[3].* 1) Dept Psychiatry, Mass General Hosp, Boston, MA; 2) Dept Epidemiology, Harvard Sch Pub Health, Boston, MA; 3) Dept Biostatistics, Harvard Sch Pub Health, Boston, MA; 4) Dept Neurology, Mass General Hosp, Boston, MA.

A consideration of effect sizes as well as p-values can help reduce controversy surrounding association findings in complex diseases, as they allow comparison of an effect's magnitude and direction and are not dependent on sample size. For case-control studies, an odds ratio (OR) can be estimated directly or by using logistic regression to control for known confounders. For family-based studies, where unaffected relatives (e.g., sibs) serve as controls to prevent confounding by admixture, *Mantel-Haenzel* ORs and *conditional* logistic regression, both stratified on family, must be used; *crude* ORs *not* stratified on family are biased downward. Case-control and family-based ORs can differ due to population admixture, ascertainment factors, and other uncontrolled confounders. In the absence of these factors, if--as is likely in complex diseases--multiple genes and other familial factors jointly contribute to risk, family-based ORs will generally be higher than case-control ORs. These points are illustrated below for two Alzheimer's disease (AD) risk factors: the established apolipoprotein E-4 (APOE-4) and the recently reported alpha-2-macroglobulin (A2M-2). We report both conditional and crude ORs on 120 sibships discordant for AD (n=467; p-values are from discordant sibpairs only) and crude ORs on the 120 proband cases vs. 129 cognitively intact elderly controls. Future work will compare multiple samples and consider p-values and confidence intervals for ORs based on all available sibs.

OR (p)	Family, conditional	Family, crude (wrong)	Case-control
APOE-4+	2.5 (.002)	1.9 (.008)	9.5 (.0001)
A2M-2+	2.3 (.03)	1.5 (.08)	1.2 (.43)

.

Program Nr: 1084 from the 1999 ASHG Annual Meeting

Analysis of joint mismatch distributions of sequences from mitochondrial hypervariable regions 1 and 2, in a sample of individuals from major world populations. *A. Bobrowski[1], M. Kimmel[2], D.N. Stivers[1], R. Chakraborty[1]*. 1) Human Genetics Center, University of Texas at Houston, Houston, TX; 2) Dept Statistics, Rice Univ, Houston, TX.

We developed a mathematical model, which makes possible to predict joint distributions of numbers of mismatches in two or more regions of the genome, based on the infinite sites models, under mutation-drift equilibrium or various patterns of population growth. One of the predictions is different correlation between numbers of mismatches in the two regions, depending on the pattern of the past population growth (constant, slowly growing, or rapidly growing). In this way, the method provides additional insight into the demographic history of the populations. Also, we developed expectations and variances of sample statistics under different growth scenarios. As an application we used a sample of mitochondrial sequences from hypervariable regions 1 and 2, representing all major world populations (Europeans, Asians and Africans). The patterns of joint distributions of numbers of mismatches markedly differ from one population to another. African mtDNA data are most consistent with rapid expansion, while Asian data seem to indicate early occurrence of population mixture. (Research supported by NIH grants GM 41399, GM 45861, and by the Keck's Center for Computational Biology at Rice University).

Program Nr: 1085 from the 1999 ASHG Annual Meeting

Frequency of *GJB2* (connexin 26) mutations in African American and Caucasian populations in North Carolina.
J.K. Booker, Z. Zhou, L.M. Silverman, E.M. Rohlfs. Dept. of Pathology & Lab. Med., Univ. of North Carolina, Chapel Hill, NC.

More than 80% of individuals with non-syndromic autosomal recessive deafness are either homozygous or compound heterozygous for mutations in the *GJB2* gene that encodes the connexin 26 protein. The most frequently observed mutation is 35delG. Carrier frequencies for 35delG have been shown to vary from 0.73% in the Ashkenazi Jewish population (where 167delT is seen at a frequency of 4%) to 3.2% in individuals from Italy and Spain. In preparation for offering clinical mutation analysis for autosomal recessive deafness, we determined the carrier frequency of the 35delG mutation in North Carolinians, primarily comprised of Caucasians and African Americans. DNA samples collected for unrelated genetic analysis were tested for the 35delG mutation by an allele specific PCR assay. The 35delG mutation was found in 2/500 African Americans (0.4%) and 10/500 Caucasians (2.0%). The 35delG carrier frequency is significantly lower in African Americans than Caucasians ($p=0.02$) and may be the result of admixture. The 35delG mutation is thought to have occurred several times based on haplotype analysis; it is not known whether it occurred in Africa. The only study of the carrier frequency in the United States tested 173 African Americans without finding the 35delG mutation. In addition to the 35delG analysis, we developed a PCR mediated site directed mutagenesis assay to screen for the *GJB2* R143W mutation identified in a village in eastern Ghana with an extremely high frequency of non-syndromic recessive deafness. To date we have tested 200 African Americans for the R143W mutation without detecting it. This study suggests that the 35delG mutation will account for a significant proportion of non-syndromic recessive deafness in the North Carolina population. Complete sequence analysis will be necessary to identify additional *GJB2* mutations, both in Caucasians and African Americans with non-syndromic recessive deafness, with the potential to identify recurrent mutations in the African American population.

Program Nr: 1086 from the 1999 ASHG Annual Meeting

Genetic analysis of schizophrenia in isolated Daghestanian kindreds. *K. Bulayeva[1], K. Roeder[2], S.A. Bacanu[3], P. Bennett[4], B. Devlin[3], B. Byerley[1]*. 1) Department of Psychiatry, Univ. of California , Irvine, CA; 2) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 3) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA; 4) Department of Psychiatry, University of Utah, Salt Lake City, Utah.

Despite differing cultures and environments, the worldwide prevalence and presentation of schizophrenia are remarkably homogeneous. Our goal is to identify genes that underlie susceptibility to schizophrenia in the ethnically diverse population of Daghestan, a Russian republic composed of 26 Caucasoid ethnic groups. Most of the ethnic groups reside in remote highland villages that can be classified as 'primary isolates'. Prolonged reproductive isolation and severe environmental conditions in the highland villages have created genetically diverse isolates in this region (Bulayeva,1991, Genetic Basis of Human Psychophysiology. Moscow:Nauka, 218 p). Due to the substantial endogamy and inbreeding, each isolate is essentially an extended family or kindred. Notably some kindreds have numerous affected individuals, yet others are disease free. These kindreds should prove a valuable resource for genetic analysis of schizophrenia. As part of an ongoing study, 12 large kindreds have been partially ascertained. Of the 292 subjects sampled thus far, 87 are chronic schizophrenic cases primarily from five ethnic groups, Avars, Dargins, Koumiks, Tindalls and Laks. A 10 cM genome screen (CHLC 9.0 markers) using these subjects has recently been completed by the Mammalian Genotyping Service. Due to sparse sampling and inbreeding, linkage analysis on these kindreds is quite challenging. As one approach, we are using descent graph methods developed by Sobel and Lange (1996; Am J Hum Genet 58:1323-1337) and implemented in Simwalk2. Analysis of these large, complex pedigrees has proven tractable, albeit computer-intensive. We present results for whole-genome marker-sharing statistics.

Program Nr: 1087 from the 1999 ASHG Annual Meeting

Epidemiologic phenotype in Irish families with neural tube defects. *J. Byrne*[1,2]. 1) Center VI, Children's Natl. Med. Center, Washington, DC; 2) Boyne Research Institute, Drogheda, Ireland.

This abstract introduces the term "epidemiologic phenotype" in the context of studies of the etiology of neural tube defects (NTDs). Both the epidemiologic phenotype and the clinical phenotype of NTDs are unusually complex and probably heterogeneous in origin. In contrast to the clinical phenotype (the proband's diagnosis), the epidemiologic phenotype can be thought of as those characteristics that affect other family members, or that influence NTD rates overall, i.e., area differences and incidence declines. Both the clinical and the epidemiologic phenotype may be considered as representing the sum of genetic and environmental factors associated with NTDs. Among the features of the epidemiologic phenotype of NTDs previously reported are excess risk for a recurrence in sibships, excess miscarriages in sibships, and preferential maternal inheritance. Some of these characteristics have been related to the clinical phenotype, i.e., high or low spina bifida. This study of Irish families extends our knowledge about the features of the NTD epidemiologic phenotype. With historically high rates of NTDs and relative homogeneity of the population Ireland presents a unique opportunity to study the origins of NTDs. Interviews with 77 Irish NTD families revealed a large number of factors occurring to excess ($p<.05$), including preferential maternal transmission. These are: large family size and excess miscarriages in NTD sibships, excess risk for NTDs and other malformations in sibs, excess birth defects on the maternal side and, for the first time, subfertility and infertility among maternal relatives. NTDs are etiologically complex resulting from the combined action of multiple factors, both genetic and environmental, acting together. Further studies that continue to expand the epidemiologic phenotype and relate it to the clinical phenotype and ultimately to the genotype will enhance our understanding of the contributions of gene and environment to the etiology of NTDs.

Program Nr: 1088 from the 1999 ASHG Annual Meeting

The relationship between IL-1 genotype and clinical response to recombinant IL-1 receptor antagonist therapy in rheumatoid arthritis. *N.J. Camp[1,3], A. Cox[1], F.S. diGiovine[1], D. McCabe[2], W. Rich[2], G.W. Duff[1]*. 1) Molecular and Genetic Medicine, University of Sheffield, UK; 2) Amgen Inc, CA; 3) Current affiliation: Genetic Research, IHC, UT.

Rheumatoid arthritis (RA) is a multifactorial inflammatory disease with a genetic component. Interleukin-1 (IL-1) plays a central role in the pathogenesis of RA, and agents which antagonise its activity can be of therapeutic benefit. One such molecule, the IL-1 receptor antagonist (IL1ra), blocks IL-1 activity by binding to the IL-1 receptor. The genes for IL1alpha, IL1beta and IL1ra are clustered within 430kb on chromosome 2. Using markers in the IL-1 region, we investigated the effect of IL-1 genotype on clinical response of patients with RA to IL1ra treatment, using data from a recent clinical trial of recombinant IL1ra.

A positive response was considered to be a reduction of at least 50% in the number of swollen joints presented by the patient by week 24. The treatment dose considered was 150mg, and 91 patients were included in these analyses. The response rate to treatment, independent of genotype, was 48.4% (44/91). A significant association was found between carriage of the rarer allele at IL-1A(+4845) and response to treatment (p=0.0009, OR=4.85(1.85,12.70)). The response rate for individuals carrying the rare allele at IL-1A(+4845) was 63.4%, compared with 26.3% for those who did not. Associations were also seen between IL-1A(-889) and IL-1B(+3954) and response to treatment, but these were more consistent with linkage disequilibrium with IL-1A(+4845) rather than independent associations or epistatic effects. Logistic regression also confirmed the role of genotype at IL-1A(+4845) in response to treatment. Carriage of the rare allele at IL-1A(+4845) was chosen for inclusion in the model (p=0.0008) with a predicted OR of 5.08(1.97,13.06).

In conclusion, we have found an association between IL-1A genotype and response to IL1ra treatment of RA. This could be used to predict a subset of RA patients who are more likely to respond to therapy with IL1ra (63.4%) than those who do not carry this allele (26.3%).

Program Nr: 1089 from the 1999 ASHG Annual Meeting

The HGDP-CEPH Human Genome Diversity Panel. *H.M. Cann[1], C. De Toma[1], A. Marcadet-Troton[1], G. Thomas[1], J. Dausset[1], L.L. Cavalli-Sforza[2].* 1) Foundation Jean Dausset-CEPH, Paris, France; 2) Department of Genetics, Stanford University School of Medicine, Stanford, CA.

The Human Genome Diversity Project (HGDP) has been organized for the promotion and coordination of studies involving the typing of large samples of individuals from populations throughout the world with hundreds of genetic DNA markers. Such studies promise an improved understanding of human evolution, and are also relevant for mapping genes implicated in complex disorders. The objectives of the initial HGDP project, undertaken in collaboration with CEPH, are to 1) assemble a collection of existing lymphoblastoid cell lines (LCLs) from 1000 individuals from 40-50 populations and 2) develop a set of genetic markers to be used for characterization of the genetic structure of various populations. Each HGDP participant will type the DNA from the LCL panel with local markers, and a common set of markers will also be used for typing by a core group of laboratories. The results of DNA typing will be deposited in a database initially available to participants and later to the public.

Currently the panel contains 367 mycoplasma-negative LCLs stored at -180° C at CEPH. Each LCL is tested locally (optionally) for mycoplasma and on reception at CEPH with a PCR-based procedure. Sixty three mycoplasma+ LCLs have been found and discarded. Geographic origin of populations represented in the current panel are Africa (2 populations), the Middle East (2), Pakistan (8), India, Laos, Melanesia, New Guinea and France. To date DNA has been prepared at CEPH from 318 LCLs, the amounts ranging from 0.7 to 3.5 mg. per cell line (less than 1 mg. for 7 lines). CEPH will send to participants a minimum of 1 mg. of DNA from each of the 1000 LCLs in 96 well format. Identifying information for each LCL will be limited to the sex and geographic and population origin of the sampled individual.

A list of LCL contributors will be presented.

Program Nr: 1090 from the 1999 ASHG Annual Meeting

Comorbidity between psychotic disorders in the Maudsley twin psychosis series. *A.G. Cardno[1,2], F.V. Rijsdijk[3], P.C. Sham[3], R.M. Murray[3], P. McGuffin[3]*. 1) Psychological Medicine, UWCM, Cardiff, UK; 2) Medical Genetics, UWCM, Cardiff, UK; 3) Institute of Psychiatry, London, UK.

Background: Operationally-defined schizophrenia, schizoaffective disorder and mania show evidence of substantial heritability. However, whether these disorders share genetic risk factors in common is controversial. This issue can be investigated by applying biometrical model fitting to data from twins. Methods: One hundred and sixty six probandwise twin pairs (77 MZ and 89 same-sex DZ), where the proband met criteria for RDC lifetime-ever schizophrenia (Sz), schizoaffective disorder (Sa), or mania (Ma) were ascertained from the Maudsley Twin Register in London. Correlations in liability were calculated for each disorder in MZ and DZ pairs, and across the three pairings of Sz-Ma, Sz-Sa, and Sa-Ma, both within twins and within pairs. For each pairing, a correlated liability model was fitted. For all three disorders considered together, independent pathway and common pathway models were fitted. Results: Under the correlated liability model all three pairings of disorders showed significant genetic correlations. The analyses of the three disorders together suggested common and diagnosis-specific genetic contributions to variance in liability to both schizophrenia and mania, but negligible diagnosis-specific genetic effects for schizoaffective disorder. Conclusions: These results are consistent with a degree of overlap in the genes contributing to RDC schizophrenia, schizoaffective disorder and mania, when these disorders are defined on a non-hierarchical lifetime-ever basis.

Program Nr: 1091 from the 1999 ASHG Annual Meeting

Interactions between genetic and reproductive factors in breast cancer risk in African-American women. *V. Chaudru[1], A. Laing[2], G.M. Dunston[2,3], L. Adams-Campbell[2], R. Williams[2], J. Lynch[4], D. LaSalle Leffall[2], R. DeWitty[2], B.L. Gause[2], G.E. Bonney[2,3], F. Demenais[1,2].* 1) INSERM U.358, Paris, France; 2) Howard University Cancer Center, Washington, DC; 3) The National Human Genome Center at Howard University, Washington, DC; 4) Washington Hospital Center, Washington, DC.

Although considerable progress has been made in the identification of breast cancer (BC) genes, BC remains a complex disease involving a major genetic component and other risk factors, mainly related to the reproductive life. We have investigated interactions between genetic and reproductive factors in BC risk in 245 African-American families, ascertained through 245 BC probands followed at Howard University Hospital and Washington Hospital Center (Washington, DC). Information on BC history and reproductive factors (age at menarche, number of children, number of spontaneous and induced abortions, menopausal status) was recorded for the probands and female first-degree relatives. Segregation analysis of BC was conducted by use of the class D regressive model taking into account a variable age of onset of disease, as implemented in the REGRESS program. Our results show significant evidence for the segregation of a rare dominant gene ($p<0.0001$) and additional sister-sister dependence ($p=0.0001$). Age at menarche is found to interact significantly with this gene, and an interaction with spontaneous abortions is suggested. A late age at menarche increases BC risk in susceptible women but has a protective effect in non-susceptible women. A history of spontaneous abortions has a protective effect in susceptible women whereas it increases BC risk in non-susceptible women. These findings agree partially with those previously reported in a French study (Andrieu and Demenais, Am J Hum Genet, 61:678, 1997) where a dominant gene was found to interact with the number of children and there was an indication of interaction, although not significant, with age at menarche. Investigation of interactions between genetic and reproductive factors in different populations exposed to different environment can have important implications for BC risk assessment.

Program Nr: 1092 from the 1999 ASHG Annual Meeting

Comparison of Genehunter 1.2 max LOD, max Heterogeneity LOD, and max NPL statistics for disease gene localization using simulated data. *C. Chen[1], D. Gordon[2], S. Finch[3], N. Mendell[3].* 1) Case Western Reserve University, Cleveland OH; 2) Rockefeller University, New York NY; 3) State University of New York at Stony Brook, Stony Brook NY.

This study compares the performance of the maximum LOD(MLOD), maximum heterogeneity LOD(MHLOD) and maximum GENEHUNTER 1.2 Nonparametric Linkage(MNPL) score for disease-gene localization. We use a simulation study considering: (i)4 disease models, (ii)100 replicates for each model, (iii) 58 pedigrees whose structure matches a field study with 592 subjects (iv)3 marker loci with 3 equally frequent alleles each, (v)marker distances of 10cM between each marker locus (vi)disease locus placed halfway between the second and third marker and (vii)either 0% unlinked families (linkage homogeneity) or 50% unlinked families (linkage heterogeneity). The disease models have: (i) a disease allele, A, with frequency 0.03, penetrance of the disease allele for those homozygous for A of 0.8, penetrance of the disease allele for those homozygous for the normal allele, B, of 0.01 and (ii)either complete dominance or complete recessivity of the disease allele. For each replicate we obtain the marker with MNPL, the marker with MLOD, and the marker with MHLOD and compute the distance of these markers from the disease locus. The MLOD (and MHLOD) are obtained by maximizing LOD (or HLOD) over penetrances, and allele frequencies, and recording the maximum of these two scores.

Comparison of distances between the location with the MLOD, MHLOD and MNPL values based on our 15-replicate pilot study indicates that (i)for data simulated under linkage homogeneity, the same location is identified by both the MLOD and MHLOD statistics; under linkage heterogeneity the location of MHLOD is much closer to the true position of the disease locus than the position of MLOD (ii) for either linkage homogeneity or heterogeneity, the position indicated by MHLOD is closer on average to the disease locus than the location identified by MNPL. Findings for the remaining 85 replicates will be presented at the meeting.

Program Nr: 1093 from the 1999 ASHG Annual Meeting

Apolipoprotein(a) polymorphisms and plasma lipoprotein(a) concentrations in Non-Hispanics Whites and Hispanics. *L. Chiu[1], R.F. Hamman[2], C.E. Aston[1], M.I. Kamboh[1].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Preventive Medicine and Biometrics, University of Colorado School of Medicine, Denver, CO.

Elevated levels of plasma Lipoprotein(a) [Lp(a)] are thought to be a risk factor for atherosclerosis and coronary heart disease. Plasma levels of Lp(a) are highly variable between individuals, ranging from 0.1 mg/dl to > 100 mg/dl. These levels are under strict genetic control and genetic variation in the apolipoprotein(a) [apo(a)] gene accounts for almost all variation in Lp(a) levels. In this study, we investigated the relationship between two apo(a) polymorphisms (kringle 4 and 5' pentanucleotide repeat) and plasma Lp(a) levels in normoglycemic non-Hispanic Whites (NHWs) (n=390) and Hispanics (n=214) from the San Luis Valley, Colorado. Mean (±SD) and median Lp(a) levels were 9.6±12.5 mg/dl and 3.8 mg/dl, respectively, in NHWs and 12.1±15.6 mg/dl and 4.9 mg/dl, respectively in Hispanics. The number of observed kringle 4 repeats ranged from 11 to 38 in NHWs and from 10 to 41 in Hispanics. Spearman's correlation revealed an inverse relationship between the size of the kringle 4 repeat and plasma Lp(a) levels in both populations ($r = -0.38$; $p<0.0001$ in NHWs and $r = -0.64$; $p<0.0001$ in Hispanics). About 30% and 48% of the variation in plasma Lp(a) was explained by this polymorphism in NHWs and Hispanics, respectively. This study confirms that the kringle 4 polymorphism in the apo(a) gene is a significant determinant of Lp(a) levels in both study groups. A pentanucleotide repeat polymorphism in the 5' promoter region of the apo(a) gene did not show significant impact on plasma Lp(a) levels in either NHWs or Hispanics.

Program Nr: 1094 from the 1999 ASHG Annual Meeting

Haplotype Analysis of Chemokine Receptor Polymorphisms. *V.J. Clark[1,2], R.J. Peterson[1], M. Dean[1].* 1) Laboratory of Genomic Diversity, NCI-FCRDC, Frederick, MD; 2) InterCollege Graduate Program in Genetics, Pennsylvania State University, University Park, PA.

Chemokines are small intercellular signaling molecules that recruit immune cells to the site of inflammation and infection. Chemokine and chemokine receptor variants influence susceptibility to HIV-1 infection and progression and the efficiency of the immune system. In addition, these proteins are important in tumorigenesis and metastasis. Therefore, studies of variation in these genes, and their cell-surface receptors, may be crucial to understanding how gene function affects the complex process of cancer. Haplotype analysis of Single Nucleotide Polymorphisms (SNPs) has been increasingly important in the study of complex disease. Here, we characterize haplotypes comprising alleles at eight SNPs in the CCR2-CCR5 chemokine receptor gene region, a span of 20 kb on chromosome 3p21, using the 5' nuclease assay (TaqMan). This work is part of the NCI Cancer Genome Anatomy Project (CGAP) effort to characterize SNPs in cancer genes. Forty three-generation CEPH families, comprising 489 individuals, were screened. Haplotype states and frequencies were determined by pedigree analysis and by maximum likelihood estimation in 98 grandparents. No recombinants were needed to explain the data, yielding an upper 95% estimate of recombination at 0.004. Both pedigree analysis and maximum likelihood estimation yielded the same small number of haplotypes for which linkage disequilibrium was nearly maximal. These results suggest that maximum likelihood estimation of haplotype states and frequency, and linkage disequilibrium analysis, will be an effective strategy in the CCR2-CCR5 gene region. For genetic epidemiology studies, base line CCR2-CCR5 allele and haplotype frequencies have been determined in African American (n=30), Hispanic (n=30), and Asian (n=30) populations. As a final step, these haplotypes are being used for association analyses in case/control cohorts for lung cancer (n=271), breast cancer (n=196), AIDS-related lymphoma (n=200), and AIDS-related Kaposi's sarcoma (n=200).

Program Nr: 1095 from the 1999 ASHG Annual Meeting

HLA DQB1, DQA1, DRB1 genes and haplotypes in a normal Mexican mestizo population from Guadalajara.

L.M. Cortes-Prieto[1,2], L.M. Balatazar[3], M.G. Lopez[1], F.J. Perea[1], M.P. Gallegos-Arreola[1], S.E. Flores[1], L. Sandoval[1], N. Olivares[1], R. Chakraborty[4], F. Rivas[1]. 1) Genetics/Molecular Medicine Divisions, CIBO, IMSS, Guadalajara, Mexico; 2) Immunology Graduate Program, CUCS, UdeG, Guadalajara, Mexico; 3) Medical Sciences Graduate Program, Universidad de Colima, Colima, Mexico; 4) University of Texas-Houston.

Out of 32 families living in Guadalajara, 156 healthy individuals were PCR-SSP typed. Alleles and haplotypes were counted in 54 random subjects, upon which linkage disequilibrium was estimated. Genotypes at each locus were distributed in agreement with Hardy-Weinberg expectations. Observed gene frequency (%, 2n=108) were for DQB1 (QB): *0201 (17), 0301 (16), 0302 (28), 0303 (7), 0402 (7), 0501 (18), 0502 (1), 0503 (1), 0601 (1), 0602 (5) and 0603 (1); for DQA1 (QA): *0101 (8), 0102 (3), 0103 (4), 0104 (10), 0201 (10), 0301 (30), 0401 (13), 0501 (22) and 0601 (0); for DRB1 (RB): *0101-3 (12), 0301,2 (6), 0401-11 (25), 0701,2 (12), 0801-4 (8), 0901 (2), 1001 (3), 1101-4 (8), 1201,2 (2), 1301,2 (6), 1303,4 (0), 1401,4,5 (2), 1402,3 (7), 1501,2 (4), 1601,2 (1) and other (4). Fifty-six distinct QB-QA-RB haplotypes were identified. The most commonly observed (five or more) were *0302-0301-0401/-11 (15); *0201-0201-0701/2 (8); *0501-0101-0101/3, *0301-0501-1402/3, *0402-0401-0801/4 (6); and *0301-0501-1101/4 (5). Normalized linkage disequilibrium (D') inversely correlates with the corresponding expected hapalotype frequency (F). Observed haplotypes with F>0.02 and (D')>0.5 were for QB-QA *0301-0501 (0.77), *0302-0301 (0.53), *0301-0101 (-0.80), *0501-0501 (-0.76), *0302-0201 (-0.67); for QB-RB *0202-0701/2 (0.63), *0501-0101/3 (0.81), *0302-0401/11 (0.59), *0302-0801/4 (-0.6); and for QA-RB *0301-0401/11 (0.68), *0401-0401/11 (-0.71), *0301-0101/3 (-0.74). Normalized global disequilibrium estimates were 0.55, 0.67, and 0.55 for QB-QA, QB-RB, and QA-RB, respectively. Preliminary comparisons of gene and haplotype frequency distribution with some worldwide populations indicate, as expected, that the present population is similar to other Latin American mestizo groups. Program Nr: 1096 from the 1999 ASHG Annual Meeting

Why are the majority of hereditary cases of breast cancer sporadic? A simulation study. *J. Cui, J.L. Hopper.* Centre for Genetic Epidemiology, The University of Melbourne, 200 Berkeley Street, Carlton, Victoria 3053, Australia.

Several population-based studies[1-2], including those people of Ashkenazi Jewish descent[3], have observed that 50% or more of women with breast cancer who are found to carry a germline mutation in BRCA1 or BRCA2 do not report having a family history of the disease. That is, the majority of 'hereditary' cases are 'sporadic'. Furthermore, the great majority of 'familial breast cancers' are being found not to be 'hereditary'. To investigate this phenomenon, we conducted a simulation study to evaluate the chance that a case (proband) is a mutation carrier, given the number of affected relatives. This has been undertaken for a range of plausible values of the allele frequency found in the literature (0.001 to 0.01), and the increased risk in mutation carriers relative to that in non-carriers (10 to 25, equivalent to lifetime risks of 40% to 80%, respectively). Incidence data for breast cancer in the Australian population were used to define the risk for non-carriers. Families consist of the mother, the maternal and paternal grandmothers, and sisters and aunts. The number of female siblings was generated according to a Poisson distribution, and age assigned according to a Weibull distribution fitted to the population-based Australian Breast Cancer Family Study[4]. It was found that the simulated family history distribution of cases and prevalence of mutation carriers were similar to those observed in the population-based studies. Family history of breast cancer was not a strong predictor of mutation status; as is being observed empirically in samples from the population, each affected relative increases the odds of being a mutation carrier by only 2- to 3-fold. The probability of being a mutation carrier was generally low except in families with extreme histories of breast cancer. Reference: 1. Peto J. et al. *J Natl Cancer Inst* 1999; 91: 943-949. 2. Program Nr: 1097 from the 1999 ASHG Annual Meeting

MTHFR C677T mutation in parents of children with neural tube defects and in normal mestizo and native Mexican populations. *I.P. Davalos[1,2], N. Olivares[1], M.T. Castillo[1], J.M. Cantu[1], L. Sandoval[1], M.C. Moran-Moguel[1], R. Chakraborty[3], F. Rivas[1]*. 1) Genetics/Molecular Medicine Divisions, CIBO, IMSS, Guadalajara, Mexico; 2) Human Genetics Graduate Program, CUCS, UdeG, Guadalajara, Mexico; 3) University of Texas-Houston.

C677T mutation of the methylenetetrahidrofolate reductase (MTHFR) gene, associated with the thermolabile form of the enzyme, has reportedly been found increased in neural tube defects (NTD), though this association is still uncertain. A group of 107 mestizo parents of NTD children and four normal Mexican pupulations: 101 mestizo (M), 50 Huichol (H), 38 Tarahumara (T), and 21 Purepecha (P) were typed for the MTHFR C677T variant by the PCR/RFLP (HinfI) method. Twenty Caucasian (C) individuals were also studied. Genotype frequencies were in agreement with the Hardy-Weinberg expectations in all six populations. C677T allele frequency (AF, %) was 45 in the NTD group, 44 in M, 56 in H, 36 in T, 57 in P, and 35 in C. Pairwise interpopulation comparisons of AF disclosed very similar distribution between NTD and M groups (exact test, $p=0.92$). Among normal populations, differences between M and individual native groups were NS ($0.21>p>0.06$), as it was between M and C ($p=0.29$). However, very similar high frequency of the variant was found in H and P (56 and 57, $p=1.0$). With pooled data, these populations were significantly different to M and C in AF ($p<0.03$). Although genotypes were not studied in NTD affected children, similar AF in groups NTD and M does not support a causal relationship between NTD and parental MTHFR C677T genotypes. So, C677T variant cannot be regarded as a genetic risk factor for NTD in Mexican mestizo parents. Otherwise, C677T in Mexico, especially in Huichol and Purepecha natives, is very frequent as compared with other worldwide groups.

Program Nr: 1098 from the 1999 ASHG Annual Meeting

Prediction of lung cancer cases using logistic regression and classification and regression tree models. *M. de Andrade, J.S. Barnholtz, M.R. Spitz.* UT MD Anderson Cancer Center, Dept. of Epidemiology, Houston, TX.

Recent advances in technology for identifying genetic mutations and their products have led to an interest in correlating biologic markers with epidemiological factors with a view to better understanding the natural history and etiology of diseases. There is a concomitant need for research to determine the relevant statistical methods for data analysis and interpretation. Thus a primary goal in risk characterization is to develop statistical models that reliably characterize the inter and intraindividual variability of biomarkers that predict risk for disease. Once the mechanisms of biomarker variability have been established, methods to characterize individuals into high and low risk strata can be efficiently defined so that classical epidemiological methods can be applied. Our purpose in this project is to ascertain the prognostic effect of cancer biomarkers and environmental risk factors for lung cancer through risk assessment models. To build these models, we apply two statistical methods (logistic regression and classification and regression tree). To compare these models, we use the lung cancer data from a minority study conducted at The University of Texas M. D. Anderson Cancer Center.

Program Nr: 1099 from the 1999 ASHG Annual Meeting

Effect of Biomarker Misclassification: Comparison of Two *N*-acetyltransferase 2 (*NAT2*) Genotyping Methods.

A.C. Deitz[1], D.W. Hein[2], R.B. Hayes[3], N. Rothman[3], W. Chow[3], W. Zheng[4], T.R. Rebbeck[1]. 1) Epidemiology and Biostatistics, Univ. of Pennsylvania, Philadelphia, PA; 2) Dept. Pharmacology and Toxicology Univ. of Louisville, Louisville, KY; 3) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 4) School of Public Health, Univ. of South Carolina, Columbia, SC.

Genotype is often used as a surrogate biomarker of phenotype in studies evaluating cancer etiology. Genotype misclassification, thus phenotype misclassification, is dependent in part, upon the specific genotype assay and may contribute to inconsistencies observed across studies. We investigated the effect of this misclassification by comparing two *NAT2* genotyping methods: a commonly used method that detects three coding region variants, *M1*, *M2* and *M3*, *vs.* one that detects all 26 reported *NAT2* alleles. Genotype data were obtained from three unpublished case-control studies, two comprised primarily of Caucasians from Poland (n=418) and Iowa (n=482) and a third (n=293) comprised of 45% African-Americans. Genotypes were used to assign individuals to rapid (R), intermediate (I), or slow (S) acetylator phenotype groups. The 3-allele method resulted in deduced phenotype misclassifications of 3.6%, 4.8% and 14%, respectively, among the three studies. Spearman correlation coefficients were 0.94, 0.91 and 0.78. Sensitivity (proportion of individuals classified as R or I phenotype by the 3-allele method relative to the 26-allele method) was 100% in each of the studies and specificities (proportion of individuals classified as S phenotype by the 3-allele method relative to the 26-allele method) were 94%, 95% and 86%. When the *M4* allele, commonly found in African Americans, was included in the third study, specificity increased to 96% and the correlation between methods increased to 0.92. Our analyses indicated that there was little difference between the two genotyping methods. However, since misclassification may affect odds ratio estimates, sample size requirements, and evaluation of gene-environment interactions, genotype-disease association studies need to consider the potential effects of genotype misclassification.

Program Nr: 1100 from the 1999 ASHG Annual Meeting

Y-chromosomes shared by descent or by state: results of a Dutch micro-geographic study. *P. de Knijff[1], T. Kraayenbrink[1], L.P. ten Kate[2], E. Bakker[1]*. 1) MGC Department of Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Department of Clinical Genetics, University Hospital Free University, Amsterdam, Netherlands.

The genetic variation at the Y chromosome was studied among 275 males from four distinct Dutch regions and a pooled random Dutch population sample. For this analysis we used 7 short-tandem-repeat (STR)-loci, 3 single-nucleotide-polymorphisms (SNP's) and an ALU ins/del polymorphism (which we, for simplicity will also include as a SNP in this abstract), all from the non-recombining part of the Y-chromosome. The 4 SNP's defined 6 distinct **Y-haplogoups** , the 7 STR's defined 145 **Y-haplotypes** and when SNP's and STR's were combined, 163 distinct Y-chromosomes could be identified. Marked differences between the regions, based on the relative frequencies of individual alleles and haplogoups/haplotypes, were found. By means of haplotype-mismatch analysis it was found that these regional differences could be atributed to a different time-scale and region of origin of a number of Y-chromosomal immigration events into the Netherlands. Keeping in mind that the regions were only separated by 50-150 km with no apparent geographic or cultural barriers, these results illustrate the power of Y-haplotypes as a tool to recognize population substructures. In addition, we paid specific attention to those STR-based haplotypes which were shared between SNP- defined haplogroups. For this purpose, we assume that any similarity between such haplotypes is more likely due to mutation processes (which we define here as identical by state, IBS) rather then because of a direct, albeit ancient, descent (designated identical by descent, IBD). Since Y-chromosome STR-based haplotypes are frequently used for forensic identification purposes it seems not irrelevant to obtain a more detailed knowledge of this phenomenon before databases containing such information could be used with confidence.

Program Nr: 1101 from the 1999 ASHG Annual Meeting

A partial central Asian/eastern Siberian origin of the Saami mtDNAs. *G.A. Denisova, M.V. Derenko, B.A. Malyarchuk.* Genetics Lab, Inst Biol Probl of the North, Magadan, Russia.

Linguistic and nuclear-gene data suggest that the Saami originated in western Siberia and extensively admixed with European populations. However, an almost completely European origin of the Saami is supported by the mtDNA studies. It was shown that the less than 6.5% of the Saami mtDNAs are members of Asian superhaplogroup M (Lahermo et al., 1996) and up to 78% of them comprise the variation of two European haplogroups V and U5 (Torroni et al., 1998). Previously, Sajantila et al. (1995) observed that the Saami are characterized by incidence (5.2%) of the mtDNA HVS I nucleotide motif 16129A-16185T-16223T-16224C-16260T-16298C. To elucidate the origin of these mtDNA sequences, we have performed an extensive survey of previously published and our unpublished data sets for this nucleotide motif. The survey of European and Asian mtDNAs revealed that among European populations this Saami nucleotide motif is characteristic with frequency <1.5% only for the Russians from northern-central European part of Russia. In spite of the absence of these mtDNAs in western Siberian populations studied (the Kets and the Samoyedic-speaking Selkups; Kazakovtseva, 1998), this Saami motif is more common in Asian populations where it shows the highest frequency (26.2%) in the Evens of eastern Siberia and the lower frequencies in the central and eastern Asia (3.9% in the Mongolians, 3.1% in the Koreans, 1.1% in the Kirghiz) and southern Siberia (2.5% in the Buryats, 5.9% in the Altaians). Even though these HVS I sequences are more common in the Saami and the Evens than in central Asians, analysis of sequence divergence appears to indicate that these mtDNA sequences harbor a much higher diversity in central Asia (0.91%) than in Siberia (0.23%) and northern Europe (0.13%). These divergence values suggest that the Mongoloid component of the Saami mitochondrial gene pool originated in a population of central Asia and expanded into northern Europe from eastern Siberia. The early Neolithic migrations of peoples from eastern Siberia to northeastern Europe are also supported by archaeological and anthropological record (Alexeeva et al., 1997).

