Shotgun cloning and sequencing of the cosmid spanning the 3q23 breakpoint revealed the presence of a known EST, derived from a testis cDNA library. 5' and 3' RACE PCR on the EST resulted in the cloning of a transcript of 2.5 kb. By comparison of the cDNA sequence obtained by RACE PCR with the genomic sequence of the assembled cosmid contigs, 3 exons/2 introns have been determined. No significant homologies with known genes have been identified until now. Southern blot hybridisation with the RACE products on the t(3;4) translocation patient revealed a rearrangement, suggesting that this gene is disrupted by the translocation. By its position, this novel gene is an important candidate for BPES. Cloning of the full-length cDNA, Northern studies and mutation analysis in BPES patients are currently underway in order to assess its possible role in BPES.

This study is supported by the Fund of Scientific Research-Flanders (FWO).

Program Nr: 1240 from the 1999 ASHG Annual Meeting

A new genome wide screening of 281 affected subjects in 84 families with adult-onset Primary Open Angle Glaucoma (POAG). *T. Desai[1], D. Van Hoewyk[1], I. Stoilov[1], A. Child[2], G. Brice[2], M. Sarfarazi[1].* 1) Molecular Ophthalmic Genetics; Surgical Research Center, Department of Surgery, University of Connecticut Health Center, Farmington, CT; 2) Department of Cardiological Sciences, St. George's Hospital, London, UK.

The purpose of this study was to identify new chromosomal locations in families with adult onset Primary Open Angle Glaucoma (POAG) that do not map to the six previously known loci of GLC1A->GLC1F. A random genome wide screening of 281 subjects with adult onset POAG in 84 families was performed. Approximately 83% of these families have between 3-7 affected members. Our strategy was to screen the genome with 169 markers at 20 cM intervals, followed by another 217 intervening markers and at a final resolution of 5-10 cM. Using an ABI-877 Integrated thermal cycler and/or GenAmp 9700 systems, multiplex PCR reactions were carried out. The amplified products of 8-12 markers were loaded onto 96 well gels on an ABI-377 DNA sequencer. The results were evaluated with GENESCAN and GENOTYPER softwares. The genotypes obtained during this screening were evaluated using both parametric (2-point and multipoint LOD scores; haplotype transmission data) and non-parametric (sib pairs) methods of linkage analysis. As a result of this screening, we obtained LOD score values of over 2.00 (ranging between 2.04 to 2.73) for 5 new locations on chromosomes 1, 7, 16, 18 and 19. LOD scores of over 1.00 (ranging between 1.08 to 1.91) have also been observed for other locations on chromosomes 3, 11, 12, 14, 17 and 21. However, linkage to all of these new loci still needs to be confirmed. This is currently being done by saturation mapping, additional genotyping of normal subjects and by further evaluation of haplotype transmission data of both normal and affected individuals within these families. Positive identification and confirmation of new loci for POAG will be a major contribution to the overall understanding of the genetics, complexity and heterogeneity of primary open angle glaucoma. Supported by NIH (EY-09947), IGA (G249) and InSite Vision, Inc.

Program Nr: 1241 from the 1999 ASHG Annual Meeting

Physical and EST mapping on chromosome 9: Candidate Genes for the geniospasm (GSM1) locus. *P.H. Dixon[1], V.J. Stinton[1], S.J. Humphray[2], S. Hammond[2], P.J. Howard[2], I. Dunham[2], N. Wood[1], M.B. Davis[1].* 1) Neurogenetics Unit, Institute of Neurology, London, England; 2) The Sanger Centre, Hinxton Hall, Cambridge, England.

Hereditary geniospasm is a movement disorder characterised by episodes of involuntary tremor of the chin and lower lip. The condition presents early in childhood, and may be precipitated by stress, concentration and emotion. A recent genome-wide scan in a four-generation family, with geniospasm inherited as an autosomal dominant trait, revealed linkage to a 2.1cM region on the long arm of chromosome 9, band 9q13-q21, between the markers D9S1806 and D9S175. The GSM1 critical region appears to span a region of 3 megabases, based upon a YAC map of the region. Here we describe progress to physically characterise this region with a detailed small-insert contig (PAC/BAC clones) ready for long-range sequencing as part of the chromosome 9 sequencing project, and the localisation of brain-specific ESTs to this region, which are being investigated as candidate genes for hereditary geniospasm. A database screen has revealed the presence of 12 ESTs isolated from brain cDNA libraries that map to this region. Confirmation of the localisation of these ESTs is underway, using the YAC contig, together with PACs and BACs from the critical region. BLAST analysis of each of these potential candidates has revealed no significant homologies to previously characterised sequences. Thus, our analysis describes progress towards a sequence-ready physical map of this region and has identified candidate loci for the GSM1 gene on chromosome 9.

Program Nr: 1242 from the 1999 ASHG Annual Meeting

Draft and Finished Sequencing of Human Chromsome 16. *N.A. Doggett, M.O. Mundt, D.C. Bruce, A.C. Munk, D.L. Robinson, M.D. Jones, J.M. Buckingham, L.A. Chasteen, E.H. Saunders, L.A. Goodwin, A.L. Williams, J.L. Longmire, P.S. White, L.L. Deaven.* DOE Joint Genome Institute, Center for Human Genome Studies, Los Alamos National Laboratory, Los Alamos, NM 87545.

We are pursuing a plasmid-based approach toward the large scale sequencing of human chromosome 16. Our strategy for sequencing involves nebulization to randomly break DNA, size selection of 3 kb and larger fragments, double adapter cloning into plasmid, and sequencing of both ends up to 4.5X random sequencing coverage. Assembly of sequence contigs is assisted with JAVA tools which exploit the inherent relationship of the paired-end sequences. Closure and finishing is achieved by a combination of primer walking, shatter libraries, longer reads, and alternate chemistry reactions. We have recently introduced the use of the Mermade 96 channel oligonucleotide synthesizer which enables us to reduce the level of shotgun in favor of targeted primer walks. We have also begun double-end plasmid draft sequencing to 4X coverage in Phred Q20 bases, producing ordered and oriented contigs. Drafting accelerates the sequencing process, and we have completed over 2 Mb in this format during the past few months. To date we have submitted more than 5.2 Mb of finished sequence, including a 3.0 Mb contig from 16p13.3 spanning four disease genes-- TSC2, PKD1, MEFV and CREBP. G+C content is high across the region, with a maximum of 57% found in a finished clone. Gene density approaches one gene/10 kb in some stretches. Alu content has also been high, with up to 30 Alus in a finished cosmid. Sequence comparison analysis is semi-automated with use of the SCAN program (developed at LANL). This program launches a suite of sequence similarity searches and gene prediction algorithms and summarizes the results into a single integrated annotation report. The quality of finished sequence is ensured by stringent criteria including; > 95% of bases with Phrap scores > 40 and > 95% of bases covered in both strands (or 2 chemistries), assembly validation by restriction fragment analysis with 3 enzymes, and post submission quality assessment.

Program Nr: 1243 from the 1999 ASHG Annual Meeting

Chromosomal localization of novel cDNAs using real-time fluorescent PCR (TAQMAN) on radiation hybrid panels. *P. Dowd, M. Roy, A.D. Goddard.* Molecular Biology, Genentech, Inc., So San Francisco, CA.

The construction of a human gene map is a key step in the identification of disease-causing genes and is important in understanding the organization of the genome. The use of radiation hybrid (RH) panels to localize loci on framework maps is an efficient method for accomplishing this task. A PCR based approach to testing gene-specific STSs on the G3 RH panel (http://www-shgc.stanford.edu /Mapping/index.html) and the Genebridge4 RH panel (http:/www-genome.wi.mit.edu/ cgi-bin/ contig/rhmapper.pl) has been used to localize approximately 500 novel genes. Initial mapping accomplished by analyzing PCR products from the hybrid panels on agarose gels has been replaced by real-time fluorescent. The application of the TaqMan real-time PCR system (ABI PRISM 7700, Perkin-Elmer-Applied Biosystems) to screening RH panels has increased our throughput, sensitivity and accuracy. The coupling of gene-specific PCR primers with a nested dual-labeled fluorogenic hybridization probe increases the specificity of the reaction by removing signal from non-specific PCR products which do not hybridize to the internal, labeled probe. The TaqMan reactions are characterized by the cycle at which the amplification product is first detected above a threshold (CT) rather than the amount of PCR product accumulated after a fixed number of cycles providing us with rapid and sensitive detection of product. We have used chromosomal location data to aid in the identification of candidate genes and in the analysis of disease-related genomic alterations.

Program Nr: 1244 from the 1999 ASHG Annual Meeting

Signing on to Expression Profiles. *M.M. Dressman[1], E. Holland[2], M.H. Polymeropoulos[1], C. Lavedan[1]*. 1) Pharmacogenetics, Novartis Pharmaceuticals, Gaithersburg, MD; 2) MD Anderson Cancer Center, Houston Texas.

Unique expression patterns of a large number of genes can now define cell specific signatures under a given context. Cell specific signatures will be invaluable to understanding differentiation, cell type specificity and the cellular biology of environmental responses. Expression signatures could greatly enhance drug development by increasing efficacy and decreasing toxicity of therapeutic compounds. We have used (Affymetrix) oligonucleotide microarrays to survey and compare the expression profiles of 7000 human genes from cells of various origins, including lymphocytes, umbilical vein endothelial cells (HUVEC), a breast adenocarcinoma cell line (MCF7) and a glioblastoma cell line (U373MG). Environmental context such as time in culture, state of differentiation, media composition, CO2 content and culture confluency may alter cell signatures. Chemical compound manipulation of cell lines provides one mechanism to dissect function at the gene expression level. For example, extended treatment of endothelial cells with vascular endothelial growth factor (VEGF) results in greater than two fold changes in expression level of ~100 genes, while extended treatment of glioma cell lines with platelet derived growth factor (PDGF) results in greater that two fold changes in 39 genes. Analyzing expression data from multiple cell lines can also be used to identify similarities of expression profiles for all cell lines. We have observed that an average cell type expresses 2335 out of 7000 genes assayed (~ 33 %). Sixty-four percent of the 2335 genes are expressed in endothelial, U373MG, and MCF7 cells, with a total of 630 expressed at similar levels in all three cell types despite variation in growth media. Additional cell types are being analyzed to refine the universal and cell-specific signatures.

Program Nr: 1245 from the 1999 ASHG Annual Meeting

Further gene identification in the *dn* critical region. *S.S. Drury[1], D. Scott[2], D. Arnaud[1], J. Bishop[2], R. Poche[1], M. Batzer[1], M. Lovett[3], V. Sheffield[2], R. Smith[2], P. Deininger[2], B. Keats[2].* 1) Genetics & Biometry, LSU Sch MEd, New Orleans, LA; 2) Department of Pediatrics, Univ. of Iowa, Iowa City, IA; 3) University of Texas Southwestern Meidcal Center, Dallas, TX.

The deafness locus (*dn*) has been mapped by linkage analysis to mouse chromosome 19. The orthologous region on human chromosome 9 contains the DFNB7/11 locus for autosomal recessive nonsyndromic hearing loss and it is likely that the *dn* gene and the gene causing DFNB7/11 are homologues. The *dn* mouse is a naturally occurring mutation in the curly-tail (*ct*) stock and homozygous *dn/dn* mice have profound sensorineural hearing loss with degeneration of the organ of Corti and the stria vascularis. No other phenotypic abnormalities exist in the mutant mouse. Recombination data and flourescent in situ hybridization (FISH) studies strongly support the existence of an inversion on the *dn* chromosome relative to the *ct* chromosome that is hypothesized to have caused the deafness phenotype. One side of the inversion is contained on BAC 124J3 and we are screening a subclone contig of this BAC for rearrangements at the genomic level indicative of the breakpoint. Several other ESTs, identified with exon trapping, mapping to this region, are also being examined. We have mapped three genes to the *dn* locus and excluded them as candidates genes using Northern analysis, rtPCR, and direct sequencing. These genes included TMEM2, a member of the Arrestin family, and ZNF216. Additionally, we have examined the known genes that map to this region, including lipocortin, and have found no mutations in the *dn* mouse. To date, no mutations have been found in the DFNB7/11 families in any of these genes.

Program Nr: 1246 from the 1999 ASHG Annual Meeting

Fine structure mapping of the hereditary inclusion body myopathy locus. *I. Eisenberg[1], T. Levi[2], A. Sanilevich[1], M. Shemesh[1], H. Hochner[1], M. Sagi[5], J.G. Seidman[2], M. Sadeh[3], Z. Argov[4], S. Mitrani-Rosenbaum[1].* 1) Unit for Development of Molecular Biology and Genetic Engineering, Hadassah Hospital, Hebrew Univ.-Hadassah Medical School, Jerusalem, Israel; 2) Dept. of Genetics, Harvard Medical School, Boston; 3) Dept. of Neurology, Wolfson Hospital, Holon; 4) Dept. of Neurology; 5) Dept. of Genetics, Hadassah Hospital , Jerusalem, Israel.

We have previously mapped the gene responsible for the recessive form of Hereditary Inclusion Body Myopathy (HIBM) in Persian Jews to a 10cM interval on chromosome 9p1-q1, and showed that the disease is linked to the same locus in other ethnic groups such as Afghani and Iraqui Jews, and a non Jewish family from India. Also, Nonaka et al., have shown that an HIBM type of the disease described in Japanese patients links to the same locus. In order to narrow the gene locus and identify putative candidate genes for HIBM, we have extended our linkage studies to 40 families using two-point linkage and linkage disequilibrium analyses, and used yeast and bacterial artificial chromosome (YAC and BAC) libraries to physically map the HIBM gene.

Linkage analysis and recombination events allowed us to define the HIBM interval to a 1cM region. Furthermore, we have identified microsatellite markers which are in strong linkage disequilibrium with the disease. b tropomyosin, a skeletal muscle protein which maps within this region, was excluded as the disease causing gene because an intragenic polymorphism did not exhibit linkage disequilibrium in HIBM probands. Subsequently we have identified a YAC insert, about 1 megabase long, which contains both markers flanking the HIBM interval. Exon trapping of this insert allowed us to identify 2 novel genes. We have established the exon/intron structure of these genes which are being screened for putative mutations causing HIBM. Furthermore, data from the most recent integrated genomic map (GeneMap98) revealed that more than 10 new ESTs physically map to this region.

We conclude that the HIBM gene resides in a 1 megabase interval on chromosome 9 and speculate that a novel muscle protein encoded there is mutated in HIBM.

Program Nr: 1247 from the 1999 ASHG Annual Meeting

High resolution physical and transcript mapping of the critical interval for the ARSACS gene identifies two candidate genes. *J.C. Engert[1], C. Doré[1], J. Mercier[2], P. Berubé[1], P. Lepage[1], B. Ge[1], K. Morgan[1], T.J. Hudson[1], A. Richter[2]*. 1) Centre for Genome Research, Research Institute, Montreal General Hospital; 2) Service de Génétique Médicale, Centre de Recherche Mére-Enfant,Hôpital Sainte-Justine, Montréal, Québec,Canada.

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS, OMIM 270550) is an early onset neurodegenerative disease associated with prominent myelinated retinal nerve fibers. The high prevalence of ARSACS in the Charlevoix-Saguenay region of Quebec (carrier frequency of 1/22) and rarity elsewhere is indicative of a founder effect. In a previous study we localized the disease gene to chromosome region 13q11 by identifying excess sharing of a marker allele in patients. Haplotype reconstruction revealed a major ancestral haplotype and an unrelated minor one. To create a detailed physical map of the ARSACS region, we screened CEPH mega-YACs with 41 chromosome 13 STSs mapping to 13q11-q12. The YAC contig, composed of 27 clones, extends from D13S175 to D13S221. A high resolution BAC and PAC map was constructed that includes the ARSACS critical region flanked by D13S1275 and D13S292. These YAC and BAC/PAC maps allowed the accurate placement of 29 genes and ESTs previously mapped to the proximal region of chromosome 13q. We confirmed the position of two candidate genes (SGCG and KIAA0730) within the ARSACS critical interval, and mapped the 27 other genes and ESTs to nearby intervals. Six BAC/PAC clones form a contig between D13S232 and D13S787, the 450 Kb critical interval defined by fine structure linkage disequilibrium mapping. Sample sequencing of M13 subclones obtained from these BACs and PACs identified six new EST clusters in addition to the two known transcripts. Sequencing of additional M13 subclones, and extension of these known ESTs will allow us to characterize the candidate genes for ARSACS.

Program Nr: 1248 from the 1999 ASHG Annual Meeting

Analysis of 7 Mb from human chromosome 21: Gene identification relevant to Down syndrome and features of genome organization. *K. Gardiner, D. Slavov, R. Lucas, C. Reimer, K. Clancy, A. Rynditch.* Eleanor Roosevelt Inst, Denver, CO.

To identify novel genes of relevance to Down syndrome and to investigate potential regulatory sequences, we are analyzing the chromosome 21 sequence generated by centers in Japan and Germany. To date, annotation of >7 Mb, dispersed throughout the long arm, has consisted of exon prediction with four programs, protein and EST database searches, 2-sequence Blast searches and CpG island identification, followed by RT-PCR for verification and refinement of predicted novel gene models. In this analysis, 40 well characterized or related genes were found. Success of exon prediction for these genes suggests that this analysis alone should reveal >90% of genes. However, within the same 7.5 Mb, novel genes (those lacking any protein homology) are being predicted with the following characteristics: a) exon + EST genes: 4 genes with excellent patterns of predicted exons and one or more matches in dbEST; b) exon - EST genes: 20 genes with good or marginal patterns of predicted exons and no matches in dbEST; c) EST - exon genes: 7 genes without patterns of reliable exon prediction but with matches in dbEST; d) CpG island genes: 11 genes consisting of strong CpG islands that are apparently unique sequences and found in >50 kb regions lacking any consistent exon predictions. For a subset of novel genes, RT-PCR and RACE experiments helped to verify and refine the models, and were used to define expression in early development and in adult brain regions potentially relevant to Down syndrome. These also revealed examples of complex alternative processing, especially in brain, that may have important implications for regulation of protein function. To begin identification of regulatory sequences, complete gene structures were determined for the 40 known genes. This identified a number of very large introns, a number of very short intergenic distances, and at least one potentially bidirectional promoter. Relating observed gene size and gene density to the isochore model of the mammalian genome also permits a refined estimate of the total number of genes on chromosome 21.

Program Nr: 1249 from the 1999 ASHG Annual Meeting

Concerted evolution within and between rDNA clusters on human acrocentric chromosomes. *I.L. Gonzalez[1], J.E. Sylvester[2]*. 1) Research Department, A.I. Dupont Institute, Wilmington, DE; 2) Nemours Children's Clinic, Jacksonville, FL.

It is known that the human rRNA genes (rDNA), which are clustered on the 5 acrocentric chromosomes, contain sequence variation not only in the intergenic spacer, but also in the coding regions. However, due to the concerted evolution that operates on tandemly-repeated genes the rDNA are much more similar than would be expected of interspersed repeats. We examined the question of how similar are rDNA copies within single clusters and compared this to homologous and non-homologous intercluster similarity, by cloning and sequencing rDNA fragments derived from specific acrocentric chromosomes isolated in somatic cell hybrids. The fragments include 28S coding sequences, intergenic spacer, regulatory regions upstream of the promoter, and segments of adjacent non-rDNA. Our results indicate: [1] Preferential homogenization within clusters, where differences among clones are usually of the same magnitude as the pcr error rate. [2] rDNA from homologous chromosomes are not more similar than rDNA from non-homologues. [3] While regulatory and coding regions show very low divergence among all chromosomes examined, the intergenic spacer of some of the chromosomes is 10 times more divergent. [4] Sequences from the terminal rDNA are slightly diverged from those of internally-located rDNA repeats. [5] All acrocentrics examined have the same distal junction to non-rDNA. [6] Sequences distal to rDNA are surprisingly homogeneous. [7] rDNA pseudogene fragments located in the distal region do not evolve in concert with parent sequences in rDNA. We conclude that intracluster homogenization of rDNA is very efficient and much more prevalent than homologous and non-homologous exchanges.

Program Nr: 1250 from the 1999 ASHG Annual Meeting

GENE EXPRESSION PROFILING IN HUMAN TISSUES OF HYPOTHALAMUS-PITUITARY-ADRENAL AXIS BY EXPRESSED SEQUENCE TAGS (ESTs) AND FULL-LENGTH cDNA CLONING. *Z. Han[1], R. Hu[2], H. Song[2], Y. Peng[1,2], Q. Huang[1,2], S. Ren[1], Y. Gu[1,2], C. Huang[1], Y. Li[1], C. Chang[1], G. Fu[1], Q. Zhang[2], B. Gu[2], T. Wu[1], Y. Yu[1], S. Xu[1], S. Fu[1], M. Chen[2], J. Chen[2], Z. Chen[1,2]*. 1) Chinese National Human Genome Center at Shanghai, Shanghai,China; 2) Shanghai Institute of Endocrinology, Rui-Jin Hospital,Shanghai Second Medical University, Shanghai,China.

Hypothalamus-pituitary-adrenal (HPA) axis is an essential part of neuroendocrine system. To obtain a first overview of transcriptional genomics in this axis, genes expressed in human hypothalamus (HT), pituitary (NP), and adrenal gland (AD) were catalogued by generating a large amount of expressed sequence tags (ESTs), followed by bioinformatics analysis. Totally, 25973 sequences of good quality were obtained out of 31130 clones (83.4%) from cDNA libraries of the three tissues (HT, NP and AD). After eliminating 5329 ESTs corresponding to repetitive sequences and mitochondrial DNA, 20644 ESTs could be assembled into 9176 clusters when overlapping and/or redundant ESTs were integrated. 2778 clusters (30.3%) corresponded to known genes, 4165(44.8%) to dbESTs, while 2233 (24.3%) to novel ESTs. The gene expression profiles reflected very well the functional characteristics of the three levels in HPA axis, with myelin basic protein, growth hormone and steroidogenic acute regulatory protein genes as most highly expressed in HT, NP and AD, respectively. Subsequently, 150 full length cDNAs of novel genes were cloned and sequenced, which may be involved in critical life processes such as gene expression, processing and transport of secretory proteins, signal transduction, metabolism, development, and differentiation. In addition, some new findings were made with regard to the physiology of HPA axis, including the existence of steroidogenic enzyme gene transcription in hypothalamus, the high expression of human osteoinductive factor in pituitary possibly as a new pituitary hormone, and a local CRH-ACTH-cortisol system in AD. Moreover, mRNA isoforms as a result of alternative splicing were found in several genes, including the growth hormone gene. All these data may contribute to the understanding of the neuroendocrine regulation of human life.

Program Nr: 1251 from the 1999 ASHG Annual Meeting

Collection of informative SNPs by PLACE-SSCP analysis of pooled DNA. *K. Hayashi, T. Sasaki, M. Inazuka, A. Suzuki, Y. Kukita, T. Tahira.* Div. Genome Analysis, Inst. Genet. Inf., Kyushu Univ, Fukuoka, Fukuoka, Japan.

A high-resolution genome map densely marked with informative single nucleotide polymorphisms (SNPs) is expected to be a powerful tool for genome-wide association studies of polygenic traits. However, an extensive work is needed to collect many such markers, and suitable new strategy/technique is preferred to alleviate the task. We previously developed a polymorphism/ mutation detection method, PLACE-SSCP, in which PCR products are fluorescently post-labeled and separated by automated capillary electrophoresis in SSCP conditions (Inazuka et al., Genome Res. 7, 1094-1103,1997). This method is scalable, involving minimal human intervention. We show here, that PLACE-SSCP analysis of pooled DNA is efficient in finding informative SNPs, because in the analysis, SNP-allele frequencies in the pool are accurately estimated from heights of separated peaks. We started from 48 STS on chromosome 6, which are reported to contain 61 candidate SNPs (Wang et al., Science 280, 1077-1082, 1998). Two ethnic groups (53 Japanese and 78 Caucasian) were examined by the method, and all STSs in selected individuals were sequenced to verify the SNPs. We found that; (1) 17 of the 61 SNPs (28 %) were likely to be monomorphic, (2) heterozygosity of 11 of quantified 34 SNPs (32 %) was less than 20% in both populations, and (3) 12 of the quantifiable 34 SNPs (35 %) had noticeably different allele distribution between the two populations. We also found 11 new SNPs in the examined 51 STSs. In the present method, allele frequencies of 34 of the 44 confirmed SNPs (77 %) were quantifiable. Software for resolving and quantifying overlapped SSCP peaks is being developed, which should enable quantification of 90 % of the SNPs.

Program Nr: 1252 from the 1999 ASHG Annual Meeting

Construction of a PAC contig in the putative 7q32 imprinted region flanking *MEST/PEG1*. *S. Hayashida, Y. Asada, K. Yamasaki, T. Kishino, N. Niikawa.* Human Genetics, Nagasaki Univ. Sch. of Med., Nagasaki, JAPAN.

MEST/PEG1, a gene expressed paternally in mesodermal derivatives in early embryonic stages, is the first imprinted gene mapped to chromosome 7q32. Loss of MEST function is thought to contribute to intrauterine and postnatal growth retardation associated with maternal uniparental disomy for chromosome 7 (mUPD7). Since imprinted genes are clustered in general at a chromosomal region, we speculate that a similar imprinted-gene cluster may exist at 7q32 region and functions of some such genes may contribute to the phenotype of mUPD7. As an initial step toward the isolation of imprinted genes at 7q32, we adopted an integrated approach involving construction of a PAC contig and EST mapping in the vicinity of *MEST*. PAC clones covering *MEST* were first isolated by PCR-based screening of a PAC library and end-sequencing of the framework PACs allowed further isolation of adjacent PACs to construct a ~1Mb PAC contig spanning *MEST*. Regions with only one-fold coverage and several small gaps in the contig were filled with BAC clones. Ordering of PACs in the contig was confirmed by interphase FISH and a YAC contig spanning the region of *D7S530*, *MEST* and *D7S649*. Using these genomic sources, ESTs from "Gene Map 99" were localized by PCR. This allowed us precise mapping of 12 ESTs including 3 known genes (*UBE2H,CPA1* and *CPA2*) in the contig. In the course of construction of the contig, BLAST searches with end-sequences of PACs identified three previously unmapped ESTs. The PAC contig constructed and ESTs mapped precisely will help us to analyze imprinting of genes including *MEST* at 7q32.

Program Nr: 1253 from the 1999 ASHG Annual Meeting

Construction of a physical and transcriptional map of human chromosome 17p13.3 to identify a new tumor suppressor gene implicated in breast cancer. *C. Hoff[1], P. Seranski[1], T. Detzel[1], B. Korn[1], J. Ramser[2], R. Reinhardt[2], U. Hamann[1], A. Poustka[1]*. 1) Molecular Genome Analysis, German Cancer Research Center, Heidelberg, Germany; 2) Maxplanck institut for molecular genetic, Berlin, Germany.

Chromosome 17 aberrations like gene amplifications and loss of heterozygosity (LOH) are the most common genetic abnormalities in sporadic forms of human breast cancer. Although LOH mapping studies on 17p in breast tumors showed that the common LOH region contains the p53 gene in 17p13.1, mutations in p53 have been found in only 17-40 % of the investigated cases. Existence of LOH in breast cancer tumors distal to TP53 suggests that there is a new tumor suppressor gene in 17p13.3. LOH confined to 17p13.3 has also been found in medulloblastoma, astrocytoma, ovarian cancer, bladder cancer and osteosarcoma. We are constructing an integrated physical map in 17p13.3 with overlapping sets of yeast artificial chromosome (YACs), P1 derived artificial chromosome (PACs) and cosmids covering approximately a 1,5 Mb interval of sequence ready map. Focusing on the specific region of interest observed through LOH analysis using three polymorphic markers on 60 breast tumors, we have continued our work by transcript mapping on the precisely mapped clones. So far 30 ESTs have been identified and fine mapped, most of them show no homology to known sequences. In parallel the complete genomic sequence of the region is in progress. This allows the detection of additional potential coding sequence using exon prediction algorithms like GENESCAN and GRAIL. Structure / functional based approaches and expression profiling will allow the rapid identification of new tumor suppressor candidate genes. Profiling in normal breast and tumor samples is based on Northern blot hybridization and RT-PCR on the one hand and on complex hybridisations of EST specific PCR products on mini arrayed nylon filters on the other hand.

Program Nr: 1254 from the 1999 ASHG Annual Meeting

Microdeletions in the Y chromosome in idiopathic infertile men. *M.J.V. Hoffer[1,2], J.W.A. de Vries[2], B. Redeker[1], S. Repping[2], L.G. Brown[3], D.C. Page[3], J.M.N. Hoovers[1], F. van der Veen[2], N.J. Leschot[1]*. 1) Dept. of Clinical Genetics, Academic Medical Center, Amsterdam, The Netherlands; 2) Center for Reproductive Medicine, Dept. of Gynaecology and Obstetrics, Academic Medical Center, Amsterdam, The Netherlands; 3) Howard Hughes Medical Institute, Whitehead Institute and Dept. of Biology, Massachusetts Institute of Technology, Camebridge, MA, USA.

Molecular genetic analysis in infertile men have shown the existence of three different regions of Azoospermia Factors (AZF-a, -b and -c) in intervals 5 and 6 of the human Y chromosome. Deletions in one of these regions can cause spermatogenic defects ranging from azoospermia to mild oligozoospermia. Recently, a fourth region, AZF-d, has been described (Mol. Reprod. Dev. 1999;53:27) which is located between the AZF-b and AZF-c region. 20% of the microdeletions was found in the AZF-d region and seem to be associated with a less severe phenotype, i.e. mild oligozoospermia or even normal sperm count associated with abnormal sperm morphology. Therefore, we have screened 200 infertile men (undergoing ICSI) using sequence tagged sites (STSs) as well as gene specific markers. The markers used included 12 STS markers located in all the AZF regions and 6 markers for the X/Y homologous genes on the long arm. By means of this strategy, we found one deletion within AZF-b and 4 within AZF-c. We found no deletions of the AZF-a and d region. In conclusion, the AZF-c region and not the AZF-d region seems to be the most interesting one for studying the etiology of male infertility.

Program Nr: 1255 from the 1999 ASHG Annual Meeting

Computational methods for evaluating clone sampling efficiency in normalized cDNA libraries. *J. Hoh[1], D. Gordon[2], T. Lints[2], T.C. Matise[2], J. Ott[2].* 1) Columbia University, New York, NY; 2) Rockefeller University, New York, NY.

Large-scale gene expression analysis using cDNA microarrays promises to yield new insights into the biological properties at the molecular level. Such microarrays can be constructed from normalized cDNA libraries derived from tissues of particular interest (TOI) (Library I), or from more complex libraries in which a substantial proportion of all genes expressed by the organism are represented (Library II). Library I provides a more efficient means to sample the genes in TOI, whereas Library II is valuable to investigators with broader interests. Here, we develop quantitative methods to assess the relative efficiency of sampling from these two libraries.

To perform this analysis, we address the following 2 problems: 1) how many clones from the tissue-specific normalized library (I) must be sampled in order to acquire a specified proportion of the genes expressed in the TOI? 2) how many clones from the more complex normalized library (II) must be sampled in order to acquire a specified proportion of the genes expressed in the TOI and, in so doing, what proportion of the genes expressed in other tissues (non-TOI) would be acquired? For each of problems 1 and 2, we have developed analytical expressions for the probabilities of acquiring all genes expressed in TOI for a given sample size (the solution is reminiscent of, but not identical to, the well-known coupon collecting problem in combinatorics). Computer simulation will be applied to investigate more general questions. We will assume both perfect normalization (each gene in the library has the same frequency) and more realistic normalizations where the frequency of each gene falls within, for example, a 10-fold or 100-fold range.

Program Nr: 1256 from the 1999 ASHG Annual Meeting

A format for the collection of accurate and useful data on sequence variation. *O. Horaitis, R.G.H. Cotton, & 32 Members of the HUGO Mutation Database Initiative.* Mutation Research Centre, 7th Floor Daly Wing, 41 Victoria Pde, Fitzroy VIC 3065, Australia, Tel: 61-3-9288-2980, Fax: 61-3-9288-2989, cotton@ariel.ucs.unimelb.edu.au.

Disease causing genes are being described with increasing frequency as the Human Genome Project progresses. Similarly disease causing mutations are described at increasing rates such that some single gene disorders are now known to be caused by hundreds of mutations e.g. 870 for the CFTR gene causing cystic fibrosis. If we assume that the number of genes in the genome are 100,000 and that there are 100 changes per gene causing inherited disease and cancer, it is likely that there will be 10 million disease causing events eventually described. However, polymorphisms may be around one third this level. This information must be documented accurately and completely so that the many user groups have confidence in it. **The HUGO Mutation Database Initiative (MDI) (http://ariel.ucs.unimelb.edu.au:80/~cotton/mdi.htm)** has been considering the quality control problem so that it can make a recommendation for collection of data concurring mutational change. Extensive consultation with MDI members has developed an internet based user interface for entry of allelic variations into databases. The most important questions to ensure the mutation described is certain or likely to cause disease are as follows:

- 1. Is the change found in a 2nd PCR sample amplified from the patient's DNA?
- 2. Is the change always present when the phenotype is present?
- 3. Is a conserved residue affected?
- 4. Has expression analysis been performed?
- 5. Have 50 normal chromosomes been tested?

Many other questions relating to detection methods, RNA, etc. are also asked, some relating to the linkability with other databases such as providing a reference sequence and accession number. Reasons for these will be explained. The complete form will be shown and the final format recommended at the next MDI meeting on 19th October 1999.

Program Nr: 1257 from the 1999 ASHG Annual Meeting

Transcript mapping of the Usher syndrome type 3 region on chromosome 3q21-q25. *T.H. Joensuu[1,2], R.H. Hämäläinen[1,2], A-E. Lehesjoki[1,2], A. de la Chapelle[2,3], E-M. Sankila[1,4].* 1) Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) Department of Molecular Genetics, The Folkhälsan Institute of Genetics, Helsinki, Finland; 3) Comprehensive Cancer Center, The Ohio State University, Columbus, Ohio; 4) Department of Ophthalmology, Helsinki University Hospital, Helsinki, Finland.

Usher syndrome type 3 (USH3) is characterized by autosomal recessive inheritance, progressive bilateral sensory neural hearing loss, retinal degeneration, and variable vestibular dysfunction. We previously assigned an USH3 locus to 3q21-q25 by linkage and refined its localization to a 1-cM region between markers D3S1299 and D3S3625. In order to identify the USH3 gene, we constructed a bacterial artificial chromosome (BAC) contig between the flanking markers D3S1299 and D3S1279. Novel polymorphic markers were generated from the BACs, and used to genotype USH3 families to further narrow the critical region. By analyzing linkage disequilibrium and historical recombinations in 79 Finnish USH3 chromosomes the location of USH3 was refined to a less than 250 kb genomic interval. A number of STSs generated from the isolated BAC ends and novel ESTs have been localized to the map. Four out of seven ESTs, which mapped within the minimal USH3 region, were found to represent two separate genes, namely SIAH2 and KIAA0001. These were studied as potential candidate genes for USH3 and excluded as causative by sequencing the complete coding regions in patients. Further analysis of the remaining ESTs is ongoing. BACs covering the critical region are being sequenced and a complete transcript map is under construction in order to identify the USH3 gene.

Program Nr: 1258 from the 1999 ASHG Annual Meeting

Synteny between human chromosome 18q and mouse chromosome 18 extends throughout the 18q- syndrome dysmyelination critical region. *T.L. Johnson-Pais[1], C.L. Buller[2], R.J. Leach[1,2].* 1) Department of Pediatrics, University of Texas Health Science Center, San Antonio, TX; 2) Department of Cellular and Structural Biology, University of Texas Health Science Center, San Antonio, TX.

Common features of the human chromosome deletion syndrome 18q-, resulting from hemizygosity of a portion of 18q, include dysmyelination of the central nervous system (CNS), mental retardation, and short stature. Because breakpoints for this syndrome vary, a 2Mb critical region for dysmyelination in 18q23 has been defined by genotype/phenotype mapping. This critical region includes the gene for myelin basic protein (MBP); however, mouse models have shown that loss of MBP alone is not sufficient to cause dysmyelination. Thus, we want to create a "deletion" mouse model missing the region homologous to the human dysmyelination critical region. In order to create a model that has a deletion of MBP and surrounding genes, we have to determine whether synteny exists between human and mouse in the dysmyelination critical region. Important evidence that this region of chromosome 18 is conserved between human and mouse is that the MBP gene and the gene for the galanin receptor 1 (GALR1) are tightly-linked on both human chr 18q23 and mouse chr 18. We have mapped the mouse homologs for ESTs (or complete genes) that have been localized to human chr 18q23 in the dysmyelination critical region with the use of the Jackson Laboratory (C57BL/6JEi x SPRET/Ei)F1 x C57BL/6JEi (BSB)) and (C57BL/6JEi x SPRET Ei/F1 x SPRET Ei (BSS)) interspecies backcross mapping panels. We have shown that the mouse homologs of at least 2 additional genes and 4 ESTs from 18q23 map to the telomeric region of mouse chr 18. We are currently localizing the mouse homologs of 6 additional human ESTs that map to 18q23. This extended region of synteny, which includes ESTs that map both inside and outside the dysmyelination critical region, proves that this region of the genome is well-suited for the creation of a mouse model that will lack the same genes deleted in humans with dysmyelination and 18q- syndrome.

Program Nr: 1259 from the 1999 ASHG Annual Meeting

Genomic sequence analysis in mouse t-complex region. *G.J. Kargul[1], P. Waeltz[1], P. Ma[2], E.Y. Chen[2], M.S.H. Ko[1], R. Nagaraja[1]*. 1) Laboratory of Genetics, National Institute on Aging, Baltimore, MD 21224; 2) Celera Genomics, 850 Lincoln Center Drive, Foster City, CA 94404.

A systematic analysis of 10 Mb of the mouse t-complex region on chromosome 17 has been undertaken to define the content of genes involved in early embryonic development. Mapping and sequence analysis are complicated by the presence of a number of large duplications and inversions in this region. We have initiated the effort to construct an unambiguous STS/BAC based physical map by integrating newly mapped markers (11 Wsu and 16 Ertd markers). We are also identifying corresponding BAC clones for other markers already placed in the t-complex region, making additional STSs from inter-B1 products of individual BACs, and integrating additional genetic data available for the region to complete a physical map and resolve duplicated regions. Thus far, three BACs spanning approximately 600 kb have been sequenced and are being analyzed. The region, syntenic with human 16p13, contains 28 STSs integrated with 33 overlapping BAC clones. In one stretch of 175 kb, genomic sequence were found that encode the transcripts for Nubp2 (Nucleotide binding protein 2; corresponding to EST, D17Wsu11e) and D17Wsu15e. The same sequence also contains the known but previously incompletely mapped Als (which binds and stabilizes the IGF/IGFBP3 complex in serum to extend its half-life), as well as the nucleoside diphosphokinase 3 genes and the 3'end of the Rsp29 gene. Five additional potential coding regions with CpG islands would yield an overall average of at least one gene every 18 kb, making this region of the t-complex part of the highest gene density fraction of the genome.

Program Nr: 1260 from the 1999 ASHG Annual Meeting

Identification of retina-specific transcripts through in silico subtraction and construction of a genome-wide retinal gene map. *N. Katsanis[1], P. Culpepper[1], T. Thangarajah[2], C. Weber[2], M. James[2], J.R. Lupski[1], K. Worley[1]*. 1) Mol and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Wellcome Institute, Oxford, UK.

Since the inception of the EST project, the numbers of partial sequences in Genbank have increased exponentially, reaching over 1.5 million human sequences from >100 tissue sources and developmental stages. However, it is difficult to examine large numbers of ESTs and address biologically important questions because of the lack of specialized software and other technically limiting factors. Although advances in microarray technology offer new possibilities for high throughput gene expression studies, the number of sequences that can be spotted and evaluated with this technology remains limited compared to the vast numbers of unique sequences in dbEST. We are interested in identifying new retina-specific genes, map them in the human genome and perform expression analyses. To achieve our goal, we have used some 50,000 retinal ESTs that have been deposited in dbEST by designing a package of programs that process all retinal ESTs and extract sequences only when they are found in retinal cDNA libraries and no other tissue, thus increasing the probability that these sequences represent retina-specific transcripts. Through this *in silico* subtraction we identified some 950 sequences potentially representing novel genes, in addition to some 150 sequences derived from known transcripts such as ABCR, RETGC, RPE65, Rhodopsin and CRX. We have mapped these genes in the human genome with the Genebridge 4 radiation hybrid panel to create a retinal transcript map, onto which we have superimposed all known uncloned retinopathies, thus generating a plethora of candidates for these disorders. We have integrated our findings into a bipartite database, RetBase, consisting of the mapping and sequence information of all unique EST clusters (RetMap) and the expression database (RetExpress), both of which will be shortly available to the scientific community. Our approach serves both as a powerful tool in disease gene identification for eye-related diseases as well as a prototype for transcript maps of other tissues.

Program Nr: 1261 from the 1999 ASHG Annual Meeting

Molecular Cloning, Tissue Specific Expression and Assignment to Chromosome 13q12 of Human Connexin 30, GJB6, a Candidate Gene for Nonsyndromic Hearing Loss. *P.M. Kelley[1], S. Abe[2], J.W. Askew[1], S.D. Smith[3], S-i. Usami[2,4], W.J. Kimberling[1]*. 1) Dept Genetics, Boys Town National Research Hospital, Omaha, NE 68131; 2) Dept. of Otorhinolaryngology, Hirosaki University School of Medicine, Hirosaki 036-8562 JAPAN; 3) Center for Molecular Genetics, Munroe-Meyer Institute, University of Nebraska Medical Center, Omaha, NE 68198; 4) Dept. of Otorhinolaryngology, Shinshu University School of Medicine, Matsumoto 390-8621 JAPAN.

Mutations in connexin 26 are responsible for approximately 20% of genetic hearing loss and 10% of all hearing loss. However, only about 75% of the mutations predicted to be in Cx26 are actually observed. While this may be due to mutations in noncoding regulatory regions, an alternative hypothesis is that some cases may be due to mutations in another gene immediately adjacent to Cx26. Another gap junction gene, connexin 30, is found to lie on the same PAC clone which hybridizes to chromosome 13p12. Human connexin 26 and connexin 30 are expressed in the same cells of the cochlea. Cx26 and Cx30 share 77% identity in amino acid sequence but Cx30 has an additional 37 amino acids at its C terminus. These considerations led us to hypothesize that mutations in Cx30 might also be responsible for hearing loss. Sixty recessive nonsyndromic hearing loss families from both European and Japanese populations were screened for mutations. In addition, 21 dominant hearing loss families were tested. No significant mutation has been found in the dominant or recessive families.

Program Nr: 1262 from the 1999 ASHG Annual Meeting

A complete map of 80 human ribosomal protein genes. *N. Kenmochi[1], T. Uechi[1], S. Higa[1], M. Sakai[1], M. Yoshihama[1], N. Maeda[1], D.C. Page[2], T. Tanaka[1].* 1) Dept. of Biochemistry, School of Medicine, University of the Ryukyus, Okinawa, Japan; 2) Howard Hughes Research Laboratories at Whitehead Institute/MIT, Cambridge, MA.

Although the ribosome is essential for cell growth and development, the effects of ribosomal mutations and their role in human disease have been explored barely. However, it has been recently shown that mutations of an rp gene (*RPS19*) cause congenital anemia and, in *Drosophila*, the quantitative deficiency of any of a number of ribosomal proteins results in *Minute* phenotypes, including reduced body size, diminished viability and fertility, and short, thin bristles. Thus, we are assuming that rp gene defects could cause various kinds of human diseases.

To explore this possibility, we have been systematically mapping the human rp genes and have finally completed the map including all the 80 distinct genes. Because localization of rp genes is complicated by the existence of processed pseudogenes, multiple strategies were devised to identify PCR-detectable STSs at introns. The developed STSs were subjected to radiation hybrid panels (GeneBridge4 and G3) and all has been placed quite precisely on the physical map of the human genome. We localized 56 previously unmapped rp genes, and refined or corrected 24 previously reported map positions. Though functionally related and coordinately expressed, the human rp genes are widely dispersed; both sex chromosomes and 20 autosomes (all but chromosome 7 and 21) carry one or more rp genes. Chromosome 19, known to have a high gene density, contains an unusually large number (13) of rp genes. This map provides a foundation for the study of the possible roles of ribosomal protein deficiencies in chromosomal and Mendelian disorders.

Program Nr: 1263 from the 1999 ASHG Annual Meeting

Revealing of rDNA deleted monomers and short disperced rDNA homologous sequences in human genome. *P.M. Kirilenko, N.S. Kupriyanova, A.P. Ryskov.* Dept. of Genom Organization , Institute of Gene Biology, Moscow, Moscow, Russia.

Recently, analysing rDNA containing clones in cosmid library of human chromosome 13 we have found variants harboring extended deletions flanked by (tc)n microsatellite clusters in intergenic ribosomal spacer (rIGS). Now we try to find similar deletions in a total cellular human rDNA. We have performed a series of PCR amplifications for a number of unrelated individuals with 20-mer primers corresponding to the borders of 25kb deletion in one of the rIGS cloned variants. For all individuals similar PCR patterns have been obtained revealing a number of fragments one of which showed a size analogous to the cloned deleted rDNAvariant and ability to hybridize with identical markers. It can signify an existence of sought for deleting variants in human cellular rDNA. Analysis of the other amplificants after their cloning and sequencing revealed a complex mixture of chimeric rDNA-non rDNA sequences as well as nonribosomal DNA of distinct types originating from different chromosomes. It can mean an existence of short rIGS homologous sequences dispersed throughout human genome.

Program Nr: 1264 from the 1999 ASHG Annual Meeting

Genomic sequencing and identification of 39 genes on human chromosome 21. *J. Kudoh[1], K. Shibuya[1], K. Kawasaki[1], A. Shintani[1], K. Nagamine[1,2], J. Wang[1], S. Asakawa[1], S. Minoshima[1], N. Shimizu[1].* 1) Dept. Mol. Biol., Keio Univ. Sch. Med., Tokyo, Japan; 2) Dept. Cell Technol., Eiken Chemical, Tochigi, Japan.

We have been analyzing genomic sequence of human chromosome 21. Our targets are 4 regions in the 21q (approximately 6.5 Mb in size); 1.2-Mb region containing CBR1, SIM2, and HLCS, 440-kb region containing ETS2, 3-Mb region between MX1 and D21S171, and 2-Mb region between APP and D21S292. We use a shotgun sequencing strategy in combination with primer walking and nested deletion methods (Genome Res., 7:250-261, 1997) to completely determine the sequence of each BAC, cosmid, and PAC clone. We have determined approximately 3.5-Mb of sequence with estimated accuracy of >99.999% and will finish sequencing of the entire 6.5-Mb region by the end of 1999. Genomic sequence was subjected to homology search and analysis for protein coding potential using GRAIL and GENSCAN. Putative exon sequences were used as probes to screen corresponding cDNA clones or as primers to amplify cDNA fragments by PCR. Nucleotide sequence of these cDNA clones and those registered in databases allowed us to identify 13 new genes including CBR3, C21orf5, SIM2, PDE9A, KNP1 (Keio novel protein 1), KNP3/TRPC7, KNP5/C21orf2, AIRE, DNMT3L, NR4, NR7, NR8, and LPAAT3, and 26 known genes including CBR1, KIAA0136, CAF1A, HLCS, ERG, ETS2, MX2, MX1, TMPRSS2, WHITE, TFF3, TFF2, TFF1, NDUFV3, PKNOX1, CBS, U2AF1, CRYAA, KIAA0179, PDXK, CSTB, NNP-1, TMEM1, PWP2, KIAA0653, and PFKL. The sequence information is available through our Web site (http://www.dmb.med.keio.ac.jp) or Web site (http://www-alis.tokyo.jst.go.jp) of Japan Science and Technology Corporation (JST) which should be useful for further finding of new genes.

Program Nr: 1265 from the 1999 ASHG Annual Meeting

A physical map of the atopy locus on human chromosome 13q14. *N.I. Leaves, G.G. Anderson, S. Bhattacharyya, Y. Zhang, R. Cox, W.O.C.M. Cookson.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, England, OX3 7BN.

Atopy is common familial syndrome underlying asthma. It is a complex genetic trait that is characterised by raised Immunoglobulin E (IgE) responses to common allergens.We have previously identified a region on chromosome 13q14 that is linked to atopy and to total serum immunoglobulin A. Linkage to the region has been replicated by us and other groups. We have now typed 60 published microsatellite markers within the region and shown linkage to atopy in three panels of subjects comprising a total of 604 sibling pairs. The locus shows a maximum lod score >5, with a 1 lod support interval of <5cM. We have constructed a physical YAC STS content map to cover the entire area. The map comprises of 41 STSs and 17 microsatellite markers. YACs were sized by pulsed field gel electrophoresis and hybridization with total human DNA. All YACs were analysed by FISH for chimerism. The YAC contig spans approximately 6Mb and consists of 10 clones with an average insert size of 1.3Mb and an average depth of 1.5 clones. A PAC/BAC contig was then established to cover the peak of linkage in the central 1.5Mb of the YAC map. This contig was constructed using 10 published STSs and 60 novel STSs generated from clone ends by anchor bubble PCR. All PACs and BACs were confirmed as hybridizing uniquely to 13q14 by FISH. The PAC/BAC contig was integrated into the YAC map using the common STSs and by forming a *Not*I and *Sal*I pulsed field restriction map. The PAC/BAC contig contains 38 clones with an average insert size of 114Kb. The contig has an average depth of 2.8 and spans approximately 1.5Mb. Anchor bubble PCR was then used to identify novel microsatellite markers from the PAC/BAC map. Twenty-five microsatellites were recovered, eight of which were polymorphic and were typed in our panels. Genetic analysis showed all markers were strongly linked to atopy. Markers within a central 600kb also showed positive TDT tests to atopy and the serum IgE level. Gene recovery is now in progress using cDNA selection and the eighteen ESTs confirmed as mapping onto the PAC/BAC contig.

Program Nr: 1266 from the 1999 ASHG Annual Meeting

Regional mapping panels for human chromosomes 1, 2, and 7. *J.C. Leonard, L.H. Toji, P.K. Bender, C.M. Beiswanger, J.C. Beck, R.T. Johnson.* NIGMS Human Genetic Cell Repository, Coriell Cell Repositories, Coriell Institute for Medical Research, Camden, NJ.

The NIGMS Human Genetic Mutant Cell Repository is establishing a collection of well-characterized somatic cell hybrid regional mapping panels for each human chromosome. With the cooperation of its advisers and various chromosome committee members, the CCR has identified regional mapping panels for chromosomes 1, 2, and 7 from the hybrids in the collection submitted by S. Bodrug, D. Callen, D. Cox, B. Emanuel, T. Glover, K. Grzeschik, V. vanHeyningen, D. Ledbetter, G. Scherer, T.B. Shows, J. Trent, D. Warburton, and J. Wasmuth. These panels consist of hybrids that define 8 to 10 intervals for each chromosome.

Hybrids were characterized by the submitters; recharacterization performed at the CCR supported the submitters' descriptions of the hybrids. The human chromosome content of the hybrids was confirmed by G-band analysis and *in situ* hybridization with total human DNA and in some cases, with specific chromosome paints or alpha satellite probes. In addition, DNA samples prepared from the hybrids were characterized by Southern blot hybridization and/or by PCR with probes or primers for each human chromosome in the specific human derivative or deletion chromosome.

The NIGMS Human Genetic Cell Repository now has regional mapping panels for chromosomes 1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 13, 15, 16, 17, 18, 21, 22, and X. These panels are available as cell cultures or as DNA.

Program Nr: 1267 from the 1999 ASHG Annual Meeting

Identification of differentially expressed genes in human Th2 cells. *X. Li[1], T. Beaty[2], S. Huang[1].* 1) Clinical Immunology, Johns Hopkins University, Baltimore, MD; 2) Department of Epidemiology, School of Hygiene and public health, Johns Hopkins University, Baltimore, MD21205.

Identification of differentially expressed genes in human Th2 cells Xiaodong Li1, Terri H. Beaty2, and Shau-Ku Huang1 1.Division of Clinical Immunology, Asthma and Allergy Center, 2. Department of Epidemiology, Johns Hopkins University School of Medicine, Baltimore, MD 21224 T heper 2(Th2) cells are associated with allergic diseases, including asthma, and are potential targets for developing novel therapies. The mechanisms governing the development of Th2 cell phenotype are currently unclear, and the exact signaling pathways leading to Th2-dominant immune response remain to be determined. To this end, we have developed an efficient and reliable method to identify differentially expressed genes associated with the activation of Th2 cells. This was accomplished by combining suppressive subtractive hybridization (SSH) and high throughput cDNA array analysis. The use of SSH to equalize high and low copies of transcripts and to remove common sequences between tester and driver cell populations allows us to generate probes significantly enriched for differentially expressed genes. We used allergen-stimulated human Th2 cells as tester, and either resting Th2 cells or stimulated Th1 cells as driver populations. Genes differentially expressed in the tester but not in the driver could be examined directly by the use of cDNA microarray. A database is being generated to contain lists of differentially expressed genes of Th2 cells at different time points after activation by allergen exposure.

Program Nr: 1268 from the 1999 ASHG Annual Meeting

Genomic organization and characterization of a human MSUD locus (E1a gene of BCKAD complex) on chromosome 19q13.2: mapped to a single BAC clone. *L.D. Love-Gregory[1], J.R. Newton[2], R.E. Hillman[1,2,3], C.L. Phillips[1,2,3]*. 1) Genetics Area Program; 2) Department of Biochemistry; 3) Department of Child Health, Division of Medical Genetics, University of Missouri-Columbia, Columbia, MO.

Maple Syrup Urine Disease (MSUD), an autosomal recessive metabolic disorder, results from defects in the multienzyme branched chain a-keto acid dehydrogenase (BCKAD) complex (incidence 1/200,000). In Old Order Mennonite communities, MSUD estimated at 1/176 live births, results from a tyrosine to asparagine substitution (Y438N formerly Y393N) in the BCKAD E1a gene (attributed to a founder effect). We found 19% of non-Mennonite MSUD patients also have the Y438N allele (either homozygote or compound heterozygote).

To determine if the prevalence of the Y438N E1a allele in non-Mennonite MSUD patients is the result of a founder effect, we propose to evaluate microsatellite markers tightly linked to the E1a gene (chromosome 19q13.2). In an effort to refine the genomic map of the E1a locus, to establish informative microsatellites for accurate haplotype analysis, and to characterize genomic organization, we screened a human BAC library (Research Genetics, Huntsville, AL) using E1a exon 9 sequence to isolate BAC clones containing the entire E1a gene and its flanking regions. Presently, we have 1) identified two overlapping BAC clones, 228O8 and 123G5 (approximatetly 130 Kb each), 2) determined by southern blot hybridization to exons 1, 4, 5, 7, and 9 sequences and PCR amplification of exons 4, 7, and 9 sequences that BAC 228O8 contains exons 5-9 of the E1a gene, and BAC 123G5 contains the entire E1a gene (exons 1-9, 55 Kb), and 3) determined by southern blot analysis the presence of at least one CA-repeat within BAC 123G5, which is close to the E1a locus. Presence of the entire BCKAD E1a gene and CA repeat(s) within BAC 123G5 will allow us 1) to continue to refine the genomic map of this locus within chromosome 19q13.2, and 2) to identify and characterize informative microsatellites and single nucleotide polymorphisms for haplotype analyses of the non-Mennonite MSUD Y438N alleles.

Program Nr: 1269 from the 1999 ASHG Annual Meeting

Is there a "Goldenhar" gene in 4p15.3? *H.-J. Ludecke[1], J.M. Graham, Jr.[2], S. Lindow[1], B. Horsthemke[1].* 1) Institut für Humangenetik, Universitätsklinikum, Essen, Germany; 2) Medical Genetics Birth Defects Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Oculo-auriculo-vertebral (OAV) dysplasia or Goldenhar "syndrome" is characterized by hemifacial microsomia, microtia, preauricular tags, and epibulbar dermoids. Although most cases are sporadic, several families with autosomal dominant transmission of the disease with variable expression have been described, but without an association to a particular chromosomal region.

We describe a girl with multiple exostoses, hemifacial microsomia, microtia, an epibulbar dermoid cyst, a large VSD, hypoglycemia, immunodeficiency, and mild developmental delay. The patient has an apparently balanced translocation t(4;8)(p15.3;q24.1), which disrupts the *EXT1* gene on chromosome 8q24 in intron 5. Some clinical features of the OAV spectrum as well as immunodeficiency also occur in some patients with Wolf-Hirschhorn syndrome and a large deletion in 4p. In order to identify genes in 4p responsible for the OAV phenotype of our patient, we have constructed a genomic l-phage library from the patient's DNA and isolated clones for both translocation junctions. Furthermore, we constructed a PAC clone contig and identified two YAC clones covering the chromosome 4 breakpoint. This allowed us to map the breakpoint between D4S403 and D4S1601. Sequencing of the translocation junctions revealed microdeletions of 10 bp and 57 bp on chromosomes 4 and 8, respectively, flanked by short nucleotide stretches present on both normal chromosomes. Preliminary analysis of approximately 4.5 kb of DNA of the chromosome 4 breakpoint region did not reveal any potential gene sequences.

Interestingly, the homeobox gene *BAPX1* maps approximately 100 kb proximal to the translocation breakpoint. The orthologous gene of *Xenopus* is expressed in a region of the developing facial cartilage. Although our data indicate that the gene is not disrupted by the translocation, it may be affected by a position effect. The *CD38* gene in 4p15, which plays a role in T and B lymphocyte development, does not map to any of our clones and thus may not be involved in the immunodeficiency in our patient.

Program Nr: 1270 from the 1999 ASHG Annual Meeting

Mouse A9 cells containing a single human chromosome for the analysis of genomic imprinting. *S. Maegawa[1], N. Kubota[1], E. Nanba[1], J. Inoue[2], H. Kugoh[2], K. Mitsuya[2], M. Meguro[2], K. Shigenami[2], T.C. Schulz[2], M. Oshimura[2,3]*. 1) Gene Research Center, Tottori University, Yonago, Tottori, Japan; 2) Department of Molecular and Cell Genetics, School of Life Sciences, Faculty of Medicine, Tottori University, Yonago, Tottori, Japan; 3) Core Research for Evolutional Science snd Technology (CREST), Japan Science and Technology Corporation (JST), Japan.

To develop a systematic in vitro approach for the study of genomic imprinting, we generated human/mouse A9 monochromosomal hybrids. We made whole cell fusion and microcell-mediated chromosome transfer to generate A9 hybrids containing a single, intact, bsr or neo-tagged human chromosome derived from primary human fibroblasts. A9 hybrids that contained either human chromosome 1, 2, 4, 5, 6, 7, 8, 10, 11, 15, 18, 19, 20, or X were identified by fluorescence in situ hybridization and DNA analyses. The parental origin of these chromosomes was determined by DNA polymorphic analysis using microsatellite markers, and matched hybrids containing maternal and paternal chromosomes were identified for chromosomes 1, 5, 6, 10, 11, 15, 18 and 19. The parental-origin-specific expression patterns of several known imprinted gene on different human chromosomes were maintained in the A9 hybrids. This library of human monochromosomal hybrids is valuable resources for the mapping and a novel in vitro system for screening of imprinted genes and for their functional analyses. *in vitroin vivoin situ*.

Program Nr: 1271 from the 1999 ASHG Annual Meeting

A cDNA selection approach to isolate Y chromosome genes expressed in testis. *E. Makrinou[1], K. Taylor[1], M. Lovett[3], R. Del Mastro[3], Y. Edwards[2]*. 1) Biology,The Galton Laboratory, University College of London, London, England; 2) Medical Research Council, Human Biochemical Genetics Unit, The Galton Laboratory; 3) University of Texas; Southwestern Medical Centre; Dallas USA.

Statistical analysis has revealed that 2-7% of couples remain childless at the end of their reproductive life. In about half of these cases of infertility, the problem lies with the male partner. It is expected that genes expressed in the testis and involved in spermatogenesis, will occur on the mammalian Y chromosome. This view has been confirmed with the isolation of the RBM and DAZ gene families. In an effort to identify further Y-linked testis specific genes, a cDNA selection library was constructed, using adult testis cDNA, and DNA from 1,000 Y-linked cosmid clones. This library was made in collaboration with M. Lovett and R. Del Mastro at the University of Texas. Screening with vector sequencs and Y chromosome repeat sequences, has led to the elimination of 91% of the clones. 414 potential cDNA clones remain, and so far 60 have been sequenced. cDNA clones with homology to EST's and STS's on the Y chromosome have been identified. Five of these seem to represent novel members of two gene families. These genes have been localised on the Y chromosome by FISH analysis, and RT-PCRs on tissues that have been known sex determined, show that they are expressed in testis. We are in the process of screening a panel of DNA from oligo- and azoospermic patients for deletions in these genes.

Program Nr: 1272 from the 1999 ASHG Annual Meeting

Molecular characterization of carnitine palmitoyltransferase 1 deficiency in a Canadian Hutterite family. *N. ABADI[1], L. THUILLIER[1], C. PRASAD[5], L. DILLING[5], F. DEMAUGRE[1], C. PRIP-BUUS[3], A. BELBACHIR[1], M. BRIVET[4], N. KADHOM[2], J.P. BONNEFONT[1,2]*. 1) Genetic Biochemistry Unit and; 2) Unit INSERM U393, CHU Necker, PARIS; 3) Ceremod CNRS UPR 9078 MEUDON; 4) Biochemistry Unit,CHU Bicetre, FRANCE and; 5) Health Science Center, Section of Genetics and Metabolism, Winnipeg, CANADA R3AIR9.

Carnitine palmitoyltransferase (CPT) deficiencies are autosomal recessive disorders of mitochondrial long-chain fatty acid (LCFA) oxidation. While the “muscular“ and “hepato- cardio- muscular“ phenotypes of the diseases have been ascribed to a deficiency of CPT2, an enzyme of the inner mitochondrial membrane, the “hepatic“ presentation is known to result from a CPT1 deficiency. CPT1, an enzyme of the outer mitochondrial membrane that controls LCFA oxidation, has two distinct isoforms (the so-called “liver“ and “muscle“ CPT1s) encoded by two different genes. More than 10 patients with a L-CPT1 deficiency have been hitherto reported, but only one CPT1 mutation has been identified to date. We report here the resolution of the molecular defect in three L-CPT1 deficient patients belonging to an extended inbred Hutterite kindred (Haworth et al. J. Pediatr. 1992:553-557). The patients suffered from recurrent attacks of hypoketotic hypoglycemia with hepatomegaly. CPT1 activities in their fibroblasts were 10 to 15 % of controls. Sequencing of the full-length L-CPT1 cDNAs detected a homozygous G®A transition at nt 2129, predicting a Gly710®Asp substitution in all three patients. This mutation was not found in genomic DNAs from 50 controls. The substituted aminoacid is located within a stretch of 16 aminoacids highly conserved across species and CPT isoforms. This stretch has recently been suggested to be involved in the binding of carnitine to CPT2 in the rat. A functional analysis based on heterologous expression of the mutant CPT1 in yeast is under progress to study the consequences of the mutation upon the enzyme activity and the CPT1 immunoreactive protein. This analysis might contribute delineating a protein region critical for the function of this enzyme.

Program Nr: 1273 from the 1999 ASHG Annual Meeting

Trimethylaminuria is caused by mutations of the *FMO3* gene in a North American cohort. *B.R. Akerman[1], D.M. Lambert[1], H. Lemass[5], L.M.L. Chow[3], C. Greenberg[4], O.A. Mamer[2], E.P. Treacy[1]*. 1) Biochemical Genetics Unit, McGill Univ./Montreal Children's Hosp, Montreal, QC, Canada; 2) Mass Spectrometry Unit, McGill Univ., Montreal, QC, Canada; 3) Hospital for Sick Children, Toronto, ON, Canada; 4) Children's Hospital, Winnipeg, MB, Canada; 5) Mater Hospital, Dublin, Ireland.

Flavin-containing monooxygenases (FMOs) are microsomal NADPH-dependent enzymes that catalyze the oxygenation of nitrogen, sulfur, phosphorous and other heteroatom-containing chemicals, drugs and pesticides. Currently known FMOs comprise a 5-member family. In adult human liver, FMO3 constitutes the predominant form that metabolizes the above to polar readily excreted oxygenated metabolites. Trimethylaminuria (TMAuria; McKusick 136131) is an autosomal recessive condition caused by a partial or total incapacity to catalyze the N-oxygenation of the odorous compound trimethylamine (TMA), derived from dietary choline and lecithin. The result is a severe body odor and associated psychosocial conditions. This inborn error of metabolism, previously considered rare, is being increasingly detected in severe and milder presentations. We have previously shown that 4 mutations of the *FMO3* gene are causative of TMAuria in Australians (Treacy et al. 1998; Akerman et al. 1999). Of 28 individuals referred to our Unit for investigation of malodor from N. America, 10 had severe TMAuria (less than 50% of TMA oxidation) as measured by a FAB-MS assay of TMA and TMA N-oxide. We performed mutation analysis in 8 of these probands. In addition to three previously described FMO3 mutations (P153L, E305X and R492W), we detected 4 new mutations: 2 missense (A52T, (1); R387L, (2)) and one nonsense mutation (E314X). The fourth allele is apparently composed of 2 relatively common polymorphisms (K158-G308) found in the general population. Screening for known *FMO3* mutations indicates that severe TMAuria alleles are rare in a Quebec control population and thus TMAuria is predicted to be rare in this population. We conclude that one predominant mutation (P153L) and an increasing number of private mutations of different ethnic origins will account for TMAuria in North Americans.

Program Nr: 1274 from the 1999 ASHG Annual Meeting

Detection of 16 new mutations in Fabry disease. *G. Altarescu, L. Goldfarb, K-Y. Park, C. Kaneski, S. Litvak, R. Schiffmann.* NINDS, National Institutes of Health, Bethesda, MD.

Objective: Characterization of alpha-galactosidase A (AGA) gene mutations in a cohort of Fabry disease patients (n=32).Introduction: Fabry disease is an X-linked inborn error of metabolism caused by deficient activity of the lysosomal enzyme alpha-galactosidase A. Glycosphingolipids accumulate in different tissues causing multisystem disease. The main manifestations of Fabry disease include vascular damage in the heart, brain, and kidney, leading to organ failure in early adulthood. The 12-Kb gene for alpha-galactosidase A is located on chromosome Xq22.1 and consists of 7 exons varying in size from 92 to 291 base pairs. Mutations identified in the AGA gene are found throughout all exons. Most families have private mutations consisting of: large rearrangements, insertions, deletions and point mutations.Material and Methods: Blood and skin biopsy specimens were collected from 32 Caucasian patients (30 males and 2 females, 25 families). DNA was extracted using Puregene Genomic DNA Isolation Kit, Gentra Systems Inc. The cells were lysed in the presence of a DNA preservative using an anionic detergent and the genomic DNA was isolated by precipitation with alcohol 70%. Each of exons was amplified by PCR. The samples were then sequenced and the mutations identified.Results: Sixteen of the mutations detected were novel: point mutations, small insertions or deletions leading to the following amino acid changes:Met51Lys; His9X; Pro6X; Val123Met;Trp162X; Glu 250X; Gly261Asp; Lys240X; His302X; Ile 303X; Leu403X; Ser 345 X; Phe 396X (X-stop codon). Conclusions: Our investigation confirms that Fabry disease is associated with multiple mutations in the AGA gene. These findings emphasize the large variety of mutations causing Fabry disease. We have found additional 16 novel mutations to the 125 previously described AGA variants.

Program Nr: 1275 from the 1999 ASHG Annual Meeting

Biochemical and molecular investigations of nonketotic hyperglycinemia. *D.A. Applegarth[1,2], J.R. Toone[2], M.B. Coulter-Mackie[2]*. 1) Director, Biochem Diseases Lab, British Columbia Children Hosp, Vancouver, BC, Canada; 2) Department of Pediatrics, University of B.C. Vancouver, Canada.

Non ketotic hyperglycinemia (NKH) is an autosomal recessive disorder with an incidence in British Columbia, Canada of 1:63,000 live births. It is the commonest disease of amino acids in BC, after PKU, with an incidence greater than the sum of all urea cycle diseases over a 25 year period. One third of patients die in the neonatal period. Those who survive have profound neurological impairment because there is no adequate therapy. NKH is caused by a deficiency of glycine cleavage enzyme (GCE) which is a 4 protein complex (P, H, T and L proteins). L protein deficiency causes additional abnormalities in branched chain amino acid and organic acid metabolism. Identification of P, H or T protein deficiency has rarely been done since the assays require purification of the proteins of the complex. Following a diagnosis of NKH by GCE assay in liver, we have devised a screening strategy to determine which protein is deficient. Liver glycine exchange (Hirago and Kikuchi (1980) JBC 255:1166411670) without added purified H protein has no activity in patients with P or H protein deficiency and shows activity in patients with T protein deficiency. This enzymatic screening strategy is illustrated by the work-up of a patient with classical NKH presenting as a neonate and with no evidence of branched chain amino acid abnormalities. A liver biopsy showed absence of GCE activity and present glycine exchange activity. The patient was shown to be homozygous for R320H (Nanao et al (1994) Hum Gen 93: 655-658) in exon 8 of the T protein gene.

Program Nr: 1276 from the 1999 ASHG Annual Meeting

Protein sufficiency and growth in Phenylketonuria (PKU). *G.L. Arnold, C.J. Vladutiu, J. DeLuca, E. Blakely.*
Division of Pediatric Genetics, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA.

Children with PKU often exhibit sub-optimal growth. This has been attributed to various factors, including inadequate protein intake or poor utilization of L-amino acid protein supplements. We reviewed the records of 39 children ages 3-20 years with classic, early and continuously treated PKU in order to study the relationship between protein sufficiency and growth. Variables included plasma prealbumin, age, and height percentile for age on the National Center for Health Statistics growth curves. Plasma prealbumin values were available for the most recent three or four annual evaluations. For most children, variability between these annual values was less than 10%. For the two children with more variability in prealbumin measurements, the mean value of three annual measurements was used.

Mean age was 8.9 years, mean height was at the 45.8%ile, and mean plasma prealbumin was 20.6 mg/dl. We identified a significant correlation between height percentile and prealbumin, such that children with lower plasma prealbumin tended to be shorter ($r=0.387$, $p<0.025$). There was also a strong correlation between age and prealbumin, with older children having higher prealbumin ($p<0.01$). However, there was no correlation between height percentile and age. Children whose height was less than the 25%ile had lower prealbumin than those with height greater than the 75%ile (17.25 vs 23.0 mg/dl, $p<0.01$). Children with prealbumin <20 mg/dl were younger than those with higher prealbumin (6.6 years vs. 10.6 years, $p<0.001$) and were significantly shorter (30%ile vs. 57%ile,$p<0.004$). These data identify a relationship between growth and plasma prealbumin in PKU, and suggest protein insufficiency plays a role in poor growth in children with PKU.

Program Nr: 1277 from the 1999 ASHG Annual Meeting

Pendred syndrome : Phenotypic heterogeneity in two families carrying the same PDS missense mutation. *H. Ayadi[1], S. Masmoudi[1], I. Charfeddine[2], M. Hmani[1], M. Grati[3], A. Ghorbel[2], A. Boulila-Elgaed[1], J.P. Hardelin[3], M. Drira[2]*. 1) Dept Immunology, Fac de Medecine de Sfax, Sfax, Tunisia; 2) Service d'ORL, CHU H. Bourguiba, 3018 Sfax, Tunisie; 3) Unit de gntique des dficits sensoriels, Institut Pasteur, 25, rue du Dr. Roux, 75725 Paris 15, France.

Pendred syndrome is a recessively inherited disease which is classically defined as the association of congenital sensorineural hearing loss, thyroid goitre and positive perchlorate discharge test. This disease has recently been shown to be caused by mutations in the PDS gene, which encodes an anion transporter called pendrin. Molecular analysis of the PDS gene was performed in two consanguineous large families from Southern Tunisia comprising a total of 23 individuals affected with profound congenital deafness; the same missense mutation, L445W, was identified in all affected individuals. Widened vestibular aqueducts were found in all the patients who underwent CT scan exploration of the inner ear. In contrast, goitre was present only in 11 affected individuals, who interestingly had a normal perchlorate discharge test whenever performed. Therefore, the present results further question the sensitivity of the perchlorate test for the diagnosis of Pendred syndrome and would support the use of a molecular analysis of the PDS gene in the assessment of individuals with severe to profound congenital hearing loss associated with inner ear morphological anomaly, even in the absence of a thyroid goitre.

Program Nr: 1278 from the 1999 ASHG Annual Meeting

SEVERE HYPOGLYCEMIA AS A PRESENTING SYMPTOM OF CARBOHYDRATE-DEFICIENT GLYCOPROTEIN SYNDROME. *D. Babovic-Vuksanovic[1], M.C. Patterson[1], W.F. Schwenk[1], J.F. O'Brien[1], J. Vockley[1], H.H. Freeze[2], D.P. Mehta[2], V.V. Michels[1]*. 1) Dept Medical Genetics, Dept Pediatric and Adolescent Medicine, Dept Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) The Burnham Institute, La Jolla, CA.

Carbohydrate-deficient glycoprotein syndrome (CDGS) Type Ib is a newly recognized form of CDGS caused by deficiency of phosphomannose isomerase (PMI). The phenotype in affected patients is fundamentally different from the CDGS Type Ia. There is no cognitive or neurologic impairment, but marked gastrointestinal and liver symptomatology. We describe clinical, biochemical and molecular findings in a 2 years, 6 month old girl with PMI. Our patient presented with severe and persistent hypoglycemia, and subsequently developed protein-losing enteropathy, liver disease and coagulopathy. Six months of therapy with mannose supplementation resulted in clinical improvement and partial correction of biochemical abnormalities. It is important to increase awareness of this disease since early diagnosis and therapy may be beneficial. CDGS Type Ib should be considered in the differential diagnosis of patients with unexplained hypoglycemia, especially in presence of other symptoms such as chronic diarrhea, cyclic vomiting, liver disease or coagulopathy.

Program Nr: 1279 from the 1999 ASHG Annual Meeting

Facioscapulohumeral Muscular Dystrophy Myoblasts Have Increased Susceptibility to Oxidative Stress. *K.A. Barrett[1,2], J.D. Forrester[1], R. Tawil[1], R.C. Griggs[1], D.A. Figlewicz[1,2].* 1) Department of Neurology, University of Rochester School of Medicine & Dentistry , Rochester, NY; 2) Department of Neurobiology & Anatomy, University of Rochester School of Medicine & Dentistry, Rochester, NY.

Facioscapulohumeral Muscular Dystrophy (FSHD), the third most common muscular dystrophy, with an estimated prevalence of 1:20,000, is inherited as an autosomal dominant trait. Although no specific gene defect has been identified, FSHD has been associated with a deletion in a repeat region on chromosome 4q35. In culture, FSHD myoblasts display general signs of necrosis (cytoplasmic vacuoles and swelling) and differentiate into disorganized, vacuolated myotubules. In an effort to better understand this phenotype, the current study exposed FSHD myoblasts, myotubes and normal control cells to paraquat, a generator of superoxide radicals, and staurosporine, a protein kinase C inhibitor. Cells were obtained from muscle biopsies and grown to approximately 60% confluence in high serum-containing growth media. Normal growth media was removed from the myoblast cultures and replaced with media containing varying concentrations of paraquat or staurosporine for 24 and 72 hours. Survival for each concentration of toxin was expressed as a fraction of growth in sister wells containing normal growth media. Another set of cells was differentiated into myotubules and processed as described above. Results demonstrate a statistically significant increased susceptibility of FSHD myoblasts to paraquat compared to normal control myoblasts, whereas no such difference was observed for staurosporine exposure. FSHD myotubules and normal myotubules possess an equivalent vulnerability to both toxins. These results are in stark contrast to dystrophin lacking cells. In a similar study, Rando et al (1997) found that dystrophin lacking myotubules, but not myoblasts, were differentially susceptible to oxidative stress. The current work indicates a defect early in myogenesis in FSHD, perhaps in cell cycle regulation. Supported in part by grants from the MDA-USA; New York State Dept of Education; and the Wayne C. Gorell, Jr. Laboratory of the University of Rochester.

Program Nr: 1280 from the 1999 ASHG Annual Meeting

A simple PCR based assay allows detection of a common mutation, IVS8-1G>C, in DHCR7 in Smith-Lemli-Opitz Syndrome patients. *K.P. Battaile[1], C.L. Maslen[2], F.D. Porter[3], R.D. Steiner[1]*. 1) Pediatrics and Molecular & Medical Genetics, Oregon Health Sciences University, Portland, OR; 2) Department of Medicine, Oregon Health Sciences University, Portland, OR; 3) Heritable Disorders Branch, NICHHD, Bethesda, MD.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive condition resulting from a deficiency of the enzyme 7-dehydrocholesterol-delta7-reductase. SLOS is a clinically heterogeneous syndrome with symptoms ranging from severe congenital anomalies to mild mental retardation. We and other groups have previously reported that mutations in DHCR7 cause SLOS. We have developed a novel PCR based assay to detect the common mutation in SLOS, IVS8-1G>C, which is a G to C transversion in the splice acceptor site 5 to exon 9. This mutation results in the elimination of a ScrF1 restriction and the inclusion of 134 bp of intron in the cDNA, presumably due to the use of an alternate upstream splice site. Our assay involves amplification of a 129 bp region of the genomic DNA then digestion of the PCR product with ScrF1 followed by visualization of products by agarose gel electrophoresis.

Using this novel assay we rapidly screened genomic DNA from 18 patients and 43 controls. We found heterozygosity for this mutation in 10, and homozygosity in 1 of 18 unrelated patients and none of the controls. The high incidence of this mutation in SLOS in conjunction with the simplicity and reliability of this PCR based assay makes this a convenient test to aid in patient diagnosis and carrier detection, and opens up the possibility of prenatal molecular genetic diagnostic testing.

Program Nr: 1281 from the 1999 ASHG Annual Meeting

EFFECTS OF WILD-TYPE OR MUTANT HUNTINGTIN IN STRIATAL CELLS. *J.H Bauer*[*2], D. Rigamonti*[*1], C. De-Fraja[1], L. Conti[1], S. Sipione[1], C. Sciorati[3], E. Clementi[3], A. Hackam[4], M.R. Hayden[4], Y. Li[2], J.K. Cooper[5], C.A. Ross[5], C. Vincenz[2], E. Cattaneo[1]*. 1) Institute of Pharmacological Sciences, University of Milano, Via Balzaretti 9, 20133 Milano, Italy; 2) Dept. of Pathology, University of Michigan, Ann Arbor, MI, U.S.A; 3) Di.Bi.T. San Raffaele Hospital, Milano, Italy; 4) University of British Columbia, Vancouver, British Columbia, Canada; 5) Dept. of Psychiatry, Johns Hopkins University, Baltimore, U.S.A.

Huntington's Disease (HD) is due to a defect in a gene called IT15 characterized by the presence of an unstable CAG repeat encoding for a polyglutamine sequence. Despite ubiquitous expression of the normal and mutant Huntingtin (Htt) protein, HD results in a selective neuronal loss prominent in the basal ganglia and in the cerebral cortex. The mechanism of cell death and the functions of either the normal or the mutant proteins are still unknown. Cellular models of HD would greatly assist this analyses. DARPP-32 positive striatal derived ST14A cells (Cattaneo and Conti, Journal Neurosci. Res., 1998) have been stably transfected with various constructs containing different portions of the Htt protein in the wild-type or in the mutant form. We found that wild-type Htt acts by protecting cells from a variety of apoptotic stimuli. Protection takes place upstream of caspase 3. The full length protein also modulates the toxicity of the poly-Q expansion. Cells expressing full length mutant protein are susceptible to fewer death stimuli than cells expressing truncated mutant Huntingtin *co-first authors (supported by the Huntington's Disease Society of America, the Hereditary Disease Foundation, Telethon (Italy #E840), C.N.R. (Italy, #98.01050.CT04) to E.C., NIH-ROI E50811 and DAMD 17-96-1-6085 to C.V. and NIH NS16375 to C.A.R.).

Program Nr: 1282 from the 1999 ASHG Annual Meeting

Normal size cubilin in a patient with megaloblastic anemia 1. *E.V. Bawle[1], S.K. Moestrup[2].* 1) Genetic Metab/Disorders, Children's Hosp Michigan, Detroit, MI; 2) Dept.of Medical Biochemistry,Univ of Aarhus,Aarhus,Denmark.

Megaloblastic anemia 1(MGA1,OMIM 261100)is an autosomal recessive disorder characterized by juvenile megaloblastic anemia, neurological symptoms and benign proteinuria. It is caused by selective malabsorption of intrinsic factor(IF)-vitamin B_{12}complex and is also known as Imerslund-Gräsbeck's disease. Recently, circumstantial evidence for a defective IF-B_{12}intestinal receptor named cubilin as the basis for this condition has been published. Moreover,in 17 Finnish families with MGA1,mutations in CUBN,the gene encoding cubilin,have been reported,indicating CUBN to be the disease causing gene. A missense mutation with normal size cubilin was reported in the majority of those families. We report a MGA1 patient of German-Scottish ancestry with normal size cubilin. Her symptoms began at the age of 8 years with weakness in lower extremities,ataxia and urinary incontinence. Her fullscale IQ was in the borderline range(72) and she was having difficulty in keeping up with 3rd grade work. She showed proximal muscle weakness and loss of sense of vibration in the lower extremities. An EMG & nerve conduction in the legs showed demyelinating motor and sensory neuropathy. Brain MRI showed mild cortical atrophy. Her hemoglobin was normal but there was macrocytosis of the RBCs. Methylmalonic & methylcitric aciduria were found by organic acid screening. Serum vitamin B_{12}level was <60 pg/ml(normal 187-1059)with normal folate level.IF blocking antibodies were not detected in the serum. Urine had 10-20 RBCS/hpf,132 mg/dl protein,and protein/creatinine of 1.A Schilling test with & without IF showed B_{12}urinary excretion of 0.4%& 0.2%(average normal 20%)confirming IF-B_{12}receptor defect. Her neuropathy disappeared and school work improved with a B_{12}injection every 10 days. An analysis of a freshly obtained immediately frozen urine by SDS-PAGE showed the same protein profile of proteinuria as other MGA1 patients. The size of the urine cubilin estimated by western blotting was comparable to that of normal urine and IF-B_{12}affinity purified cubilin thus excluding a major deletion in CUBN. Our patient either has a functional defect in the cubilin or there is genetic heterogeneity.

Program Nr: 1283 from the 1999 ASHG Annual Meeting

Mutational analysis, carrier detection, and parental origin of mutation studies in 39 families affected with Hunter syndrome. *A. Bellows, J. Thompson.* Department of Human Genetics, University of Alabama at Birmingham, Birmingham, AL.

Hunter syndrome (Mucopolysaccharidosis type II) is an X-linked disorder resulting from a deficiency of the lysosomal sulfatase, iduronate-2-sulfatase (IDS). Two forms of Hunter syndrome, mild and severe, are recognized representing the two ends of a wide spectrum of clinical manifestations. The clinical variability seen among Hunter patients is believed to be due to genetic heterogeneity within this gene. The IDS gene maps to Xq28, spans 24kb, and contains 9 exons and 8 introns. In the present investigation, 39 patients were enzymatically diagnosed with Hunter syndrome by the demonstration of IDS deficiency. To further delineate the IDS gene defects, total RNA and genomic DNA were extracted from peripheral leukocytes or cultured fibroblasts from the patients and their at-risk female relatives. Mutation detection was performed by sequencing of cDNA fragments. Mutation confirmation and heterozygote analysis was done by restriction enzyme digestion or sequencing of the appropriate exon from genomic DNA. Among the 39 mutant alleles identified, there were 24 missense mutations, 1 nonsense mutations, 8 mutations affecting splicing, 5 small deletions or insertions, and 1 complete deletion of the IDS gene. Fifteen of the mutations were novel and unique, however, 1 of the new mutations was found in 2 unrelated patients. Five mutations (R88C, S333L, S349R, R468Q, and 1122C®T) were found repeatedly in this study, indicating that these codons are hotspots for mutation. The majority of the mutations (64%) were found in exons 3, 8, and 9. Of the 34 mothers available for study, 29 (85%) were identified as carriers. In the patient with the complete deletion, haplotype analysis revealed haploinsufficiency in both the proband's mother and sister, thus confirming their heterozygote status. Haplotype analysis was used to determine the parental origin of mutation. In 10 families in which multigenerational members were available, 5 families were found to have a paternal origin of mutation and 5 had a maternal origin. The present investigation further emphasizes the genetic heterogeneity of the IDS gene.

Program Nr: 1284 from the 1999 ASHG Annual Meeting

Cloning and expression of guinea pig lysosomal a-**mannosidase and characterization of a mutation causing** a-**mannosidosis in a guinea pig colony.** *T. Berg, J.J. Hopwood.* Chemical Pathology, Women's and Children's Hospital, Adelaide, South Australia.

Lysosomal a-mannosidase is an exoglycosidase involved in the degradation of glycoproteins. Deficiency of this enzyme leads to the lysosomal storage disorder a-mannosidosis. The inherited form of a-mannosidosis has been identified in humans, cattle, cats, and recently, also in guinea pigs. At the cellular level the disease is characterized by lysosomal accumulation of mannose-containing oligosaccharides. Clinically, affected individuals express progressive mental deterioration in addition to a number of non-neurological symptoms involving the visceral organs and the blood and the skeletal systems. Affected cattle and cats usually die before they reach 6 months of age. The phenotype in guinea pigs is significantly milder as affected animals survive into adulthood (>1 year). Hence it resembles the human form where most patients survive into adulthood. In order to characterize the guinea pig model at the molecular level, we used a PCR-based strategy to isolate and sequence the full length a-mannosidase cDNA from guinea pigs. The cDNA sequence contained an open reading frame encoding 1007 amino acids with 79% sequence identity to the human a-mannosidase sequence. Transient expression of the cDNA in COS-7 cells gave a 7 fold elevation in the a-mannosidase level. Sequencing of the a-mannosidase cDNA from an affected animal revealed a mutation causing substitution of a conserved arginine with tryptophan (R227W). Further, PCR-based screening demonstrated that the R227W mutation was uniquely associated with a-mannosidosis in the guinea pig colony and thus supporting the notion that the R227W mutation is causing disease. Mass spectrometry revealed that the storage products in guinea pigs cells and urine contained only single GlcNAc residues at their reducing ends. Hence, the stored oligosaccharides in guinea pigs are, in contrast to the other animal models, identical to the storage products in human patients. This work will form the basis for development and evaluation of therapeutic strategies for neuronal storage diseases using guinea pigs as a convenient model.

Program Nr: 1285 from the 1999 ASHG Annual Meeting

Prolidase deficiency: Clinical and biochemical characterization of the disease and prenatal diagnosis in a genetic isolate in Israel. *Z.U. Borochowitz[1], T.C. Falik-Zaccai[1], M. Jaffe[2], P. Savoie[3], N. Abeling[4], A.H. van Gennip[4], P. Hechtman[3].* 1) Simon Winter Inst Medical Gen, Bnai-Zion Med. Ctr. Haifa, Israel; 2) Dep. Pediatrics, Bnai Zion Med. Cent. Haifa Israel; 3) Dep. Clin Biochem, Montreal Child Hosp, Canada; 4) AMC.Univ of Amsterdam, The Netherlands.

Prolidase deficiency (PD) is a rare autosomal recessive metabolic disorder. The clinical phenotype varies among affected individuals from no manifestation to severe progressive skin lesions, severe infections and impaired cognitive development. We have studies 6 patients from a large, highly consanguineous, Arabic Moslem kindred and report here the first prenatal diagnosis for PD. Three of the 6 patients presented within the first year of life with fulminant sepsis. The 3 others presented with various degrees of developmental delay, failure to thrive, facial dysmorphism and eczema. One patient developed clinical and immunologic abnormalities consistent with systemic lupus erythematosus. Using Bidimentional TLC and amino acid analyzer on urine samples before and after hydrolysis has revealed large amounts of iminopeptited in the urine of 5 of the 6 patients. Prolidase activity was absent in fibroblasts of 2 patients. Following the biochemical analysis prenatal diagnosis was offered to couples at risk within the large kindred. Amniocytes were cultured and studied for prolidase specific activity (uMoles Proline/h/mgProt) which was found to be markedly reduced. The fetus was predicated to be affected but parents have decided to continue the pregnancy. Diagnosis of PD was confirmed after birth studying prolidase activity in cultured fibroblasts of foreskin (1.42 +/-0.54) compared to healthy control (20.46 +/-0.99) and resembling a known unrelated PD cell line (0.23+/-0.26) and his affected sister (0.20 +/-0.16). At the age of 4 month this baby is well developed for his age, slightly dysmorphic and suffers severe episodes of bronchitis and diarrhea. PD is highly prevalent in this Arabic village. Prenatal diagnosis to couples at risk of a non treatable metabolic disorder of such highly variable expression is complicated and should be considered following comprehensive genetic counseling.

Program Nr: 1286 from the 1999 ASHG Annual Meeting

Analysis of PON1 Status Requires Both Genotype and Phenotype. *V.H Brophy, G.P. Jarvik, R.J. Richter, L.S. Rozek, J.J. Lum, C.E. Furlong.* Medicine, Div. of Med. Genetics, University of Washington, Seattle, WA.

Paraoxonase (PON1), an HDL associated enzyme, is believed to protect against atherosclerosis by metabolizing oxidized lipids. PON1 also hydrolyzes the bioactive oxon forms of organophosphate pesticides such as parathion, diazinon, and chlorpyrifos. Two polymorphisms have been identified in the coding sequence of human PON1: met/leu at position 55, arg/gln at 192. While $PON1_{192}$ affects the relative rates of hydrolysis for different substrates, $PON1_{55}$ does not. Previous studies found that $PON1_{M55}$ individuals have lower levels of PON1 mRNA and activity. In this study, we examined the relationships between genotype and PON1 levels. We found considerable overlap in activity level for diazoxon and paraoxon hydrolysis among the $PON1_{55}$ genotypes. Of 274 individuals whose $PON1_{192}$ status was detected by two-dimensional enzyme analysis, 129 (46%) were $PON1_{QQ192}$. Of these, 31 (24%) were $PON1_{LL55}$, 69 (54%) $PON1_{L/M55}$ and 29 (23%) were $PON1_{MM55}$. Analysis of $PON1_{QQ192}$ individuals showed that while the average PON1 diazoxonase activity was 13395 U/L (±3409.8) for $PON1_{LL55}$ and 9120.3 U/L (±2804) for $PON1_{MM55}$, a given $PON1_{MM55}$ could have more than twice the activity of a $PON1_{LL55}$ individual. The $PON1_{192}$ and $PON1_{55}$ polymorphisms account for 74.5% of the interindividual variation in PON1 paraoxonase and only 33.9% in the diazoxonase activity. After adjustment for $PON1_{192}$ genotype the $PON1_{55}$ polymorphism accounts for only 17.3% of the paraoxonase and 13.4% of the diazoxonase residual activity.

$PON1_{R192}$ has a high turnover number for paraoxon than $PON1_{Q192}$ but lower for diazoxon and soman. Seven previous studies have found that the R_{192} allele raises the risk of cardiovascular disease while five studies have found no correlation. The studies, however, examined the genotype of PON1 only, not expression levels. We found expression level varies widely among individuals and within a genotype. Diazoxonase activity varied 5-fold among $PON1_{QQ192}$, 6-fold among $PON1_{Q/R192}$, and 6-fold among $PON1_{RR192}$. Quantification of PON1 enzyme activities may improve the predictive power of PON1 genotype as a risk factor in cardiovascular studies.

Program Nr: 1287 from the 1999 ASHG Annual Meeting

Enzymatic and molecular pre and postnatal diagnosis of ceroid lipofuscinoses in France. *C. Caillaud[1], J. Manicom[1], J.P. Puech[1], P. Lobel[2], L. Poenaru[1]*. 1) Dept Genetique, CHU Cochin, Paris, France; 2) Center for Advanced Biotechnology and Medicine, Piscataway, New Jersey 08854, USA.

The neuronal ceroid lipofuscinoses (NCL) are a group of inherited neurodegenerative disorders characterized by the accumulation of intralysosomal autofluorescent lipopigments, particularly in neurons. Their main clinical signs are psychomotor retardation, impaired vision and seizures. Four NCL forms have been described according to clinical and morphological features : infantile (INCL), late-infantile (LINCL), juvenile (JNCL) and adult (ANCL). Infantile NCL is caused by defects in the gene CLN1, which encodes a palmitoyl protein thioesterase. Four genes are involved in LINCL : CLN2, encoding a pepstatin-insensitive peptidase, CLN5, encoding a transmembrane protein of unknown function, and two uncloned genes, CLN6 and CLN7. In JNCL, the product of the defective gene, CLN3, is a lysosomal transmembrane protein. The gene responsible for the adult form, CLN4, remains to be identified. Patients with LINCL, the most frequent clinical form in France, were tested for the pepstatin-insensitive peptidase (or pepinase) activity. Only half of the patients exhibited a lack of pepinase activity. These patients were tested for CLN2 mutations, using PCR and automatic sequencing. Two previously described mutations were found in one patient each : an intronic G>C transversion at the 3 splice junction of intron 5 and an Arg208Stop in exon 6. Novel mutations were characterized in the other patients : two point mutations, Gln509Stop in exon 12 and Ser153Pro in exon 5, one 11-bp deletion in exon 13 and a A>G transition at the 3' splice junction of intron 8. A prenatal diagnosis was performed for a couple at risk for the infantile form of ceroid lipofuscinosis. The enzymatic and molecular methods were in accordance, revealing a pepinase deficiency and the presence of both parental mutations. This prenatal diagnosis was the first done by using such techniques in France. Our results demonstrates 1-the usefulness of a new enzymatic method for pre and postnatal diagnosis of LINCL patients, 2-the heterogeneity of the CLN2 mutations, 3-the diversity of the loci involved in the pathogenesis of LINCL.

Program Nr: 1288 from the 1999 ASHG Annual Meeting

A retroviral gene trap insertion at the mouse *rab9* locus. *J.P. Cannon[1], S.M. Colicos[1], S.R. Pfeffer[2], J.W Belmont[1].* 1) Dept Mol & Human Genetics, Baylor Col Med, Houston, TX; 2) Dept Biochem, Stanford Univ School of Med, Stanford, CA.

Rab9 is a member of a large family of GTPases involved in membrane system-specific vesicular trafficking within cells. Dominant-negative mutant analysis has implicated Rab9 in endosome to trans-Golgi trafficking. Rab9 is required for recycling of the mannose-6-phosphate receptor (MPR) from endosome to trans-Golgi and, therefore, plays an essential role in lysosomal enzyme targeting. We have identified a retroviral gene trap insertion at the mouse *rab9* locus, downstream of a single *rab9* coding exon. Expression of the proviral bgeo gene, presumably directed by signals from the endogenous *rab9* locus, was localized to the heart, liver, branchial arches, and limb buds at embryonic day 11.5. bgeo expression in the adult was observed in the brain, liver, myocardium, and autonomic ganglia that innervate the heart. Northern blot hybridization detected *rab9* transcripts in several adult mouse tissues, with highest expression found in the adult liver. Mapping using an interspecific backcross panel placed the mouse *rab9* locus on the distal X chromosome, between the markers *DXMit149* and *DXMit122*. The *rab9*^{bgeo1} allele is apparently subject to X inactivation based on a varietgated pattern of expression in female heterozygotes. Western blot analysis of liver protein from hemizygous mutant males and homozygous mutant females showed that the *rab9*^{bgeo1} gene trap allele is hypomorphic, producing approximately 10% percent of wildtype levels of protein. *rab9*^{bgeo1} mutant animals are fertile and present no overt phenotype by six months of age. In order to better understand the role of the residual protein function, we have developed a null allele by targeted recombination in ES cells. High level male chimeras have been obtained indicating that *rab9*^{null} is not a cell autonomous lethal. Null fibroblast cell lines are being developed for studies of lysosomal enzyme transport and MPR recycling.

Program Nr: 1289 from the 1999 ASHG Annual Meeting

Respiratory-Chain Enzyme Activities in Muscle from HSP Patients. *R. Carrozzo[1], F. Piemonte[1], C. Casali[2], G. Tozzi[1], C. Patrono[1], A. Tessa[1], E. Bertini[1], F.M. Santorelli[1].* 1) Molecular Medicine Unit, Bambino Gesu Hosp, Rome, Italy; 2) Inst of Neurology, La Sapienza University, Rome, Italy.

Hereditary spastic paraplegia (HSP) is a heterogeneous group of disorders characterized by progressive weakness and spasticity of the lower limbs due to degeneration of corticospinal axons. HSP is classified according to both the mode of inheritance (autosomal dominant, recessive, and X-linked) and whether progressive spasticity occurs in isolation (pure forms) or with other neurologic abnormalities (complicated HSP), including optic neuropathy, retinopathy, dementia, ataxia, and deafness. It has been shown that the first HSP gene (SPG7) encodes for a protein (paraplegin) which localizes to mitochondria. Homozygous SPG7 mutations produce typical morphological signs of mitochondrial oxidative phoshorylation (OXPHOS) defects. This suggests an altered OXPHOS mechanism for neurodegeneration in HSP-type disorders. We analyzed respiratory chain enzymes in muscle from HSP patients, negative for paraplegin alterations. Morphological examination of the biopsied muscle (deltoid in four cases, biceps femoralis in two) showed reduced histochemical stain for cytochrome c oxidase (COX) and subsarcolemmal accumulation with succinate dehydrogenase (SDH) stain. Biochemically, we found a statistically sigificant COX reduction (1.6+/-0.4; controls 2.3+/-0.1; $p<0.05$) when values were corrected for the activity of citrate synthase. Complex I activity was also reduced in two patients (40%; and 60%; controls). SDH activity was normal. Interestingly, all the affected enzymatic activities are under a double genetic control, the nDNA and mtDNA. This might suggest a still unclear role for mtDNA sequences in spite of lack of maternal transmission. The role of the mitochondrial antioxidant system in HSP patients is also being investigated. Our data propose the methodical use of a muscle biopsy when examining HSP patients to recognize mitochondrial alterations.

Program Nr: 1290 from the 1999 ASHG Annual Meeting

Molecular analysis of Japanese patients with homocystinuria due to cystathionine beta-synthase deficiency. *S. Chen, M. Ito, T. Saijo, E. Naito, I. Yokota, J. Matsuda, Y. Kuroda.* Department of Pediatrics, School of Medicine, University of Tokushima, Japan.

Homocystinuria due to cystathionine b-synthase (CBS) deficiency is an inborn error of sulfur-amino acid metabolism. More than ninety mutations of the CBS gene in patients with homocystinuria have been reported worldwide, however, the molecular basis of this condition in Japanese is not clear. In this study, we identified eight mutations in six Japanese homocystinuric patients from five different families. The mutations detected included five novel mutations (A194G, G775A, A1321T, exon 9 skipping and 1590-1593 GTTC deletion) and three previously reported mutations (G346A, G430A and exon 12/exons11 and 12 skipping), however, the cause for exon 12/exons 11 and 12 skipping was different from the previous reports. When expressed in Escherichia coli cells, all of the mutant proteins exhibited decreased catalytic activity in vitro, confirming that all of the mutations were pathogenic. Compared with the molecular characteristics of other ethic groups, this study found that exon skipping, nonsense mutation and frame shift mutations in CBS gene were relatively common in Japanese homocystinuric patients.

Program Nr: 1291 from the 1999 ASHG Annual Meeting

Increased elastolysis in Cutis Marmorata Telangiectasia Congenita (CMTC). *D. Chitayat[1], A. Hinek[2], M. Beghetti[3], H.. Tresurer[2], M.M. Silver[4], D. Nykanen[3]*. 1) Division of Clinical Genetics; 2) Cardiovascular research; 3) Division of Cardiology; 4) Department of Pathology. Department of Pediatrics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada.

CMTC is a systemic condition characterized by a reticular vascular skin lesions present from birth. The skin lesions are often extensive and associated with ulcerations and other complications including hemihypertrophy or hemiatrophy, aplasia cutis congenita, intracerebral hemorrhage, glaucoma, hypothyroidism, pulmonary hypertension and developmental and growth delay, seizures, macrocephaly and terminal transverse defects of the limbs. We report a child with CMTC who was born with extensive generalized phlebectasia and nevus vascularis reticularis and developed skin ulcers, intracerebral hemorrhage, retinal detachments, hypothyroidism and pulmonary hypertension. He died at the age of 20 months. Autopsy confirmed multiorgan telangiectasia, ectatic capillary and venous proliferation and severe medial thickening of the small pulmonary arteries. Further studies revealed that his fibroblast culture did not contain any elastic fibers but synthesized normal amounts of tropoelastin, formed normal microfibrillar scaffolds and produced abundant collagen type I and fibronectin. The patients fibroblasts serine elastase(s) activity was twice as high as in controls. Moreover, while incubation of the CMTC fibroblasts with 0.4 M copper sulfate significantly increased their elastolytic activity, addition of 0.4 M calcium chloride or 1-antitrypsin, but not phenantrolin and C-64 (inhibitors of metalo- and serine- proteases, respectively) reduced their elastolytic activity to normal levels. We therefore postulate that the elastolytic activity of the serine protease(s) stimulated by an increased tissue concentration of copper can result in a process which leads to the connective tissue and vascular disorders observed in our patient with CMTC.

Program Nr: 1292 from the 1999 ASHG Annual Meeting

Expression and characterization of normal and mutant human propionyl-CoA carboxylase in *E.coli*. *M. Chloupkova[1], K. Ravn[2], M. Schwarz[2], J.P. Kraus[1]*. 1) Dept Pediatrics, C-233, University of Colorado School of Medicine, Denver, CO; 2) Dept Clin Genet, Rigshospitalet, Copenhagen, Denmark.

Propionic acidemia is an autosomal recessive disorder caused by a deficiency of propionyl-CoA carboxylase (PCC). Human PCC, a mitochondrial matrix enzyme, is composed of nonidentical a and b subunits encoded by the nuclear encoded PCCA and PCCB genes, respectively. We have previously reported on successful expression of human PCC in *E.coli*. The a and b PCC cDNAs were subcloned, without their leader sequences, into a plasmid with two different promoters. Assembly of active PCC necessitated a coexpression of GroES and GroEL chaperones. We have since optimized the expression and purification of recombinant PCC to yield ~3mg/l of culture of homogeneous, fully assembled active enzyme. The kinetic properties of the recombinant PCC are nearly identical to those for PCC purified from human liver. The size of the native enzyme is consistent with an a_6b_6 organization. The relative simplicity and gentle nature of the purification procedure is ideally suited for the purification of selected mutant PCC enzymes.

Almost 60 mutations have been reported in the PCCA and PCCB genes, however, only the T428I mutation in the b subunit has been expressed and partially characterized. Exon 15 in the b subunit is one of the two sites where a number of mutations have been identified in propionic acidemia patients. The 513insP has been found at an unusually high carrier frequency of 1:17 in the Inuit population of Greenland. We have introduced this mutation into our expression construct and expressed the mutant protein in *E.coli*. The insertion of a proline completely inactivated the enzyme. Western blot analysis revealed normal amount of a and b subunits suggesting that the observed lack of activity is not due to failure to express the protein or due to the instability of the mutant subunits. We are currently analyzing additional mutations found in exon 15 in bPCC.

Program Nr: 1293 from the 1999 ASHG Annual Meeting

Glycine cleavage enzyme complex (GCE): Expression and characterization of the hydrogen-carrier (H) protein component. *F.M. Choy[1], L. Sharp[1], D.A. Applegarth[2].* 1) Dept Biol, Univ Victoria, B.C., Canada; 2) Dept Pediatrics, Univ British Columbia, Vancouver,Canada.

The H protein is a lipoic acid-containing protein and one of the 4 essential components (H, L, P, & T proteins) of the GCE, the major catabolic pathway of glycine. Defects in these protiens result in reduced GCE activity and constitute the biochemical basis of non-ketotic hyperglycinemia (NKH). Most NHK patients with the neonatal phenotype have a defect in the P protein. GCE activity assay for the biochemical diagnosis of NKH from P protein defects requires the presence of purified H protein in excess. Chicken liver is usually used as the source because it is available commercially and H protein is expressed in the liver (besides kidney & brain). However, the purification is time consuming and the yield is low. We have isolated the full length cDNA of H protein from the rabbit by reverse transcription of liver mRNA. It is comprised of 2 regions that encodes a 48-amino-acid mitochondria target sequence and a 125-amino acid residue that constitutes the mature matrix protein. There is a 73 and 98.4% sequence homology in these regions to human, versus a 43.6 and 84.5% homology in the same regions between chicken and human. Our data demonstrate that the mitochondria target and mature matrix protein regions in the H protein gene may have evolved differently. Gene diversification is noted in the former which reflects the species specificity. However, the later is very well conserved and suggests a very similar structure-function of the mature protein among these species in evolution. The mature H protein cDNA was cloned in-frame 3' to the *Saccharomyces cerevisiae* a-secretion signal in pPICZaA vector and transformed into *Pichia pastoris* KM71 strain using electroporation. Aliqots were taken from the culture medium of *P. pastoris* following methanol induction from 0 to 96 hr. The apo-H protein was highly expressed in the secreted form after 24 hr of induction and was maintained up to 96 hr. The production of sufficient amounts of recombinant H protein will facilitate the biochemical characterization of the GCE and its implications in NKH.

Program Nr: 1294 from the 1999 ASHG Annual Meeting

Why cells die in inherited neuronal degenerations (INDs): exponential death kinetics exclude cumulative damage, identify a constant or decreasing death risk, and suggest a mutant steady state model. *G.A. Clarke[1,2], R.A. Collins[2], C.J. Lumsden[3], R.R. McInnes[1,2,3].* 1) Program in Devel. Biol., Hospital for Sick Children, Toronto; 2) Dept. Molec. & Med. Genet., U of Toronto; 3) Institute. Med. Sci., U of Toronto, Canada.

INDs are generally characterized by a delay - varying from months to decades - in the onset of clinical symptoms. This presymptomatic interval has been assumed to reflect age-dependent cumulative damage. For example, cell death in INDs such as Alzheimer's disease has been suggested to result from an excess O_2 radicals which overwhelm protective mechanisms, damage macromolecules, and cumulatively disrupt metabolism (e.g. Coyle and Puttfarken, Science, 262:689, 1993; Cassarino and Bennett, Brain Res. Rev. 29:1, 1999). The cumulative damage hypothesis predicts that the probability of cell death will increase over time. To test this hypothesis, we used regression analysis to determine whether the kinetics of neuronal death in 11 animal models of inherited retinal degeneration and in patients with Parkinson's disease could be fit to mathematical models in which the risk of cell death either increased, decreased, or remained constant with age. Our analyses clearly demonstrate that the temporal patterns of cell death in these diseases are best explained by models in which the risk of death remains constant or decreases exponentially with age. Thus, the probability of neuronal death is not increased by cumulative damage (if such damage occurs), and the time of death of any neuron is random. The role of mutation is therefore to increase the probability of cell death; different mutations increase the probability to different degrees. These findings suggest that i) exponential kinetics may be a shared feature of most, if not all INDs, ii) the chance of rescuing a mutant neuron with treatment does not diminish with age, and iii) the kinetics are most simply accomodated by a biochemical model in which mutation imposes a mutant steady-state on the neuron, a state in which the risk is increased that homeostasis will fail, triggering apoptosis.