Program Nr: 1102 from the 1999 ASHG Annual Meeting

The putative ancestral sequences to the main Mongoloid mtDNA haplogroups occur in the Buryat mitochondrial gene pool. *M.V. Derenko[1], B.A. Malyarchuk[1], I.K. Dambueva[2], G.A. Denisova[1], I.A. Zakharov[3]*. 1) Genetics Lab, Inst Biological Prob of North, Magadan, Russia; 2) Genetics Dept, Inst Experiment Biol, Ulan-Ude, Russia; 3) Genetics Lab, Vavilov Inst General Genetics, Moscow, Russia.

It has been proposed recently (Macaulay et al., 1999) that modern Eurasian mtDNA derived from the 16223 sequence (in HVSI), which, during an Upper Paleolithic expansion, gave raise to, among others, clusters A, I, M, W, X, and, after the 16223T-C/12705T-C events, all the reference-sequence-derived clusters (B, F, T, U, H, and V). The 16223T-C mutation therefore appears to be the cause of a deep split in the global phylogeny of Eurasian mtDNA. By HVSI sequencing of 40 Buryats from the South Siberia region we identified a mtDNA cluster, referred to as "16223T sequences", comprising one-forth of the Buryat lineages and occurred also in seven of the 371 Koreans, one of the 103 Mongolians and two of the 48 Havik. The sequences in this cluster are characterized by the only transition C-to-T at position 16223, and grouped near the center of the tree arguing for its ancestral position. The haplogroup status of these Buryat sequences was determined by RFLP typing for diagnostic RFLPs defining Asian and New World-specific haplogroups A, B, C, D. The RFLP identification of 16223T HVSI sequences revealed the lack of exact congruence in the RFLP-HVSI identification of those mtDNAs. The 16223T Buryat sequences were determined as a different RFLP haplotypes including C and D. One of the 16223T sequence types is characterized also by 9 bp deletion in COII-tRNALys intergenic region and presumably belongs to B haplogroup. The remaining 16223T sequences belong to "other" RFLP category. This finding appears to indicate the putative ancestral state of the 16223T HVSI sequences to haplogroups C and D at least. The 16223T sequences found in Buryats appear to be closely related to the root of the global Eurasian phylogeny, which probably lies at the 16223 node. Two 16223T Buryat sequences unclassified in the RFLP analysis but clearly non A-D and identified as "other" RFLP haplotypes therefore could be considered as a root sequence, which encompasses virtually all Eurasian mitochondrial variation.

Program Nr: 1103 from the 1999 ASHG Annual Meeting

The evolution of a variant at the *NIDDM1* locus in primates. *A. Di Rienzo[1], G. Ybazeta[1], A. Pluzhnikov[2], N. Cox[1], Y. Horikawa[3], G. Bell[3], R. Hudson[4].* 1) Dept of Human Genetics; 2) Dept. of Statistics; 3) Dept of Biochemistry & Molecular Biology; 4) Dept of Ecology & Evolution, Univ of Chicago, IL.

A variant at the *NIDDM1* locus, termed UC-SNP43, was recently proposed to account for the linkage of this region to type 2 diabetes. In pre-historical times, genetic variants contributing to diabetes susceptibility are hypothesized to confer a *thrifty* genotype allowing efficient storage of energy and fat in times of abundance and better survival during famines. Such a hypothetical selective advantage may result in patterns of variation that depart from neutrality expectations. As a step towards testing this hypothesis, we investigated the evolution of UC-SNP43 in primates. Unlike many other human polymorphisms, the non-human primates did not all share one of the two alleles found in humans (G/A). While chimpanzees, Old and New World Monkeys carried the G allele, the gorilla and orangutan carried the A allele. These results may be explained most parsimoniously by three independent mutation events. Assuming neutrality, we assessed the probability of these data given the phylogeny of primates under the general model for nucleotide substitution at a single site. The substitution rate was estimated based on the overall amount of human-chimpanzee and human-orangutan sequence divergence at this region. The probability of these data (or data with more substitutions) under neutrality turned out to be 0.011, implying that natural selection acted on this variant. One possible adaptive scenario is that positive selection drove alternative alleles to high frequency or fixation in different primate lineages. Alternatively, UC-SNP43 is an old balanced polymorphism arisen in the hominid ancestors. Under the latter scenario, great ape populations may be expected to be polymorphic at this site. We typed UC-SNP43 in a sample of 38 and 30 chromosomes from common chimpanzee and orangutan, respectively, and did not find evidence of polymorphism. Thus, if the old balanced polymorphism hypothesis is true, either one allele is at rather low frequency or different alleles were fixed in the non-human great apes. Overall, these data argue in favor of a history of non-neutral evolution for this variant.

Program Nr: 1104 from the 1999 ASHG Annual Meeting

Mitochondrial DNA variation in Ethiopian populations: evidence of regional diversification of East African groups. *B.P. Donham[1,2], T.G. Schurr[3], D.L. Donham[2], C. Panter-Brick[4], D.C. Wallace[1,2].* 1) Center for Molecular Medicine, Emory University, Atlanta, GA; 2) Department of Anthropology, Emory University, Atlanta, GA; 3) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX; 4) Department of Anthropology, Durham University, Durham, UK.

We have characterized the mitochondrial DNA (mtDNA) variation of 157 Ethiopians by restriction fragment length polymorphism (RFLP) and control region (CR) sequence analyses. Ninety-six of these samples were collected in the Maale area, which is located in southwest Ethiopia, whereas the remaining 61 samples were collected in northern Ethiopia from several different ethnic groups. While approximately two thirds of the mtDNAs in sub-Saharan Africa belonged to macro-haplogroup L, which encompasses haplo-groups L1 and L2, this was not the case for the East African Ethiopians. Of the Ethiopian mtDNAs that belonged to macro-haplogroup L, most belonged to haplo-group L1 rather than L2. The majority of the remaining mtDNAs belonged to haplo-group L3, which lacks the HpaI 3592 site. Comparisons of the CR sequence and RFLP haplotype data also showed that several putative L3 mtDNAs are derivatives of haplogroup L1 that have lost the diagnostic Hpal 3592 site. A number of Ethiopian samples had the RFLP motif of Asian macro-haplogroup M, i.e., the DdeI 10394 and AluI 10397 sites. This result suggested that East Africa is either the source area for macro-haplogroup M mtDNAs which were subsequently spread into Asia, or that Asian mtDNAs have been introduced into Africa more recently through genetic back-flow. We also found a marked difference in the frequency of macro-haplogroups L and M in Ethiopian populations, with southern groups having 29% L and only 6% M, and the northern groups having 24% L and 26% M. These differences indicate that there may be significant regional differences in the genetic composition of Ethiopian populations.

Program Nr: 1105 from the 1999 ASHG Annual Meeting

Stroke Risk in Sibling Pairs with Sickle Cell Disease. *M.C. Driscoll[1], A. Hurlet[2], B. Berman[3], B. Files[4], L. Styles[5], K. Patel[1]*. 1) Dept Hematology/Oncology, Children's Natl Medical Ctr, Washington, DC; 2) Columbia Univ, College of P and S, NY, NY; 3) Rainbow Babies and Children's Hosp, Cleveland, OH; 4) E Carolina Univ, Greenville, NC; 5) Children's Hosp, Oakland, CA.

Cerebrovascular disease is a common complication of sickle cell disease (SCD) where 10% of patients with Hb SS have clinical stroke and another 17% have subclinical stroke by age 20. The incidence of first stroke in the pediatric SCD population is 0.7% per year, in contrast to the incidence in the pediatric non-SCD population of 0.0025%. The risk factors for clinical stroke in SCD are TIAs, acute chest syndrome, decline in hemoglobin, and increased systolic blood pressure. Although environmental risk factors for stroke in the adult non-sickle cell population are well defined, evidence for a genetic component is accumulating. A genetic risk for stroke is suggested by twin studies where the concordance for stroke is 17.7% for monozygotic twins and 3.6% for dizygotic twins and in family studies where the relative risk is increased with a parental history of stroke. This study aims to determine if there is an additional genetic risk (i.e. besides homozygosity for the sickle mutation) for stroke in a subset of patients with SCD by estimating the stroke risk in sibling pairs. The 8 pediatric centers surveyed have a SCD patient population of 3,589 patients (2235 Hb SS) less than 20 years. The incidence of stroke among the Hb SS patients is 153/2235 (6.8%). The incidence of stroke among 203 sib-pairs with Hb SS is: no stroke: 163 pairs, stroke in 1 sib: 31 pairs, stroke in both sibs: 9 pairs. Comparison of the risk for stroke in the total Hb SS group to the sib-pair group reveals an increased risk in the sib-pair group (OR = 4.2, CI 2.1-11.9, $p<0.01$). These data suggest that the relative risk for stroke in sib-pairs with SCD is higher than the overall risk for stroke in the SCD population and suggests a genetic component in a subset of SCD patients. Efforts to identify epistatic genes modifying the sickle phenotype may best be accomplished by methods currently developed for complex traits using sib-pair analysis and genome scanning or association testing for candidate genes for cerebrovascular disease.

Program Nr: 1106 from the 1999 ASHG Annual Meeting

The patterns of ancient and recent human germline mutations are similar: putatively neutral polymorphisms in human *F9* genomic sequences. *J.B. Drost, J. Feng, Q. Liu, S.S. Sommer.* Dept Molecular Genetics, City Hope Natl Medical Ctr, Duarte, CA.

The great majority of Factor IX (*F9*) mutations found in patients with hemophilia B occurred during the past 150 years. Forty-one polymorphic positions in *F9* intronic regions have been identified by restriction endonuclease fingerprint (REF) scanning of up to 20 kb in 11 randomly chosen regions of the 32 kb of genomic *F9* sequence from 84 individuals (1.538 megabases total). From these data, mutations which occurred during our species' distant past were characterized relative to an ancestral haplotype determined by analysis of seven non-human primate species. At least 21 of the mutations producing polymorphisms predate the separation of Africans and non-Africans. Thus, the mutations characterized are of very early origin. Twenty-four extant human haplotypes were identified, all of which differed dramatically from the ancestral haplotype. Recombination alone could have generated at least half of the observed haplotypes. When these ancient mutations are compared with 142 recent independent mutations from patients with hemophilia B, the pattern (transitions, transversions, and microdeletions/insertions) are similar, compatible with the hypothesis that germline mutation is due to endogenous processes that have changed little during human evolution.

Program Nr: 1107 from the 1999 ASHG Annual Meeting

French Canadian ascending genealogies: Tools for better linkage disequilibrium fine mapping. *M.-P. Dube[1], B. Brais[2], M. Jomphe[3], G.A. Rouleau[1]*. 1) 1. Centre for Research in Neuroscience, McGill University, Montreal General Hospital, 1650 Cedar Avenue, Montreal, Qc, Canada; 2) 2. Centre de recherche du CHUM-Campus Notre-Dame, 1560 Sherbrooke est, Montreal, Qc, Canada; 3) 3. Projet Balsac, Institut interuniversitaire de recherches sur les populations, Université du Québec à Chicoutimi, 555 boulvard de l'Université, Chicoutimi, Qc, G7H 2B1, Canada.

Linkage disequilibrium in founder populations provides a powerful tool for fine mapping of genes. The French Canadian population also provides ascending genealogies that can be used to complement linkage disequilibrium mapping. We report a computerized method for linkage disequilibrium fine mapping using French-Canadian ascending genealogies. The method involves two steps. First, the likely founding couple of the mutation-bearing chromosome is identified using a computerized randomization statistic. Then, using a delete-d jackknife resampling scheme, the distribution of gene mapping estimates is calculated from the count of ancestral recombinants and ancestral meioses joining the identified founding couple to the disease gene carriers. The count of ancestral meioses is estimated by randomly sampling possible disease-gene genealogies from the founding couple to the carriers. Gene mapping estimates are calculated from each marker individually, and confidence intervals of the estimates are derived from the jackknife distributions. The method, when applied to French Canadian families with oculopharyngeal muscular dystrophy (OPMD), successfully confirmed the localization of *PABP2* responsible for OPMD to a 335 kb interval on chromosome 14.

Program Nr: 1108 from the 1999 ASHG Annual Meeting

Comparison of Linkage Disequilibrium (LD) across Long Genomic Regions in Different Populations. *F. Durocher[1], A.M. Dunning[2], D. Teare[1], E. Dawson[3], S. Rhodes[3], B. Ponder[2], D. Easton[1].* 1) CRC Genetic Epidemiology Unit, Strangeways Research Centre, Cambridge, United Kingdom; 2) CRC Dept. of Oncology, Strangeways Research Centre; 3) Sanger Centre, Hinxton, UK.

The spacing of SNP markers is critical to the success and feasibility of whole genome association studies since, to give complete coverage, all the markers used will have to be in LD with their nearest neighbours. LD is affected by factors such as recombination, genetic drift, relative age of markers ans is unlikely to be uniform across the whole genome. Optimum marker spacing should reflect the strength of LD in a region. Recently founded populations have fewer haplotypes and LD may extend over longer physical distances than outbred populations or populations of small effective size and would therefore allow wider marker-spacing, thus reducing the number of genotypings necessary for a complete genome scan. The aim of our study is to draw long-range physical maps, showing the strength and extent of LD between markers, so that direct comparisons can be made between in- and out-bred populations. We are trying to identify random chromosomal regions where accurate physical maps are available over long distances and are currently working on two: Chromosome 13q12-13 and Chromosome 22q. We are initially using 8 markers on chromosome 13 over 1.3 Mb and 22 SNPs on chromosome 22, covering 0.12 Mb. We are comparing LD in these regions between the outbred East Anglian British population and the Afrikaner, the Finnish and the Ashkenazi Jewish founder populations, which have different characteristics. We are using D' to compare LD and a Monte-Carlo approach to determine significance levels and confidence regions. Initial results indicate that 5 out of 6 neighbouring pairs of markers on chromosome 22 showed significant LD, extending between markers up to 54 kb. There is also significant LD over at least 0.4 Mb of chromosome 13 but not all markers will exhibit LD with their nearest neighbours. Generally, Afrikaners have higher LD than East Anglian, but this is not always the case.

Program Nr: 1109 from the 1999 ASHG Annual Meeting

Polymorphisms in the HLA-linked olfactory receptor genes in the Hutterites. *A.C. Eklund[1], R. Raha-Chowdhury[2,3], C. Ober[1]*. 1) Human Genetics, University of Chicago, Chicago, IL; 2) Department of Pathology, Cambridge University, Cambridge, UK; 3) Department of Genetics, Yale University School of Medicine, New Haven, CT.

Genes in the MHC have been associated with mate choice and odor preferences in a variety of animals. Although the role of HLA genes in human mate choice has been controversial, studies in the Hutterites have demonstrated fewer than expected numbers of couples who match for an HLA haplotype, suggesting that in this population there is avoidance of mates with HLA haplotypes that are similar to one's own haplotype. Recently, 18 olfactory receptor (OR) genes have been mapped to the HLA region, telomeric to the HLA-F locus, providing a potential mechanism for HLA-based odor recognition and perhaps mate preferences in humans. In this study we genotyped a sample of Hutterites with diverse HLA haplotypes for polymorphisms in the HLA-linked olfactory receptor gene, FAT11. Most of the single exon in this gene (amino acids 1-251 of 316) was sequenced in DNA samples from 14 Hutterites who are homozygous for six different haplotypes. Studies in DNA representing the remaining 46 ancestral Hutterite haplotypes that occur only as heterozygotes are underway. Two single nucleotide polymorphisms were detected, both of which resulted in amino acid substitutions (Phe587Leu and Ala642Val). Phe587 and Val642 occurred together on three haplotypes (A2-Cw*1601-B51-DRB1*1301-DQB1*0603, A24-Cw*0304- B60-DRB1*1501-DQB1*0602, and A1-Cw*0602-B57- DRB1*0701-DQB1*0303), Leu587 and Ala642 occurred together on two haplotypes (A26-Cw*1203- B38-DRB1*1501-DQB1*0602 and A32-Cw*1203-B35 -DRB1*1101-DQB1*0301), and Phe587 and Ala642 occurred on a single haplotype(A3-Cw*0401-B35 -DRB1*0101-DQB1*0501).Thus at least three alleles of the FAT11 gene are present in the Hutterites. This level of variation in the FAT11 gene as well as in other OR genes in this region could contribute to the observed patterns of mate choice in the Hutterites and to individual variation in odor preferences, hypotheses that are currently under investigation. (Supported by HD21244 and GM19652).

Program Nr: 1110 from the 1999 ASHG Annual Meeting

Patterns of Genetic Diversity and Isolation by Distance. *E. Eller.* Anthropology, University of Utah, Salt Lake City, UT.

The pattern of human genetic diversity from 60 short tandem repeat (STR) loci surveyed in 15 Old World populations is consistent with a process of isolation by distance (Eller, 1999, Am. J. Phys. Anthropol. 108: 147-159). These data also show a linear decline in heterozygosity with genetic distance from Africa, consistent with an African origin of modern humans. Because STRs exhibit extremely high heterozygosity, they should be free of ascertainment bias while restriction site polymorphism (RSP) markers should be sensitive to bias since RSP markers were originally ascertained in Europeans.

Here I present the results of similar analyses from 30 RSP markers in 13 Old World populations. The main findings include the following:

1. Population differences in these markers are again consistent with a process of isolation by distance. Mantel tests show that approximately 66% of genetic distance can be explained by geographic distance. These results are similar to those from the STR data.

2. F_{ST} is 0.107. This value is similar to the STR R_{ST} value of 0.0918 and is consistent with other published values of F_{ST} and G_{ST} from a variety of genetic systems as well as craniometric data.

3. There is no excess of heterozygosity in African populations as was observed in the STR data set or an *Alu* data set (Stoneking et al. 1998, Genome Res. 7: 1061-1071). Instead, there is an excess of heterozygosity in the European populations (Northern Europeans and French) as well as in the Cambodians and the Malay. This pattern most likely is a result of ascertainment bias: these polymorphic RSP markers were first detected in Europeans. The high heterozygosity in European populations is consistent with other analyses of this data set (Jorde et al. 1995, Am. J. Hum. Genet. 57: 523-538; Rogers and Jorde 1996, Am. J. Hum. Genet. 58: 1033-1041) and with computer simulations incorporating ascertainment bias (H. Harpending, pers. comm.). These observations emphasize that we must take into account sampling bias before drawing conclusions about genetic diversity or relative effective population sizes.

Program Nr: 1111 from the 1999 ASHG Annual Meeting

Mutational diversity in inbred Middle Eastern populations. *P. Erlich[1], A. Adato[1], L. Raskin[1], H. Kalinsky[1], M. Korostishevsky[1], A. Berry[1], L. Farrer[2], B. Bonne-Tamir[1].* 1) Dept. of Human Genetics & Molecular Medicine, Tel-Aviv University, Ramat-Aviv, Israel; 2) Genetics Program, Dept. of Medicine Boston Univ. School of Medicine Boston, MA.

Rapid discovery of disease causing genes is revealing that mutations and/or haplotype profiles for various genetic disorders are often population specific. In earlier studies of Wilson Disease and Usher Syndrome, type IB in various Israeli ethnic groups (Kalinsky, et al. Hum Mut 11:45-151, 1998; Adato et. al. Am J Hum Genet 61:813-821, 1997), we documented mutations and haplotypes characteristic of each group. The Middle East is an area rich in small isolated communities and consanguineous kindreds. In these communities, it is assumed that all cases of single-gene disorders, particularly rare recessives, are the result of single ancestral founder mutations. Although families of Middle Eastern origin have proved invaluable to efforts for mapping and subsequently identifying genes for a variety of inherited conditions, several studies have demonstrated the existence of allelic and locus heterogeneity for Mendelian diseases within communties. For example, we observed two different mutations and three distinct genotypes in the ATP7B gene in an inbred Druze kindred with Wilson disease. Recently, in a highly consanguineous Israeli Palestinian kindred with non-syndromic deafness, we discovered three different coding sequence mutations in GJB2 (the connexin 26 gene). In another study of hereditary deafness in four Druze families from one village, we discovered that four different genes are responsible for the deaf phenotype: (1) the widespread 30delG mutation in GJB2, (2) a novel PDS (Pendred syndrome gene) mutation, (3) a novel OTOF mutation, and (4) an as yet unidentified gene in the fourth family. This remarkable heterogeneity may be due in part to misdiagnosis of subtly presenting syndromes as non-syndromic disorders and positive assortative mating (particularly in such instances as the deaf community). Awareness of such situations is important when considering disease gene searches or implementation of genetic screening and counseling programs in genetic isolates or inbred communities.

Program Nr: 1112 from the 1999 ASHG Annual Meeting

Heterogeneous mutations causing b-**Thalassemia in a highly inbred South Mediterranean population.** *D.M. Fathallah, R. Hafsia, M. Bejaoui, A. Hafsia, F. Amri, S. Abbes, R. Amami, MF. Ben Dridi, B. Mtimet, K. Dellagi.* The Hemoglobinopathies Study Group, Inst Pasteur de Tunis, Tunis, Tunisia.

b-Thalassemia is a single gene disorder affecting hemoglobin synthesis. It has been reported worldwide with a high incidence in countries of the Mediterranean basin, the Middle East and South Asia. In Tunisia (North Africa) a 5% frequency of b-globin morbid alleles is observed and the population is higly inbred with a consanguinity rate of 20%. The mutations producing b-Thalassemia in 45 Tunisian patients were investigated by 6 six different techniques (DGGE, PCR/ASOlabelled with P32, PCR/ASO labelled with digoxigenine, RG/PCR, PCR/Restriction analysis and direct sequencing of PCR generated b-globin specific DNA fragments). These techniques were compared and DNA sequencing was found to be the most appropriate for typing b-thalassemic patients. The spectrum of mutation uncovered was very heterogeneous as 13 different mutations were observed. 33.7% of the b-thalassemic alleles were identified as codon 39 (C to T) and 6.7% as IVS1-110 (G to A) while several mutations which had not previously been reported in the Tunisian population were observed with various incidence (4.5% for IVS1-nt 5 (G/C) frequent in population of South East Asia and 2.3% for IVS 2-nt 848 (A/C), reported almost exclusively in the Afro-American groups). Considering the six other mutations previously reported in the Tunisian patients with b-thalassemia, the total of mutations observed in this population raised to 20. The heterogeneity of the spectrum of mutations contrasts with the high inbreeding of this population. The extent of this heterogeneity could be explained either by the well documented passage of different populations over the centuries in this part of the world (Berbers, Punics, Romans,Vandals, Arabs, Black Africans, Turkish, Spanish and French) or by a high propension of the b-globin gene to spontaneously mutate or a combination of both phenomena.

Program Nr: 1113 from the 1999 ASHG Annual Meeting

A Genome-Wide Linkage Analysis in Hypertensive African American and White Siblings for Loci that Influence Variation in Pulse Pressure: The HyperGEN Network of the Family Blood Pressure Program. *K.A. Fisher[1], D.K. Arnett[1], L. Atwood[1], S. Hunt[2], H. Coon[2], M. Province[3], D.C. Rao[3], R. Myers[4], A. Oberman[5], C.E. Lewis[5].* 1) Division of Epidemiology, University of Minnesota, Minneapolis, MN; 2) Cardiovascular Genetics, University of Utah, Salt Lake City, UT; 3) Division of Biostatistics, Washington University Medical School, St. Louis, MO; 4) Boston University School of Medicine, Boston, MA; 5) Division of Preventive Medicine, University of Alabama, Birmingham, AL.

Pulse pressure (PP), an indicator of large arterial stiffness, is considered an important marker of cardiovascular health. A previously published segregation analysis indicated the presence of a major gene that influenced variability in PP in humans. Variants in the angiotensin-1 receptor gene are also reportedly associated with PP; however, limited information is available regarding whether there are genomic regions which harbor a major gene influencing PP. As part of the Hypertension Genetic Epidemiology Network, African American (AA) and white hypertensive siblings were recruited from five field centers. The mean age of the siblings was 52 in AA and 60 in whites. All were diagnosed with hypertension before the age of 60. Six seated blood pressure measurements were taken using an oscillometric method (Dinamap), and the last 5 of 6 measures were used in analysis. To reduce variability in PP (the difference between systolic and diastolic BP) contributed by non-genetic sources of variation, PP was adjusted for height, age, and physical activity. Sex-specific standardized residuals were created separately for each race group. The genome scan consisted of a 10 cM marker map (CHLC8) with 385 polymorphic, anonymous microsatellite marker loci. A multipoint linkage analysis was performed on 221 AA and 291 white sibpairs using a Haseman-Elston QTL regression analysis (MAPMAKER/SIBS). Analyses were performed separately in AAs and Whites. There was no evidence for linkage of any marker with PP. The highest lod score observed was on chromosome 19 (LOD=1.2) in AA. In this study population, little evidence was found for a genomic region with sufficiently large effect on PP.

Program Nr: 1114 from the 1999 ASHG Annual Meeting

MtDNA variation in Central Indian populations. *P. Fisher[1], K. Das[2], M.K. Das[2], P.A. Reddy[3], P.H. Reddy[3], S.S. Mastana[1]*. 1) Human Sciences Department , Loughborough University, Loughborough, Leics, UK; 2) Anthropometry and Human Genetics Unit, ISI, Calcutta, India; 3) NHGRI, NIH, Bethesda, MD, USA.

Indian population is genetically, geographically and socio-culturally very diverse. The patterns of present day genetic diversity in India offer important clues to the evolutionary history of human populations. Caste structure has played an important role in shaping up the observed genetic variation. Therefore it is challenging to analyse and document patterns of genetic diversity. We have surveyed mtDNA sequence variation among Eight Central Indian caste and tribal populations using PCR amplification and sequencing of HVR1 region. Estimates of mtDNA sequence diversity ranged from 0.004 to 0.028 and G_{ST} estimates among castes groups were lower than tribal populations. Comparisons are made with mtDNA haplotypes from Caucasian, Asian, African and other Indian populations to assess relative position of these populations.

Program Nr: 1115 from the 1999 ASHG Annual Meeting

Linkage Disequilibrium study on Nonsyndromic Cleft Lip/Palate on three racial heterogeneous populations from Colombia. *I. Fonseca[1], T. Restrepo[1], N. Rojas[2], A. Mario[2], C. Isaza[3], M. Arcos-Burgos[1]*. 1) Biology, Universidad de Antioquia, Medelln, Colombia; 2) Smile operation, Colombia; 3) Universidad del Valle, Cali, Colombia.

In order to compare racial effects on predisposition to develop Nonsyndromic Cleft Lip/Palate (CLP), we have ascertained pedigrees and cases and controls from three different regions from Colombia, Antioquia (100 families), Cundinamarca (170 cases) and Valle (119 cases) characterized by its different racial components, Caucasoid, Amerindian and Negroid, respectively. In all of them could be determined, by using the unified model of complex segregation, that only a major gene was able to explain the predisposition to CLP. Preliminary linkage disequilibrium analysis by using the exact test Linkage disequilibrium analysis on 6p21.3-21.5 with the microsatellite markers D6S272, D6S1019, D6S1006, D6S1959 shows that strong Hardy-Weinberg disequilibrium is observed only at the marker D6S1959 ($p<0.0001$) due to an increasing number of the heterozigotes ($f=0.44$). In other studies, the genomic region surrounding this marker has shown linkage to CLP. We think that increasing the resolution of this area mapping by using admixture linkage disequilibrium (MALD) could be performed.

Program Nr: 1116 from the 1999 ASHG Annual Meeting

A novel founder mutation in variegate porphyria patients from Chile and its future implications. *J. Frank[1,4], V.M. Aita[2], W. Ahmad[1], H. Lam[1], C. Wolff[3], A.M. Christiano[1,2].* 1) Dept. of Dermatology, Columbia University, New York, NY; 2) Dept. of Genetics and Development, Columbia University, New York, NY; 3) Dept. of Medicine, University of Chile, Santiago, Chile; 4) Dept. of Dermatology, University Clinic of the RWTH Aachen, Aachen, Germany.

Variegate porphyria (VP) (OMIM 176200) results from a partial deficiency in the activity of protoporphyrinogen oxidase (PPO), the penultimate enzyme of the porphyrin-heme biosynthetic pathway. The disease is usually inherited in an autosomal dominant fashion with incomplete penetrance. Clinically, VP is characterized by cutaneous symptoms on the sun exposed areas of the skin and by acute neurovisceral attacks which can lead to coma and death. In an effort to characterize the molecular basis of VP in South America, we studied 8 of 21 reported VP families from Chile by PCR, heteroduplex analysis, automated sequencing, restriction enzyme digestion and haplotyping analysis. We detected 3 different mutations, 1239delTACAC, R168H, and 1330delT. Interestingly, 1239delTACAC, which results in a frameshift and a downstream premature termination codon, was found in patients from 4 unrelated families, living in different parts of Chile. Therefore, we performed haplotype analysis using 15 microsatellite markers which closely flank the PPO gene on chromosome 1q22, in the order ptel-D1S196-ATA38A05-D1S426-D1S1677-D1S104-D1S1679-D1S2705- D1S484-D1S2707-D1S398-D1S1653-D1S1600-D1S1595-D1S303-D1S2140-pcen. This interval spans approximately 21 cM on the Genethon linkage panel, indicating that these 15 markers and the PPO gene are tightly linked. Haplotype analysis revealed the occurrence of 1239delTACAC on the same chromosome 1 haplotype in 11 mutation carriers from 4 unrelated families with VP, consistent with 1239delTACAC representing a founder mutation for VP. These findings comprise the first genetic studies of the porphyrias in South America, and will streamline and facilitate the elucidation of the molecular basis of VP in Chile as well as in its neighboring countries Argentina, Peru and Bolivia by first screening for the mutation 1239delTACAC.

Program Nr: 1117 from the 1999 ASHG Annual Meeting

Molecular reconstruction of the genealogy of the isolated population of the Costa Rican Central Valley. *N.B. Freimer[1], R. Ophoff[1], D. Meshi[1], W. Poon[1], P. Oefner[2], S. Service[1]*. 1) Dept Psychiatry, LPPI, Univ California, San Francisco, CA; 2) Department of Biochemistry, Stanford University, Palo Alto, CA.

The potential value of homogenous isolated populations in genetic mapping studies is increasingly clear. However, genetic evidence supporting the homogeneity of particular isolates is usually lacking. The development of population-specific Y-chromosome polymorphisms provides an important tool for reconstructing the genealogy of a population at the molecular level. We are using the isolated population of the Costa Rican Central Velley for several mapping studies of complex traits, such as severe bipolar mood disorder. It is thought that this population is mainly descended from the admixture between approximately 80 Spanish settles and a small group of indigenous Amerindians, primarily in the 17th and 18th centuries. This admixture was followed by substantial population growth in isolation, with minimal new immigration. To study the molecular genealogy of this population we genotyped individuals (bipolar patients and controls) sampled from the Central Valley at an Amerindian-specific SNP (DYS199) and 10 microsatellite markers located in the non-recombining regions of the Y chromosome. Testing mitochondrial polymorphisms in these individuals completed the molecular genealogical study. We will compare the molecular homogeneity in patients versus controls and discuss the implications for association studies in isolated populations.

Program Nr: 1118 from the 1999 ASHG Annual Meeting

Longevity in Iceland: Fertility and Genetics. *M.L. Frigge[1], D.F. Gudbjartsson[1,2], H. Gudmundsson[1], K. Stefánsson[1].* 1) deCODE genetics, INC., Reykjavík, Iceland; 2) Institute of Statistics and Decision Sciences, Duke University, Durham, NC.

An article recently appeared (Westendorp and Kirkwood, Nature, 1998) in which the authors analyzed the relationship between longevity and reproductive success in the British aristocracy during the period from 740 to 1875 AD. They report that in that population longer lived women both have fewer children and start having children later than women who die younger. They suggest that this provides evidence for the first time in a human population that there is a trade-off between reproduction and the somatic maintenance needed for longevity. Numerous newspaper articles have interpreted this as suggesting that if women want to live longer they should hold off having children. Having access to a unique genealogical database of all Icelanders from the present back to the founding of the country in 870 AD, there was interest in determining whether the pattern observed for a small number of British aristocracy would hold up for the entire modern population history of Iceland -- about 750,000 persons, of which 275,000 are currently alive. Iceland is an ideal population for this study since the population is quite homogeneous with respect to many conditions which might otherwise confound such a study of longevity in other European populations during this time period. Here evidence is reported that Icelandic women who live longer do not have fewer children on average than those who die younger. Nor do longer lived Icelandic women begin having children later in life. Similar results are presented for Icelandic men. The genealogical database also provides a singular opportunity to investigate the familial clustering of longevity in an entire human population, and thus to assess the genetic component of longevity in Iceland. Traditional measures of relatedness, such as recurrence risk (1.8 for sibs, 1.3 for cousins) are presented along with some new measures designed to take advantage of the whole population genealogy.

Program Nr: 1119 from the 1999 ASHG Annual Meeting

Rheumatoid Arthritis Severity and Dosage of the Shared Epitope: Results of a Meta-Analysis. *J.D. Gorman[1], J.J. Chen[2], G. Thomson[3], M.E. Suarez-Almazor[4], L.A. Criswell[1]*. 1) Division of Rheumatology, University of California, SF; 2) School of Public Health, Saint Louis University, St. Louis, MO; 3) Department of Integrative Biology, University of California, Berkeley, CA; 4) Department of Public Health Services, University of Alberta, Edmonton, AB, CANADA.

Objective:To evaluate by meta-analysis the risk of severe RA in relation to dosage of the HLA-DRb1 shared epitope (SE). **Methods**: A MEDLINE search and hand searches of 6 journals were conducted for studies with molecular typing and 1 or more of 6 desired outcomes. Authors were contacted for incomplete data, and all were asked for original data sets, with covariate information. Woolf's weighted ORs were pooled across studies and tested for homogeneity. When possible, ethnic and clinical subgroup analyses were performed. **Results**: 41 studies met inclusion criteria (5433 patients, 17 countries, 5 continents). ORs for the association of 1 SE copy (OR1) and 2 SE copies (OR2) with each outcome are shown below (*reference group=0 SE alleles). A strong dosage effect of the SE was apparent only for joint surgery [OR for 2 vs.1 SE copies=2.1 (1.3-3.4)]. Breslow-Day homogenity tests indicated substantial heterogeneity across studies for all outcomes except surgery, partly explained by ethnic variation.

	RF+	RA Course	Erosions	Surgery	Nodules	Other EAMs
OR1*/95%CI	1.8/1.4-2.4	1.5/1.0-2.2	1.8/1.4-2.2	1.8/1.0-3.3	1.5/1.2-2.0	1.2/0.8-1.8
OR2*/95%CI	2.6/1.8-3.8	1.7/1.0-2.8	2.2/1.6-2.9	3.7/1.9-7.4	1.7/1.3-2.3	1.8/1.1-2.8

Conclusions: Results of this meta-analysis demonstrate a dose-dependent increased risk for surgery. Although this was not observed for other outcomes, caution should be exercised given their heterogeneity. Further identification of important sources of heterogeneity will require thorough examination of covariate effects.

Program Nr: 1120 from the 1999 ASHG Annual Meeting

The inheritance of Rheumatoid Arthritis in Iceland. *S.F.A. Grant[1], M. Frigge[1], J. Thorsteinsson[2], B. Gunnlaugsdottir[2], A. Geirsson[2], A. Vikingsson[2], K. Erlendsson[1], D. Oskarsson[1], A. Kong[1], J. Gulcher[1], K. Stefansson[1], K. Steinsson[2]*. 1) Decode Genetics, Reykjavik, Iceland; 2) Dept of Rheumatology and Center for Rheumatology Research, National Hospital, Reykjavik, Iceland.

Rheumatoid Arthritis (RA) is the commonest form of inflammatory arthritis, affecting approximately 1% of the world's population. Although there is a large body of evidence showing that RA is immune mediated, the etiology remains unresolved. From animal models, a genetic component is believed to influence the onset and severity of the disease. In humans it has long been suggested that variation in genes encoded in the HLA region accounts for approximately one third of the genetic component in RA, with other studies suggesting that additional loci contribute to the disorder. Twin studies have shown a concordance rate between 15 and 30% whilst the prevalence ratio for siblings of RA patients is approximately 5. However, these findings should be regarded with caution as studies in small proportions of a heterogeneous population are susceptible to sampling error and selection bias.

We have developed a population-based computerized genealogy database to examine multigenerational relationships amongst individuals in the homogeneous population of Iceland. Using an algorithm, the Minimum Founder Test (MFT), the least number of founders accounting for our RA patient list was compared with 500 sets of same sized control groups. A significantly fewer number of founders are necessary to account for our patient list than for the random sets of matched controls ($p<10^{-8}$) where average pair-wise IBD sharing for patients is greater than 6 standard deviations higher. In addition, the general risk of developing RA is 1.07% and the recurrence risk for siblings is ls = 4.41.

This data confirms that there is a significant genetic component to RA.