Program Nr: 1295 from the 1999 ASHG Annual Meeting

A new phenotypic variant of X-linked adrenoleukodystrophy (ALD) presenting in the newborn period. *D. Corzo[1], G.F. Cox[1], N.M. Hobbs[2], E.J. Quackenbush[1], P. Watkins[3], A. Moser[3], H. Moser[3]*. 1) Div Genetics, Dept Medicine, Children's Hospital, Boston, MA; 2) Div General Pediatrics, Dept Medicine, Children's Hospital, Boston, MA; 3) Kennedy-Krieger Institute, Baltimore, MD.

ALD protein (ALDP) is a peroxisomal membrane protein thought to be involved in the import or anchoring of very long chain fatty acid Co-A synthetase (VLCFAS). Its deficiency leads to impaired degradation and consequent accumulation of saturated VLCFA. Several distinct phenotypes of X-linked ALD exist with ages of onset usually after age 3. We describe an unusual case with a severe neonatal onset.

A 3.3 kg full-term male was born to non-consanguineous French Canadian parents. Hypotonia, poor suck, cholestatic jaundice, and bilateral sensorineural hearing loss were noted in the newborn period and followed by failure to thrive (FTT). Physical exam revealed jaundice, hepatomegaly, hypotonia, and no significant dysmorphism. At two months, he experienced seizure-like activity and had an abnormal EEG. He died at four months from complications of severe FTT, gastrointestinal bleeding, and respiratory failure. .

Laboratory testing revealed increased plasma VLCFA with normal pipecolic acid, phytanic acid, and RBC plasmalogens. In cultured fibroblasts, VLCFA were increased, while phytanic and pristanic acid oxidation and plasmalogen synthesis were normal. Blood and urine total bile acids were increased without detectable di- or trihydroxycholestanoid acids. Brain MRI showed diffuse increased T1 hyperintensities in white matter. Brain MR spectroscopy showed prominent signals consistent with lipid. Electron microscopy of liver revealed peroxisomes of normal size and number. Catalase distribution in fibroblasts was normal. Immunofluorescent staining in fibroblasts revealed a normal pattern for acyl CoA oxidase, absent ALDP, and an unusual pattern of staining for VLCFAS.

This case represents a novel and severe neonatal form of X-linked ALD. Identification of the specific mutation responsible for this phenotype may provide insights into ALDP function.

Program Nr: 1296 from the 1999 ASHG Annual Meeting

Structural basis of phenylketonuria. *R.H. Cotton[1], I.G. Jennings[2], B. Kobe[2].* 1) Mutation Res Ctr, Fitzroy, St Vincents Hosp, Melbourne, Australia; 2) Structural Biology Laboratory, St. Vincent's Institute of Medical Research, Fitzroy, Melbourne, Australia.

Phenylalanine hydroxylase (PAH) is the enzyme that converts phenylalanine to tyrosine as a rate limiting step in phenylalanine catabolism and protein and neurotransmitter biosynthesis. Over 300 mutations have been identified in the gene encoding PAH that result in a deficient enzyme activity and lead to the disorders hyperphenylalaninemia and phenylketonuria. The determination of the crystal structure of PAH now allows the determination of the structural basis of any mutation resulting in PAH deficiency. We present an analysis of the structural basis of 105 classified mutations and the mutations for which the activity of the corresponding expressed proteins has been tested in vitro. We find that the mutations can be classified into six categories, based on the distinct structural and functional effects of the mutations in each category. Missense mutations and small amino acid deletions account for three categories: active site mutations, dimer interface mutations, and domain structure mutations. The remaining three categories are truncation mutations (caused by the introduction of premature stop codons), frameshift mutations, and splicing mutations. The structural information will help predict the likely effects of unclassified and newly discovered mutations.

Program Nr: 1297 from the 1999 ASHG Annual Meeting

A novel major deletion in the alanine glyoxylate aminotransferase gene in type 1 hyperoxaluria. *M.B. Coulter-Mackie[1,2], G. Rumsby[3], J. Toone[1,2], D. Applegarth[1,2]*. 1) Biochemical Diseases Lab, British Columbia Children Hosp, Vancouver, BC, Canada; 2) Department of Pediatrics, University of B.C., Vancouver, Canada; 3) Department of Chemical Pathology, UCL Hospitals, London, UK.

Primary hyperoxaluria type 1 (PH1) is an autosomal recessive disease characterized by progressive kidney failure due to deposition of insoluble calcium oxalate and caused by a deficiency of the liver peroxisomal enzyme alanine glyoxylate aminotransferase (AGT). If AGT is deficient, glyoxylate is converted to insoluble calcium oxalate salts. There is a common polymorphism, the minor allele, in the AGT gene (AGXT) that occurs in up to 20% of the general population. Detection of this allele is useful for diagnostic linkage studies. The minor allele itself is without clinical consequences but when overlaid with a G170R missense alteration the AGT mislocates to the mitochondria. PH1 was confirmed in our patient at age 5 by AGT assay of a liver biopsy. AGT was about 14% of normal consistent with the presence of a mislocation mutation. DNA analysis was performed on the patient, parents and unaffected brother. Typing of the major and minor alleles using markers in intron and exon 1 suggested a deletion of at least part of AGXT. A G170R mislocation mutation in exon 4 was identified in the patient and her father but not the mother but the patient appeared to be homozygous. The results for G170R and the major/minor allele assignments were consistent with deletion and hemizygosity of the affected region of the gene. Analysis of an intron 4 VNTR was consistent with the presence of a deletion extending at least as far as intron 4. The linkage of 3 extragenic microsatellite markers, D2S140, D2S125, and D2S395 was not disrupted. The family members were informative for 2 polymorphisms in AGXT: C1342A in the 3'UTR and A776G in exon 6. Heterozygosity suggests the gene is intact from exon 6 onwards. A combination of PCR and testing for the A776 suggests the 3' end of the deletion is within exon 5 or intron 5. The 5' end is upstream from exon 1. We are using a combination of long range PCR and Southern blotting to delineate the extent of the deletion. This represents the first major deletion documented in AGXT.

Program Nr: 1298 from the 1999 ASHG Annual Meeting

X-linked ichthyosis due to partial deletions of the steroid sulfatase gene. *S. Cuevas-Covarrubias[1], M. Valdes-Flores[2], A. Jimenez-Vaca[1], S. Kofman-Alfaro[1]*. 1) Genetica, Hosp General de Mexico, Mexico, DF, Mexico; 2) Instituto Nacional de Ortopedia, Mexico, DF, Mexico.

X-linked ichthyosis (XLI) is an inherited disease due to steroid sulfatase (STS) deficiency. Onset is at birth or early after birth with dark, regular and adherent skin scales in extremities and trunk. 85-90% of XLI patients have a complete deletion of the STS gene, located on Xp22.3 However, three partial deletions have been reported in the literature, one spanning exons 2-5 and the other two lacking the 3' end of the STS gene. This study describes two partial deletions of the STS gene in two non-related XLI cases. Our initial sample included 90 subjects that were classified as XLI patients through STS assay in leukocytes using 7-3H-dehydroepiandrosterone sulfate as a substrate. Amplification of the 5' and 3' ends of the STS gene was initially performed in all subjects through PCR. Only two patients showed partial amplification of the STS gene, one observed at the 5' end and the other at the 3' end. In these cases, amplification of exons 2 and 5-9 of the STS gene was subsequently performed. The patient with the deletion of the 3' end only amplified exon 1 and the patient that lacked the 5' end only amplified exons 6-10. We informed two novel intragenic deletions of the STS gene causing XLI.

Program Nr: 1299 from the 1999 ASHG Annual Meeting

Topological analysis of the polytopic membrane glycoprotein Niemann-Pick C1. *J.P. Davies, R. Gordon, Y.A. Ioannou.* Human Genetics, Mount Sinai School of Medicine, New York.

Niemann-Pick type C1 (NPC1) is an inherited lysosomal cholesterol storage disorder which results in progressive neurodegeneration and premature death. Recently, the defective gene was identified and is predicted to be a multitopic membrane glycoprotein. NPC1 shares only limited similarity to other known proteins; most notably, a small region is homologous to the putative sterol-sensing domains (SSD) of hydroxymethylglutaryl-Coenzyme A reductase (HMGR) and sterol regulatory element binding-protein cleavage-activating protein (SCAP), two cholesterol-regulated genes. However, the precise function(s) of NPC1 are unknown. To assist our studies we have determined its topology, using glycosylation/ deglycosylation analyses, epitope tagging using the Flag octapeptide sequence, and immunoelectron-microscopy. These studies revealed that NPC1 contains 13 transmembrane domains; 3 large lumenal hydrophilic regions; a single large cytoplasmic loop; a lumenal amino terminus and a cytoplasmic carboxy-terminal tail. Interestingly, the putative SSD of NPC1 is oriented exactly as in HMGR and SCAP, whose topologies have been determined. This strongly suggests that both the protein sequence and its orientation are functionally important in all three proteins. These data will significantly aid our future studies to determine the exact function(s) of this large membrane glycoprotein.

Program Nr: 1300 from the 1999 ASHG Annual Meeting

Mutation analysis of the mevalonate kinase gene in patients with Hyper-IgD and periodic fever syndrome (HIDS): Identification of 3 new mutations. *M. Delpech[1], L. Cuisset[1], JPH. Drenth[1,2], SD. van der Velde Visser[3], G. Grateau,[1,4], JWM. van der Meer[2]*. 1) Genetique Moleculaire Humaine, EA2500, Inst. Cochin Genet Moleculaire, Paris, France; 2) Department of Medicine, Division of General Internal Medicine, University Hospital St. Radboud, Nijmegen, The Netherlands,; 3) Department of Human Genetics, University Hospital St. Radboud, Nijmegen, The Netherlands,; 4) Service de Medecine Interne, L'Hotel-Dieu (AP-HP), Paris, France.

The hyperimmunoglobulinemia D and periodic fever syndrome (HIDS) is a rare familial autosomal recessive disorder featuring recurrent fever. Typical attacks occur every 4 to 8 weeks, and symptoms include lymphadenopathy, abdominal distress, joint involvement and skin lesions. They are associated with an intense acute phase response and all HIDS patients have constantly high serum IgD values (> 100 U/ml) with attacks but also during intervals. We and others recently established mevalonate kinase (ATP:mevalonate 5-phosphotransferase, EC 2.7.I.36) (MVK) as the causative HIDS gene. MVK follows 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase in the synthetic pathway of cholesterol. Four missense mutation (H20P, P167L, I268T, V377I), a 92 bp loss stemming from a deletion or from exon skipping, and the absence of expression of one allele were found in a total of fourteen patients. The V377I (G->A) mutation appeared to be the most common mutation in HIDS. Here we present a study on the mutation spectrum of the MVK gene on nine additional patients. Mutations were found in 18 alleles (100%), of which 8 (44%) carried the V377I (G->A) mutation and 4 (22%) carried the I268T (T->C) mutation. In the six remaining alleles, five different mutations were found. Only two of them, (H20P and the absence of expression of one allele) have been described before. All the three new mutations represent missense mutations and are H20N, R215Q and G326R. These result confirm that the V377I (G->A) mutation is the most common mutation in HIDS and reveal that the I268T (T->C) mutation is also frequent.

Program Nr: 1301 from the 1999 ASHG Annual Meeting

Investigation of functional domains in human lysosomal b**-hexosaminidase A.** *E. Denis[1,2], F. Kaplan[1,3,4], B. Boulay[1], P. Hechtman[1,2,3,4].* 1) McGill University-Montreal Children's Hospital Research Institute; 2) Department of Biology, McGill University; 3) Department of Human Genetics, McGill University; 4) Department of Pediatrics, McGill University, Montreal, Quebec, Canada.

The major b-hexosaminidase isozymes in humans are Hex A (deficient in Tay-Sachs disease, TSD), an ab heterodimer and Hex B (deficient in Sandhoff disease) a bb homodimer. Hex S, the aa homodimer is physiologically unstable. Mature a and b subunits share 60% sequence identity. The b subunit hydrolyzes neutral substrates. The a subunit hydrolyzes neutral (4MUG) and charged substrates (4MUGS). Only Hex A hydrolyzes the natural substrate, G_{M2} ganglioside, in the presence of the G_{M2} activator protein (AP). We investigated regions of the a and b subunits involved in AP binding, subunit dimerization, and substrate specificity. We constructed chimeric cDNAs: $a_{\mathbf{1/2}}b_{\mathbf{1/2}}$ comprises the 5' 50% of the a-cDNA and the corresponding 3' 50% of the b-cDNA; $b_{\mathbf{3/4}}a_{\mathbf{1/4}}$ comprises the 5' 75% of the b-cDNA and the 3' 25% of the a-cDNA. Chimeric cDNAs were expressed in a TSD neuroglial cell line which produces no endogenous a subunits. The chimeric isozymes were chromatofocused and assayed for hydrolysis of a) 4MUG , b) 4MUGS and c) G_{M2} ganglioside (in the presence of AP/detergent). Transfection of both cDNA constructs lead to expression of homodimeric and heterodimeric chimeric proteins, albeit at lower yields than transfection of normal a-cDNA. $(b_{3/4}a_{1/4})_2$ (homodimer) and $(b_{3/4}a_{1/4})b$ (heterodimer) hydrolyzed 4MUG but neither hydrolyzed 4MUGS or G_{M2} ganglioside. By contrast, $(a_{1/2}b_{1/2})_2$ and $(a_{1/2}b_{1/2})b$ hydrolyzed both 4MUG and 4MUGS. However, while G_{M2} ganglioside hydrolysis by these isozymes could be detected in the presence of detergent (which can replace AP in vitro) no activity was observed in the presence of the AP. These results suggest that a) both constructs contain sufficient information to form both heterodimeric and homodimeric chimeric proteins b) $b_{3/4}a_{1/4}$ is absent in an a domain essential to the hydrolysis of negatively charged substrates and c) $a_{1/2}b_{1/2}$ is absent in an a domain essential to AP binding. Future studies will allow us to more precisely define the a subunit regions essential to these functions.

Program Nr: 1302 from the 1999 ASHG Annual Meeting

Obesity, Diabetic Ketoacidosis (DKA), Malignant Hyperthermia (MH), and Rhabdomyolysis (RM): A New Phenotype of Carnitine Palmitoyl Transferase Type II (CPTII) Deficiency? *J. DiPaola, P.H. Schwartz, N. Anas, T.J. Butler, J. Cappon, S.A. Stein.* Crit Care, Neurol and Brain and Tissue Bank, Child Hosp Orange County , Orange, CA.

Two, unrelated, obese, 15-year-old hispanic boys presented with a clinical picture of new onset DKA after a 1 - 2 week history of fatigue, malaise, polydipsia and polyuria. The clinical course of both patients was catastrophic and led to cardiac arrest. One (A) was successfully resuscitated. The other (B) died in multisystem organ failure. The laboratory values for both were also very similar. Glucose levels at presentation were 1400 mg/dL (A) and 1900 mg/dL (B). Severe metabolic acidosis was noted. Creatine phosphokinase levels reached 47,000 U/L (A) and 68,000 U/L (B). The Mb isoenzyme was elevated but the enzyme/isoenzyme ratios were normal. Both patients had abnormal EKGs, most likely related to electrolyte disturbances. They required endotracheal intubation and high doses of inotropes for cardiovascular support. Both patients had myoglobinuria and developed severe renal failure that required hemodialysis. They also developed MH, measured rectally at 42.8 C (A) and 42.6 C (B), successfully treated with dantrolene. Muscle biopsy of A showed non-specific diffuse myofiber degeneration and regeneration typical of RM; enzymatic testing showed 10% residual CPTII activity which was negative for the S113L mutation. Autopsy of B revealed multisystem organ failure, severe hemorrhagic pancreatitis, and fatty metamorphosis of the liver with hepatomegaly and cirrhosis. The association of DKA and RM, particularly in adults, is well known. There have also been reports of MH in association with diabetes. While RM has been reported in CPTII deficiency, it is usually associated with strenuous exercise or starvation. To our knowledge there has been only one other recognized case similar to those presented here. These cases raise the possibility that CPTII deficiency is the underlying cause for the entire clinical picture and that appropriate preventive measures to avoid MH and a shift to fat metabolism should be taken in addition to measures to control DKA.

Program Nr: 1303 from the 1999 ASHG Annual Meeting

Alterations in SREBP2 expression in Niemann Pick C (Npc1$^{-/-}$) LDL receptor knockout mice. *R.P. Erickson, W.S. Garver, M. Midura-Kiela, R.A. Heidenreich.* University of Arizona College of Medicine, Angel Charity for Children - Wings for Genetic Research, Steele Memorial Children's Research Center, Department of Pediatrics, Section of Medical and Molecular Genetics, Tucson, AZ.

Niemann-Pick disease type C (NPC) is a devastating inborn error of metabolism with hepatic and neurological symptoms. Early biochemical and pathological analyses of both mouse and human NPC tissues and cell lines reveal a massive accumulation of unesterified cholesterol, the source of which is low density lipoprotein (LDL). The sterol regulatory element binding proteins (SREBPs) are membrane-bound proteins found in the endoplasmic reticulum (ER) membrane that regulate cholesterol synthesis, including LDL receptor expression. Using mouse liver homogenates, we provide evidence indicating an upregulation of SREBP2 in the NPC1$^{-/-}$/LDLR$^{-/-}$ mouse compared to NPC1$^{-/-}$/LDLR$^{+/+}$ mice of the same age. However, while the amount of SREBP2 is downregulated in NPC1$^{-/-}$/LDLR$^{+/+}$ mice with increasing age, the amount of SREBP2 is upregulated in NPC$^{-/-}$/LDLR$^{+/+}$ mice with increasing age. These results suggest a functional relationship between NPC1$^{-/-}$/LDLR$^{+/+}$ and SREBP2 in the maintenance of intracellular cholesterol levels.

Program Nr: 1304 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of repiratory chain disorders. *L. Faivre, D. Chretien, J.C. von Kleist-Retzow, V. Cormier-Daire, A. Rötig, P. Rustin, A. Munnich.* Department of Genetics, Hopital Necker Enfants Malade, Paris, France.

A reliable prenatal diagnosis is an important goal for genetic counseling in mitochondrial respiratory chain deficiency. In the absence of detectable mitochondrial DNA (mtDNA) mutations, measurement of respiratory chain enzymes activities represents the only hope of prenatal diagnosis, especially as only a few nuclear disease genes have been identified. We carried out enzymatic prenatal diagnosis in 16 pregnancies from 9 unrelated couples using uncultured choriocytes and/or amniocytes. Inclusion criteria were i) a previous child with a fully documented disease, ii) absence of mtDNA mutation, and iii) the existence of an enzyme defect in cultured skin fibroblasts of the proband. In 5/16 pregnancies, the fetus was found affected, the pregnancy was terminated and the diagnosis was further confirmed on postabortion tissues. In 9/16 cases, the tests were normal, the pregnancies were continued and resulted in the birth of an unaffected healthy child. Unfortunately, in 2/16 cases, a fetus which appeared normal from early prenatal diagnosis, turned out to be affected with the disease. From this experience, we conclude that an abnormal result should be considered reliable, but a normal result between 8 and 12 weeks of gestation does not give a definitive clue as to the child condition after birth. We therefore suggest the following guidelines: i) a choriocentesis or an amniocentesis should be proposed in early pregnancy, ii) a second amniocentesis at 28 weeks of gestation should be offered in order to avoid false negative result because of late expression of the disease, iii) a careful and repeated ultrasound survey in the third trimester, and iv) prenatal diagnosis should not be proposed for a complex I deficiency as this enzyme activity cannot be accurately measured in fetal cells.

Program Nr: 1305 from the 1999 ASHG Annual Meeting

Analysis of the flavin-containing monooxygenase (*FMO3*) gene for mutations in Australia identifies a high carrier frequency for TMAuria and a novel deletion in a Greek patient. *S.M. Forrest[1], M.A. Knight[1], B.R. Akerman[2], E.P. Treacy[2]*. 1) Murdoch Institute, Royal Children's Hospital, Parkville, Victoria, Australia; 2) C.R. Scriver Biochemical Genetics Unit, Montreal Children's Hospital, Quebec, Canada.

Trimethylaminuria (TMAuria) is an inborn error of metabolism resulting from the inability to metabolize the dietary-derived odorous amine trimethylamine by N-oxygenation. Affected individuals consequently suffer a severe body odor with associated psychosocial conditions. This inborn error of metabolism is uncommon and spread non-randomly throughout specific populations. The majority of affected Australian individuals are of British or Irish origin. We have recently shown that mutations of the flavin-containing monooxygenase type 3 gene, *FMO3* - the catalytically dominant active liver isoform, cause this condition. Two common mutations were identified in our Australian cohort, E305X and P153L, accounting for 88% of mutations in Australians of British/Irish origin. Two other mutations, M66I and R492W, were found in a compound heterozygous state in one other Australian patient. Screening for the alleles E305X and P153L in 57 unaffected controls has indicated that 7 individuals carry P153L giving a carrier frequency of 1/8 and suggesting that this condition has a significantly higher incidence in Australia.

In a Greek individual with severe TMAuria we have now identified a novel homozygous deletion of exons 1 and 2 of the *FMO3* gene encompassing 12kb of genomic DNA. This deletion was not detected in 40 Greek control chromosomes. As this deletion should result in complete absence of functional FMO3, this patient will be unable to metabolise a number of other FMO3 substrates in addition to TMA. Thus, in addition to the common *FMO3* gene mutations causing TMAuria in Australians of British/ Irish origin, other 'private mutations' may be segregating in Australians of diverse ethnic backgrounds.

.

Program Nr: 1306 from the 1999 ASHG Annual Meeting

Molecular study of Persistent Hyperinsulinemic Hypoglycemia of Infancy (PHHI): genetic heterogeneity and phenotype-genotype correlations in a series of 143 patients. *J.C. Fournet[1,2], C. Mayaud[1], M.S. Gross-Morand[1], P. de Lonlay[1,3], V. Verkarre[1,2], J. Rahier[5], F. Brunelle[4], J.J. Robert[3], C. Nihoul-Fekete[5], J.M. Saudubray[3], C. Junien[1]*. 1) INSERM UR 383, Hosp Necker-Enfants Malades, Paris, France; 2) Department of Pathology,Hosp Necker-Enfants Malades, Paris, France; 3) Pediatrics-Metabolism, Hosp Necker-Enfants Malades, Paris, France; 4) Pediatric surgery, Hosp Necker-Enfants Malades, Paris, France; 5) Department of Pathology, Brussels, Belgium.

Persistent Hyperinsulinemic Hypoglycemia of Infancy (PHHI) ("nesidioblastosis") is characterized by profound hypoglycemia due to inappropriate hypersecretion of insulin and is linked to, at least, two morphological forms: a focal form and a diffuse one. Focal forms are characterized by a somatic loss of the maternal chromosomal region 11p15 carrying imprinted genes and the genes SUR1 and KIR6.2 coding for the two subunits of the K+ATP channel of B cell in FoPHHI but not in DiPHHI. In order to determine the extent of genetic heterogeneity and to look for potential phenotype/genotype correlation, we have screened 143 patients with PHHI for mutations in 27 exons on 39 of the SUR1 gene and of the entire KIR6.2 gene. In 10 focal forms out of 27 (37%), we have found a paternally transmitted mutation of the gene SUR1. In one patient, we have found the first KIR6.2 mutation associated with a focal form. This paternal mutation is reduced to homozygosity by loss of the maternal allele, restricted to the lesion. In 116 diffuse forms and in non operated cases, we have found 26 SUR1 mutations (23 undescribed) (22,4%) and 2 new KIR6.2 mutations (1,7%). Furthermore we have developed SUR1 and KIR6.2 mutation databases (hhtp://www.umd.necker.fr:2007) which allowed us to define mutation-rich regions and phenotype-genotype correlations.

Program Nr: 1307 from the 1999 ASHG Annual Meeting

DNA and enzyme diagnostics for tripeptidyl peptidase I (CLN2) involved in classical late infantile neuronal ceroid lipofuscinosis. *P.F. Franken[1], J.L.M. Keulemans[2], M.H. Breuning[1], O.P. Van Diggelen[2], P.E.M. Taschner[1]*. 1) Department of Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Department of Clinical Genetics, Erasmus University Rotterdam, Rotterdam,The Netherlands.

The neuronal ceroid lipofuscinoses (NCL) are a heterogeneous group of recessive neurodegenerative disorders with an estimated incidence of 1: 50,000 in the Netherlands. These disorders are characterized by visual failure, seizures, mental deterioration, and lysosomal storage of autofluorescent lipopigments. The differential diagnosis of NCL is difficult, because many different forms exist. Recently, 4 genes involved in NCL have been identified, including two genes for the genetically heterogeneous late infantile NCL. The gene involved in classical late infantile NCL (LINCL) or Jansky-Bielschowsky disease (MIM 204500), CLN2, encodes the lysosomal enzyme tripeptidyl peptidase I (previously known as pepstatin-insensitive proteinase). Routine diagnostic procedures for lysosomal storage disorders should commence with enzyme analysis, which will detect enzyme defects caused by known as well as unknown mutations in the corresponding genes. Recently, a new fluorogenic enzyme assay with increased sensitivity has been developed for tripeptidyl peptidase I. The assay is three orders of magnitude more sensitive than the original assay of Sleat et al. (Science 277:1802 (1997)) and has been validated on classical LINCL patients with known CLN2 mutations. The new assay has been used to confirm the clinical diagnosis of 7 LINCL patients. Subsequently, the screening for mutations in the CLN2 gene can be limited to LINCL patients who are tripeptidyl peptidase I deficient. We have used single strand conformation analysis of genomic PCR products containing the different CLN2 exons, followed by direct sequencing, to identify mutations in our collection of 26 independent LINCL patients. Prior to the new enzyme assay, six patients were found to carry the IVS5-1 G®C splice site mutation on 10 chromosomes.

Program Nr: 1308 from the 1999 ASHG Annual Meeting

Aortic root calcification precedes obstructive coronary artery disease in children with homozygous familial hypercholesterolemia. *C.A. Friedrich[1], D.M. Kolansky[2], S.M. Paridon[3], B.J. Clark[3], E.S.C. Brown-Parr[1], J.M. Wilson[1], D.J. Rader[2].* 1) Medicine/Medical Genetics, University of Pennsylvania, Philadelphia, PA; 2) Medicine/Cardiology; 3) Pediatrics/Cardiology.

Homozygous familial hypercholesterolemia (HFH) is a rare disorder due to LDL-R gene mutations associated with markedly accelerated atherosclerosis. Most patients develop coronary artery disease (CAD) by their teens or twenties but frequently experience a myocardial infarction or sudden death without preceding symptoms. There are no clear guidelines for the cardiovascular evaluation of asymptomatic patients with HFH. Electron beam CT scanning (EBCT) for coronary artery calcification is a non-invasive method for quantitating coronary plaque burden and may predict the risk of CAD in adults. We therefore sequentially evaluated 22 children and adolescents with HFH with EBCT scans, and with coronary artery angiograms. This is the largest FH cohort studied with EBCT. We defined CAD as any lesion that caused more than 50% stenosis of a coronary artery. Ages at initial evaluation ranged from five to 17 years old. Five patients had at least one coronary artery stenosis greater than 50% at the time of their initial EBCT. Only one of these five had coronary artery calcification. However, four had substantial calcification present in the ascending aorta and aortic arch, and the fifth patient developed aortic calcification one year after his first evaluation. Of those patients without significant coronary artery lesions, fourteen had calcification in the ascending or thoracic aorta. Two of these 14 patients also had coronary artery calcification. Three children (ages 5 to 14) had no aortic or coronary artery calcification, and no CAD. Three of the 14 originally found to have calcification without significant CAD developed CAD stenoses greater than 50% over the next three years. We conclude that aortic root calcification usually precedes development of clinically significant coronary artery atherosclerosis in children with HFH. EBCT may therefore be a useful non-invasive tool in evaluating asymptomatic HFH patients. Asymptomatic patients without aortic root calcification are unlikely to have CAD on angiography.

Program Nr: 1309 from the 1999 ASHG Annual Meeting

Mammalian *PEX13*: cDNA cloning by functional complementation on newly identified peroxisome assembly-defective Chinese hamster ovary cell mutants, characterization, and mutation analysis. *Y. Fujiki[1,2], R. Toyama[1], S. Mukai[1,2], A. Itagaki[1], N. Shimozawa[3], R.J.A. Wanders[4], S. Tamura[1].* 1) Department of Biology, Graduate school of Science, Kyushu University, Fukuoka 812-8581, Japan; 2) CREST, Japan Science and Technology Corporation, Tokyo, 170-0013, Japan; 3) Department of Pediatrics, Gifu University Faculty of Medicine, Gifu 500-8076, Japan; 4) Department of Clinical Biochemistry and Pediatrics, Academic Medical Centre, University of Amsterdam, P.O. Box 22700, 1100DE, Amsterdam, The Netherlands.

We isolated peroxisome biogenesis mutants, ZP128 and ZP150, from rat *PEX2*-transformed Chinese hamster ovary cells, using the 9-(1'-pyrene)nonanol/ultraviolet (P9OH/UV) method. The mutants lacked morphologically recognizable peroxisomes and showed a typical peroxisome assembly-defective phenotype such as severe loss of catalase latency and high sensitivity to 12-(1'-pyrene)dodecanoic acid/UV treatment. ZP128 and ZP150 were found to belong to a recently identified complementation group H, by complementation group analysis by means of *PEX* cDNA transfection as well as cell fusion. Human cDNA encoding peroxin Pex13p was isolated from a liver cDNA library by functional complementation of peroxisome deficiency in ZP128, using a transient transfection assay. Pex13p comprising of 403 amino acids is a peroxisomal integral membrane protein, exposing both the N-terminal part and C-terminal src homology 3 (SH3)-domain to the cytosol. A stable transformant of ZP128 with the *PEX13* was morphologically and biochemically restored for peroxisome biogenesis. Chinese hamster *PEX13* was also isolated, of which deduced amino acid sequence showed 93%, 26%, and 25% identity with human, *Saccharomyces cerevisiae*, and *Pichia pastoris* Pex13p, respectively. Therefore, ZP128 and ZP150 are the first mammalian cell lines with a phenotype of impaired *PEX13*. Analysis of mutation(s) in *PEX13* of mutant ZP150 is underway.

Program Nr: 1310 from the 1999 ASHG Annual Meeting

Elevated 1-methyl histidine in a subgroup of autism patients. *D.K. Gavrilov, N. Takahashi, M. Muskopf, C. Wang, J.H. Miles, R.E. Hillman.* Depts of Biochemistry, Child Health and Neurology, Univ of Missouri, Columbia, MO.

Autism is highly genetic neuropsychiatric disorder with poorly understood biologic basis. Of 182 consecutive autism probands screened for the presence of 1-methyl histidine (1-MeHis) in the urine by qualitative 2-dimensional electrophoresis, 16.5% (30/182) had elevated levels. Quantitative 1- MeHis levels were obtained by HPLC. The high 1-MeHis group was compared with 2 control groups: 21 consecutive autism probands without elevated 1-MeHis and 44 consecutive non-autism patients referred for metabolic screening. The levels of 1-MeHis were normalized to the urine creatinine. The non-autism control group mean ± 2SD was used to establish the normal range (13 ± 26 mmol/ mmol creatinine). The 1-MeHis distribution in the autism control group was not significantly different (16 ± 20). The 1-MeHis mean in the elevated 1-MeHis autism probands was statistically higher than in either control group (t-test values of 6.795, $p<0.001$ and 5.55, $p<0.001$ respectively). **Results:** A group of autistic patients was identified with elevated excretion of 1-MeHis and a correlation with the 1 MeHis levels was noted. This subgroup differed significantly from the remainder of autism probands in four areas: 1) the male:female ratio was higher with highest values in a subgroup with 1-MeHis>100 (16:1 vs 7.5:1); 2) the incidence of seizures is higher (12/28 vs. 2/17, $p<0.05$), (8/17 in the subgroup with 1-MeHis>100; 3) the family history of attention deficit hyperactivity disorder (ADHD) was lower than in the control autistic group ($p<0.05$) (0/17 in the subgroup with 1-MeHis>100 vs 6/20 or 30% in the control subgroup and 4) significantly higher incidence of dismorphic clinical features - 52.9% vs 28.6% in the control group. A tendency towards IQ<70 was noted in the subgroup with 1-MeHis > 100 (13/14 or 92.9% vs 12/17 or 70.6%). Follow up of two patients with extremely high levels of 1-MeHis have shown at least 10 times reduction of 1-MeHis excretion after treatment with combination of vit. B_6, folic acid and dimethyl glycine. Delineation of homogeneous groups is necessary for identification of disease causing genes.

Program Nr: 1311 from the 1999 ASHG Annual Meeting

Increased thickness of large arteries: a new marker of Fabry's disease. *D.P. Germain[1], O. Lidove[2], J.P. Grunfeld[2], X. Jeunemaitre[1], X. Girerd[3], V. Remones[1], S. Laurent[3], P. Boutouyrie[3].* 1) Genetique, Hopital Broussais, Paris, France; 2) Nephrologie, Hopital Necker, Paris, France; 3) INSERM U337, Hopital Broussais, Paris, France.

Fabry's disease is an X-linked inborn error of sphingolipid metabolism due to defects in the lysosomal alpha-galactosidase A gene. The enzymatic defect results in systemic deposition of uncleaved glycosphingolipids in the lysosomes of vascular endothelial and smooth muscle cells in most tissues. The major clinical manifestations in FD are primarily due to a progressive small vessels pathology with angiokeratoma, renal failure and vasculopathy of the heart and brain. Death usually occurs in adult life from renal, cardiac or cerebral complications of vascular disease. Early indicators measuring the progressive accumulation of glycosphingolipids could be of high interest for the care of FD patients. We hypothesized that this could be possible at the site of large arteries by using recently developed high precision echotracking devices. Nineteen FD male patients, without end-stage renal disease, were compared with 22 male controls (Co) matched for age, renal function and blood pressure (BP). Common carotid (CCA) and radial artery (RA) diameter (Di), intima-media thickness (IMT), and distensibility (Dist) were determined with high definition echotracking system and aplanation tonometry. An increased radial artery thickness was associated to Fabry's disease ($p<0.001$) independently of age and mean BP. RA Dist was increased two-fold in FD patients (9.1±0.9 vs 4.8±0.7 $kPa^{-1}.10^3$). RA IMT increased with age in FD patients and controls, but the slope was three-fold higher in FD patients (6.2±2.0 vs 1.8±0.6 mm/year). CCA IMT was significantly increased in patients with FD ($p<0.001$), without significant difference in diameter and distensibility. In conclusion, FD patients have an accelerated thickening of large arteries, which is more prominent in muscular (RA) than elastic (CCA) arteries. This new noninvasive hallmark could be of particular interest for the monitoring of future enzyme replacement therapy.

Program Nr: 1312 from the 1999 ASHG Annual Meeting

Respiratory activity, antioxidant defences, cell growth and apoptosis in human ubiquinone-deficient skin fibroblasts. *V. Geromel, N. Khadom, D. Chretien, A. Munnich, A. Rotig, P. Rustin.* INSERM U393, Hopital Necker, Paris, France.

Beside its well established role in electron transfer in the mitochondrial respiratory chain, ubiquinone has been claimed to exert, through its antioxidant properties, a major role in controlling free radical level in the cell, in the apoptotic process, possibly acting as a control partner in aging. We previously reported a widespread ubiquinone deficiency in two siblings presenting as encephalomyopathy. No ubiquinone could be detected in the cultured skin fibroblasts that accumulated farnesyl-pyrophosphate, an intermediate compound in ubiquinone synthesis. We next investigated the consequence of the ubiquinone deficiency on cell respiration and oxidation of various substrates in detergent-permeabilized fibroblasts and found a surprisingly high level of residual activities, suggesting that the pool function of ubiquinone may be necessary only under specific conditions. Comparing cell growth between ubiquinone-deficient and control fibroblasts revealed a limited decrease of cell growth in patient fibroblasts. Accordingly, DNA fragmentation tested with the TUNEL reaction and nuclear morphology as revealed by Hoechst 33242 did not significantly differ between patient and controls. Even serum withdrawal in the culture medium did not specifically affect ubiquinone-deficient fibroblasts. Finally, antioxidant enzymes (superoxide dismutases, catalase, glutathione reductase, transferase or peroxidase) were not increased in response to the ubiquinone deficiency However, the addition of idebenone, a short chain homologue of ubiquinone prone to auto-oxidation, induced a higher lethality in ubiquinone-deficient fibroblasts, suggesting that ubiquinone may act as an antioxidant in situ in these cells. It therefore appears that in human skin fibroblasts, ubiquinone i) can act as an electron carrier in the respiratory chain independently of its pool function; ii) does not directly control cell growth through a putative regulation of the apoptotic process; iii) but may participate to the defenses of the cells against oxidative stresses.

Program Nr: 1313 from the 1999 ASHG Annual Meeting

Characterization of *hSCO2* mutations involved in cytochrome oxidase deficiency. *D.Moira Glerum[1], L. Papadopoulou[2], E. Schon[2], D. Adams[1]*. 1) Dept of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Dept of Neurology, Columbia University, New York, NY 10032.

Defects in mitochondrial function are increasingly being identified as the cause underlying a number of different neurodegenerative disorders. A subset of these disorders arise due to specific deficiencies in cytochrome oxidase (COX). COX is the terminal electron acceptor in the mitochondrial respiratory chain and consists of 13 polypeptide subunits, along with 2 heme molecules and 3 copper atoms. Provision of copper to the apoenzyme is a prerequisite for assembly of a functional enzyme. Studies in the yeast *Saccharomyces cerevisiae* have shown that some 40 nuclear gene products are required. In particular, Cox17p and Sco1p are involved in providing copper to mitochondria and COX (Glerum et al, 1996). The human homologs for these two proteins have been identified, and recently, mutations in *hSCO2* (a human homolog of yeast *SCO1*) have been shown to segregate with COX deficiency in patients with fatal infantile cardioencephalomyopathy (Papadopoulou et al, submitted). We now demonstrate that, although highly similar, *hSCO2* is not an ortholog of yeast *SCO1*. In an effort to characterize the effects of the mutations, we have introduced the parallel mutations into the yeast *SCO1* gene and transformed the mutated constructs into a yeast *SCO1* knock-out strain. We will present data delineating the impact of these mutations on cytochrome oxidase assembly, using spectral analysis of mitochondrial hemes, COX activity assays and determination of growth rates in non-fermentable carbon sources. The results demonstrate that the mutations adversely affect COX assembly and provide an explanation for the COX deficiency seen in the patients. The creation of site-directed mutants in the yeast homologs of human genes provides an *in vivo* approach to determining the nature of mutations associated with human COX deficiencies.

Program Nr: 1314 from the 1999 ASHG Annual Meeting

Human Congenital Hypotransferrinemia: case report and molecular studies. *S. Goldwurm[1], C. Casati[1], S. Strada[1], P. Santambrogio[2], N. Venturi[1], P. Arosio[2], M. Cazzola[3], A. Piperno[1], G. Masera[1], A. Biondi[1]*. 1) Pediatric Clinic, University of MIlano-Bicocca, Monza (MI) Italy; 2) DIBIT, Scientific Institute San Raffaele, Milan, Italy; 3) Department of Internal Medicine, University of Pavia, Italy.

Human congenital hypotransferrinemia is a rare disorder characterised by the virtual absence of transferrin (Tf) in the serum. No information on the molecular basis of the defect is known. Following the identification of a child affected by hypotransferrinemia, we investigated the molecular basis of the defect and planned to characterise the DNA mutation that underlies this disease. After the diagnosis, the patient received monthly RBCs transfusions. Subsequently he was treated with plasma transfusions: the first plasma-apheresis raised the serum Tf concentration to 120 mg/dl followed by a good erythropoietic response and a normal kinetic of Tf. At present, the patient is regularly infused with plasma to keep his Hb over 10 mg/dl. He has a normal growth and no other symptoms or signs were observed. To prove that the molecular defect causing hypotransferrinemia was due to a mutation in the Tf gene, we perform an haplotype analysis of the Tf gene on 3q21-3 in the porband's family (26 individuals). We could observe the association between one affected haplotype shared with the proband and intermediate serum levels of Tf, thus indicating that the disease is inherited as a recessive trait and that the mutation is in the Tf gene. A Southern analysis excluded the presence of gross deletions or rearrengements, while Northern analyses on PBL did not detect a Tf mRNA in controls as well as in the patient. The amount of serum Tf in our patient was confirmed to be around 3 mg/dl by an ELISA assay, approximately 1/100 of normal values. In a Western analysis most of the patient's Tf run at the normal level, but a smaller band was detected. These data suggest that two different mutations are present in the 2 alleles, one in the regulatory region of the gene reducing the expression of an otherwise normal protein, the other in the coding region affecting the structure and therefore the processing of the protein.

Program Nr: 1315 from the 1999 ASHG Annual Meeting

Hetereogeneity of the MELAS3243 mutation. *O. Guardamagna[1], A. Peduto[1], C. Bondone[1], S. Baglieri[1], M. Spada[1], E. Lamantea[2], F. Carrara[2], M. Zeviani[2].* 1) Pediatrics, Univ. di Torino, Torino, Italy; 2) Istituto Neurologico Besta, Milano, Italia.

MELAS is a progressive neurodegenerative disease whose presentation is typically characterized by mitochondrial encephalomiopathy, lactic acidosis and stroke-like episodes. We present here a 3 yrs old female patient whose history is characterized by mild psycomotor retardation, growth failure and hypotonia. She was referred to our department because affected by food refusal and worsening hypotonia, as a consequence of an intercurrent illness. She was treated with total parenteral nutrition and recovered her normal clinical condition. The neurologic examination was normal. While hospitalized she acutely started vomiting and developed a serious metabolic acidosis. Blood lactate was elevated. Clinical and radiological analysis demonstrated a picture of ileum paralitycum. This picture was later aggravated by seizure and coma till fatal outcome. The muscolar biopsy revealed the presence of "ragged red fibers", an histologic feature suggesting a mitochondrial disorder. This suspect was then confirmed by the demonstration of a defect of the respiratory chain Complex I and Complex IV (3.3 nmol/min mg, nv 15-31 and 25 nmol/min mg, nv 80-180 respectively). The mitochondrial DNA analysis allowed to identify the heteroplasmic point mutation at the nucleotide 3243, an A to G transition at the tRNALeu(UUR) gene. This particular presentation, as well as previous demonstration of this mutation in patient without neurologic disease, confirms the clinical hetereogeneity of the A3243G mutation and suggest a deficiency in the mitochondrial respiratory chain of smooth muscle cells in the present patient.

Program Nr: 1316 from the 1999 ASHG Annual Meeting

Association of a Glucocorticoid Receptor Gene Marker With Human Essential Hypertension. *V. Guerrini, S. Rutherford, D.R Nyholt, L.R Griffiths.* Genomics Res Ctr, Sch Hlth Sci, Griffith University-Gold Coast, Southport QLD, Australia.

Recently, a bi-allelic polymorphism in the glucocorticoid receptor gene (GRL) has been shown to be associated with individuals at high risk of developing hypertension and accumulation of abdominal visceral fat, a known risk factor for cardiovascular disease. The evaluate the role of GRL in essential hypertension and obesity, case-control studies were conducted using 88 hypertensive, 123 normotensive, 150 lean and 94 obese subjects. Genotypes for a highly polymorphic microsatellite marker (D5S207) located within 200 kb of the glucocorticoid receptor gene, were determined by PCR. Allele frequencies between hypertensive and normotensive groups were significantly ($P = 0.0005$) different whereas no significant differences were observed between lean and obese populations. In conclusion, the results suggest that the glucocorticoid receptor gene or perhaps another gene located in close proximity and in linkage disequilibrium with D5S207, is involved in hypertension development.

Program Nr: 1317 from the 1999 ASHG Annual Meeting

Very long chain acyl-CoA dehydrogenase deficiency: clinical phenotypes, prenatal diagnosis and four novel mutations. *G. He, B.Z. Yang, J.H. Ding, D.S. Roe, C.R. Roe.* Courtwright/Summers Inst Metab, Baylor Univ Medical Ctr, Dallas, TX.

Very long chain acyl-CoA dehydrogenase (VLCAD) deficiency, an autosomal recessive disorder, is a severe defect of mitochondrial fatty acid oxidation that presents as two clinical phenotypes: a neonatal cardiomyopathy and a mild hypoglycemia form. The proband was a two-day-old girl with sudden death. In the subsequent pregnancy, prenatal diagnosis was performed using in vitro analysis of the mitochondrial beta-oxidation pathway in amniocytes. The prenatal screening revealed C12, C14:1 and C16 accumulation indicating VLCAD deficiency. Enzyme assay confirmed the diagnosis. To investigate the mutation(s), VLCAD cDNA and genomic DNA from the cultured fibroblasts were amplified and sequenced. Two novel mutations were identified: a G1613C (Arg538Pro) and a one base deletion (A770del) resulting in a frameshift and premature termination. In another case, the plasma acylcarnitine profile of a 3 1/2 year old patient with recurrent hypoglycemia revealed an elevation of C14:1, characteristic of VLCAD deficiency. In vitro analysis and enzyme assay of the patient's fibroblasts confirmed the deficiency. The sequence analysis of the VLCAD cDNA and genomic DNA from this patient identified two novel mutations: a C953T (Pro318Leu) mutation in exon 10 and a C1194A (Tyr398Stop) mutation which created a premature stop codon in exon 12. The correlation of the mutant genotype to clinical phenotype is briefly discussed.

Program Nr: 1318 from the 1999 ASHG Annual Meeting

Revealing the molecular basis of cystinosis in Dutch patients by mutation detection in the CTNS gene. *S.G. Heil[1], N.M.J. Van der Put[1], H.G. Brunner[2], J.M.F. Trijbels[1], L.A.H. Monnens[1], H.J. Blom[1]*. 1) Pediatrics, University Hospital Nijmegen, Nijmegen, The Netherlands; 2) Human Genetics, University Hospital Nijmegen, Nijmegen, The Netherlands.

Nephropathic cystinosis is an inborn error of metabolism with an autosomal recessive inheritance pattern. Cystinosis is characterized by lysosomal storage of the amino acid cystine due to an impaired transport of cystine out of the lysosomes. Clinical features are renal Fanconi syndrome, failure to thrive and crystals in the eye-lens.

Recently, the gene responsible for membrane transport of cystine (CTNS), has been cloned. This gene encodes an integral membrane protein, which is called cystinosin. The CTNS gene has 12 exons and its 2.6 kb mRNA codes for a 367-amino acid cystine transporter with 7 transmembrane domains.

Mutation detection of European patients revealed a common 65-kb deletion, and several other mutations spread throughout the entire coding region.

In the present study, we observed the common 65-kb deletion in 48% of the alleles of the examined Dutch patients. Furthermore, we screened for mutations in the CTNS gene of Dutch patients by direct sequencing of the different exons.

Next to cystine determination in polymorphic nuclear cells, molecular genetic analysis enables early diagnosis which is critical for the proper treatment of this disease.

Program Nr: 1319 from the 1999 ASHG Annual Meeting

Identification of LDL-R independent lysosomal targeting of cholesteryl esters (CE) and triglycerides (TG) using lysosomal acid lipase gene targeted mice. *M. Heur[1], H. Du[1], J. Mishra[1], D. Witte[2], G.A. Grabowski[1]*. 1) Div Human Genetics, Children's Hosp Res Fdn, Cincinnati, OH; 2) Div Pediatric Pathology, Children's Hosp Res Fdn, Cincinnati, OH.

Understanding regulation of cholesterol metabolism is essential due to the myriad of physiological functions of cholesterol and because hypercholesterolemia is the major risk factor for heart disease. Dietary CE, an important participant in regulation of cellular cholesterol metabolism, are delivered to the lysosomes where they are cleaved by lysosomal acid lipase (LAL) into cholesterol and free fatty acid. Cholesterol then exits the lysosome and participates in various cellular processes including regulation of cellular cholesterol metabolism. The objective of this study was to test the hypothesis that the low-density lipoprotein receptor (LDL-R) pathway is the major route through which dietary CE and TG are trafficked to the lysosomes. LAL knockout mice (LAL -/-) were bred to LDL-R knockout mice (LDL-R -/-) to produce offspring lacking both LAL and LDL-R (LAL -/-, LDL-R -/-). LAL -/- mice display massive hepatosplenomegaly secondary to CE and TG storage whereas LDL-R -/- mice appear normal physiologically and with respect to their serum lipid profiles. The elimination of LDL-R in LAL -/- mice would be expected to drastically reduce the hepatomegaly of LAL -/- mice. However, LAL -/-, LDL-R -/- mice had hepatosplenomegaly similar to LAL -/- mice. LAL -/-, LDL-R -/- total plasma cholesterol level was 60.37 mg/dL; this was similar to those of LAL -/- and LDL-R -/- mice, (54.43 mg/dL and 87.16 mg/dL, respectively). Total liver cholesterol levels in LAL -/-, LDL-R -/- and LAL -/- mice were similar while that of the LDL-R -/- mouse was about 10 fold lower than that in the LAL -/- mouse. The total liver cholesterol level of LAL -/-, LDL-R -/- mouse was 71.01 mg/mg while those of LAL -/- and LDL-R -/- mice were 109.11 mg/mg and 11.89 mg/mg, respectively. These data suggest a major role for alternate pathways in lysosomal delivery of dietary lipids in the absence of the LDL receptor.

Program Nr: 1320 from the 1999 ASHG Annual Meeting

Mutation Analysis in Succinic Semialdehyde Dehydrogenase (SSADH) deficiency (4-Hydroxybutyric Aciduria).

B.M. Hogema[1,2], C. Jakobs[1], C.B.M. Oudejans[1], R.B. Schutgens[1], M. Grompe[2], K.M. Gibson[2]. 1) Dept. Clin. Chem., Free Univ., Amsterdam, The Netherlands; 2) Biochem. Genet. Lab. and Dept. Mol. Med. Genet., Oregon Health Sci. Univ., Portland, OR.

SSADH deficiency is a rare heritable defect in the GABA degradative pathway leading to 4-hydroxybutyric (4-HB) aciduria; pathophysiology may relate to accumulated GABA, 4-HB acid, or synergism between both. Despite fairly consistent enzymatic and metabolic findings, the clinical phenotype featuring mainly nonspecific neurologic anomalies is highly heterogeneous. We undertook molecular analysis in cells derived from affected patients and performed mutation screening in samples obtained from 25 patients (21 families) using combined RT-PCR/genomic PCR and sequence analysis. The results were: three RNA splicing mutations (loss of exon 8; loss of exon 9, and a splicing mutation resulting in skipping of the first 14 bp of exon 4); one insertion (AG insertion at nt 457), one deletion (14 bp following nt 460); four nonsense mutations (Y128X, W204X, R412X and R514X), and 8 missense mutations (P182L, C223Y, T233M, A237S, G268E, P382L, G409D and G533R). This represents 21 alleles/18 mutations and adds substantively to our previous report of two exon-skipping mutations (AJHG 63, 399 (1998)). With the exception of the P182L, C223Y and G533R alleles, the mutations represented highly conserved residues in other (putative) SSADH proteins and other human aldehyde dehydrogenases. Thus far our analysis provides no clear insight into genotype/phenotype correlations, and indicate that most mutations are private within the families studied.

Program Nr: 1321 from the 1999 ASHG Annual Meeting

MUTATION ANALYSIS ON KOREAN PATIENTS WITH CITRULLINEMIA. *K.M. Hong[1], S.H. Hahn[2], M.K. Paik[1]*. 1) Department of Biochemistry, Wonkwang University College of Medicine, Iksan, Jeon-Buk, 570-749, Korea; 2) Departement of Pedriatics, Ajou University School of Medicine, Suwon, 442-749, Korea.

Citrullinemia is an autosomal recessive disease resulting from mutations in argininosuccinate synthetase (ASS) gene. In order to identify the frequent mutations in Korean patients with citrullinemia, studies on two patients were initially undertaken. The mRNAs were prepared from their fibroblasts, and the ASS cDNAs were amplified, cloned and sequenced. Both of them showed exon 7 deletion in their mRNAs resulted from splicing mutation previously reported as IVS-6^{-2} (a transition of A to G at the second nucleotide position within the 3' splice cleavage site of intron 6). This finding was confirmed by gDNA sequencing of the amplified product including the exon 7 and the surrounding partial intron sequences. Frequent IVS-6^{-2} mutation was reported in Japanese patients with citrullinemia, but not in Caucassian patients who showed extreme mutational heterogeneity. Although very limited number of patients were evaluated in this study, IVS-6^{-2} mutation might also be a frequent mutation in Korean patients suggesting possible founder effect. A point mutation in exon 13 and a novel insertional mutation in exon 15 were also identified in mRNAs of the patients. It appears that citrullinemia in Korean patients would be resulted from one common mutant allele (IVS-6^{-2}) and other rare alleles.

Program Nr: 1322 from the 1999 ASHG Annual Meeting

Isolation of novel genes involved in early stage of ectopic ossification by means of differential display method using *ttw* (tiptoe walking), a mouse model of ectopic ossification. *S. Ikegawa[1], Y. Koshizuka[1,2], M. Sano[1,3], K. Nakamura[2], A. Nagano[3], Y. Nakamura[1]*. 1) Laboratory of Genome Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 2) Department of Orthopaedic Surgery, Faculty of Medicine, The University of Tokyo, Tokyo, Japan; 3) Department of Orthopaedic Surgery, Hamamatsu University Scool of Medicine, Hamamatsu, Japan.

Ectopic ossification (bone formation at ectopic sites in the body) is often a severe complication of joint arthroplasty, neurologic trauma, and muscle injury; Ectopic ossification causes serious clinical conditions including OPLL (ossification of the posterior longitudinal ligament of the spine) and fibrodysplasia ossificans progressiva. Its pathogenesis, however, remains unclear. A naturally-occurring mouse mutant, *ttw* (tiptoe walking) is an excellent model for ectopic ossification. The mouse exhibits ossification of ligaments of the extremities and the spines, tendons and cartilages. The ossification of the spinal ligaments are radiographically and histologically very similar to that of human OPLL. We previously reported that the *ttw* phenotype is caused by a nonsense mutation in a gene encoding nucleotide pyrophosphatase, a membrane-bound ectoenzyme implicated in phosphate-pyrophosphate metabolism. To clarify the pathological mechanism of ectopic ossification, we examined the effect of dietary calcium and phosphate to the *ttw* phenotype, and found a high phosphate diet markedly accelerated the ectopic ossification of *ttw*. To isolate genes involved in this rapid and severe ectopic ossification, we investigated the gene expression in this model using differential display method. We have so far identified several novel genes which exhibited increased/decreased expression according to the diet, and characterized them. Our identification of the novel genes would give novel insights into mechanism of calcified tissue metabolism and ectopic ossification as well as the etiology of human OPLL.

Program Nr: 1323 from the 1999 ASHG Annual Meeting

Primary carnitine deficiency (PCD) as a novel cause of hereditary recurrent myoglobinuria. *F. Invernizzi, B. Garavaglia, M. Mora, C. Antozzi, F. Taroni.* Istituto Nazionale Neurologico C. Besta, Milan, Italy.

Common metabolic causes of paroxysmal myoglobinuria include enzyme defects of glycogen metabolism as well as defects of mitochondrial enzymes (most commonly CPT2) of long-chain fatty-acid oxidation. Although carnitine is an essential cofactor for long-chain fatty-acid oxidation, primary carnitine deficiency (PCD) has never been associated with pure recurrent myoglobinuria. Usually, it is a life-threatening disorder characterized by progressive cardiomyopathy and skeletal myopathy and/or hypoketotic hypoglycaemia and liver failure. We describe one new patient with exercise-induced myoglobinuria, no glycogen or lipid accumulation in skeletal muscle, normal activities of CPT2 and glycolytic enzymes, and normal profiles of urinary organic acids and plasma free fatty acids. The proband was a 22-year-old woman who had manifested recurrent episodes of paroxysmal myoglobinuria and muscle weakness since the age of 15y. There was no sign of cardiomyopathy, as documented by echocardiography. Plasma total carnitine was 10.5 mmol/l (n.v. 45±3). [^{3}H]L-carnitine uptake in fibroblasts was reduced to 25% of the control mean. After a few months of daily administration (3-6 g) of L-carnitine, treatment appeared to be beneficial. Muscular strength improved and metabolic attacks significantly reduced. A second muscle biopsy performed after 5 months of treatment demonstrated normalization of total L-carnitine levels. In conclusion, our findings indicate that PCD should always be considered as a cause of recurrent myoglobinuria even in the absence of lipid accumulation in muscle. Molecular analysis of the recently discovered PCD gene (*OCTN2*) is in progress, in order to clarify the molecular defect which underlies this unusual phenotype. (Partly supported by a Telethon-Italia grant to F.T.).

Program Nr: 1324 from the 1999 ASHG Annual Meeting

Liver transplantation for methyl malonic acidopathy (MMA disease) is not curative: cerebral production of methyl malonic acid (MMA) is significant in the pathogenesis of disease. *P. Kaplan, A.M. Mazur, M. Palmieri, G.T. Berry.* Biochemical Genetics,Childrens Hospital of philadelphia, Univ of Pennsylvania, PA 19104-3499.

Treatment of organic acidopathies, mainly nutritional, has variable, sub-optimal outcomes. Ideal treatment would entail enzyme replacement by enzyme infusion, liver or bone marrow transplantation [Tx], or gene therapy. Orthotopic liver Tx was done in a 19 month boy with mut0 MMA, at his parents request. Blood, cerebrospinal fluid[CSF] and urine levels of MMA were elevated 2455 fold, 1642 fold[1 measurement] & 200-1200 fold respectively pre-Tx.Post-Tx,these levels decreased by ~50% in blood and urine, but only by 10-20% in 5 of 6 CSF analyses, and remain elevated in all fluids 28mos post-Tx. Average CSF:plasma MMA was 2:1 pre-Tx and 4:1 post-Tx. Dietary protein 1.2gm-2gm/kg/day is tolerated without acidosis or bicarbonate therapy. Truncal & axial tremors developed post-Tx, were attributed to tacrolimus therapy, and resolved after many months. Growth, neurologic status and renal function continue to be normal. Metabolic decompensation has not occurred despite several infections and stresses. Conclusions: Liver Tx does not cure or significantly ameliorate the disease in mut0 MMA. This is the first longitudinal study of MMA disease comparing levels in CSF with other body fluids pre - and post-Tx. MMA production in brain appears to contribute significantly to the burden of disease but does not affect neurologic or cognitive function significantly in the proband.

Program Nr: 1325 from the 1999 ASHG Annual Meeting

A novel nonsense mutation (G5920A) in the mtDNA COX I gene: another cause of myopathy with myoglobinuria. *C.L. karadimas[1], P. Greenstein[2], J.T. Joseph[2], E. Bonilla[1], K. Tanji[1], S. Shanske[1], C.M. Sue[1], S. DiMauro[1]*. 1) Department of Neurology, Columbia University, College of Physicians & Surgeons, New York, NY; 2) Deparments of Neurology and Pathology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA.

A 34-year-old man had life-long intolerance to sustained exercise, intermittent weakness, and recurrent myoglobinuria. There was no evidence of multisystem disorder, and family history was negative for neuromuscular diseases. Muscle biopsy showed numerous COX-negative ragged red fibers. Electron microscopy confirmed the presence of overabundant and structurally abnormal mitochondria. Analysis of respiratory chain enzymes in muscle homogenate revealed a marked decrease of COX activity (13% of normal), while the activities of other complexes were normal. Direct sequencing of the mitochondrial genes encoding COX subunits revealed a G5920A heteroplasmic mutation in the COX I gene, changing a Trp to a stop codon. No other potential pathogenic nucleotide changes were detected nor did we find this mutation by PCR/RFLP analysis in 100 control muscles. This mutation predicts the loss of almost the entire COX I protein, thus easily explaining the clinical, morphological, and biochemical phenotype of the patient. (Supported by NIH grant P01 HD32062 and by a grant from the Muscular Dystrophy Association).

Program Nr: 1326 from the 1999 ASHG Annual Meeting

Glucose-6-phosphate dehydrogenase deficiency in Wilson's disease patient aggravates copper induced toxicity: Possible role of depleted levels of glutathione. *G. Kaur[1], R. Prasad[2], B.R. Thapa[3]*. 1) Deptt. of Physiology, Govt. Medical College,Chandigarh, India; 2) Deptt. of Biochemistry, Postgraduate Institute of Medical Education and Research,Chandigarh, India; 3) Deptt. of Gastroenterology, PGIMER, Chandigarh,India.

A five and a half years male child of Wilson's disease was admitted at early onset with both hepatological and neurological manifestations as well as glucose-6-phosphate dehydrogenase deficiency. Neurological manifestations have been reported mostly after 12 years of age. This study is of utmost importance from molecular basis of pathophysiology and clinical point of view. Work-up for Wilson's disease showed urinary copper:313mg/24 h, post-D-penicillamine urinary copper:459mg/24 h, and serum ceruloplasmin:3.6 mg/dl. In this case, plasma GSH level was found to be 0.64mmol GSH conjugated/g Hb, which is markedly lower than age-matched control (1.2mmol/g Hb). In this patient superoxide dismutase activity in RBC hemolysate was 0.352 units/g Hb, which was lower than that in the age-matched control (0.611 units/g Hb). Membrane lipid peroxidation was assessed by measuring malondialdehyde (MDA) in RBC hemolysate and found to be 0.069mmol MDA/g Hb. It was significantly higher than the normal level (0.029mmol MDA/g Hb). Thus, as a result the potential prooxidant action of excess copper and low level of glutathione could be significant determinants for cell susceptibility to the deleterious action of free copper which may lead to early onset of disease with both hepatological and neurological manifestations.

Program Nr: 1327 from the 1999 ASHG Annual Meeting

Rapid noninvasive diagnosis of nonketotic hyperglycinemia (NKH) by proton MR spectroscopy in a Korean newborn patient with NKH. *E. Kim[1], K. Kim[1], S. Pi[1], H. Yoo[2]*. 1) Division of Neonatology, Asan Medical Center, Seoul, Korea; 2) Medical Genetics Clinic & Laboratory, Asan Medical Center, Seoul, Korea.

Nonketotic hyperglycinemia (NKH) is an autosomal recessive inherited metabolic disorder caused by the defects in the glycine cleavage system(GCS; EC2.1.2.10), a multienzyme system that consists of four individual components. The NKH is clinically characterized by rapidly progressing neurologic symptoms, such as muscular hypotonia, seizures, apneic attacks, and lethargy or coma in the neonatal period. Increased glycine concentrations in plasma, urine, and especially in cerebrospinal fluid (CSF) without ketosis are key biochemical features. A Korean newborn patient who is the first normal full term product from healthy parents of non-consanguinous marriage, developed a sudden apneic attack at 28 hours after birth with frequent hiccups. Initial laboratory work-up revealed no metabolic acidosis, no hypoglycemia, no hyperammonemia, no ketosis, and no abnormal neurosonographic findings. However, electroencephalogram showed a burst-suppression pattern. Based on these clinical features, presumptive diagnosis of NKH has been made. By using localized proton MR spectroscopy, we identified a pathologic peak signal of glycine in the parietooccipital white matter and in the basal ganglia before the result of the ratio of CSF glycine concentration to that of plasma was available, which turned out to be 0.13. The follow-up proton MR spectroscopy was performed with treatment. The proton MR spectroscopy can be utilized as a non-invasive adjunctive diagnostic or monitoring tool for NKH patients.

Program Nr: 1328 from the 1999 ASHG Annual Meeting

Genetic, biochemical and pathological studies of four Japanese patients with neonatal Gaucher disease. *M. Kobayashi, H. Ida, Y. Eto.* Dept Pediatrics, Jikei Univ, Minato-ku, Tokyo, Japan.

Gaucher disease (GD) is caused by a deficiency of glucocerebrosidase, resulting in strorage of glucocerebroside (GC) in reticuloendothelial system such as liver, spleen and bone marrow. The clinial hallmark of GD is a variable phenotypic expression. There are three clinical phenotype-type 1 (non-neuronopathic form), type 2 (acute neuronpathic form) and type 3 subacute neuronopathic form). This classification is based on the onset and severity of neurological symptoms. The phenotypic expression of type 2 GD was thought to be sterotypic in presentation, with infantile onset, progressive neurological deterioration and death by 2 years old. We identified 85 Japanese patients with GD until 1998. Of 85 patients 15 patients were classified into type 2 GD. Of 15 cases with type 2 four cases manifested none-immune hydrops fetalis and they died within 2 months. Few biochemical and pathological studies have not been performed in this clinically unique patients. Up to date only three reports performed mutation analysis of lethal type 2 GD, demonstrating that two were homozygous for RecNciI and one patient was genotyped as compound heterozygote for a novel recombinant allele and a rare splice junction mutation. We here described pathological, biochemical and genetic studies of four Japanese patints with neonatal GD. The massive accumulation of GC was found not only in liver and spleen but in lung, kidney, brain and thymus in all cases. The pathological findings were characterized by destruction of tissues rather than accumulation of Gaucher cells. The genotypes of three patients examined were 1447-1466 del 20 ins TG/L444R, 1447-1466 del 20 ins TG/? and IVS2+1/?. These data suggest that Japanese neonatal GD shows quite unique genetic, pathological and biochemical findings.

Program Nr: 1329 from the 1999 ASHG Annual Meeting

Homozygosity mapping indicates high prevalence of complementation group A in Tunisian Fanconi anemia patients. *S. Abdelhak[1], C. Bouchlaka[1], H. Ben Abid[2], M. Frikha[3], S. Nabli[4], A. Saad[4], F. Fakhfakh[3], H. Ayadi[3], A. Hafsia[2], H. Joenje[5], K. Dellagi[1], For the Tunisian Fanconi anemia Study Group[1,2,3,4]*. 1) Immunology Dpt, Institut Pasteur de Tunis, Tunis, Tunisia; 2) Hematology Dpt, Aziza Othmana Hospital, Tunis, Tunisia; 3) Hematology Dpt, Habib Bourguiba Hospital, Sfax, Tunisia; 4) Hematology Dpt, Farhat Hached Hospital, Sousse, Tunisia; 5) Clinical Genetics and Human Genetics Dpt, Free University Medical Center, Amsterdam,The Netherlands.

Fanconi anemia (FA) is an autosomal recessive rare disorder characterized by bone marrow failure, multiple congenital malformations and an increased risk to develop cancer due to chromosomal instability. At least eight complementation groups have been defined, five of which have been mapped to human chromosomes. FANCA, the gene responsible for the most prevalent complementation group, has been identified and mapped to chromosome 16q24.3. In the present study, six polymorphic markers overlapping the FANCA region, have been used to genotype 15 FA families from different geographical areas of Tunisia. Homozygosity mapping showed that in 12 of these families the patients were homozygous by descent for these markers, suggesting an assignment to complementation group A. Two families were not informative. One patient born to consanguineous parents was heterozygous for all the markers overlapping FANCA region as well as for markers of FANCC, G and D genes. This family may thus belong to group B, E, F or H or to a new complementation group. Our results are compatible with a high prevalence of complementation group A in Tunisia.

Program Nr: 1330 from the 1999 ASHG Annual Meeting

A General Family Test of Linkage Disequilibrium for Quantitative Traits. *G.R. Abecasis, L.R. Cardon, W.O.C. Cookson.* Wellcome Trust Center for Human Genetics, University of Oxford, OX3 7BN, United Kingdom.

High-resolution mapping is an important step in the identification of complex disease genes. In outbred populations, linkage disequilibrium is expected to operate over short distances and could provide a powerful fine-mapping tool. Here we build upon recently developed methods for linkage disequilibrium mapping of quantitative traits to construct a general approach that can accommodate families of any size, with or without parental information. Variance components are used to construct a test that utilizes information from all individuals but is not biased in the presence of linkage or familiality. Family data allows for the construction of an expected genotype for every non-founder, and we show that focusing on orthogonal deviates from this expectation makes it possible to distinguish association due to linkage disequilibrium from other types of association. For smaller families, a permutation test is described for situations where multivariate normality is violated and maximum likelihood estimates of the variance components are unreliable.

Simulation studies are used to investigate power and error rates of these approaches, and to highlight situations in which violations of multivariate normality assumptions warrant the permutation test. The relationship between power and the level of linkage disequilibrium for this test suggests that the method is well suited to the analysis of dense maps. The relationship between power and family structure is investigated and these results are applicable to study design in complex disease, especially for late-onset conditions where parents are usually not available. When parental genotypes are available, power does not depend greatly on the number of offspring in each family but only the total sample size. Power decreases when founder genotypes are not available, but the loss in power is negligible for larger families. Finally, we identify some situations where the number of individuals to genotype can be reduced with little loss in power.

Program Nr: 1331 from the 1999 ASHG Annual Meeting

Disequilibrium mapping of quantitative trait loci in the Hutterites. *M.A. Abney[1], M.S. McPeek[2], C. Ober[1].* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept of Statistics, Univ of Chicago, Chicago, IL.

Founder populations facilitate the search for genes that underlie complex phenotypes because of the relatively small number of independent genomes and recent origins. However, the large, complex genealogies that are characteristic of these populations pose considerable analytical and computational challenges. We have developed disequilibrium-based methods to map quantitative trait loci in the Hutterites. To detect recessive traits, we calculate at each locus a homozygosity-by-descent (HBD) statistic, which takes into account the exact known relationship between the parents of each subject, the genotype at the marker locus and at each flanking locus, and the distance to flanking loci. We consider both regression and normal mixture models based on this statistic, adjusting for covariates, and including polygenic components of variance. We also consider dominant and additive trait models. We use simulation to assess the statistical properties of the methods and determine significance. We apply the method to various quantitative traits in the Hutterites.

Program Nr: 1332 from the 1999 ASHG Annual Meeting

Magnitude of Type I Error of Heterogeneity Lod Score for Two-point Analysis. *P.C. Abreu*[1], *D.A. Greenberg*[2], *S.E. Hodge*[1,3,4]. 1) Div. of Biostatistics, Columbia Univ, New York,NY; 2) Dept. of Psychiatry, Mount Sinai Medical Ctr, New York,NY; 3) Dept. of Psychiatry, Columbia Univ,New York, NY; 4) NYSPI, New York, NY.

Linkage heterogeneity is a major confounding factor in linkage analysis. The classical distribution theory of the log likelihood ratio test statistic does not hold when testing for linkage and heterogeneity, i.e., mixture alternatives. We used computer simulations to explore the mixture problem in the genetic linkage context. We investigated the type I error of the heterogeneity lod score (HLOD), i.e., maximizing the lod score over both recombination fraction q and admixture parameter a. We examined two situations: (a) assuming a single genetic model and (b) maximizing HLOD over dominance models (dominant vs. recessive). We generated data sets of both phase-known and phase-unknown families under autosomal dominant inheritance with full penetrance. The asymptotic distributions of the linkage test statistics are a mixture of three c^2 distributions in the phase-unknown case, and of two c^2 distributions in the phase-known case.

For part (a) significance levels for phase-unknown families did not increase when maximizing w.r.t q and a compared to significance levels when maximizing only w.r.t q. For the phase-known case, the significance levels were increased somewhat when maximizing over both a and q compared to only w.r.t q, but the increase did not reach an additional degree of freedom. In part (b), when maximizing HLOD over q, a, and dominance model, the significance levels for the phase-unknown case were essentially the same as when maximizing only w.r.t q and dominance model, but not a. The significance levels for phase-known families are slightly higher than for phase-unknown. Because the correction for maximizing over dominance model (Hodge et al, 1997) is already very conservative, we recommend no additional increase in the correction of type I error for phase-known families. That is, the inflation of type I error when maximizing the max HLOD over dominance model can be corrected by increasing the lod score cutoff from a nominal value 3.0 to a cutoff value of 3.3, the same correction as for simply maximizing the max lod score over dominance model.

Program Nr: 1333 from the 1999 ASHG Annual Meeting

Evaluation of the CMT1A locus in African-American CMT patients. *M. Ahearn[1], L. Baumbach[1], E. Perera[1], K. Jackson[2], T. Bird[3], W.A. Bradley[1]*. 1) Univ. of Miami Medical School, Miami, FL; 2) Tulane Univ. Medical School, New Orleans, LA; 3) VA Medical Center, Seattle, WA.

The vast majority of reported patients with severe, dysmyelinating Charcot-Marie-Tooth Disease (CMT1) are of Caucasian ancestry. African-American (AA) CMT1 patients are greatly underrepresented clinically, as well as in published molecular studies, raising clinically interesting questions regarding possible ethnic-specific genetic differences which may modify disease phenotypes. We report our evaluation of the CMT1A locus in seven AA families. These studies have focused on identif ication of disease causing mutations in the 17p11.2 region in these families, as well the prevalence of a *pmp22* intron 3 EcoR1 polymorphism we previously reported (AJHG 61:A343,1997).

We have completed analysis of four of the seven probands, with the remaining patient and family studies nearing completion. Patient 1, Cuban ethnicity with African-American ancestry, has the 1.5 mB CMT1A duplication; Patient 2, who displays a Dejerrine-Sottas phenotype, has a novel *pmp22* point mutation; and it appears that patients 3 and 4 lack the CMT1A duplication and are being tested for *pmp22* mutations. Each of these patients also had the EcoR1 polymorphism, in comparison to a 35% frequency in African- American control samples. This polymorphism has never been reported in Caucasian CMT1A patients. Interestingly, patient 1, affected with CMT since early childhood, was significantly more symptomatic at the same age than her affected mother, who has the duplication, but does not have the EcoR1 polymorphism. Patients 3 and 4 are members of unrelated families which have had multiple members affected by their early thirties. Identification of the disease-causing mutations, and analysis of the segregation of the *pmp22* polymorphism in these kindreds, is being completed.

These investigations represent the first analyses of the CMT1A locus in African-American CMT patients and address a possible association of the apparently AA-specific *pmp22* polymorphic variant with disease presentation.

Program Nr: 1334 from the 1999 ASHG Annual Meeting

Genome scan in Finnish families with keratoconus. *T. Alitalo[1,2,3], H. Tyynismaa[1,2], M. Uusitalo[2], P. Sistonen[4], A. Dammert[5], T. Latvala[5].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) The Folkhalsan Institute of Genetics, Department of Molecular Genetics, Helsinki, Finland; 3) Depts. of Obstetrics and Gynecology, Helsinki University Central Hospital ,Helsinki,Finland; 4) Finnish Red Cross, Blood Transfusion Center, Helsinki, Finland; 5) Dept. of Ophthalmology, University of Oulu, Finland.

Keratoconus is a bilateral noninflammatory thinning disorder of the cornea with an incidence of approximately 1/2000 in the general population. Histopathological findings include stromal thinning, iron deposition in the epithelial basement membrane, and breaks in Bowman's layer. The most common treatment for keratoconus is contact lenses, but when contact lenses fail, corneal transplant is the best surgical option. Pedigrees with keratoconus in both sexes in two or three successive generations suggest autosomal dominant inheritance. In general, the dominant pattern is irregular, affecting approximately 1 in 10 blood relatives instead of the expected 1 in 2, implying variable expression or incomplete penetrance. We have collected blood samples from 22 Finnish keratoconus families with autosomal dominant pattern of inheritance and confirmed the diagnosis by re-examining the eyes of the family members. All the families originate from a restricted geographical region. To localize the keratoconus gene, we have started a genome wide scan with a panel of 369 markers with an average spacing of 10 cM. Initial analysis of the genotype data using GENEHUNTER revealed one region with suggestive linkage. We have also performed SSCP analyses, and excluded TIMP2 as the causative gene in keratoconus.

Program Nr: 1335 from the 1999 ASHG Annual Meeting

Investigation of HLA-DR effects on susceptibility to Rheumatoid Arthritis (RA) using family-based association and affected sib-pair linkage methods in a large sample of European families. *H. Alves[1], M. Martinez[2], D. Charron[3], V. Lepage[3], C. Stavropoulos[4], F. Tores[2], R. Westhovens[4], F. Cornélis[5], European Consortium E.C.R.A.F.[4].*
1) Department of Rheumatology, S Joao Hospital, Porto, Portugal; 2) INSERM U358, Paris, France; 3) Laboratoire D'Histocompatibilité, Hopital St Louis, Paris, France; 4) EEC-BIOMED2; 5) Univeristé Paris 7-Denis Diderot, France.

The mode of inheritance of RA is not known, but susceptibility to RA is associated to HLA-DR. The shared-epitope (SE) hypothesis has been postulated to support direct involvement in susceptibility of specific HLA-DR alleles. Others have suggested that DR effects may vary with epidemiological or clinical factors as gender, severity and onset of the disease. A complex genetic mechanism of the HLA-DR gene and genetic heterogeneity can explain these conflicting results. Small sample sizes and population stratification problems have also entangled these investigations. To date, the ECRAF consortium (Cornelis et al., 1998) is one of the largest collection of triads (one RA sib and parents, n=160) and ASP (at least 2 RA sibs, n=361) ever collected. Linkage disequilibrium to HLA-DR SE alleles (SE=0101, 0403, 0404, 0405, 0408, 1001, X= other alleles) was tested using family-based statistics in the triad sample. Probands from the different groups (France, n=84; Belgium, n=23; Spain, n=20; Italy, n=19, Portugal, n=14) have similar gender ratios, mean age of onset and clinical characteristics. TDT test was highly significant ($p=310^{-5}$). All SE alleles were significantly associated to RA except 0404 and 0408 alleles (p>5%). No significant differences for the parental origin of the transmitted alleles were found. Investigations of SE distributions by epidemiological and clinical characteristics of probands showed significant differences for the presence/absence of rheumatoid factors: SE alleles are more frequent in RF+ than in RF- probands (p=0.002). Linkage to the HLA-DR region (tested markers are D6S276, Tnfa and DR) was confirmed in our ASP sample (MLS=11.71). However, simple DR gene effects, as the SE hypothesis, can not explain our ASP linkage data.

Program Nr: 1336 from the 1999 ASHG Annual Meeting

A new locus for autosomal dominant hearing loss DFNA28 mapped to chomosome 8q22. *D.W. Anderson[1], A.J. Griffith[1], S. Rudy[1], T. San Agustin[2], T.B. Friedman[1], R.J. Morell[1].* 1) Laboratory of Molecular Genetics, NIDCD, NIH, Rockville, MD; 2) NIDRR, U.S. Dept. of Education, Washington, DC.

We have ascertained a large American family with an autosomal dominant form of nonsyndromic sensorineural hearing loss. The hearing loss is postlingual, with an onset as early as seven years of age, and gradual progression to moderate to severe levels by the fifth decade. The audiometric pattern is variable, with predominant impairment of high frequencies in some affected individuals and middle frequencies in others. Speech discrimination scores are normal, indicating that the loss is cochlear in origin.

Twenty-four individuals from four generations, including 9 affected individuals, were initially screened with STR markers linked to the reported DFNA and DFNB loci. These loci were all eliminated from consideration on the basis of two point linkage analysis. A genome wide scan using the Weber 8 panels was performed. Linkage to marker GAAT1A4 , at 8q22, was detected with a LOD (z) = 4.86 at q = 0. Haplotype analysis using markers flanking GAAT1A4 defined a 4 cM critical region between markers D8S546 and D8S545. This region excludes two loci for syndromic deafness: Branchio-Oto-Renal syndrome (BOR) and Hereditary Motor Sensory Neuropathy-Lom (HMSNL). There are no nonsyndromic deafness loci mapped to chromosome 8q22. Therefore, this family represents a new deafness locus, DFNA 28.

Program Nr: 1337 from the 1999 ASHG Annual Meeting

Microsatellite marker associations around the HLA-C region in Finnish psoriasis patients and controls. *K. Asumalahti[1], T. Laitinen[1], M. Lokki[2], H. Mannila[3], U. Saarialho-Kere[4], R. Itkonen-Vatjus[5], J. Kere[1].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Finnish Red Cross, Transfusion Service, Tissue-typing Laboratory, Helsinki; 3) Department of Computer Science, University of Helsinki; 4) Department of Skin Diseases, University Hospital of Helsinki; 5) Department of Skin Diseases, Central Hospital of Kainuu, Kajaani.

Psoriasis is a chronic skin disease characterized by hyperproliferation of epidermal keratinocytes and mononuclear cell mediated inflammation affecting 2-3% of Caucasoid population. In recent years, several candidate loci for psoriasis have been reported. The oldest and still strongest evidence has been found in HLA association studies and the HLA-Cw*0602 allele has been suggested as a major locus for psoriasis in many populations with the relative risk (RR) of 3-4. We verified the same allele association using SSP-PCR method in 142 psoriasis patients from the central eastern part of Finland (the Kainuu province). The Kainuu population is genetically isolated with a strong founder effect. Thirty-seven percent (52/142) of psoriasis patients were HLA-Cw*0602 positive compared to 9.6% (11/115) of healthy family based controls (RR 3.9). The relative risk was even higher (5.1) among the type I psoriasis patients (26/53, 49%). To estimate our power to identify a susceptibility allele in psoriasis by haplotype analysis, we studied four polymorphic microsatellite markers spanning 5cM across the HLA-C locus. The HLA-Cw*0602 allele was found in 35 unrelated chromosomes among the patients. The initial results showed that markers on both sides of the HLA-Cw*0602 identified altogether 15 different 2 marker haplotypes, but two of the haplotypes identified 60% (21/35) of the susceptibility chromosomes.

Program Nr: 1338 from the 1999 ASHG Annual Meeting

Linkage of systolic blood pressure to D21S1440 in Mexican Americans. *L.D. Atwood[1], P.B. Samollow[2], J.E. Hixson[2], M.P. Stern[3], J.W. MacCluer[2].* 1) Epidemiology, University of Minnesota, Minneapolis; 2) Genetics, Southwest Foundation for Biomedical Research, San Antonio; 3) Medicine, University of Texas Health Science Center, San Antonio.

We performed a genome scan of systolic blood pressure (SBP) on approximately 441 individuals in 10 randomly ascertained families of the San Antonio Family Heart Study. We defined a likelihood-based single-locus Mendelian model incorporating sex-specific and genotype-specific effects of age (linear and quadratic), BMI, and diastolic blood pressure (DBP) as covariates. A threshold correction was used for individuals on high blood pressure medication. Randomization of individuals across pedigrees showed that the effect of pedigree structure was significant (p=0.01), and a likelihood ratio test rejected the polygenic model (p=2.36E-64). Together, these two results indicate that SBP is oligogenic. Sex-specific and genotype-specific effects of age (p=6.12E-14 and p=2.58E-36) and BMI (p=3.39E-4 and p=8.04E-4) were highly significant, indicating that SBP has significant interaction effects. DBP had a very strong linear effect (p=3.91E-118), but did not have sex-specific or genotype-specific effects (p=.764 and p=.058).

Using model parameters that gave the global maximum likelihood we performed two-point linkage analysis using 401 highly polymorphic markers. SBP showed suggestive linkage to only two markers, *D18S844* (Z=2.09, q=0.11) and *D21S1440* (Z=2.82, q=0.00). For an oligogenic trait a combined segregation and linkage analysis (CSL) may be able to isolate a single locus signal more effectively than a fixed model analysis. Therefore, for these two markers we performed a CSL analysis in which both the segregation and recombination parameters for a two-locus model were maximized simultaneously. This model was maximized twice, once with the recombination fraction free and once with it fixed at 0.5. The resulting CSL lodscores showed that *D18S844* remained suggestive (Z=2.01, q=0.11). However, *D21S1440* reached significance (Z=3.24, q=0.00). A examination of GeneMap98 showed no obvious candidate genes near either marker.

Program Nr: 1339 from the 1999 ASHG Annual Meeting

Meta-analysis for interpreting results from multiple genome scans. *J.A. Badner, E.S. Gershon.* Dept Psychiatry, Univ Chicago, Chicago, IL.

Lander and Kruglyak gave guidelines for interpreting linkage results based on estimating how often a particular threshold for significance would be exceeded by chance in a single genome scan. A criterion for significant linkage was recommended to be a threshold that would be exceeded 0.05 times by chance in a single genome scan. These criteria do not always enable interpretation of the results of multiple genome scans of a genetic trait. In some cases, there may be several scans that show significant results within the same region but none of the individual results would meet criteria for significant linkage. In other cases, two or more studies exceed criteria for significant linkage but several other studies do not show nominally significant results with the same region. This may occur due to low power to detect genes of small effect using the criteria recommended by Lander and Kruglyak. One possibility is to combine the results of these studies. However, this is difficult to do in many instances. We propose a type of meta-analysis which involves combining p values across the studies. We make recommendations for criteria of linkage using this analysis. Comparisons of the power of this meta-analysis with Lander and Kruglyak criteria are presented. We apply this method of meta-analysis to the evidence for linkage of IDDM susceptibility loci.

Program Nr: 1340 from the 1999 ASHG Annual Meeting

Identification of and adjustment for genotyping errors in data on sibpairs when parental genotypes are unavailable. *M. Bahlo*[1], *K.W. Broman*[2], *T.P. Speed*[1,3]. 1) Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia; 2) Marshfield Medical Research Foundation, Marshfield, WI; 3) University of California, Berkeley.

In affected sibpair studies of late-onset diseases, such as prostate cancer, DNA samples for subjects' parents are often unavailable. In such situtations, genotyping errors cannot be detected by the usual methods, since all possible genotypes conform to Mendel's rules. We have studied two approaches to dealing with genotyping errors in such data, making use of multipoint marker information. First, we consider a likelihood ratio statistic to identify genotypes likely to be in error. Second, we calculate IBD probabilities given multipoint marker data using an incomplete penetrance function which allows for the presence of errors. We present the results of a simulation study comparing the power to detect a disease susceptibility gene when (a) genotyping errors are ignored, (b) genotypes likely to be in error are detected and removed, and (c) using an analytic method which allows for the presence of genotyping errors. We studied the effect of marker density, different error models, gene effect, sample size and error rate on the outcome. Genotyping errors are shown to erode the power to detect linkage. The effect may be ameliorated by use of methods to detect or allow for the presence of errors, though marker density must be quite high.

Program Nr: 1341 from the 1999 ASHG Annual Meeting

Mapping of human $GABA_A$ receptor subunit genes and generation of polymorphic markers. *M.E.S. Bailey, G.R. Riboldi Tunnicliffe, A. McDonnell, M. Ennis, J. Du, K.J. Johnson.* Division of Molecular Genetics, IBLS, Univ. of Glasgow, Glasgow, U.K.

$GABA_A$ and $GABA_C$ (g-aminobutyric acid types A and C) receptors mediate a significant proportion of fast inhibitory neurotransmission in the vertebrate central nervous system and retina. The receptors are pentameric assemblies of membrane-spanning subunits that enclose a chloride-selective, GABA-gated channel. The subunits share a common structure and have been classified in 7 subclasses (a - e, p, and r) based both on their relative degree of sequence similarity and on their pharmacology. Each of the 19 known mammalian subunits is encoded by a separate gene, all of which are members of the inhibitory branch of the ligand-gated ion channel (LGIC) gene superfamily. We have localised several of these subunit genes in detail, particularly those lying on human chromosome 4p, using linkage, radiation hybrid and STS/YAC mapping techniques. We have mapped *GABRR3* (the previously uncloned human orthologue of the rat r3 subunit gene) to human chromosome 3q. During these studies, we generated and characterised polymorphic, microsatellite markers for *GABRA2*, *GABRA4*, *GABRG2* and *GABRR1*. These will prove of use in linkage analysis of human neurological and psychiatric disorders and traits.

Most of the subunit genes in this family are arranged in 4 clusters on different chromosomes. Our human mapping data, along with existing data and the preliminary results of our comparative mapping study in *Fugu*, indicate that there has been a striking degree of conservation of gene order and orientation within these paralogous clusters. Phylogenetic analysis using PAUP has yielded a model for the evolution of this gene family that is largely consistent with the genomic localisations of its human members; this model lends support to the idea that two genomic duplication (tetraploidisation) events occurred early in chordate evolution. The role of regulatory and coding sequence variation in influencing human traits, and the possible links between gene cluster conservation and functional specialisation of the paralogous genes are just starting to be addressed.

Program Nr: 1342 from the 1999 ASHG Annual Meeting

Automated lane tracking and sizing of DNA fragments. *F.K. Bandukwala[1,2], M.W. Perlin[1,2,3]*. 1) Cybergenetics, Co., Pittsburgh, PA; 2) School of Computer Science, Carnegie Mellon University, Pittsburgh, PA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Human editing of DNA fragment data is a key bottleneck precluding the cost-effective automation of microsatellite and SNP genotyping data. When the data are derived from electrophoretic separation of fluorescently labeled markers on sequencing gels, the analysis tasks include tracking lanes and sizing DNA fragments. Fully automated lane tracking and sizing can be challenging in the presence of data artifacts, such as geometric peak and lane distortions. We have developed a pattern recognition module based on signal processing methods that implements this automation for our TrueAllele(TM) automated genotyping software.

Our method automatically extracts the lanes by first analyzing the largest size row of size standards (SS). Steps include deconvolution (for increased signal to noise), model function fitting (with two-dimensional Gaussian functions), and feature extraction (using shape parameters). Once the distributions of all the peaks in one SS row have been identified, the pattern is transferred to the next SS row by identifying matching geometric features in the next region. Matched features require consistency between intensity shape near the data peak, and consistency between geometric constraints. The peak data in SS row k are extracted by distorting the pattern of SS row (k-1), and obtaining a good fit between that pattern and strong candidate peaks in SS row k.

Our method automates the lane tracking and sizing of 96-lane ABI/377XL gels on Macintosh, Windows, and UNIX computers. On an iMAC computer, after an initial ten minute learning run, the processing time is reduced to about two minutes per gel. The program generates internal quality measures that can eliminate human review for the majority of gels, and direct user attention to problematic data regions on poorly-tracking gels.

Program Nr: 1343 from the 1999 ASHG Annual Meeting

The role of chemokine receptors in susceptibility to multiple sclerosis. *L.F. Barcellos[1], A.M. Schito[1], J.B. Rimmler[2], E. Vittinghoff[1], A. Shih[1], R. Lincoln[1], D.E. Goodkin[1], J.L. Haines[3], M.A. Pericak-Vance[2], S.L. Hauser[1], J.R. Oksenberg[1]*. 1) Dept. Neurology, Univ. California, San Francisco, CA; 2) Center for Human Genetics, Duke Univ., Durham, NC; 3) Program in Human Genetics, Vanderbilt Univ., Nashville, TN.

The etiology of multiple sclerosis (MS) pathogenesis is complex with involvement of both environmental and genetic influences. Recent results obtained from full genome screening identified several susceptibility regions, supporting a polygenic model for MS. Among these regions, evidence for weak linkage was observed at 3p/3cen suggesting the presence of a MS gene(s) of modest effect. Encoded here are two chemokine receptors, CCR5 and CCR2B. Clinical, experimental and epidemiological studies strongly suggest that both are potential MS candidate genes. We examined the ch.3p21-24 region in 125 MS families (322 total affecteds and 200 affected sibpairs) and performed genetic analyses of CCR5 and CCR2B loci and two nearby markers (D3S1289 and D3S1300) using both linkage and association-based tests. Modest linkage was observed for D3S1300 in the HLA-DR2 negative families only, 1.74(q=0.01) and 1.57(q=0.01), using both affected recessive or affected dominant models, respectively. Results obtained from ARP (SimIBD), sib-pair analyses (ASPEX), and association testing (sib-TDT) for each locus were not significant. However, significant effects on age of onset in patients were present for both gender and CCR5 phenotype (presence or absence of 32 bp deletion or D32) variables. Age of onset was approximately 3 years later in males compared to female MS patients (p=0.004) and approximately 3 years later in individuals with the CCR5D32 allele (p=0.018) after controlling for gender effects. This was not observed in a sample of 238 sporadic patients indicating that heterogeneity may exist between the two groups. Our results suggest that CCR5D32 may delay age of onset in familial MS. Polymorphisms within several chemokine receptors have recently been shown to significantly influence the risk of HIV infection and to delay progression. It will be of interest to examine the role of CCR5 in MS disease progression, CNS activity and severity.

Program Nr: 1344 from the 1999 ASHG Annual Meeting

Patterns of maternal transmission in asthma at chromosome 12q21.31. *K.C. Barnes[1], L.R. Freidhoff[1], R.A. Mathias[1], R.P. Naidu[2], R. Nickel[1], P.N. Levett[2], T.H. Beaty[1].* 1) Johns Hopkins University, Baltimore, MD; 2) University of West Indies, Barbados.

Asthma and stopy are referred to as multifactorial traits because disease expression is thought to be influenced by interactions between major and minor genes, and modulated by interacting non-genetic factors, such as environment. 'Developmental noise' (e.g., fetal-maternal environment) may interact with certain susceptible genotyopes, subsequently manifesting as diease. Epidemiologic data supports the joint effects of genetic susceptibility and parent-of-origin effect on the transmission of asthma, and several groups have reported evidence for linkage between maternal alleles and asthma or atopy at different loci, including chromosomes 4q, 11q, and 16q. We investigated the parent-of-origin effect on the transmission of asthma, allergis rhinitis (AR), and high serum total IgE (tIgE) in a set of 33 multiplex families from Barbados, ascertained through an affected offspring to determine: (1) the observed frequency and odds ratios (OR) of disease for the offspring of affected mothers compared to the offspring of affected fathers; and (2) preferential transmission of maternal or paternal alleles to affected probands using 22 chromosome 12q markers and transmission/disequilibrium testing (TDT). Offspring (asthma=130; AR=123; high tIgE=199) with an affected mother were more than twice as likely to be affected (asthma: OR, 2.7; 95% CI, 1.56-4.62; AR: OR, 2.1; 95% CI, 1.28-3.42; high tIgE: OR, 2.25; 95% CI, 1.46-3.45). Using the allele-by-allele TDT on 87 independent trios for asthma, we observed modest evidence for linkage disequilibrium in five markers (P=0.0001-0.03). The frequency of allele 237 in marker D12S326 was equal among mothers and fathers of affected offspring; however, we observed a maternal transmission of allele 237 in 90% of the cases compared to a paternal transmission rate of 45% (c^2=-10.74;P<0.00001). We found no evidence for a parent-of-origin effect for any of the 12q markers and AR or tIgE. Our findings suggest that asthma susceptibility is dependant upon both inheritance of a given 12q genotype and inheritance of that genotype from one's mother (not father).

Program Nr: 1345 from the 1999 ASHG Annual Meeting

Genome Scan for Linkage to Gilles de la Tourette Syndrome. *C.L. Barr[1], K.G. Wigg[1], R. Kurlan[2], A.J. Pakstis[3], K.K. Kidd[3], D. Pauls[4], L.-C. Tsui[5], P. Sandor[1]*. 1) Psychiatry, Toronto Hosp Western Div, Toronto, ON, Canada; 2) Neurology, University of Rochester School of Medicine, Rochester, NY; 3) Genetics, Yale University School of Medicine, New Haven, CT; 4) Child Study Center, Yale University School of Medicine, New Haven, CT; 5) Genetics, The Hospital for Sick Children, Toronto, ON, Canada.

Gilles de la Tourette Syndrome (TS) is a neuropsychiatric disorder characterized by both motor and vocal tics. Despite clear evidence for a genetic predisposition to TS from family, twin, and adoption studies, there have been no confirmed linkage findings. In this study we searched for linkage to TS in multi-generational families segregating TS using a panel of 386 markers with the largest interval between any 2 markers being 28 cM and an average distance between markers of 10 cM. We tested for linkage using an autosomal dominant model with reduced penetrance and using non-parametric methods. No significant evidence for linkage was found with parametric analysis. A Logarithm of the Odds (LOD) score of greater or equal to one under the autosomal dominant model was observed in twenty four of these markers in at least one of the families tested. No LOD scores greater than 2 were observed with any of the markers. For the non-parametric analysis, 8 markers were observed with a p value less than 0.00005 for significance evidence of linkage in at least one family. However caution should be used in the interpretation of the non-parametric analyses as this statistic (the Affected-Pedigree-Member method) is know to have a high false positive rate. Further support for linkage in these regions is required before linkage can be assumed.

Program Nr: 1346 from the 1999 ASHG Annual Meeting

Tardive Dyskinesia in Schizophrenia: Potential Role and Interaction of the Cytochrome P450 1A2 and Dopamine D3 Receptor Genes. *V.S. Basile[1], V. Ozdemir[2], M. Masellis[1], M.L. Walker[1], W. Kalow[2], H.Y. Meltzer[3], J.A. Lieberman[4], S.G. Potkin[5], F.M. Macciardi[1], J.L. Kennedy[1].* 1) Neurogenetics Section, Clarke Division, Centre for Addiction and Mental Health(CAMH), University of Toronto, Toronto, ONTARIO, Canada; 2) Department of Pharmacology, University of Toronto, Toronto, Canada; 3) Department of Psychiatry, Vanderbilt University, Nashville, USA; 4) Department of Psychiatry, University of North Carolina, Chapel Hill, USA; 5) Department of Psychiatry, University of California, Irvine, USA.

Long term neuroleptic treatment of schizophrenia induces tardive dyskinesia (TD) in predisposed patients. Upregulation of dopamine D2-like receptors may play a role in neuroleptic-induced TD. Following our initial report of DRD3 association with TD (Badri et al. 1996), research has currently focused attention on the D3 receptor (Steen et al., 1997; Basile et al., 1999; Segman et al., 1999). Inter-individual variation in neuroleptic metabolism may also contribute to an individual's propensity to develop TD. This study investigates genetic aspects of pharmacodynamic factors in TD by assessing the role of the D2, D3 and D4 receptor genes (DRD2,DRD3,DRD4), as well as pharmacokinetic factors by assessing polymorphisms of the cytochrome P450 1A2 and 2D6 genes(CYP1A2, CYP2D6). 112 neuroleptic treated schizophrenia patients were assessed for TD severity using the Abnormal Involuntary Movement Scale (AIMS). Analysis of covariance (ANCOVA), which incorporated risk factors for TD, was utilized to detect differences in TD severity across genotypes. The MscI polymorphism of DRD3 was found to be associated with TD ($F[2,95]=8.25$, $p<0.0005$) (Basile et al., 1999). Analysis of the Bsp120I RFLP of CYP1A2 revealed a significant association with TD ($F[2,99]=11.37$, $p<0.0005$). Assessing for a putative gene-gene interaction between CYP1A2 and DRD3, we have been able to detect a probable epistatic effect ($p<0.00007$). The remaining candidate genes did not exhibit any significant associations. Although replication is necessary, this study supports a role for both DRD3 and CYP1A2 in the pathogenesis of TD.

Program Nr: 1347 from the 1999 ASHG Annual Meeting

Follow-up of genomic screen for Autistic Disorder. *M.P. Bass[1], C.M. Wolpert[1], M.M. Menold[1], S.L. Donnelly[1], S.A. Ravan[2], T.D. Church[1], L. Zaeem[1], A. Zimmerman[3], J.R. Gilbert[1], H.H. Wright[2], R.K. Abramson[2], D.T. DeLong[4], J.M. Vance[1], M.L. Cuccaro[2], M.A. Pericak-Vance[1].* 1) Center for Human Genetics,Duke University Medical Center, Durham, NC; 2) W.S.Hall Psychiatric Institute, University of South Carolina, Columbia, SC; 3) John Hopkins University Medical Center, Baltimore, MD; 4) Division of Neurology, Pediatrics, Duke University Medical Center, Durham, NC.

Last year we reported results of our genomic screen for Autistic Disorder (AD), a neurodevelopmental disorder characterized by impairment in social, communicative, and behavioral functioning. Suggestive evidence for linkage (parametric or MLS LOD score ³ 1 or affected relative pair p-value < 0.05) was found for regions on chromosomes 2, 3, 6, 7, 15, 18, 19, and X. Chromosome 7, 15, 18, and 19 presented the most promising results and were prioritized for follow-up in an expanded data set of AD families (N=89). All affected individuals included in this study met DSM-IV/ICD10 criteria for AD, as determined by the Autism Diagnostic Interview-Revised (ADI-R) (Lord et al., 1994). We also genotyped a potential region on chromosome 13 (Vieland et al., 1998). The findings on chromosomes 13 and 18q were not replicated in these data, although the region on 18p did give slightly positive parametric results (maximum LOD score of 0.61). Chromosomes 15 and 19 continue to give evidence of linkage in our data set (maximum LOD score of 2.04 and maximum MLS of 1.21 for the regions on 15 and 19, respectively). Chromosome 7 data also remained interesting and is reported elsewhere (Ashley-Koch et al., this conference). In addition to the linkage findings, chromosomes 7 and 15 have associated cytogenetic abnormalities in the regions of interest. Updated results and follow-up analyses of additional promising regions will be presented.

Program Nr: 1348 from the 1999 ASHG Annual Meeting

Linkage analysis of five X-linked infantile spinal muscular atrophy (XL-SMA) families reveals a major disease locus located between Xp11.3-Xp11.2. *L.L. Baumbach[1], D. Dressman[2,3], A. Meindl[4], N.T. Bech-Hansen[5], E. Hoffman[2,3].* 1) Univ Miami Sch Medicine, Miami, FL; 2) Univ Pittsburgh Sch Med, Pittsburgh, PA; 3) Children's National Medical Center, Washington, D.C; 4) Ludwig Maximilians University, Munchen, Germany; 5) University of Calgary, Calgary, Alberta.

We have described an X-linked recessive form of infantile lethal motor neuron disease (MIM 30021), which closely resembles Werdnig- Hoffman disease, except for additional features of early onset or congenital contractures and/or fractures (*AJHG*, 61S, #1554, 1997). Other defining attributes include congenital onset of severe hypotonia, muscle biopsy indicative of neurogenic atrophy; and loss of anterior horn cells upon autopsy. Here we report clinical information and results of linkage studies conducted in six additional, unrelated XL-SMA families. Families were recruited based on the above diagnostic criteria, and four of the six new families evaluated for linkage to a candidate disease gene region, Xp11.3-q11.2, previously reported by our group in one family (*Hum Molec Genet.*, 4(7):1213-16, 1995). The remaining two families were not adequate for generation of a significant LOD score. Genomic DNA was analyzed using X-chromosome highly polymorphic markers. Concordance analysis was used to define maternal meiotic recombination breakpoints surrounding a disease gene region, followed by multipoint linkage analysis with additional DNA markers. Results were interpreted using the *LINKAGE* and *VITESSE* programs.

Results indicate that these four families are linked to the same candidate disease gene interval, Xp11.3-q11.2, also reported in the first family referenced above. Multipoint linkage analysis has been completed for three of these families and has refined this interval to a region defined by DXS991-DXS1003, with a maximum LOD score of 2.73. The total additive LOD score for these three families, and the family previously published, is 5.36 at a *Theta* of 0.00. There has been no evidence for genetic heterogeneity in these families. These results strongly support the existence of a major disease locus for XL-SMA between DXS 1003-DXS 991 (Xp11.3-Xp11.21).

Program Nr: 1349 from the 1999 ASHG Annual Meeting

Genome scan for quantitative traits involved in cardiovascular disease. *M. Beekman[1, 2], D.I. Boomsma[3], P. De Knijff[2], G.P. Vogler[4], C.C. Kluft[1], G.J.B. Van Ommen[2], R.R. Frants[2], P.E. Slagboom[1].* 1) Dept of Vascular and Connective Tissue Research, TNO-Prevention and Health, Leiden, The Netherlands; 2) Dept of Human Genetics Leiden University Medical Center, Leiden, The Netherlands; 3) Dept of Psychology, Free University of Amsterdam, Amsterdam, The Netherlands; 4) Center for Special Populations and Health, Pennsylvania State University, Pennsylvania, USA.

Genetic epidemiology has convincingly demonstrated the existence of genetic effects on quantitative traits such as cholesterol level, blood pressure and triglyceride level. The aim of our study is to map and identify quantitative trait loci (QTLs) for these risk factors of cardiovascular disease by performing a genome scan. In the past 16 months 91,000 genotypings were done for 85 loci at the most interesting chromosomes using two automated laser fluorescent DNA sequence analyzers (ALFexpress). From population based samples of Dutch, Swedish and Australian twins, which have been investigated in previous epidemiological studies, phenotypic data on apolipoprotein A1, A2, B and E levels, triglyceride levels, LDL and HDL cholesterol levels, blood pressure and BMI have been obtained. The 520 dizygotic (DZ) twin pairs in these populations are being genotyped for 229 highly polymorphic microsatellite markers with an average spacing of 18 cM. We composed for this genome scan 80 multiplex PCR reactions randomly typing loci in packages of 3 to 5 chromosomes, thereby enabling statistical analyses of chromosomes during the search. Our genotyping procedure requires for a complete 18 cM spaced genome scan less than 5 mg of genomic DNA isolated from blood or mouth swabs.

In the Dutch twin population (N=192 pairs) suggestive linkage (LOD of 2.8) was found at a 50 cM wide chromosomal region determining 50 percent of the variation in LDL cholesterol. This effect would account for most of the expected genetic contribution to LDL cholesterol. We are currently fine mapping this region in the Dutch twin sample by genotyping 232 parents and 50 additional siblings.

Program Nr: 1350 from the 1999 ASHG Annual Meeting

Confirmation of linkage of Van der Woude syndrome to chromosome 1q32: Evidence of association with STR alleles suggests possible unique origin of the disease mutation. *S. Beiraghi[1], A. Miller-Chrisholm[2], W.J. Kimberling[3], C. Sun[2], Y. Wang[2], L. Russell[2], M. Khoshnevisan[2], A.L. Storm[4], R.E. Long Jr.[5], P.D. Witt[4], M. Mazaheri[5], S.R. Diehl[2].*

Van der Woude (VWS) is an autosomal dominant craniofacial disorde with high penetrance and variable expression of its clinical features of cleft lip and/or cleft palate, lip pits and hypodontia. The gene has been mapped to a <2 cM region of chromsome 1q32. The aim of our study was to refine the localization of the VWS gene and to further assess possible heterogeneity. We recruited four multiplex VWS families. We used automated genotyping methods to characterize 19 short tandem repeat markers on chromosome 1 in the VWS candidate gene region. We performed two point and multipoint LOD score analyses using a high penetrance autosomal dominant model. All families show positive LOD scores without any recombination in the candidate region. The largest two point LOD score was 5.87. Our results are fully consistent with previous mapping of the VWS gene between D1S491 and D1S205. Our assay method for Short Tandem Repeat (STR) markers provided highly accurate size estimation of marker allele fragment sizes and, therefore, enabled us to determine the specific alleles segregating with the VWS gene in each of our four families. We observed a striking pattern of STR allele sharing at several closely linked loci among our four Caucasian VSW families recruited at three different locations in the U.S. This suggests the possibility of a unique origin for a mutation responsible for many or most cases of VWS.