Program Nr: 1121 from the 1999 ASHG Annual Meeting

Head injury, APOE genotype, and familial risk of Alzheimer disease. *Z. Guo[1], L.A. Cupples[1], J.L. Haines[2], L.A. Farrer[1], for the MIRAGE Study[1]*. 1) Boston University School of Medicine, Boston, MA; 2) Vanderbilt University School of Medicine, Nashville, TN.

Some studies have suggested that head injury is a risk factor for Alzheimer disease (AD), and that this risk is heightened among carriers of the apolipoprotein E (APOE) e4 allele. We examined the effects of head injury and APOE genotype on AD risk in a large family study. A total of 2,233 probands who met criteria for probable or definite AD and their 14,668 family members (4,465 parents, 7,694 siblings, and 2,509 spouses) were ascertained at 13 centers in the U.S., Canada and Germany. Conditional logistic regression comparing probands with their unaffected spouses yielded odds ratios for AD of 9.9 (95% CI = 6.5-15.1) for head injury with loss of consciousness and 3.1 (2.3-4.0) for head injury without loss of consciousness. Survival analysis showed that at age 93 years the cumulative risk of AD among parents and siblings was 77±7% for those with head injury and 34±1% for those without head injury. Similar patterns were observed in spouses, although the total risk was low. Among parents and siblings, the relative risk of AD was 4.0 (2.9-5.5) for head injury with loss of consciousness and 2.0 (1.5-2.7) for head injury without loss of consciousness. Among spouses, the relative risk of AD was 6.1 (2.6-13.9) for head injury with loss of consciousness and 1.3 (0.4-4.1) for head injury without loss of consciousness. The joint effects of head injury and APOE genotype were evaluated in a sub-sample of 942 probands and 327 controls (spouses and siblings). Among e4 homozygotes, the odds of AD was 10.3 (1.6-65.3) for those with head injury and 7.9 (4.3-14.3) for those without head injury, compared to those lacking both factors. Among e4 heterozygotes, the odds of AD was 5.7 (3.1-10.5) for those with head injury and 3.1 (2.1-4.7) for those without head injury. Head injury in the absence of e4 increased AD risk 3.3 times (2.0-5.5). We conclude that head injury is a risk factor for AD independent of APOE e4. Although there is no significant interaction between head injury and a family history, the lifetime risk of AD is extremely high among first-degree relatives with a prior head injury.

Program Nr: 1122 from the 1999 ASHG Annual Meeting

High prevalence of complement C7 deficiency among healthy blood donors of Morrocon Jewish ancestry. *D. Halle[1], A. Sasson[1], D. Elstein[1], M. Schlesinger[2], A. Zimran[1]*. 1) Shaare Zedek Medical Center , Jerusalem, Israel; 2) Barzilai Medical Center, Ashkelon, Israel.

It is well recognized that the cytolytic acticity of the complement system is critical for resistance to Neisseria meningitidis. More than a decade ago we initiated a study to assess the prevalence of terminal complement deficiencies among survivors of sporadic meningococcal disease in Israel (QJM, 240:349-358, 1987). We uncovered an unexpectedly high prevalence of C7 and C8 deficiency among subjects of Moroccan Jewish ancestry, but not a single case among the subjects of Ashkenazi Jewish ancestry although the latter represents the largest ethnic group both in Israel and hence, in our series. Cloning of the complement component genes in recent years, has led to identification of the mutation in the Moroccan population, initially via RFLP and then via sequencing, which is G357R. In the current study, PSM-PCR site-directed mutagenesis was used in conjunction with designer primers in order to locate the mutation specific to our Moroccan population. We describe a new method using the restriction enzyme Mlu 1 to cut the mutant allele and Dde 1 to cut the normal allele. The advantages of this protocol include simplicity of design, completion within hours, accuracy, and it is inexpensive. In all, 284 healthy subjects (568 alleles) who were of Moroccan ancestry on both sides were screened. Five heterozygotes were uncovered, giving an allele frequency of approximately 0.9% in this ethnic group. Although there have been a few studies which suggest beneficial effects of terminal complement deficiencies (e.g. protection against autoimmune diseases, multiple sclerosis), these theories have not been extrapolated to Jewish populations. With the availability of this method, larger screens may be attempted and the issues of gene frequency and selective advantage addressed.

Program Nr: 1123 from the 1999 ASHG Annual Meeting

Familialty of quantitative traits derived during an oral glucose tolerance test in normoglycaemic relatives of one type 2 diabetic parent. *T. Hansen[1], C. Ekstroem[1], S.A. Urhammer[1], H. Eiberg[2], J.J. Holst[2], O. Pedersen[1]*. 1) Steno Diabetes Center, Gentofte, Denmark; 2) University of Copenhagen, Denmark.

The present study was undertaken in order to describe the familiality of quantitative traits which could be obtained during an oral glucose tolerance test (OGTT). Sixty families containing 224 offspring and 32 spouses of type 2 diabetic parents were examined by a 4 hour 75g OGTT. Plasma glucose, s-insulin, s-C-peptide levels were analysed at 18 time points, and p-GIP (glucose dependent insulinotropic polypeptide) and p-GLP-1 (glucagon like peptide 1) were analysed at 12 time points during the OGTT. Familiality (h2) of the examined traits was estimated as the ratio of the additive genetic variance to the total phenotypic variance using a variance component model and adjusting for body mass index, age and gender. Familiality of each trait was examined 1) in the fasting state, 2) as incremental area under the curve (AUC) from 0-120 min and from 0-240 min 3) and as the highest h2 obtained for a single time point.

h2 (SE)	Glucose	Insulin	C-peptide	GIP	GLP-1
Fasting	0.71 (0.15)	0.35 (0.22)	0.56 (0.15)	0.67 (0.21)	0.91 (0.32)
AUC 0-120	0.39 (0.24)	0.19 (0.25)	0.54 (0.22)	0.28 (0.22)	0.75 (0.23)
AUC 0-240	0.40 (0.24)	0.21 (0.25)	0.54 (0.22)	0.24 (0.22)	0.77 (0.15)
Peak	0.56 (0.24)	0.46 (0.24)	0.47 (0.23)	0.46 (0.25)	0.57 (0.15)
	(140 min)	(10 min)	(160 min)	(90 min)	(90 min)

In conclusion, several quantitative traits obtained during an OGTT are highly familial, and will be used to search for prediabetic quantitative trait loci.

Program Nr: 1124 from the 1999 ASHG Annual Meeting

Characterization of b**-thalassemia mutations in Armenia.** *K. Harutyunyan[1], V. Surin[2], H. Youssoufian[3], V.M. Der Kaloustian[4]*. 1) Institute of Molecular Biology, National Academy of Sciences, Yerevan, Armenia; 2) Center of Hematology, Academy of Medical Sciences, Moscow, Russia; 3) Departments of Molecular and Human Genetics and Medicine, Baylor College of Medicine, Houston, Texas, U.S.A; 4) Departments of Pediatrics and Human Genetics, McGill University, Montreal, Quebec, Canada.

Armenia is one of the countries of the former Soviet Union situated in the region of the Caucasus. Its population is around 3.5 million, composed more than 95% of Armenians, but also of Yezidis, Kurds and Russians. Armenians are recognized as a separate ethnic group since 750 B.C.

To-date, 12 families with members suffering from b-thalassemia (b° and b^+ forms) have been registered in the country. We have performed mutation analysis by direct sequencing of the PCR fragments of the b-globin genes of two unrelated Armenian patients. Three mutations were identified. CD15 (TGG-TAG),IVS1,nt(T-C), and CD8(-AA). The haplotype of these patients have been determined. The population studies for the gene frequency of b-thalassemia in Armenia, as well as the characterization of the mutations in the other known patients are in progress. Although these mutations have been previously found in patients with other ethnic backgrounds, we are reporting them for the first time in Armenians. (This work was supported in part by a grant from the Armenian branch of the Open Society Institute).

Program Nr: 1125 from the 1999 ASHG Annual Meeting

Prevalence of Factor V Leiden Mutation in Greek Patients with Homozygous Sickle Cell Anemia or Double Heterozygous Sickle Cell/ Thalassemia. *T. Hatzis[1], K. Makatsoris[2,3], M. Drosou[5], C. Pantos[3], V. Malliopoulou[3], T. Antoniadi[2], M. Gavalaki[4], E. Economou-Petersen[4], M.B. Petersen[2], H. Karageorgiou[3].* 1) Haematology, "Mitera" Maternity Hospital, Athens, Attica, Greece,; 2) Department of Genetics and Molecular Biology, "Mitera" Maternity and Surgical Center, Athens, Greece; 3) Department of Pharmacology, University of Athens Medical School; 4) Thalassemia Treatment Unit, Drakopoulion Blood Bank Center; 5) Thalassemia Treatment Unit, Piraeus General Hospital, Athens, Greeceâ.

In Caucasians the G1691A mutation of the factor V gene (FV Leiden) creates increased risk for thromboembolism. Homozygous Sickle Cell Anemia (S/S) or double heterozygous Sickle Cell/ Thalassemia (S/thal) patients suffer frequent and recurrent thromboembolic events, whose cause has not yet been identified as a single risk factor. The aim of this study was to estimate the FV Leiden prevalence in Greek patients with homozygous Sickle Cell Anemia or double heterozygous Sickle Cell/ Thalassemia. Results on a population of 29 patients are shown here and are compared with the results of a study among healthy Greek blood donors, as previously determined: 29 patients with (S/S) or (S/thal):allele frequency 10.3%, carrier rate 17.1%. 160 healthy Greek blood donors: allele frequency 2.5%, carrier rate 5%. Conclusions: although the population studied is small, these results indicate a contradiction to previous similar studies in other populations, that have shown smaller carrier rates among S/S and S/thal patients and suggested an obvious beneficial advantage when this thrombogenic mutation is absent in people who have many other survival risks since birth.

Program Nr: 1126 from the 1999 ASHG Annual Meeting

Concordance in geographic patterning of ancient and modern Amerindian mtDNA variation. *M.G. Hayes, S.W. Carlyle, D.H. O'Rourke.* Department of Anthropology, University of Utah, Salt Lake City, UT.

We report original research on ancient DNA variation in three geographic regions, the North American Arctic, the eastern Great Basin, and the US Southwest, as well as published data on aDNA variation in the western Great Basin (Kaestle 1998) and the US Midwest (Stone and Stoneking 1998). Comparisons of these ancient samples to contemporary American Indian populations inhabiting the same geographic locales demonstrates concordance in the geographic patterns of variability over time. At least in North America, the observed mtDNA geographic patterns are of considerable antiquity and have been stable for at least the past two to four millenia. The aDNA data from this diverse collection of archaeological samples indicate that all major mtDNA lineages characterizing modern Amerindian populations were present prehistorically. These results are most obvious in examination of mtDNA haplogroup frequencies based on RSP and length polymorphisms, but are also consistent with the limited sequence data available from ancient samples. While fewer ancient South American samples have been molecularly characterized, the correspondence between ancient populations and contemporary groups appears to hold. These results indicate that 1) early colonists to the Americas possessed considerable mtDNA diversity, weakening claims for a reduction in Amerindian molecular variation as a result of a founding bottleneck; 2) population substructure in Amerinds is of considerable antiquity and has been relatively stable for long periods of time; and 3) regional patterns of molecular variability were essentially unaffected by population declines at contact or later non-Amerindian admixture. This work was supported by grants from the Physical Anthropology, Archaeology, and Arctic Social Science programs of the National Science Foundation, the Wenner-Gren Foundation for Anthropological Research, and the University of Utah.

Program Nr: 1127 from the 1999 ASHG Annual Meeting

Common paraoxonase gene variants, mortality risk and fatal cardiovascular events in elderly subjects. *B.T. Heijmans[1,2], R.G.J. Westendorp[2], C. Kluft[1], A.M. Lagaay[2], D.L. Knook[1,2], P.E. Slagboom[1].* 1) Gaubius Laboratory, TNO Prevention and Health, Leiden, The Netherlands; 2) Section of Gerontology and Geriatrics, Department of General Internal Medicine, Leiden University Medical Center, Leiden, The Netherlands.

The enzyme paraoxonase may be an important modulator of cardiovascular disease risk because of its ability to protect LDL from oxidation. We examined whether two functional variants of the paraoxonase gene (Met-55/Leu and Gln-192/Arg) were associated with all-cause mortality and fatal cardiovascular events. This was done within a population-based study among subjects aged 85 years and over in a cross-sectional and a prospective design.

In the cross-sectional analysis the distribution of both paraoxonase genotypes was similar in the subset of 364 elderly subjects who were born in Leiden, The Netherlands, as compared to 250 young subjects whose families originated from the same geographical region. The polymorphisms were in linkage disequilibrium ($P<0.00001$). The rare Arg-allele almost always occurred in combination with the frequent Leu-allele, which gives rise to a common haplotype carrying both putative risk-alleles. The frequency of this haplotype was similar in elderly and young subjects (0.313 versus 0.284, respectively).

The complete cohort of 666 elderly subjects was followed over 10 years. The risk of all-cause and cardiovascular mortality were not increased in elderly subjects with the paraoxonase Leu/Leu (RR, 1.1 [95% CI, 0.9-1.5] and 1.3 [95% CI, 0.8-2.0], respectively) or the Arg/Arg genotype (RR, 0.9 [95% CI, 0.7-1.2] and 0.7 [95% CI, 0.4-1.3], respectively). In a subset of patients with diabetes, the all-cause mortality risk was nonsignificantly increased in Arg/Arg carriers.

Paraoxonase gene variants, previously associated with coronary artery disease, are not likely to have a major effect on the risk of fatal cardiovascular disease in the population at large. Adverse effects of the gene variants might be observed in subjects exposed to factors that enhance oxidative stress such as diabetes.

Program Nr: 1128 from the 1999 ASHG Annual Meeting

Familial clustering of myocardial infarction in the Icelandic population: Evidence for genetic components. *A. Helgadottir[1], H. Petursson[1], A. Kong[1,2], J. Gulcher[1], M. Frigge[1], V. Gudnason[3], K. Stefansson[1].* 1) deCODE Genetics Inc, Reykjavik, Iceland; 2) Departments of Human Genetics and Statistics, University of Chicago; 3) Icelandic Heart Association Heart Preventive Clinic, Reykjavik, Iceland.

Many studies have shown that coronary heart disease and myocardial infarction (MI) aggregate within families. All of them have included relatively small proportions of populations. This is a population-based study which determines the significance of familial clustering among Icelandic MI patients. We took advantage of our population-based genealogical database, to study how 6860 MI patients cluster into families. Data regarding the study group were collected between 1981 and 1995, from all MI sufferers in Iceland, by the Icelandic Heart Association as part of the World Health Organization MONICA Project. Control groups were created from the genealogy database in such a way that every person in the study group corresponded to one person in the control group, born in the same year. We have developed a tool called the Minimum Founder Test which compares minimum number of ancestors required to account for the group of patients with the minimum number of ancestors required to account for the control groups, at different timepoints in the past. Going back to the years between 1800 and 1900 the minimum number of founders representing the group of patients were significantly fewer than those representing the control groups. The kinship coefficient for the myocardial infarction patients was 1.7 10-4 compared to an average kinship coefficient, for 500 control groups (each consisting of 7466 individuals), of 1.6 10-4 (SD: 2.4 10-6). The relative risk for first-, second-, and third degree relatives were 1.4, 1.2 and 1.1, respectively. The risk of early onset MI for siblings and first cousins of patients with early-onset MI were 3.5 and 1.7, respectively. This study is the first population-based study using an extensive genealogy database examining the genetic contribution to MI. Our study encourages the search for genes responsible for increased susceptibility to MI in the Icelandic population.

Program Nr: 1129 from the 1999 ASHG Annual Meeting

The relationship of Lp(a) levels with coronary artery disease is genotype dependent for three apo(a) gene polymorphisms in Asian Indians in Singapore. *C.K. Heng[1], W.F.K Ho[1], N. Saha[2], M.C. Tong[3], Y.S. Tan[3], M.I. Kamboh[2]*. 1) Dept Pediatrics, National Univ Singapore, Singapore, Singapore; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, U.S.A; 3) Singapore Heart Centre, Singapore General Hospital, Singapore,Singapore,Singapore.

In this study, we genotyped the pentanucleotide (TTTTA), +93 and kringle-4 (K4) sites of the apo(a) gene in Asian Indians residing in Singapore. The study subjects consisted of 226 angiographically confirmed CAD patients and 161 healthy age-matched controls. We used the logistic regression model with genotype data and Lp(a) as predictors and CAD status (with or without the disease) as the dependent variable. Probability curves for CAD occurrence was plotted against Lp(a) concentrations. Characteristic sigmoid curves associated with each genotype were obtained. The predicted probabilities of CAD susceptibility for two groups of K4 pooled genotypes were similar at Lp(a) concentration of < 1mg/dl but those with >24 repeats had their probabilities increased at a higher rate than those with <24 repeats, along with increasing Lp(a) level. For TTTTA, the probability curves criss-crossed at 13mg/dl for the 2 pooled genotypes. Below 13 mg/dl, the risk of CAD was higher for those with <8 repeats and vice versa beyond 13 mg/dl. The +93 genotypes showed a very distinctive trend with the *CT/TT* individuals at higher risk of CAD compared to the common *CC* genotype across the whole range of Lp(a) levels. Our findings underscored the complex web of relationships between risk factors and genetic variations when used to predict CAD risk. Current analytical methods could only demonstrate such complex relationships crudely by means of separate CAD probability plots of each genotype and its associated intermediate trait. The overall CAD risk as a function of the relationships between many predictive genes and intermediate traits could not be elucidated with such simplistic representations. Insightful revelations would be obtained only when more advanced models that could integrate all the relevant predictors are developed.

Program Nr: 1130 from the 1999 ASHG Annual Meeting

Global correlations between gene frequencies and disease rates. *S.R. Hirth[1], N.J. Schork[1,2,3,4,5]*. 1) Epidemiology and Biostatistics, Case Western Reserve U., Cleveland, OH; 2) Program for Population Genetics, Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) The Jackson Laboratory, Bar Harbor, ME; 4) The Genset Corporation, La Jolla, CA; 5) Genset, SA, Paris, France.

Ecological studies assessing the relationship between environmental factors and disease frequencies across populations have been a popular and useful way of investigating initial hypotheses about the etiology of several common disorders. In recent years, population genetics studies have also been carried out for many of these same global populations, providing the opportunity to link gene frequencies to such ecological studies. We have searched publicly available databases for situations where all three types of information are available for the same population. For such cases, we then combined population gene frequencies for several commonly typed polymorphisms with the available data on disease rates and environmental exposures, by population, to investigate possible correlations. We present results for several common disorders for which information is available, including the correlation between HLA gene frequencies and tuberculosis across global populations. Further, we describe how studies such as these can be a valuable source of information regarding the design and conduct of public health initiatives and research programs.

Program Nr: 1131 from the 1999 ASHG Annual Meeting

A measure of ambiguity in SNPs in presence of linkage disequilibrium. *S.E. Hodge, J. Hoh.* Columbia Univ, New York, NY.

The extent of haplotype ambiguity in a string of single nucleotide polymorphisms (SNPs) was quantified by Hodge et al. (Nat Genet 21: 360, 1999). In their measure, the level of ambiguity increases with increasing numbers of loci and as loci become more polymorphic. That work assumed linkage equilibrium (LE). However, linkage disequilibrium (LD) provides additional information about the haplotypes at a site, thereby diluting the level of ambiguity. The ambiguity vanishes altogether when LD reaches its maximum value. Here, we extend the ambiguity measure (f) to allow for LD between each successive pair of SNPs. We derive the formula f= 4yz, where x, y, z, and w are the frequencies of the ++, +-, -+, and -- haplotypes, respectively, and w.l.o.g. xw > yz. Alternatively, f can be expressed in terms of the allele frequencies and the LD parameter d. We also extend the formula to triads of two parents plus one child. In genome-wide LD studies to map common disease genes, a dense map of SNPs has been utilized to detect association between a marker and disease. Therefore, the measurement of ambiguity can help investigators to determine a more efficient map, designed to minimize ambiguity and subsequent information loss. We calculate our measure for relevant SNPs in the published LPL dataset (Clark et al., AJHG 63: 595, 1998; Nickerson et al., Nat Genet 19: 233, 1998), obtaining values ranging from a low of 0 to a high of 11%, in that particular dataset.

Program Nr: 1132 from the 1999 ASHG Annual Meeting

Lactase haplotype diversity in the Old World. *E.J. Hollox[1], M. Poulter[1], M. Zvarik[2], V. Ferak[2], A. Krause[3], T. Jenkins[3], N. Saha[4], A. Kozlov[5], D.M. Swallow[1].* 1) MRC Human Biochemical Genetics Unit, Galton Laboratory, University College London, London, UK; 2) Department of Molecular Biology, Comenius University, Bratislava, Slovakia; 3) Department of Human Genetics, University of the Witwatersrand, Johannesburg, Republic of South Africa; 4) Department of Human Genetics, University of Pittsburgh, USA; 5) ArctAn-C Innovative Research Laboratory, Moscow, Russia.

Lactase persistence is a genetic trait present at different frequencies in different populations: it is frequent in northern Europeans and certain African and Arabian nomadic tribes, groups that have a history of drinking fresh milk. Selection is likely to have had an important role in the establishment of these varying frequencies. We have previously shown that the lactase persistence/non-persistence polymorphism in humans is *cis*-acting to the lactase gene and that lactase persistence is associated, in Europeans, with the most common 70kb lactase haplotype, termed **A** (Harvey et al. Ann. Hum. Genet. 62,215-223 1998). We have studied polymorphisms in over 1000 chromosomes to examine 11-site haplotype frequencies in 11 populations that differ in lactase persistence frequency. Our data show that there are four common haplotypes (**A,B,C,U**) that are not closely related, having a minimum of three sites different from each other. These four haplotypes account for over 80% of all haplotypes in non-African populations, but only account for 48% of all haplotypes in sub-Saharan African populations. The **A** haplotype is shown to be at a much higher frequency in northern Europeans, where persistence is common, as compared to other populations where persistence is rare. The **U** haplotype has an unusual distribution, being common in East Asia and sub-Saharan African populations but only observed in two individuals from Indo-European populations. Analysis of 70kb haplotypes is small enough to observe linkage disequilibrium yet large enough to observe recombinational events. A model of the relationship between haplotypes suggests generation of diversity by point mutations and recombinations, probably including an ancient recombination within a region rich in repetitive elements.

Program Nr: 1133 from the 1999 ASHG Annual Meeting

Phylogenetic networks: search for traces of ancestral Australian/Papuan Y-pool on the Asian main land. *B. Horst[1], P. Forster[2], A. Eigel[3], B. Brinkmann[1]*. 1) Institut fuer Rechtsmedizin, Universitaet Muenster, Germany; 2) The McDonald Institute, University of Cambridge, United Kingdom; 3) Institut fuer Humangenetik, Universitaet Muenster, Germany.

Within recent years worldwide systematic genetic studies have been started to investigate the diversity of the human genome. Medical benefits could be obtained by the assessment of the prevalence and distribution of inherited deseases in the different populations of the world. Also understanding normal population variations is of great interest in regard to anthropological goals. Regarding migration of modern humans into Asia it is thought today that at least two independent migration waves took place. 50,000 to 70,000 years ago a southern wave brought people through Ethiopia along the southern coastal line to New Guinea and Australia. A second expansion started 50,000 years ago in nothern Africa to Central- and North-Asia, the Arctic and also America. Phylogenetic trees based on genetic distances have shown unstable clustering of Southeast Asian populations with New Guineans/Australians and other non-Africans. Short Tandem Repeat (STR) polymorphisms on the non-recombining part of the Y-chromosome are especially useful for the study of male specific lineage evolution because they are only influenced by mutation events and not by meiotic recombination. Because of the multitude of plausible trees it is often a challenging task to reconstruct phylogenies from human Y-chromosomal DNA variation. Networks are a new method to express a large number of trees by displaying alternative potential evolutionary paths. We constructed networks from population data of five Asian / Australian populations (Japanese, Han-Chinese, Thais, Papuans and Aboriginies) comparing two different network methods. All individuals were typed for the STR-loci DYS19, DXY156-Y, DYS389 (with its four subsegments), DYS390, DYS391, DYS392 and DYS393 on the Y-chromosome. In this context we were especially searching for traces of the ancestral Australian/Papuan Y-pool on the Asian mainland.

Program Nr: 1134 from the 1999 ASHG Annual Meeting

Secondary sex ratio in the offspring of Finnish retinoschisis carrier females. *L.L. Huopaniemi[1,2], J. Fellman[2], A. Rantala[1,2], A. Eriksson[2], H. Forsius[2], A. de la Chapelle[2,3], T. Alitalo[1,2,4].* 1) Dept of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) The Folkhalsan Institute of Genetics, Departments of Molecular Genetics and Population Genetics,Helsinki, Finland; 3) Comprehensive Cancer Center, Ohio State University, Ohio, USA; 4) Depts. of Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland.

X-linked retinoschisis (RS) is the most common cause of juvenile macular degeneration. The disease causes progressive impairment of vision with variable degrees of severity. The gene defective in retinoschisis, XLRS1, was recently cloned and more than 90 disease causing mutations have been identified. XLRS1 is believed to be expressed solely in the retina. Three founder mutations contribute to the high incidence of RS in Finland. Already in the 1960s it was noticed that the Finnish RS carriers tend to have more sons than daughters. In our present study, we have analyzed the carrier status for a single widespread founder mutation (214G>A) of 202 females, and compared the secondary sex ratio (SSR) in the offspring of the 149 carrier females with reported normal SSR values. Our statistical analysis suggests that the SSR in the children of RS carrier females (SSR 129.8) is significantly higher than in the normal Finnish population (SSR 106). In order to evaluate factors which might contribute to the skewed secondary sex ratio, we performed a RT-PCR assay to check the expression of XLRS1 in various pregnancy and reproduction related tissues. We found that XLRS1 is expressed in the uterus, but not in the other tissues studied. We hypothesize that the 214G>A mutation leads to sex-specific or sex-limited changes in embryonic implantation or survival.

Program Nr: 1135 from the 1999 ASHG Annual Meeting

Are the familial determinants of lipid levels the same in diabetic and non-diabetic individuals? *G. Imperatore, W.C. Knowler, J. Roumain, R.L. Hanson.* Diabetes Arthritis Epidemiolog, NIDDK/NIH, Phoenix, AZ.

Linkage analysis of quantitative traits related to cardiovascular diseases, such as serum total cholesterol (TC), serum total triglyceride (TG), and high density lipoprotein cholesterol (HDL) concentrations, may help to identify susceptibility loci for these complex disorders. Diabetes is highly prevalent in some populations and it is possible that different loci may be involved in diabetic and non-diabetic individuals. Therefore, we estimated the correlation between the familial determinants in diabetic and non-diabetic siblings for these quantitative traits in 1232 Pima Indian sibships.

The sibships included 1734 diabetic and 2256 non-diabetic persons aged at least 20 years. Covariance components methods were used to estimate, for each trait, the heritability (including genetic and familial environmental effects) within diabetic siblings, heritability within non-diabetic siblings, and the covariance (reflecting the correlation) between diabetic and non-diabetic siblings. These parameters were estimated for TC, TG, and HDL. Prior to analysis each trait was log-transformed and adjusted for age and sex, and, among diabetic individuals, for duration of diabetes.

For TC heritability was 48% within non-diabetic siblings and 31% in diabetic siblings. For TG heritability was 44% in non-diabetic siblings and 42% in diabetic siblings. For HDL heritability was 33% in non-diabetic siblings and 34% diabetic siblings. These traits were also significantly ($P < 0.0001$) correlated among siblings discordant for diabetes (heritabilities = 37%, 47%, and 45% for TC, TG, and HDL). These estimates imply that correlations between familial determinants in diabetic and non-diabetic siblings are > 0.96 for each trait.

Familial determinants of TC, TG, and HDL are largely the same in diabetic and non-diabetic individuals. Linkage analyses of these traits are justified in pooling diabetic and non-diabetic persons, after adjusting for diabetes.

Program Nr: 1136 from the 1999 ASHG Annual Meeting

Chinese surnames are polyphyletic in origin: Evidences based on 19 Y-SNPs. *L. Jin[1,2], B. Su[2], J. Xiao[1], J. Akey[2], D. Lu[1], D. Shen[2], R. Chakraborty[2], J. Tan[1]*. 1) Institute of Genetics, Fudan University, Shanghai, China; 2) Human Genetics Center, University of Texas - Houston, TX.

Analysis of surnames for genetic purposes has been suggested and widely used due to their nature of patrilineal transmission in most of the populations. Surnames appeared in China at least 3000 years earlier than in Europe or Japan and there are between three and four thousand surnames used by the Han Chinese. A genetic analysis of a general Han population of 1,500 male individuals born in 28 different Provinces across China has been conducted at 19 Y chromosome single nucleotide polymorphic markers (Y-SNPs). The results of this analysis demonstrate that large isonymous populations tend to have multiple distinct haplotypes, implying a polyphyletic origin. This observation is consistent with the historical records that in general, the larger an isonymous population is, the more origins that surname has. Therefore, it is not necessarily a valid approach to use the number of surnames to estimate the number of founders in a Chinese population (either isolated or panmictic) without a genetic study of Y chromosome markers.

Program Nr: 1137 from the 1999 ASHG Annual Meeting

The survival of persecuted Jews in Spain and Portugal in the 15th century led to endogamic preservation and emergence of an autosomal recessive retinitis pigmentosa mapped to chromosome 15q22. *J. Kaplan[1], S. Gerber[1], J.-M. Rozet[1], L. Santos[2], L. Lopes[2], O. Gribouval[1], I. Perrault[1], D. Ducroq[1], F. Ferraz[3], A. Munnich[1].* 1) Unité de Recherches sur les Handicaps Génétiques de l'Enfant, INSERM U393, Hôpital Necker, Paris, France; 2) Servico de Ophtalmologia, Hospital Dos Capuchos, Lisboa, Portugal; 3) Servico de Genetica, Hospital Dona Estefania, Lisboa, Portugal.

The last Marranos are the survivors of Spanish Jews persecuted in the late fifteenth century, escaped in Portugal and forced to convert to save their lives. Isolated groups still exist in mountainous areas such as Belmonte in the Beira Baixa province of Portugal. We report here the genetic study of a highly consanguineous endogamic population of Crypto Jews of Belmonte affected with autosomal recessive retinitis pigmentosa (RP). A large-scale linkage analysis was carried out in order to localize the disease-causing gene. All previously known autosomal recessive RP loci were first excluded in this population. Then, an exclusion map was performed using fluorescent oligonucleotides of the Genescan Linkage Mapping Set, version II (Perkin-Elmer) at an average distance of 10 cM throughout the genome. A total of 239 polymorphic markers were studied in this population and six markers were constantly found homozygous in nine affected individuals providing evidence of close proximity of these markers with respect of the disease locus on chromosome 15q22. No known RP gene has been mapped to this interval, but the gene encoding the retinal rod Na-Ca-K exchanger (SLC24A1) and mapping to the 15q22 region, was excluded. Subsequently, starting from flanking markers, a YAC contig covering the genetic interval was constructed. Interestingly, a gene which expression is highly restricted to the outer nuclear layer of retinal photoreceptor cells was found to map to one YAC of this contig. A search for mutations was undertaken allowing to ascribe the RP in this population to an homozygous mutation in this gene. Preliminary haplotype studies support the view that this mutation is relatively ancient and will provide help tracing the origin and migration of Sephardi Jews.

Program Nr: 1138 from the 1999 ASHG Annual Meeting

Mitochondrial DNA Haplotype Studies in Colombian Amerindian Populations show two Possible Migration Routes into South America. *G. Keyeux[1], C. Rodas[1], D. Carter[2], J.E. Bernal[1]*. 1) Inst de Genetica Humana, Univ Javeriana, Bogota, DC, Colombia; 2) Microbiology Dept, Univ of Sydney, Australia.

Mitochondrial DNA haplotype studies as well as D-loop sequencing have been useful in studying the origins of Native American populations. Four main haplotypes and possibly a fifth lineage are defined by a few restriction sites and deletion/insertion polymorphisms and a limited set of control region mutations. Haplotypes have been characterized in North-, Central- and South-American Amerindian, North American Nadene and Aleutian populations, and also Siberian, Central-Asian and South-East Asian populations in the hope of fully depict the route(s) of migration between Asia and America in the past 25.000 years. Very little of the South American settlement is known and Colombia, presumably an obligate turning-plate in the migrations between North- and South America, had not been studied yet. In an effort to remedy this, we have analyzed mitochondrial haplotypes in 25 different ethnic groups from all over Colombia. Our results indicate a varied distribution of the four founder A-D lineages in the different populations. Some private polymorphisms, and the presence of other lineages, some presumably corresponding to other Asian haplotypes, were also detected in a few populations. The distribution of A/D haplotype frequencies in our groups, which is inverted once the natural barrier of the Andes cordillera is reached, points to possibly two migrational waves into South America. These two migrational waves relate the Central American and North-west Colombian groups, on the one side of the Andes, and the Lowland-Amazonian and South American groups on the other side.

Program Nr: 1139 from the 1999 ASHG Annual Meeting

Assessment of Medical Insurance Benefit Data on Congenital Anomalies in Korea. *S-S. Kim[1], S-C. Jung[1], K-S. Yoon[2], H-J. Kim[3], M-J. Kwon[4], J-S. Lee[1,5]*. 1) Div. of Genetic Diseases, National Institute of Health, Korea; 2) Eulji Medical Coll., Korea; 3) Ajou Univ. Coll. of Medicine, Korea; 4) Sungnam Inha Hosp., Inha Univ., Korea; 5) Yonsei Univ. Coll. of Medicine, Korea.

To access the accuracy of Medical Insurance Treatment Data(MITD) as a source to estimate prevalence of congenital anomalies, the correspondence of ICD 10 disease codes in MITD was evaluated through case by case comparison of medical records from 3 university hospitals(n=3,528). Medical Insurance encompassed 97.9% of total Korean population in 1996 and 53,102 children under 4 years old took medical examination with complaints of congenital anomalies. The correspondences of MITD with medical records were 92.1% for in-patients and 56.6% for out-patients with ICD 10 three character disease categories. Medical records for some patients could not be reviewed because there were no corresponding records with identical personal identification codes(6.0% for in-patients, 10.2% for out-patients). It was found through reviewing medical records that a cardiovascular malformation accompanied with other defects in the same category, and just one principal diagnosis was reported in MITD. Disease codes for cleft lip and/or cleft palate were described without strict distinction in medical records. So, after categorize three character disease codes included in congenital cardiovascular anomalies or cleft anomalies respectively, the overall agreement rise to 97.1% for in-patients and 81.7% for out-patients in infant under 1 year old. There were differences in correspondence among congenital anomalies by system ranging from 79.3% to 99.3% for in-patients and from 33.3% to 85.0% for out-patients. The estimated birth prevalence of several congenital anomalies considering above agreement were 9.1 per 1000 infants for congenital anomalies of circulatory system(Q20-Q28), 3.4 for other congenital anomalies of the digestive system(Q38-Q45), and 3.8 for congenital anomalies of eye, ear, face and neck(Q10-Q18). Our study showed that MITD can give limited but useful information on the outline of congenital anomalies in Korea where National Surveillance System or Registry for congenital anomalies does not yet established.

Program Nr: 1140 from the 1999 ASHG Annual Meeting

Prospective epidemilogic study of birth defects in Korea, a community based pilot study. *Y.K Kim[1], H.J. Kim[2]*. 1) Ajou Univ. School of Medicine, Suwon, Korea; 2) Genetics Clinic & Lab. of Medical Genetics, Ajou Univ. School of Medicine, Suwon, Korea.

This prospective epidemiological study of birth defects is a part of national effort to characterize congenital birth defects & genetic disorders in Korea and to establish National Genetic Database. The registry form was designed to identify, Down syndrome, facial cleft (cleft lip/or cleft palates), ONTD, polydactyly, ambiguous genitalia & other major malformations. The study was conducted in all hospitals in the province of Suwon, total 34 hospitals delivering one to 300 pregnancies per month, from May 1, 1997 to April 30, 1999 for two years. All outcome of the pregnancies including liveborns, stillborns and TOPs (20weks gestation) were subject of the evaluation for the presence of above major birth defects. Each delivery unit was requested to fill out registry form and monthly statistics were collected and analyzed. In addition, medical records of two tertiary hospitals on babies born during the study period were also searched and analyzed. The total number of delivery was 30,319 including 332 twins and 1 triple gestations, yielding 30,653 babies including 270 stillbirth and 26 TOPs (>20weeks gestation). The overall incidence of congenital anomalies was 1:86 (357 cases among 30,653 babies). Down syndrome was reported in 14 liveborns and 11 TOPs, an incidence of 1:125, facial clefts were 48 liveborns, 6 stillbirth, and 1 TOP, an incidence of 1: 557, ONTD was 6 liveborns and 2 TOPs, an incidence of 1:3,832, polydactyly was 15 liveborns, an incidence of 1;2,021, and ambiguous genitalia was 3 liveborns. The incidences of 1:557 in facial clefts was higher and 1:3,832 in ONTD was lower than any reported ethnic data. Search for neonatal and pediatric medical record for birth defects yielded 39% of total anomalies indicating the importance in generating accurate data. This pilot study represented the first community based data on birth defects in Korea, differing from most of previous studies based on single tertiary hospital and the first comprehensive birth defects data ascertained from not only liveborns but also stillbirth including TOPs following abnormal prenatal diagnosis.

Program Nr: 1141 from the 1999 ASHG Annual Meeting

Microsatellite-based statistics for inferring the past population growth. *J.P. King[1], M. Kimmel[1], R. Chakraborty[2].* 1) Dept Statistics, Rice Univ, Houston, TX; 2) Human Genetics Ctr, Univ Texas, Houston, TX.

Recently, several statistics were developed for detection of past population growth, based on short tandem repeat (STR) loci, also referred to as microsatellite loci. Some of their properties were investigated in the original communications, although never were they systematically compared to each other. Microsatellite loci are an important source of information about the evolution of human genome. Also, they were found of crucial importance in gene mapping and estimation of individuals' relatedness and identity. We present results concerning the power to detect past population growth using three microsatellite-based statistics available in the current literature: (1) based on between-locus variability, (2) based on the shape of allele-size distribution, and (3) based on the imbalance between variance and heterozygosity at a locus.

The analysis is based on the single-step stepwise mutation model (SSMM). The main feature evaluated is the power of the statistics under variable mutation rate. This is an important point, since it is a standard procedure to pool data collected at a number of loci and mutation rates at these loci may not be the same. Other characteristics, such as bias and variance of the indices relative to their expectations, also are considered. Our analysis indicates that the statistic based on the imbalance between variance and heterozygosity at a locus has the highest power for detection of population growth, in particular when mutation rates vary across loci. (Research supported by NIH grants GM 41399, GM 45861, and by Keck's Center for Computational Biology at Rice Univ.).

Program Nr: 1142 from the 1999 ASHG Annual Meeting

Natural variation of the androgen receptor gene CAG repeat in human populations. *R.A. Kittles[1,2], D. Young[1,2], D. Parish-Gause[1,2], G.M. Dunston[1,2].* 1) National Human Genome Center at Howard University; 2) Department of Microbiology, College of Medicine, Howard University, Washington, DC.

The androgen receptor (AR) interacts with androgens to promote cell division in the prostate gland. Exon 1 of the AR gene contains a polymorphic CAG repeat sequence whose length is inversely related to AR transcriptional activity. Increased prostate cancer risk, particularly among African Americans has been attributed to CAG repeat lengths less than 20 repeats. However little is known about the normal range of variation for the CAG locus. Here we examine variation at the AR CAG repeat locus in 498 unrelated healthy African American males between 55 and 70 years of age. West Africans (Liberians n=33; Ghanaians and Nigerians n=42), Euroamericans (n=97), and Amerindians (n=81) were included for comparative purposes. Alleles at the AR CAG locus were typed using fluorescent dye detection using an ABI 377 DNA sequencer following PCR amplification.

Twenty-seven alleles ranging from 5 to 31 repeats were observed in the populations. Not surprisingly, African Americans possessed the largest number of alleles (k=22) and highest gene diversity (0.926 ± 0.05). Mean repeat length varied considerably between populations from 20.6 ± 2.9 to 16.4 ± 2.9 in Amerindians and Liberians, respectively ($P=7 \times 10^{-8}$). Populations of African descent possessed smaller CAG repeat lengths than the Amerindian and Euroamerican populations ($P<0.00001$). F_{ST} analyses revealed that the sample of African Americans was more closely related to Liberians than to Ghanaians and Nigerians. Significant genetic differentiation was observed between African Americans and the two non-African populations ($P<0.000001$). These results reveal that variation in androgen receptor CAG repeat length differs considerably between human populations. In our sample of healthy African American men, 70% contained CAG alleles shorter than 20 repeats while the Amerindian population only contained 30% of the shorter repeats. Our results, along with other genetic, nutritional and socioeconomic factors, may be important in understanding the increased risk of prostate cancer in African Americans.

Program Nr: 1143 from the 1999 ASHG Annual Meeting

Methylenetetrahydrofolate reductase genotypes and predisposition to atherothrombotic disease: evidence that the wild type '677 CC' genotype is protective. *L.A.J. Kluijtmans, A.S. Whitehead.* Pharmacology, University of Pennsylvania, Philadelphia, PA.

Hyperhomocysteinemia is an independent risk factor for atherothrombotic disease. Recent evidence indicates that individuals homozygous for the methylenetetrahydrofolate reductase (MTHFR) 677C allele exclusively accumulate 5-methyltetrahydrofolate, the methyl donor for homocysteine conversion, in their red blood cells, in contrast to 677 TT homozygotes who also accumulate significant levels of non-methylated folate derivatives. The latter suggests that the MTHFR 677 TT, CT and CC genotypes are qualitatively different with respect to folate utilization and hence capacity to remethylate homocysteine, and consequently raises the question whether all three genotypes confer different levels of atherothrombotic risk. A "restricted" meta-analysis of subjects from the first ten studies reporting a significantly increased risk of atherothrombotic disease conferred by the TT genotype was performed. After proportional adjustment for the greater number of TT homozygotes, the CC and CT frequencies observed in cases were compared to expectations based on the frequencies of these genotypes in controls. The observed CC frequency among cases was lower than expected in 8 of the 10 studies. In the meta-analysis, which included 1,857 cases and 2,942 controls, 643 (34.6%) cases, instead of the 713 (38.4%) expected, had the MTHFR CC genotype (P=0.010). Our findings suggest that the three MTHFR C677T genotypes confer different levels of atherothrombotic risk, and therefore strengthen the hypothesis that the MTHFR TT genotype is an important determinant in 'at risk' populations. Furthermore, the significantly decreased CC homozygote frequency among cases relative to expectation implies that this genotype is protective against atherothrombotic disease. This observation, for which a biologically plausible mechanism is proposed, is of considerable public health importance.

Program Nr: 1144 from the 1999 ASHG Annual Meeting

Effect of high consanguinity rate on the incidence of phenylketonuria in Iran. *J. Koochmeshgi, S.M. Hosseini-Mazinani, P. Nader-Esfahani.* Molecular Genetics, National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran.

Phenylketonuria (PKU), the most common inherited error of amino acid metabolism, is an autosomal recessive disease caused by mutations in the phenylalanine hydroxylase (PAH) gene. The incidence of PKU varies widely among different populations. The highest incidence of PKU to date has been reported from Iran's neighboring country, Turkey. Accumulating evidence indicate a high incidence for this disorder in Iran. Researchers studying the most prevalent mutation in the PAH gene causing phenylketonuria in Mediterranean populations, the IVS10nt546 mutation, have based their differing hypotheses about the geographical origin and pattern of diffusion of this mutation partly on their differing views on the relative importance of the rate of consanguinity and the frequency of the PAH gene mutations in the countries of this region - e.g. Cali, F. et al. Human Genetics 100,350-355(1997). To investigate the role of parental consanguinity in the high incidence of PKU in Iran, we studied 109 unrelated Iranian PKU patients. For 83 patients (76%), the parents were consanguineous. Our data suggest a very important role for consanguinity in the high incidence of PKU in Iran.

Program Nr: 1145 from the 1999 ASHG Annual Meeting

Frequency estimation for rare Y-chromosomal haplotypes. *M. Krawczak[1], L. Roewer[2].* 1) Medical Genetics, University of Wales, Cardiff, UK; 2) Institut für Gerichtliche Medizin, Humboldtuniversität, Berlin, Germany.

Microsatellite markers located on the Y chromosome have enormous potential for use in forensic medicine and kinship testing. However, since most of the human Y chromosome is non-recombining, quantification of the statistical evidence provided by a positive match is difficult. Multiplication of allele frequencies to estimate haplotype frequencies is not justified and, as emerges from empirical data, can sometimes be misleading. We have therefore developed a numerical method to obtain Y-chromosomal haplotype frequency estimates via extrapolation, based upon patterns of association observed between subhaplotypes. Application to data from 1819 Caucasian males typed for markers DYS19, DYS389I, DYS389II, DYS390, DYS391, DYS392, DYS393 and DYS385 reveals that this methodology is highly accurate for haplotypes that are already included in the database. For previously unobserved haplotypes, however, prior inclusion for the purpose of frequency estimation appears overly conservative. We suggest a compromise by which a new haplotype is used for the study of subhaplotype association but is given no weight in the actual extrapolation step. This approach ensures that rare haplotypes retain their high evidential power even if the database used for estimation is of realistic, and therefore moderate, size.

Program Nr: 1146 from the 1999 ASHG Annual Meeting

Causes of spouse blood pressure correlation in a Northeastern Brazilian sample. *H. Krieger[1,2], M. Province[1], D.C. Rao[1]*. 1) Division of Biostatistics, Washington University School of Medicine, St.Louis, MO; 2) Dept Parasitologia, Universidade de Sao Paulo, Sao Paulo, Brazil.

A large sample (1801 nuclear families) from a migrant Northeastern Brazilian population was surveyed with the scope of uncovering the causal relationships among Systolic (SBP) and diastolic (DBP) blood pressures, ethnicity (E) and Body mass index (BMI). All the variables showed significant spouse correlations overall (0.41, 0.12, 0.08, 0.12, for E, BMI, SBP and DBP, respectively). A tetra-variate path analysis model was applied to the data to estimate the impact of cohabitation time and ethnicity on the correlation structure. Neither BMI nor the BP spouse correlations varied significantly with cohabitation time, while the spouse correlation of ethnicities, as measured by the proportion of black admixture, is significantly associated with cohabitation time, indicating that a conspicuous breakdown of isolates has taken place in this population, during the 60s decade. The proportion of the BP correlations attributable to BMI correlation, although significant, is less than 2% of the expected correlation among spouse's BPs. On the other hand, the Ethnicity contribution is rather high (around 10% for the average cohabitation time), suggesting that in populations with rather high levels of ethnical admixture, ethnical homogamy is one of the most important causes of positive blood pressure correlation among spouses.

Program Nr: 1147 from the 1999 ASHG Annual Meeting

Validation of pedigree data in the presence of genotyping error. *J. Kumm, S. Browning, E.A. Thompson.* Statistics, University of Washington, Seattle, WA.

Analyses of genome scan data typically assume marker genotypes to be observed without error. This is undesirable, both in the validation of pedigree relationships and in linkage detection. We have developed a program, based on the Baum algorithm, to compute likelihoods at multiple linked loci, in the absence of genetic interference, allowing for typing error. Using real data on a 488-marker scan on sib pairs, we found that on the basis only of Chromosome 1 data, sibs (S) are often not well distinguished from halfsibs (H), but that the LOD (base 10) relative to unrelated (U) is usually at least 3. With data on Chromosomes 1-5, S is normally well distinguished from H, and U is rejected (LOD 15 to 20), and with a full genome scan the LOD for S vs H is typically at least 15. Quantiles of the full-genome LOD distribution suggest a median LOD of truth vs U of 152 for sibs and 42.4 for halfsibs.

More general analyses have used real and simulated data at 100 markers on Chromosomes 1-5, using a model of independent errors at rate e. A modification excluding the possiblity of two errors in the same one-marker genotype significantly increases computational efficiency, permitting a full genome analysis including markers with more than 20 alleles. Likelihoods for putative sibs, halfsibs and unrelated pairs are computed for each of these same three relationship hypotheses. Typically, with real data the MLE $\hat{e}$ is 3 to 5%, whereas for the simulated data $\hat{e}$ is 0. For e up to 5%, relationship lod scores seldom change by more than 3. However, the algorithm also provides the posterior probability of marker genotypes, given the complete genome scans on the pair of relatives, and hence is a powerful method of detecting errors and localizing recombination events. Moreover, allowance for error is critical when a true relationship may be otherwise excluded, such as for paternity or in the joint analysis of sib trios, where a third sib can provide powerful validation (or refutation) of a putative sib pair.

Program Nr: 1148 from the 1999 ASHG Annual Meeting

Archaic lineages in modern human populations. *D. Labuda, E. Zietkiewicz, V. Yotova.* Sainte-Justine Hospital, Research Center, Department of Pediatrics/University of Montreal, Montreal (Quebec) H3T 1C5 Canada.

Excess in protein, mitochondrial and nuclear DNA diversity among Sub-Saharan Africans was either taken as evidence of greater antiquity of African populations or explained by a relatively larger effective population size of Africans in the recent past. Among 36 segregating sites previously found in dys44, an 8 kb DNA segment from the dystrophin gene, 21 were distributed worldwide, 13 were specific to sub-Saharan Africans and only two were absent from the African sample. The age distribution of these polymorphisms, based on their new allele frequencies, indicated that the specific variants originated less than 150,000-50,000 years ago, suggesting that the excess of African diversity accumulated after the divergence.

The present study concerns dys44 haplotypes analysed in a worldwide sample of 868 X-chromosomes. In contrast to expectations, African-specific polymorphisms occur clustered on the same background haplotypes and show decayed linkage disequilibrium. These and other characteristics indicate that African-specific sites have a longer genetic history than that suggested by prior age estimates and must have originated before their appearance in the present-day populations. Our findings can be explained by genetic hybridization of the ancestral humans expanding outside and into Africa with local populations from more archaic, albeit related lineages. *Supported by the Medical Research Council of Canada..*

Program Nr: 1149 from the 1999 ASHG Annual Meeting

What predisposes long normal GAA allele to full expansion in Friedreich ataxia? GAA variability and haplotype studies in different human groups. *M.Z. Labuda[1], N.E. Barucha[2], M. Pandolfo[1]*. 1) Ctr de Recherche LC Simard, CHUM, Montreal, PQ, Canada; 2) Bombay Hospital, Mumbai, India.

Friedreich ataxia (FRDA) is an autosomal recessive neurodegenerative disorder with a carrier frequency of about 1:90 in Caucasians. Over 95% of the FRDA causing mutations are GAA-repeat expansions in the first intron of the frataxin gene. All chromosomes with expansion share the same four-marker haplotype (FAD1 ITR4, ITR3, CS2) or can be derived from the consensus A-T-C-C haplotype by 1-2 recombinations. Interestingly, chromosomes carrying long normal (LN) alleles (16-34 GAA) also carry the same haplotype. This support the concept that they form a reservoir for recurrent expansions, independently confirmed by direct observation of new expansions. Recently we tested FRDA patients from India and Ecuador, and found that they all carry expansion associated with the European A-T-C-C haplotype suggesting a single origin of all expanded alleles in Indo-Europeans. Among FRDA patients sent to us from multi-ethnic Centers in Canada and USA, 170 carried GAA expansion(s). Of these, all were of Indo-European or Middle East descent. To our knowledge no patient of non-European origin with GAA expansion in frataxin gene was reported. In order to get an insight into the origin of expansion mutation we tested the GAA polymorphism in different human groups; Amerindians (n=30) mixed Orientals (n=47), African Americans (AA) (n=43). We identified two Orientals and fourteen (32%) AA to carry LN alleles (12-23 repeats). All but one of these alleles carried pure GAA, similar to European LN chromosomes. The high frequency of LN alleles among AA can not be accounted for by admixture with Caucasian chromosomes where only 18% of LN alleles are observed. Since LN alleles in AA do not seem to be prone to expansion we are presently investigating the ancestral relation between LN chromosomes of AA and European origin. In summary, our results further support the notion of a single origin of GAA expanded chromosomes in the human history and suggest that in addition to the presence of LN allele there are other features of A-T-C-C chromosome that predispose to full expansion.

Program Nr: 1150 from the 1999 ASHG Annual Meeting

Genome-wide linkage analysis of human fatness: The HyperGEN Blood Pressure Study. *C.E. Lewis[1], D. Arnett[2], I. Borecki[3], H. Coon[4], R.C. Ellison[5], S. Hunt[4], A. Oberman[1], S. Rich[6], M.A. Province[3]*. 1) Preventive Medicine, Univ. of Alabama-Birmingham, Birmingham, AL; 2) Epidemiology, Univ. of Minnesota, Minneapolis, MN; 3) Biostatistics, Washington Univ., St. Louis, MO; 4) Cardiovascular Genetics, Univ. of Utah, Salt Lake City, UT; 5) Preventive Medicine & Epidemiology, Boston Univ., Boston, MA; 6) Bowman Gray, Winston-Salem, NC.

Measures of human adiposity and body composition exhibit substantial familial resemblance; however, the mode of inheritance is complex. We conducted a full genome search for genes potentially influencing two related phenotypes: body mass index (BMI, kg/m^2) and percent body fat (PBF) from bioelectric impedance. Genotypes for 387 markers spaced roughly equally throughout the genome (CHLC-8) were typed by the NHLBI Mammalian Genotyping Service (Marshfield, WI) on the first 579 Caucasian hypertensive sibpairs and 247 African-American hypertensive sibpairs recruited by the HyperGEN network, a study of hypertension genetics in the NHLBI Family Blood Pressure Program. Hypertension was defined as BP³140/90 or on anti-hypertensive Rx. The search for quantitative trait loci for obesity phenotypes was carried out using the “model-free” variance component method as implemented in SEGPATH (Province et al. 1999). Each of the phenotypes was adjusted for the effects of age, within sex and race, and the linkage analysis was carried out separately within race using group-specific marker allele frequencies from additional random samples. The highest lod score detected was 2.5 for PBF near the telomere of 1p in the Caucasian sibs. The lod score for BMI in Caucasians was 2.3 at this same location, providing some confirmatory evidence. However, lod scores for both phenotypes were nearly zero in the African-American sibs at that location. Suggestive linkages were also found for BMI on chromosome 3p (lod=2.2) and for PBF on 10q (lod=2.1)and 12q (lod=2.1)in the Caucasians, while the highest lod score in the African-American sibs for these phenotypes was only 1.6 (chromosome 7). The current analysis represents only about the first half of the sibships collected in HyperGEN; a replication phase is underway, along with finer mapping in the most promising regions.

Program Nr: 1151 from the 1999 ASHG Annual Meeting

Molecular epidemiology analysis of human germline mutation in Mainland China. *X. LI[1], J-z. Liu[2], J. Drost[1], E.C. Thorland[3], Q. Liu[1], T. Lind[3], S. Roberts[3], H.Y. Wang[2], S.S. Sommer[1].* 1) Molecular Genetics, City of Hope/Beckman Research, Duarte, CA; 2) Inst. Medical Sciences, Chinese Acad.Med.Sci., Beijing, China; 3) Mayo Clinic/Foundation, Rochester, MN.

Germline mutations are the major source of genetic variation that allow a species to evolve over time but at a cost of Mendelian disease and genetic predisposition to multifactorial diseases. Previous analyses have revealed a similar pattern of germline mutations in the human factor IX gene (*F9*) among a variety of ethnically and geographically diverse populations that is compatible with the ancient pattern that has shaped the mammalian genome, primarily by germline mutations from endogenous mechanisms. Here, we compare the pattern of germline mutation in a population of hemophilia B patients from Mainland China (n=66), which constitutes one-fifth of the world's population, to that in U.S. Caucasians (n=213), Blacks (n=34), and Mexican Hispanics (n=31) (p=0.8 and 0.9, six and eleven mutations categories, respectively in a global analysis). The similar pattern of germline mutation in all ethnic groups studied to date is compatible with the hypothesis that endogenous processes predominate in human germline mutations.

Program Nr: 1152 from the 1999 ASHG Annual Meeting

DNA polymorphism in the study of gene geography of East Europe. *S.A. Limborska[1], P.A. Slominsky[1], E.V. Balanovskaya[2], O.V. Belyaeva[1], T.V. Pogoda[1], M.I. Shadrina[1], S.N. Popova[1], O.P. Balanovsky[1], D.A. Verbenko[1], E.K. Khusnutdinova[4], A.I. Mikulich[5], L.V. Bets[3], A.V. Stepanova[3], V.A. Spitsyn[2].* 1) Inst of Molecular Genetics, RAS, Moscow, Russia; 2) Medical Genetic Scientific Center, RAMS, Moscow, Russia; 3) Moscow State University, Moscow, Russia; 4) Bashkir Science Center of Ural Branch of RAS, Ufa, Russia; 5) Institute of Ethnography, Minsk, Byelarus.

We have analysed the normal variability of mini- and microsatellite loci and also insertion/deletion polymorphism in 32 East European populations with different level of Caucasoid and Mongoloid components. Different types of synthetic maps were constructed using reliability theory. Four maps od genetic distances were prepared based on calculation of distances from mean gene frequencies of these linguistic families (Indo-European, Uralic and Altaic) and from total mean frequencies of East European region at all. The data reveal the influence of gene pool of each people on the neighboring populations, that provides the interaction of various ethnic factors in the forming of the gene pool of this area. At the same time the results show that each ethnic-linguistic community keeps its own geneic characteristics distinguished from others.

Program Nr: 1153 from the 1999 ASHG Annual Meeting

Haplotype analysis at the FRAXA locus in Thai subjects showing no founder effect. *P. Limprasert[1], V. Saechan[1], N. Ruangdaraganon[2], T. Sura[2], P. Vasiknanonte[1], W.T. Brown[3]*. 1) Faculty of Medicine, Prince of Songkla Univ, Songkhla, Thailand; 2) Ramathibodi Hospital, Mahidol Univ, Bangkok, Thailand; 3) New York Institute for Basic Research, Staten Island, NY, USA.

The prevalence of fragile X syndrome (FXS) is approximately 7 % in developmentally delayed Thai boys. This is somewhat high compared to previous studies. To determine if FXS may have a specific haplotype association we analyzed 91 unrelated control subjects and 19 unrelated FXS patients using 3 markers (DXS548, FRAXAC1 and FRAXE) and a single nucleotide polymorphism (ATL1: A or G). FRAXAC1 and DXS548 are located ~ 7 Kb and ~ 150 Kb proximal to the FRAXA-CGG whereas ATL1 and FRAXE are located ~ 5.6 Kb and ~ 600 Kb distal to the FRAXA-CGG. We found 36 haplotypes in the contol group and 14 haplotypes in the FXS group. No significant association of a specific haplotype in either the control or FXS groups was found. Interestingly, of 14 haplotypes in the FXS group, 7 haplotypes were not found in the control group possibly suggesting new mutations or admixture of immigrant haplotypes. We observed that most diverse haplotypes came from different FRAXE alleles. This may reflect that recombination or mutation involving the FRAXE was involved. For this reason we analyzed haplotypes from the remaining markers (DXS548-FRAXAC1-ATL1). We found 2 major haplotypes (20-18-G and 20-19-A) with no significant haplotype differences between the control group (60/91 of 20-18-G and 20/91 of 20-19-A) and FXS group (11/19 of 20-18-G and 5/19 of 20-19-A). The other haplotypes were found 11/91 in the control group and 3/19 in the FXS group. This suggests that no founder chromosome is associated with Thai FXS. These findings contrast with most other reports on FXS founder effects in different ethnic groups. Our data imply that the Thai FXS chromosomes may originate independently in unrelated individuals.

Program Nr: 1154 from the 1999 ASHG Annual Meeting

Association study of aldose reductase gene polymorphism and diabetic nephropathy in Chinese population. *J. Liu, L. Ji, X. Han.* Department of Endocrinology and Metabolism, People's Hospital, Beijing Meidcal University, Beijing, P.R.China.

Diabetic nephropathy (DN) is one of the major causes of morbidity and mortality in patients with diabetes mellitus. Recently studies have shown that genetics play a important role in the predisposition to DN. Aldose reductase (AR) play a important role in the pathogenesis of DN and, clinically , AR inhibitor is effective in controlling the progression of DN. Several studies have suggested that polymorphism of AR gene is associated with susceptibility of DN and DR. Goal: To test the hypothesis that AR gene contributes to the genetic predisposition to DN in Chinese NIDDM population. Study design: A case--control studies was carried out to investigate the allelic distribution of AR gene polymorphism in the following groups of individuals: 1). Normal subjects of the Han Nationality living in northern China (n=117), 2) NIDDM control: long-standing non-insulin-dependent-diabetes mellitus(NIDDM) patients without DN and diabetic retinopathy (DR) (n=76), 3) DN group : NIDDM patients with DN an DR (n=62) , and(4) DR group: NIDDM patients with DR but not DN (n=39). Results: (1) 9 alleles and 27 genotypes were identified in the subjects studied. (2) The frequency of Z+2 allele was significantly increased in DN group (DN vs. NIDDM control and DR group , P=0.041; DN group vs. DR group , P=0.037) Conclusions: Our results suggested that AR gene or gene nearby contribute to genetic susceptibility of diabetes nephropathy in Han Chinese living in northern China and diabetic patients carrying Z + 2 allele had a increased risk of developing DN.

Program Nr: 1155 from the 1999 ASHG Annual Meeting

Frequency of Common Thrombophilic Mutations in the South Carolina Population: Factor V Leiden, Prothrombin 20210, and MTHFR. *J.W. Longshore, K. MacClenahan, K. Brenkusova.* Molecular Diagnostic Lab, Greenwood Genetic Ctr, Greenwood, SC.

In the past few years, many of the molecular mechanisms involved with thrombosis have been identified. Among them are the factor V Leiden and prothrombin 20210A mutations which have been implicated in up to 65% of cases of inherited thrombophilia. Additionally, the MTHFR 677T mutation has been associated with an increased thrombotic risk and elevated plasma homocysteine levels. These mutations have been noted to occur frequently in the Caucasian population. In order to determine the frequency of these three mutations in the South Carolina population, a series of 512 consecutive births was studied. The population consisted of 254 males and 258 females with an ethnic distribution of 51.9% Caucasian, 43.9% African-American, 2.7% Hispanic, and 1.4% of other races. For factor V Leiden, 4.10% of the study population was heterozygous and a single homozygote was detected. Heterozygosity for the prothrombin 20210A mutation was detected in 0.78% of the consecutive births. As expected, the MTHFR mutation had the highest frequency with 35.9% of the study population being heterozygous and 7% being homozygous for the mutation. When the data was stratified for race, the Caucasian population had heterozygote frequencies of 5.64%, 1.5%, and 47% for factor V Leiden, prothrombin 20210A, and MTHFR 677T while the African-American population frequencies were 2.23%, 0%, and 22.32% respectively. Interestingly, coinheritance of these thrombophilic mutations was often noted in our screened population.

Program Nr: 1156 from the 1999 ASHG Annual Meeting

Methylenetetrahydrofolate reductase C677T and A1298C gene mutations in an inbred group of *Mazateco* Indians:An ethnic genetic marker for some Amerindian populations? *M.A. Lopez, J. Zuniga, J. Granados, O.M. Mutchinick.* Dept of Genetics[1], Immunology[2],Inst Nac Nutricion S Zubiran ,Mexico,DF.

MTHFR gene mutations have a worldwide distribution.The C677T transition has been extensively studied in many populations of similar and different ethnic groups.Prevalence of the homozygote TT varies from as low as 1.5% in blacks to as high as 34.8% in Mexicans (Mutchinick et al., 48th ASHG Meeting).More recently (1998) a new common mutation (A1298C) was described in Caucasians.While homozygous TT has a thermolabile enzyme that alter folate metabolism and induce a moderate hyperhomocysteinemia (HCY), the CC homozygote has a milder defect without HCY. Compound heterozygous behaves as TT homozygous. These genotypic arrays are recognized as important risk factors for neural tube defects (NTD) and cardiovascular disease (CVD). The high frequency of the C677T mutation observed in our population prompted us to study both mutations in 102 healthy Mazateco Indians. The aim was to know more about the prevalence of these MTHFR gene mutations and the potential disease risk they could represent for Amerindian populations. Blood samples were processed for DNA, MHC and other genetic markers. PCR amplified fragments of 142bp and 163bp were digested with TaqI and MboII restriction enzymes, followed by electrophoresis in agarose 4% and polyacrilamide 20%, to identify mutations C677T and A1298C respectively. Our results shows: 1) extremely high frequency of the C677T mutation with 70.6% of homozygous TT, and gene frequencies of 20.1 and 79.9% for C and T alleles respectively; 2) very low frequency of the A1298C mutation with 85.3% homozygous AA, and 0% homozygous CC, and gene frequencies of 92.6 and 7.4% for A and C alleles respectively, 3) very low prevalence (3.9%) of compound CT/AC heterozygotes, and 4) genotypes for C677T mutation are in H-W disequilibrium (p: <.001). MHC typing showed a high prevalence of an autochthonous otherwise rare haplotype. These results may suggest that the MTHFR C677T could be a very popular mutation in Amerindian populations, explaining in part the high prevalence of NTD in Mexico and some Central American countries, and representing maybe a higher risk for CVD.

Program Nr: 1157 from the 1999 ASHG Annual Meeting

Significant influence of the +93 C/T polymorphism in the apolipoprotein(a) gene on Lp(a) concentrations in the Asian Indian neonates from Singapore. *P.S Low[1], C.K Heng[1], S.C. Quek[1], N. Saha[2], M.I. Kamboh[2]*. 1) Dept Pediatrics, National Univ Singapore, Singapore, Singapore; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburg, PA.

We studied the influence of the +93 *C/T* polymorphism in the apo(a) gene on plasma level of lipoprotein(a) [Lp(a)] in 282 South Asian Indian neonates using cord blood of both genders. Genotypes of kringle-4 (K4) and pentanucleotide repeats (PNR) polymorphisms were also available for adjusting their confounding effect on Lp(a) concentrations. The frequencies of the rare *T* allele was 0.15. The genotype distribution did not deviate significantly from a population at Hardy-Weinberg equilibirum. Significantly different mean Lp(a) levels were observed in descending order for the following genotypes *CC* > *CT* > *TT* ($F = 5.00$, $P = 0.007$) using 3-way ANOVA with K4 and PNR genotypes as the other 2 grouping factors. Our observation is in accordance to findings that the *T* allele was responsible for a reduction of apo(a) translation rate by 60% in vitro. The +93 polymorphism was able to explain 4.8% of the total variation in cord plasma Lp(a) levels. Based on a subset of 120 neonates with grandparental history of coronary artery disease, we found no significant difference in Lp(a) levels between neonates with family history and those without. Pearson's chi-square test was also not significant for cross tabulation of family history and +93 genotypes, indicating a similar genotype distribution between the two subgroups.

Genotype	Mean [lnLp(a)+1](SD)	Geometric Mean	*n*
CC	0.46 (0.52)	0.58	210
CT	0.23 (0.37)	0.26	63
TT	0.15 (0.14)	0.15	9

Program Nr: 1158 from the 1999 ASHG Annual Meeting

Genetic polymorphisms in Transforming Growth Factor-b1 and the risk of Alzheimer's Disease. *E.K. Luedecking[1], S.T. DeKosky[1,2], H. Mehdi[1], M.I. Kamboh[1,2].* 1) Departments of Human Genetics; 2) Psychiatry, Univ Pittsburgh, Pittsburgh, PA.

Alzheimer's Disease (AD) is a multifactorial disease with the possible involvement of several genetic components. Genetic studies have yet to determine all genes involved in the pathogenesis of AD. Transforming growth factor-b1 (TGF-b1) is a candidate gene for AD. It is a multifunctional cytokine whose overexpression has been shown to promote the deposition of amyloid-b peptide in senile plaques. The goal of this study was to investigate the association of three polymorphisms in TGF-b1 with the risk of AD. Two of the polymorphisms in TGF-b1 are located at positions -800 (G®A) and at -509 (C®T), and the third site is in the coding region at codon 263 (Thr®Ile). We screened DNA samples of 428 sporadic, late-onset patients and 421 controls by PCR based assays. There was no statistically significant difference in genotype or allele frequency distributions between cases and controls for the -800 and codon 263 polymorphisms (p=0.38 and p=0.60). The overall genotype distribution at the -509 site was statistically significant (p=0.017). The frequency of the -509/TT genotype was significantly higher in AD patients than controls (p=0.015). This suggests that the C®T mutation may alter the regulation of the TGF-b1 gene and could possibly explain the overexpression of TGF-b1 in AD patients. The functional role of the -509 polymorphism was tested by Dual-Luciferase Reporter Assay. We sub-cloned the -509 C and -509 T alleles in front of the firefly luciferase reporter gene in pGL3-basic vector and cotransfected with pRL-CMV vector containing *Renilla* luciferase gene as a control for transfection efficiency in COS-1 cells. The activity of each promoter allele was directly measured by the ratio of firefly luciferase activity to *Renilla* luciferase activity. We observed an allele-specific effect on promoter activity of the TGF-b1 gene. The level of luciferase produced by the -509 T promoter allele was 2.8-fold greater than that produced by the -509 C allele (p=0.010). This data suggest that the -509 polymorphism has a functional effect on the promoter activity of TGF-b1.

Program Nr: 1159 from the 1999 ASHG Annual Meeting

Modeling Gene-Gene Interactions in Complex Traits. *F. Macciardi, V.S. Basile, J.L. Kennedy.* Centre for Addiction and Mental Health (CAMH), University of Toronto, 250 College St., Toronto ON M5T 1R8, Canada.

Complex issues such as gene-gene interaction require advanced statistical techniques. Consider each of two genes A and B, positioned on different chromosomes and hence not in linkage disequilibrium, that have been shown to have an effect on a given trait or disease, and we are interested in evaluating the combined effect of these two genes on the phenotype in question. The gene A/gene B interaction is based on the finding that either gene per se increases the risk for the trait, measured as a quantitative trait, i.e. a continuous variable. Continuous dependent variables are usually analyzed using the Analysis of Variance, where independent factors are represented by genotypes at loci A and B. Within the ANOVA model, we can test the effect of a possible genetic interaction contrasting the joint vector representing the double "pathological" variants for genes A and B against the other possible vectors combining the alternative genotypes of A and B: in this way we investigate whether the combined effect of possessing a pathogenic genotype for both loci shows a larger than expected outcome for the dependent variable (i.e., the phenotype) as compared to the effect of possessing only one pathogenic genotype, either A or B. Indeed, we know (Frankel and Schork 1996) that a genetic epistatic and/or additive interaction is not revealed by marginal effects, equivalent to a statistical interaction in the ANOVA model, and thus a non-significant value for the A x B effect is not an appropriate test to exclude a genetic interaction. In a "real data" example for the loci CYP1A2 and DRD3 with a movement disorder phenotype, we illustrate how the two genes interact with each other, using a contrast model for epistatic interaction.
Frankel and Schork: Who is afraid of epistasis ? Nature Genetics 14:371-373, 1996.

Program Nr: 1160 from the 1999 ASHG Annual Meeting

DNA based testing for the identification of progressive pseudorheumatoid dysplasia carriers. *A.M Alkhateeb[1], J. Al-Alami[1], S.M Leal[2], H.E El-Shanti[1]*. 1) Jordan University of Science & Technology, Irbid, Jordan; 2) The Rockefeller University New York, NY, USA.

Progressive pseudorheumatoid dysplasia is a skeletal dysplasia affecting the articular cartilage causing joint swelling and stiffness with additional changes in the spine similar to spondyloepiphyseal dysplasia tarda. It is a rare autosomal recessive disorder with high prevalence amongst Arabs specially the Jordanian population. The gene for this disorder has been mapped to the long arm of chromosome 6 and then fine mapped to a 2.1 cM interval. This area is covered by 3 highly polymorphic trinucleotide microsatellite markers (ATA11D10; ATA56D06; ATA16B01). Three families from Jordan proved to be linked to the same locus without a common hapolotype for the three markers. Linkage to the same locus supports the idea of a homogeneous disorder and the absence of a common haplotype indicates no common ancestor genes were inherited in our patients. Individuals at risk from the three families who agreed to participate and wanted to know their carrier status were included in the study. The study involved genotyping with the 3 microsatellite markers using PCR based non-isotopic polyacrylamide gel electrophoresis all available family members. The genotypes of the individuals together with haplotype analysis are capable of identifying heterozygous status with 98% certainty. This figure will rise to 100% once the gene is cloned and the actual mutation is identified. We here present DNA based testing for carrier identification for an autosomal recessive skeletal dysplasia. This testing is a preliminary tool for heterozygote and homozygote identification to be used in premarital counseling, prenatal diagnosis and presymptomatic diagnosis.

Program Nr: 1161 from the 1999 ASHG Annual Meeting

Genetic research in pharmaceutical clinical trials: investigator participation and ethics committee review and approval. *W. Anderson[1], J. Arbuckle[2], T. Arledge[1], C. Brazell[2], S. Concannon[1], L. Foster[2], A. Hughes[1], A. McCarthy[2], M. Mosteller[1], S. Ray[1]*. 1) Clinical Genetics Division, Glaxo Wellcome Research and Development, Research Triangle Park, NC; 2) Clinical Genetics Division, Glaxo Wellcome Research and Development, Greenford, Middlesex, UK.