.

Program Nr: 1351 from the 1999 ASHG Annual Meeting

Mapping of a gene for non specific X-linked mental retardation : evidence for linkage to chromosomal region Xp21.3-Xp22.1(MRX54). *L. Ben Jemaa[1], V. desportes[2], R. Zemni[1], R. M'rad[1], F. Maazoul[1], C. Beljord[1], H. Chaabouni[1], J. Chelly[2]*. 1) genetique, faculte de medecine de tunis, tunis, tunisia; 2) INSERM U129 ICGM France.

X-linked nonspecific mental retardation (MRX) is a heterogeneous condition in which mental retardation (MR) appears to be the only consistent manifestation. Large genetic interval of assignment obtained on individuals families by linkage analysis, and genetic and phenotypic heterogeneity , are usually major obstacles to fine-map and identify the related disease genes. Here we report a large Tunisian family (MRX54) with an MRX condition. X-linked recessive inheritance is strongly suggested by the segregation of MR through 7 unaffected carrier females to 14 affected males in two generations. Two-point linkage analysis demonstrated significant linkage between the disorder and several markers in Xp21.3-22.1 (maximum LOD score Zmax =3.56, recombination fraction *=0 at DXS1202), that was confirmed by multipoint linkage analyses. Recombinant events observed with the flanking markers DXS989 and DXS1218 delineate a refined locus of about 2.7 cM in accordance with the physical distance between these two markers. The small interval of assignment observed in this family overlaps not only with 9 large MRX loci previously reported in Xp21.3-22.1, but also with two inherited microdeletions in Xp21.3-22.1 involved in non specific MR. Although the involvement of several genes located in Xp21.3-22.1 region cannot be ruled out, data reported in this study could be used as a starting point for the search of such gene(s).

Program Nr: 1352 from the 1999 ASHG Annual Meeting

The cathepsin D Ala224Val polymorphism is not associated with the risk of Alzheimer's disease. *T. Bhojak[1], S.T DeKosky[2], M.I Kamboh[1,2].* 1) Departments of Human Genetics; 2) Psychiatry, Univ Pittsburgh, Pittsburgh, PA.

Cathepsin D (Cat D) is an intracellular acid protease that is ubiquitously distributed in lysosomes. It is active in intracellular protein breakdown and has in vitro b-secretase-like properties. The Cat D gene is located on chromosome 11p15. A C®T (Ala®Val) transition at position 224 of the Cat D gene (exon 2) may be associated with increased pro Cat-D secretion and altered intracellular maturation. It has been hypothesized that increased activity of Cat D would result in altered APP processing and resultant increase in b-amyloid production. A recent study by Papasstiropoulos et al. (Neurosci. Lett. 1999; 262: 171-174) reported that carriers of the *CatD*T* allele were at a 2.4 fold increased risk for developing Alzheimer's Disease (AD) as compared to non-carriers, and this risk was independent of the APOE polymorphism. To confirm this association, we screened 446 sporadic, late-onset cases and 316 age-matched controls for the Cat D polymorphism. We found no significant association of the Cat D polymorphism with the risk of AD. The frequency of the *CatD*T* allele was 10% in AD cases and 9% in controls. Upon stratifying the data by *APOE*4* and non-*APOE*4* carriers, there was no significant difference in the frequency of the *CatD*T* allele between cases and controls (p=0.46) either. Our data indicate that the *CatD*T* Ala224Val polymorphism does not affect the risk of AD.However, a more detailed characterization of the Cat D gene may shed more light on its role in the development of AD.

Program Nr: 1353 from the 1999 ASHG Annual Meeting

A Genomic Survey for Substance Dependence in Families of Alcoholics. *L.J Bierut[1, 2], J. Rice[1,2], A. Goate[1,2], T. Foroud[2], H. Edenberg[2], C.R. Cloninger[1,2], H. Begleiter[2], M. Conneally[2], R. Crowe[2], V. Hesselbrock[2], T-K. Li[2], J. Nurnberger, Jr.[2], B. Porjesz[2], M.A. Schuckit[2], T. Reich[1, 2].* 1) Psychiatry, Washington University, St. Louis, MO; 2) Collaborative Study on the Genetics of Alcoholism.

Alcohol and substance dependence co-occur in the same individual more frequently than expected by chance alone. Evidence from family and twin studies support both common and specific addictive factors predisposing one to alcohol and other substance dependence. This is a report of a linkage study to locate genetic loci for marijuana and cocaine dependence in families of alcoholics. Subjects were part of the Collaborative Study on the Genetics of Alcoholism (COGA). Individuals who met criteria for both DSM-IIIR alcohol dependence and Feighner definite alcoholism were identified in substance abuse treatment settings, and their relatives were recruited as a sample at high risk for substance dependence. All subjects were interviewed using a semi-structured interview (SSAGA) that evaluated alcohol and substance dependence, and other psychiatric disorders. Male and female probands had high rates of marijuana and cocaine dependence (marijuana dependence 47% men 40% women; cocaine dependence 47% men 51% women), and there was significant familial aggregation of marijuana and cocaine dependence. A genomic screen for genetic loci linked to marijuana dependence (110 families - 159 affected sibling pairs) and cocaine dependence (89 families - 117 affected sibling pairs) was performed using affected sibpair analysis (ASPEX). The strongest evidence for linkage with marijuana and cocaine depende was at the same locus on chromosome 1 (Marijuana: Lod score=2.1 59% sharing; Cocaine: Lod score 1.93 60% sharing). This location on chromosome 1 has also shown evidence of linkage with alcohol dependence.

Program Nr: 1354 from the 1999 ASHG Annual Meeting

Primary Ciliary Dyskinesia: A genome-wide linkage analysis reveals extensive locus heterogeneity. *J.-L. Blouin[1], U. Radhakrishna[1], C. Gehrig[1], G. Duriaux Sail[1], A.J. Sainsbury[1], L. Bartoloni[1], M. Meeks[2], V. Dombi[1], D. Probst[1], B. Afzelius[3], M. Armengot[5], E. Chung[2], M. Jorissen[4], D.V. Schidlow[5], R.M. Gardiner[2], H. Walt[1], L. Van Maldergam[4], P.-A. Guerne[1], C.D. Delozier Blanchet[1], S.E. Antonarakis[1]*. 1) University and Cantonal Hospital of Geneva, and University Hospital of Zurich, Switzerland; 2) University College London, UK; 3) University of Stockholm, Sweden; 4) University of Leuven, and Institute of Pathology and Genetics of Loverval, Belgium; 5) University Hospital of Valencia, Spain and Allegheny University, PA.

Primary Ciliary Dyskinesia (PCD), is an autosomal recessive disorder affecting ciliary and flagellar movement (incidence: 1/30,000). Dysmotility to complete immobility of cilia results in upper respiratory tract infections, bronchiectasis and male sterility. 50% of cases have situs inversus (Kartagener syndrome). We have collected blood samples from 61 families. A genome-wide linkage search was performed in 31 multiplex families using 188 evenly-spaced microsatellites (19 cM interval). We performed a power calculation on our sample using q-value of 0.10 (scenario using a marker map density of 19 cM interval). The maxELOD was 18.22 (meanELOD=15.43). The sample was adequate to detect a Lod score of 3.74 at q=0.10 for a model in which 50% of the families were not linked to a locus. Linkage analysis was conducted on all families (all PCD), and in subgroups of families with situs inversus (PCD-SI), and in families with dynein arm deficiency (PCD-DAD). We analysed the genotype data with both parametric (PL, recessive model), and non-parametric (NPL) methods. No marker showed statistically significant values for linkage, but several chromosomal regions (4q, 5p, 8q, 16p, and 19q) were identified with suggestive evidence of linkage. The highest statistically suggestive scores were on chromosomes 4q (NPL p=0.00043, all PCD), 16p (NPL Zall=2.96, PCD-DAD), 8q (NPL Zall=2.85, PCD-DAD, PL ZH=2.43, PCD-SI), 19q (PL ZH=2.46, PCD-SI). At least 3 genes may be responsible for PCD supporting the genetic heterogeneity suggested by the spectrum of ultrastructural defects observed in cilia and flagella in PCD patients.

Program Nr: 1355 from the 1999 ASHG Annual Meeting

Fine mapping of region 1p32-p34.1 that contains the third major locus for autosomal dominant hypercholesterolemia. *C. Boileau[1], L. Villéger[1], J-P. Rabès[1], M. Devillers[1], M. Krempf[2], A. Cenarro[3], M. Farnier[2], M.J. Kotze[4], G.M. Kostner[5], M. Martinez[1], C. Junien[1], M. Varret[1]*. 1) INSERM U383 and U358, Paris, France; 2) CHU Hôtel Dieu, Nantes and Point Médical, Dijon, France; 3) Universidad de Zaragoza, Spain; 4) MRC Cape Heart Group, Tygerberg , South Africa; 5) University of Graz, Austria.

Autosomal Dominant Hypercholesterolemia (ADH), one of the most frequent hereditary disorders, is characterized by an isolated elevation of LDL particles that leads to premature mortality from cardiovascular complications. It is generally assumed that mutations in the LDLR and APOB genes account for ADH and we have shown that ADH is genetically more heterogeneous than conventionally accepted. We identified 13 Caucasian ADH families in which we excluded linkage to the LDLR and APOB genes thus demonstrating the implication of a new locus we named “FH3”. Genetic linkage was obtained in 4 pedigrees (HC2, S601, S150, S113) for chromosome 1 markers, localizing the FH3 locus in a 9 cM interval at 1p32-p34.1. By radiation hybrid mapping, four candidate genes (FABP3, SCP2, APOER2 and EPS15) at 1p32-p34.1 were located outside the critical region, demonstrating no identity with the FH3 gene. Heterogeneity tests estimated that 27% of these non-LDLR/non-APOB ADH families were linked to the FH3 locus. These results indicated the implication of a fourth locus called “FH4” that we are currently mapping by linkage analysis. To refine the localization of the FH3 gene, we have tested other regional polymorphic markers in the 4 originally linked pedigrees. In the HC2 family, the FH3 gene is now linked to a conserved haplotype defined by markers tel-D1S2892-D1S2722-D1S2645-cen that span an area of 2.8 cM. We are currently testing 5 new ADH families for which linkage was excluded to the LDLR and APOB genes. This should enable us to further shorten the genetic interval in which the FH3 gene is located. Furthermore, we are constructing a YAC contig of the area to undertake its physical mapping and map regional STSs.*tel-D1S2892-D1S2722-D1S2645-cen*.

Program Nr: 1356 from the 1999 ASHG Annual Meeting

Interference in the analysis of genetic marker data. *S. Browning, E.A. Thompson.* Statistics, University of Washington, Seattle, WA.

Analysis of identity by state (IBS) data at multiple linked markers requires assumptions about the crossover formation process. Haldane's Poisson process model is typically assumed. Other models, such as the chi-square renewal model can provide a much better fit to available data. We have developed methods for analyzing IBS data under a range of crossover models.

For a pair of individuals with IBS data at 433 markers (Puffenberger and Chakravarti, unpublished data),we compared the results of relationship inference under Haldane's model and under the chi-square model. A Markov chain Monte Carlo (MCMC) approach was used to calculate likelihoods under the chi-square model. For this pair, evidence of relationship increased slightly when the chi-square model (parameter m=2), rather than Haldane's model, was assumed (the LOD score for the most likely relationship vs. unrelated rose from 34.36 to 34.53). The most likely relationship for the pair was aunt-niece under both models.

Although the effect of the model on the relationship LOD score is small, it is important to know this. Also, interference can have a major effect on posterior identity by descent (IBD) probabilities, in one example changing them by 50%. A different MCMC approach allows estimation of these IBD probabilities among sets of individuals, at up to 12 linked loci, under alternative crossover models. We applied this method to data on trios of related individuals at 12 loci on chromosome 1 and on chromosome 19. IBD probabilities under Haldane and chi-square (m=2) models are compared.

We also investigated the amount of information in idealized IBD data (IBS data with infinitely dense and informative markers) to distinguish between models for crossing-over. Likelihoods on simulated data were calculated using a Monte Carlo method. We found that approximately 40 Morgans of IBD data from half-sibs are usually sufficient to distinguish between Haldane's model and the chi-square (m=2) model.

Work supported by NIH grant GM-46255 and a Burroughs Wellcome Fund PMMB training fellowship.

Program Nr: 1357 from the 1999 ASHG Annual Meeting

Linkage of familial schizophrenia to chromosome 13q32. *L.M. Brzustowicz[1,2], W.G. Honer[3], E.W.C Chow[4,5], D. Little[1], J. Hayter[1], M. Khan[1], L. Scutt[5], J. Hogan[5], D. Hayden[5], K. Hodgkinson[5], A.S. Bassett[4,5].* 1) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ; 2) Department of Psychiatry, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, NJ; 3) Department of Psychiatry, University of British Columbia, Vancouver; 4) Department of Psychiatry, University of Toronto, Ontario; 5) Genetics Section, Schizophrenia Research Program, Centre for Addiction and Mental Health, Queen Street Division, Toronto, Ontario.

Over the past four years, a number of investigators have reported findings suggestive of linkage to schizophrenia with markers on chromosomes 13q32 and 8p21, with one recent study reporting significant linkage to these regions. As part of an ongoing genome scan, we evaluated microsatellite markers spanning chromosomes 8 and 13 for linkage to schizophrenia in 21 extended Canadian families (N=261 subjects). Markers were from the Cooperative Human Linkage Center linkage mapping screening set, with average spacing of 10 cM and average heterozygosity of 0.76. Families were analyzed using FASTLINK under both autosomal dominant and recessive models, using broad and narrow definitions of schizophrenia. All models produced positive lod scores with markers on 13q, with higher scores under the recessive models. The maximum three-point lod scores were obtained under the recessive broad model: 3.92 at q = 0.1 with D13S793 under homogeneity and 4.42 with a = 0.65 and q = 0 with D13S793 under heterogeneity. Positive lod scores were also obtained under all models for markers on 8p. While a maximum two-point lod score of 3.49 was obtained under the dominant narrow model with D8S136 at q = 0.1, multipoint analysis with closely flanking markers reduced the maximum lod score in this region to 2.13. These results provide independent significant evidence of linkage of a schizophrenia susceptibility locus to markers on 13q32, and are supportive of the presence of a second susceptibility locus on 8p21.

Program Nr: 1358 from the 1999 ASHG Annual Meeting

Cholestasis with lymphedema (Aagenaes syndrome): Genome screen and evaluation of candidate regions. *L. Bull[1], E. Roche[1], K. Eiklid[2], C. van der Hagen[2], A. Knisely[3], O. Aagenaes[2], N. Freimer[1]*. 1) UCSF, San Francisco, CA; 2) University of Oslo, Oslo, Norway; 3) University of Texas Medical Branch, Galveston, TX.

Cholestasis with lymphedema (CL), or Aagenaes syndrome, was first described in a Norwegian pedigree, in which the disease demonstrates probable autosomal recessive inheritance. Most Norwegian patients come from the same region, and are descended from a couple born circa 1570. CL is characterized by neonatal-onset cholestatic jaundice, accompanied by elevated levels of serum bile acids, bilirubin, and ALAT, and lasting 1-5 years. Recurrent cholestatic episodes occur in later childhood and adulthood. Lymphedema may be apparent at birth, or begin during childhood, and becomes chronic. Studies on urinary bile acids suggest no inborn bile acid metabolism abnormality. To identify the CL gene, we performed a genome screen using DNA from members of the Norwegian pedigree, and 385 autosomal microsatellite markers. A standard linkage analysis was not feasible because the structure of the pedigree is too complex, and too many samples are unavailable. Therefore, we designed a screening strategy to identify genome regions potentially shared identical by descent among several of these distantly related patients; two sib-pairs and a cousin pair were included. We identified candidate regions based on: 1) data consistent with linkage in the two sib pairs, 2) data consistent with linkage in the cousin pair, 3) evidence for marker haplotypes shared by affected individuals, and 4) evidence that particular marker alleles are more frequent than expected on the disease chromosomes. We paid particular attention to 5 regions containing genes previously found to be mutated in forms of hereditary liver disease or lymphedema (*BSEP*, *FLT4*, *PGY3*, *FIC1*, and *JAG1*). We have obtained no genetic evidence that CL is due to mutation in any of these candidate genes. We are currently evaluating 20 candidate regions identified in the genome screen on the basis of the genetic criteria outlined above. These regions are being evaluated by additional genotyping of the samples included in the genome screen, as well as in a larger sample of Norwegian CL patients.

Program Nr: 1359 from the 1999 ASHG Annual Meeting

Effects of order of analysis in mapping complex disease. *S.B. Bull, P. Nikolakakos, J. Biernacka.* Lunenfeld Research Institute and Public Health Sciences, University of Toronto, Toronto, ON, Canada.

In large genome scans with high-throughput genotyping, families are often typed in batches as they are recruited, leading to group-sequential-type data analysis. Evidence for linkage that emerges as the data accumulate may guide decisions to increase marker density in interesting regions or to set targets for additional family recruitment. Because of the practicalities of family studies, however, it is unlikely that the order in which families are typed is random and early results may differ systematically as well as randomly from final ones.

Using permutation sampling of affected-sib-pair families from a genome scan of complex disease, we investigated variability associated with using a subset of the families and with changing the order of analysis of accumulating data. With genotyping data for one chromosome, we examined the LOD score profile and the maximum value of the LOD and its location, based on the semi-parametric linkage model of Kong and Cox implemented in GHplus. We tabulated the frequency of detecting LODs above a specified threshold in the final analysis, given a maxLOD above/below a specified threshold in an early analysis. The effects of group sequential sample sizes, threshold values, and underlying genetic effects were explored in a large number of permutation samples. This approach is useful to quantify the extent to which early analyses may be potentially beneficial or misleading.

Program Nr: 1360 from the 1999 ASHG Annual Meeting

Selection Strategies for Disequilibrium Mapping of Quantitative Traits in Nuclear Families. *L.R. Cardon, W.O.C. Cookson, G.R. Abecasis.* Wellcome Trust Center for Human Genetics, University of Oxford, OX3 7BN, United Kingdom.

Quantitative traits provide effective descriptions of conditions as varied as allergy, obesity and reading ability. These phenotypes involve the interaction of a number of environmental and genetic factors, the identification of which is a major challenge for current mapping efforts. Allele sharing methods of linkage analysis allow the mapping of genetic factors to broad chromosomal resolutions. It is well established that the low power of these methods can be greatly improved by the use of selected samples, but the resolution of linkage analysis is limited by the number of recombination events in typical pedigrees.

Linkage disequilibrium extends for short distances across the genome and is a powerful fine-mapping tool. Family based methods of linkage disequilibrium mapping can distinguish association due to linkage disequilibrium from confounding effects due to population sub-structure. However, the power of these tests to detect effects that are in loose disequilibrium with the etiological mutation is low. It is likely that the efficiency of these methods will also improve if the most informative families are selected for analysis. We examined the performance of different sib-pair selection strategies, including single selection as well as concordant, discordant and extreme sib-pair strategies, and the effect of the marker and trait allele frequencies, the phase in which they are associated, and the amount of disequilibrium. Our results show that selection of extremely discordant sib-pairs is most powerful, although it is typically impractical. Selection of sib-pairs where at least one offspring has a very extreme phenotype can be an effective and practical alternative, and is more powerful than selecting extreme concordant sib-pairs. The different selection strategies favor different trait allele frequencies, and we show that this is an important consideration in marker choice.

Program Nr: 1361 from the 1999 ASHG Annual Meeting

Linkage analysis for a common multifactorial disease, the non syndromic familial orofacial cleft. *P. Carinci[1], L. Scapoli[2], M. Martinelli[2], F. Pezzetti[2], F. Carinci[3], S. Granini[2], I. Marchesini[2], M. Tognon[2].* 1) Dept Histology & Embryology, Univ Bologna, Bologna, Italy; 2) Dept Morfology & Embriology, Univ. Ferrara, Italy; 3) Chair of Maxillo-Facial Surgery, Univ Ferrara, Italy.

Nonsyndromic orofacial cleft is a common congenital anomaly, it represents an example of complex genetic trait in which clinical and genetic heterogeneity is observed. Although environmental influences on facial development have been described, a strong genetic component has been well established. The nature of the genetic contribution remains to be clarified, however an oligogenic mode of inheritance seems to be plausible. Several chromosome regions and candidate genes have been investigated for this malformation providing evidences of the involvement of at least three loci: OFC1 on 6p23, OFC2 on 2p13 and OFC3 on 19q13.2. In recent years, linkage analysis was greatly enhanced by the use of dense human genetic maps consisting of highly polymorphic microsatellite markers. At the same time, several statistic methods were developed to test the linkage hypothesis where complex diseases are concerned. We used this approach to investigate the OFC. For our OFC investigation, 45 families from Veneto region were enrolled. DNA was typed by PCR followed by electrophoretic analysis. Since the OFC malformation was found associated with chromosomal abnormalities involving the 6p23, this region is one of the most investigated for mapping study. We selected 8 microsatellite markers to test the presence of linkage in our family set. Locus heterogeneity for approx. 60% of families linked to D6S259 was observed1. A similar approach was applied for the 2p13 chromosome region study. Genetic heterogeneity was confirmed and evidence of linkage was obtained in previously identified 6p23-linked-families2. In a further investigation we studied the 19q13.2 region, by using the Lod score method. However both APM and TDT, model-free and non-parametric method respectively, support the hypothesis of an involvement of the BCL3 oncogene, which maps in 19q13.2, in causing the OFC3. 1Scapoli L. et al. 1997 Genomics 43:216-220. 2Pezzetti F, et al. 1998 Genomics 50:299-305. 3Martinelli M, et al. 1998 Genomics 51:177-181.

Program Nr: 1362 from the 1999 ASHG Annual Meeting

Genetics variation in two paraoxonase genes (PON1 and PON2) and risk of coronary heart disease in Hispanics and non-Hispanic Whites. *Q. Chen[1], J. Markey[1], R.F. Hamman[2], M.I. Kamboh[1]*. 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Preventive Medicine and Biometrics, University of Colorado, Denver, CO.

Serum paraoxonase (PON) is an HDL-associated enzyme which is believed to inhibit LDL oxidation and this may provide protection against the risk of coronary heart disease (CHD). Three PON-like genes, designated PON1, PON2 and PON3 have been identified and mapped to chromosome 7q21-q22. Two common polymorphisms in the PON1 (Gln192Arg) and PON2 (Ser311Cys) genes have been found to be associated with the risk of CHD in several Caucasian or Caucasian-derived populations. In this study we have examined the association of these two polymorphisms with the risk of CHD in two nested case-control cohorts of Hispanics (cases=82; controls=416) and non-Hispanic Whites (cases=93; controls=598). Among controls, the frequency of the Arg192 allele was significantly higher in Hispanics than non-Hispanic Whites (42.9% vs. 27.6%; $p<0.0001$), but the frequency of the Ser311 allele was comparable between the two groups (20.6% vs. 23.4%; $p=0.13$). In both groups, the genotype and allele frequencies of the two polymorphisms were not significantly different between cases and controls. Stratification of the PON1 data by PON2 Ser311/Ser311 genotype, however, showed a significant difference in the PON1/Arg192 allele frequency between cases and controls (29.2% vs. 41.7%; $p=0.015$) in Hispanics. Similarly, stratification of the PON2 data by PON1 Gln192/Gln192 carries showed a significantly higher frequency of the PON2/Cys311 allele in controls than cases (19.3% vs. 10.0%; $p=0.041$) in Hispanics, but not in non-Hispanic Whites. These inconsistent findings indicate that additional studies are needed to detect new mutations in the three PON gene cluster to identify functional mutations with regard to the risk of CHD.

Program Nr: 1363 from the 1999 ASHG Annual Meeting

A Single Nucleotide Polymorphism Map of a Bipolar Disorder Candidate Region on Chromosome 18q21.3-22.1.
Y.S. Chen, D.V. Leontiev, F.J. McMahon. Department of Psychiatry, University of Chicago, Chicago, IL.

A susceptibility gene for bipolar affective disorder may reside on chromosome 18q21-22. Based on multipoint linkage results using a dense set of microsatellite markers, we have selected a 24 cM region as a starting point for linkage disequilibrium mapping of this gene using single nucleotide polymorphisms (SNPs). In this region, we selected 114 sequence tagged sites (STSs), mostly gene-based, for SNP screening. Each STS is PCR amplified from a panel of 12 unrelated subjects (3 probands from 18q-linked families and 9 controls), the PCR product is purified, concentrated, and the forward strand is sequenced on an ABI 377 sequencer. Pherograms are then compared visually for candidate SNPs, based on the presence of 2 peaks at a single nucleotide position. To date, we have screened 15 STSs, representing ~22 kb of total sequence. We have detected 14 candidate SNPs and 2 small insertion/deletion polymorphisms (IDPs). Two SNPs were disconfirmed by reverse-strand sequencing, thus SNPs or IDPs occur at the rate of ~1/1500 bp in this region of the genome. The sequences from 3 STSs showed both homozygotes. About 1/3 of STSs contained more than one SNP, usually in complete linkage disequilibrium, but one STS contained 2 SNPs 36 bp apart that defined 4 different haplotypes. Automated resequencing of STSs is an efficient means for detecting sequence diversity for use in mapping complex traits.

Program Nr: 1364 from the 1999 ASHG Annual Meeting

Molecular study of X-chromosome mosaicism in Turner syndrome patients using the DNAs extracted from archived cytogenetic slides. *E.H. Cho[1], S.Y. Park[1], J.W. Kim[1], H.K. Ahn[2], J.Y. Jun[2], S.K. Choi[1]*. 1) Genetic Research Laboratory, Samsung Cheil Hospital, Seoul, Korea; 2) Obstetrics and Gynecology, Samsung Cheil Hospital, Seoul, Korea.

To study the X chromosome mosaicism in the cytogenetically pure 45,X Turner syndrome patients, we used the PCR technique with the DNAs extracted from archived cytogenetic slides. We amplified the DNAs using nested primers targeted to a highly polymorphic short tamdem repeat(STR) of the human androgen receptor gene (HUMARA) for the detection of X chromosome mosaicism. This assay is a very sensitive and useful method which can be applied to the DNAs extracted from archived cytogenetic slides to detect X mosaicism. We tested 50 normal Korean females to determine whether the HUMARA locus is highly polymorphic among the Korean. 85% of Korean population showed heterozygosity in the HUMARA locus. We analysed the 24 DNAs extracted from archived slides of patients and abortuses with Turner syndrome in cytogenetic analysis. We observed the heterozygosities of 50% from pure 45,X patients, 83% from patients with mosaic Tuner syndrome and 8.3% from abortuses of pure 45,X. Using the PCR technique of the HUMARA locus in the archived cytogenetic slides, we detected X chromosome mosaicism which could not be detected in cytogenetic analysis.

Program Nr: 1365 from the 1999 ASHG Annual Meeting

Systematic search for susceptibility genes in bipolar affective disorder - evidence for a disease locus at 10q26. *S. Cichon[1], G. Schmidt-Wolf[1,2], M. Pützstück[1], S. Hemmer[1], M. Albus[3], M. Borrmann[3], B. Lerer[4], E. Franzek[5], D. Lichtermann[5], B. Weigelt[5], C. Windemuth[2], T. Wienker[2], W. Maier[5], M. Rietschel[5], P. Propping[1], M.M. Nöthen[1]*. 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Institute of Medical Statistics, University of Bonn; 3) Mental State Hospital Haar; 4) Hadassah University Hospital, Jerusalem, Israel; 5) Departments of Psychiatry, Universities of Würzburg, Bonn, and Dresden.

A potential susceptibility locus for bipolar affective disorder on chromosome 10q has recently been suggested. As part of a systematic genome scan for bipolar susceptibility genes, we genotyped 19 evenly spaced microsatellite markers covering whole chromosome 10 in a sample of 75 families (66 families from Germany, one family from Italy, 8 families from Israel) comprising 429 individuals. Parametric two-point linkage analysis was performed employing a dominant and a recessive genetic model. Two models of affection were used: affection status model (ASM)-I included only individuals with bipolar I (BPI) phenotype as affected, all other psychiatric diagnoses were coded as "unknown"; ASM II included all individuals with a diagnosis of BPI, bipolar II (BPII), schizoaffective disorder, bipolar type (SA/BP), and unipolar, recurrent (UPR). Using a dominant model and ASM II, D10S217 produced a LOD score of 2.86 at theta=0.05. With the neighbouring marker D10S587, a maximum LOD score of 1.48 at theta=0.15 was obtained. In a second step, we genotyped 14 additional markers spanning a 30 cM region containing D10S217 and D10S587. The best two-point LOD scores were found for D10S1757 (2.12 at theta=0.1), D10S216 (1.29 at theta=0.15), and D10S1727 (1.66 at theta=0.1). Non-parametric multipoint analysis using the GENEHUNTER program gave a maximum Z-all score of 3.2 (p=0.00098) at D10S216.

Program Nr: 1366 from the 1999 ASHG Annual Meeting

Meta-analysis of asthma and atopy. *A.R. Collins.* Dept Human Genetics, Univ Southampton, Southampton, England.

A central problem in complex inheritance is to map oligogenes for disease susceptibility prior to sequencing. Even large studies may have low power to map genes of small effect by linkage and association and confirmatory samples are always required. Combination of evidence, broadly called meta-analysis, offers a way forward. The simplest form of analysis uses published material and is useful for summarising evidence and delimiting candidate regions prior to follow-up studies. To apply meta-analysis to asthma and atopy 156 publications detailing linkage and association at 518 loci have been reviewed. Evidence from a marker may be summarised by a nominal significance level P and transformed to a corresponding lod (Z). Problems with published summaries are that P values may not have been corrected for multiple tests and many statistics have a minimum corresponding to Z=0. Nevertheless analysis of this material gives further insight into the importance and limits of the main candidate regions and their relationship to candidate genes. Important chromosomes include 6 with the HLA region being particularly significant. The HLA-DRB1 gene has 33 reports with atopy and also 5 reports with asthma for which the total lod is greater than 5. For chromosome 5 IL4 is associated primarily with atopy (Z=14) and ADRB2 with asthma (Z=9), suggesting different specificities. Other important chromosomes are 16,11,12,13 and 14. Retrospective collaboration, through the analysis of data already published individually offers the possibility of more rigorous analysis of these candidate regions. Such an analysis is being piloted for chromosome 5.

Program Nr: 1367 from the 1999 ASHG Annual Meeting

A quantitative trait locus influencing variation in ACTH precursor levels maps to chromosome 13 in Mexican Americans. *A.G. Comuzzie[1], A. White[2], L. Almasy[1], J.E. Hixson[1], J.W. MacCluer[1], J. Blangero[1]*. 1) Dept Genetics, Southwest Fdn Biomed Res, San Antonio, TX; 2) Schools of Biological Sciences and Medicine University of Manchester, Manchester, U.K.

Adrenocorticotropic hormone (ACTH) which stimulates the synthesis and secretion of adrenal steroids (e.g., cortisol, adrenal androgens, and mineralocorticoids)is synthesized as part of 2 precursors, POMC and pro-ACTH which are found in the circulation. In an attempt to identify genes involved in the regulation of this very important pro-hormone we have conducted a genome scan on serum levels of ACTH precursors in members of the San Antonio Family Heart Study. This analysis used 432 individuals distributed over 10 families, all of which were genotyped for 330 markers producing an average map density of 15cM. Linkage analysis was conducted using a variance component approach implemented in the program package SOLAR. Quantitative genetic analysis of ACTH precursors detected an additive genetic heritability of 51%. The maximum LOD score detected in the multipoint linkage scan was 2.62 ($p = 0.0003$) near *D13S788* on chromosome 13. Only one other region on chromosome 19 reached a suggestive level of significance (LOD = 2.0 between *D9S889* and *D9S254*). The 95% confidence interval for the chromosome 13 QTL overlaps the region containing the serotonin receptor 2A gene (*HTR2A*) which is a strong positional candidate gene for the regulation of POMC expression given the observed effects of serotonergic compounds on ACTH secretion in mammals. This work was supported by NIH grants HL45522, and MH59490.

Program Nr: 1368 from the 1999 ASHG Annual Meeting

A possible role for the interleukin-1 genes in early onset psoriatic arthritis. *A. Cox[1], N.J. Camp[2], M. Dale[1], F.S. di Giovine[1], L. Kay[3], D.J. Walker[3], G.W. Duff[1]*. 1) Div Molecular & Genet Medicine, Univ Sheffield, Sheffield, UK; 2) Genetic Research, IHC, Salt Lake City, Utah; 3) Freeman Hospital, Newcastle, UK.

Psoriatic arthritis is a complex, heterogeneous disorder with a genetic component to its etiology. The class I region of the major histocompatibility complex (MHC), in particular HLA-Cw6, is strongly associated with both psoriasis and psoriatic arthritis, but other genetic determinants have yet to be identified. Both the skin and joint manifestations of psoriatic arthritis are characterised by leukocyte infiltration and chronic inflammation. Therefore we have considered the genes of the interleukin-1 (IL-1) cluster as candidates, since IL-1 is one of the central mediators of these processes. The genes for IL-1 alpha, IL-1 beta, and the IL-1 receptor antagonist are clustered within 430kb on the long arm of chromosome 2. We investigated the relationship between IL-1 genotype and age at onset of psoriasis in psoriatic arthritis, since previous work had indicated that distinct IL-1 alleles may be associated with different age of onset groups in psoriasis itself. A cohort of 187 caucasian psoriatic arthritis patients and 840 healthy controls from the UK were genotyped for 4 biallelic markers in the IL-1 gene cluster. Two markers were associated with psoriatic arthritis in the overall dataset; IL-1B+3954 (p=0.004), and IL1RN+2018 (p=0.02). Comparison of the odds ratios of these two markers individually with the odds ratio for a composite genotype indicated that the IL1B+3954 was probably the primary association and that the IL1RN+2018 association was due to linkage disequilibrium. The other 2 markers investigated were not associated with the disease. The IL1B+3954 association was present only in the early onset cases, (age at onset <45 years), and stratification analysis indicated that it was primarily in the Cw6 negative patients (odds ratio (95%CI) = 1.9(1.2,3.0), n=103, vs. 1.2 (0.7,2.3), n=78). Thus, IL-1 may be implicated in early onset psoriatic arthritis, confirming previous results in caucasian psoriasis patients. A family-based replication study is in progress to confirm this result.

Program Nr: 1369 from the 1999 ASHG Annual Meeting

Genetic linkage of the Muckle-Wells syndrome to chromosome 1q44. *L. Cuisset[1], JPH. Drenth[2], JM. Berthelot[3], A. Meyrier[3], G. Vaudour[3], RA. Watts[4], DGI. Scott[4], A. Nichols[4], S. Pavek[5], C. Vasseur[1], JS. Beckman[5], M. Delpech[1], G. Grateau[1]*. 1) Genetique Moleculaire Humaine, EA2500, Inst. Cochin Genet Moleculaire et Service de Medecine Interne de l'Hotel-Dieu, Paris, France; 2) Department of Medicine, Division of General Internal Medicine, University Hospital St. Radboud, Nijmegen, The Netherlands; 3) Service de rhumatologie, L'Hotel-Dieu, Nantes,Service de nephrologie, Hopital Broussais, Paris, Service de pediatrie, Centre hospitalier general, Saint-Quentin, France; 4) Dept of Rheumatology, Ipswich Hospital, Dept of Rheumatology, West suffolk Hospital, United Kingdom; 5) Genethon, Evry, France.

The Muckle-Wells syndrome (MWS) is a hereditary inflammatory disorder characterized by acute febrile inflammatory episodes comprising abdominal pain, arthrisis and urticaria. Subsequent progressive nerve deafness develops and after several years the disease is complicated by multiorgan AA type amyloidosis (MIM 191900) with renal involvement and end-stage renal failure. The mode of inheritance is autosomal dominant, but some sporadic cases have also been described. No specific laboratory findings have been reported. The genetic basis of MWS is unknown. Using a genome wide search strategy in three families, we identified the locus responsible for MWS at chromosome 1q44. Our results indicate that the gene is located within a 13.9-cM region between the markers D1S2811 and D1S2882 with a maximum two-point LOD score of 4.66 (q= .00) at D1S2836 assuming full penetrance. Further identification of the specific gene responsible for MWS therefore provides the first biological element for characterizing MWS otherwise than on its variable clinical expression.

Program Nr: 1370 from the 1999 ASHG Annual Meeting

Linkage Analysis of Keloids. *K.D. Davis, S.M. Williams.* Microbiology, Meharry Medical College, Nasville, TN.

Keloids are benign, fibrous growths caused by abnormal wound healing that occur predominantly in darker pigmented races. The precise molecular and biochemical dysfunctions that lead to keloid formation remain unknown; however, there appears to be a strong genetic predisposition to keloid formation. We have undertaken a linkage analysis study to identify the chromosomal location of the predisposing gene(s) for the purpose of ultimately cloning and characterizing the genetic lesion. Markers linked to candidate loci were screened in two African-American families, of which nine out of twenty-three members are keloid formers. Based on the biochemical and molecular mechanisms involved in keloid formation, an array of candidates have been analyzed and excluded. These candidates include: alpha-1 type vii collagen, alpha-1 type II collagen, collagen x, alpha-1 collagen type xix, angiotensinogen, c-fos serum response factor, natural killer cell stimulatory factor, insulin-like growth factor, transforming growth factor beta, transforming growth factor beta 3, transforming growth factor beta type II receptor, epidermal growth factor receptor, interleukin 5 alpha receptor, interleukin-11 receptor alpha chain, interleukin 1 receptor antagonist, and the intracellular hyaluronic acid binding protein. A genome-wide search is currently underway. Approximately 620 cMs of 3490 cMs on the Genebridge 4 radiation hybrid map of autosomal chromosomes have been excluded. The genome-wide search will continue in an attempt to uncover a chromosomal location of the predisposing gene(s) responsible for keloid formation.

Program Nr: 1371 from the 1999 ASHG Annual Meeting

A score for MCMC genome screening. *E.W. Daw, E.A. Thompson, E.M. Wijsman.* Univ Washington, Seattle, WA.

Monte Carlo Markov chain (MCMC) techniques have shown promise in dissecting complex genetic traits. The methods introduced by Heath (AJHG 1997) and implemented in the program Loki have been able to localize genes for complex traits in both real and simulated data sets. Loki iteratively places quantitative trait loci (QTL) on chromosomes. The hit rate in each region estimates the posterior probability of linkage. We count hits not only by location, but also by QTL effect size, allowing estimation of the relative contribution of each QTL. Unfortunately, assessment of the significance of results has been difficult. Here, we introduce a score, the simulated log odds of placement (slop), for assessing oligogenic QTL detection and localization.

The slop compares hits on real chromosomes to hits on pseudo chromosomes unlinked to the trait. The pseudo chromosomes, generated by random gene drop, match the real ones for the map, allele frequencies, and missing data patterns in the observed pedigree structures. Both real and pseudo chromosomes are analyzed simultaneously with Loki. On a 2-dimensional grid of location and QTL effect:

slop = $\log_{10}$(max(0,(hits on real chr.-1))/(hits on pseudo chr.+1)).

The slop is similar to the lod score in being a log odds ratio, but differs in many other respects. For example, while lod scores are calculated under a single trait model, the slop is calculated with Monte Carlo integration over a large number of model parameters, including the number of trait loci and the relative additive/dominance effects at each locus. In analyses of real Alzheimer's Disease (AD) and simulated data, known genes produce slop scores over 3, but no pseudo chromosomes produce a slop this large. We use the real AD and simulated data to investigate the distributional properties of the slop in the presence and absence of trait genes, and to determine more precise significance thresholds.

Support: NIH grants GM 46255 and AG 05136.

Program Nr: 1372 from the 1999 ASHG Annual Meeting

Genome-wide scan for quantitative trait loci influencing HDL3 level in the Framingham Heart Study. *A.L. DeStefano[1,2], L.A. Cupples[2], M.D. Harmon[1], J.D. Keen[3], D. Housman[3], P.W.F. Wilson[1], R.H. Myers[1]*. 1) Boston University School of Medicine, Boston, MA; 2) Boston University School of Public Health, Boston, MA; 3) Massachusetts Institute of Technology, Cambridge, MA.

High density lipoprotein (HDL) cholesterol is recognized as a protective factor for coronary heart disease. Therefore, identification of genes that influence HDL level may be important in understanding the biochemical pathway of lipid metabolism, for assessing an individual's risk for CHD, and for targeting coronary prevention. HDL is composed of several subfractions, which may be under the control of separate genes. Examination of an individual subfraction may reduce the genetic complexity as well as the environmental noise present when considering total HDL level. In this study we focus on the identification of quantitative trait loci contributing to HDL3 level in the Framingham Cohort. HDL3 level was determined by double precipitation methods for Framingham Offspring blood samples obtained in 1987-91 and 1991-95. For genetic analysis, regression methods were used to adjust mean HDL3 level for physical activity index, alcohol and cigarette use, gender, age, estrogen use and menopausal status. A genome-wide scan (average distance 10cM) was conducted by the Mammalian Genotyping Service (Marshfield Medical Research Foundation) in 237 families (1167 genotyped individuals). Twopoint and multipoint LOD scores were computed using the variance component methods implemented in SOLAR for residual HDL3. Heritability was estimated to be .59. The maximum two-point LOD scores were 2.1 on chromosome 1, 2.0 on chromosome 7 and 1.9 on chromosome 10. Multipoint analysis resulted in a maximum observed LOD score of 1.9 on chromosome 7.

Program Nr: 1373 from the 1999 ASHG Annual Meeting

A genome scan for creatinine clearance among hypertensive siblings: The HyperGEN Network of the NHLBI Family Blood Pressure Program. *A.T. DeWan[1], J. Eckfeldt[1], D.C. Rao[2], S. Hunt[3], C.E. Lewis[4], S. Rich[5], D.K. Arnett[1].* 1) University of Minnesota, Minneapolis, MN; 2) Washington University, St. Louis, MO; 3) University of Utah Medical School, Salt Lake City, UT; 4) University of Alabama, Birmingham, AL; 5) Wake Forest University School of Medicine, Winston-Salem, NC.

Decreased renal function is often a complication of hypertension. Creatinine clearance measurements estimate the glomerular filtration rate, an indicator of renal function. While it is suggested that renal function has an underlying genetic component, there is limited information suggesting influential genetic regions or candidate genes contributing to the variability in creatinine clearance. As part of the HyperGEN study (a multicenter study to investigate the genetics of hypertension) we assessed creatinine clearance measurements in a large bi-racial sample of hypertensive sibs (n=171 African American (AA) and 270 white sibpairs). All participants were hypertensive prior to the age of 60, and the mean age of the siblings was 52 in AA and 60 in whites. To reduce the variability from non-genetic sources of variance in creatinine clearance, values were regressed on age, weight, pulse pressure, age at hypertension diagnosis, insulin replacement, educational status and physical activity in AA and age, lean body mass and pulse in whites. Standardized residuals were calculated separately for men and women in both racial groups. We conducted multipoint Haseman-Elston linkage analysis using MAPMAKER/SIBS with 387 anonymous markers (CHLC8 marker set). Our best evidence for linkage to creatinine clearance was on chromosome 3 at 166.3 cM (LOD = 2.38) and chromosome 15 at 38.3 cM (LOD = 2.03) in African-Americans and on chromosome 1 at 158.2 cM (LOD = 2.05) in Whites. There were also LOD scores greater than 1.0 on chromosomes 2, 7 and a second peak on chromosome 3 in African-Americans and on chromosomes 3, 6, and 10 in Whites. These data suggest there may be influential genetic regions contributing to renal function, and that these regions may differ by race.

Program Nr: 1374 from the 1999 ASHG Annual Meeting

Identifying marker genotyping errors and mutations in sibling-pair linkage data. *J.A. Douglas[1], M. Boehnke[1], K. Lange[2]*. 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Biomathematics, Univ California, Los Angeles, CA.

The widespread use of sibling-pair data for the investigation of complex diseases and quantitative traits, coupled with the availability of high-resolution genetic maps, demands appropriate methodology for the detection of marker genotyping errors and mutations. Previous methods have relied upon apparent Mendelian incompatibilities or close double recombinants in order to flag potential errors and mutations. Both, however, require genotype data from additional family members beyond the sibling pair to infer gene flow or to construct linkage phase. In many studies, especially those of late-onset complex traits where parental DNA is often unavailable, data restrict analyses to sibling pairs only.

Recently, we described a method for identifying siblings and markers with relatively unlikely genotypes based on a hidden Markov model in the context of multipoint mapping (Douglas et al. 1998). Assuming a map of tightly linked markers, we calculated the posterior probability of genotyping error at each marker for each sibling pair, conditional on all marker data for the pair and a prior error rate. We have now developed the FORTRAN 77 program SIB-MED to perform these analyses on a sample of sibling pairs. In addition, we have incorporated Monte Carlo simulation to assess the significance of each posterior error probability calculated from our sample. Genotypes characterized by unusually high posterior error probabilities may be considered for exclusion, review, or retyping.

We have examined the impact of genotyping errors and our method of error detection on both real and simulated linkage data. We illustrate that even moderate error rates of 1-2% can result in the loss of as much as 50% of linkage information, given efforts to fine map a putative disease locus. Though simulations suggest that our method generally detects only 20-50% of genotyping errors, depending on map density, marker position, and marker allele frequencies, it appears to flag exactly those errors that have the largest impact on linkage results. In many cases, removal of identified errors by our method restores most, if not all, of lost linkage information.

Program Nr: 1375 from the 1999 ASHG Annual Meeting

Multipoint linkage analysis of the pseudo-autosomal region using affected sibling pairs. *J. Dupuis[1], P. Van Eerdewegh[1,2].* 1) Genome Therapeutics Corporation, Waltham, MA; 2) Department of Psychiatry, Harvard Medical School, Boston, MA.

Methods for multipoint linkage analysis based on sibling amount of sharing identical-by-descent (IBD) are widely available, both for autosomal and X-linked markers. However, with this approach, data from the pseudo-autosomal region pose special challenges since same gender sibling pairs will share more material IBD in that region of the genome, with and without the presence of a disease-susceptibility gene. This increased sharing will be more pronounced for markers closely linked to the sex-specific region. Conversely, opposite-gender sibling pairs will share less material IBD. Failure to take this inequality in sharing into account may result in a false declaration of linkage if the study sample contains an excess of same-gender pairs due, for example, to gender specific prevalences. A linkage may also be missed when an excess of opposite-gender pairs is present. We propose a maximum LOD score method to take into account this expected increase/decrease in sharing when analyzing markers in the pseudo-autosomal region. We illustrate the new method with a simulation study on 500 sibling pairs using marker DXYS154 with published allele frequencies (10 alleles). Setting the probability of sampling a gender concordant pair at 68%, which would be achieved if one gender was 4 times more likely to be affected than the other gender, the uncorrected LOD score under H_0 (no linkage) ranges from 0 to 8, with 56 out of 100 replicates yielding LOD scores greater than 3. On the other hand, the corrected maximum LOD score did not produce any false positive results in 100 replicates. Even without gender distortion, the corrected LOD score improves power. The probability of exceeding a LOD score of 3 went from 28% to 55% in the case of a recurrence risk to offspring, l_O, of 1.5, and from 81% to 98% for l_O=2.0, by using the corrected LOD scores. For quantitative traits, we demonstrate with the Haseman and Elston method the same inflation in type-I error in the absence of an appropriate correction, and the inadequacy of permutation tests to estimate levels of significance when all phenotypic values are permuted irrespective of gender.

Program Nr: 1376 from the 1999 ASHG Annual Meeting

Screening of the SCA8 expansion. *A. Durr[1], G. Stevanin[1], A. Herman[1], A-S. Lebre[1], M. Frontali[2], A. Brice[1]*. 1) INSERM U289, Hopital de la Salpetriere, Paris, France; 2) Istituto di Medicina Sperimentale del CNR, Rome, Italy.

Inherited ataxias are widely represented among the group of neurodegenerative diseases caused by trinucleotide expansions. Recently, an untranscribed CTA/CTG repeat expansion in the spinocerebellar ataxia 8 (SCA8) gene was reported in patients with autosomal or recessive cerebellar ataxia but not in controls (Koob et al, 1999). We screened 352 chromosomes from French controls and 241 index patients of European origin, including 145 presenting with a non SCA1-7 autosomal dominant cerebellar ataxia (ADCA), 24 with recessive ataxia and 72 with sporadic ataxia. Repeat expansions above the threshold of 92 repeats (from 92 to 122) were found in 8 ADCA (5%) and 1 sporadic (1%) cases. The SCA8 expansion segregated in a small ADCA kindred but not in another. Alleles with 104 and 123 CTA/CTGs were also detected, however, in 2 healthy controls (1%), age over 57, with no known family history of neurological disorders. Two patients with Lafora's disease and essential tremor carried also expansions. Intermediate sized alleles (IA) ranging from 68 to 89 CTA/CTG repeats were detected in 2 patients with ADCA as well as in several patients from a single SCA3/MJD family. These IA did not segregate with the disease in the corresponding families and did not influence the phenotype of the SCA3/MJD patients. The expanded and intermediate sized alleles were moderately unstable during transmissions with changes ranging from -5 to +1 CTG repeats. In conclusion, the SCA8 expansion was found in ADCA and sporadic ataxic patients as well as in controls and patients with other neurological disorders from Europe. These results combined with the absence of cosegregation in a family with ADCA highly suggest that SCA8 expansions represent rare alleles that are not directly responsible for the disease.

Program Nr: 1377 from the 1999 ASHG Annual Meeting

Sampling strategies for the discovery of single nucleotide polymorphisms. *M.A. Eberle, L. Kruglyak.* Department of Molecular Medicine, Fred Hutchinson Cancer Research Center, Seattle, WA.

Discovery and mapping of single nucleotide polymorphisms (SNPs) is a major and rapidly growing enterprise in human genetics. A key issue when searching for new SNPs is what sampling strategies will be most effective in SNP discovery. In addition, it is important to understand how the frequency of SNPs restricted to a single sub-population (private) compares to those shared across multiple populations (public). We have formulated a model using the coalescent process that allows us to simulate various population histories in order to examine SNP frequencies within and across different populations. We will show results from models of populations with varying histories and degree of isolation and examine optimal sampling strategies for these models.

Program Nr: 1378 from the 1999 ASHG Annual Meeting

Genome-wide scan for schizophrenia in the Finnish population: Evidence for a locus on chromosome 7q22. *J. Ekelund[1,2], D. Lichtermann[1,2], I. Hovatta[1,2], P. Ellonen[1], J. Suvisaari[2], J.D. Terwilliger[3], H. Juvonen[2], T. Varilo[1], R. Arajärvi[2], M-L. Kokko-Sahin[2], J. Lönnqvist[2], L. Peltonen[1]*. 1) Dept. of Human Molecular Genetics and; 2) Dept. of Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland; 3) Dept. of Psychiatry and Columbia Genome Center, Columbia Univ., NY, USA.

We have carried out a genome-wide scan in a schizophrenia study sample of 134 affected sib-pairs collected from the isolated population of Finland. We genotyped 370 polymorphic markers, followed by fine mapping of the two most promising regions, one on chromosome 1 and another on chromosome 7. The most significant finding was a two-point lod score of 3.18 with marker D7S486 using a dominant model and treating all individuals with any schizophrenia spectrum disorder as affected. Multipoint analysis with MAPMAKER/SIBS resulted in a MLS of 3.53 between markers D7S501 and D7S523 using the broadest diagnostic model, including MDD and Bipolar type I as affecteds in addition to the aforementioned phenotypes. Slightly higher lod scores for this region were obtained when only individuals from the late settlement region of Finland populated in the 16th century were included in the analysis. Some support was also obtained for linkage to chromosome 1q32.2-q41, a region previously identified in a genome-wide scan of a study sample from a regional sub-isolate of Finland. To increase the statistical power we also genotyped a study sample consisting of families with three or more schizophrenic children. In total 415 individuals in 89 families were analyzed. We obtained a maximal two-point lod score of 1.95 for marker D7S657, i.e. about 20 cM proximal to the maximal lod score in the sib-pair material. When pooling this data to that obtained in the analyses of the sib-pair material, the lod score increased for the more proximal markers while decreasing for the more distal markers. For the multipoint analysis, the marker order was confirmed by radiation hybrid mapping. No significant association was found for any of the markers, and therefore an even tighter marker map might be required to finemap the putative locus on chromosome 7.

Program Nr: 1379 from the 1999 ASHG Annual Meeting

Phenotypic variation at the chromosome 12 CFEOM1 locus. *E.C. Engle[1], B.A. Lee[1], C. Sener[2], B. Turgut[2], A.N. Akarsu[2], A.R. Khamis[3], A. Mousawi[3], E.I. Traboulsi[4]*. 1) Children's Hosp, Boston, MA; 2) Hacettepe University, Ankara, Turkey; 3) Al-Jazeirah Hospital, Abu-Dhabi, UAE; 4) Cleveland Clinic, Cleveland, OH.

The syndromes known as 'congenital fibroses of the extraocular muscles' (CFEOM) are ocular-motility disorders manifested as restrictive ophthalmoplegias with ptosis. Although these syndromes are thought to arise from dysfunction of the oculomotor nerve, their molecular etiology is unknown. Inherited forms of CFEOM have been described, and three genetic loci (CFEOM1-3) identified. CFEOM1, or 'classic' CFEOM, is AD with full penetrance, maps to 12cen, and affected individuals have bilateral infraduction and ptosis. CFEOM2 is AR, maps to 11q13, and affected individuals have bilateral exotropia and ptosis. CFEOM3 is AD, maps to 16qter, and is variably expressed -- some individual's eyes are down and out with ptosis, while others have only mild deficits in vertical gaze. Prior to this report, it was felt that each of these syndromes could be distinguished based on a family's clinical presentation alone.