Glaxo Wellcome (GW) is a research-based company whose people are committed to fighting disease by bringing innovative medicines and services to patients throughout the world and to the healthcare providers who serve them. As part of the strategy of developing innovative medicines, GW has incorporated genetic research into several ongoing development programs. Since the impact of genetic variation on response to medicines (pharmacogenetics) is a new science, GW established standardized procedures, study documents, and educational materials in conjunction with bioethics experts for investigators, study subjects, and ethics committees. Participation in the genetic research studies is voluntary. To ensure that information was presented consistently, GW developed templates for a genetic research protocol and an informed consent document. A video was produced to help investigators and study subjects understand the nature of the genetic research, use of the DNA sample, and use of genetic results. To supplement the consent and subject video, brochures with general background information were created. As of May 31, 1999, 1412 of 3817 investigator sites around the world (or 37%) were participating in genetic research; 6118 samples have been collected. For 28 sites participating in various studies, ethics committee approval was not granted. Reasons for non-participation by investigators and non-approval by ethics committees will be discussed in detail.

.

Program Nr: 1162 from the 1999 ASHG Annual Meeting

Inherited Connexin 26 mutations associated with non-syndromic hearing loss in the Israeli population. *K.B. Avraham[1], T. Sobe[1], S. Vreugde[1], H. Shahin[1,2], M. Kanaan[2], Y. Yaron[3], A. Orr-Urtreger[3], M. Frydman[4], M. Shohat[5]*. 1) Department of Human Genetics and Molecular Medicine, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 2) Life Sciences Department, Bethlehem University, Bethlehem, Palestinian Authority; 3) Genetics Institute, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel; 4) Genetics Institute, Haim Sheba Medical Center, Tel Hashomer, Israel; 5) Department of Medical Genetics, Rabin Medical Center, Petah Tikva, Israel.

Connexin 26 (GJB2) mutations lead to hearing loss in a significant proportion of all populations studied so far, despite the fact that at least fifty other genes are also associated with deafness. The entire coding region of connexin 26 was sequenced in hearing impaired children and adults in Israel in order to determine the percentage of hearing loss attributed to connexin 26 and the types of mutations in this population. Thirty-one percent of all tested harbored GJB2 mutations, the majority of which were 35delG and 167delT mutations. Several parameters such as age of onset, severity of hearing loss and audiological characteristics, including pure-tone audiometry, tympanometry, auditory brainstem response (ABR), and otoacoustic emissions were examined to establish whether genotype-phenotype correlations exist. All GJB2 mutations were associated with prelingual, but not postlingual, hearing loss. Severity ranged from moderate to profound hearing loss, with variability even among hearing impaired siblings. The study here has direct clinical ramifications for genetic counseling in the hearing impaired population, both in Israel and the rest of the world.

Program Nr: 1163 from the 1999 ASHG Annual Meeting

Development of a Multiplex ARMS™Test for the Detection of Polythymidine Splice-Site Variants in Intron 8 of the CFTR gene. *A.I. Bayliffe, S.J. Kelly, N.H. Robertson, S. Little.* Product Development, AstraZeneca Diagnostics, Northwich, Cheshire, ENGLAND.

In cases of cystic fibrosis (CF) involving class I and II CFTR mutations chronic pulmonary disease is observed at variable levels with chronic pancreatitis. However, some CF patients present with milder symptoms ranging from sinopulmonary problems and pancreatic sufficiency (PS-CF), to congenital bilateral absence of the vas deferens (CBAVD).

Polythymidine (polyT) splice-site acceptor alleles 7T, 9T, and 5T occur at frequencies in the general population of 85%, 10%, and 5% respectively, and impact the splicing efficiency of exon 9. The most inefficient splice variant, the 5T allele, has been identified as contributing to expression of CF and CBAVD phenotypes in individuals with certain CF genotypes.

We have developed a single-tube multiplex ARMS™ allele specific amplification test, which genotypes for 5T, 7T, and 9T variants. Genomic DNA is added to a reaction tube and polyT alleles are detected by ARMS™, with subsequent analysis by standard agarose gel electrophoresis. The presence or absence of diagnostic product bands of defined sizes indicate polyT allele status. The test was validated using a large panel of DNA samples and was shown to be very reliable. The procedure is simple to perform, and provides rapid results (turn around in half a day), which are easy to interpret. The test has application to the detailed diagnosis of CF and infertility. Information on distribution of polyT variants with respect to CF genotype will be discussed in the context of previously published results.

Program Nr: 1164 from the 1999 ASHG Annual Meeting

Molecular analysis in Brazilian cystic fibrosis patients reveals five novel mutations. *A.L.F. Bernardino[1], A. Ferri[1], M.R. Passos-Bueno[1], C.A.E. Kim[2], C.M.A. Nakaie[2], C.E.T. Gomes[3], N. Damaceno[4], M. Zatz[1]*. 1) Centro de Estudos do Genoma Humano,Departamento de Biologia, Universidade de S.Paulo, SP, Brazil; 2) Instituto da Crianca, Universidade de S.Paulo, SP, Brazil; 3) Departamento de Pneumologia, Escola Paulista de Medicina, UNIFESP, SP, Brazil; 4) Departamento de Pediatria, Santa Casa de Misericordia, SP, Brazil.

Cystic Fibrosis (CF) is the commonest severe autosomal recessive disorder in the Caucasian population, with an estimated incidence of 1 in 2500 live births and a carrier frequency of 1 in 25. The CFTR gene at chromosome 7q31 has 27 exons spanning 230 Kb and encodes a protein of 1480 aminoacids. More than 800 different mutations in the CFTR gene have been already reported to the Cystic Fibrosis Genetic Analysis Consortium so far, the most common of all being the DF508 mutation. We have analyzed 160 CF Brazilian patients diagnosed with CF (73% Caucasians and 27% of mixed Negroid, Indian and Caucasian background). Screening of mutations in 320 CF chromosomes was performed through SSCP/Heteroduplex analyses assay followed by DNA sequencing of the 27 exons and exon/intron boundaries of the CFTR gene. The frequency of CFTR variants of T tract length of intron 8 (IVS8 Tn) was also investigated. This analysis enabled the detection of 232/320 CF mutations (72.2%) and complete genotyping of 61% of the patients. The DF508 mutation was found in 48.4% of the alleles. Another fifteen mutations (previously reported) were detected: G542X, R1162X, N1303K, R334W, W1282X, G58E, L206W, R553X, 621+1GT, V232D, 1717-1GA, 2347 delG, R851L, 2789+5GA and W1089. Five novel mutation were identified, V201M (exon 6a), Y275X (exon 6b), 2686 insT (exon 14a), 3171 delG (exon 17a), 3617 delGA (exon 19). These results contributed to the molecular characterization of CF in the Brazilian population and to enhance our knowledge on genotype/phenotype correlation. In addition, the identification of the novel Y275X mutation allowed pre natal diagnosis in a high risk fetus. Supported by FAPESP, CNPq, PRONEX.

Program Nr: 1165 from the 1999 ASHG Annual Meeting

Challenges in Molecular Testing for connexin-26 Mutations in Children Referred for Non-Syndromic Deafness.
J.K. Brock, L.C. Kwong, F. Kozak, R.D. Wilson, S. Langlois. Children's/Women's Hlth Ctr BC, Vancouver, BC, Canada.

Mutations in connexin-26 (Cx26) account for a majority of AR non-syndromic deafness. Testing for two common mutations (30delG and 167delT) is predicted to identify over 90% of hearing loss due to Cx26 in European and Ashkenazi Jewish populations, and is a cost effective approach to the diagnosis of the etiology of deafness in children. We have analysed Cx-26 mutations in eight patients referred for AR or sporadic sensorineural deafness from diverse ethnic backgrounds. As the frequency of 30delG and 167delT in some ethnic populations is unknown and since the Cx-26 gene is relatively small, we have taken the approach of direct gene sequencing to identify mutations. Two patients were homozygous for 30delG, one patient was heterozygous for 30delG/unknown and four patients were heterozygous for mutations other than 30delG and 167delT: 176-191del(16), V27I and V37I. Deletion 176-191del(16) was found in one patient and generates a frameshift, altering the amino acid sequence starting at codon 59 and introducing a premature stop codon. V27I was found in one patient, a child with two deaf siblings; and V37I was found in two patients, one of who was also heterozygous for 30delG. Mutations at V27 and V37 may have pathological significance since both are conserved residues. However, V27I and V37I have each previously been reported in one out of 192 alleles in random control samples, leading the authors to speculate that they represent polymorphisms (Kelley et al, 1998, AJHG 62:792). We have subsequently screened 120 alleles from random samples for both V27I and V37I: one was positive for V37I; none were positive for V27I. Thus, the significance of these mutations in our patients remains unclear, but suggests a pathogenic role in AR deafness. Gene sequencing has identified three out of eight patients whose deafness may be based on mutations in Cx-26 that would have been missed using mutation analysis for 30delG and 167delT alone. Although sequencing results must be interpreted with caution, direct DNA sequencing has the potential to identify a larger proportion of patients with Cx-26 related hearing loss, and provide families with a defined recurrence risk.

Program Nr: 1166 from the 1999 ASHG Annual Meeting

ATM mutation scanning from genomic DNA of ataxia-telangiectasia patients by [Detection of Virtually All Mutations]-SSCP (DOVAM-S). *C.H. Buzin[1], V.Q. Nguyen[1], C.Y. Wen[1], G. Nozari[1], A. Mengos[1], X. Li[1], J.S. Chen[1], F.K. Fujimura[1], R.A. Gatti[2], S.S. Sommer[1]*. 1) City of Hope National Medical Center, Duarte, CA; 2) UCLA School of Medicine, Los Angeles, CA.

The ATM gene, which is mutated in the autosomal recessive disease ataxia-telangiectasia (A-T), contains 66 exons spanning ~146 kb of genomic DNA and produces one of the largest known proteins. The size of the ATM gene and the lack of mutational hotspots has hampered the detection of all mutations. DOVAM-S is a modification of SSCP in which up to 20 segments of DNA are analyzed in a single lane under five different electrophoresis conditions, including various matrices, buffers, temperature, and additives. In previous blinded or prospective studies of hemophilia B and A patients, DOVAM-S detected 100% of 87 and 84 mutations in the Factor IX and Factor VIII genes, respectively. In this study, 17.5 kb of the ATM gene were screened in 70 segments (166-367 bp each) that included exons 4-65 (coding regions) and the adjacent intronic splice junctions. Segments were grouped into four lanes of 17 or 18 amplicons and electrophoresed under five conditions. Segments showing abnormal mobilities were sequenced; mutations were confirmed by reamplification and sequencing from genomic DNA. In a blinded analysis of DNA from 19 A-T patients, a total of 80 sequence changes (39 unique mutations and/or polymorphisms) were detected. All known sequence changes within the scanning region were found. In addition to the known changes, 2 new common polymorphisms (in multiple samples) and 5 rare DNA variants were detected. An additional 12 putative causative mutations were also detected: 4 nonsense mutations, 2 deletions resulting in frameshifts, 2 mutations at the initiation codon, 1 exonic splice junction mutation and 3 missense mutations. Most of the new mutations are predicted to truncate the protein; thus, few missense mutations produce the A-T phenotype. Studies are in progress to screen genomic DNA from 41 additional A-T patients.

Program Nr: 1167 from the 1999 ASHG Annual Meeting

Referrer and patient expectations and realisation of genetic consultation in 7 countries. *K. Challen, V. Baranov, C. Bartsocas, J. Burn, J-P. Fryns, E. Ginter, H. Harris, R. Harris, I. Nippert, R. Salonen, J. Schmidtke, LP. Ten Kate.*
Genetic Enquiry Centre, St Mary's Hospital, Manchester.

Under 25% of patients (425) could expect ongoing care from a clinical geneticist in our study of 1794 referrals to 9 genetic centres in 7 countries. It is therefore important to consider referrer and patient expectations of their "snapshot" encounter with the genetic centre. Most referrers (66%) specifically requested specialist counselling; significantly more GPs and significantly fewer self-referrals ($p<0.001$). 733 (41%) referrers requested a clinical diagnosis, although this was lower in self-referred patients and those from GPs and obstetricians ($p<0.001$), perhaps reflecting increased rates of self and GP referral because of family history. For example, there was a significantly lower expectation of clinical diagnosis in patients whose eventual diagnosis was hereditary cancer ($p<0.001$). In only 74 (4%) cases did the geneticist consider that the patient's reasons for attending differed from the referrer's, despite only 24 (1%) having received a home visit before the genetic consultation. 520 (29%) patients were assessed purely clinically; significantly fewer amongst GP-referred patients ($p<0.001$) and, interestingly, significantly more amongst those with a final diagnosis of hereditary cancer ($p<0.001$). 721 (40%) patients had cytogenetic tests; significantly more amongst obstetric referrals, presumably reflecting high rates of referral for prenatal diagnosis. Of the 1186 (66%) cases in which a provisional diagnosis was given by the referrer, 693 (58%) were modified at the genetic centre. The likelihood of diagnostic modification varied widely between referrers, being significantly lower in GP and obstetric referrals. The final status of the diagnosis (certain, likely or uncertain) also varied widely between referrers, with significantly higher rates of certainty for obstetric referrals and significantly lower rates for GPs ($p<0.001$). It would seem that the service required from a genetic centre is affected greatly by its referrer customer base, and therefore that due account must be taken of health service structure in the planning and development of genetic services.

Program Nr: 1168 from the 1999 ASHG Annual Meeting

Typical Hispanic Population with Nontraditional Barriers. *S.M. Chenevert, H.A. Northrup, A.J. Tucker.* The University of Texas, Medical School Houston, TX.

Charts of 600 prenatal genetic counseling patients from a primarily Hispanic population (86%) receiving care in 6 outreach clinics in Houston, Texas were analyzed. Our goal was to identify barriers for acceptance of prenatal testing and diagnosis and thereby improve counseling through a better understanding of the population. Typical barriers already identified in the literature include: low socio-economic status, language, Catholic religion, and foreign born vs US born. Analysis of our population reveals low socioeconmic status (~60% qualify for public assistanc with the majority of remaining qualifying for Medicaid), Spanish speaking (seen by bilingual counselor), 34% Catholic (49% unspecified), and 83% foreign born. On average, 1/3 of our patients accepted prenatal testing of some form (high resolution U/S, amniocentesis, etc) but only 16.6% accepted an amniocentesis specifically. Additional data gathered includes: average age of mother, gestational age (GA) at time of GC visit, reason for referral, citizenship status, religion, ethnic background, acceptance of testing vs. follow through and specific characteristics of those who chose amniocentesis. From our analysis we can eliminate the most commonly described barriers of language, religion and being foreign born as the major barriers to our population. A lack of follow through with testing decisions was observed. Potential reasons include the amount of paperwork required to receive public assistance and the late gestational age (18.5 weeks) at the time of their first appointment with the genetic counselor (GC). To determine a causative factor for later referral, we analyzed time between referral and GC appointment (~2 weeks) giving an average GA of ~17 at time of referral. This is a significant barrier in light of 1) spacing of clinics (7-31 days depending on the clinic) and 2)the wait for prenatal diagnosis appointments. Our findings reinforce the need to educate both the population and physicians regarding the importance and availability of GC services. It is important to respect the heterogenity among Hispanic populations. Our data demonstrate that cultural stereotyping should be avoided.

Program Nr: 1169 from the 1999 ASHG Annual Meeting

Factor IX gene mutations in Korean hemophilia B patients. *Y.H. Cho, C.H. Lee, S.H. Shim, H.K. Seo.* Dept Medical Genetics, Hanyang Univ Col Medicine, Seoul 133-791, Korea.

Hemophilia B is an X-linked recessive bleeding disorder, resulting from mutations of the coagulation factor IX gene. Hemophilia B is known as to be caused by a variety of mutations, which can be found in the whole coding regions. The purposes of this study were to find out molecular defects of factor IX gene in Korean hemophilia B patients, and to establish a strategy for prenatal and carrier diagnosis. The promoter region, 8 exons and their intron boundaries of factor IX gene in genomic DNAs of 15 Korean hemophilia B patients were amplified by PCR, and this PCR products were screened for the mutations with the methods of SSCP(single strand conformation polymorphism) and BESS T-scan. And DNA sequence analysis was performed by subcloning of PCR product and dideoxy reactions. With SSCP analysis, 9 cases showed mobility shifts. Three cases out of the remaining 6 cases showed abnormal band patterns in BESS T-scan. Eighty percents (12/15) of mutation screening rates were achieved. One point mutation was detected in one cases of each at exon B, C, E and F, respectively, and in 2 cases at exon G. And 6 cases at exon H. In DNA sequence analysis, all of 12 detected mutations showed sequence alterations. Five cases were transversion, and 8 cases were transition, and 4 cases of transitions were on CpG dinucleotide sites. Nine cases were missense mutations and 3 cases were nonsense mutations. Five mutations were known by previous studies, and 7 cases were novel mutations found in this study. This study showed that the mutations in factor IX gene of Korean hemophilia B patients are extremely heterogeneous and wide spread over entire coding regions, although majorities of mutations showed a tendency to aggregate on exon H. In this study, a strategy for direct method of prenatal and carrier diagnosis for hemophilia B was established, and it will be useful to use this direct method as complementary to indirect linkage analysis.

Program Nr: 1170 from the 1999 ASHG Annual Meeting

The analysis of newborn dried-blood-spot specimens for cystic fibrosis mutations using PCR/OLA and capillary electrophoresis. *H. Chow, J.W. Eastman, R. Wong, J.E. Sherwin.* Gen Disease Lab, California Dept Hlth Services, Berkeley, CA.

Cystic Fibrosis (CF) is a common autosomal recessive disorder that can be lethal in childhood unless good continuous medical care and nutritional enhancement are provided early in life. To evaluate newborn screening in California for CF, the Genetic Disease Laboratory examined an in vitro assay (PE Applied Biosystems) that screened samples for the presence of 31 prevalent mutations by oligonucleotide ligation assay (OLA) and capillary electrophoresis. Two hundred and ninety-six newborn heelstick dried-blood-spot (DBS) specimens collected in 1987, 1995 and 1997 from all areas throughout the State were analyzed. A 3mm-diameter disk (3 µL of blood) was used for genomic DNA extraction. Multiplex PCR with 15 pairs of primers was used for amplification. The primers flanked regions (exons 4, 7, 9, 10, 11, 20 and 21, intron 17) of the gene where the mutations may be detected. The OLA that followed PCR provided sequence-coded electrophoretic mobility and fluorescent labeling for identification of the 31 allelic CF genotypes. An internal size standard was added to each sample for size measurement. The PE ABI Prism 310 genetic analyzer was used for the automated capillary electrophoresis. The capillary was fused silica cut to 30cm long, with inner diameter 75m. Linear polyacrylamide gel was used so that it would rinse out after each samples electrophoresis. Of the 296 newborn samples, none was homozygous. There were five heterozygous mutations, one I507, three F508, and one R117H. This gives a carrier frequency of 1 in 59, an expected result for the heterogeneous California population. The assay is an efficient method for identifying the 31 CF mutations. Pipetting for PCR and OLA are manual, the electrophoresis is automatic. For a 48-sample tray, twenty-four hours is the approximate analysis time. For high-throughput newborn screening, we are exploring a two-tiered approach in which immunoreactive trysinogen (IRT) is used to identify specimens for DNA analysis. A typical screening laboratory can test 250 DBS specimens for IRT, and analyze five specimens with the highest IRT results by the PCR/OLA capillary electrophoresis method, with one-day turnaround time.

Program Nr: 1171 from the 1999 ASHG Annual Meeting

Data collection in the Great Plains Genetics Service Network. *C.A. Christianson[1], P.S. Ing[2], J.M. Smith[3].* 1) University of South Dakota, Rapid City, SD; 2) Boys Town National Research Hospital, Omaha, NE; 3) University of Iowa College of Medicine, Iowa City, IA.

The goals of the GPGSN Database Committee were to: 1) describe demographically the patients seen for counseling & evaluation (C&E) & prenatal (PND) services in the region, and 2) provide a list of patients by diagnosis. In 1984, a system was designed to collect pre-patient-per-visit data on the delivery of genetic services (not diagnoses, not prevalence or incidence of genetic diseases). The C&E minimum data set (MDS) included 26 items. There were 21 items in the PND MDS.

A review of the data collected since 1987 suggests we were unsuccessful in completely accomplishing either goal. Although the most consistent data were collected between 1994 & 1997, inclusively, only 7 items in the C&E MDS and 10 items in the PND MDS had known valid data of >90%.

For the C&E patients: we were consistently unable to collect data related to socioeconomic status & diagnosis; 70% were under the age of 10; there were more males (56%) age 10 or younger and more females (67%) ages 20 to 40; 57% were new referrals & the most common reasons for referral were an abnormal phenotype & follow up.

For the PND patients: we were consistently unable to collect data related to pregnancy outcomes; most were referred for AMA or an abnormal maternal serum screen; 90% were referred by private physicians; diagnostic ultrasounds, amniocentesis and AFAFP were the most common tests performed; the racial distribution of PND patients reflected the regional birth statistics, and 54% were under the age of 35.

We conclude that a successful system should include: (1) adequate financial resources (personnel, hardware, software) at the center level to provide consistent data & at the regional level to analyze the data and provide timely technical assistance to the centers; (2) clear goals; (3) dedicated, focused, & expert leadership. Supported in part by grant MCJ-191002, Great Plains Genetics Service Network.

Program Nr: 1172 from the 1999 ASHG Annual Meeting

Palm-print on a sticker as a replacement of the blood for the DNA tests. *Y. Chung, C. Hwang, E. Kim.* I. D. Gene, Inc, Seoul, Korea.

DNA is omnipresent as far as cells could be traced. However, most of DNA samples are obtained from the blood for routine analysis. Blood-drawing is painful, potentially prone to infection, and requires special legal obligations for handling. We developed the skin as an alternative source of DNA for routine DNA tests. Examinees leave palm-prints on a sticker. From only a tenth of a square inch of the palm-print, we were able to obtain enough DNA for the DNA profiling using multiplex PCR systems. DNA extracted from the sticker showed exactly the same sequence as that obtained from the blood for the examined genetic regions including D8S306, TH01 and ACE gene. The DNA profiles for 13 STR loci matched exactly those of the blood DNA in 25 examined human samples. The palm-print DNA was successfully applied for paternity determination for over 30 cases during the past several months in our company. The examinees just made palm-prints on the delivered sticker and returned them to the laboratory like any ordinary letter. The DNA on the sticker was very stable that we could not detect any differences at least from a 9-month-old DNA. Furthermore, the fingerprint left on the sticker could be visualized by staining with crystal violet and identified the source of the DNA eliminating the need for the witness for the sample collection. The palm-print DNA on a sticker could be a convenient medium for most kinds of routine DNA tests and for academic research as well as for the DNA banks.

Program Nr: 1173 from the 1999 ASHG Annual Meeting

Identification of a new CFTR gene deletion by a real-time quantitative PCR method. *B. Costes[1], E. Girodon-Boulandet[1], D. Vidaud[2], E. Flori[3], P. Conteville[1], P. Fanen[1], F. Niel[1], M. Vidaud[2], M. Goossens[1]*. 1) INSERM U468, Hopital Henri-Mondor, Creteil, France; 2) Laboratoire de Genetique Moleculaire, Faculte de Pharmacie, Paris, France; 3) Service de Cytogenetique, Hopital de Hautepierre, Strasbourg, France.

We describe a novel CFTR gene deletion identified by an original approach of quantitative PCR using real-time detection, in a fetus from a turkish consanguineous couple, who presented with an hyperechogenic bowel. The use of the CF-OLA kit (PE-Biosystems), detecting 31 mutations, led us to suspect a deletion at the homozygous state in the fetus. A deletion of exon 19 was confirmed by quantitative PCR making use of the fluorescent TaqMan methodology (PE-Biosystems). The parents decided to continue the pregnancy despite the probable diagnosis of CF, which was confirmed after birth on the basis of positive sweat tests. RT-PCR analysis of CFTR mRNA of placental cells exhibited a shorter transcript than the wild type, corresponding to an in frame deletion of exon 19. Long range PCR experiments and subsequent direct sequencing showed a 5.3kb deletion removing exon 19, termed 3600+15kb del5.3kb (del19), with a direct AACT motif at the breakpoints. Immunoprecipitation experiments performed with the mutant transiently expressed in HeLa cells revealed a non matured 140 kDa form, whereas the wild-type CFTR exhibited a fully processed 170 kDa form. The mutant protein is thus predicted to be not expressed at the apical membrane of epithelial cells, accounting for the CF phenotype. Prenatal diagnosis is now possible for future pregnancies of the couple, if requested, as well as carrier testing in the family. This case illustrates the power of the real-time quantitative PCR approach in the rapid diagnosis of CF. This methodology should be offered as a new molecular tool in diagnosis of CFTR deletions.

Program Nr: 1174 from the 1999 ASHG Annual Meeting

Preliminary studies before systematic screening of hemochromatosis : prevalence and penetrance of C282Y homozygosity. *V. David[1], R. Moirand[2], CNAM St Brieuc[3], CNAM Rennes[4], CNAM St Nazaire[5], J.Y. Le Gall[1], Y. Deugnier[2], A.M. Jouanolle[1]*. 1) Fac de Medicine, UPR 41 CNRS, Rennes, Cedex, France; 2) Clinique des maladies du foie, CHU Pontchaillou, Rennes, France; 3) CNAM St Brieuc, France; 4) CNAM Rennes, France; 5) CNAM St Nazaire, France.

Hemochromatosis is considered as one of the most frequent inherited disorders in Caucasians and its systematic screening may be advocated. In Northern Europe, because most cases of hemochromatosis are related to homozygosity for the C282Y mutation on the HFE gene, genetic testing might be proposed for this general screening. However, before launching such a program in general population, it is mandatory to assess the prevalence and the penetrance of C282Y homozygosity. We tested the C282Y mutation frequency in a cohort of 1000 newborns from maternity hospitals in 4 different parts of Brittany. The homozygote frequency was 5/1000 and heterozygote frequency was 12%, which corresponds to higher frequencies than that expected from previous phenotypic studies. Moreover we are achieving a large survey of 10.000 subjects (men aged from 25 to 40 years and women aged from 35 to 50 years) from 3 different Breton health care centers. C282Y testing is performed in all subjects, and serum iron indexes (serum iron, transferrin saturation TS and ferritin) are measured in the first thousand people tested and in all subjects detected as C282Y homozygotes. Based upon wild C282Y homozygotes, upper normal of values have been calculated for serum iron indexes. Among the first 3017 subjects tested, 443 were found heterozygotes (14.7%), and 18 homozygotes for C282Y. All men had increased iron indexes (TS 50-92%) consistent with hemochromatosis. 6 out of the 12 women presented with elevated TS (49-98%) and the others had no phenotypic expression of the disease in the absence of pathological blood loss. Phenotypic expression was not relevant to age or genital status. These preliminary results (i) confirm the high frequency of genetically defined hemochromatosis (C282Y homozygosity), and (ii) suggest that the penetrance of the C282Y mutation is incomplete and modulated by either environmental or additional genetic factors.

Program Nr: 1175 from the 1999 ASHG Annual Meeting

Follow-up of mexican patients with genetic diseases at the National Institute of Pediatrics. *V. del Castillo, N. Urraca, C. Esmer.* Resarch Department of Human Genetics, Instituto Nacional Pediatria, SSA, DF, Mexico.

Children with genetic diseases must be followed-up by long periods of time in order to watch for new findings or just waiting to be diagnosed. Some of them do not return to receive medical attention which may have serious consequences. We analyze the patients' attendance to the genetic consultation, investigate some of the causes of stop seeking advice and determine the differences between those seeing for the first time at the office and those seeing while being hospitalized. Four hundred records were evaluated from 1992 and 1996. Our results show a mean follow-up period of 8.3 months (range 0-79) and the average of times on consultation was 2.8 times (range 1-16). Forty-eight percent of hospitalized patients were evaluated only once and 14%, twice. Of the 300 children analyzed from the outpatient consultation, 22% and 21% attended once and twice respectively, showing significant differences between hospitalized versus office patients (p=0.00). The patient's diagnosed status didn't affect the follow-up. 97 patients were discharged, 7 died, 55 continued being followed by us, 62 attended to other services at the hospital but not ours and 179 didn't assist at all. Diagnosed patients received genetic counseling more frequently than undiagnosed patients did (62% vs 5%). On the diagnosed group genetic advice was given to 65% and 78% of the office patients in 1992 and 1996 respectively (Not significant); 23% and 50% of the hospitalized patients on the same years (p=0.04), and the differences between this two groups were significant (p=0.005). We conclude that keeping the genetic patient on follow-up is a difficult task, sometimes before receiving genetic advice. New educational strategies must be planned to avoid this worrisome situation.

Program Nr: 1176 from the 1999 ASHG Annual Meeting

Microsatellite DNA Analysis Using High Performance Liquid Chromatography. *J.M. Devaney[1], J.E. Girard[2], M.A. Marino[1]*. 1) Transgenomic, Inc., Gaithersburg, MD 20878; 2) American University, NW Washington, DC 20016.

The genetic uniqueness of individuals is a central tenet of human biology. One method to examine the uniqueness of an individual is the use of microsatellite or short tandem repeat (STR) length polymorphisms. STRs are tandemly repeated units of sequence ranging between 2 and 7 basepairs in length that have high levels of heterozygosity, distinguishable alleles that are length polymorphic as a result of the number of repeating units, and are amplified using the PCR reaction. STR systems are useful for disease diagnostics (Fragile X, Huntingtons disease), paternity testing, physical and genetic mapping, cancer detection, and forensics. The human genome has an abundance of these sequence occurrences averaging one tri- or tetra- nucleotide repeat unit every 15 kb. Analysis of STRs using slab gel electrophoresis requires lengthy and labor-intensive procedures. An alternative to electrophoresis is ion-pair reverse-phase high performance liquid chromatography (IP-RP HPLC). The WAVE Nucleic Acid Fragment Platform (Transgenomic, Inc.) employs IP-RP HPLC, which has been shown to give strict and reproducible size-based separation of DNA fragments up to 2,000 bp when run in a non-denaturing mode. The system is also automated, which allows for unattended analysis of 96 samples directly from the PCR plate. Another distinct advantage of IP-RP HPLC is that resolved products can be collected for subsequent analyses such as sequencing. The following discussion describes the use of WAVE technology in the separation, sizing, and typing of alleles from the locus HUMTHO1 located in intron 1 of the human tyrosine gene with a chromosomal position of 11p15-15.5. The alleles were sized in their native state (double stranded). The repeating unit of HUMTHO1 is (AATG) and the alleles are numbered according to the number of tandem repeats present in the PCR-amplified products. This non-electrophoresis platform discriminated the six alleles of THO1 with a resolution greater than 3. This locus is widely used in forensic and parentage assessment cases, therefore it serves as a great model for microsatellite sizing and typing.

Program Nr: 1177 from the 1999 ASHG Annual Meeting

Development & validation of ELUCIGENE™ reagents for CF screening. *E. Docter, A.J. Gladwin, S.L. Weston, N.H. Robertson, S. Little.* AstraZeneca Diagnostics, Northwich, Cheshire, UK.

Screening for cystic fibrosis is becoming more widespread and there is a need for a cost-effective method which can reliably detect many mutations. Here we report on the development and validation of multiplex ARMS™ allele specific amplification reagents which combined detect 20 CFTR mutations selected on the basis of their reported prevalence in the Caucasian European population. The primary application of these reagents is screening for individuals who may be carriers of one of the following mutations: 1717-1G>A, G542X, W1282X, N1303K, DF508, 3849+10kb C>T, 621+1G>T, R553X, G551D, R117H, R1162X, R334W, A455E, 2183AA>G, 3659delC, 1078delT, DI507, R347P, S1251N and E60X. In addition these reagents generate genotype information for the most common mutation, DF508, thus making the test highly valuable in both disease diagnosis and screening applications.

Genomic DNA is added to 3 tube multiplex reactions, amplified by PCR and resultant reaction products separated by agarose gel electrophoresis. Detection is based on the presence or absence of a diagnostic band of a defined size indicating whether or not a particular mutation is present in the sample. This rapid and simple procedure, which requires minimal equipment, can be carried out in less than one day and in contrast to alternative methods requires no subsequent manipulation after amplification other than gel loading. The reagents were validated on a panel of over 250 previously typed samples, including clinical samples collected and extracted by a variety of different methods and was shown to be completely reliable.

Program Nr: 1178 from the 1999 ASHG Annual Meeting

BRCA testing among non-geneticist physicians: Level of knowledge and the extent to which they are discussing and ordering testing. *T. Doksum[1], N.A. Holtzman[2], B.A. Bernhardt[2]*. 1) Abt Associates Inc., Cambridge, MA; 2) Johns Hopkins Medical Institutions, Baltimore, MD.

As part of a 1998 study to assess the diffusion of genetic testing among non-geneticist physicians, we surveyed 2,250 oncologists, Ob-Gyns and internists about 1) their knowledge about BRCA testing and 2) whether or not they had ever discussed and/or ordered BRCA testing. We hypothesized that physicians who had discussed or ordered the test would be more knowledgeable compared to those who had not. The overall response rate to the mail questionnaire was 40%. Only 13% of internists, 21% of Ob-Gyns, and 40% of oncologists were able to correctly answer all four basic knowledge questions. The majority of oncologists (84%) and Ob-Gyns (72%) but only one-fourth of internists (28%) reported that they had ever discussed BRCA testing with any patient. Few respondents had ever ordered a BRCA test, and usually did so through a genetics professional (29% of oncologists, 15% of Ob-Gyns, 10% of internists) rather than directly from a laboratory (15% of oncologists, 6% of Ob-Gyns, 1% of internists). Among oncologists, knowledge was significantly higher among those who had ever discussed the test ($p<.01$) or ordered the test either directly or indirectly ($p<.01$) compared to those who had not. Among Ob-Gyns and internists, knowledge was not significantly associated with having discussed or ordered the test. These findings suggest that, despite low levels of knowledge about BRCA testing, many non-geneticist physicians have discussed testing for breast cancer susceptibility and some have directly ordered testing.

Program Nr: 1179 from the 1999 ASHG Annual Meeting

Genetic Evaluation of Male Factor Infertility. *T.M. Dunn[1], M.M. McGovern[1,2], N. Bar-Chama[3], N.B. Kardon[1,2].* 1) Dept Human Genetics, Mount Sinai Medical Ctr, New York, NY; 2) Dept Pediatrics, Mount Sinai Medical Center, New York, NY; 3) Dept Urology, Mount Sinai Medical Center, New York, NY.

The evaluation of couples with primary infertility has revealed that male factors are present in 50% of cases. With the widespread availability of Assisted Reproductive Techniques, it has become extremely important to evaluate males for genetic etiologies of infertility including chromosome abnormalities, Y chromosome microdeletions, and single gene disorders. Our center began a formal comprehensive male factor infertility genetic evaluation program in July 1997 which includes genetic consultation and pedigree analysis, routine chromosome analysis, PCR screening for Y chromosome microdeletions, and cystic fibrosis (CFTR) mutation analysis, including the 5T variant. To date we have evaluated 100 patients who presented with either azospermia or oligospermia. The results of the genetic laboratory tests identified 4 patients with chromosome abnormalities, three patients with Y-chromosome deletions, two patients homozygous for 2 different cystic fibrosis mutations, and five patients heterozygous for one cystic fibrosis mutation. Pedigree analysis identified one patient with Kallmann syndrome and another patient heterozygous for Spinal Muscular Atrophy, Type 1. Overall, a genetic etiology for male infertility was identified in 16% of men studied. Since the most common abnormality detected in our population was a cystic fibrosis mutation, it's extremely important to screen partners to assess reproduction risk before considering newer reproduction options, ie. ICSI, in order to provide prenatal diagnosis options. The risk of transmitting the Y chromosome microdeletions to male offspring is also an issue that should be considered by couples considering ICSI. Based on the high rate of genetic etiologies detected in our series we recommend that male factor infertility patients have a complete genetic evaluation including pedigree analysis, a specific CFTR panel, chromosome analysis and PCR screening for Y chromosome microdeletions. Follow-up genetic counseling of all patients found to have a genetic etiology is also necessary to ensure that appropriate screening of partners is achieved.

Program Nr: 1180 from the 1999 ASHG Annual Meeting

Clinical diagnostic testing for Presenilin-1 (PS-1) gene mutations and diagnosis of early-onset familial Alzheimer's disease (EOFAD). *K.C. Fafel[1], U.A. Ananth[1], J.G. Jones[1], J. Elles[1], S.K. Allen[1], Y. Liang[2], Y-Q. Song[2], P. St. George-Hyslop[2], W.K. Seltzer[1], M.A. Boss[1]*. 1) Athena Diagnostics, Inc., Worcester, MA; 2) Centre for Research in Neurodegenerative Diseases, Toronto, Ontario.