We now report two different families that reveal phenotypic overlap between these syndromes. The first is an AD family with a partially penetrant and clinically distinct phenotype that most closely resembles CFEOM3, but maps to the CFEOM1 locus with a maximum lod score of 10.8 at D12S85. The second is an AR family not linked to the CFEOM2 locus, for whom a lod score of 2.0 (the maximum possible, given the family size and structure) is obtained at the CFEOM1 locus with reduction to homozygosity in the two affected children. Interestingly, this suggests that there are both AD and AR forms of CFEOM1.

These data establish that there is greater phenotypic heterogeneity at the CFEOM1 locus than previously reported, and blur our ability to distinguish the different CFEOM loci based solely on clinical presentation. Identifying the CFEOM1 gene mutations in these two families as well as in classic families should provide insight into the genetic mechanisms underlying CFEOM, and should be valuable to our understanding of the role these genes play in the normal and abnormal development of the oculomotor system.

Program Nr: 1380 from the 1999 ASHG Annual Meeting

Improved Identification of Most Probable Relationships in Relative Pairs. *M.P. Epstein, W.L. Duren, M. Boehnke.* Department of Biostatistics, University of Michigan, Ann Arbor.

Linkage analysis of a genetic trait can be compromised if the relationship of a pair of individuals is misclassified. Misclassification due to non-paternity, sample switches, or unknown adoption can lead to loss of power to detect linkage, either due to exclusion of families owing to apparent non-Mendelian inheritance, or to inclusion of pairs of individuals less closely related than assumed in the analysis. Sample duplications and misclassification of MZ twins as full sibs can lead to an increase in false-positive linkage results.

Boehnke and Cox (1997) introduced a likelihood ratio method to determine the most probable relationship in pairs of individuals. Multipoint probabilities of a pair's marker data are calculated assuming particular relationships given population marker allele frequencies and intermarker distances. Likelihood ratios comparing each potential relationship to the most likely relationship are calculated, and the strength of support for the most likely relationship determined. This method was implemented in a FORTRAN 77 program called RELPAIR. In data from simulated 20-cM genome scans of markers with four equifrequent alleles, this method correctly identified the true relationship with frequency 0.9994 for full sibs, 0.9980 for half sibs, and 0.9992 for unrelated pairs.

We have extended the work of Boehnke and Cox (1997) in several directions. The original method assumed autosomal marker data with no genotyping error, and only tested whether pairs of putative sibs were full sibs, half sibs, MZ twins, or unrelated. We now assess all possible pairs of individuals within a sample, include X-linked data in the multipoint probabilities, allow explicitly for the possibility of random genotyping error, and test for parent/offspring relationships. Extension to other relationships is planned. Using simulated data, we will present the classification rate estimates of true parent/offspring pairs and assess the impact of genotyping error and inclusion of X-linked data on relationship inference. The extensions will soon be included in the RELPAIR program available at www.sph.umich.edu/group/statgen.

Program Nr: 1381 from the 1999 ASHG Annual Meeting

MALDI-TOF mass spectrometry for high throughput SNP detection: Application to type 2 diabetes. *M.R. Erdos[1], A. Braun[2], K. Mohlke[1], K. Silander[1], S. Ghosh[1], F.S. Collins[1], for the FUSION (Finland-US Investigation of NIDDM) Study Group[1].* 1) NHGRI, NIH, Bethesda, MD; 2) Sequenom, Inc., San Diego, CA.

Matrix-Assisted Laser Desorption Ionization (MALDI) mass spectrometry has recently been introduced as a powerful analytical tool for the analysis of short DNA sequences by mass. Ions are generated by laser bombardment of DNA fragments embedded in a matrix of 3-hydroxypicolinic acid. These large DNA ions are accelerated through a path towards the detector measuring the time of flight (TOF) which is correlated with the mass of the DNA fragment. SNP analysis by MALDI-TOF is initiated by multiplex PCR amplification of genomic DNA, using primers flanking the SNPs of interest. A locus-specific primer which abuts the variable nucleotide of each SNP is then used in a primer oligo base extension reaction; primer extension is performed with DNA polymerase in the presence of dideoxynucleotides that terminate the reactions at a specific length determined by the allele present. The extended products are then purified and subjected to mass spectrometric analysis. In a pilot study, we have designed and successfully implemented the multiplex analysis by MALDI-TOF mass spectrometry of five genes with known polymorphisms that have been implicated in diabetes. The variants tested are SNPs in peroxisome proliferator-activated receptor gamma 2, insulin receptor substrate-1, insulin receptor substrate-2, uncoupling protein-2 and glucokinase genes. These genes are known to play a role in insulin sensitivity, insulin receptor signaling, obesity, and/or glucose metabolism, all traits which are associated with type 2 diabetes. Genotypes in the pilot study have been highly reproducible. We are currently extending this analysis to 582 probands of diabetic sib-pairs and 232 controls consisting of elderly non-diabetic Finnish subjects. Comparison of SNP allele frequencies between diabetic probands and controls should allow the identification or elimination of these candidate gene variants for association with type 2 diabetes in the Finnish population.

Program Nr: 1382 from the 1999 ASHG Annual Meeting

Screening of candidate genes for primary congenital lymphedema on 5q35.3. *A.L. Evans[1], G. Brice[1], V. Sotirova[4], P. Mortimer[2], J. Beninson[5], K. Burnand[3], J. Rosbotham[2], A. Child[1], M. Sarfarazi[4].* 1) Cardiological Sciences, St.George's Hospital , London, UK; 2) Department of Medicine, St. george's Hospital, London, UK; 3) Department of Academic Surgery, St. Thomas's Hospital, London, UK; 4) Surgical Research Center, Department of Surgery, University of Connecticut Health Center, Farmington, CT; 5) Department of Dermatology, Henry Ford Hospital, Detroit.

Primary lymphedema is a chronic tissue swelling, most frequently of the lower limbs, resulting from deficient lymphatic drainage. We have previously reported a locus for the primary congenital lymphedema (PCL), to the most telomeric portion of chromosome 5q35.3. In 5 PCL families, no recombination was observed with D5S408 (Z=10.03) and D5S2006 (Z=8.46) with a combined multipoint score of 16.55. This locus mapped below D5S2073 and WIAF-2213, but no telomeric flanking marker was identified. Recently, a second locus for lymphedema-distichiasis (lymphedema associated with a double row of eyelashes) has also been mapped to 16q24.3 (abstract submitted by Jeffery et. al.). Analysis of 20 pubertal onset lymphedema (Meige disease) families in our panel did not demonstrate any significant linkage to either of these two loci thus suggesting that at least one other locus remains to be discovered for this most common form of lymphedema. The vascular endothelial growth factor-C receptor gene (FLT4), an interesting candidate for PCL, is located within the critical interval. To date, we have found no disease-specific mutations. In addition, we have mapped five new candidate genes in to this vicinity using the GeneBridge4 radiation hybrid (RH) mapping panel and several other 5q35-specific RH clones. These genes have been completely sequenced in affected individuals but as yet, no mutations have been found. The screening of several other genes is currently in progress.

Program Nr: 1383 from the 1999 ASHG Annual Meeting

A novel craniofacial asymmetry mutation maps to mouse Chromosome 7 at the site of a random transgenic insertion. *E.T. Everett[1,2], J.K. Hartsfield,Jr.[1,3], E.M. Simpson[4].* 1) Dept Oral Facial Development, Indiana Univ Sch Dentistry, Indianapolis, IN; 2) Dept Dermatology, Indiana Univ Sch of Medicine, Indianapolis,IN; 3) Dept Medical & Molecular Genetics, Indiana Univ Sch of Medicine, Indianapolis,IN; 4) The Jackson Laboratory, Bar Harbor, ME.

A tendency toward sidedness is present in most normal human faces. Approximately 2-3 % of the general population and 34% of a dentofacial deformities population exhibit clinically apparent facial skeleton asymmetry. Facial asymmetry as part of a recognized syndrome (i.e., hemifacial microsomia) occurs in about 1 in 4000 livebirths and is second only to CL(P) as a birth defect involving craniofacial development. A recessive insertional mutation has been identified in the transgenic mouse line C57BL/6J-TgN(*Zfy1lacZ*)218BriEms that displays variable expression of anterior transverse malocclusion, craniofacial dysmorphia, and occasional maxillary bending. Homozygous transgenic mice also exhibit a variable but high incidence of runting and infertility. The absence of the phenotype in mice heterozygous for the transgene insertion suggests that this is due to a loss of function of an endogenous gene. Fluorescence in situ hybridization (FISH) analysis utilizing the transgene construct as a probe and hybridization to metaphase chromosomes prepared from a female homozygous transgenic mouse, maps the insertion of the transgene complex, and thus the mutation, to the distal region of mouse Chromosome 7, band F5. This region is syntenic with human chromosomes 10q, 11, and 16p. Immediate efforts are underway to clone DNA sequence flanking the integration site to facilitate the goal of identifying the endogenous gene(s) disrupted. The identification and characterization of genes that contribute to symmetrical growth and development of craniofacial structures will contribute to our understanding of the pathogenetic mechanisms leading to congenital and acquired disorders of facial skeleton asymmetry.

Program Nr: 1384 from the 1999 ASHG Annual Meeting

Association between angiotensin-converting enzyme and Alzheimer disease. *L.A. Farrer[1], G. Korovaitseva[2], E.A. Rogaeva[3], S. Petruk[2], S. Keryanov[2], S. Premkumar[1], Y. Song[3], T. Sherbatich[2], Y. Molyaka[2], N.D. Selezneva[2], S. Voskresenskaya[2], V. Galimbet[2], S. Sorbi[4], R. Duara[5], S. Gavrilova[2], P.H. St. George-Hyslop[3], E.I. Rogaev[2].* 1) Genetics Program, Boston Univ Sch Medicine, Boston, MA; 2) Russian Academy of Medical Sciences, Moscow, Russia; 3) Univ Toronto, Toronto, Ontario, Canada; 4) Univ Florence, Firenze, Italy; 5) Univ Miami Sch Medicine, Miami, FL.

The D allele for an insertion/deletion polymorphism in angiotensin-converting enzyme (ACE) has been linked to heart disease, stroke, and Alzheimer disease (AD). We investigated the ACE polymorphism in 151 patients meeting criteria for probable or definite AD and 206 ethnically matched controls from Russia and in 236 AD patients and 169 controls from North America using allele association methods and logistic regression. The D allele was more frequent among AD cases between ages 66 and 70 compared to age-matched controls in both the Russian (p=.02) and North American (p=.0006) data sets. In this age group, the effect of D (OR=11.2, 95% CI=2.9-44.0) appeared to be independent of and equal or greater in magnitude to the effect of APOE e4 (OR=7.8, 95% CI=3.5-7.4). ACE was not associated with AD in any other age stratum. Our results suggest that APOE and ACE genotypes may be independent risk factors for late-onset AD. In contrast to our findings, an association between the I/I genotype and AD was observed in 3 cohorts from the UK (Kehoe et al, Nat Genet 1999). However, the OR's were considerably less (1.8 to 2.7) and subjects were not stratified by age. These discrepent results suggest that an AD susceptibility allele is located elsewhere in ACE or a nearby gene. Alternatively, if D/D increases risk of stroke among persons below age 60, the D allele may influence AD risk by promoting small cerebrovascular infarcts, the cumulative effect of which is not manifest until about age 65. Evidence from our controls samples and a study of centenarians showing an increased frequency of D/D with age might explain the sudden diminution of the association after age 70. Thus, ACE may be an example of a gene with pleiotropic age-dependent effects on disease and survival.

Program Nr: 1385 from the 1999 ASHG Annual Meeting

Association between a CAG repeat polymorphism in the hKCa3 channel gene and spinocerebellar ataxia (SCA).

K. Figueroa[1], D. Geshwind[2], S. Perlman[2], P. Chan[3], C. Tanner[3], S. Pulst[1]. 1) Dept Medicine/Neurology, Cedars Sinai Medical Ctr, Los Angeles, CA; 2) Reed Neurological Research Center 710 Westwood Plaza UCLA School of Medicine Los Angeles, CA 90095-1769; 3) Parkinson's Institute 1170 Morse Avenue Sunnyvale, CA 94089.

Mutations in ion channels have been found to cause a variety of mendelian genetic diseases. HKCa3, a human calcium-activated potassium channel contains a polymoprhic polyglutamine repeat. Although not causative, longer polyQ tracts in this channel have been associated with psychiatric diseases in some studies. The spinocerebellar ataxias (SCAs) are a clinically and genetically heterogeneous group of neurodegeneative disorders. To date, nine different loci causing SCA have been identified: SCA1, SCA2, Machado-Joseph disease (MJD)/SCA3, SCA4, SCA5, SCA6 SCA7, SCA8 and dentatorubopallidolusian atrophy (DRPLA). Expansion of a CAG repeat in the disease genes has been found in five of these disorders. To test the involvement of this gene as a risk factor for ataxia we examined the genotypes of the hKCa3 CAG repeat polymorphisms in a case-control study in a population of 113 ataxic patients negative for the known SCA mutations and 152 age matched controls. Overall allele distribution between the three samples was similar with a CAG_{19} allele being the most common. One patient had an allele with 28 repeats which was 6 repeats longer than the next longest allele with CAG_{22}. However, since an allele of this size has been reported in one study as occurring in a normal individual (age unknown) it is not clear that this expansion is pathogenic. We next examined whether the CAG genotype at this locus was associated with the presence of ataxia. The overall genotype distribution was significantly different in patients with ataxia compared with normal controls by chi-square test (P=0.049). These results provide evidence for a possible association between longer alleles in the hSKCa3 gene and ataxia. These studies need to be replicated in a separate sample set and should examine this gene as a possible locus modifying age of onset in spinocerebellar ataxias.

Program Nr: 1386 from the 1999 ASHG Annual Meeting

A general approach to improving QTL detection in humans. *W.F. Forrest, E. Feingold.* Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Most linkage studies for mapping quantitative trait loci (QTLs) in humans take one of two approaches. One approach is to use allele-sharing statistics based on identity-by-descent information with subjects ascertained because they possess anomalous phenotypes (e.g. discordant and/or concordant sibling pairs). The other approach studies the distribution of trait values given the inheritance vector (IBD information) for the pedigree. Both Haseman-Elston regression and variance components methods fall into this category. In this second type of study families need not be ascertained because of anomalous phenotypes, but typically they are at least to some extent. We show that these two approaches to QTL mapping contribute complementary rather than redundant information, and thus that statistics of the two types can be combined to form more powerful tests of linkage. We demonstrate this principle with a simple statistic for sibling pairs that combines the traditional Haseman-Elston statistic and the standard ``mean test'' for IBD sharing. We show with simulations that the combined statistic is more powerful than either test alone whenever the ascertainment is at least moderately based on phenotype. We also include suggestions for how statistics might be combined in more complicated situations than a sibling pair study.

Program Nr: 1387 from the 1999 ASHG Annual Meeting

A Transcript Map of the Chromosome 20 Type 2 Susceptibility Locus. *S.C. Fossey[1], J.A. Price[2], J.K. Pendleton[2], J.R. Snyder[2], C.S. Brewer[2], B.I. Freedman[3], S.S. Rich[4], D.W. Bowden[2].* 1) Dept Molecular Genetics, Wake Forest Univ Medical Ctr, Winston-Salem, NC; 2) Dept Biochemistry, Wake Forest Univ Medical Ctr, Winston-Salem, NC; 3) Dept of Internal Medicine, Wake Forest Univ Medical Ctr, Winston-Salem, NC; 4) Dept of Public Health Sciences, Wake Forest Univ Medical Ctr, Winston-Salem, NC.

Genetic linkage to chromosome 20q12-13.1 in Caucasian Type 2 diabetes families has been reported by multiple research groups (Bowden et al., Diabetes 46:882-886, 1997; Ji et al., Diabetes 46:876-881, 1997; Zouali et al., Hum Mol Genet 6:1401-1408, 1997; Ghosh et al., PNAS (USA) 96(5):2198-2206, 1999). HNF-4a, the gene responsible for maturity onset diabetes of the young, type 1, (MODY1) is localized to this same region, but mutations in HNF-4a do not account for the 20q linkage in Type 2 diabetes. An effort to positionally clone the diabetes gene(s) located on chromosome 20q12-13.1 is underway. To facilitate our efforts, we have constructed a physical map of this region, consisting of overlapping BAC and YAC clones (Price et al., AJHG, suppl:61, 1997). Concurrently, we have identified several regions of linkage disequilibrium within this interval (Price et. al., submitted). The genetic markers D20S888 and adenosine deaminase (ADA) show strongest evidence for linkage disequilibrium with Type 2 diabetes in this interval. We are generating a high resolution 2 Mb transcript map around each of these markers. Forty overlapping BAC clones around the ADA locus have been isolated and ordered. To this framework, 42 ESTs, 31 genetic markers and 11 known genes have been mapped to specific BACs. Flanking the D20S888 locus, we have ordered 21 BACs and localized 20 ESTs, 15 genetic markers and 6 known genes. We have surveyed 11 candidate genes, including ADA, HNF-4a, Syndecan-4, Receptor for Activated C Kinase 7 (Rack7), stress responsive serine/threonine kinase 2 (Krs-2), and Phospholipid Transfer Protein (PLTP1) for allelic variants associated with Type 2 diabetes. We are currently evaluating novel ESTs for contribution to Type 2 diabetes.

Program Nr: 1388 from the 1999 ASHG Annual Meeting

DFNA27, a new locus for autosomal dominant hearing impairment on chromosome 4. *R.A. Fridell[1], E.A. Boger[1], T. San Agustin[2], M.J. Brownstein[3], T.B. Friedman[1], R.J. Morell[1].* 1) Lab. Molecular Genetics, NIDCD, NIH, Rockville, MD; 2) NIDRR, DOEd, Washington D.C; 3) Lab. of Genetics, NIMH, NHGRI, NIH, Bethesda, MD.

Nonsyndromic hereditary hearing impairment is an extremely heterogeneous disorder. The continued identification of genes associated with hearing loss provides an effective means of uncovering essential components of the auditory system and promises an increased understanding of the molecular basis for sound transduction. We have ascertained a family segregating autosomal dominant nonsyndromic sensorineural hearing loss. In eleven affected individuals in this family, age of onset for the hearing loss was variable, ranging from pre-teens to late twenties. Affected individuals under the age of 40 years exhibit moderate to profound hearing loss (~30-90 dB). In older affected individuals, hearing loss is profound (> 90 dB). To map the locus responsible for hearing loss in this family, we first excluded known deafness loci and then performed a genome-wide scan with STR markers from the Weber 8 screening panel. Strong evidence for linkage was found to an approximately 15 cM region between markers D4S428 and D4S392 (maximum LOD= 4.76 at q = 0 for D4S3248). This region does not contain any other known nonsyndromic deafness genes and the new locus has been designated DFNA27. Progress in refining the DFNA27 genetic interval and identifying candidate genes will be reported.

Program Nr: 1389 from the 1999 ASHG Annual Meeting

Evidence that a dodecamer duplication in the gene HOPA in Xq13 is not associated with mental retardation. *M.J. Friez, J.W. Longshore, K. Sossey-Alaoui, R.L. Nelson, M.M. May, R.C. Michaelis, R.C. Stocco dos Santos, A.K. Srivastava, C.E. Schwartz, R.E. Stevenson.* Greenwood Genetic Center, Greenwood, SC 29646.

A recent study suggested that a dodecamer duplication in exon 42 of the HOPA gene in Xq13 may be a significant factor in the etiology of X-linked mental retardation. In an effort to investigate this possibility, we determined the incidence of the dodecamer duplication in two groups of non-Fragile X males and in two control groups (newborn male infants and male college students). The duplication was found in 4% of male patients from one non-Fragile X group, but in no male patients from either the other non-Fragile X group or families with X-linked mental retardation. In addition, the duplication was found in 1.5% of the newborn male and 2.5% of the male college student control populations. The incidence of the duplication was not significantly different between any of the groups in the study. These findings do not corroborate the findings of the previous study, and indicate that the HOPA dodecamer duplication does not convey an increased susceptibility to mental retardation.

Program Nr: 1390 from the 1999 ASHG Annual Meeting

A Genome Scan for Major Infectious Disease Susceptiblity Genes. *A.J. Frodsham[1], S. Best[1], K. Young[1], L. Zhang[1], M.R. Thursz[2], M. Chiaramonte[3], A.V.S. Hill[1].* 1) The Wellcome Trust Centre for Human Genetics, Oxford. OX3 7BN. UK; 2) Imperial College of Medicine, St Marys Hospital, London. W2 1NY. UK; 3) Instituto di Medicina Interna, Universita di Padua, 35126 Padova, Italy.

Changes in host genetics can powerfully affect a pathogen's ability to live in the hosts internal environment and under the surveillance of the host's immune system. In many infectious diseases it is apparent that many more people may be exposed to the pathogen than actually develop the disease. The reason for this may be environmental factors, differences in pathogen virulence or genetic differences between individuals. Evidence that host genetics play a role in susceptibility to infectious disease comes from twin and adoption studies, associations with HLA alleles and associations between candidate genes and infectious diseases. A Danish adoption study found that susceptibility to infectious disease was strongly influenced by heritable factors. The death of a biological parent before the age of 50 from an infectious cause was associated with a six-fold increased risk to the offspring of death from an infectious disease. Twin studies have shown a greater concordance in monozygous twins as compared to dizygous twins in a range of infectious diseases including pneumonia, leprosy, hepatitis B, malaria and tuberculosis. The aim of our study is to determine by linkage analysis the loci involved in the susceptibility to infectious disease. Using fluorescence based microsatellite technology and affected sibling pair linkage analysis, we have performed a genome wide scan using 32 extended pedigrees which contained a total of 61 independent, chronically infected sibling pairs. We used a panel of 299 polymorphic markers, which cover all 23 chromosomes with an average spacing of 10-20cM. Strongest evidence of linkage was found on chromosome 6, with a peak MLS score of 2.67 (p=0.0002) located at 6q26-27. We have analysed further microsatellites to fine map this region to an average spacing of 3cM and have localised the peak of linkage to a 1.2cM region on 6q26. We are investigating positional candidates in this region for evidence of association with infectious disease.

Program Nr: 1391 from the 1999 ASHG Annual Meeting

Genetic localization of the adult-onset autosomal dominant leukodystrophy (adld) gene to chromosome 5q. *Y. Fu[1], C. Coffeen[1], Y. He[1], L. Ptacek[1,2,3]*. 1) Human Genetics, Univ Utah, Salt Lake City, UT; 2) Department of Neurology, Univ Utah, Salt Lake City, UT; 3) Howard Hughs Medical Institute, Salt Lake City, UT.

The hereditary leukodystrophies represent a group of neurological disorders, in which complete or partial dysmyelination occurs in either the central nervous system (CNS) and/or the peripheral nervous system(PNS). Adult-onset autosomal dominant leukodystrophy (ADLD) is a slowly progressive, fatal multi-system neurological disorder, characterized by symmetrical wide-spread myelin loss in the CNS. The ADLD phenotpye is similar to that of chronic progressive multiple sclerosis(MS). We report the mapping of the gene that causes ADLD to an 6 cM region on chromosome 5q31. Linkage analysis of a previously reported American/Irish kindred yielded a LOD score of 5.72 at O=0.0 with the microsatellite marker D5S804, and linkage analysis of an additional family of Scottish/Irish origin increased the LOD score to 7.02 at 0=0.0 with D5S 804. Localization of the gene causing ADLD is the first step toward cloning the disease gene and characterizing function of the protein encoded by wild-type and mutant genes. New insight from this work will lead to better understanding of the pathophysiology of this disorder specifically and possibly to the molecular basis of leukodystrophy and MS in general. Ultimately such work will lead to better diagnosis and treatment for patients.

Program Nr: 1392 from the 1999 ASHG Annual Meeting

Monitoring myeloid and lymphoid chimerism with DNA markers is an useful tool in predicting early relapse after allogeneic BMT. *R. Galavotti[1], E. Trabetti[1], R. Fasolo[2], D. de Sabata[2], F. Benedetti[2], P.F. Pignatti[1].* 1) Section of Biology & Genetics, DMIBG, Univ. Verona, Italy; 2) Dpt. of Clinical Experimental Medicine, Univ. Verona, Italy.

Bone marrow transplantation is a powerful therapy used in a large number of hematological disorders. Relapse occurs in 10-30% of transplated patients, but in some cases, such as in CML, it can be easily reversed by a timely immunotherapy. It is therefore important to detect early relapse. From 1993 to 1998, 40 patients (CML, AML, ALL, MDS, MM, NHL), 18 males and 22 females, median age 36 (range 17-51 years) were transplanted in the BMT Unit of our Hospital. The median follow-up is 33 months (range 7-70). The conditioning regimen was TBI+Cytoxan for 36 and Busulphan+ Cytoxan for 4 patients. All the patients underwent frequent clinical and lab controls and peripheral blood (T and non-T) and bone marrow examination by DNA analysis at +21, +54, +90, +180 days, and then every year, after BMT. When available, cytogenetics and bcr/abl or other transcripts were used as additional data to follow the patients.DNA markers D1S80, ApoB, F8VWF, HUM-TH01, and others as necessary, were used. At present 26/40 pts are alive and well, with 100% donor myeloid and lymphoid cells. In 4 pts a transient mixed chimerism in the lymphoid lineage dissappeared within 90 days, and they have now a full donor engrafment. In 13 pts a mixed chimerism was demonstrated at any time during follow up. 1 pt with more than 5 year follow up has a mixed chimerism in lymphoid cells, that is compatible with a long survival. 8 pts (6 CML and 2 ALL) relapsed. In 6/6 CML pts DNA analysis detected the reapparance of autologous myeloid cells before any clinical evidence of disease. The data was confirmed in 5/6 cases by cytogenetics (Ph+) and bcr/abl transcript analysis. In 1 case there was no cytogenetic or transcript evidence, so that DNA was the only data predictive of relapse available. In conclusion, DNA analysis was a sensitive and general method to demonstrate donor engraftment in all patients studied. In many cases, as in MDS and MM, where no specific cytogenetic or molecular marker tests were available, it produced the only useful data.

Program Nr: 1393 from the 1999 ASHG Annual Meeting

Nonparametric disequilibrium mapping when haplotypes are available. *X. Gao, F.A. Wright.* Human Cancer Genetics, The Ohio State University, Columbus, OH.

A new method is described for the identification and mapping of haplotypes associated with disease in linkage disequilibrium studies. The method is applicable in situations where disease haplotypes and an appropriate sample of control haplotypes are available. By searching over observed haplotypes using variable window widths for contiguous markers, the haplotype most strikingly associated with disease is identified and mapped. The method naturally incorporates multi-allelic markers, and unlike other approaches is truly multipoint, in that multiple marker loci are used and the existing disequilibrium among markers (in both disease and control chromosomes) is built into the observed data. A statistic $S(a,b)$ is defined on the set of haplotypes beginning at marker position a and ending at position b, and is chosen to reflect striking associations of one or more of these haplotypes with disease status. The overall association evidence at marker position x is then $S^*(x) = max_{a£x£b}\, S(a,b)$. The approach is motivated by current progress toward large-scale association studies in outbred populations. However, the method appears to also offer considerable advantages for fine-scale mapping in isolated populations. One unique aspect of the method is the ability to distinguish and separately map multiple founding ancestral mutations. Data from cystic fibrosis and hereditary non-polyposis colon cancer are used as examples, and further refinements are proposed.

Program Nr: 1394 from the 1999 ASHG Annual Meeting

A family with X-linked epilepsy mapping to Xp11-Xq13. *C.C Garcia[1], M.R.H Buddles[1], M. Seager[2], J.A Goodship[1].* 1) Biochemistry and Genetics, Newcastle University, Newcastle-upon-Tyne , UK; 2) Northgate Hospital, Morpeth, UK.

We report a large X-linked epilepsy family. The clinical features are epilepsy with onset between teenage years and the third decade, learning difficulties and intermittent aggressive behaviour. The affected males are not dysmorphic. Some of the affected males have all three features whilst others have only epilepsy or learning difficulties with behavioural disturbance. Fragile X syndrome has been excluded.

17 microsatellite markers spanning the X chromosome were analysed in 17 family members including 8 affected males. GATA72E05(DXS7132) cosegregated with the disease. Recombinations with GATA69C12(DXS6810) mapping to Xp11 and GATA31D10(DXS6800) mapping to Xq13 defined a 30cM critical region. Monoamine oxidase A (MAOA) was a strong candidate gene given its chromosomal location and the mutation identified by Brunner (Science 262:578-580, 1993) in a family with a similar phenotype. However, the disorder in the family we describe does not segregate with a dinucleotide repeat polymorphism at the MAOA locus.

Program Nr: 1395 from the 1999 ASHG Annual Meeting

Heterozygote advantage of the MTHFR gene: Are heterozygous C677T/MTHFR women at lower risk of having children with nonsyndromic cleft lip with/without cleft palate? *D.A. Gaspar[1], R.C. Pavanello[1], M. André[2], S. Steman[3], M. Zatz[1], D.F. Wyszynski[4], S.R. Matiolli[1], M.R. Passos-Bueno[1]*. 1) Depto. de Biologia, Univ. de São Paulo, São Paulo, SP, Brazil; 2) Faculdade de Odontologia Universidade de São Paulo, São Paulo, Brazil; 3) Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brazil; 4) Laboratório de Epidemiologia Genética, Departamento de Salud Publica, Universidad de Buenos Aires, Argentina.

It has been shown in several populations that the C677T polymorphism of the 5, 10- methylenetetrahydrofolate reductase (MTHFR) gene is associated with an increased risk for neural tube defects (NTD), when both the mother and child have a TT genotype. Interestingly, Tolarova et al. (Am J Hum Genet 1998 63:A27) suggested that there is an increased proportion of TT homozygotes among CL/P Argentinean patients as compared to controls. These findings, however, are still controversial. We analysed the C677T polymorphism by comparing 77 Caucasian CL/P patients and 59 white mothers of CL/P patients to controls matched by age, socio-economic and ethnic background. The T allele and the TT genotype frequencies did not differ statistically among the tested groups and were in Hardy-Weinberg equilibrium both in controls and CL/P patients. However, unexpectedly, this polymorphic system was in Hardy-Weinberg disequilibrium among mothers of CL/P patients due to a relatively lower proportion of heterozygotes. Although this result could be a random variation, we hypothesised that CT heterozygotes might have an advantage towards the homozygotes in relation to this trait. The more independent confirmation of these results, showing a role of the maternal genotype predisposing to CL/P would provide new insights into the complex aetiology of this common birth defects. Supported by FAPESP, PRONEX, CNPq, HHMI.

Program Nr: 1396 from the 1999 ASHG Annual Meeting

Analytic Solution of Detection Rates when Genotype Errors Introduced into Family at Single Nucleotide Polymorphism Locus. *D. Gordon, J. Ott.* Lab Statistical Genetics, Rockefeller Univ, New York, NY.

Errors in human linkage data such as misreads by automated machines (allelic errors) or sample swaps (genotype errors) can increase type I error rates and reduce power in TDT tests. The goal of our analysis is to analytically determine the rate at which genotype errors are detected through Mendelian inconsistency in trios (parent 1, parent 2, child) that are genotyped at a single nucleotide polymorphism (SNP) locus that is in Hardy-Weinberg equilibrium (HWE).

In our error model, it is assumed that any of the three correct genotypes in a trio is replaced by a different genotype with constant probability, e. Further, it is assumed that errors occur randomly and independently. Hence, the probability of 1 to 3 errors occurring in a trio, conditional on at least one error occurring in the trio, is computed using the binomial distribution. It is also assumed that the trios arise from a population in HWE at the SNP locus. Using standard probability theory, the probability that errors are detected, or detection rate, for a randomly selected trio from the population may be calculated using the error rate e of genotype swaps and the allele frequency p of one of the two alleles at the SNP locus.

We compute this detection rate for various values of e and p . It can be shown that the theoretical maximum detection rate is 75%, but this detection rate is never achieved in practice. The values of e considered are 0.001, 0.005, 0.01, 0.02, 0.05, 0.1, and 0.2. The values of p considered are 0.01, 0.05, 0.1, 0.25, and 0.5. The maximum detection rate for these values is 66%, when e is 0.001 and p is 0.01. The minimum detection rate is 42%, when e is 0.001 and p is 0.5. For any fixed setting of e, the minimum detection rate occurs when allele frequencies are equal, i.e., $p = 0.5$. Also the detection rate appears to be much more sensitive to changes in the allele frequency p than to changes in the error rate e.

Program Nr: 1397 from the 1999 ASHG Annual Meeting

A common framework for model-based or model-free, twopoint or multipoint, linkage and/or linkage disequilibrium analysis of complex traits. *H.H.H. Goring[1], J. Ott[1,2], J.D. Terwilliger[1,3].* 1) Columbia U., NY; 2) Rockefeller U., NY; 3) NY State Psychiatric Inst., NY.

In linkage and/or linkage disequilibrium (LD) analysis, one computes the joint probability of a set of trait phenotypes (Ph) and a set of observed marker genotypes (G_M) in one's data. In conventional model-based analysis, this probability is computed as $P(Ph,G_M) = P(Ph|G_M)P(G_M) = S_{GD}\ P(Ph|G_D)P(G_D|G_M)P(G_M)$, by partitioning over all possible trait-locus genotype combinations for all individuals in the dataset (G_D). $P(Ph|G_D)$ is a function of the mode of inheritance, while $P(G_D|G_M)$ is a function of linkage and LD. By contrast, in model-free analysis methods, one computes this probability as $P(G_M,Ph) = P(G_M|Ph)P(Ph)$. One can estimate $P(G_M|Ph)$ without assuming anything about the genotype-phenotype relationships, if the ascertained samples have the same pedigree and phenotype structure (Ph) (e.g. affected sib-pairs, trios, or singletons). Though one does not model the genotype-phenotype relationships explicitly, the likelihood certainly depends on them, since $P(G_M|Ph) = S_{GD}\ P(G_M|G_D)P(G_D|Ph)$. $P(G_M|G_D)$ is a function of linkage and LD, and $P(G_D|Ph)$ is a function of how well the trait phenotypes predict the trait-locus genotypes. Since it is possible to find markers arbitrarily close to any trait locus, thereby increasing $P(G_M|G_D)$, the power of a study is dominated by $P(G_D|Ph)$, and the ascertainment and study design can thus be more important than the choice of statistical analysis method. We show how model-free analysis of linkage and/or LD can be performed by using deterministically assigned *pseudomarker* genotypes. In contrast to most conventional model-free methods, the pseudomarker analogs can be applied to different data structures jointly, thus using the total data more efficiently. These methods also have better statistical properties and are more powerful. We further show that twopoint analysis and multipoint analysis using *complex-valued recombination fractions* are algebraically isomorphic. This allows multipoint analysis, either model-based or model-free using pseudomarkers, to be performed with the same degree of robustness to trait-locus genotype errors as twopoint analysis.

Program Nr: 1398 from the 1999 ASHG Annual Meeting

Maximizing the Maximum Lod Score (MMLS): Application to Multipoint Analysis and Estimates of Gene Location. *D.A. Greenberg[1], P.C. Abreu[2]*. 1) Dept Psychiatry, Mount Sinai Medical Ctr, New York, NY; 2) Division of Biostatistics, School of Public Health, Columbia University, New York, NY.

The best available method for analyzing genetic linkage data remains an open question. We have demonstrated in previous work that performing a lod score analysis twice, once assuming dominant and once asuming recessive inheritance, and then taking the larger of the two values (designated MMLS) often has the most power to detect linkage. The power of the MMLS approach is comparable to analysis under the true model, even after correcting for multiple tests (Greenberg et al, 1998). We had demonstrated this using computer simulation under a variety of complex inheritance models. However, that previous work was done using two-point analysis, and the question has repeatedly arisen as to whether our findings will hold using multipoint analysis. In the current work, we extend our tests of the MMLS approach to multipoint linkage analysis and to a larger variety of generating inheritance models, including four heterogeneity models, four epistatic two-locus models, and two different additive models. We also examined the estimated position of the maximum in a chromosomal interval of 10 markers separated by recombination fractions of 0.1. We analyzed simulated data using lod scores (LS), lod scores assuming heterogeneity (HLOD), and NPL scores. Several conclusions can be draw:

First, our results indicate that, like two-point analysis, MMLS in multipoint analsyis provides good power to detect linkage even when the data originate from a variety of complex models.

Second, in all cases, we found that estimates of position were good to excellent for all three statistics,except that when heterogeneity was present, the lod score without heterogeneity performed poorly.

Third, the analyses using the lod scores and/or the HLOD had more power to detect linkage than NPL in all cases that we examined, although there was less difference between the methods for the additive models.

Program Nr: 1399 from the 1999 ASHG Annual Meeting

DFNA25, a novel locus for dominant, nonsyndromic, high frequency sensorineural hearing impairment. *C.C. Greene, P.M. McMillan, S.E. Barker, M.M. Lesperance.* Otolaryngology-Head & Neck Surgery, University of Michigan, Ann Arbor MI.

This is a study of a family of Czech descent from the midwestern United States with nonsyndromic dominant, progressive, high frequency sensorineural hearing impairment. Twenty-three of the patients studied are affected as compared to the 90th percentile for sex and age as measured in an unselected population (Robinson 1988). The youngest affected member was diagnosed at birth and the onset of hearing impairment for all affected members usually occurred in the first 2 decades of life. An estimate of the ability to detect linkage was calculated using the statistical software program SLINK (Ott, 1989). Ninety-nine-point-five percent of the 200 replicates of the pedigree generated by SLINK yielded a logarithm-of-odds (LOD) score over 3.0 (average maximum LOD score 9.75). Genotyping was performed using the polymerase chain reaction with radiolabeled primers and polyacrylamide gel electrophoresis. Linkage to known dominant loci for hereditary sensorineural hearing impairment was excluded by analyzing genotype data with the statistical software program MLINK (Ott, 1989). DNA from 50 patients (16 affected) informative for linkage analysis was then submitted to the Mammalian Genotyping Service for high-throughput genotyping across the entire genome. The genotype data for all markers was analyzed with MLINK. Linkage was detected to chromosome 12q21-q24 by analysis of a polymorphic marker within the phenylalanine hydroxylase (PAH) gene (LOD score of 4.02 at $q = 0.1$). Further genotyping of nearby markers and haplotype analysis revealed that the gene responsible for the hearing impairment in this family (DFNA25) maps to a 30 cm region defined by affected recombinants at D12S1052 and D12S1597. The region of human chromosome 12q21-24 has homology with a region of mouse chromosome 10. We are in the process of further narrowing the genetic interval by testing additional markers in the region. Haplotype analysis of these data and a discussion of candidate genes will be presented. (Supported by 1K08 DC 00161-01A1 and a grant from the Mammalian Genotyping Service of the National Heart, Lung and Blood Institute).

Program Nr: 1400 from the 1999 ASHG Annual Meeting

Haplotype Analysis of X Linked Migraine Pedigrees Refines the Migraine Susceptibility Locus to Xq24. *L.R. Griffiths[1], D.R. Nyholt[1], R.A. Lea[1], R.P. Curtain[1], P.J. Brimage[2].* 1) Genomics Res Ctr, School Health Science, Griffith Univ, Southport QLD, Australia 4217; 2) Institute of Neurological Sciences, Prince of Wales Hospital, Randwick, NSW 2031, Australia.

Recent studies in our laboratory have provided evidence for a X linked genetic component in familial typical migraine [1]. Using two large multigenerational pedigrees, designated MF7 and MF14, we were able to demonstrate significant excess allele sharing with a number of Xq microsatellite markers; MF7 giving a maximum NPL score of 2.57 at DXS1001, (P = 0.031) and MF14 giving a NPLmax of 2.74 at DXS1123 (P = 0.012). However, although combined analysis of the two pedigrees indicated excess allele sharing more towards the MF14 peak, the fact that the different peak regions of MF7 and MF14 were approximately 46cM apart, clearly indicated the need for finer gene mapping in these pedigrees. Therefore, to further localise and increase the information content across the implicated regions on chromosome Xq, the present study utilised additional microsatellite markers combined with haplotype analysis. Multipoint linkage analysis of genotype results was performed using the Sall scoring function in the GENEHUNTER-PLUS package, whilst reconstruction of the most likely haplotypes and determination of crossover events were calculated using the exact-likelihood method implemented in GENEHUNTER. Results from the study indicated significant evidence for X-linkage, with a peak LOD score of 2.388 (P = 0.0005) equidistant between DXS1001 and HPRT. Haplotype analysis was able to reduce this region further, indicating that the most likely localisation for the migraine susceptibility gene is the within a 5Mb region on the X chromosome. Hence we have provided further evidence for the location of a X chromosomal migraine gene and have been able to more firmly localise this locus to Xq24.

Program Nr: 1401 from the 1999 ASHG Annual Meeting

Spinal muscular atrophy with respiratory distress is heterogeneous and one form (SMARD) maps to 11q13-q21.

K. Grohmann[1], T.F. Wienker[2], K. Saar[3], S. Rudnik-Schöneborn[4], G. Stoltenburg-Didinger[1], A. Pfeufer[1], G. Novelli[5], B. Wirth[2], A. Reis[3], K. Zerres[4], C. Hübner[1]. 1) Neuropediatrics, Charite, Humboldt-University, Berlin, Germany; 2) Institute of Medical Statistics, University Bonn, Bonn, Germany; 3) Microsatellite Center MDC, Berlin, Germany; 4) Department of Human Genetics, University, Aachen, Germany; 5) Department of Biopathology, Tor Vergata University, Rome, Italy.

Spinal muscular atrophy (SMA) is linked to markers on 5q13. SMA plus phenotypes are not linked to the SMA locus. Here we report an diaphragmatic SMA. In both SMA and diaphragmatic SMA severe limb muscle weakness is the common symptom. In contrast to SMA, where lumbar spinal cord, lower limbs and proximal muscles are predominantly affected, in diaphragmatic SMA cervical spinal cord, diaphragm, upper limbs and distal muscles are predominantly affected. Genome wide linkage scan in a consanguineous Lebanese family with five affected sibs (age of onset: 6-10 weeks) revealed linkage of SMARD to markers on 11q13-q21. For D11S1358 a maximum two-point LOD score of 3.16 at recombination fraction (Q)=0 was obtained. Multipoint linkage analysis yielded a maximum LOD score of 3.86 placing SMARD locus between D11S1883 and D11S917 which are 32.4 cM apart. Muscle histology revealed neurogenic atrophy without signs of reinnervation, and motor end plates presynaptic and postsynaptic degeneration. In one child the diameter of anterior spinal roots was reduced in specimen from the upper spinal cord. The locus on 11q13-q21 was supported by the haplotype analysis in a non-consanguineous German family with two affected children (onset: 9-12 weeks). In contrast, a third Italian family with two affected children (onset: birth) did not map to this region. It appeared that SMARD is autosomal recessively inherited. The histological findings offer two different pathophysiological concepts. Degeneration of anterior horn cells suggests dying forward atrophy. In contrast, end plate degeneration suggest dying back atrophy. In conclusion, diaphragmatic SMA is clinically and genetically heterogenous. One form (SMARD) maps to 11q13-q21.

Program Nr: 1402 from the 1999 ASHG Annual Meeting

Analysis of Chromosome 12 Candidate Genes in Late-onset Alzheimer Disease (AD). *J.M. Grubber[1], A.M. Saunders[1], L.H. Yamaoka[1], W.K. Scott[1], E.R. Martin[1], D.M. Hill[1], C.L. Standen[1], D.E. Schmechel[1], P.M. Conneally[2], G.W. Small[3], E.H. Lai[4], A.D. Roses[4], J.L. Haines[5], M.A. Pericak-Vance[1]*. 1) Dept.of Medicine, Duke Univ., Durham, NC; 2) Dept. of Medical and Molecular Genetics, Indiana Univ., Indianapolis, IN; 3) Dept. of Psychiatry, UCLA School of Medicine, Los Angeles, CA; 4) Genetics Directorate, GlaxoWellcome R&D, RTP, NC; 5) Program in Human Genetics, Vanderbilt Univ., Nashville, TN.

Three AD-causing genes: amyloid precursor protein, presenilin 1, and presenilin 2; and one susceptibility gene, apolipoprotein E, have been identified. Recent research indicates that the most promising location for a fifth AD gene is chromosome 12. We report results for 10 chromosome 12 candidate genes: neurotrophin-3 (NTF3); tumor necrosis factor receptor 1 (TNFR1); human complement component (C1r); oxidized low-density lipoprotein receptor (OLR1); islet amyloid polypeptide (IAPP); Kirsten rat sarcoma 2 viral oncogene (KRAS2); parathyroid hormone-like hormone (PTHLH); mitochondrial ATP synthase, beta subunit (ATP5B); human brain sodium channel 2 (hBNaC2); and interleukin-4 Stat (IL-4 Stat). These genes span approximately 65 cM from 12p13 to 12q13 and were chosen based on function, location, and availability of intragenic polymorphisms. The first 7 genes are located on 12p; the final 2 are located on 12q. ATP5B is in the 12p13-12qter region. The studies were performed on either: 1) 54-77 families collected by Duke, UCLA, Indiana University, and Massachusetts General Hospital; or 2) 348 families ascertained by Duke, UCLA, and NIMH. These two Caucasian, AD data sets contain at least 2 sampled affected individuals per family (³ 60) and some overlapping families. We performed sib-pair association studies (S-TDT) for all of the genes. In addition, we performed both parametric and non-parametric (MLS) two-point linkage analyses. The most significant p-value for the S-TDT was 0.10 for PTHLH. The maximum two-point lod scores for all of the data were 0.662 (parametric) for KRAS2 and 0.59 (non-parametric) for IAPP. We find no evidence that any of the ten candidate genes examined here is the sought after chromosome 12 AD susceptibility gene.

Program Nr: 1403 from the 1999 ASHG Annual Meeting

Genetic heterogeneity and epistasis in familial psoriasis: A meta-analysis of genome-wide studies. *C. Gu*[1], *A.M. Bowcock*[2]. 1) Division of Biostatistics; 2) Division of Human Genetics, Washington Univ Sch Medicine, St Louis, MO.

Psoriasis is a common inflammatory skin disease that affects ~2% of the Caucasian population. Evidence for a genetic etiology of psoriasis is revealed by numerous studies of its association with the human leukocyte antigens (HLA) complex, especially HLA-C and -B loci. Recently, additional susceptibility loci have been reported by researchers worldwide. These include loci within 17q25, 4q, 1q21-q23 and 20p. Although replication of these findings has not been always successfully achieved by independent groups, several high-quality genome-wide studies provided rich information for meta-analyses to quantitatively synthesize linkage evidences and to establish exploratory models to account for genetic epistasis and heterogeneity. We selected 8 such studies from an exhaustive MEDLINE search and performed various meta-analysis procedures. For example, a weighted inverse-normal method was used to derive a combined non-parametric p-value of 0.000372 for linkage to 17q, which gives ample evidence for PSORS2 and enhanced confirmation of the genetic heterogeneity of psoriasis. Further analysis using more sophisticated models is currently in progress, in which a novel test of heterogeneity is used by modeling study-specific covariates. These findings will aid in the understanding of the genetic etiology of psoriasis and in providing guidance for the design of future studies.

Program Nr: 1404 from the 1999 ASHG Annual Meeting

Fine linkage disequilibrium mapping of triple A syndrome in inbred North African families. *S. Hadj-Rabia[1], R. Salomon[1], A. Pelet[1], M.H. de Laet[2], B. Chaouchi[3], F. Bakiri[4], J.L. Chaussain[5], A. Munnich[1], S. Lyonnet[1]*. 1) Dept of genetics, Hopital Necker, Paris, France; 2) Dept of Surgery, Hopital d'Enfants, Brussel, Belgium; 3) Dept of Surgery, Hopital d'Enfants, Tunis, Tunisia; 4) Dept of Endocrinology, Hopital Bologhine, Alger, Algeria; 5) Dept of Endocrinology, Hopital St- Vincent-de-Paul, Paris, France.

Triple A syndrome (3A, MIM231550) is a rare autosomal recessive disorder characterized by ACTH resistant Adrenal insufficiency, Achalasia of the cardia, and Alacrimia. The 3A gene has been previously mapped to chromosome 12q13 in a 6 cM interval between loci D12S1629 and D12S312. In order to refine this localization, we have extended linkage analysis to 12 families (22 affected individuals) mostly originating from North Africa (7/12). We confirm that the 3A gene maps to the 12q13 region (Zmax=10.89 at Q=0 for D12S1604) and suggest that 3A is a genetically homogeneous disorder. Recombination events as well as homozygosity for polymorphic markers allowed to reduce the genetic interval to a 3.9 cM region between D12S368 and D12S312 loci. Moreover, total linkage disequilibrium was found at the D12S1604 locus between a rare allele and the mutant chromosomes in North-African patients (16/16). Conversely, only partial disequilibrium was found at either the D12S1651 (12/16) and the D12S1618 loci (6/16) that are telomeric and centromeric to D12S1604 respectively. Analysis of markers at 5 contiguous loci showed that most of the 3A chromosomes are derived from a single founder chromosome. As all markers are located in a 0 cM genetic interval and only allele 5 at the D12S1604 locus was conserved in all mutant chromosomes, we speculate that this mutation results from an ancient Arabian founder effect that occured before migration to North Africa. Since linkage disequilibrium at D12S1604 was also found in two patients from Southern Europe (France and Croatia), the founder effect might well extend to other Mediterranean countries. Taking advantage of a YAC contig encompassing the 3A minimal physical region, the gene was then mapped to a 1.7 Mb DNA fragment accessible to gene cloning.

Program Nr: 1405 from the 1999 ASHG Annual Meeting

A novel locus DFNA24 for congenital autosomal dominant hearing loss maps to 4q in a large Swiss German kindred. *F.M. Häfner[1], T. Linder[1], A.A. Salam[2], D. Balmer[3], A. Baumer[3], A. Schinzel[3], T. Spillmann[1], S.M. Leal[2].* 1) Deptartment of Otohinlaryngology and Head and Neck Surgery, University Hospital of Zurich, Zurich, Switzerland; 2) Laboratory of Statistical Genetics, The Rockefeller University, New York, NY; 3) Institute of Medical Genetics, University of Zurich, Zurich, Switzerland.

A novel locus for non-syndromic hearing loss has been identified in a Swiss German kindred with congenital bilateral autosomal dominant sensorineural hearing loss. This kindred has a history of hearing loss that dates back to the middle of the 19th Century. Audiometric and DNA samples were obtained on a total of 48 pedigree members. Twenty-six family members were considered to be affected and 22 unaffected. Affected family members' audiograms displayed a mild to profound hearing loss, mainly in the frequencies between 0.5 KHz and 4KHz. The affected members all had sloping audiograms affecting mainly the mid to high frequencies. Hearing impaired individuals with severe to profound hearing loss in the high frequencies also had moderate hearing loss in the mid and low frequencies. The hearing loss appears to be non-progressive with no correlation between severity of hearing loss and current age. No evidence for acquired risk factors predisposing to hearing loss was observed for any of the affected family members.

A genome scan was carried out on this family and a maximum multipoint lod score of 6.7 was obtained. The locus that segregates in this family maps to 4q. Additional work is being carried out to further refine the genetic region for this novel locus.

This work was supported by the NHLBI Mammalian genotyping service, NIH-NIDCD grant DC03594 and the American Hearing Research Foundation. .

Program Nr: 1406 from the 1999 ASHG Annual Meeting

Chromosome 16p13-cen and the MHC in multiple sclerosis. *J.L. Haines[1], M.E. Garcia[1], M.B. Gardiner[1], L.F. Barcellos[2], R.R. Lincoln[2], J.R. Oksenberg[2], S.L. Hauser[2], J.B. Rimmler[3], M.A. Pericak-Vance[3].* 1) Program in Human Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Dept. of Neurology, Univ. of California, San Francisco, CA; 3) Center for Human Genetics, Duke Univ., Durham, NC.

Multiple sclerosis (MS) is an autoimmune disorder of the central nervous system characterized by demyelination and inflammation and has a complex genetic architecture. Our previous genomic screen (MSGG, Nat Genet 13:469-71,1996) yielded 19 potential (lod > 1.00) chromosomal regions for harboring susceptibility alleles, including the MHC in 6p21 and regions 19q and 16p13-cen. We further estimated that approximately 1/3 of the total genetic effect in MS is explained by the HLA-DR2 association (MSGG, Hum Molec Genet, 7(8): 1229-1234, 1998). We also investigated a susceptibility locus on chr. 19q (Gardiner et al., ASHG abs#1674, 1998) and found evidence for an independent MS locus. We genotyped 5 markers in 16p13-cen, spanning 17 cM, in 98 multiplex families with 144 affected sibling pairs (ASPs). Fifty-two of these families were in the original screen. Analysis included two-point lod scores using dominant and recessive affecteds-only, low penetrance models and two-point ASP tests using ASPEX. We tested for interaction between the MHC and 16p13-cen with TWOLOC, a two-trait-locus ASP test. We found maximal two-point lod scores of 2.53, Q=0.15, for D16S2613 and of 1.70, Q=0.20, for D16S287. Two-point ASP analyses gave MLS scores of 1.22 and 1.85 for D16S2613 and D16S287, respectively. The 98 families were then stratified into three categories: 1) all affected individuals had the associated HLA-DR2 allele; 2) some affecteds had it; and 3) no affecteds had it. All strata had some evidence for linkage, with two-point lod scores of 1.00 or greater in this region, suggesting independence of the two loci. Independence of the chromosome 16 region was confirmed by TWOLOC analysis which gave an MLS of 7.27 in the general model and 6.28 in the additive model. HLA-DR alone gave an MLS of 4.22 and D16S287 alone gave an MLS of 2.72. These results suggest that 16p13-cen may harbor an independently-acting MS locus.