The PS-1 gene on chromosome 14 is known to be the major gene for autosomal dominant early-onset familial Alzheimer's disease (EOFAD). Studies have shown that a variety of PS-1 mutations distributed throughout the gene are responsible for an estimated 30-50% of EOFAD. Clinical diagnostic testing for PS-1 gene mutations at Athena employs a sequencing strategy utilizing genomic DNA as template for exon 4 and cDNA for exons 5 through 13. Mutation identification in the entire coding region of the PS-1 gene (1,404bp) is carried out by sequencing in both the forward and reverse directions. RNA and DNA specimens analyzed from 242 patients detected 20 different mutations in 34 individuals. The previously reported Glu318Gly polymorphism was found in eight additional patients. Mutations identified consisted of 18 missense (17 heterozygous and 1 homozygous), one 6bp insertion and one deletion, distributed in exons 5, 6, 7, 8, 9, 10 and 13. Neither the insertion nor the exon 10 deletion mutation disrupted the reading frame of the protein. The overall positive rate of the PS-1 test was 14% with previously unreported mutations accounting for 70% of total mutations detected. Three of the previously unreported missense mutations were found to reoccur in apparently unrelated families. Interestingly, we identified individuals with two missense mutations in siblings from a single family. No nonsense or synonymous codon mutations have been detected to date. The median age of PS-1 mutation positive patients at time of testing was 44 years (range 31 to 65 years) with the exception of one symptomatic individual who was 78. Thirty three out of the 34 positive patients referred for PS-1 mutation analysis were reported to be symptomatic at time of testing. Our experience with clinical diagnostic testing for PS-1 mutations indicates that a substantial proportion of individuals presenting with EOFAD possess identifiable mutations leading to confirmation of disease diagnosis.

Program Nr: 1181 from the 1999 ASHG Annual Meeting

Fragile X syndrome: Population carrier screening and implication for prenatal diagnosis. *T.C. Falik-Zaccai[1], E. Shachak[1], Z. Borochowitz[1], N. Magal[2], S. Zatz[2], M. Shochat[2], H. Ziv[3], R. Navon[3], C. Ligum[4], R. Shomrat[4].* 1) Simon Winter Inst Human Gen, Bnai-Zion Med Ctr Haifa, Israel; 2) Genet. Inst. Shnieder Med Cent Petach Tikva, Israel; 3) Meir Med Cent Kfar Sava, Israel; 4) Genet. Inst. Soraski Med Cent Tel Aviv, Israel.

Fragile X syndrome (Fra) is a common cause of learning disability and mental retardation (MR). Identification of women carriers of the common premutation or full mutation in the FMR1 gene is mandatory for accurate genetic counseling and prenatal diagnosis. We have conducted a screening program between 1992 and 1997 for the detection of women carriers of the Fra. Women were offered testing on a self pay basis during routine prenatal visits or were referred by their physician, nurses or friends. 9426 healthy women with no family history of MR or learning disability requested the testing as well as 404 women with a family history of undefined MR. Screening was performed by Southern blotting for the presence of premutation or full mutation alleles followed by confirmation of their size by PCR when possible. We have found 111 women carriers of alleles of more then 52 CGG repeats among the group of women with no family history of MR, a prevalence of 1/85. Three full mutation alleles were identified in this group, a prevalence of 1/3145. Among the group with positive family history of MR 7 premutation alleles and 1 full mutation allele were found, a prevalence of 1/58 and 1/404 respectively. The identified carriers were offered genetic counseling and prenatal diagnosis. All carriers elected to perform prenatal diagnosis. Expansion of the CGG repeat size in the fetuses was documented for alleles of 49 repeats and above. Expansion of CGG repeat size to a full mutation was documented for alleles greater then 70 repeats only. These results indicate that the prevalence of carriers of Fra is high in Israel and a comprehensive national screening program should be considered. The DNA testing for carrier status was accepted by most women approached and requests for such testing are more common todate. When accompanied by genetic counseling and prenatal diagnosis it has established an important addition to current medical practice.

Program Nr: 1182 from the 1999 ASHG Annual Meeting

Discrimination of Diagnostic Criteria for Testing for BRCA1/2. *M.H. Fries[1], C. Holt[2], I. Carpenter[1], L. Martin[2], R. Hume[2], J. Flanagan[1], J. Daniels[2], G. Hudson[1], M. Cadman[1], R. Weatherly[1], M.E. Nunes[1]*. 1) Air Force Medical Genetics Cen, Keesler Medical Center , Keesler AFB,MS; 2) Madigan Army Medical Center, Ft. Lewis, WA.

The DOD Familial Breast/Ovarian Cancer Research Project has offered genetic counseling and testing for BRCA1/2 mutations on a research basis to patients who meet specific diagnostic criteria: patients with breast/ovarian cancer with 1) a family history of two or more 1st or 2nd degree relatives with breast cancer only *or* breast/ovarian cancer; 2) a 1st or 2nd degree relative with diagnosis of breast/ovarian cancer <45; 3)breast/ovarian cancer diagnosed <45; 4)bilateral breast cancer or other primary cancers; as well as 5)male patients with breast cancer; *and* 6)unaffected patients with a family member with a known BRCA1/2 mutation. Risk for BRCA1 mutation was calculated using the Couch model. 101 patients met criteria, including 33 who met criteria in more than one category (personal age of onset of cancer <45 + strong family history; personal age of onset of cancer <45 + other primary cancers; personal history of cancer and family history of 2 or more 1st/2nd degree relatives with onset of disease <45, and history of bilateral disease and/or multiple primaries + strong family history). 90 patients chose to test. In this group, mutations were found in 14 patients(15.5%) and unclassified variants identified in 20 (22.2%). When criteria were compared, the most common indications for testing were onset of breast/ovarian cancer<45 (n=32) and onset of breast/ovarian cancer <45 + strong family history (n=21). However, when the number of mutations and unclassified variants were compared separately across all diagnostic criteria (including those with more than one category) using c^2test, no significant differences were seen among the categories to suggest that one criteria was more predictive of mutations or variants than another. Couch values for patients with mutations ranged from 3.2% to 43.5% (range for all patients:1.2% to 69.7%). These findings emphasize the importance of using multiple diagnostic criteria plus Couch risk values of >3% as possible managed care guidelines for patient testing.

Program Nr: 1183 from the 1999 ASHG Annual Meeting

Informative molecular analyses for over 90% of hemophilia A families by direct mutation detection. *F.K. Fujimura, C.Y. Wen, C. Buzin, V.Q. Nguyen, W. Li, S.S. Sommer.* City of Hope National Medical Center, Duarte, CA.

Identification of causative mutations within the factor VIII gene is critical for accurate evaluation of carrier status of at-risk females and for prenatal diagnosis in hemophilia A families. Our analysis of over 200 hemophilia A families resulted in detection of factor VIII gene sequence alterations in over 90% of these families. Initially, analysis is performed on a DNA sample from an affected individual or, if an affected individual is not available, from an obligate carrier. All samples from severe hemophilia A families are tested by a novel amplification method for the factor VIII gene inversion. These inversions are detected in about half of the cases of severe hemophilia A. Samples not having a factor VIII gene inversion are scanned for mutations, either by direct DNA sequence analysis or by rapid mutation scanning methods that permit cost-effective scanning of all 26 exons plus the associated splice junctions of the factor VIII gene. In a prospective analysis of 88 DNA samples we have shown that our mutation scanning method is as sensitive as DNA sequencing for detection of mutations in the factor VIII gene. Furthermore, mutation scanning has several advantages over full gene sequence analysis including higher throughput and lower costs. The samples not having detectable mutations may have factor VIII gene mutations located outside of the analyzed regions of the gene, may have mutations in the factor VIII binding site of the von Willebrand factor gene, or may be due to misdiagnosis. To date, we have not detected any von Willebrand Normandy mutations in samples from 18 hemophilia A families not having detectable mutations in the factor VIII gene. This tiered analysis starting with factor VIII gene inversion analysis, followed by mutation scanning of all exons and intron junctions of the factor VIII gene and, if necessary, analysis of von Willebrand factor Normandy mutations, permits detection of putatively causative mutations in at least 90% of these families. Appropriate individuals in these families with identifiable mutations, in turn, can be offered very accurate carrier analysis and prenatal diagnosis.

Program Nr: 1184 from the 1999 ASHG Annual Meeting

Autosomal recessive LGMDs in Spanish families: the mutational spectrum. *P. Gallano[1], A. Lasa[1], A. Saenz[2], C. de Diego[1], A. Cobo[2], E. del Rio[1], M. Urtasun[2], M.J. Rodriguez[1], E. Gallardo[1], J.J Poza[2], F. Garcia Bragado[3], I. Illa[1], A. Lopez de Munain[2], M. Baiget[2]*. 1) Hospital Sant Pau, Barcelona, Spain; 2) Hospital Ntra. Sra. de Aranzazu, San Sebastian, Spain; 3) Hospital Virgen del Camino, Pamplona, Spain.

Autosomal recessive limb girdle muscular dystrophy (LGMD2) is a clinically and genetically heterogeneous group of diseases characterised by progressive proximal limb muscle weakness. Seven different loci have been mapped and six genes have been identified: calpain 3 at LGMD2A (15q15), dysferlin at LGMD2B (2p12), four components of the sarcoglycan (SG) complex: -SG at LGMD2D (17q21), -SG at LGMD2E (4q12), -SG at LGMD2C (13q12) and -SG at LGMD2F (5q33). The gene product at LGMD2G (17q11) is still unknown. We have studied 182 families with a muscular dystrophy history from all over Spain in which a dystrophinopathy was excluded by genetic and immunochemical/Western blot tests. The immunochemical analysis with -, -, - and -SG antibodies allowed us to distinguish between sarcoglycanopathies and the other forms of LGMD2. The molecular studies were based on: 1) The identification of point mutations by SSCP analysis and sequencing, 2) Linkage analysis using different microsatellites markers. We have diagnosed 115 families: 79 LGMD2A, 2 LGMD2B, 23 LGMD2C, 8 LGMD2D and 3 LGMD2E. In the sarcoglycanopathies the observed phenotype varied from severe (DMD-like) to moderate with mutations spreading all over the SG genes. The C283Y mutation in the -SG gene was observed exclusivelly in the Gypsy population and was always associated with a severe phenotype. In the LGMD2A families a recurrent mutation in exon 22 (2362AG->TCATCT) of the CAPN3 gene was found in the Basque population associated with the classical phenotype described by Fardeau et al. The remaining mutations were distributed all over the gene and were associated to different degrees of phenotypic variability. The clinical and immunochemical studies do not allow to perform an accurate diagnosis of LGMDs. Molecular studies are the most reliable tool in order to classify each of the different entities.

Program Nr: 1185 from the 1999 ASHG Annual Meeting

Factors Influencing Decisions to Decline Cancer Genetic Counseling Services. *K.P. Geer[1], W.F. Cohn[2], M.E. Ropka[2], S.M. Jones[3], S. Miesfeldt[4].* 1) Virginia Kincaid Fellow, Division of Surgical Oncology, University of Virginia Health Sciences Center (UVA-HSC), Charlottesville, VA; 2) Department of Health Evaluation Sciences, UVA-HSC, Charlottesville, VA; 3) Cancer Center, UVA-HSC, Charlottesville, VA; 4) Division of Hematology/Oncology, UVA-HSC, Charlottesville, VA.

Introduction: Genetic counseling services continue to develop nationwide to provide risk assessment and management strategies to individuals at risk for inherited cancer predisposition. Despite a plethora of research on factors influencing choices related to genetic testing for cancer risk, limited data have been published on psychosocial and economic issues that lead individuals to decline cancer genetic counseling services. **Purpose:** To identify potential barriers to broad utilization of cancer genetic counseling services. **Methods:** Using a cross-sectional design, 77 subjects were randomly selected from 117 individuals who declined cancer genetics evaluation in our institution between May 1995-October 1998. Of the 54 individuals contacted, 37 (69%) participated in a semi-structured telephone interview. **Results:** Of the participants, 19 (53%) were college graduates; 34 (92%) were female; 36 (100%) were Caucasian; and 26 (72%) were between 36-55 years. Median income was $40,000-59,000. Twenty-four (65%) had only a family history of cancer; 13 (35%) had a combined family and personal history of cancer. Responses to the question, "Why did you decide not to have the cancer genetics evaluation?", were: *potential impact on insurability for self or family* (15); *cost* (12); *emotional impact on self or family* (11); *no perceived benefit* (11); *time involved* (9); *difficulty collecting family history* (4); *other* (17). **Conclusion:** To address barriers to utilization of cancer genetic counseling services, the following changes in policy and practice are recommended: legislation to protect individuals with genetic risk for cancer from insurance discrimination; coverage of cancer genetics evaluations by third party payors; individualized emotional support throughout the decision-making process; education on potential benefits for the individual and family members; and development of strategies to streamline the genetic evaluation process.

Program Nr: 1186 from the 1999 ASHG Annual Meeting

Single tube genotyping of the Apolipoprotein E gene by ARMS™ allele specific amplification. *A.J. Gladwin, S.L. Weston, N.H. Robertson, S. Little.* AstraZeneca Diagnostics, Northwich, Cheshire, UK.

Elevated levels of cholesterol, lipids and lipoproteins are known to increase the risk of atherosclerosis and coronary artery disease in humans. Apolipoprotein E (Apo E), an important component in lipoprotein metabolism, serves as a ligand for the uptake of lipoproteins from the circulation by the liver. It is also expressed in the nervous system in astrocytes. In the general population, Apo E can be present as three isoforms: Apo E2, E3 and E4. Homozygosity for the E2 genotype (E2/E2) is associated with type III hyperlipidemia.

We have developed a single-tube multiplex ARMS™ allele specific amplification test, which simultaneously genotypes for E2, E3 and E4 variants. Genomic DNA is added to a reaction tube and the Apo E genotypes are differentiated by *ARMS*, with subsequent analysis by standard agarose gel electrophoresis. The presence of diagnostic product bands of defined sizes indicate Apo E status. The test has been validated on a large panel of samples and has been shown to be very reliable. The procedure is more simple and rapid than conventional RFLP and PAGE analysis and results are typically available within 1/2 working day.

.

Program Nr: 1187 from the 1999 ASHG Annual Meeting

Utility of ELUCIGENE™ MCAD reagent for detection of the 985A>G mutation of the medium chain acyl CoA dehydrogenase gene in neonatal bloodspot samples. *D. Halsall[1], J. Calvin[1], T. Elsey[1], A.F. Heeley[2], G. Ellison[3], N.H. Robertson[3].* 1) Department of Clinical Biochemistry, Addenbrooke's Hospital, Cambridge, UK; 2) Biochemical Genetic Diagnostic Unit, Peterborough District Hospital, Peterborough, UK; 3) AstraZeneca Diagnostics, Gadbrook Park, Northwich, UK.

Medium chain acyl CoA dehydrogenase deficiency (McKusick 201450) is the most common inherited defect of fatty acid metabolism. A point mutation (985A>G) accounts for approximately 90% of the disease-causing mutant genes in this condition (Yokota *et al.* Am J Hum Genet (1991) 49:1280-1290). This potentially fatal condition is amenable to treatment and thus is a candidate for neonatal screening. A test for use in these circumstances must be cost-effective, reliable, robust and suitable for the analysis of blood spot samples. We report on the utility of the ELUCIGENE™ MCAD reagent for detection of the 985A>G mutation. The test method is based on ARMS™ allele specific amplification. A cohort of 500 blood spots collected for routine biochemical screening in East Anglia was analysed. Genomic DNA prepared from the blood spot samples by ethanol extraction was added to reaction mix comprising ELUCIGENE™ reagent, followed by PCR and subsequent analysis of the amplification products by agarose gel electrophoresis. Interpretation of results was achieved by absence or presence of amplification products of a defined size. All steps were performed in a 96 well plate format to allow semi-automation of the process. The frequency of the 985A>G mutation was determined in this cohort to be 1:125 (95% confidence limit 1 in 49 to 1 in 458, Poisson distribution) and no homozygotes were detected. This frequency is similar to values contained in other UK regions (Seddon *et al.* Lancet (1995) 345:135-136).

Program Nr: 1188 from the 1999 ASHG Annual Meeting

Continuing care for genetic patients in 9 European centres. *H.J. Harris, V. Baranov, C. Bartsocas, J. Burn, K. Challen, J-P. Fryns, E. Ginter, R. Harris, I. Nippert, R. Salonen, J. Schmidtke, LP. Ten Kate.* Genetic Enquiry Centre, St Marys Hosp, Manchester.

Patients often need contining and coordinated care when they have genetic disorders affecting several systems and generations. Genetic service providers might be expected to recontact patients with news of advances in diagnosis and treatment and to ensure that relatives are aware of their inherited risk and screening and preventive options. However poor coordination of care is frequently cited by genetic patient organizations as a cause for concern. In our study the need for continuing care was reported in 857 (48%) of 1794 patients referred consecutively to 9 medical genetics centers in 7 European countries. One or more of the following were expected to provide continuing care: clinical geneticist 47.4%, obstetrician 31.9%, pediatrician 25.7%, GP 13.4%, surgeon 12.2% and "other" 30.5%. The clinical geneticist offered continuing care significantly more often when the diagnosis remained uncertain. Written reports were sent to patients (86.3%), referrer (77.4%) and GP (40.2%); the proportions did not differ significantly whether continuing care was needed or not. The need to contact the patient's family was reported in 312 (17%) overall but in 128 (66.6%) of 192 cases of hereditary cancer (breast, ovary, bowel, MEN). 84.4% of patients referred because of hereditary cancer agreed to have their families contacted (when relevant), 99% of patients made the first contact but only 17.7% had assistance from professionals. 42.4% hereditary cancers were detailed on genetic registers. In 97% of all cases collaborators reported that "all continuing care needs will be provided" but in the absence of a recall and recontact system it is difficult to assess the quality of continuing care after completion of the specialist geneticist episode. Resource limitations, ethical problems and wide variations in national health care systems have been shown to affect implementation (Concerted Action on Genetic Services in Europe, CAGSE).

Program Nr: 1189 from the 1999 ASHG Annual Meeting

Hereditary cancer referrals to genetic centres. *R. Harris, V. Baranov, C. Bartsocas, J. Burn, K. Challen, J-P. Fryns, E. Ginter, HJ. Harris, I. Nippert, R. Salonen, J. Schmidtke, LP. Ten Kate.* Genetic Enquiry Centre, St Marys Hosp, Manchester.

By late 1998 hereditary cancer accounted for 192 of 1794 (10.7%) consecutive referrals to 9 medical genetics centres in 7 European countries, making it the second commonest reason for referral after PND. Some centres had much higher frequencies (up to 35.4%), perhaps because of their special interests and the specialty of referrers. For example 12/13 (93.3%) referrals from oncologists concerned hereditary cancer and comparable figures from other specialists were surgeons 22/50 (44%) and gynaecologists 10/25 (40%), compared with obstetricians who showed the lowest frequency of such referrals, 12/516 (2%). But the greatest *absolute* number of referrals for hereditary cancer, 60 of 192 hereditary cancer referrals (31%) came from GP even though only 212/1794 (11.8%) of all referrals were from GP. The overall pattern of referral from GP differed very significantly from other referral sources ($P<0.001$). Genetic services need to adapt to molecular advances and to increasing public awareness in ways which are appropriate to the type of health care system of the country. Where GP acts as gatekeeper controlling access to specialists it appears that a higher proportion of high-profile genetic disorders will be referred directly to genetic clinics. In other countries primary care is provided by specialists who may feel more confident to deal themselves with hereditary variants of diseases in their specialty, although earlier studies by UK National Confidential Enquiry into Counselling by Non-geneticists were not completely reassuring on this point. The present study is continuing by assessing all 1794 referrals to the nine European centres including the quality of referrals and of continuing care in different specialties.

Program Nr: 1190 from the 1999 ASHG Annual Meeting

Sex determination of fetus by polymerase chain reaction using maternal plasma and serum. *H. Honda, N. Miharu, Y. Ohashi, N. Honda, K. Ohama.* Dept Obstetrics & Gynecology, Hiroshima Univ. School of Med., Hiroshima, Japan.

In order to assess the possibility of the fetal sex determination using maternal plasma and serum, detection of Y chromosome specific sequences was performed with polymerase chain reaction (PCR). Peripheral blood samples were obtained from 52 pregnant women at 10-17 gestationals' weeks prior to amniocentesis. For plasma separation, 4ml of each blood sample was collected into EDTA-containing tubes for plasma separation, and 6 ml of each blood sample was collected into EDTA-free tubes for serum separation. DNA was extracted from 0.8 ml of each plasma or serum with QIAamp blood kit. To detect Y chromosome specific sequences, DYS14 and DYZ3, 40 cycles of PCR was carried out with each DNA solution. The PCR products of DYS14 and DYZ3 are 198 bp and 175 bp, respectively, and they were analyzed by 2.5% agarose-gel electrophoresis and ethidium-bromide staining. The PCR results were compared to cytogenetic analyses of amniocentesis. Cytogenetic analysis of amniocentesis revealed that 27 pregnant women had a male fetus and the remaining 25 pregnant women had a female fetus. Both DYS14 and DYZ3 sequences were detected in plasma samples obtained from 23 of 27 pregnant women having a male fetus, while both DYS14 and DYZ3 sequences were detected in all serum samples obtained from 27 pregnant women having a male fetus. Neither DYS14 and DYZ3 sequences were detected from both plasma and serum samples obtained from all the 25 pregnant women having a female fetus.These data indicates that it is possible to determine fetal sex by PCR using maternal serum, and maternal serum and plasma would be useful and powerful materials for prenatal diagnosis in the future.

Program Nr: 1191 from the 1999 ASHG Annual Meeting

Does China needs its own Down's screening strategy? *X. Hou[1], F. Song[1], L. Zhang[1], G. Feng[1], B. Qi[1], J. Han[2]*. 1) Laboratory of Medical Genetics, ShenYang Maternal Child Care Hospital, Liaoning, P.R. China; 2) Genaco Biomedical Products, Inc. USA.

China's family planning program is undertaking a major change. After about 20 years of strict population control, the government is now beginning to focus on promoting prenatal genetic services. There are over 20 million newborns a year in China, however, virtually no prenatal screening service is available for such common diseases as Down syndrome. During the past year, we have established the first large-scale prenatal Down screening and diagnostic program in China. ELISA kits were used for quantitatively measuring maternal serum levels of AFP and hCG. A computer program (Chinese version) was used for risk factor calculations. At risk pregnancies (about 5%) underwent amniocentesis and diagnoses were made by both cytogenetic and molecular genetic analyses. Here, we would like to discuss a strategic issue, i.e., in China, should we change the cut-off value and let more patients undergo amniocentesis to improve Down's detection rate? Currently, patients with risk factors over 1/300 are invited for amniocentesis. Using this cut-off value, about 5% pregnancies will be recognized as "at risk". If all at risk pregnancies elected amniocentesis, about 65% of Down's could be detected. If the cut-off value is changed to 1/500, about 12% pregnancies may require amniocentesis and more than 80% of Down's can be detected. We propose to change the cut-off value based on the following considerations: (1) China still has the "one baby per couple" family planning policy in place. Under this circumstance, patients are more concerned about the "quality" of the baby and therefore, the perceived risk for amniocentesis associated miscarriages is lower. (2) A simple, fast, and cheaper molecular method is used for Down's diagnosis. This method made the prenatal diagnosis more affordable and less labor intensive. Although different social and economical backgrounds may present arguments for making changes in screening strategies, more careful and scientific studies are needed to support such modifications.

Program Nr: 1192 from the 1999 ASHG Annual Meeting

Screening of single nucleotide sequence changes using hairpin-shaped and fluorescently labeled probes. *X. Hu, L. Chen, S. Soares, J. Sorge.* Stratagene Inc, La Jolla, CA.

Single nucleotide sequence changes are the largest source of human DNA sequence diversity and contribute to the development of multifactorial as well as monogenic diseases. The demand is growing for high-throughput methodologies that are sensitive enough to distinguish nucleic acid sequences differing by as few as a single nucleotide. Molecular beacons are hairpin-shaped oligonucleotide probes that fluoresce when hybridized to their target. The presence of the hairpin stem significantly enhances the specificity of the probes, enabling them to distinguish targets that differ by a few down to a single nucleotide. We have developed a series of molecular beacons for the detection of single or multiple nucleotide changes in human genes. These nucleotide changes are associated with disease predisposition or development such as those occurring in the CCR2, CCR5, SDF-1, Factor V, prothrombin, HFE, MTHFR and CFTR genes or with abnormal drug metabolism in the CYP2C19 and NAT2 genes. For the detection of a sequence variation, two molecular beacons with complete sequence match to either the wild-type or the mutant variant are used in the same PCR reaction. Because these molecular beacons are labeled with fluorophores that emit distinct fluorescent light, the three possible allelic representations of a sequence change can be determined simultaneously. In addition, because the test is performed in closed tubes and no post-PCR manipulation of samples is required, the technique saves time and effort and reduces the risk of contamination. Thus, the hairpin-shaped fluorescently labeled probes are particular suitable for high-throughput screening of single nucleotide sequence changes.

Program Nr: 1193 from the 1999 ASHG Annual Meeting

Outcome of the Routine Assessment of Patients with Mental Retardation in a Genetics Clinic. *A. Hunter.* Genetics Program, Children's Hosp Eastern Ont, Ottawa, ON, Canada.

An impression that we had limited success diagnosing children with developmental delay/mental retardation (MR) led us to review hospital and genetics clinic records of 411 index patients seen from 1986 to 1997. Objectives were to establish how often and under what circumstances we made a syndrome/genetic diagnosis and to determine the utility of laboratory tests. This clinic based study differs from series studying institutionalized patients, small groups of children with selected presentation, and clinics specializing in assessment of MR. A specific syndrome/genetic diagnosis was made in 19.9% of cases and in 4.4% the referring diagnosis was excluded. Associated with making a diagnosis was referral from a pediatrician or neurologist, absence of cerebral palsy, the presence of more than 3 minor anomalies and/or an unusual appearance, a recognizable gestalt or a key anomaly. There was a linear relationship between making a diagnosis and the number of minor anomalies. Not associated with making a diagnosis were, year the patient was seen, degree of MR, number of prior specialists, presence of a major malformation, seizures, and head circumference <3rd or >97th%. While chromosome studies were less often ordered in patients with mild MR, the positivity rate was unaffected by severity of MR. It was correlated with the presence of minor anomalies and/or an unusual appearance. None of 134 cytogenetic studies on patients with <=3 minor anomalies alone was diagnostic. Fragile X studies were less often ordered as severity of MR increased; 10/14 positive tests were among those with mild delay; 13/14 diagnoses were predicted on facial gestalt, the 14th had megalotestes and joint laxity. Targeted molecular and FISH studies were limited in number. When ordered by genetics the positive rate was >60%, contrasting 0% when ordered by other physicians. Our use of the laboratory was inconsistent and not clearly based on the findings in a particular child. Changes in referral patterns and the evaluation process could provide significant economies of time and laboratory use, while resulting in few missed diagnoses.

Program Nr: 1194 from the 1999 ASHG Annual Meeting

A rapid and accurate detection of the SMA gene carriers using real-time quantitative PCR. *S. Ichikawa[1], X. Chen[3], P.-Y. Kwok[3], C.H. Wang[1,2].* 1) Department of Biochemistry, University of Missouri-Columbia, Columbia, MO; 2) Department of Psychiatry and Neurology, University of Missouri-Columbia, Columbia, MO; 3) Division of Dermatology, Washington University, St. Louis, MO.

The spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disorder characterized by degeneration of the spinal cord motor neurons. The gene responsible for SMA has been identified and named survival of motor neuron (SMN). The SMN gene is present in two highly homologous isoforms: the telomeric SMN1 and the centromeric SMN2. These SMN gene copies can be differentiated by a single base-pair polymorphism on exon 7. Currently, the clinical application of this gene discovery has been hampered by the complex genomic organization of the SMN gene copies. The previously reported methods for SMN gene copy number measurement are laborious and sometimes require radioactive labeling. We report here a rapid and accurate method for measurement of SMN1 gene copy number. We developed two allele-specific primers (utilizing the exon 7 polymorphism) to selectively amplify the SMN1 gene copies. We then combined this allele-specific PCR with a TaqMan chemistry to measure SMN1 gene copy number. The ABI PRISM 7700 Sequence Detector allows rapid measurement of SMN1 gene copy number using real-time quantitative PCR. We performed double blind assays to predict the affected and carrier status on 48 individuals from nine SMA families including the probands and the immediate relatives. We predicted that the DNA samples from the SMA patients would retain no SMN1 copy, the carriers would retain one SMN1 copy, and the non-carriers would retain two SMN1 copies. We detected 16 of 17 (94%) affected individuals, 25 of 25 (100%) carriers, and 5 of 6 (83%) non-carriers. The overall accuracy was 96% (46 of 48). The affected status was confirmed by SMN1 gene deletion assays using SSCP, and the carrier status was confirmed by microsatellite genotyping using markers flanking the SMN gene on chromosome 5q13. These results indicate that this new method combining allele-specific PCR and TaqMan chemistry can be used for a rapid and accurate detection of the SMA mutant gene carriers.

Program Nr: 1195 from the 1999 ASHG Annual Meeting

Delivery of genetic services to the Manitoba Hutterites in the molecular era. *A.M. Innes[1], K. Wrogemann[1], T. Zelinski[1], G. Coghlan[1], S. Maendel[2], M. Maendel[2], J. Evans[1], C.R. Greenberg[1]*. 1) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada; 2) Fairholm Hutterite Colony, Portage La Prairie, MB, Canada.

The Hutterites are an Anabaptist sect living on the North American prairies, including the Canadian province of Manitoba. They have a number of features relevant to studies of genetic diseases including high rates of fertility, high levels of consanguinity and excellent genealogic records. In addition, virtually all Hutterites descend from fewer than 60 common founders. A comprehensive list of genetic disorders in the Hutterites has been published only once previously (Bowen,P. Am J Med Genet. 22:449-51, 1985). We report herein an updated list of disorders observed in the Hutterites obtained by reviewing the database of the Section of Genetics and Metabolism at the University of Manitoba. More than 25 Mendelian disorders and traits have been identified amongst the Hutterites including those unique to this population (Bowen-Conradi syndrome, Wd blood group), and disorders over-represented in this population (carnitine palmitoyl transferase-1 deficiency, Limb-Girdle Muscular Dystrophy) as well as more common diseases (Cystic Fibrosis). The genes for many of these disorders have now been cloned and, in some instances, specific Hutterite mutations have been characterized. Work is ongoing in our laboratories to map and clone other disease-associated genes found in this population. In the past, we have found individual Hutterite families to be receptive to and highly interested in genetic counseling. Given the progress at the molecular level, and given the importance of community autonomy and participation with respect to genetic health issues, we have initiated discussions with representatives of the community as a whole. We hope to provide the Hutterites with a more comprehensive appreciation of their genetic heritage and to present options including community based screening for specific disorders. Preliminary discussions suggest a high level of interest in pursuing novel approaches to delivery of education and genetic testing to this community.

Program Nr: 1196 from the 1999 ASHG Annual Meeting

DHPLC analysis of all coding exons of TSC1 and TSC2: a highly sensitive screen for molecular diagnosis. *A.C. Jones[1], B. Hoogendoorn[2], M.C. O'Donovan[2], J.R. Sampson[1], J.P. Cheadle[1]*. 1) Institute of Medical Genetics, UWCM, Cardiff, Wales, UK; 2) Department of Psychological Medicine, UWCM, Cardiff, Wales, UK.

The TSC1 and TSC2 genes are mutated in tuberous sclerosis. They have complex genomic structures (21 and 41 coding exons) and exhibit diverse mutational spectra with few recurrent mutations. We have developed a rapid semi-automated screen of all TSC1 and TSC2 coding exons and splice junctions using denaturing high performance liquid chromatography. Analysis was performed at the melt temperature suggested by the DHPLCMelt software (RTm) and RTm + 2 °C. Sensitivity in a series of 150 unrelated TSC families is in excess of 66% (99 mutations identified with analysis at this time incomplete in samples from 27 cases). This compares favourably with SSCP (sensitivity 61%) and heteroduplex analyses (58%) which have already been completed for all patients. Using Southern blot analysis and long PCR 24 of the 150 cases (16%) were found to have whole exon or multi-exon deletions that can not be detected by any of the exon screening approaches.

Program Nr: 1197 from the 1999 ASHG Annual Meeting

Pharmacogenomic study outcome models for quantitative drug-response traits. *D.A. Katz[1], F. Yang[1], N.J. Schork[2].* 1) Abbott Laboratories, Abbott Park, IL; 2) Genset Corporation, La Jolla, CA.

When undertaking a pharmacogenomic association study, prior assessment of the likelihood of various genetic hypotheses is useful. Favored genetic hypotheses can be used as models to assess the potential utility of the study. An observed trait distribution can be thought of as the sum of several component distributions. A statistical test is applied to determine whether a sum of components explains the observed data better than a single skewed component. Each component distribution could represent the distribution of trait values for the population having a certain gene. For an available set of patient samples, the power to detect the genes represented in each model can be calculated. By setting clinically relevant threshholds, the sensitivity and specificity of a diagnostic test for each gene can be determined. We will demonstrate these procedures utilizing serum alanine aminotransferase data from a long-term study of the leukotriene synthesis inhibitor Zyflo®, and the sample sets now in use to discover genes related to drug-related hepatic adverse events. We will show how characteristics of the genetic map used to find genes, sample size, and the genes themselves influence study power.

Program Nr: 1198 from the 1999 ASHG Annual Meeting

Detection of cryptic Y chromosome mosaicism by coamplification PCR with archived cytogenetic slides of Turner syndrome patients. *J.W. Kim[1], E.H. Cho[1], Y.M. Kim[1], J.Y. Han[2], J.Y. Jun[2], S.Y. Park[1]*. 1) Genetic Research Laboratory, Samsung Cheil Hospital, Seoul, Korea; 2) Obstetrics and Gynecology, Samsung Cheil Hospital, Seoul, Korea.

Turner syndrome is one of the most common cytogenetic abnormality. Y chromosome or Y-derived material is present in 6-9% Turner syndrome patients. It is known that the presence of Y chromosome may predispose them to gonadoblatoma formation with an estimate risk of 15-25%, so it is crucial to identify whether Turner syndorme patients have Y-derived material. In this study, 26 archived slides, which were analyzed as pure 45,X and mosaic 45,X/46,XX by cytogenetic analysis, were screened. Coamplification PCR having the advantage of providing rapid results and confirming PCR failure was performed using the exon 46 of dystrophin gene in Xp21 and DYZ3 of Y centromeric region. One archived slide of pure 45,X cytogenetically was found to have cryptic Y-derived materials. The result of this study indicates that the archived cytogenetic slides can be rapidly and efficiently applied for the detection of hidden Y chromosome in Turner syndrome patients.

Program Nr: 1199 from the 1999 ASHG Annual Meeting

Cancer risk assessment programs--whose domain? *E.R. Knell, C. Presant.* Los Angeles Oncologic Institute, Los Angeles, CA.

Cancer risk assessment, once primarily limited to the research realm, has moved into clinical practice, but little research has been done to analyze and compare aspects of these programs. We surveyed our genetic counseling colleagues to ascertain how their programs are coordinated and conducted, sampling from counselors throughout the country, to enable an objective comparison of some aspects of these programs. This survey did not include programs conducted only by physicians, as sampling was through the NSGC cancer risk assessment interest group.

Of the 30 institutions responding, 20 were not for profit, 7 for profit, and 3 did not state. Overwhelmingly, they were clinical (N=19, 63%), or a combination of both research and clinical (N=9, 30%). While the majority (N=17, 57%) relied on a team of the genetic counselor and oncologist to determine if and which genetic testing would be offered, the genetic counselor was the sole consultant in 11 (36.7%) of programs. Most programs offered 2-4 sessions, and often (N=22, 73%) the genetic counselor was the only professional for the first one or several sessions, encompassing genetic education and often risk assessment. For the result sessions, if testing was done, an oncologist and genetic counselor were usually present (N=21, 70%), although often the physician was not in attendance for the entire session. This presentation will include a review of these and other aspects of these programs, stressing the importance of a team approach but acknowledging the often primary role of the genetic counselor in many programs. This key role for the genetic counselor is a corollary of the extensive time requirement of counseling services and the technical and specialized knowledge required of the assessment and other phases of the consultation.

Program Nr: 1200 from the 1999 ASHG Annual Meeting

Trisomy 9 mosaicism detected by interphase FISH in noninvasively obtained and directly prepared tissues. *J. Kobori, B. Pettersen, K. Nguyen, S. Lew, V. Marquez, X. Li.* Genetics Department, Kaiser Permanente Northern California, San Jose, CA.