Program Nr: 1407 from the 1999 ASHG Annual Meeting

Allelic association and frequency of polymorphisms of the ADRB2 and CD14 genes in Icelanders with moderate to severe atopic asthma. *H. Hakonarson[1], U.S. Bjornsdottir[2], K. Kristjansson[1], J. Gulcher[1], E. Ostermann[1], C. Valiant[1], K. Carpenter[1], T. Gislason[2], D. Gislason[2], A. Gudnadottir[1], K. Stefansson[1]*. 1) deCode genetics INC., Reykjavik, Iceland; 2) Division of Allergy and Pulmonary Medicine, Vifilstadir University Hospital, Reykjavik, Iceland.

Several genes that map to chromosome 5q 31-33 reportedly influence the expression of the atopic asthmatic (AA) phenotype and specific polymorphisms (polym) in these genes may predispose to AA. In this regard, two common polym exist in the ADRB2 at amino acid 16 (gly for arg) and 27 (glu for gln) both of which are functionally relevant. The latter has been associated with BHR and elevated IgE levels in asthmatics. A polym in the CD14 gene (CD14/-159) was recently associated with the regulation of IgE levels. To analyze whether the allelic frequency of these polym is increased in Icelandic AA, we genotyped DNA from 94 AA age 12-40 years with moderate to severe asthma based on methacholine challenge tests, PFT values and response to drug therapy. DNA from 94 unrelated non-AA subjects was analyzed as control (CO). The population frequencies of the ADRB2 16 (A/G) and ADRB2 27 (C/G) alleles were not statistically different between CO (G16:55.2%; C27:62.5%) and AA (G16:55.8%; C27:60.5%). Moreover, the frequencies of the various allelic combinations of the ADRB2 16 and ADRB2 27 polym encoding for arg vs gly and gln vs glu (i.e., G16G27; A16C27; G16C27 and A16G27) were not statistically different between CO and AA. Similarly, the population frequencies of the C and T alleles of CD14 were not statistically different between the AA (C:58.5%) and CO (C:54.5%). Further, there were no statistical differences in the frequencies of the various allelic combinations of the CD14 and ADRB2 16 or ADRB2 27 polym. We conclude that: 1) The allelic frequency of the ADRB2 16, ADRB2 27 and CD14/-159 polym is not different between CO and AA in Iceland; 2) In contrast to previous reports, neither the ADRB2 16 or ADRB2 27 alleles (nor CD14/-159) were in linkage disequilibrium. These results suggest that polymorphisms in the ADRB2 and CD14 genes do not directly influence or predispose to the AA phenotype in Icelanders with moderate to severe AA.

Program Nr: 1408 from the 1999 ASHG Annual Meeting

A novel locus for Leber congential amaurosis (LCA) with anterior keratoconus mapping to chromosome 17p13.

A. Hameed[1,2], S. Khaliq[2], M. Ismail[2], N.D. Ebenezer[1], T. Jordon[1], S.Q. Mehdi[2], A.M. Payne[1], S.S. Bhattacharya[1]. 1) Molecular Genetics, Inst. Ophthalmology, London, London, UK; 2) Research Laboratories, Biomedical and Genetic Engineering Division, Islamabad, Pakistan.

LCA is a clinically and genetically heterogeneous group of childhood retinal degenerations inherited in autosomal recessive manner. It is diagnosed at birth or during the first few months of life. Infants are totally blind or have greatly impaired vision, a fundal appearance ranging from normal to pigmented and an extinguished electroretinogram. LCA is caused by mutations in the RetGC-1 (17p13.1) RPE65 (1p31) and CRX (19q13.3) genes and a gene on chromosome 14q24. Anterior keratoconus is a bilateral non-inflammatory progressive corneal ectasia. Clinical signs include stromal thinning, conical protrusion, a ring-like deposition of iron around the base of the cone (Fleischers ring), fine vertical lines in the deep stroma and Descemets membrane (Vogts striae), anterior stromal scarring and enlarged corneal nerves. Keratoconus is most commonly an isolated disorder, although it has been described in association with many ocular and systemic disorders such as Downs Syndrome, mitral valve prolapse, and LCA. A two generation consanguineous Pakistani family with autosomal recessive LCA and keratoconus was identified. All affected individuals have bilateral keratoconus and congenital pigmentary retinopathy. Based on a whole genome linkage analysis we have mapped the first locus for this combined phenotype to chromosome 17p13. Linkage analysis gave a two point LOD score of 3.21 for marker D17S829. Surrounding this marker is a region of homozygosity of 23.2cM, between the markers D17S1866 and D17S960 within which the disease gene is predicted to lie. Mutation screening of the nearby Ret-GC1 gene, which has been shown to be associated with LCA, revealed no mutations in the affected individuals of this family. Furthermore Ret-GC1 was genetically excluded from the critical disease region based on the existing physical map. We therefore suggest that this combined phenotype maps to a new locus and is due to an as yet uncharacterised gene within the 17p13 chromosomal region.

Program Nr: 1409 from the 1999 ASHG Annual Meeting

An Autosomal Genomic Scan for Loci Linked to Indices of Insulin Sensitivity and Secretion in Nondiabetic Pima Indians. *R.L. Hanson, G. Imperatore, S. Kobes, W.C. Knowler*. DAES, NIDDK, Phoenix, AZ.

Type 2 diabetes mellitus is predicted by low insulin sensitivity and by diminished insulin secretion, and linkage analyses of these quantitative traits may identify genes important in the pathogenesis of diabetes. We conducted a linkage study of indices estimating insulin sensitivity and secretion among 521 nondiabetic adult Pima Indians from 212 sibships who had participated in an autosomal genomic scan (516 markers) for loci linked to type 2 diabetes.

The indices were calculated from fasting and two-hour serum insulin (I_0, I_2) and plasma glucose (G_0, G_2) concentrations obtained from an oral glucose tolerance test. The insulin sensitivity index [ISI = $(I_0G_0)^{-1}$] and the corrected insulin response [CIR = $I_2/(G_2(G_2\text{-}70\ mg/dl))$] were used as measures of insulin sensitivity and secretion respectively. Linkage was assessed by variance components methods.

The strongest evidence for linkage with ISI occurred on chromosome 14p (LOD=3.1), near D14S742; modest evidence for linkage was also found on chromosome 7q (LOD=1.2) near D7S479 in an area which is also linked to diabetes in Pimas (LOD=1.8, Am J Hum Genet. 1998; 63: 1130). The stongest evidence for linkage with CIR was found on chromosome 13q (LOD=2.2) near D13S800; additional evidence for linkage occurred on chromosome 1 (LOD=1.4) near D1S534, near another area which showed linkage to diabetes (LOD=2.5).

These analyses show strong evidence for a locus on chromosome 14 influencing insulin sensitivity and suggestive evidence for a locus on chromosome 13 influencing insulin secretion. They also suggest that the putative diabetes-susceptibility genes previously identified on chromosomes 1 and 7 may operate by influencing insulin secretion and sensitivity, respectively.

Program Nr: 1410 from the 1999 ASHG Annual Meeting

A correlated physical and genetic map of the refined PLS locus interval on chromosome 11q14. *T.C. Hart[1], S. Walker[1], S.A. Callison[1], P.L. Bobby[1], E. Firatli[2], D.W. Bowden[1].* 1) Wake Forest Univ Sch Medicine, Winston-Salem, NC; 2) University of Istanbul, Istanbul, Turkey.

Papillon Lefevre syndrome is an autosomal recessive condition characterized by palmoplantar hyperkeratosis and severe, early onset periodontitis that results in premature exfoliation of the primary and secondary dentitions. Three groups have independently localized a major locus for PLS to overlapping genetic intervals on chromosome 11q14. Only a few markers were common to the 3 different studies. To correlate teh 3 studies, we have constructed an integrated genetic map of the PLS critical region. We have extended our linkage studies of 16 consanguineous PLS families and sub-localized the PLS locus to the genetic interval flanked by D11S4147 and D11S931. Results of genetic analysis of the genetic markers spanning this interval suggest a genetic distance of approximately 2.8 cM. This corresponds to a physical distance of 4 Mb, containing at least 10 known genes and 40 ESTs. As part of our effort to identify the gene and specific mutation(s) that cause PLS, we have developed and correlated physical and genetic maps of the PLS candidate interval. We have developed a YAC contig that spans this genetic interval. We have confirmed the placement of 30 ESTs and genes on this contig. We have also evaluated expression of these ESTs/genes in gingiva as well as palmar and plantar skin. We present an integrated genetic map of the PLS candidate interval, correlated this map to the genetic map and determined which of these genes/ESTs are expressed in the tissues affected by the PLS phenotype. These findings should accelerate the search to identify the gene responsible for PLS.

Program Nr: 1411 from the 1999 ASHG Annual Meeting

Use of optical scanning capabilities to ensure accurate and efficient data entry in a multicenter genetic study. *C. Haynes[1], E. Crew[1], C. Blach[1], E.R. Hauser[1], J.E. Stajich[1], B.D. Slotterbeck[1], J.B. Rimmler[1], J.V. Vance[1], J.R. Gilbert[1], S.R. Brewster[2], A.D. Roses[2], P.K. Manasco[2], M.A. Pericak-Vance[1]*. 1) Duke Univ Med Ctr, Durham, NC; 2) GlaxoWellcome R & D, RTP, NC.

The identification of genetic risk factors in complex phenotypes is a rapidly expanding area. The success with which genes are discovered depends on many factors including the availability of large well-defined clinical populations. Multiple accrual sites allow genetic studies of complex phenotypes access to the large numbers of families needed for a successful study. However, capturing and maintaining the data necessary in such a global enterprise can be challenging. We have developed a prototype system that employs optical scanners to ensure consistent, dependable, and accurate data collection for a series of multicenter projects. Ascertainment is a two step process; first, there are established general forms used by all sites across several disease projects that collect general past medical history, ethnicity, and family history data common to all studies. The second phase is study specific and includes disease-specific clinical and epidemiologic forms. Data are collected, scanned, and verified at each accrual site which eliminates transcription errors and errors associated with manual data entry. Verified data are then transmitted electronically to the core database site (Duke University). Blood samples are collected using a specially designed form with peel-off bar coded labels that assure the identity of specimens. A key element is that all patient identifying information (name, addresses, contact information, etc) remains in a database local to the original accrual site; only anonymous information (patient identifier number, date of birth, clinical and family structure data, etc) are databased at the central core. This system insures patient confidentiality yet allows patient access for longitudinal studies. Each accrual site has specialized software which enables the site to track and view the complete set of data it has collected. Using this schema we have initiated global ascertainment networks in Parkinson disease, early-onset cardiovascular disease, osteoarthritis and asthma.

Program Nr: 1412 from the 1999 ASHG Annual Meeting

TDT with errors: a likelihood based approach. *S.C. Heath, J. Ott.* Lab Statistical Genetics, Rockefeller Univ, New York, NY.

The Transmission/Disequilibrium Test (TDT) is a non-parametric test for linkage. It does not requires large families, and can have more power to detect small effect loci than conventional linkage analysis methods, and has therefore been proposed as a method for performing genome scans for complex disease loci.

In the absence of genotype errors the TDT is an unbiased test for linkage. However, genotype errors lead to an inflation of the type I error rate whenever marker frequencies are unequal. We present a likelihood based approach for diallelic loci which tests whether the probability of transmission of a '1' allele from heterozygous parents to an affected child is different from 1/2. This is essentially the the same test as the TDT, but can allow for both genotype errors and missing genotype data. As well as the transmission probability (t), the likelihood depends on the genotype frequencies (p) and the error rate (e). These are often unknown, so the test uses their maximum likelihood estimates. To perform the test we calculate the likelihood ratio $T=2\ \mathrm{Log}(p',e',t')/\mathrm{Log}(p\bullet,e\bullet,t=1/2)$, which under the null hypothesis is approximately distributed as a chi-squared variable with 1 df. This test is unbiased in the presence of errors or missing (at random) genotype data. If, however, the data has been 'cleaned' before analysis (i.e., families with Mendelian inconsistencies have been removed), then e will be estimated at 0, and the estimate of t will (normally) be biased. It is therefore important that the test is performed on the original data. If this is not possible then an alternative approach, which we will also discuss, is to use both affected and unaffected offspring, estimating the transmission probability separately for each class of offspring and testing whether the two probabilities differ.

If TDT is to be a useful tool for detecting disease loci and given that genotype errors do exist, it will be necessary to use methods that either explicitly allow for errors or, at least, are robust to the presence of errors. It is hoped that the methods presented here will prove useful in this regard. This work was supported by NIH grants GM58757-01 (SCH) and HG00008 (JO).

Program Nr: 1413 from the 1999 ASHG Annual Meeting

Mapping of the Fanconi Anemia Complementation Group D (*FANCD*) gene to a 200 kb Region on Chromosome 3p25.3. *J.A. Hejna[1], C.D. Timmers[1], C. Reifsteck[1], D.A. Bruun[1], L.W. Lucas[1], P.M. Jakobs[1], S. Toth-Fejel[1], N. Unsworth[1], S.L. Clemens[1], D.K. Garcia[2], S.L. Naylor[2], M.J. Thayer[3], S.B. Olson[1], M. Grompe[1], R.E. Moses[1]*. 1) Dept. of Molecular & Medical Genetics, Oregon Health Sciences University, Portland, OR; 2) Department of Cellular and Structural Biology, University of Texas Health Science Center, San Antonio, TX; 3) Vollum Institute, Oregon Health Sciences University, Portland, OR.

Fanconi anemia (FA) is a rare, autosomal recessive disease characterized by pancytopenia, sensitivity of cells to DNA cross-linking agents, and a predisposition to cancer. Of the eight known complementation groups, group D is rare, represented by only one family in the OHSU FA Cell Repository. Microcell-mediated chromosome transfer (MMCT) of a neomycin-marked human chromosome 3 into an immortalized FA group D fibroblast cell line, PD20, has localized the gene to chromosome 3p22-26. Marker analysis of a non-complemented microcell hybrid, PD20-3-8, sub-localized *FANCD* to an 8cM region centered around marker D3S1597, between D3S3591 and D3S3589. To narrow the region further, an additional 250 microcell hybrids were produced and analyzed. Of these, 7 remained sensitive to mitomycin C (MMC) and diepoxybutane (DEB). Three of these clones had lost the informative markers D3S3591, D3S1597, D3S1317, and D3S1263, suggesting that a large deletion had occurred during chromosome transfer. The remaining four clones retained the D3S1597 marker, suggesting the presence of small deletions adjacent to but not including D3S1597. A 1.2 Mb BAC/P1 contig was constructed, centered around D3S1597 and bounded by D3S3691, telomeric, and the gene ATP2B2, centromeric. Using BACs as probes, fluorescent in situ hybridization (FISH) analyses of the four additional non-complemented PD20 hybrids identified a small region of overlapping deletions. The overlapping deletions in these five independent non-complemented microcell hybrid cell lines localize *FANCD* to a 200 kb region on 3p25.3.

Program Nr: 1414 from the 1999 ASHG Annual Meeting

MISSENSE MUTATION E318G OF THE PRESENILIN-1 GENE IS ASSOCIATED WITH INCREASED RISK IN FINNISH ALZHEIMERS DISEASE PATIENTS. *S. Helisalmi[1, 2], M. Hiltunen[1, 2], A. Mannermaa[2], A.M. Koivisto[1], M. Lehtovirta[1], M. Ryynänen[3], I. Alafuzoff[1, 4], H. Soininen[1].* 1) Department of Neurology, Kuopio Univ Hospital and Kuopio Univ, Kuopio, Finland; 2) Chromosome and DNA laboratory, Kuopio Univ Hospital, Kuopio, Finland; 3) Unit of Clinical Genetics, Kuopio Univ Hospital, Kuopio, Finland; 4) Department of Pathology, Kuopio Univ, Finland.

Several different missense mutations of the presenilin-1 (PS-1) gene cosegregate with early onset Alzheimers disease (AD) in an autosomal dominant manner. The role of missense mutation E318G in exon 9 is controversial since it has been reported to cause AD as well as to be a rare polymorphism not related to AD. We have studied the frequency of the E318G variant in Eastern Finnish AD and control populations. Sequencing of the coding region of PS-1 from 16 unrelated familial cases revealed four patients with E318G mutation. No other PS-1 gene mutations or polymorphisms were detected. Additional 64 sporadic neuropathologically confirmed definite AD cases and 235 clinically verified controls and 35 neuropathologically confirmed controls were screened for the E318G variant using PCR-RFLP method. The E318G variant allele frequency was 25%, 11% and 4% in familial, sporadic and control cases, respectively. This data indicates increased risk of disease both in familial ($p = 0.005$; OR 7.6 (2.2-25.7)) and in sporadic AD cases ($p = 0.03$; OR 3.1 (1.1-8.2)) when compared to controls. In addition, genotyping of the microsatellite markers D14S77 and D14S1025, located at the vicinity of the PS-1 gene, showed that these markers were in linkage disequilibrium in the AD patients group carrying the E318G mutation. This data suggests that the E318G variant is likely nonpathogenic, because some controls also carried this change. However, it is possible that the variant is in linkage disequilibrium with pathogenic change elsewhere in PS-1 gene (e.g. promoter region).

Program Nr: 1415 from the 1999 ASHG Annual Meeting

Fine mapping and analysis of linkage disequilibrium in chromosome 15 linked autosomal recessive familial amyotrophic lateral sclerosis (*ALS5*). *A. Hentati[1], Y. Yang[1], K. Ouahchi[1], W-Y. Hung[1], F. Hentati[2], T. Siddique[1]*. 1) Dept Neurology, Northwestern Univ Med Sch, Chicago, IL; 2) Institut National de Neurology, Tunis, Tunisia.

Autosomal recessive amyotrophic lateral sclerosis (RFALS) is a rare form of motor neuron disease. RFALS is distinguished from the more common sporadic and autosomal dominant forms of amyotrophic lateral sclerosis by an earlier age at onset and slower progression of the disease symptoms. Clinical and genetic locus heterogeneity have been established in RFALS. We have previously mapped *ALS5*, the most common locus for RFALS to a 6-cM interval between D15S146 and D15S123 on chromosome 15q15-q22. None the markers that were available in this interval showed linkage disequilibrium with *ALS5* in three families from Tunisia. However, these markers were not evenly distributed and linkage disequilibrium was not excluded from two sub-segments between D15S214 and D15S514 and between D15S222 and D15S515. Here we report the refinement of *ALS5* to a smaller segment between D15S129 and D15S222. We have also isolated three new CA repeat markers from PACs that mapped to the ALS5 candidate region. One marker, 199I16R, maps between D15S214 and D15S514 and two markers, 112B14R and 18K11-2, map between D15S222 and D15S515. There was no linkage disequilibrium between 119I16R and ALS5. However, the alleles from markers 112B14 and 18K11-2 that are associated with the *ALS5* mutation were identical in two of the three families from Tunisia. These data strongly suggest *ALS5* maps in a 4-Mb segment between D15S214 and D15S222 and that more than one mutation causes *ALS5* in the Tunisian population.

Program Nr: 1416 from the 1999 ASHG Annual Meeting

New program: AUTOSCAN 1.0 automated use of linkage analysis programs. *T. Hiekkalinna, L. Peltonen.* University of California, Los Angeles, Department of Human Genetics, CA.

The use of linkage analysis programs consists of multiple file handling processes and production of input files specific for various statistical programs. This basically trivial process is time consuming and error prone since it repeats basic steps multiple times. Our aim was to develop a helper program to automate the tedious process of the creation of input files from genotype data of genome-wide scans, which would allow efficient analyses of several different phenotypic traits. In practice, this program enables the analyses of a whole genome-wide scan for all chromosomes in a single run. Our Unix-shell-script program AUTOSCAN automatically creates data files, uses MAKEPED (converts pre-linkage format files to linkage format), DOWNFREQ (estimates allele frequencies from pedigree data), and PEDCHECK (Mendelian checking) programs and finally starts statistical analyses via the ANALYZE package. ANALYZE performs parametric linkage analysis (MLINK), nonparametric affected sib-pair analysis (ASP), family-based association analysis (TDT, HRRR), and homogeneity testing (HOMOG). Input files for AUTOSCAN are the pedigree files for all chromosomes, the disease model file, the number of loci file, and the ANALYZE input file. The AUTOSCAN also allows easy handling of several phenotype traits and trait features by only changing the disease model file after each run. The program has now been tested by several research groups in the Department of Human Genetics, UCLA, and is available for downloading from our web page http://www.genetics.ucla.edu/software/autoscan.

Program Nr: 1417 from the 1999 ASHG Annual Meeting

Genome-wide linkage disequilibrium mapping of late onset Alzheimer's disease. *M.J. Hiltunen[1,2], A.J. Mannermaa[2], A.M. Koivisto[2], S. Helisalmi[1,2], M. Lehtovirta[2], M. Ryynänen[3], P. Riekkinen Sr[4], H. Soininen[2].* 1) Department of Neurology, Kuopio Univ Hospital, Kuopio, Finland; 2) Chromosome & DNA Laboratory, Kuopio Univ Hospital, Kuopio, Finland; 3) Unit of Clinical Genetics, Kuopio Univ Hospital, Kuopio, Finland; 4) A.I. Virtanen Institute, Kuopio Univ, Kuopio, Finland.

Alzheimers disease (AD) is a complex neurodegenerative disorder, for which several disease-associated loci have been located on various chromosomes. In order to find novel susceptibility genes for late onset AD, we have performed a population based genome-wide search using linkage disequilibrium mapping. To avoid population stratification, late onset AD patients and age-matched controls were carefully chosen from the same geographical area in Eastern Finland, where the population is mainly descended from a small group of original founders. Initial results from genome-wide search indicated regions in chromosomes 1, 3, 6, 8, 10, 13, 14, 18, 19, 22 and X to be in linkage disequilibrium in the AD population. The more precise examination of the chromosome 13q12 region indicated association with two adjacent microsatellite markers D13S292 and D13S787. Stratification of the AD patients and controls into the groups according to the apolipoprotein E, sex, and familial/sporadic status indicated that 13q12 locus was associated with female familial AD patients regardless of ApoE genotype. Based on the physical data from the region 13q12, markers D13S292 and D13S787 were estimated to reside in a 810 kb long YAC clone 754h7 together with two infant brain-derived ESTs and the H,K-ATPase a-subunit protein gene. The localization of these sequences at the linkage disequilibrium region suggests that they may be candidate genes involved in a sex-specific effect during development of AD.

Program Nr: 1418 from the 1999 ASHG Annual Meeting

Application of high-throughput SNP genotyping to complex endocrine diseases. *J.N. Hirschhorn[1,2], D. Altshuler[1,3], P. Sklar[1,3], S. Bolk[1], K. Lindblad[1], C. Lindgren[4], Y.-M. Lim[1], C.R. Lane[1], J. Nemesh[1], L. Groop[4], E.S. Lander[1]*. 1) Whitehead Institute/MIT, Cambridge, MA; 2) Children's Hospital, Boston, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Lund University, Malmö, Sweden.

Common polygenic diseases have proven largely refractory to classical linkage analysis. It has been proposed that association studies using common sequence variants may provide a more powerful approach to understanding these clinically important genetic disorders. To help test this hypothesis, we developed rapid, reliable technologies to genotype single nucleotide polymorphisms (SNPs) and are applying these technologies to two common endocrine diseases.

Primer-directed, single base extension (SBE) in the presence of fluorescent ddNTPs reliably detects single nucleotide differences. By performing multiplex SBE reactions on multiplex PCR products, we can genotype 50-100 SNPs at once. Each SBE primer contains both a locus-specific sequence and one of 166 generic sequence tags. The multiplex SBE reaction is analyzed by hybridization to a generic array of 166 complementary oligonucleotide tags spotted on a glass slide; each SBE product hybridizes to a different location in the array. The generic array format and high degree of multiplexing allow fast, inexpensive SNP genotyping.

We are in the process of discovering coding SNPs (cSNPs) in over 300 genes relevant to endocrine disease. We have employed SNP-based methods to genotype these cSNPs in ongoing large-scale association studies for type 2 diabetes mellitus and abdominal obesity. The diabetes study involves 370 cases and parental controls (trios) and the abdominal obesity study involves 500 trios with extremes of waist-hip ratio. We perform transmission disequilibrium testing and thereby avoid false-positive associations due to ethnic admixture. In addition to novel cSNPs, we have typed all SNPs that have been previously associated with type 2 diabetes in case-control studies. Surprisingly few of the reported associations were found to be replicable, likely due to poopulation admixture confounding the original case-control studies and/or the rarity or absence of some SNPs in our populations.

Program Nr: 1419 from the 1999 ASHG Annual Meeting

A genome-wide scan for susceptibility genes for type 1 diabetes in scandinavian families.. *P. Holm[1], K. Åkesson[1], C.S. Bartsocas[3], G. Dahlquist[3], A. de Levia[3], C. Juliér[2], I. Kockum[1], M. Lathrop[2], H. Luthman[1], J. Nerup[3], F. Pociot[3], K.S. Rønningen[3]*. 1) Department of Molecular Medicine, Rolf Luft's Centre for Diabetes Research, Karolinska Institute, Sweden; 2) The Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) European Consortium for IDDM Genome Scan (ECIGS).

Type 1 diabetes is a complex autoimmune disease, where particular alleles in the HLA region on chromosome 6p21 show a major contribution to the disease susceptibility. Previous studies of type 1 diabetes involving MZ twins and HLA identical sibs have shown that the major genetic contribution is from the HLA region. Other genes outside the HLA region are also involved. Identification of genes outside the HLA complex requires a large family and population material, preferably from homogenous populations. ECIGS (European Consortium for IDDM Genome Scan) was formed in order to perform a comprehensive linkage analysis with the aim to identify genes in other regions than HLA that may increase the risk for type 1 diabetes. A genome-wide scan was performed in 89 Norwegian families (102 concordant sib pairs), 183 Swedish families (220 concordant sib pairs), and 152 Danish families (174 concordant sib pairs), using 321 fluorescent markers with an average spacing of 11 cM. Non-parametric allele sharing methods were used for linkage analysis. Linkage was confirmed to two previously reported regions, IDDM1 on chromosome 6p21.3 (HLA) and IDDM15 located centromeric to HLA on chromosome 6, and two new regions also showed significant linkage to type 1 diabetes.

Program Nr: 1420 from the 1999 ASHG Annual Meeting

Methods for detecting genetic interactions using affected sib pairs. *P. Holmans, J. Rice.* Psychiatry, Washington Univ., St Louis, MO.

It is likely that several loci contribute to the genetic susceptibility to complex diseases, and that considerable interactions between these loci may exist. If two loci interact epistatically, a positive correlation is expected between the number of alleles shared identical by descent (ibd) at each locus, whereas heterogeneity should produce a negative correlation.

We consider three methods for detecting such interactions. Firstly, one can calculate the estimated ibd sharing for each sib pair at locations corresponding to lod score peaks obtained by single locus analysis, and test for a significant correlation. Secondly, one can select the pairs for which the estimated ibd is greater (if testing for epistasis) than a pre-determined value at the first locus. The test statistic for the second locus is calculated using only these pairs, and its significance determined by comparison with results obtained from samples of equivalent size randomly selected from the dataset. The third method models the probability that a sib pair inherit an allele ibd from a given parent as a logistic regression with the number of alleles shared ibd at the first locus included as a covariate.

Expected lod scores were calculated under a variety of two locus models, to determine the circumstances under which detection of interactions may be feasible. The statistical powers of the methods were compared by applying them to datasets containing sibships of various sizes simulated under these models.

Program Nr: 1421 from the 1999 ASHG Annual Meeting

Allele frequency estimation and comparison by SNP genotyping of genomic DNA pools. *B. Hoogendoorn, M.J. Owen, N. Williams, N. Norton, J. Austin, M.C. O'Donovan.* Dept Psychological Medicine, Univ Wales Col Medicine, Cardiff, Wales.

The ability to efficiently and cheaply genotype single nucleotide polymorphisms in large samples is fundamental to molecular genetic analysis of disease and, in particular, common complex diseases. We have combined primer extension analysis of SNPs with denaturing high performance liquid chromatography (DHPLC) (Hoogendoorn et al. 1999). After amplification of a fragment of DNA containing the SNP, an oligonucleotide primer is annealed immediately upstream from the polymorphism. In the presence of the appropriate dNTPs and ddNTPs, the primer is extended by one or more bases depending upon the sequence at the polymorphic site. The alleles are then distinguished on the basis of size of the extended product after DHPLC. We have used this method to screen pooled DNA samples to estimate and compare allele frequencies of SNPs. Our data suggest that this technique will allow accurate measurement of both the absolute allele frequencies in the pooled samples and the difference in allele frequency between pooled DNA samples from affecteds and controls. Thus, the analysis of pooled DNA samples by primer extension and DHPLC offers an efficient and relatively inexpensive method for screening large numbers of candidate polymorphisms in large sample sizes.

Program Nr: 1422 from the 1999 ASHG Annual Meeting

Power and false positive rates in two-stage genomic screens. *A.M Hossain, J.L. Haines, M.E. Garcia.* Program in Human Genetics, Vanderbilt Univ. Med. Center, Nashville, TN.

A 2-stage approach to genomic screens involves an initial screen using a low threshold and then a test of positive regions in a second data set. The goal is to reduce the amount of genotyping necessary and to eliminate false positive findings by requiring replication. To test the 2-stage screening strategy, we employed the Erehwon population of the GAW11 problem 2 simulated data sets (Greenberg, et al., Genetic Epi, in press) which consisted of 2500 families with sib-pairs and parents. The underlying genetic model had 3 loci, two of which interacted, spaced among 300 highly informative markers. We generated 1000 replicates of data sets of 100 or 200 families. We randomly picked 2 of the 1000 sets to create the initial and second data sets and this was done 1000 times. The data were analyzed using ASPEX. Peak regions were defined by choosing Maximized Lod Scores (MLS) of at least 0.5, 0.75, or 1.0 for any marker; markers with MLS lower than the criterion but located no more than 10cM away from the peak were considered part of the region.

Not surprisingly, sample size affected the power to replicate the true regions (using MLS=0.5, 58.1% power with 100 families and 81.6% with 200). However, replication of false positives remained high despite the increase in sample size (18.5% vs. 17.7%). Higher MLS critical values reduced the false positive rates but also decreased the power. With MLS=1.0, the false positive rates were reduced to 6% for both 100 and 200 families, but the power decreased to 31.4% (100 families) and 56.0% (200 families). Thus, a 2-stage approach using the same criterion in both data sets may not achieve its goal of weeding out false positive results while maintaining power.

Another problem in genomic screening is localization. The average distance between the true locus and the peak in either the first or second data set was 11-12cM, while the distance between peaks in the two data sets was 13-14cM. The distance between peaks for false replications was not substantially different at 12cM.

Program Nr: 1423 from the 1999 ASHG Annual Meeting

Transmission/disequilibrium test (TDT) approach at the van der Woude syndrome (vWS) locus in familial nonsyndromic cleft lip with or without cleft palate (NSCL/P). *C. Houdayer[1], V. Soupre[2], G. Morgant[1], A. Munnich[3], M.-P. Vazquez[2], M. Bahuau[1,2]*. 1) Service de Biochimie et Biologie Moléculaire, Hôpital Trousseau, Paris, France (biochimie.trousseau@trs.ap-hop-paris.fr); 2) Service de Chirurgie Maxillofaciale et Réparatrice et Stomatologie, Hôpital Trouseau, Paris, France; 3) Service de Génétique Médicale, Hôpital Necker Enfants-Malades, Paris, France.

NSCL/P is a most common congenital malformation condition in humans. Inheritance is generally regarded as multigenic, allelic variation at different loci (TGFa, TGFb3, RARA, etc.) determining a fraction of the genetic risk, as demonstrated by association/TDT studies. On the other hand, vWS is a rare autosomal dominant clefting condition with cardinal features of lower-lip pits (the highest penetrant trait), and CL/P or cleft palate (alone), present in half of the gene carriers. The *vWS* gene has been localized to a 1.6-cM region in 1q32, also containing highly polymorphic marker D1S3753 and flanked by D1S205 and D1S491. Some vWS families harbor a more or less extended deletion at this locus, indicating that vWS proceeds by haploinsufficiency. In order to investigate possible involvement of the *vWS* locus in genesis of NSCL/P, we opted for a TDT approach based on 45 NSCL/P trios selected from 45 multiplex NSCL/P families. Patients and their parents were screened using markers D1S205, D1S491, and D1S3753 (kindly provided by Jeffrey C. Murray, University of Iowa). As expected, no deletion was observed in any of the 45 kindreds. Chi square analysis for transmitted vs. non-transmitted alleles of the three markers yielded no value significantly departing from random assortment. These results indicate that either *vWS* is not a locus for NSCL/P or that a substantially larger cohort is needed for detecting association.

Program Nr: 1424 from the 1999 ASHG Annual Meeting

Fine-mapping of a putative schizophrenia susceptibility locus on chromosome 1q32 identified in a genetic isolate of Finland. *I. Hovatta[1,2], T. Varilo[1], P. Ellonen[1], R. Arajärvi[2], J. Lönnqvist[2], L. Peltonen[1].* 1) Department of Human Molecular Genetics, National Public Health Institute, Helsinki, Finland; 2) Department of Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland.

We have performed a genomewide search for genes predisposing to schizophrenia in a northeastern community of Finland, representing a genetic subisolate inhabited by 40 families some 300 years ago. Ancestors of the studied schizophrenia families with two or more affected were traced back to the 17th century, and 80% of the families were shown to be interrelated via multiple links between ancestors, the most simple links leading to a single founder couple born about 1650. We carried out a genome scan based initially on the monitoring of shared marker alleles among affecteds and subsequently on segregation analyses in core families. We identified four chromosomal regions showing lod scores >1.0 in two-point parametric linkage analysis: 1q32 (Zmax=3.82), 4q31 (Zmax=2.74), 9q21 (Zmax=1.95), and Xp11 (Zmax=2.01). The chromosome 1 region seemed most interesting after the initial scan, not only because of the highest lod scores obtained, but also for a putative 6.6 cM haplotype segregating in four schizophrenia families. Further, an independent sib pair-based genome scan from Finland also provided encouraging lod scores with markers on this region. We have now genotyped altogether 23 markers on about 10 cM region surrounding the haplotype and ordered them in radiation hybrid panels. 20 families with at least two affected siblings and additional 61 families with one affected patient from the isolate were used. We are implying various linkage and linkage disequilibrium based statistical tests to monitor for allelic association and shared chromosomal haplotypes to narrow down the positive region, still farely wide for positional cloning attempts.

Program Nr: 1425 from the 1999 ASHG Annual Meeting

A database of human chromosome 21 SNPs: A tool for association studies to dissect the contribution of minor loci to complex diseases. *A. Imhof, S.E. Antonarakis, H.S. Scott.* Division of Medical Genetics, University of Geneva Medical School, Geneva, Switzerland.

Minor loci for 3 complex phenotypes have been mapped to human chromosome 21 (HC21) by conventional linkage studies including loci controlling Schistosoma mansoni infection intensity (EJHG 1999 7:88), familial combined hyperlipidemia (AJHG 1999 64:1453-63), and bipolar affective disorder (e.g. AJHG 1999 64:210). Several monogenic human disorders have been mapped to HC21 and the genes for some of these disorders identified. Due to its small size (the smallest human chromosome) and medical importance (trisomy 21 causes Down syndrome), HC21 has acted as a model for genomic studies and will be among the first human chromosomes to have its sequence entirely determined (the non-repetitive 21q) as finished genomic sequence. There are already 116 known HC21 genes, mainly telomeric to 21q22.1, a large region the minor loci for the above complex disorders map. Thus an excellent infrastructure exists to identify HC21 SNPs to use in association studies of the diseases above, providing an opportunity to study the efficiency of a high density of SNPs in revealing minor loci for complex diseases. We are using 3 search strategies to identify HC21 specific SNPs by blastn. The following sequences are searched against all human database entries; i) HC21 mRNA sequences, ii) consensus contigs constructed from HC21 STSs identical to HC21 genomic sequence (including ESTs) against all human database entries and iii) HC21 genomic sequence. SNPs are automatically extracted from the blast analyses by a parsing program according parameters for frequency and quality. Putative SNPs and alignments are available at http://medgen.unige.ch/snps/genes1.html. We have already identified 152 putative HC21 SNPs from 60 of the 93 human HC21 genes analysed, 50 from coding regions of the genes (at least 2 independent database entries for each sequence variant). Several SNPs have been confirmed by allele specific oligonucelotide (ASO) hybridization. We are presently testing three SNPs on ASO nitrocellulose coated microarrays as a feasibility study to scale up to a HC21 SNP chip to allow high throughput analyses.

Program Nr: 1426 from the 1999 ASHG Annual Meeting

Mutation in Europe, Polymorphism in China. *M. Jeanpierre[1], Y. Zhang[1,2], J. Forner[1], J.A. Urtizberea[3], H. Cann[4], J.C. Kaplan[1], F. Qishi[2]*. 1) Port-Royal Hospital, Paris, France; 2) Ruijin Hospital, Shanghai, China; 3) Institut de Myologie, Paris, France; 4) CEPH, Paris.

Facioscapulohumeral muscular dystrophy, one of the major forms of muscular dystrophy, is associated with deletions of a 3.3 tandemly repeated sequences (D4Z4) in the subtelomeric region on the long arm of chromosome 4. The link between D4Z4 rearrangement (fragment <28 kb) and the muscular dystrophy is not understood and still a mystery. The proof that the variation of number of repeated sequences is the cause of the disease and not merely an associated polymorphism stems from the concomitant occurrence of de novo D4Z4 rearrangements and a severe clinical course. Since facioscapulohumeral muscular dystrophy is about three time less frequent in Asian populations than European populations, D4Z4 mutation rates should vary in these populations or the consequences of the mutation should not be the same in Europe and Asia. We have studied 155 Shanghai inhabitants and observed short EcoRI fragments (25-28 kb) in 7 individuals, normal upon clinical examination by an experienced neurologist. Further studies made unlikely that these short fragments originate from the homologous chromosome 10 locus. Since the distribution of D4Z4 mutations is skewed toward shorter sizes (<24kb) in Chinese FSHD patients, the frontier between normal and disease alleles must depend on genetic background.

Program Nr: 1427 from the 1999 ASHG Annual Meeting

Molecular analysis of *FBN1*in 3 families with Marfan syndrome. *J.W. Jennings, J.D. Ranells, D.R. Hilbelink, B.G. Kousseff, O.T. Mueller.* Pediatrics/Genetics, University of South Florida, Tampa, FL.

Upon performing a phenotypic analysis of 104 individuals evaluated for MFS for the purpose of re-evaluating the diagnoses in light of the revised criteria for MFS, molecular studies of the fibrillin-1 gene (FBN1) were then performed on 3 families. This involved linkage analysis, heteroduplex mismatch analysis, exonal cloning, restriction digest, and sequencing.

In two families linkage served to identify an affected allele in prepubescent individuals who otherwise did not have the major manifestations of MFS as seen in other family members. In a large MFS family displaying intrafamilial heterogeneity, a novel missense mutation (D757N) was identified in exon 18. The change involved the substitution of a guanine for an adenine at the first position of codon 756, and the aberrant exon was identified in all five affected members by mutation detection analysis, DNA sequencing and by the creation of a novel EcoRI restriction site. The mutation resulted in the substitution of asparagine for the wild type, aspartic acid, in the seventh calcium binding EGF-like domain of the fibrillin-1 protein in a non-consensus region. Likewise, 2 polymorphisms (i.e. exon 18-46 A/G and exon 56 +17 G/C) cosegregated with the affected allele.

In the other family linkage analysis showed that the mother and her two daughters carried the affected FBN1 allele, 3 neutral sequence changes were identified in exon 15, intron 17 and intron 40. No sequence alterations were found. Only one individual from the third family with a definitive diagnosis of MFS was available for testing due to his father's death. Mutation screening revealed no mutations or polymorphisms in the affected individual and his two sons.

These methods isolated a novel mutation and four neutral polymorphisms, indicating that the methods were sensitive enough in identifying sequence alterations. These results support the genetic heterogeneity surrounding the Marfan-like phenotype, suggest that mutations in FBN1 as well as other genes contribute to such, and express the need to locate other genes responsible by linkage and/or candidate gene strategies.

Program Nr: 1428 from the 1999 ASHG Annual Meeting

Identification of seven novel single-nucleotide polymorphisms (SNPs) at the human tissue-type plasminogen activator (t-PA) locus; Association between a polymorphic Sp1 binding site and vascular t-PA release. *C. Jern*[1,2], *P. Ladenvall*[1], *U. Wall*[1], *S. Jern*[1]. 1) Clinical Experimental Research Laboratory, Heart and Lung Institute, Sahlgrenska University Hospital/Ostra, Goteborg University, Sweden; 2) Institute of Clinical Neuroscience, Deptartment of Neurology, Sahlgrenska University Hospital, Goteborg University, Sweden.

We recently reported that an Alu insertion polymorphism of the tissue-type plasminogen activator (t-PA) gene is associated with vascular t-PA release rates in man. Aim of the study was to search for putative functional genetic variants linked with this polymorphism. DNA from healthy individuals with a miscellany of Alu genotypes and t-PA release rates were studied. Upstream regulatory as well as 3-flanking regions were subjected to direct DNA sequencing and coding regions were screened by SSCP analysis. In total, 8.2 kb genomic sequence were examined. Seven single nucleotide polymorphisms (SNPs) were identified. Three of these were in linkage disequilibrium with the Alu polymorphism; one in an upstream regulatory region, one in exon 6, and one in intron 10. The upstream SNP resides within a Sp1 binding motif, and gel shift analysis revealed stronger binding of Sp1 to the C than the T allele. Subjects homozygous for the C allele (the most conserved Sp1 motif) had more than twice the t-PA release rate than subjects carrying the T allele. Variations in exon 6 and intron 10 were silent and without effect on splicing, respectively. Our findings suggest that the newly identified SNP in the Sp1 binding site contributes to the physiological t-PA expression in vivo.

Program Nr: 1429 from the 1999 ASHG Annual Meeting

Characterization of the Chromosome 16p13.1 PXE locus in an Afrikaner population. *E.W. Johnson[1,2], K.A. Curry[1], J.M. Peloquin[1], S.M. Novak[2], C.G. Dokken[2], S.F. Terry[3], L.G. Bercovitch[4], D. Viljoen[5], C.D. Boyd[6]*. 1) Neurogenetics, Barrow Neurological Institute, Phoenix, AZ; 2) Marshfield Medical Research Foundation, Marshfield, WI; 3) PXE International, Sharon, MA; 4) Dept. of Dermatology, Brown University, Providence, RI; 5) SAIMR, Dept. of Human Genetics, Univ. of Witwatersrand, Johannesburg, South Africa; 6) The Pacific Biomedical Research Center, Univ. of Hawaii, Honolulu, HI.

Pseudoxanthoma elasticum (PXE) is a disorder of the connective tissue that shows both autosomal dominant and autosomal recessive inheritance patterns. PXE causes calcification of the elastic fibers mainly effecting the vascular and ocular systems. Previous research has narrowed the locus for a gene for PXE to a region on chromosome 16p13.1 between markers D16s3079 and D16s3103. We have through the efforts of PXE International, obtained DNA from an extended Afrikaner population affected with familial PXE. In this study we attempt to narrow this locus using 15 STRP markers that define the critical interval described above. Initial results indicate that there is a common Afrikaner haplotype in a number of affected individuals from several different families in this population. This common haplotype spans the entire critical interval in many families. The presence of this common affected haplotype indicates that at least some of the affected members of the Afrikaner community shared a common ancestor affected with familial PXE in the not so distant past. To date there is no indication of any ancestral crossover events in the families examined that would aid in narrowing the critical interval where the PXE gene might be found. There are several families where incomplete family collection has limited our ability to define haplotype completely and accurately. Efforts are currently underway to collect DNA from crucial individuals from these families and to define familial haplotype in an effort to uncover informative ancestral crossover events.

Program Nr: 1430 from the 1999 ASHG Annual Meeting

Haplotype analysis of markers on chromosome 2q21.2-q22 in nemaline myopathy in the Amish: Evidence for genetic heterogeneity. *J.J. Johnston[1], R.I. Kelley[2,3], D.H. Morton[2,3], T.O. Crawford[4], L.G. Biesecker[1], C.A. Francomano[1]*. 1) NHGRI, NIH, Bethesda, MD; 2) Department of Pediatrics, Johns Hopkins University, Baltimore, MD; 3) The Clinic for Special Children, Strasburg, PA; 4) Department of Neurology, Johns Hopkins University, Baltimore, MD.

We have previously described an autosomal-recessive form of nemaline myopathy. This disorder of both muscle and central motor function has an incidence of 1 in 500 among the Lancaster County Old Order Amish. The disease has become known as "chicken breast disease" among the Amish because the affected children develop a severe pectus carinatum preterminally. The first signs of the disease appear at birth with excessive jitteriness, ankle clonus, and multiple large joint contractures, although some mothers report abnormal vibratory fetal movements from the 7th month gestation. The jitteriness resolves as the children lose their deep tendon reflexes over the first two to three months. Thereafter they remain hypotonic, but later they develop a rigid pectus carinatum with progressively restricted thoracic movement and die of pulmonary insufficiency in the second to fourth year. Intelligence throughout is normal. Quadriceps muscle biopsy of three children showed disproportionately small type I myofibers with Z-band streaming and abundant nemaline rods. Nebulin is a skeletal muscle protein that is believed to regulate the assembly of Z disks, and nebulin mutations have been identified in families with recessive nemaline myopathy. We have collected DNA from a large Old Order Amish pedigree including samples from seven affected children to perform linkage analysis. Our initial studies have focused on nebulin as a candidate gene for this disorder. Haplotype analysis of several microsatellite markers from the 4-centimorgan region surrounding the nebulin gene on chromosome 2q21.2-q22 has shown recombination between the markers and the disease, excluding nebulin as a candidate gene for this disorder, and demonstrating genetic heterogeneity among families with autosomal recessive nemaline myopathy. We are now focusing on a genome wide screen to identify the gene which is responsible for this disorder in the Amish population.

Program Nr: 1431 from the 1999 ASHG Annual Meeting

Unravelling the genetic complexity of cleft lip in the mouse model, the A/WySn strain. *D.M. Juriloff, M.J. Harris.* Dept Medical Genetics, Univ British Columbia, Vancouver, BC, Canada.

Cleft lip, CL(P), in the A/WySn mouse strain models human CL(P) in genetic complexity and in embryopathology. It is not yet known whether the genetic components are homologs of human genetic CL(P) risk factors. Previously, we mapped a recessive causative gene, *clf1*, to Chr 11 near *D11Mit10*, using a congenic strain. In this study, using a genome screen for linkage on affected segregants after a cross of A/WySn with the normal strain C57BL/6J (1299 first backcross embryos) and using testcrosses of AXB/BXA Recombinant Inbred strains, we have demonstrated an epistatic relationship between *clf1* and a second recessive locus, *clf2*. High risk of CL(P) requires simultaneous homozygosity for "A" strain alleles at both loci. Homozygosity at either locus alone is not sufficient to cause CL(P).

The map position of *clf1* was confirmed to be a 2 cM region between *D11Mit146* and *D11Mit166*, linked to *Neurod2*. The *clf2* locus maps to Chr 13, near *D13Mit13*, linked to *Neurod3*. As both CL(P) loci are linked to paralogs, they may themselves be paralogs in conserved duplicated linkage groups, and functional redundancy may be the origin of the epistasis and complex transmission genetics.

Genetic maternal effects on risk of CL(P) confer another layer of genetic complexity. The prerequisite epistatic genotype for CL(P) in embryos interacts with maternal genotype; A/WySn mothers produce the maximum risk of CL(P). Genetically equivalent first backcross embryos in F1 mothers had no CL(P) in contrast to 2.7 percent in A/WySn mothers ($P<.05$). Reciprocal crosses between A/WySn and AXB-6/Pgn produced 20 percent and 10 percent CL(P) in A/WySn and AXB-6/Pgn mothers, respectively ($P<.05$).

We suggest that a similar combination of epistatic interaction and genetic maternal effects may contribute to the genetic complexity of risk of human CL(P).

Program Nr: 1432 from the 1999 ASHG Annual Meeting

An NdeI polymorphism 3' to the T-cell receptor b **chain gene may be restricted to individuals of African-American ancestry.** *J.A. Kant[1], Z-Y. Chen[1], W.T. Hofgärtner[1], K. Okuyama[1,2].* 1) Dept Pathology, S764B Scaife, Univ Pittsburgh Medical Ctr, Pittsburgh, PA; 2) Dept Obstetrics/Gynecology, Hokkaido University School of Medicine, Sapporo 060, Japan.

T-cell receptor (TCR) b chain gene rearrangement is used to identify clonal T-lineage lymphoproliferative processes using Southern blot analysis with any of a number of restriction endonucleases. The enzyme NdeI is a useful enzyme in these studies because it detects rearrangement into both b D-J-C loci and produces a modestly smaller germline restriction fragment of 21.0 kb than the more-commonly used BamHI. We recently reviewed a consecutive series of 337 patient samples analyzed with NdeI, 7 of which demonstrated an apparent polymorphism as an additional 27 kb germline fragment. This is a useful observation for investigators performing clonality assays to avoid a possible misdiagnosis. All samples demonstrating the polymorphism for which information about ethnic background was available (6 of 7) came from individuals of African-American descent. We have confirmed by direct DNA sequencing of both strands in all samples demonstrating the 27 kb germline fragment that the polymorphism results from a G>A transition at nucleotide 206319 of the Genebank sequence U66061. Studies are underway to define the distribution of this polymorphism in a broader series of African-American, Hispanic and Asian samples.

Program Nr: 1433 from the 1999 ASHG Annual Meeting

Genetic studies on Finnish families with familial hemiplegic migraine. *M. Kaunisto[1,2], M. Kallela[1], P. Marttila[3], M. Färkkilä[1], H. Havanka[4], E. Hämäläinen[2], I. Hovatta[5], A. Orpana[2], L. Peltonen[3], A. Palotie[3], M. Wessman[1,2].* 1) Departments of Biosciences and Neurology, University of Helsinki, Helsinki, Finland; 2) Laboratory of Helsinki University Central Hospital, Helsinki, Finland; 3) Departments of Pathology and Human Genetics, UCLA, LA, USA; 4) Länsi-Pohja Central Hospital, Kemi, Finland; 5) Department of Human Molecular Genetics, National Public Health Institute, Helsinki, Finland.

Familial hemiplegic migraine (FHM) is an autosomal dominant subtype of migraine with aura. Patients with FHM have migraine attacks which are associated with hemiparesis or hemiplegia. In addition, some patients have progressive cerebellar ataxia. The gene for approximately a half of the reported FHM-families has been localized to chromosome 19p13. This gene, *CACNA1A*, encodes the a1A subunit of a P/Q-type voltage-gated calcium channel. 5 different missense mutations in *CACNA1A* (in FHM) have been published so far. FHM has shown to be a genetically heterogeneous disease after 2 groups found linkage to chromosome 1q.

We studied 9 families (71 members) fulfilling the IHS diagnosis criteria for FHM. These families originate from a database of 255 Finnish migraine families. Altogether 25 subjects were classified as affected: they fulfilled the IHS criteria for migraine with aura and had some degree of hemiparesis with their attacks. We analyzed the families for linkage to 3 chromosomal areas (19p13, 1q21-23 and 1q31) previously linked to FHM. 3 of the 9 families gave suggestive evidence for linkage to 19p13 showing positive lod scores with several markers. The total maximum LOD score was 3.3. For these families haplotypes segregating with the disease were determined. This data gave evidence against a major founder effect. Evidence for linkage to chromosome 1q was not obtained. We are currently screening these families for mutations in *CACNA1A* gene. So far no mutations have been found in 15/47 exons. These 15 exons include all previously published FHM mutation sites. However, we observed 4 previously described polymorphisms. Our data indicates that the Finnish FHM-mutations at least in these families are different from the previously published ones.

Program Nr: 1434 from the 1999 ASHG Annual Meeting

Refinement of the locus for Autosomal Recessive Retinitis Pigmentosa (RP25) linked to Chromosome 6q in a family of Pakistani Origin. *S. Khaliq[1,2], A. Hameed[2], M. Ismail[2], S.Q. Mehdi[2], D.A.R. Bessant[1], A.M. Payne[1], S.S. Bhattacharya[1]*. 1) Molecular Genetics, Inst. Ophthalmology, London, London, UK; 2) Research Laboratories, Biomedical and Genetic Engineering Division, Islamabad, Pakistan.