Mosaic chromosome aneuploidy can have variable presentations and phenotypes. Suspicion of a mosaic chromosome aneuploidy when lymphocyte analysis reveals a normal karyotype generally requires analysis of invasively obtained tissue such as skin fibroblast culture. To study the possibility of mosaic trisomy 9 in a 15 year old boy with severe mental retardation, aggressive behavior, and dysmorphic features, cells were collected noninvasively from buccal smear and urine, and directly prepared for fluorescence in situ hybridization (FISH) analysis. F.V. was born full term in the Philippines after an uncomplicated pregnancy, labor, and delivery. Cytogenetic analysis of blood lymphocytes was done at one year of age to evaluate dysmorphic features and developmental delay. Results were reported as trisomy 9. Original data from this study are not available. Genetics evaluation in the U.S. at age thirteen years revealed normal physical growth. He had dysmorphic features including tall forehead, flat occiput with low posterior hair line, arched and medial flare to eyebrows, deep-set upslanting eyes with anterior displacement of inner canthi, simple ears, short and broad nose, high narrow palate, and joint hyperextensibility with short distal phalanges. Repeat cytogenetic analysis of blood lymphocytes showed a normal male karyotype in 100 cells. Interphase FISH using dual-color labeled ABL/BCR DNA probes (Vysis, Inc.) specific for 9q34 and 22q11.2 (as an internal control) revealed trisomy 9 in 3% (3/100) of cells in buccal smear and 12% (12/100) in urine. FISH analysis of a normal control using the same probes showed no cells with trisomy 9 (0/100). This result confirms the diagnosis of trisomy 9 mosaicism. This patient's limited phenotype can be explained by the variable distribution of trisomy 9 mosaicism. This technique is a simple, noninvasive, and reliable tool for the study of chromosome aneuploid mosaicism. Its application should be considered prior to analysis of invasively collected tissues.

Program Nr: 1201 from the 1999 ASHG Annual Meeting

Detection of collagen I, II and XI gene defects in osteochondrodysplasias. *J. Korkko, L. Ala-Kokko, M. Kinnarney, D. Prockop.* Ctr Gene Therapy, MCP Hahnemann Univ, Philadelphia, PA.

Collagen I is the major protein of skin, tendon and bone; collagen II is one of the main components of cartilage and vitreous of the eye. Collagen XI is a minor cartilage component co-expressed with collagen II. The genes coding for these proteins are complex in that they consist of over 50 exons and are repetitive. Therefore it's been difficult to establish a practical and reliable method for mutations detection. We have adapted conformation sensitive gel electrophoresis (CSGE)procedure to analyze these genes for mutations in osteochondrodysplasia patients. The mutation detection rates were the following:

Gene(s) analyzed	Referral diagnosis	Found/studied	%
COL1A1/COL1A2	OI I	49/56	88%
	OI II and III	34/41	83%
	OI IV	11/15	73%
	OI vs child abuse	2/25	8%
	Osteoporosis	1/52	2%
COL2A1	Achondrogenesis II	19/20	95%
	SED, SEMD	21/33	64%
COL2A1/COL11A1	Stickler/Marshall sd	43/58	74%

.

Program Nr: 1202 from the 1999 ASHG Annual Meeting

Genetic and Health Care Decisions of Adolescent Daughters of Breast Cancer Patients. *Y.G. Korneluk[1], M. Cappelli[1], S. Verma[2], A. Hunter[1], E. Tomiak[2], J. Allanson[1], C. DeGrasse[3], L. Corsini[2].* 1) Children's Hospital of Eastern Ontario Ottawa, Ontario, Canada; 2) Ottawa Regional Cancer Centre; 3) Ottawa Regional Women's Breast Health Centre.

Adolescent daughters of breast cancer patients are often viewed by oncologists and other health care professionals as “the patients of the future” because some are at increased risk for the development of breast cancer. Furthermore, compared to other family members, they may also be at increased risk for emotional problems when their mothers are diagnosed with the disease. In light of the high incidence of breast cancer and recent developments breast cancer genetics, it is important that we develop effective ways of educating and treating these patients of the future. Our primary goals are to investiage: (a) the adolescent's thoughts and plans with respect to their own breast health, including attitudes towards genetic testing, (b) the psychological functioning of adolescent girls at risk for a hereditary form of breast cancer, and (c) family coping with the illness. We are utilizing a case-comparison design to compare 100 families in which the mother has been diagnosed with breast cancer (BC) to 100 families from the general population (GP) on a variety of self-report measures and an interview. Our protocol was established with the help of focus groups conducted with families with adolescent daughters (N= 16). Data collection has begun, and we have recruited 53 families (N =41 GP and N = 12 BC) to date. We predict that factors related to family coping and attitudes about breast cancer prevention and treatment will be associated with adolescent daughter's functioning and attitudes about breast cancer treatment, prevention, and detection strategies including breast cancer gene testing.

Program Nr: 1203 from the 1999 ASHG Annual Meeting

Diagnosis of maternal UPD 7 by methylation specific PCR. *R. Kosaki[1,2], K. Kosaki[2,3], W. Robinson[4], L. Shaffer[5], W. Craigen[5], N. Matsuo[1].* 1) Health Ctr, Keio Univ; 2) Dept of Peds; 3) Pharmacia-Upjohn Fund for Growth & Development Research, Keio Univ Sch of Med, Tokyo, Japan; 4) Dept of Med Genet, Univ of British Columbia, Vancouver, Canada; 5) Dept of Mol Hum Genet, Baylor Col of Med, Houston, TX.

About 10 percent of patients with Russell-Silver syndrome have maternal uniparental disomy of chromosome 7 [UPD7]. The purpose of this report is to present a methylation specific PCR assay [MSPCR] to diagnose maternal UPD7 by analyzing methylation status the PEG1/MEST, the only imprinted gene on chromosome 7. The putative promoter of the PEG1 contains a CpG island which is methylated on the maternal allele and unmethylated on the paternal allele. Therefore, in patients with maternal UPD7, only the methylated allele is present. In order to evaluate methylation status of PEG1 gene, methylation specific PCR was used. From the published genomic sequence of the putative promoter region of the PEG1 gene (GenBank #Y10620), DNA sequences after bisulfite modification were deduced by converting all cytosines to thymines for the unmethylated allele and by converting all cytosines to thymines with the exception of those in the CpG dinucleotide for the methylated allele. Based on the differences between two sequences, methylated allele- and unmethylated allele- specific primer pairs were designed. Bisulfite-modified DNA from 4 patients with maternal UPD7 amplified only with the methylated allele specific- pair while modified DNA from a patients with paternal UPD7 amplified only with the unmethylated allele-specific pair. Modified DNA from 50 normal unrelated individuals amplified with both primer pairs. The advantages of the present method over conventional linkage analysis is as follows: 1) MSPCR can be performed without obtaining parents samples. In this regard, MSPCR is not subject to the problem of non-paternity, which jeopardize the result of linkage testing; 2) MSPCR consists of only two sets of PCR while linkage analysis requires evaluation of multiple markers because informativeness of the markers is not known prior to testing. We conclude that MSPCR assay is a simple and robust assay for maternal UPD7.

Program Nr: 1204 from the 1999 ASHG Annual Meeting

Client-defined outcomes for clinical genetic services. *S.T. Kozel[1], H. Radtke[1], C. Mills-Lovell[1], C. Ferrang[2], D.B. Flannery[1]*. 1) Department of Pediatrics, Medical College of Georgia, Augusta, GA; 2) Quality Management Program, Medical College of Georgia.

Quality of health care services is assessed through measurement of outcomes, yet defining valid outcomes for clinical genetic services has been an elusive task. A continuous quality improvement program at the Medical College of Georgia afforded the opportunity to discover patient/families' perspectives in identifying outcomes of genetic services. Each patient/family ("client") received a satisfaction survey to complete anonymously at the end of their clinic visit. One of the questions in the survey asked if the clients found the genetic visit helpful; another, open-ended, question asked the clients to identify what aspects of the service were helpful. 444 surveys were distributed; 237 were returned (53.4%). 226 responded to the helpfulness question; 225 reported the service was helpful (99.6%). 158 clients responded to the open-ended question; many wrote multiple responses. Responses to this question were analyzed, and 5 themes were identified. 72.1% reported that **gaining knowledge and understanding** was a helpful result of the service. Examples cited included reaching a diagnosis, and understanding the implications of the condition. A **decrease in worry and anxiety** was a helpful outcome for 11.6%. For example, clients reported relief when told that their child's development was proceeding as expected. An **increased sense of personal control** was reported by 9.3%, including being able to use information gained to determine whether or not to have another child. A **decreased sense of guilt** was identified by 5.8% as a helpful outcome of the service, as a result of understanding the cause of the condition. 12.8% of the responses could only be placed in an "**other**" category. Most of these responses stated that "everything" was helpful, or that the care and concern of the genetics team was helpful. It can be concluded that almost all clients perceived genetic services to be beneficial. These data suggest that future studies should focus on the above five themes for the development of outcome measures to assess the quality of genetic services.

Program Nr: 1205 from the 1999 ASHG Annual Meeting

Genetic research on anonymous samples and data - benefits exceeding impediments. *K.T. Kristjansson, R.Th. Valdimarsson, J. Gulcher, H. Gudbjartsson, K. Stefansson.* deCODE Genetics, Inc, Reykjavik, Iceland.

Modern computer technology allows for extensive data collection and handling of information like never before, making issues about privacy of personal information more valid than ever. In the field of medical research there are increased demands for irreversibly removing all personal identifiers off samples and data. This can have devastating effect on the research value of collected genetic material and data banks. On the other hand, the patients and participants in our research deserve the best possible protection but effective usage of their personal information and biological samples they have donated for the purpose of scientific advancements in medicine for current and future generations. We have developed a comprehensive custom-made computer system that stores and maintains anonymous information about individuals in research projects. It keeps track of blood and DNA samples, phenotypes and the genealogy at every stage from the time that the blood enters the lab till the creation of genotypes. Personal identifiers are encrypted using an 128-bit symmetric encryption algorithm (Advanced Encryption Standard Candidate). The encryption methods are complemented with access restrictions, making the system very secure. A governmental official who stores the encryption key secures anonymity of the samples and the data. The components of the system, except for the coding /decoding, are tied together in a centralized ORACLE database server. They are interactive and accessible through a simple to use graphical interface. This system provides the following benefits to genetic research: a) Privacy to personal information, b) Possibilities of updating information on individuals without risking privacy b) Minimizes losses and erroneous handling by incorrect placement or record keeping by humans, c) Fast genealogy and pedigree drawing, d) Easy data managing and research planning, e) Flexibility in genotype/phenotype correlation, f) Quality control of PCR and genotyping results, g) Minimizing the possibility of result biasing by facilitating blinded genotype analyses.

Program Nr: 1206 from the 1999 ASHG Annual Meeting

Mutation detection using DNA chromatography (DHPLC). *A.I. Kuklin[1], R. Haefele[2], P.D. Taylor[2], D.T. Gjerde[2], K. Hecker[2], K. Munson[1]*. 1) Applications Laboratory, Transgenomic Inc., San Jose, CA; 2) Research and Development, Transgenomic Inc., San Jose, CA.

A novel polymer matrix together with instrumentation and software modeling of the DNA-polymer interaction, now offers an alternative to gel-based analysis of DNA for SNP/mutation discovery and other applications. The technology provides an automated alternative to SSCP and DGGE for mutation scanning with no a priori knowledge of the nature of the location of the mutant. Here we present data and discuss optimization of protocols for pooling so that a higher throughput is achieved in scanning for sequence variants. We demonstrate the applicability of fluorescence detection in mutation screening and discuss various technical approaches.

Program Nr: 1207 from the 1999 ASHG Annual Meeting

The performance of fetal cell sorting by magnetic-activated cell sorting and FISH - a ciritical evaluation. *P. Kuo.* Dept OB/GYN, National Cheng-Kung Univ Hosp, Tainan, Taiwan, Republic of China.

Background: Although advances have been made in the enrichment and isolation of fetal cells for analysis, there is still no consensus on the frequency of fetal NRBCs in maternal blood. The inconsistent findings of the previous studies most likely arise from the highly variable performance of the current sorting technologies and the inadequate enumeration of fetal cells. This prompted us to investigate the perofrmance of magnetic-activated cell sorting (MACS) and FISH in a systemic approach. Materials and Methods: From each of the 43 participants, 30-40 ml of peripheral venous blood was collected at 10-16 weeks' gestation. Approximately 3x10,000,000 nucleated cells were subjected to the initial separation using a triple density gradient of Histopaque. After the initial separation, the cells were equally subdivided into three parts. Two parts were simultaneously subjected to two separate miniMAC columns for selection of CD 71-positive cells. The remaining cells were subjected to amplification of the ZFY gene by nested PCR. All cells in the CD 71-positive fraction were evaluated with dual-color FISH to detect XY cells. Results: The number of cells in the CD 71-positive fraction ranged from 43000 to 926000. Although there is no statistically significant difference between the results obtained from two columns, the results were highly variable for some paired experiments. In 22 pregnancies carrying the male fetus, the number of XY cells ranged from 0-76. The estimated frequencies of XY cells in the CD 71-positive fractions were also highly variable for some paired experiments. The sensitivity of detecting XY cells was 95.5% (42/44) for FISH and 100% (22/22) for PCR. In pregnancies carrying the female fetus, XY cells could be detected by both FISH and PCR in two, and by PCR only in one. The number of XY cells ranged from 1 to 11. Discussion: The present study clearly demonstrates the highly variable performance of MACS in fetal cell isolation. Detection of male cells in pregnancies carrying the female fetus may reflect vanishing-twin phenomenon or contamination by granulocytes/lymphocytes persisting from previous male pregnancies.

Program Nr: 1208 from the 1999 ASHG Annual Meeting

Arrayed Primer EXtension (APEX) as a new DNA resequencing and mutation detection technology. *A. Kurg[1], N. Tõnisson[1], E. Lõhmussaar[1], A. Metspalu[1,2].* 1) Institute of Molecular and Cell Biology, University of Tartu, Estonian Biocentre, Tartu, Estonia; 2) Asper Ltd., Tartu, Estonia.

Development of a method for rapid identification of large number of mutations is an attractive challenge for medical genetics. A current alternative to gel-based methods is the use of DNA microarrays, devices displaying specific oligonucleotides or DNA fragments, precisely located on a small-format solid support. We present Arrayed Primer EXtension (APEX) method that combines the advantages of both, an array-based method, with that of the Sanger dye terminator method. We describe an integrated system with chip and template preparation, multiplex primer extension on the array, fluorescence imaging equipment and data analysis. The method is based upon a two dimensional array of oligonucleotides, immobilized via 5' end on a glass surface. A patient DNA sample is amplified by PCR, digested enzymatically, and then annealed to the immobilized primers, which promote sites for template-dependent DNA polymerase extension reactions. Four unique fluorescently labeled dideoxy nucleotides are used to extend each primer by only one base. A mutation will be detected by a change in the color code of the primer sites. We have developed and realized a total internal reflection fluorescence (TIRF) based excitation mechanism combined with a CCD camera detector for high-throughput image acquisition. The signals from the spectrally separated dyes are resolved with dual selection by excitation with color-specific laser and band-bass filtering of the emitted fluorescence. Imaging is followed by a software analysis to convert the fluorescence information into sequence data. The signal to noise ratio of APEX is, on the average 30:1 which enables identification of a heterozygous mutation with a high confidence level. The systems currently used include resequencing of the p53, -thalassemia, and BRCA1/BRCA2 mutation detection tests and a system to analyze genome-wide SNP markers.

Program Nr: 1209 from the 1999 ASHG Annual Meeting

Minisatellite Analysis Clarifies Mutation, Nonidentity and Sample History. *R.V. Lebo, T. Maher, L. Farrer, E. Yosunkaya, J. Milunsky.* Center for Human Genetics and Depts. Pediatrics and Medicine, Boston University School Medicine, Boston, MA.

Highly polymorphic simple sequence repeats (SSRs) provide a ready resource to resolve (1) meiotic repeat number modification or (2) failure to PCR amplify an allelic site from (3) nonparentage (4) maternal cell contamination of a fetal sample, (5) abnormal PCR amplification, (6) twin or sample nonidentity and (7) questionable sample history. These categories have been resolved routinely with a posterior likelihood of the correct categorization exceeding 99.9 percent. This reliability, which is required to introduce most DNA evidence into a court of law, provides a robust standard to resolve molecular diagnostic ambiguities. Among the 48 pedigrees tested for spinal muscular atrophy linkage and 155 tested to determine parentage, we characterized 4 cases in which an offspring did not carry a parental allele resulting from failure to amplify one allelic target site or meiotic repeat number modification. Standard parentage testing with both parents is routinely completed using six unlinked SSR loci with calculated heterozygosities exceeding .80. Testing twelve loci readily resolved parentage with only one available parent. In the 4 cases that a parent failed to pass one allele to his offspring at one tested locus, parentage was resolved by testing six additional unlinked loci and three to six syntenic loci. Removal of artifactual PCR amplification bands was accomplished by further purification or dilution of DNA samples. Suspected maternal cell contamination detected by simple sequence repeat (SSR) analysis of DNA extracted from a CVS cell culture was confirmed by amniocentesis. The CVS culture gave a normal genotypic result at the SMA locus while the follow-up amniocentesis found the fetus was affected with SMA and differed with the mother's SSR alleles at multiple loci. In summary, while complex results were obtained initially in 4 in 203 pedigrees and 6 of 9,000 individual DNA samples, testing highly polymorphic SSR loci readily distinguished background inherited variability from technical artifact, questionable parentage and questionable sample history.

Program Nr: 1210 from the 1999 ASHG Annual Meeting

Rapid detection of a-**thalassaemia deletions and** a-**globin gene triplications by multiplex PCRs.** *Y.T. Liu[1], K. Miles[1], J.M. Old[2], C.A. Fisher[2], D.J. Weatherall[1], J.B. Clegg[1].* 1) MRC Molecular Haematology Unit, Institute of Molecular Medicine, University of Oxford; 2) National Haemoglobinopathy Reference Service, Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK.

The a-thalassaemias are the most common single-gene diseases in the world. They are characterized by a reduction or complete absence of a-globin gene expression. Normal individuals have two a genes on each chromosome 16 (aa/aa). The loss of one (-a) or both (--) of these *cis*-linked genes is the most common cause of a-thalassaemia. Traditionally, molecular characterization of a-thalassaemias has been carried out using Southern blot analysis. The method is both labour-intensive and expensive. Moreover, its success depends heavily on the quality of the genomic DNA under test and the quantity available. PCR-based assays, which are more rapid, less expensive and more sensitive, have been described previously, but for various reasons have not found their way into routine use. Since the majority of a-thalassaemias worldwide are mainly caused by a few common underlying deletions, e.g. $-a^{3.7}$, $-a^{4.2}$, $--^{SEA}$, $--^{MED}$, $-(a)^{20.5}$, $--^{FIL}$ and $--^{THAI}$, we developed a universal PCR approach, based on three simple and reliable multiplex PCR assays, that allows rapid detection of these seven common deletions as well as the $aaa^{anti3.7}$ and $aaa^{anti4.2}$ triplications, which could be useful in predicting the clinical phenotype of thalassaemia intermedia. Furthermore, in populations where b-thalassaemia with a normal HbA_2 is common, a simple and reliable method for distinguishing heterozygous a^0-thalassaemia from b-thalassaemia trait would also facilitate carrier screening and prenatal diagnosis for b-thalassaemia. We are applying this strategy to screen population samples for these common a-thalassaemia deletions from Southeast Asians to determine their population frequencies. Additional applications, including multiplex amplification from whole blood, will be presented.

Program Nr: 1211 from the 1999 ASHG Annual Meeting

Psycho-social and familial impact of liver transplantation in patients with Familial Amyloid Polyneuropathy (FAP). *A. Lopes[1,2], M. Branco[1], M. Fleming[1], T. Coelho[1], A. Sousa[1], M. Caetano-Pereira[2]*. 1) Centro Estudos Paramiloidose, Porto, Portugal; 2) Transplantation Department, HGSA, Porto, Portugal.

Liver transplantation (L. T.) changed considerably the way FAP patients face and live their diseases. At the same time it imposes an important psychological burden at the moment of the transplantation. In order to evaluate and understand these issues a study of psychological, familial and social impact was designed, whose aim was the assessment of the following dimensions: *Psychopathological traits, Depression, Anxiety and Quality of Life*.

Thirty-one patients transplanted over one year (1997-1998) were evaluated using the following instruments: *Quality of Life Scale (SF 36), Depresssion Inventory (IACLIDE), Brief Symptom Inventory (BSI), Rorschach Test and a Half Structured Interview*. Two moments of evaluation were chosen: just before liver transplantation and nine to twelve months after. Another group of FAP patients refused for surgery was evaluated with same instruments.

Changes in depression, anxiety, somatization and some dimensions of quality of life were found. After L.T. the subjets presented: (1) lower levels of somatization, depression and anxiety (measured in BSI); (2) lower levels of depression (measured in IACLIDE); (3) upper levels of physical functioning, general health, vitality and social functioning (measured in SF36).

These results indicate that L.T. has an important impact on psychic and social life of FAP patients. They also point out to the need of psychological support during that period.

Program Nr: 1212 from the 1999 ASHG Annual Meeting

Direct comparison of SAGE and GeneChip on quantitative accuracy in the transcript profiling analysis. *H. Aburatani[1], M. Ishii[1], S. Hashimoto[2], S. Tsutsumi[1], Y. Wada[1], K. Matsushima[2], T. Kodama[1].* 1) RCAST, Univ Tokyo, Tokyo, Japan; 2) Dept Mol Prevent Med, Univ Tokyo, Tokyo, Japan.

Among high throughput, comprehensive analysis of relative transcript expression levels, Serial Analysis of Gene Expression (SAGE) and oligonucleotide array based hybridization are currently common approaches. To compare quantitative accuracy of those methods, both analysis were carried out using the identical RNA specimens, which were prepared from blood monocytes and GM-CSF induced macrophages to study the transcript profiling in the process of differentiation from human blood monocytes into macrophages. By SAGE analysis 57,560 and 57,463 tags were obtained from monocytes and macrophages, respectively, resulting in nearly 28,000 different tags, while the oligo array hybridization was performed with Genechip (Affymetrix). As expected, the orders of mRNA abundance in each sample were not necessarily very well correlated between the two methods, probably because the hybridization intensity depends on the sequences of oligonucleotides on the array. However, comparative changes during the differentiation were very similar. Out of 20 genes, which showed highest folds of increase in expression levels, twelve were shared between the both analyses, i.e. apoE, type IV collagenase, GP-39, apoC-I, etc. These suggested that Genechip technology is reliable enough in quantitative analysis of expression profiling, although genes not present on the array cannot be analysed. Disadvantages with SAGE would be that occasionally no definite gene was assigned for a tag, or even no match found in the database. Discrepancy of the expression level was found in several genes, which are currently investigated.

Program Nr: 1213 from the 1999 ASHG Annual Meeting

Construction of 6 Mb bacterial clone contig in the reading disability region on 6p22. *J. Ahn, A. Zia, T. Won, J.R. Gruen.* Pediatrics, Yale School of Medicine, New Haven, CT.

Four independent mapping studies by 3 different groups consistently identifies a locus for developmental reading disability on 6p21.3-22. Locus size within this broad region ranges from 11cM spanning D6S422 (pter) through D6S291 (Fisher et al., AJHG, 64:146, 1999), and 10cM spanning D6S109 through D6S306 (Grigorenko et al., AJHG, 60:27, 1997), to 5cM spanning D6S461 through D6S258 (Gayan et al., AJHG, 64:157, 1999). While the centromeric portions of the common overlapping regions have been cloned in sequence-ready BAC and PAC contigs, the middle and telomeric portions are covered only by YACs. In order to complete the cloning of this region we assembled a bacterial clone contig consisting of PACs and BACs spanning approximately 6 Mb on 6p22, and markers pter-D6S1950-D6S1621-cen. Human insert DNA of YACs 966E10, 958H9, 935A8, 901A10, and 947F6, were amplified by inter-IRE and IRE-bubble PCR methods and used to screen the RPCI-11 human male BAC and the RPCI-1 human PAC libraries (Pieter de Jong, Roswell Park Cancer Institute, http://bacpac.med.buffalo.edu). The resulting BACs and PACs were grouped into bins using 74 unique STS, STR, and EST markers that were previously mapped to corresponding YACs. The bins were then connected to form a contig of approximately 6 Mb using additional STSs developed from cloned end sequences. We grouped 182 BACs and 15 PACs into 3 unconnected bins. We estimate that the bins cover approximately 5.5 Mb of genomic DNA based on the number and the sizes of clone inserts. This contig will be useful for ordering and for isolating more genetic markers, and to narrow down the reading disability locus further.

Program Nr: 1214 from the 1999 ASHG Annual Meeting

Rapid identification of polymorphisms in genomic DNA using long range PCR and transposon based sequencing.
A. Antonellis, S.C. Curtis, M.G. Pezzolesi, D.K. Moczulski, A.S. Krolewski. Joslin Diabetes Center, Harvard Medical School, Boston, MA.

As the human genome sequencing project nears completion it is becoming very important to obtain panels of polymorphisms and to construct these into physical haplotypes. To remain competitive, it will be necessary to screen large amounts of genomic DNA rapidly, accurately and efficiently. The current methods of detection are limited by the need to design and generate many products for analysis. This can delay the detection of polymorphisms by weeks or months; even more if the region has not yet been sequenced. To expedite this process we have developed a technique to screen 10kb fragments of known or unknown genomic DNA using a combination of long range PCR and transposon based sequencing.

Using DNA from 4 individuals we designed long range PCR for all 3 introns and 10kb flanking regions of the type 1 angiotensin II receptor (AT1) gene. Once amplified, we subcloned the products from each individual and selected 12 valid clones per person. The DNA samples from these clones were pooled and a transposon insertion reaction was performed. After transforming and plating this reaction, 192 clones were selected and sequenced from both sides of the internal transposon. This provided 16X coverage and the complete sequence of the unknown regions. Polymorphisms were identified as points in the assembled sequence that showed conflicting data and that occurred in more than one reaction. All polymorphisms were confirmed by direct sequencing of PCR products from the four individuals studied. Haplotypes were formed by sequencing individual monochromosomal clones for the presence of all valid polymorphisms. Processing each 10kb fragment took two weeks.

This methodology provided us with a useful map of polymorphisms to begin association studies with. We therefore conclude that this is a very powerful tool for rapidly identifying polymorphisms with a frequency of .20 or greater and for constructing long range, physical haplotypes.

Program Nr: 1215 from the 1999 ASHG Annual Meeting

Physical characterization of distal Xq28 and the syntenic mouse region: candidate gene analysis for Incontinentia Pigmenti Type 2. *S. Aradhya, D.L. Nelson, & the International IP2 Consortium.* Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Incontinentia Pigmenti Type 2 (IP2) is a neurocutaneous genodermatosis that is localized in distal Xq28 and segregates as a dominant and male lethal trait. Current physical maps in the critical region are poorly characterized, consequently hindering accurate mapping of markers, gene structure analyses and sequencing. We have constructed a BAC contig between G6PD and the Xq telomere to assist with gene studies for identifying the IP2 mutation. While confirming that clones map to Xq28 by fluorescence in-situ hybridization, we identified a pseudogene whose original copy lies on the 6q telomere. Moreover, clones betweeen DXS115-2 and DXS115-3 revealed paralogous sequences on three other chromosomes. We have also isolated mouse PAC clones to build a contig across the mouse region(s) syntenic with the human IP2 region. Mapping of mouse Mtcp1, Vbp1 and Xap130 genes indicated a break in synteny such that genes between Dxhxs52 and Vbp1 map in the middle of the murine X chromosome while Xap130 maps near the centromere. Also, a pseudogene for Vbp1 exists on mouse chromosome 3. Finally, we have performed mutation screens on 10 genes as possible candidates for IP2 using heteroduplex analysis and Southern blotting. No mutations have been found; however, several single nucleotide polymorphisms were observed.*Mtcp1Vbp1DXS115-2DXS115-3G6PDDxhxs52Xap130in-situ.*

Program Nr: 1216 from the 1999 ASHG Annual Meeting

Identification of polymorphisms affecting gene expression. *J.C Austin, B. Hoogendoorn, T. Bowen, A. Halsall, S.L Coleman, M.C O'Donovan, P. Buckland.* Department of Psychological Medicine, University of Wales College of Medicine, Heath Park, Cardiff, CF4 4XN, Wales, U.K.

The identification of common functional polymorphisms is a key objective for the human genomics community. Funded by the MRC (UK) we are contributing to this objective by 1. Screening the promoter regions of 2000 genes for common polymorphisms using denaturing high performance liquid chromatography (DHPLC) 2.Testing identified polymorphisms for functional consequences in a reporter gene system. Because our primary interest in this initiative is to facilitate the genetic analysis of neuropsychiatric disorders, this programme will focus on genes of interest to research groups working in this field. Work on the first 200 promoters suggest that the first 500 bases in the 5' flanking region of genes is a rich source of polymorphisms which are present in approximately 50% of screened fragments to date. We anticipate generating a valuable resource for the international neuropsychiatric genetics community that will 1. Contain dense maps of polymorphisms for LD studies in regions of interest to neuropsychiatric genetics groups. 2. Contain a database of polymorphisms tagged to approximately 1000 genes for LD studies of positional and functional candidate genes. 3. Contain information on functional polymorphisms regulating the expression of genes for testing in association studies of complex diseases.

Program Nr: 1217 from the 1999 ASHG Annual Meeting

Improvements in resolution and reproducibility of short tandem repeat (STR) analysis on automated slab gel apparatus. *W.R. Baubonis, D.G. MacDougall, M. Wu, T.D. Zhang, J.M. O'Connor, K.S. Seidell, M.M. Garner.* FMC BioProducts, Rockland, ME.

Analysis of Short Tandem Repeats [STRs] is the most widely used method for genotyping and forensic identification of individuals. Although Single Nucleotide Polymorphism [SNP] analysis may eventually prove more facile and rapid, the STR population databases which are already available allow for genotype-phenotype correlations to be drawn or discrete probabilities of identification of an individual to be calculated. STR analysis is commonly carried out on automated instruments, either by slab gel or capillary electrophoresis. The ability to resolve alleles with different numbers of repeats and, for automated assays, the reproducibility of the absolute electrophoretic mobility of each repeat allele, are crucial for unambiguous allele assignment. We have developed assay conditions using novel gel media on the PE Biosystems Prism® 377 DNA Sequencer which result in increased resolution between individual repeat alleles, and dramatically improved run-to-run reproducibility of fragment mobilities and individual repeats at commonly examined loci, such as D1S2667 and D1S2836. These improvements in resolution and reproducibility dramatically enhance the accuracy of automated allele calling suing software packages [e.g. GenoTyper®]. We have also developed protocols for carrying out STR analysis on the 377 using 12 cm long gels, which dramatically reduces the time necessary for analysis, relative to the standard 36 cm gels.

Program Nr: 1218 from the 1999 ASHG Annual Meeting

A complete bacterial clone contig and a partial transcript map of the hereditary paraganglioma critical region on chromosome band 11q23. *B.E. Baysal[1], P. Taschner[2], J.E. Farr[1], C.W. Richard III[3], P. Devilee[2], B. Devlin[1]*. 1) Dept Psychiatry, Univ Pittsburgh Medical Ctr, Pittsburgh, PA; 2) Dept Human Genetics Leiden University Medical Ctr, The Netherlands; 3) Wyeth-Ayerst Research, Radnor, PA.

Hereditary non-chromaffin paragangliomas (PGL, glomus tumors, MIM#168000) are mostly benign, slow-growing tumors of the head and neck region. Pedigrees with this rare genetic disorder display features consistent with genomic imprinting: children of affected fathers develop tumors in an autosomal dominant fashion with age-dependent penetrance liabilities, whereas children of affected mothers remain tumor-free in the majority of cases. Most PGL families show linkage to the *PGL1* locus on chromosome band 11q23. *PGL1* has been confined to an approximate 1.5 Mb critical interval between D11S1986 and D11S1347. We have created a high-resolution physical map of the critical region. First, we have tested regional markers on a set of small-insert and mega-YACs, and obtained an ordered set of densely distributed STSs across the critical region. Then, we used a subset of these STSs to screen an approximately 10-fold BAC library. We obtained 20 overlapping BACs spanning the critical region. We have checked the inserts and *Not*I restriction sites in each BAC by pulsed field gel electrophoresis. We mapped three *Not*I sites inside the *PGL1* critical region. We have isolated the insert ends of a set of minimally overlapping BACs, and created more than 30 new STSs. Three BAC ends contain expressed sequences, and one BAC end contains a processed pseudo-gene. We used the BAC end-derived STSs to confirm the overlap patterns between the clones. The order and overlap of a set of the clones are further confirmed by fiber-FISH analysis (see Taschner et al). We have also tested 50 regionally mapping ESTs/genes against our refined physical map. A total of 18 ESTs/genes mapped within the *PGL1* critical region. Positional analysis of the *Not*I sites and ESTs/genes within the critical region reveals a highly skewed distribution with a distal (telomeric) clustering. The genomic resources created in this study will facilitate the identification of *PGL1*.

Program Nr: 1219 from the 1999 ASHG Annual Meeting

Towards positional cloning of the Bardet-Biedl locus 1 on 11q13. *P.L Beales[1], N. Katsanis[1], D.W. Stockton[1], P.T. Mai[1], L. Baird[2], M. Leppert[2], S. Asakawa[3], N. Shimizu[3], R.A. Lewis[1], J.R. Lupski[1].* 1) Mol. and Human Genetics, Baylor College of Medicine, Houston, TX; 2) University of Utah, Salt Lake City, Utah 84112; 3) Keio University, Tokyo 160-8582.

Bardet-Biedl syndrome (BBS) is a genetically heterogeneous recessive disease primarily characterized by atypical retinitis pigmentosa, obesity, polydactyly, hypogenitalism and mental retardation. Despite the presence of at least five loci in the human genome on chromosomes 2q, 3p, 11q, 15q and 16q, as many as 50% of the mutations appear to map to the BBS1 locus on 11q13. The recessive mode of inheritance and the genetic heterogeneity of the syndrome, as well as the inability to distinguish between different genetic loci by phenotypic analyses, have hindered efforts to delineate the 11q13 region as a first step towards cloning the mutated gene. To circumvent these difficulties we collected a large number of BBS pedigrees of primarily North American and European origin and performed genetic analysis with microsatellites from all known BBS genomic regions. Heterogeneity analysis established a 40.5% contribution of the families to the 11q13 locus and haplotype construction on 11q-linked pedigrees revealed several informative recombinants, defining the BBS1 critical interval between D11S4205 and D11S913, a genetic distance of 2.9 cM, equivalent to approximately 2.6 Mb. Loss of identity by descent in two consanguineous pedigrees was also observed in the region, potentially refining the region to 1.8 Mb between D11S1883 and D11S4944. Using these markers as starting points, we constructed a BAC/PAC contig across the entire critical interval, which serves as a tool for obtaining genomic sequence and for anchoring some 107 cDNA clusters we have identified in the region. We are currently refining the genetic interval further and sequencing genes in search of mutations in BBS1-liniked pedigrees.

Program Nr: 1220 from the 1999 ASHG Annual Meeting

A Primary Transcript Map for the Van der Woude Syndrome (VWS) Critical Region Derived from 900 kb of Genomic Sequence at 1q32-q41. *B.C. Bjork[1], B.C. Schutte[1], M.I. Malik[1], K. Coppage[1], S.G. Gregory[2], D.J. Scott[2], L. Brentzell[3], Y. Watanabe[1], M.J. Dixon[3], J.C. Murray[1]*. 1) Dept. of Pediatrics, Univ. of Iowa, Iowa City, IA; 2) The Sanger Centre, Hinxton, Cambridge, CB10 1SA, UK; 3) Depts. of Dental Medicine and Surgery, Univ. of Manchester, Manchester M13 9PT, UK.

VWS is an autosomal dominant form of clefting with bilateral lower lip pits. The VWS gene was localized to a 1.6 cM region of 1q32 between D1S491 and D1S205. We constructed a sequence-ready BAC contig across the VWS critical region (VWSCR) using gene-based and anonymous STSs from our previous YAC contig. All STSs and BAC clones were shared with the Sanger Centre (U.K.) which developed a contig of 97 PAC clones over the same region. 11 overlapping clones from both contigs, spanning approximately 1.1 Mb, were selected for high-throughput genomic (HTG) sequence analysis. The complete sequence has been generated for 9 of the clones. This 1.1 Mb region is comprised of two contiguous sequences of 721 kb (contains the 350 kb VWSCR) and 129 kb that are separated by a gap of about 300 kb of which 150 kb is partially sequenced. These sequence contigs were analyzed and revealed novel polymorphisms, including an 8 kb deletion/insertion (Watanabe et al., submitted) and 11 STRPs. To identify genes in these sequences, we first used the computer program RepeatMasker2 to "mask" repetitive sequences, then performed BLAST homology searches against the non-redundant and dbEST databases in Genbank. Various gene prediction programs, utilized singly and in combination, with Genotator, were used to identify putative exons in the genomic sequence. These analyses revealed 6 genes previously mapped to the region, 9 novel genes, 8 putative gene fragments and 3 pseudogenes. As they are determined, exon sequences are screened for the presence of etiologic mutations in a panel of 97 affected individuals by SSCV analysis and direct DNA sequencing. To date, 31 normal sequence variants have been identified from this analysis of 92 exons, but no disease-causing mutations were observed. We continue to determine the expression patterns, transcript sizes and cDNA sequence of gene fragments to prioritize genes for mutation analysis.

Program Nr: 1221 from the 1999 ASHG Annual Meeting

Artificial neural network used for the detection of mutations in DNA sequence raw data traces. *L.S. Bjorkesten, T. Soderman.* Informatics and Software, Amersham Pharmacia Biotech, Uppsala, Sweden.

Mutation detection has important applications in many different areas ranging from early drug target discovery to clinical diagnostics. Even though there are many methods available there are few being as general in applicability and defining as accurately the nature of the change as direct DNA sequencing. Depending on the origin of the mutation, one should in the general case expect any mixture between a mutated DNA component and the wild-type component in the sample. Inherited mutations give rise to a heterozygote 50-50 percent mixture while induced mutations e. g. in tumour tissue may give rise to any mixture depending on the heterogeneous composition.

Base-calling strategies are traditionally designed and optimised for genomics oriented applications. The main focus is then on read-length and on the accurate assignment of pure bases. Less effort has been put into the analysis of heterozygote samples and mixtures in general.

Our ANN based mutation detection algorithm is applied as a second pass on data processed by ordinary base-calling software. Every single base position is reconsidered as potentially hiding a point mutation. A number of descriptive features derived from the raw data traces, from the actual sample as well as from a reference sample, are fed into an artificial neural network, which is trained to produce mutation assignments. The performance of the ANN based mutation detection algorithm will be discussed in terms of sensitivity and specificity and it will be pointed out that pre-processing of the descriptive features is essential in order to keep the required training at a reasonable level. Results will be presented where the false positive rate has been reduced by 97% as compared to results obtained using ordinary basecalling strategies.

Program Nr: 1222 from the 1999 ASHG Annual Meeting

Autosomal dominant hearing loss (DFNA18): Physical mapping and analysis of transcripts in the DFNA18 critical region on Chromosome 3q22. *D. Boensch[1,2], C. Neumann[1], C. Weiller[2], A. Lamprecht-Dinnesen[3], T. Deufel[1].*
1) Institut für Klinische Chemie und Laboratoriumsdiagnostik, Klinikum der Universität Jena, Germany; 2) Klinik für Neurologie, Klinikum der Universität Jena, Germany; 3) Poliklinik für Phoniatrie und Pädaudiologie, Universität Münster, Germany.

Investigating a large German pedigree with non-syndromic hearing impairment of early onset and autosomal dominant mode of inheritance, the phenotype was mapped to a 11-cM interval on chromosome 3q22 defined by the markers D3S1589, proximally, and D3S1569, distally, with a maximum two-point lod score of 3.8 for the marker D3S1292; recombination events in a non-affected sib would narrow this to the interval flanked by D3S1664 and D3S3546. DFNA18 is part of a cluster of deafness loci, along with DFNB15 and USH3 from which it has been excluded, and it is located immediately adjacent to, and in fact overlaps by a few markers with, the recently described DM2 locus where hearing loss has been described as one feature of the DM2 phenotype to which, similar as in DM1, the DFNA18 gene might contribute. The entire DFNA18 critical region is comprised in an array of three overlapping YAC clones. In order to identify candidate genes for the hearing disorder we are currently constructing a combined BAC and PAC contig by screening pooled BAC (751 CEPH, Denis Le Paslier) and PAC (704 RCPI1, Pieter de Jong) gene banks obtained through the RZPD (DHGP, Berlin) with known STS markers from the region; additional STS markers have been created by end sequencing of BAC clones. We will present the updated physical map of the region which, at present, consists of several clusters of partial contigs covering the entire region. A number of ESTs have been mapped into the interval, one of them representing a gene for a calcium ATPase, and another two (A005Y32 and WI-16414) obtained from cochlear transcripts of unknown function, and are currently analysed for mutations in affected members of the pedigree.

Program Nr: 1223 from the 1999 ASHG Annual Meeting

Genetic refinement and physical mapping of the *CMT4B* gene on chromosome 11q22. *A. Bolino[1], E.R. Levy[1], M. Muglia[2], F.L. Conforti[2], A. Gambardella[2], E. Le Guern[3], K. Christodoulou[4], A. Quattrone[2], M. Devoto[5], A.P. Monaco[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Istituto di Medicina Sperimentale e Biotecnologie, CNR, Cosenza, Italy; 3) INSERM U.289, Hôpital de La Salpêtrière, Paris, France; 4) The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 5) Rockefeller University, New York, NY.

Autosomal recessive Charcot-Marie-Tooth (CMT) diseases are a heterogeneous group of disorders in which three different pathological forms have been recognised: one with basal laminar onion bulbs or CMT4A, one with classic onion bulbs or CMT4C, and a third characterised by focally folded myelin sheaths or CMT4B. We recently mapped the *CMT4B* gene on chromosome 11q22 using homozygosity mapping and haplotype sharing on a large inbred Italian pedigree.

In the attempt to identify the *CMT4B* gene, we constructed a YAC contig across the 4 cM critical region between markers D11S1332 and D11S917. Using 19 physically ordered microsatellite markers, we performed a linkage analysis on the original CMT4B family as well as on two additional CMT4B pedigrees. In this way, we confirmed linkage of the *CMT4B* locus to the 11q22 region and, on the other hand, additional recombination events occurring in two affected individuals from the Italian inbred pedigree allowed us to narrow down to approximately 2 Mb the critical region for CMT4B, between markers D11S1757 and GATA3B05.

Then, in order to establish a transcriptional map of the enlarged CMT4B candidate region, we tested on the same YAC contig 70 ESTs retreived from public databases. 54 out of 70 EST clones have been found to be positive by PCR on the YAC clones. In particular, 31 out of 70 EST clones map to the candidate 2 Mb interval and their complete sequence has been determined. Finally, after an extensive computer analysis, we demonstrated that 17 different transcription units as well as 2 already identified genes, which might constitute potential candidates for the *CMT4B* gene, map in the interval delimited by markers D11S1757 and GATA3B05.

Program Nr: 1224 from the 1999 ASHG Annual Meeting

The University of Iowa Gene Discovery Program. *M.F. Bonaldo[1], T.E. Scheetz[1], G. Beck[1], B. Berger[1], C.L. Birkett[3], R. Brown[1], K. Crouch[1], M. Donahue[1], G. Doonan[1], J. Gardiner[1], L. Guo[1], B. Johnson[1], R. Kinkaid[1], K. Liu[3], V. Miljokovic[1], C. Roberts[3], N. Wu[1], T. Casavant[3], V. Sheffield[1], M. Bento Soares[1,2].* 1) Pediatrics, The University of Iowa, Iowa City, IA; 2) Physiology and Biophysics, The University of Iowa, IA; 3) Electrical and Computer Engineering, The University of Iowa, IA.

It is widely recognized that the generation of ESTs from 3' ends of cDNAs constitutes an efficient gene discovery strategy. The main problem with the EST approach is the redundant generation of ESTs derived from the most common RNAs. Accordingly, the use of normalized libraries in which the frequency of all clones is within an order of magnitude range has been shown to expedite gene discovery in large-scale EST programs. However, the process of normalization only contributes to minimize redundancies within (not between) libraries. To address this problem, we developed a new strategy named Serial Subtraction of Normalized Libraries (SSNL). SSNL is an iterative approach whereby all arrayed cDNA clones from a library (typically a complex mixture of individually tagged normalized libraries) are pooled and used as driver in a subtractive hybridization with the library from which they originated. Since the representation of the driver population is significantly reduced in the resulting subtracted library, redundant generation of ESTs is greatly minimized. Most importantly, this process enhances the proportional representation of rare mRNAs likely to be missed in more random approaches. SSNL has been successfully applied in two large-scale gene discovery programs that we are conducting at The University of Iowa: the Rat Gene Discovery and Mapping Program and the Brain Molecular Anatomy Project. To date we have identified 27,000 unique rat 3'ESTs and 9,244 unique mouse 3'ESTs, in a total of only 45,000 rat ESTs and 17,088 mouse ESTs. It is noteworthy that 5,616 of our mouse brain ESTs are not yet represented among the 20,970 members of the existing mouse UniGene set (UniGene build #53). We are beginning to apply the same strategy in an effort to contribute to the gene discovery goals of the NCI Cancer Genome Anatomy Project.

Program Nr: 1225 from the 1999 ASHG Annual Meeting

Using DHPLC to identify disease related polymorphisms in the human Interleukin 4 gene. *M.R. Bonner[1], M. Kabesch[2], F.D. Martinez[2], M.F. Hammer[1]*. 1) ARL Biotechnology, University of Arizona, Tucson, AZ; 2) Respiratory Sciences Center, University of Arizona, Tucson, AZ.

Denaturing High Performance Liquid Chromatography (DHPLC) is a rapid and accurate method for identifying sequence variation in PCR products by detecting mismatched heteroduplexes formed during reannealing of wild type and mutant DNA. PCR product up to 1000bp in length can be screened for single nucleotide polymorphisms (SNPs) at high accuracy when digested with restriction enzymes to create fragments smaller than 600bp. This method was used to search for SNPs in the promoter region of the human Interleukin 4 gene (IL-4), which is involved in the development of allergic diseases. A PCR product covering 925 bp of the IL-4 promoter region and including one previously identified SNP was amplified and digested with RsaI, yielding fragments of 387bp and 538bp, which were then analyzed with DHPLC. Samples showing a change in DHPLC pattern were sequenced to identify the molecular basis of the change. A blinded analysis of a panel of 60 chromosomes correctly identified the mutant and wild type chromosomes for the known SNP. DHPLC also identified a novel SNP in 8 chromosomes in the panel. Sequencing of randomly selected samples showing no change in DHPLC pattern failed to detect sequence variation. From these results we conclude that DHPLC is a sensitive, accurate and fast method for the detection of polymorphisms in candidate genes for human diseases.

Program Nr: 1226 from the 1999 ASHG Annual Meeting

Structure analysis of the PC-1 gene: association of a common amonoacid variant with insulin resistance. *M. Bozzali[1,3], L. Frittitta[2], V. Tassi[1], T. Ercolino[1], A. Argiolas[1], A. Ratti[3], R. Baratta[2], R. Vigneri[2], V. Trischitta[1], B. Dallapiccola[1], A. Pizzuti[1,3].* 1) Endocrinology, Casa Sollievo della Sofferenza, S. Giovanni Rotondo, Italy; 2) Internal Medicine, University of Catania; 3) Neurology, University of Milano.

Insulin resistance (IR) characterizes type 2 diabetes (T2D) and up to 25%; healthy individuals who are at risk to develop for T2D and cardiovascular diseases. PC-1 glycoprotein, inhibits insulin receptor. PC-1 is over-expressed in muscle, fat and fibroblasts of insulin resistant individuals and its over-expression is associated with impaired insulin receptor signaling. Human PC-1 gene is located on chromosome 6q2.2-2.3 near the region for transient neonatal diabetes (TNDM). We determined the PC-1 gene structure. Cosmid subclones from chromosome 6 YACs containing PC-1 sequences allowed to unravel the exon/intron PC-1 gene organization. PC-1 gene is about 50 Kb long with 25 exons. To more finely locate the PC1 gene, PCR analysis of a YAC contig from chromosome 6q2.2-2.3 positioned the PC-1 gene between markers D6S457 and WI-3398, making it an unlike candidate for TNDM. A highly polymorphic CA repeat follows exon 2. All the 25 exons were screened for the presence of polimorphisms. Exon 4 showed a frequent A/C transversion at codon 121 causing a Gln for a Lys change in a Cys-rich domain (K121Q). Q allele frequency in 121 healthy individuals was 17.6%;. The Q carries (39 KQ and 2 QQ) showed IR as indicated by higher glucose and insulin levels during OGTT ($p<0.001$) and by euglycemic glucose clamp ($p<0.01$). Insulin stimulation of receptor tyrosine kinase activity was reduced ($p<0.01$) in cultured skin fibroblasts from 5 KQ in respect to 5 KK healthy subjects. No difference was observed in skeletal muscle PC-1 expression between the Q carriers and KK subjects. PC-1 K121Q is associated to decreased insulin sensitivity in healthy individuals. Therefore, Q allele carriers may be at higher risk to develop diabetes. Our data suggest that PC-1 is an important candidate for the genetic regulation of whole body insulin sensitivity.

Program Nr: 1227 from the 1999 ASHG Annual Meeting

MICROMAX ™:A Unique, Highly Sensitive cDNA Microarray System for Differential Gene Expression Analysis. *B.A. Brown, J. Killian.* NEN Life Science Products, Boston, MA.

cDNA microarray technology is a powerful tool in modern functional genomics research, enabling the study of whole functional pathways or even complete genomes, as opposed to individual genes. NEN Life Science Products, Inc. has developed the first complete, fully validated microarray product system for differential gene expression analysis, through our collaboration with AlphaGene Inc.. The MICROMAX Human cDNA Microarray System I is the first in a line of microarray products designed to provide high throughput and high sensitivity expression profiling for all research lab. The system includes two identical glass microarray slides, each pre-spotted with 2400 known human genes, all key reagents, and a detailed protocol. In this first microarray, 10+ tissue sources are represented, over 40% of which are full-length genes. The 2,400 genes are characterized functionally based on Prosite "motif" search, and are readily identifiable through a gene data base resident on NEN's website, linked to the NIH GenBank.Also included in the system are reagents for cDNA synthesis, hybridization, and NEN's patented, proprietary TSA (Tyramide Signal Amplification) reagents with cyanine 3 and cyanine 5 for signal generation, amplification and detection. TSA reduces the amount of starting sample required by as much as 50-fold, and because of its exceptionally high sensitivity, permits the detection of mRNA expression at levels far below those detectable by other methods. MICROMAX represents a breakthrough in enabling application of DNA microarray technology to a broad research community, particularly in academic and government research institutions. Along with this turn-key product system, NEN also offers slide scanning and data processing services to researchers who do not have access to a laser scanner.

Program Nr: 1228 from the 1999 ASHG Annual Meeting

Improved methods for using gene arrays. *D. Brown, S. Acosta.* Research and Development, Ambion, Inc., Austin, TX., USA.

Although gene arrays are powerful tools for rapidly characterizing thousands of mRNAs within a single sample, cost prohibits their use in many applications. Maximizing the sensitivity and lifespan of an array reduces its effective cost by increasing the information that it can provide. We have found that when using standard hybridization buffers, only 1-5% of any given labeled mRNA binds to its complementary probe on a gene array. Modification of the hybridization buffer allows essentially 100% hybridization without increasing background or cross-hybridization, providing as much as 100-fold greater sensitivity. The lifespans of gene arrays are dramatically reduced by the harsh conditions used to remove labeled nucleic acids prior to reprobing. The boiling SDS washes that are typically used tend to remove the gene sequences covalently bound to the solid support, generally limiting gene arrays to three probings. To reduce the stringency of stripping washes, we have developed probes made with modified nucleotides that are stable under conditions used for hybridization and washing but that can be cleaved with the introduction of a specific reactive agent. Cleavable cDNA probes are incorporated into standard hybridization, wash, and detection protocols, then the hybridized cDNAs are degraded and removed with a mild wash. Forgoing harsh stripping protocols increases gene array lifespans by as much as three-fold. Combining the enhanced hybridization buffer and degradable probes allows 3 to 10-fold more genes to be characterized per sample and as many as 10 mRNA populations to be analyzed per gene array.

Program Nr: 1229 from the 1999 ASHG Annual Meeting

Human Chromosomal Maps of Ancient Sequence Genes. *G.A. Bruns[1,2], R.E. Eisenman[1]*. 1) Genetics Div, Children's Hosp, Boston, MA; 2) Dept Pediatrics, Harvard Medical School, Boston, MA.

By cross-species database searches, we have identified ~100 human genes that have significant homology in the *C.elegans* genome but do not recognize known proteins or protein families. As additional *C.elegans* ORFs remain to be analyzed, ~50 more human genes of this type can be expected. These genes define a small subset of human loci that encode previously unknown ancestral sequences, a number of which can be expected to be "class marking" functional or structural protein domains. We carried out human-specific BlastP searches of GenBank sequences using as bait *C.elegans* ORFs from the WormPep16 database that had no protein identifier. Any high scoring retrieve that recognized a homolog of known function or a member of a function family was excluded. The E values of the 100 new homologs ranged from $5e^{-05}$ to $4e^{-140}$ with the majority having scores of at least e^{-15}. Most of these genes have UniGene cluster numbers with at least 75% of the clusters mapped on GB3/GB4 RH panels. Ideograms of the map positions of these newly recognized ancestral genes are being generated for each of the human chromosomes. The maps are anchored, where possible, to the cytogenetic location of reference loci. These loci, when coupled to available expression data from the EST database and functional analysis in *C.elegans*, become a set of candidate genes for human inherited disorders.

Program Nr: 1230 from the 1999 ASHG Annual Meeting

Transcript map of the Usher syndrome 1C gene locus on chromosome 11p14-15.1. *G.M Caldwell[1], C.D Day[1], P.R Cooper[1], R.L Eddy[1], F. Hejtmancik[3], G.A Evans[4], R.J.H Smith[2], C.C Morton[5], M.J Higgins[1], T.B Shows[1].* 1) Cancer Genetics, Roswell Park Cancer Institute, Buffalo, NY; 2) Department of Otolaryngology, University of Iowa, Iowa City, IA; 3) National Eye Institute, National Institutes of Health, Bethesda, MD; 4) The McDermott Center for Genome Research, University of Texas Southwestern Medical Center, Dallas, TX; 5) Department of Pathology, Brigham and Women's Hospital, Boston, MA.

Usher syndrome 1C (USH1C) is a disorder characterized by congenital hearing loss, absent vestibular function and retinal degeneration. Genetic mapping has assigned the USH1C locus to a region of approximately 400 kb on chromosome 11p14-15.1 between markers D11S902 and D11S1890. To facilitate gene identification, a physical map of this region has been generated using P1 artificial chromosome (PAC) clones. A combination of direct sequence analysis, direct cDNA selection and exon trapping experiments have been used to generate a transcript map of the USH1C region. Fine mapping has localised 22 expressed sequence tags (ESTs), 4 known genes (*NEFA, BIR, SUR1* and *PI3KC2A*) and 5 exons to the region of interest. By virtue of their position, genes mapping to this region represent candidate USH1C loci. The *NEFA* (DNA binding/EF hand/acidic amino-acid-rich) gene, the *PI3K2CA* (phosphatidylinositol 3-kinase, class 2, alpha subunit) gene and the *BIR* (inward rectifier K channel) gene were examined in USH1C patient material using direct sequencing, SSCP and REF but no mutations were found. Several additional transcripts are currently being examined using the same approach. Analysis of the expression pattern and transcript size of novel genes localized within the USH1C region is currently ongoing.

Program Nr: 1231 from the 1999 ASHG Annual Meeting

Variation of individual recombination rates in normal and infertile men. *V.E.H. Carlton[1], D. Nudell[2], M. Castillo[2], N.B. Freimer[1], R. Reijo[2].* 1) Neurogenetics Laboratory, Department of Psychiatry, University of California San Francisco; 2) Department of Obstetrics, Gynecology, and Reproductive Biology, University of California San Francisco, San Francisco, CA, 94122.

Studies in inbred lab strains, such as mouse and fly, have shown that recombination rates differ between members of the same species. Additionally, a significant difference in the recombination rate over a portion of the HLA region has been observed between two normal human males. However, it is not clear how much recombination rates typically vary in normal human males. Inter-individual differences in recombination fraction may have an effect on interpreting genetic maps and on efforts to localize disease genes, in particular efforts using linkage disequilibrium analysis.

Numerous model organisms with defects in genes involved in recombination are infertile. This is unsurprising as recombination is essential for chromosome exchange during meiosis. Additionally, several studies have indicated an increase of non-disjunction (an expected result of recombination defects) in infertile men. Hence we decided to investigate if recombination is abnormal in infertile men.

By genotyping markers in individual sperm from a man, it is possible to calculate individual recombination rates over an interval. We are genotyping sperm from fertile men and from infertile men whose infertility is apparently due to oligospermia (sperm count < 5e6 sperm / ml.) Initially we are genotyping these men with D19S418 and D19S210. These markers span a male recombinational hotspot; a physical distance of less than 1.5 Mb corresponds to a genetic distance of 15 cM in the male and 0 cM in the female. Eventually, other regions will be genotyped. By typing these markers in normal and infertile men we expect to measure how much recombination rates vary in this region in normal human males and to determine if infertile men show evidence for abnormal recombination.

Program Nr: 1232 from the 1999 ASHG Annual Meeting

A physical and transcription map of 1q24.3-q31.1 for the identification of hereditary disease genes including HPC1. *J. Carpten[1], C. Robbins[1], R. Sood[1], T. Bonner[4], I. Makalowska[1], D. Stephan[1], J. Smith[1], N. Scott[1], M. Faruque[1], H. Pinkett[1], C. Graham[1], T. Connors[2], S. Morgenbesser[2], K. Su[2], K. Klingler[2], G. Landes[2], S. Gregory[5], H. Williams[5], W. Isaacs[3], J. Trent[1]*. 1) NHGRI, NIH, Bethesda, MD; 2) Genzyme Genetics Corporation, Framingham, MA; 3) Johns Hopkins Hospital Brady Urological Clinic, Baltimore, MD; 4) NIMH, NIH, Bethesda, MD; 5) Sanger Genome Sequencing Center, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK.

Several hereditary disease loci have been genetically mapped to the chromosome 1q24.3-q31.1 interval including the HPC1 locus. In addition to HPC1, camptodactyly-arthropathy-coxa vara-paricarditis syndrome (CACP), and hyperparathyroid/jaw tumor syndrome (HRPT2) have both been genetically mapped to the 1q24.3-q31.1 region. A 20Mb YAC contig of the 1q24.3-q31.1 has been confirmed by STS content mapping and spans the interval flanked by D1S212 and AFMB330XE9. Over 300 BAC and PAC clones have been identified by PCR screening of commercially available library DNA pools with public and novel markers placed on the YAC clontig. We have generated a complete 6Mb sequence ready BAC/PAC contig of the 1q25.2 interval by STS content mapping and chromosome walking. Approximatley, 130 new STS's have been generated from this contig and shown to map to the 1q25.2 interval, as well as 18 novel simple sequence repeat polymorphisms which are being used for genetic refinement of multiple disease loci. BAC/PAC contig integrity has been confirmed by restriction fingerprinting and clones from this contig are being used as templates for human chromosome 1 genome sequencing. A transcription mapping effort has resulted in the precise localization of 18 known genes and 31 EST's by database searching, exon trapping, direct cDNA hybridization, as well as sample sequencing of BACs from the 1q25.2 region. An additional 11 known genes and ESTs have been placed within the larger 1q24.3-q31.1 interval. These transcription units represent candidate genes for multiple hereditary diseases including the HPC1 gene.

Program Nr: 1233 from the 1999 ASHG Annual Meeting

Superiority of Denaturing High Performance Liquid Chromatography (DHPLC) over single-strand conformation polymorphism (SSCP) and conformation-sensitive gel electrophoresis (CSGE) for mutation detection in TSC2. *Y.S. Choy[1, 2], S.L. Dabora[1], F. Hall[1], V. Ramesh[3], Y. Niida[3], D. Franz[4], J. Kaprzyk-Obara[5], M.P. Reeve[1], D.J. Kwiatkowski[1]*. 1) Genetics Laboratory, Heme Div, Brigham & Women's Hosp, Boston, MA; 2) Division of Genetics, Children's Hospital, Boston, MA; 3) Molecular Neurogenetics Unit, Mass Genl Hosp, Boston, MA; 4) Divison of Pediatric Neurology, Children's Hospital Medical Center, Cincinnati, Ohio; 5) Department of Child Neurology, Children's Memorial Hospital, Warsaw, Poland.

Tuberous sclerosis (TSC) is an autosomal dominant tumor suppressor gene syndrome with a wide mutational spectrum in two causative genes, TSC1 and TSC2. We evaluated DHPLC as a scanning method for mutation detection in TSC2, and compared it to CSGE and SSCP. The first 20 exons of TSC2 were amplified from 84 TSC patients and screened initially by CSGE and then by DHPLC. PCR products with gel shifts or DHPLC changes were evaluated by automated sequencing. Optimization of DHPLC analysis of each exon was carried out by design of primers with minimum variation in the melting temperature of the amplicon, and titration of both elution gradient and temperature. CSGE analysis identified 40 shifts (21 unique) in the 84 patients and 20 exons. All of these same variants were detected by DHPLC, and an additional 27 changes (14 unique) were identified. Overall 15 of 28 (54%) unique single base substitutions were detected by CSGE; all were detected by DHPLC. 25 definite or probable mutations were found in these 84 patients (30%) in exons 1-20 of TSC2. In a subsequent blinded analysis of 15 samples with 19 distinct sequence variants originally detected by SSCP in another center, all variants were detected by DHPLC except one where the variation occurred within the primer. Ten other (7 unique) sequence variants were detected in these samples which had not been detected by SSCP. Overall, 12 of 19 (63%) unique single base substitutions were detected by SSCP; all were detected by DHPLC. We conclude that DHPLC is superior to both CSGE and SSCP for detection of DNA sequence variation in TSC2.

Program Nr: 1234 from the 1999 ASHG Annual Meeting

From Sequence Analysis To Diseases Identification In the Distal Human Xq28. *A. Ciccodicola, T. Esposito, M.R. Matarazzo, F. Gianfrancesco, M. Cocchia, M. Cuccurese, T. Bardaro, M. Manfellotto, M.G. Miano, C. Migliaccio, M. Vacca, A. Franze', S. Cocchia, G. Mercadante, A. Terracciano, A. Torino, V. Ventruto, M. D'Esposito, M. D'Urso.*
International Institute of Genetics and Biophysics, CNR, Naples, Italy.

The distal Xq28 region is an interesting region for its gene content, its association with genetic diseases, for the presence of the second pseudoautosomal region (XqPAR) with its unusual biology and for the Xq telomere. We have sequenced the last 500 kb of this region. By using six different algorithms to predict putative exons (GRAIL II, GENEFINDER, GENEID, GENESCAN, GENIE and FGENEH programs) and BLAST programs to search for EST matches, we show the presence of 5 genes (BBOX2; HSPRY3; SYBL1; IL9R and XAP139), 3 putative genes predicted by software analysis and one pseudogene (AMD2) in the last 500 kb of the Xq28 region. Of the three new genes (BBOX2, HSPRY3, and XAP139) one of them, BBOX2, is located in the terminal X-specific 100 kb portion, and it is homolog to a C.elegans gene. The other two genes are located in the XqPAR and, at least for HSPRY3 we have demonstrated allele specific silencing. Molecular analysis are in progress to associate these genes with disease of genetic origin mapped in this reghion, such as IP2 and Rett syndrome.

Program Nr: 1235 from the 1999 ASHG Annual Meeting

An integrated genetic and physical map of the region containing a QTL for HPFH on chromosome 6q23. *J.P. Close[1], L. Game[1], P. Stephens[1,4], J. Mitchell[1], S. Best[1], J. Rochette[2], A. Mungall[3], G. Bethel[3], S. Humphray[3], J. Riley[4], C.G. See[4], P. Sanseau[4], C. Louis-dit-Sully[1], R. Cox[1], L. Kearney[1], S.L. Thein[1]*. 1) Molecular Hematology, Institute of Molecular Medicin, Oxford, UK; 2) Genetique Medicale, Faculte de Medecine, Amiens, France; 3) The Sanger Centre, Hinxton, Cambridgeshire, UK; 4) Glaxo-Wellcome Research and Development, Stevenage, UK.

Fetal hemoglobin (Hb F) and F cell levels in adults show considerable variation and are influenced by several genetic variants, the major determinants appear to be unlinked to the b globin gene cluster. Genetic studies have recently assigned a trans-acting locus (QTL) controlling Hb F and F cell production on chromosome 6q23 in an Asian Indian kindred that includes individuals with heterocellular hereditary persistence of fetal hemoglobin (HPFH) associated with b thalassemia. The initial candidate interval of ~4 Mb was defined by the markers D6S408 and D6S292 in the 6q22.3-q23.2 region. Haplotypes of the 6q markers were constructed; key recombination events now place the QTL within a 1-2 cM interval spanning ~1.5 Mb between the markers D6S270 and D6S1626/D6S292. The refined candidate interval is spanned by 3 YACs: 917-C-6, 750-C-11 and 905-B-7, and covered by overlapping bacterial clones that consist of 231 BACs and 106 PACs ordered by STS content mapping and confirmed by restriction fragment fingerprinting. The minimum tiling path consists of 22 BAC and 1 PAC clones. 150 STSs map to this interval of 1.5 Mb giving an average STS density of ~1/10 kb. About half of the STSs are novel, all generated from end sequence of the BACs and PACs. The contig includes three microsatellite polymorphic markers, ten SNPs and seventeen unique loci identified as expressed sequence tags (ESTs) of which five relate to characterised genes. The resources should greatly facilitate the construction of a transcript map and sequence analysis of this region leading to the identification of the QTL controlling Hb F/F cell production.

Program Nr: 1236 from the 1999 ASHG Annual Meeting

Fine genetic and physical mapping of the second gene associated with Marfan Syndrome (MFS2). *G. Collod-Beroud[1], G. Jondeau[2], M. Coulon[1], G. Delorme[2], O. Dubourg[1], J-P. Bourdarias[2], C. Junien[1,3], C. Boileau[1,3].* 1) INSERM U383, Hopital Necker-Enfants Malades, Paris, France; 2) Service de cardiologie, Hopital Ambroise Pare, Boulogne, France; 3) Laboratoire central de Biochimie, d'Hormonologie et de Genetique moleculaire, Hopital Ambroise Pare, Boulogne, France.

Marfan Syndrome (MFS) was the founding member of the "heritable disorders of connective tissue". The cardinal features of this autosomal dominant syndrome are prominently observed in 3 systems: skeletal, ocular and cardiovascular. It is now well established that defects in the fibrillin gene located on chromosome 15 (FBN1) cause not only classic MFS, but also a large range of milder, overlapping phenotypes. We have been investigating a large family of more than 200 subjects with a connective-tissue disorder. The autosomal dominant phenotype segregating in this family associates anomalies in the skeleton (tall stature, arm span greater than height, arachnodactyly, scoliosis, and pectus), the heart and the aorta (mitral valve prolapse, aortic dilation, aortic dissection or rupture), skin and integument. None of the ocular features observed in classic MFS was documented in the family until ectopia lentis was identified in a young girl from the last generation. By excluding the FBN1 locus in this large family we raised the issue of genetic heterogeneity in MFS and the implication of a second locus (MFS2). Linkage analyses, performed in this family with dispersed anonymous DNA markers, have previously localized MFS2 to a region of less than 7 cM between D3S1293 and D3S2335 which map at 3p24.2-p25. The analysis was enlarged to 20 new family members (7 in the last generation). Four new dinucleotide DNA markers (D3S3473, D3S3700, D3S3598, and D3S3659 from Gnthon map) and 4 tetranucleotide DNA markers (D3S3038, D3S2466, D3S3047 and D3S1759 from CHLC) were tested in the family. These data refined the genetic localization of MFS2 to area of less than 5 Mb. This region, contained within a single YAC, has an estimated physical distance of less than 1,4 Mb. Combination of data from the different integrated maps shows less than 50 potential cDNA transcripts. Of these, there are no known genes that could make plausible candidates.

Program Nr: 1237 from the 1999 ASHG Annual Meeting

The gene of branchio-oculo-facial syndrome does not colocalize to the EYA1-3 genes or the branchio-oto-renal syndromeé. *L. Correa-Cerro[1,2], M. Dietmar[3], W. Just[1], W. Vogel[1], I. Kennerknecht[1]*. 1) Dept Medical Genetics, Univ, Ulm, Germany; 2) Doctorado en Genetica Humana, Univ, Guadalajara, Mexico; 3) Klinikum Chemnitz, Saeuglingsklinik, Chemnitz, Germany.

The branchio-oculo-facial syndrome (BOFS) is an autosomal dominant disease characterized by branchial cleft sinus or linear skin lesion behind the ear, colobomata of the iris and/or retina, lacrimal duct obstruction and auricular and lip-pits, hypertrophy of the lateral pillars of the philtrum, a broad, asymmetric nose with a broad tip. It has been postulated that BOFS could be an allelic disease to the branchio-oto-renal (BOR) and branchio-oto (BO) syndromes. The BOR gene has been localized on chromosome band 8q13.3. It was named EYA1, the human homologue of the drosophila gene eyes absent. BOR and BO are allelic defects of the EYA1 gene. In order to test the hypothesis that BOFS is also an allelic disease with BOR and BO, we studied the co-segregation of four microsatellite markers on chromosome 8q with the disease in the largest family with BOFS described in the literature. Genomic DNA was prepared from peripheral blood lymphocytes using standard procedures and the different segments were amplified by PCR. The analysis was performed on 7 members of the family including 5 affected individuals using the Allelic links software from Pharmacia Biotech. The results were exported to Cyrillic program for pedigree drawing. The segregation of the haplotypes was determined using SimWalk, the resulting haplotypes reentered into Cyrillic and evaluated for co-segregation with BOFS. The markers used here did not co-segregate with the disease. The study was extended to markers defining two other genes of the EYA family, EYA2 on chromosome 20q13.1 and EYA3 on chromosome 1p36.1-36.2. In both cases co-segregation could also be excluded. Thus, we conclude that the BOF syndrome is not allelic to BO and BOR and that the gene responsible for BOFS remains unknown. We will continue with other markers in order to find a possible candidate region for BOFS.

Program Nr: 1238 from the 1999 ASHG Annual Meeting

Applying rapid DNA microarray optimization capability to SNP screening and genotyping. *M.T. Cronin, F. Frueh, M. Pho, D. Dutta, T.M. Brennan.* Protogene Laboratories, Inc, Palo Alto, CA.

Developing large-scale discovery and testing capability for genetic variability is critical as emerging pharmacogenetic data provide increasingly detailed genotype-phenotype associations and improve phenotype prediction from composite genotypes. Such data have great potential to diminish inter-individual variability in response to xenobiotics. Genetic profiling is expected to increasingly influence and individualize pharmacotherapy optimization, thereby reducing potential for adverse drug reactions and risk from environmental exposures. However, providing individual pharmacogenetic assessment means analyzing many genes for complex mutation and polymorphism patterns. This task poses a significant challenge to current genotyping strategies.

DNA microarrays provide an efficient tool for broadly accessing polymorphism information. We have developed FlexChip™DNA microarrays to provide a highly versatile format for nucleic acid analysis, including polymorphism screening and genotyping. By using piezoelectric jet reagent delivery to array features defined by surface tension, two types of DNA arrays are made quickly and economically. Off-the-shelf, DMT-phosphoramidite chemistry has been successfully adapted for *in situ* synthesis of oligonucleotide probes up to 50 bases long on these surface tension substrates. In addition, pre-synthesized PCR products, cloned cDNAs or purified oligonucleotides are covalently immobilized using surface tension to direct localization on array surfaces.

Using NAT2 gene polymorphisms as a biomarker for drug-response and metabolism, we have successfully demonstrated the high synthesis quality and design flexibility of our array system. We have used on-the-fly array design capability to optimize microarrays to scan NAT2 sequences for evidence of polymorphisms and for accurate SNP genotyping. This is a crucial step since the rapid advancement of human genome sequencing provides new gene sequences and informative new polymorphic markers on nearly a daily basis. Results from NAT2 and other genetic analysis models will be presented.

Program Nr: 1239 from the 1999 ASHG Annual Meeting

Exclusion of the b'**-COP gene and identification of a novel candidate gene for the blepharophimosis syndrome (BPES).** *E. De Baere[1], E. Roman[1], Y. Fukushima[2], K. Verhoeven[3], G. Van Camp[3], A. De Paepe[1], L. Messiaen[1]*. 1) Department of Medical Genetics, University Hospital Ghent, Ghent, Belgium; 2) Division of Medical Genetics, Saitama Children's Medical Center, Saitama, Japan; 3) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

BPES is a rare genetic disorder presenting with blepharophimosis, ptosis and epicanthus inversus. BPES type I is associated with female infertility. A disease locus has been mapped to 3q23. Recently, we have narrowed the BPES critical interval to 45 kb by the identification of a cosmid spanning the 3q23 breakpoint in a BPES patient carrying a balanced t(3;4)(q23;p15.2) translocation.

The b'-COP gene has been mapped to 3q23, distal but in close proximity to this translocation breakpoint. Hence, this gene can be considered to be a positional candidate for BPES. The total coding region of the b'-COP gene was analysed in 10 unrelated BPES patients by direct sequencing of the cDNA and Southern blot analysis using 3 cDNA probes spanning the entire gene. As no mutations nor rearrangements were found, we provide evidence that this gene can be excluded as a candidate gene for the BPES syndrome.