Retinitis pigmentosa (RP) is a clinically and genetically heterogeneous group of retinal degenerations primarily affecting the rod photoreceptors. RP is characterised by progressive loss of vision, initially manifesting as night blindness and reduction in the peripheral visual field, and later involving loss of central vision (Bird 1985). Recently linkage of arRP to a region on chromosome 6q has been reported in several Spanish families (Ruiz et al. 1998) We studied 20 members of a 3 generation consanguineous Pakistani family with arRP. To identify the locus responsible for disease in this family we performed homozygosity analysis. Significant linkage was obtained for 3 markers on chromosome 6q in region of a previously reported locus (RetNet). A maximum lod score value of 3.30 at q. = 0.00 was observed for markers D6S257 and D6S1053 on chromosome 6q. Recombination events involving the centromeric marker D6S1053 and the telomeric marker D6S430 permitted refinement of the 6q arRP (RP25) disease critical region from the previously reported 16.1cM (Ruiz et al. 1998) to 2.4cM.The GABA receptor candidate genes were proposed as candidates for this phenotype by Ruiz et al. (1998) in their initial linkage paper. The recombination events seen in our family exclude both GABRR1 and GABRR2 as the disease gene and the area of homozygosity observed by Ruiz et al. We cannot however exclude the possibility that there are in fact two arRP loci located in close proximity on 6q, one in the Spanish population and one in the Pakistani population. The 2.4 cM critical interval contains no well characterised candidate genes, but numerous ESTs. Further analysis of these cDNA clones will be needed before mutation screening in this family can be undertaken. The identification of a family of Pakistani origin in addition to the 5 Spanish families suggests that this may be an important gene for arRP.

Program Nr: 1435 from the 1999 ASHG Annual Meeting

Identification of new microsatellite markers on chromosome 4p16. *G. Kirov, M.J. Owen.* Neuropsychiatric Genetics Unit, UWCM, Cardiff, UK.

Chromosome 4p16 has been implicated as a candidate region in psychiatric genetics due to several positive reports from linkage studies in manic depressive illness and schizophrenia. The region is being sequenced by Stanford Human Genome Center and the raw data is made freely available to the genetic community. The availability of raw unfinished sequence data allows the identification of new polymorphisms in this area. We present our approach to identifying such polymorphisms.

Methods: Firstly, we examine sequenced BAC clones with the programme SPUTNIK (http://www.abajian.com/sputnik) which identifies di-, tri, tetra- and pentanucleotide repeats. It assigns a score to each repeat based on its length and how perfect the repeat is. Thirty-eight primer pairs flanking the promising repeats were designed, based on available sequence, and 30 of those amplified successfully. In order to assess whether a marker is polymorphic we analyse only two individuals and the products from a pool from 60 individuals. In most cases this was sufficient to determine whether the marker is polymorphic, as well as to assess the range of alleles and make a judgement about its heterozygosity.

Summary of results: We have examined so far 9 BAC clones which cover an area of ~1.5Mb between markers D4S827 and D4S2983 and attempted to place at least two markers per clone. This achieves an approximate saturation of one marker at every ~100,000 bp with no gaps longer than ~150,000 bp (The size of the clones varied between 150,000 and 200,000 bp). Seven microsatellites were already available in GDB. Our method identified 12 additional markers with a heterozygoisity of 0.2 or higher. As expected, CA repeats were more likely to be polymorphic but we also identified three tetra- and one trinucleotide repeat with four or more alleles. This study confirms that it is possible to saturate this region of interest with microsatellite markers spaced at an average of 100,000 bp which will allow linkage disequilibrium mapping. Our protocol allows for one research worker to screen ~1Mb of sequence in one to two weeks.

Program Nr: 1436 from the 1999 ASHG Annual Meeting

Genetic linkage of adult onset primary open angle glaucoma to chromosome 3q in a Greek pedigree. *G. Kitsos[1], H. Eiberg[2], E. Economou-Petersen[3], M.K. Wirtz[4], P.L. Kramer[4], M. Aspiotis[1], N. Tommerup[2], M.B. Petersen[5], K. Psilas[1]*. 1) Dept Ophthalmology, Univ Ioannina, Ioannina, Greece; 2) Inst Med Biochem Genet, Univ Copenhagen, Copenhagen, Denmark; 3) Drakopoulion Blood Bank Center, Athens, Greece; 4) Oregon Health Sciences Univ, Portland, Oregon; 5) Inst Child Health, Athens, Greece.

A locus for juvenile onset primary open angle glaucoma (POAG) was assigned to chromosome 1q in families with autosomal dominant inheritance (GLC1A), due to mutations in the TIGR gene. For adult onset POAG, five loci have so far been mapped by linkage analysis in families with autosomal dominant mode of inheritance and age-dependent penetrance: GLC1B to 2cen-q13, GLC1C to 3q21-q24, GLC1D to 8q23, GLC1E to 10p15-p14, and GLC1F to 7q35-q36, showing the high degree of genetic heterogeneity in POAG. Except for the GLC1B locus, the other loci for adult onset POAG have so far been reported only in single large pedigrees, and their contribution to POAG worldwide has therefore not been established. We have studied a large family identified in Epirus, Greece, segregating adult onset POAG in an autosomal dominant fashion. Fifteen affected family members were identified from 40 at-risk individuals above 30 years of age (75% penetrance). Clinical findings included increased cup to disc ratio, characteristic changes in the visual field, and untreated intraocular pressure more than 21 mmHg, with age at diagnosis 30 years and older. Linkage was established with a group of DNA markers located on 3q, where the GLC1C locus previously had been located. Multipoint linkage analysis between the disease phenotype and microsatellite DNA markers located on chromosome 3q gave a maximum lod score of 4.22 for marker D3S1763. This represents the second adult onset POAG family linked to the GLC1C locus on chromosome 3q, and microsatellite analysis in the two families demonstrated no allele sharing within the most likely region of linkage, indicating that the genetic defect most probably was of independent origin.

Program Nr: 1437 from the 1999 ASHG Annual Meeting

Recombination breakpoint analysis for autosomal dominant exudative vitreoretinopathy (FEVR) gene. *H. Kondo[1], H. Hayashi[2], K. Oshima[2], T. Tahira[1], K. Hayashi[1].* 1) Division of Genome Analysis, Inst. Genet. Information, Fukuoka, Fukuoka, Japan; 2) Department of Ophthalmology, Fukuoka University School of Medicine, Fukuoka, Japan.

Autosomal dominant exudative vitreoretinopathy (FEVR) is an ocular disorder that affects the development of retinal vasculature and causes retinal detachments in the youth as well as retinal folds in infants. Many large families with FEVR were identified especially in the Netherlands and Japan, but linkage analysis has not been reported in Japanese family. FEVR gene locus was previously localized in 11q13-23 and closely linked to microsatellite markers D11S533 and D11S873 in European and Asian families of unidentified ethnic origin. However, the region of FEVR gene locus has not been delineated. In the present study, seven microsatellite markers including two markers above in 11q13 were analyzed in 37 individuals who belong to eight Japanese FEVR families. Two-point linkage analysis revealed that FEVR was linked to all markers in seven out of eight families although the combined LOD scores were not significant (Zmax = 2.4 at theta = 0). Next, alleles in the seven families were haplotyped according to the parent of origin. The disease haplotype was preserved in all affected individuals in the six families. However, in the seventh family, the centromeric recombination was found in one affected individual at most proximal marker (D11S1314) while telomeric recombination was found in another affected individual at the second distal marker (D11S873). Thus the critical region was narrowed to 15.2 cM. Analyses are in progress to further narrow the region.

Program Nr: 1438 from the 1999 ASHG Annual Meeting

Genomic screen for linkage of May-Hegglin anomaly. *J.F. Korczak[1], W. Jawien[2], A.Y. Lin[3], K. Hoffmeister[2], M.J. Kelley[4]*. 1) Georgetown Univ Med Ctr, Washington, DC; 2) National Naval Med Ctr, Bethesda, MD; 3) Santa Clara Valley Med Ctr, Santa Clara, CA; 4) Duke Univ Med Ctr, Durham, NC.

May-Hegglin anomaly (MHA; MIM#155100), an autosomal dominant platelet disorder, is characterized by the triad thrombocytopenia, giant platelets, and inclusion bodies in the leukocytes. About 30% of affected individuals have mild to moderate hemorrhagic symptoms and are frequently misdiagnosed and subjected to inappropriate treatments. Although about 300 cases have been reported, the genetic defect for MHA has not been identified, nor have functional studies revealed its etiology.

We evaluated three families with multiple cases (9, 2, and 2) of MHA in several generations, with affected individuals evenly distributed across genders (7 males and 6 females), and performed a genomic screen for linkage to identify chromosomal region(s) to which the MHA locus may map. Sufficient power to detect linkage was demonstrated by the program SIMLINK. Based on 200 replicates, the estimated mean and maximum lod scores at a recombination fraction of 0.05 (for a 10 cM map) were 3.3 and 6.4, respectively, assuming a rare, autosomal dominant gene with complete penetrance. DNA from 34 individuals (12 of 13 with MHA) was genotyped for 386 markers spaced 10 cM apart of the CHLC version 9 set at the Center for Inherited Disease Research (CIDR). Nonparametric two-point sib-pair linkage methods (affected sib-pair (ASP) and Haseman-Elston regression (H-E)), implemented in the S.A.G.E. (3.1) program SIBPAL, were used to test for linkage. Possible regions containing the MHA gene were suggested on chromosomes 3, 10, and 22, based on nominal *P*-values £ 0.01 for two or more adjacent markers for the ASP and/or H-E tests.

We are performing two-point lod score analysis to corroborate our findings and genotyping additional markers in regions of interest for multipoint analysis. We have also ascertained additional multiplex families to fine-map the MHA gene prior to undertaking a positional candidate approach to identify it.

Program Nr: 1439 from the 1999 ASHG Annual Meeting

Towards positional cloning of the Meckel Syndrome gene. *M. Kyttala[1,2], P. Paavola[2], R. Salonen[3], L. Peltonen[1,2].* 1) Human Genetics, University of California L.A., Los Angeles, CA; 2) Department of Human Molecular Genetics, National Public Health Institute, Helsinki, Finland; 3) Department of Obstetrics and Gynecology, Helsinki University Hospital, Finland.

Meckel Syndrome (MKS; MIM 249000) is an autosomal resessive congenital malformation syndrome leading to death soon after birth. The clinical phenotype of MKS includes central nervous system malformations, occipital meningo-encephalocele, polycystic kidneys, cystic and fibrotic changes in the liver, and polydactyly. In Finland the prevalence of MKS at birth is estimated to be 1:9000. MKS has been mapped in Finnish population into chromosome 17q22-23, but the locus heterogenity in study samples from other populations has also been reported with a linkage to chromosome 11q13 (Roume et al., 1998). We have restricted the critical chromosomal region on 17q to 700 kb using linkage disequilibrium and ancient haplotype in Finnish disease alleles. We have built a multiple coverage physical contig of PAC and BAC clones over this region and ordered them using visual mapping by fiber FISH, as well as end sequencing of the clones to develop new STS`s for screening of clones and securing the overlaps between the clones. There are total of 10 known genes and 30 EST contigs in databases in this restricted DNA region. Complete information of multiple genomic clones on the region is also available from genome databases. We isolated novel CA repeats from these clones and two of them provided almost complete allelic assosciation with the MKS (lambda:0,98; p-value<10-15) and suggests an immediate vicinity of MKS gene to these markers located 70 kb apart from each other. This information provides now basis for the final isolation of the MKS gene. We are currently sequencing coding regions of genes and EST contigs in Finnish MKS patients to search for MKS-associated DNA variations.

Program Nr: 1440 from the 1999 ASHG Annual Meeting

Multiple Trait Locus Nonparametric Linkage Regression. *C.D. Langefeld, M. Boehnke.* Biostatistics, Sch Public Hlth, Univ Michigan, Ann Arbor, MI.

Complex genetic traits may exhibit incomplete penetrance, phenocopies, heterogeneity and polygenic inheritance. Thus, improving the efficiency of linkage methods in the localization of complex disease loci and in the placement of loci and environmental factors into functional groups, may require methods that jointly consider the effects of genetic heterogeneity, epistatis and environmental factors. We propose and examine the performance of a class of nonparametric (mode-of-inheritance free) linkage (NPL) methods based on conditional logistic regression. The primary advantage of this regression approach is that it easily extends to tests of an arbitrary number of loci, other phenotypic variables, environmental factors and their interactions. For independent affected sibling pairs (ASP), we show that when the proportion of alleles shared identical by descent (IBD) is observed, the ASP mean test and the score test from a one-locus conditional logistic regression model are asymptotically equivalent tests of linkage. When the IBD proportion is observed, the single- and multiple- locus regression models have the appropriate type I error rates. When the IBD proportion is estimated, the type I error rates of the large-sample tests can be larger than the nominal level; under these conditions, we propose a permutation test. Whittemore and Halpern (1994) proposed a general class T of NPL tests based on scoring functions of all possible inheritance vectors configurations of the observed marker genotypes within a pedigree. This class of tests does not require that the mode of inheritance be specified or the IBD proportions be observed. We show that the single-locus score test from conditional logistic regression is asymptotically equivalent to T. In simulations of two popular members of T implemented in GENEHUNTER, NPL(pairs) and NPL(all), the single-locus NPL regression model have appropriate type I error rates. We discuss and illustrate extensions to multiple loci, other phenotypic variables, environmental factors and their interactions.

Program Nr: 1441 from the 1999 ASHG Annual Meeting

Promoter sequence studies of the *LGALS3* (galectin-3) gene in insulin-dependent diabetes mellitus. *Z. Larsen, O.P. Kristiansen, J. Johannesen, J. Nerup, F. Pociot.* Steno Diabetes Center, Gentofte, Denmark.

Galectin-3 is a b-galactoside-specific lectin found in many species and cell types. The gene is located on the long arm of chromosome 14 (14q21). Results from genome-wide screenings and partial ones have showed some evidence for linkage in the Galectin-3 gene region, *D14S276*. In the present study we have screened for polymorphisms in the promoter region and the intron 2 of the Galectin-3 gene which also has showed promoter activity. Combining SSCP (Single Stranded Conformation Polymorphism) and cycle sequencing methods we have identified 3 polymorphisms within 60 bp of the promoter region. Two of the polymorphisms are single base substitutions leading to different restrictions sites (*MseI* and *StuI*). The third polymorphism is a 12 bp deletion which also lead to a different restriction sites (*Eco0109I*). All three polymorphisms have high heterozygosity and were analysed for linkage to IDDM in a large homogeneous Danish family material comprising 251 families (1041 individuals) with 410 IDDM-affected offspring. Transmissions of wildtype (W) and mutant (M) alleles from heterozygous parents to offspring are shown in the table below:

	IDDM W/M	non-IDDM W/M
MseI (-715)	154/140	105/98
Eco0109I (-698)	160/157	100/114
StuI (-659)	106/110	56/66

The numbers in brackets are the distance from the transcription site. Even though Galectin-3 is a very promising candidate gene for IDDM we found no linkage to IDDM of the identified polymorphisms. An etiological mutation may still be found in the coding region of the gene, the 3UTR or combinations leading to specific haplotypes.

Program Nr: 1442 from the 1999 ASHG Annual Meeting

Genetic heterogeneity of Paget's disease of bone: exclusion of linkage to the *PDB1* and *PDB2* loci in French-Canadian pedigrees. *N. Laurin[1], J. Brown[2], A. Duchesne[1], C. Brousseau[2], D. Huot[2], Y. Lacourcière[2], G. Drapeau[2], J. Verreault[2], V. Raymond[1], J. Morissette[1]*. 1) Molecular Endocrinology, CHUL Research Center, Ste-Foy, Qc, Canada; 2) Immunology and Rhumatology, CHUL Research Center, Ste-Foy, Qc, Canada.

Paget's disease of bone (PDB), characterized by high bone remodeling and large, multinucleated osteoclasts, is transmitted as an autosomal dominant trait in some families. Two PDB disease loci: *PDB1* and *PDB2*, have been mapped to chromosome 6p21.3 and 18q21.1-q22, respectively. We reported previously that 4 French-Canadian PDB families were not linked to *PDB2*. Genetic linkage analysis has now been extended to 12 additional families with at least 2 affected first degree relatives. Diagnosis of PDB was based on total serum alkaline phosphatase, total body bone scan and skull and pelvis x-rays. Amongst the 552 individuals who have been recruited, 123 were diagnosed PDB, 265 normal and 164 unknown. Four Généthon markers spanning *PDB2* (D18S64 to D18S68) were selected. The largest pedigree (2 families) was also genotyped with 8 additional markers extending this region to 18q12.2-q23 (D18S1157 to D18S1161). No support for linkage as well as no characteristic "disease" haplotype were observed in any of the families tested. Negative lod score values below -2.00 were calculated for each of the 6 largest pedigrees. A partial genome scan was then performed with 7 selected individuals and markers spanning candidate loci for bone traits/disorders: chromosome 1 (low mineral density), 5 (craniometaphyseal dysplasia), 8 (multiple exostoses), 9 (diaphyseal medulary stenosis), 10 (spondyloepimetaphyseal dysplasia), 11 (high bone mass), 17 (Van Buchem) and 22 (minor histocompatibility Ag). None of these regions remained as candidate. A complete genome scan using Généthon markers is now in progress. Linkage to chromosome 2 and *PDB1* at 6p has already been excluded in the 3 most informative families. Our data shows that the gene(s) responsible for PDB in the French-Canadian population is/are not located at *PDB1*, *PDB2* nor on chromosome 2, demonstrating genetic heterogeneity of the disorder.

Program Nr: 1443 from the 1999 ASHG Annual Meeting

Myostatin promoter sequence and frequent allelic variation in the coding sequence. *E.C. Lawrence[1], B.F. Hurley[2], S.M. Roth[2], J.M. Hagberg[2], R.E. Ferrell[1]*. 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Dept. of Kinesiology, University of Maryland, College Park, MD.

Myostatin, also known as growth and differentiation factor 8, is a recently identified member of the transforming growth factor-beta family of regulatory molecules. Mutations in this gene caused the double-muscled phenotype in cattle and "compact" hypermuscular phenotype in mice. We ascertained a sample of Caucasian (N=107) and African American (N=41) individuals who had responded to strength training with a significant increase in muscle mass, and a second group of individuals (N=48) who were classified as non-responders on the basis of an undetected increase in muscle mass with strength training. The study sample was sequenced for the three myostatin exons and the promoter region. The coding sequence contained five missense substitutions in amino acid residues that are conserved in all mammalian myostatins sequenced to date (A55T, K153R, E164K, P198A, and I225T). Two of these, A55T in exon 1 and K153R in exon 2, are polymorphic in both the study population and in a random sample of Caucasians (N=96) and African Americans (N=96), and both the study group and the random sample showed significantly different allele frequencies between the Caucasian and African American individuals ($p<0.001$). Neither of the common polymorphisms was significantly associated with muscle mass response to strength training in either Caucasians or African Americans, although skewed allele frequencies preclude detection of small effects. No variation was detected in the myostatin promoter. The promoter contains a consensus MyoD response element at position -185, consistent with myostatin acting downstream of the myogenic transcription factor, MyoD, in muscle development.

Program Nr: 1444 from the 1999 ASHG Annual Meeting

Linkage Analysis of Calcium Channel Genes in Typical Migraine Families. *R.A Lea[1], D.R Nyholt[2], R.P Curtain[1], K.L Jordan[1], L.R Griffiths[1]*. 1) Genomics Res Ctr, Sch Hlth Sci, Griffith University-Gold Coast, Southport QLD, Australia; 2) Laboratory of Statistical Genetics, Rockefeller University, New York.

Migraine is a prevalent neurological disorder characterised by recurrent attacks of debilitating headache. The disease is genetically heterogeneous although the type and number of genes involved is still unknown. Mutations in the neuronal calcium channel gene (CACNA1A) have been shown to cause FHM, a rare and severe subtype of migraine [1]. Independent linkage analyses suggest that there are two FHM loci on chromosome 1 near the calcium channel genes CACNA1E and CACNA1S [2,3]. These findings suggest that calcium channel genes may also be involved in the more common types of migraine (with and without aura). We have previously reported linkage to CACNA1A in a large typical migraine family [4] and are currently performing linkage analyses on markers located in other calcium channel gene regions. 108 migraine families including 8 large multigenerational pedigrees have been genotyped for markers spanning the FHM implicated loci on chromosome 1 and results analysed using the GENEHUNTER-PLUS program. Although one large multigenerational family displayed some excess allele sharing, multipoint analysis of combined results significantly excluded the markers surrounding CACNA1S and CACNA1E (LOD < 2). These results indicate that if this locus plays a role in migraine it probably contributes only a small genetic effect to the disease. Other neuronal calcium channel gene markers located across the genome are currently being investigated in our migraine families. 1. Ophoff et al (1996). Cell;87:543-552 2. Gardener et al (1997). Program Nr: 1445 from the 1999 ASHG Annual Meeting

Fine-mapping and mutational analyses of cerebrotendinous xanthomatosis in US pedigrees. *M.H. Lee[1], S. Yi[1], J.D. Carpten[2], J. Cohen[3], G. Salen[4], G.T. Gerhardt[5], S. Patel[1]*. 1) Medicine, Medical University of SC, Charleston, SC; 2) Prostate-Cancer Investigation Group Laboratory of Cancer Genetics, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) University of Texas Southwestern Medical Center, Dallas, TX; 4) University Medical and Dental New Jersey, VA Hospital, East Orange, NJ; 5) Oregon Health Sciences University Department of Medicine, Portland , OR.

Cerebrotendinous xanthomatosis (CTX) is a rare Autosomal Recessive disorder of bile acid biosynthesis. Clinically, CTX patients present with tendon xanthomas, juvenile cataracts, progressive neurological dysfunction and can be diagnosed by the detection of elevated plasma cholestanol levels. CTX is caused by mutations affecting the sterol 27 hydroxylase gene. CTX patients have been identified in a number of populations, but seems to be more prevalent in the Japanese, Sephardic Jewish and Italian populations. We have assembled 12 previously unreported pedigrees and one other proband from the US. The CYP27 locus had been previously mapped to chromosome 2q33-qter. We initially fine mapped this locus to a YAC contig and used a set of flanking microsattelite markers to genotype all of the biochemically diagnosed patients with CTX. All CTX patients showed segregation with the CYP27 locus, suggesting that there is no genetic heterogeneity for this rare phenotype. Haplotype analyses and recombinant events allowed us to precisely map CYP27 between markers D2S1371 and D2S433. Fifteen mutations were identified from 9 probands analyzed thusfar; 8 had heterozygous mutations and one had a homozygous mutation. Of these, seven are novel mutations (Arg94Tyr, Arg94Gln, Tyr100Stop, Lys226Arg, Pro408Cys, Gln428Stop and a 10 bp deletion in exon 1 of CYP27 gene). In summary, we have fine mapped the CYP27 locus, identified 7 more mutations and structure-function studies are underway to correlate phenotype-genotype.

Program Nr: 1446 from the 1999 ASHG Annual Meeting

Genome wide linkage analysis for vacuolating leukoencephalopathy. *P.A.J. Leegwater[1,2], A.M. Könst[1], J. Mulders[1,3], C.B.M. Oudejans[1], R.B.H. Schutgens[1], J.C. Pronk[3], M.S. Van der Knaap[2].* 1) Clinical Chemistry, Academic Hospital; 2) Child Neurology, Academic Hospital; 3) Human Genetics, Medical Faculty, Free University, Amsterdam, The Netherlands.

Vacuolating leukoencephalopathy (VLE) is a pediatric neurologic disorder with macrocephaly and progressive cerebellar ataxia. Magnetic resonance imaging of the brain shows impressive abnormalities of the cerebral white matter which appears to be diffuse and swollen. Subcortical cysts are always present. Histopathology demonstrates the presence of numerous vacuoles between the outer lamellae of myelin sheets of the central nervous system. VLE follows autosomal recessive inheritance and the disease occurs in a variety of ethnic groups. We have performed a genome wide scan for linkage between VLE and microsatellite markers with an average spacing of 11 cM. Only 3 affected children from different first-cousin marriages were typed in the first round of analysis. Genomic regions that are identical by descent in these patients can be expected to span 20 - 30 cM. Therefore, we scored a patient positive for a region when at least 2 adjacent markers were homozygous in that region. Regions that were indicative for linkage in at least 2 of the 3 patients were analysed in additional patients. A similar strategy proved to be of great value for the localization of another childhood neurologic disorder. Eleven candidate regions were evaluated in the expanded population of 15 patients from 10 families. These families are from varying ethnic origin. Thus far, we have eliminated 7 of the 11 candidate regions. The remaining candidate regions around D2S1777, D4S1644, D17S122 and D21S1432 are further investigated with closely spaced markers.

Program Nr: 1447 from the 1999 ASHG Annual Meeting

Protective effect of CYP2D6*4 allele in Ulcerative Colitis. *S. Lesage[1,2], M. Chamaillard[1,2], JF. Colombel & EPIMAD[2], J. Belaiche & the GETAID[2], JP. Cezard & EPGWGPIBD[2], C. Tysk[2], S. Almer[2], M. Gasull[2], H. Zouali[1,2], J. Macry[2], G. Thomas[1,2], JP. Hugot[1,2].* 1) Fondation Jean Dausset, Paris, France; 2) European Concerted Action on the Genetics of the Inflammatory Bowel Diseases.

Background : The CYP2D6 enzyme (debrisoquine-hydroxylase) has a role in the metabolism of a wide range of drugs. The main polymorhism allele associated with poor metaboliser phenotype is CYP2D6*4 which is characterised by a mutation in the splicing site : 1934 G/A. An association has been recently described between CYP2D6*4 allele and Ankylosing Spondylitis (AS). This observation prompted us to analyse this polymorphism in Inflammatory Bowel Diseases (IBD) which are known to be associated with AS.

Aim of the study : To determine whether CYP2D6*4 allele is associated with IBD.

Patients and methods : A total of 395 IBD families with at least one affected child were genotyped for the 1934 G/A polymorphism. Out of these families, 247 had only Crohns Disease (CD) patients, 56 had only Ulcerative Colitis (UC) patients, and 92 mixed families had both CD's and UC's patients. The DNA samples from family members were typed by a PCR-RFLP method. Genotyping data were analyzed using a transmission disequilibrium test (TDT-like from the Analyse package).

Results : The CYP2D6*4 allele was less often transmitted to UC's patients than expected by chance (14 transmitted alleles versus 36 ; $p = 0.002$). In contrast, the CYP2D6*4 allele was equally transmitted to the CD patients (90 transmitted alleles versus 96 ; $p = 0.660$) and healthy relatives (106 transmitted alleles versus 100 ; $p = 0.676$).

Conclusion : The CYP2D6*4 allele may have a protective effect for UC. It suggests that a CYP2D6 normal metabolism pathway seems to be necessary to develop the disease.

Program Nr: 1448 from the 1999 ASHG Annual Meeting

Multicenter linkage study of schizophrenia candidate regions on chromosomes 5q, 6q, 10p and 13q. *D.F. Levinson.* Dept Psychiatry, University of Pennsylvania, Philadelphia, PA.

From the Schizophrenia Linkage Collaborative Group III (DF Levinson, SE Antonarakis, JL Blouin, PV Gejman, P Holmans, KS Kendler, C Laurent, BJ Mowry, MJ Owen, AE Pulver, AR Sanders, SG Schwab, RE Straub, DB Wildenauer, N Williams and collaborators). A multicenter sample has been formed for a series of linkage studies of schizophrenia candidate regions. The eight clinical samples have been collected by the seven collaborating groups (at University of Bonn, University of Chicago, Johns Hopkins University, LGN/CNRS, Virginia Commonwealth University, University of Queensland/University of Pennsylvania/Mt. Sinai Medical School/University of Iowa, and University of Wales) and by the NIMH Schizophrenia Genetics Initiative. In the present study, 32 markers within candidate regions on chromosomes 5q, 6q, 10p and 13q were genotyped in a total of 859 pedigrees including more than 1,900 typed individuals affected with schizophrenia or schizoaffective disorder, with an average of 970 affected sibling pairs typed per marker. Planned analyses include multipoint NPL and likelihood-based affected sibling pair analyses for each sample and for the combined sample using Genehunter 2.0 (based on separate allele frequency estimates for each sample), and a logistic regression analysis incorporating sample as a covariate to estimate the significance of heterogeneity as well as overall marker allele sharing. Preliminary NPL and ASP analyses have been completed for the eight individual samples. Different patterns of results have been observed across the four regions: the number of samples producing an NPL score > 1.0 was 4, 5, 5 and 1 respectively for chromosomes 5q, 6q, 10p and 13q; the number of samples producing an NPL score > 2.0 was 1, 2, 3 and 1 respectively; while an NPL score > 3.0 was observed for one sample for chromosome 6q and one sample for chromosome 13q. Interpretation of the results should await analyses of the combined sample, as well as the logistic regression analysis. The complete analysis will be available for presentation at the meeting.

Program Nr: 1449 from the 1999 ASHG Annual Meeting

Use of the internet for family study recruitment. *K.L. Levinson, R.E. Ferrell, D.N. Finegold.* Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Recruitment of large families with rare genetic diseases is arduous. The internet as a recruitment method for family studies offers advantages to both participants and researchers. We report on the use of a world wide web page (www.pitt.edu/~genetics/lymph) to disseminate information about primary lymphedema, solicit participation in a lymphedema linkage study, and update participants on the progress of the research. In the 675 days since the creation of the web page on August 22, 1997, there have been 16,660 hits to the site, with an average of 25 hits per day. Of the 84 families recruited into the study, 24 were recruited before the web page was created, and 40 of the remaining 60 families were recruited from the internet (67%). Lymphedema Family Study participants are located in 47 US states and 6 Canadian provinces as well as Australia, New Zealand, France, and England. Individuals recruited into the study have provided DNA samples leading to the identification of vascular endothelial growth factor receptor-3 as a causative gene for primary lymphedema. Further analysis of families unlinked to 5q34-35 will ultimately lead to the identification of additional causative genes.

Similar approaches may be useful for other research groups. Researchers may use the internet to reduce the labor intensive contact of multiple uninterested families, while considerably expanding the pool of potential subjects from which to recruit. Participants benefit from initial anonymity by requesting information about the study without disclosing any personal identifiers. Drawbacks do exist, however, since families at a distance have no opportunity for personal contact with the researchers, and many individuals have no access to the internet. While the internet appears suitable for recruitment of families for linkage studies aimed at identifying disease-causing genes, families recruited by this mechanism are likely to exhibit more severe phenotypes or highly penetrant mutations. Affection status, particularly for conditions with variable expressivity, may require confirmation by medical records or physician examination.

Program Nr: 1450 from the 1999 ASHG Annual Meeting

Dominantly inherited myasthenia gravis as a separate genetic entity unlinked to the acetylcholine receptor subunit genes and collagen-like tail subunit gene. *F.Y. Li[1], A. Szobor[2], S. Komoly[2], R. Croxen[3], D. Beeson[3], C. Larsson[1]*. 1) Department of Molecular Medicine, CMM L8:01, Karolinska Hospital, S-171 76 Stockholm, Sweden; 2) Department of Neurology, Jahn Ferenc Teaching Hospital, Semmelweis University Medical School Affiliate, Kves u. 2-4, Budapest-1204, Hungary; 3) Neurosciences Group, Institute of Molecular Medicine, John Radcliffe Hospital, Headington, Oxford OX3 9DS, U.K.

Myasthenia gravis (MG) is an organ specific autoimmune disease characterized by muscular weakness and autoantibodies against the nicotinic acetylcholine receptor (AchR). MG without autoantibody against AchR does also exist. Mutation analysis indicates that the changes of AchR subunit genes, CHRNA1 (2q24-q32), CHRNB1 (17p12-11), CHRNE (17p13-p12), CHRNG (2q21.1-21.3) or collagen-like tail subunit (COLQ) (3p24.3-3p25) are responsible for congenital myasthenic syndrome (CMS). MG occurs in both sporadic and familial forms. The vast majority of MG cases are sporadic, although familial forms are reported in up to 4 % of the cases. We present here a large Hungarian family where nine members from two generations are affected by MG. In order to establish weather MG in this family represents a separate genetic entity or is a variant linked to any of the genes known to be mutated in CMS, the family members were genotyped with microsatellite markers covering the candidate regions. Multipoint linkage analysis gave the lod scores smaller than -2 for makers within those regions. Thus, those genes are excluded as candidate genes for this family and MG in this family represents a separate genetic entity. Establishment of the underlying genetic defect in this family will add to the knowledge of MG pathogenesis.

Program Nr: 1451 from the 1999 ASHG Annual Meeting

The Additive Genetic Gamma Frailty Model for Linkage Analysis of Age-at-onset Variation for Complex Diseases. *H. Li.* Rowe Program in Human Genetics, University of California, Davis School of Medicine, Davis, CA.

Age of onset is a key factor in the linkage analysis of many complex diseases. Current methods in nonparametric linkage analysis are mainly concentrated on the affected relative pairs or affected family members with age of onset information either ignored or taken into account by specifying age-dependent penetrances for liability classes. On the other hand, gamma frailty models were developed in the biostatistics literature to model familial aggregation of age of onset. However, these frailty models can not be used directly for linkage analysis. This paper extends the gamma frailty model by incorporating inheritance vector information and provides a semiparametric approach for linkage testing. For a given inheritance vector at the putative disease locus, we construct an additive genetic gamma frailty for each individual within a nuclear family and use the Cox proportional hazard model to model age of onset. We derive the conditional hazard ratio parameter for sib pairs and define a likelihood ratio based LOD score statistic under our model. The EM algorithm is used for estimating the parameters and the maximum likelihood functions. Simulation study indicated that the proposed method is well behaved and can be more powerful than the non-parametric linkage (NPL) score statistic of GENEHUNTER. The method can be regarded as the variance-component linkage analysis method for age-at-onset data.

Program Nr: 1452 from the 1999 ASHG Annual Meeting

Perl as a Tool for Linkage Analysis. *W. Li[1], F. Haghighi[2]*. 1) Lab Statistical Genetics, Rockefeller Univ, New York, NY; 2) Dept. of Genetics and Development Columbia University, New York, NY.

For an analyst, linkage analysis entails a series of steps involving preparation of input files for specification of both the disease model and pedigree structure, and manipulation of output files to obtain the desired results. These steps are often repetitive, and when accomplished manually can be extremely time consuming and error-prone. We propose to automate such tasks with the aid of Perl scripts. Perl is a very portable programming language that allows for easy manipulation of numbers and text, files and directories and external programs. Besides UNIX, it is availab1e on MS-DOS, Win 95/NT, Macintosh and many other operating systems. Perl is widely used in computer system administration, Web based applications, and bioinformatics. We describe three examples where Perl scripts are used to facilitate linkage analysis: (1) Genome-wide linkage analysis maybe automated given the adoption of a consistent file-name notation. This involves analyzing a large pool of markers covering all 23 chromosomes, where we iteratively traverse all the chromosomes and analyze the marker data using programs from the LINKAGE package or GENEHUNTER. (2) Multiple models are often considered in the effort to find gene(s) underlying complex disorders with unknown etiologies. These models can range in complexity and can include combinations of many factors, such as different levels of disease severity, age and sex dependent penetrances, and environmental effects. For traditional linkage analysis, the input files, namely the parameter file defining the disease model and the pedigree file corresponding to the different liability classes can be quickly generated via a Perl script given a user defined disease model. (3) In assessing a putative linkage result for a marker, it is useful to examine the ranking and magnitude of individual family lod scores. The rankings maybe obtained by parsing the linkage output file and extracting the maximum individual family lod scores by a Perl script. The Perl scripts featured here as well as others are available to the research community at http://linkage.rockefeller.edu/soft/perl.

Program Nr: 1453 from the 1999 ASHG Annual Meeting

Identification of a novel locus for non-syndromic autosomal dominant hearing loss. *X.C. Li[1], S. Angeli[2], T.B. Friedman[3], R.A. Friedman[1]*. 1) CMB, House Ear Institute, Los Angles, CA; 2) Dept. of Otorhinolaryngology, Hospital San Juan de Dios, Fundacion Venezolana de Otologia, Caracas, Venezuela; 3) LMG, NIDCD, NIH, Rockville, MD.

Hearing loss is the most common sensory defect in humans. About one in every 1000 children is affected by severe hearing loss at birth or during early childhood. More than 50% of these cases are due to genetic cause with extensive genetic heterogeneity. A genetic linkage study was conducted on a large Venezuelan family with nonsyndromic autosomal dominant hearing loss. The age of onset of the deafness in this family is in the first decade and there is rapid progression leading to profound hearing loss. The deafness gene segregating in this family is mapped to a 14 cM interval on chromosome 2q, distal to DFNA16. Lod scores >3 were obtained with several markers from this region. This interval harbors PAX3 gene and several cochlear specific ESTs.

Program Nr: 1454 from the 1999 ASHG Annual Meeting

The serotonin transporter gene contributes to the genetic risk of alcoholism. *D. Lichtermann[1], D. Hranilovic[2], P. Franke[1], M. Trixler[3], M. Knapp[4], S.G. Schwab[1], W. Maier[1], D.B. Wildenauer[1].* 1) Department of Psychiatry, University of Bonn, Sigmund-Freud-Str 25, D-53105 Bonn, Germany; 2) Department of Organic Chemistry and Biochemistry, Ruder Boskovic Institute, Zagreb, Croatia; 3) Department of Psychiatry and Medical Psychology, University Medical School of Pecs, Hungary; 4) Institute for Medical Statistics, University of Bonn, Sigmund-Freud-Str 25, D-53105 Bonn, Germany.

Studies in rodents and humans have pointed to a relationship between low brain serotonin turnover and high alcohol intake that may play a crucial role in the initiation and maintenance of alcoholism. Decreased availability of serotonin transporter protein has been found in post-mortem and brain imaging studies of patients with alcoholism. A polymorphism in the promoter of the serotonin transporter gene with differential effect on transcription rate and serotonin uptake function is therefore a prime candidate for an alcoholism susceptibility gene. Initial findings of an association with alcoholism in samples of unrelated cases and controls have, however, failed replication in additional case-control studies and in one less stratification-prone family-based study or at best yielded a trend toward association with the dissocial subtype of alcoholism. This is the first study to convincingly confirm the association in a sample of 92 probands with alcohol dependence (rated by structured interview according to DSM-IV diagnostic criteria) and their parents by Transmission/diseqilibrium test (p=0.0056). The result encourages further studies to explore whether the currently limited benefits of alcoholism treatment with drugs enhancing serotonergic neurotransmission can be increased by targeting it to individuals with this specific genetic vulnerability.

Program Nr: 1455 from the 1999 ASHG Annual Meeting

DNA sequence variation in the fibroblast growth factor receptor (FGFR) genes. *D.L. Lind, D.R. Cox.* Dept. of Genetics, Stanford University, Stanford, CA.

Spontaneous mutations in three of the four FGFR genes have been identified which cause a variety of autosomal dominant diseases. A single disease-causing amino acid change has been found in FGFR1 which causes Pfeiffer Syndrome. 22 disease-causing amino acid changes have been found in FGFR2 which cause Apert Syndrome, Beare-Stevenson Cutis Gyrata, Crouzon Syndrome, Jackson-Weiss Syndrome, and Pfeiffer Syndrome. 16 disease-causing amino acid changes have been found in FGFR3 which cause Achondroplasia, Crouzon Syndrome, Hypochondroplasia, non-syndromic craniosynostosis, Saethre-Chotzen Syndrome, and Thanatophoric Dysplasia Types I and II. To date no disease-causing mutations have been found in FGFR4. The high frequency of disease-causing mutations found in FGFR2 and FGFR3 compared with FGFR1 and FGFR4 suggests a higher mutation rate in these genes. If this is the case, it may be mirrored by increased frequency of variation in the genomic sequence. We are assessing the genomic variation in all four FGFRs by direct sequencing of PCR products from 12 unrelated CEPH Caucasian individuals. Using genomic sequence for FGFR3 and FGFR4 available in Genbank, 1-2 kb PCR products were tiled across the genomic regions covering 16 kb and 13 kb respectively. In addition, we have sequenced a BAC containing the FGFR2 gene, whose genomic region spans 120 kb. 1-2 kb PCR products have been desighed to amplify portions of this genomic region, focusing on the exons and the 2-3 kb adjacent to each exon. A BAC containing FGFR1 has also been identified and is being sequenced. Preliminary data indicate that the amount and frequency of DNA sequence variation in FGFR3 differs from that in FGFR4, in a pattern consistent with an increased mutation rate in FGFR3 versus FGFR4.

Program Nr: 1456 from the 1999 ASHG Annual Meeting

Physical Mapping of the Macular Corneal Dystrophy Locus on Chromosome 16q22. *N. Liu[1,2], S. Dew-Knight[1], G.K. Klintworth[2], J.M. Vance[1]*. 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Purpose: Macular corneal dystrophy (MCD) is an autosomal recessive disease with different immunophenotypes. Previously we linked the MCD type I gene to an interval on chromosome 16q22 and suggested that MCD type II locus is linked to the same region. The purpose of the present study was to establish a physical map for the MCD interval using YAC (yeast artificial chromosome) and PAC (P1-derived artificial chromosome) libraries. Methods: The CEPH megabase YAC library on 230 96-well plates was the major source for contig formation. DNAs from these plates were pooled on the basis of a two-dimensional PCR screening strategy. Microsatellite markers within the MCD critical region were screened by PCR to get the positive YAC clones. The PAC library was used to cover gaps that could not be closed with any YACs. Results: A YAC contig was constructed between markers D16S512 and D16S518. A gap within the YAC map was successfully closed with the PAC clones. Conclusion: A physical map covering the entire MCD interval has been established using YAC and PAC libraries. This should significantly facilitate the ultimate cloning of the MCD gene.

Program Nr: 1457 from the 1999 ASHG Annual Meeting

IL13 coding region polymorphism is associated with high total serum IgE level. *X. Liu[1], R. Nickel[2,3], B. Björksten[4], U. Wahn[3], T. Beaty[1], S. Huang[2]*. 1) Department of Epidemiology, Johns Hopkins University, Baltimore, MD, USA; 2) Department of Clinical Immunology, Johns Hopkins University, Baltimore, MD, USA; 3) Department of Pediatrics,Humboldt University, Berlin, Germany; 4) Department of Pediatrics, University Hospital, Linköping, Sweden.

Interleukin-13 (IL13) and interleukin-9 (IL9) are important in the regulation of allergic responses, and their encoding genes are located at chromosome 5q31-33, where both linkage and association studies have provided evidence for existence of susceptibility genes for the total serum IgE level, bronchial hyperreactivity, and asthma. We have tested for the association between IL13 and IL9 coding region polymorphisms and total serum IgE level. This was performed by using extremely high and low IgE level (85th and 15th percentile, respectively, for at least two over four timepoints after gender adjustment) in children of the German Multicenter Atopy Study (MAS-90). The case-control comparisons suggested a significant allelic association between the IL13 coding region polymorphism and high serum total IgE level (38 cases-high IgE and 51 controls-low IgE, odds ratio =2.47, p=0.039), but there is no evidence of association with IL9 polymorphism (odds ratio =0.87, p=0.79). And additional 51 Swedish subjects (26 cases and 25 controls based on the 75th and 25th percentile of the age-gender adjusted IgE distribution) recruited from the International Study of Asthma and Allergies in Childhood (ISAAC) cohort further confirmed the significance of variation at IL13 coding region, with an odds ratio of 4 (p-value=0.025), and no significant association for IL9 polymorphism. These results suggest the IL13 coding region variant maybe associated with the development of high serum IgE phenotype.

Program Nr: 1458 from the 1999 ASHG Annual Meeting

An Extension of the Haseman-Elston Method for Arbitrary Sibships. *Y. Liu[1], D. Tritchler[1,2], S. Bull[1,3]*. 1) Public Health Sciences, University of Toronto, Toronto, Ontario, Canada; 2) Ontario Cancer Institute, University of Toronto, Toronto, Ontario, Canada; 3) Samuel Lunenfeld Research Institute of Mount Sinai Hospital, Toronto, Ontario, Canada.

Haseman & Elston (1972) developed a sib-pair method (HE) for detecting linkage to quantitative trait loci. The method is based on a simple linear regression of the squared sib-pairs trait difference on the proportion of alleles shared identical by descent (IBD) at a marker locus. Linkage is detected by a negative slope which has been traditionally assessed by a standard t-test. For sib-pairs, it has been pointed out that the pair sums also express information about linkage [Elston, 1969; Wright, 1997]. When the size of sibships is greater than two, the sibships were usually analyzed in two ways: using all n-1 independent pairs of phenotyped sibs or using all n(n-1)/2 distinct pairs of phenotyped sibs. The first way loses information and the second ignores the dependency among the sib pairs. In this paper, we introduced a new model-free linkage strategy, called HE+, which is similar to the HE method in terms of the formulation and take into account of the multivariate structure of the sibships. HE+ method can be easily extended to the case of multiple trait loci. The simulated family data from Genetic Analysis Workshop 10 [Goldin et al. 1997] was used to compare HE+ and HE method under various circumstances.

Program Nr: 1459 from the 1999 ASHG Annual Meeting

High resolution mapping of the Blepharophimosis, Ptosis, and Epicanthus inversus Syndrome (BPES) locus. *A. Loi[1], G. Pilia[1], L. Crisponi[1], M. Deiana[1], P. Gasparini[2], L. Bisceglia[2], P. Amati[3], D. Bonneau[3], M. Rocchi[4], S. MacMillan[5], P. Ma[5], E. Chen[5], D. Schlessinger[5], A. Cao[1].* 1) IRTAM, CNR, Cagliari, Italy and NIA, NIH, Bethesda, MD; 2) IRCCS, San Giovanni Rotondo, Italy; 3) CHU, Poitiers, France; 4) Universita' di Bari, Bari, Italy; 5) Perkin Elmer Co, Foster City, CA and Washington University, S.Louis, MO.

Blepharophimosis, Ptosis, and Epicanthus inversus Syndrome (BPES)(MIM110100) is an autosomal dominant disorder with developmental abnormalities affecting craniofacial features and ovarian function. In families with BPES type I the affected females have primary ovarian failure (POF) and therefore do not transmit the condition to children. In contrast, in BPES type II the craniofacial defects are not associated with POF, and both affected males and females are fertile. Linkage studies assigned the BPES locus to 3q22-q23. Aiming at positional cloning of the BPES gene, we have constructed a high-resolution physical map of the region using YAC, BAC, and cosmid clones. The availability of a BPES patient with a balanced de novo translocation t(3;7)(q23-q32) allowed us to map the locus for the disorder within 100 Kb. To facilitate the identification of candidate genes in the region,160 kb of genomic DNA was sequenced in bacterial clones spanning the breakpoint. Complete characterization of the genomic sequence is underway, with candidate genes tested for associated mutations in families segregating BPES.

Program Nr: 1460 from the 1999 ASHG Annual Meeting

Power and Significance levels of tests incorporating the unaffected sibs in families ascertained on the basis of one or more affected offspring. *K.L. Lunetta[1,2], N.M. Laird[2]*. 1) Department of Biostatistical Science, Dana Farber Cancer Institute; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

We derive a score test statistic T_{au} for testing transmission disequilibrium which incorporates the information from unaffected offspring as well as affected offspring, and is equivalent to T_{sib} of Whittaker & Lewis (1998). T_{au} takes a weighted average of the contributions of affected and unaffected offspring. We examine the power and significance levels of T_{au} using several choices of weights, including 1) using affecteds only (the traditional TDT), 2) Whittaker & Lewis weights (weight affecteds by 1- population prevalence) and 3) optimizing the statistic over the weight, and then using the correction suggested by Davies (1977) to adjust the p-value.

To compare power, we simulate samples of 100 nuclear families, each with two offspring. The families are ascertained into the sample if at least one offspring is affected; the proportion of families with the second offspring affected depends on the sibling risk ratio of the genetic model. We use a simple genetic model in which we are testing the actual disease allele, and specify allele frequency and penetrances.

In summary, we find that transmission information from the unaffected siblings of cases can in some cases add power when testing transmission disequilibrium, particularly if disease prevalence is high. If the population prevalence is used as the weight, including unaffected sibs will not decrease the power of a test. When accurate estimates of population prevalence are not available for common traits, optimizing the test statistic over the weight and applying Davies (1977) correction is often more powerful than using affected offspring alone. Future work will compare power for genetic models which are more appropriate for complex disease, incorporating a shared genetic and environmental risk for sibs beyond the gene allele being tested.

Program Nr: 1461 from the 1999 ASHG Annual Meeting

Candidate gene analysis in the lupus-prone mouse strain, BXSB. *M.A. Maibaum[1], G. Fu[1], M.E.K. Haywood[1], S. Uribe[1], S.J. Rose[1], R.B. Sim[2], M.J. Walport[1], B.J. Morley[1]*. 1) Rheumatology Section, Imperial College, Hammersmith, London, U.K; 2) MRC Immunochemistry Unit, Oxford University, Oxford, U.K.

We have performed a genome-wide linkage analysis for disease susceptibility genes in the lupus-prone recombinant inbred mouse strain, BXSB. We have analyzed reciprocal backcrosses between the non-autoimmune strain C57BL/10 (B10) and BXSB. A number of intervals showed strong linkage to disease susceptibility including four intervals on chromosome 1 (*Bxs1-4*) and one on chromosome 3 (*Bxs5*). We have initiated a candidate gene screen in these areas by comparing DNA sequences between the B10 strain and BXSB and by additional comparison with other lupus-prone strains (MRL, NZB, NZW).

Cd152 and *Cd28*, located within interval *Bxs1*, showed no variation between BXSB and B10 in the coding sequence. For *Fcgr2*, a strong candidate gene in the *Bxs3* interval, we have previously identified coding sequence polymorphisms. We have now identified sequence variation within the first 200bp of the RNA polymerase start site, which may lie in promoter control elements. Linkage analysis performed using the variation between B10 and BXSB promoter sequences as a marker, indicated that this region was closely associated with anti-nuclear antibody production and splenomegaly. The functional correlates of these sequence variants are under investigation.

Factor I, a complement system control protein, maps within the *Bxs5* interval on chromosome 3. We identified 16 nucleotide differences between BXSB and B10 *Cfi*, 11 of which alter amino acids. Preliminary analysis demonstrated that BXSB sera has higher factor I C3b-cleavage activity than B10 sera. We are presently purifying factor I from BXSB and B10 sera to assess this potential functional difference further.

Program Nr: 1462 from the 1999 ASHG Annual Meeting

Functional studies of mammalian FMRP in yeast. *D.M Absher[1], S.T. Warren[2]*. 1) Dept. of Biochemistry, Emory University School of Medicine, Atlanta, GA; 2) Howard Hughes Medical Institute, and Depts. of Biochemistry, Genetics, and Pediatrics, Emory University School of Medicine, Atlanta, GA.

Fragile X syndrome is a result of the loss of FMRP, the protein product of the FMR1 gene. This is generally caused by an expansion of the CGG repeat in the 5' UTR leading to transcriptional silencing. FMRP is known to be an RNA binding protein, that selectively binds a subset of mRNAs and interacts with polyribosomes as a large mRNP complex. A severely affected patient has been described with an I304N missense mutation which leads to an mRNP of reduced mass which fails to interact with ribosomes. Such data suggests that FMRP may play a role in the translation of certain messages, although its function remains unknown. To better understand the function of FMRP and its role in translation, we have developed a model system in which mammalian FMRP is expressed in *Saccharomyces cerevisiae*, a species without an obvious FMRP homologue. We have expressed FMRP from an integrated plasmid targeted to the Leu2 locus, using the ADH1 promoter. Sucrose gradient analysis has shown that FMRP can associate with yeast polyribosomes and that the I304N mutation can disrupt this association. Furthermore, EDTA-resistant mRNP complexes are detected in these cells, and the I304N mutant complex is abnormally small, just as it is in human cells. This suggests that FMRP engages in nucleoprotein interactions required for association with ribosomes and that at least some of the partners are conserved in yeast. Indeed, FMRP coimmunoprecipitates with at least two yeast proteins which are currently being identified by mass spectrometry. Given the ease of analysis and substantial characterization of translation in yeast, this model system may provide an approach for the functional dissection of FMRP.

Program Nr: 1463 from the 1999 ASHG Annual Meeting

Modelling Familial Hypertrophic Cardiomyopathy Using YAC Transgenesis. *S. Al-Mahdawi[1], S. Chamberlain[1], C. Huxley[1], Z. Webster[2], D. Nunez[3].* 1) Molecular Genetics, Imperial College of Science, Technology and Medicine, London, United Kingdom; 2) MRC Clinical Sciences Centre, Hammersmith Hospital, Imperial College of Science, Technology and Medicine, London, United Kingdom; 3) Clinical Pharmacology, Hammersmith Hospital, Imperial College of Science, Technology and Medicine, London, United Kingdom.

Hypertrophic cardiomyopathy is characterised by hypertrophy of the left ventricle of the heart with myocyte and myofibrillar disarray. Mutations in the coding sequences of several sarcomeric proteins, including alpha-tropomyosin, have been implicated in the pathology of this disorder. To facilitate an understanding of the natural progression of the hypertrophy, we have generated transgenic mice carrying the Asp175Asn mutation. To mimic tissue-specific and physiological expression of the wild-type protein, the mutation has been introduced in the context of the alpha-tropomyosin gene locus contained within a 210 kb human yeast artificial chromosome clone, which should include the endogenous regulatory elements. Three founder animals carrying the mutated full-length gene have been identified to date, with transmission of the YAC transgene to the expected 50% of offspring in each case. Western blot analysis using a human specific antibody demonstrated expression of the human transgene in skeletal muscle. The pathophysiological consequences of the mutation are currently being investigated at the molecular and histopathological levels.

Program Nr: 1464 from the 1999 ASHG Annual Meeting

COMT is not associated with Obsessive Compulsive Disorder - family-based vs. population-based designs. *J.P. Alsobrook[1], A.H. Zohar[2], M. Leboyer[3], N. Chabane[4], R.P. Ebstein[5], D.L. Pauls[1]*. 1) Child Study Center, Yale Univ. Sch. Medicine, New Haven, CT; 2) Scheinfeld Center for Human Genetics in the Social Sciences, Department of Psychology, Hebrew University of Jerusalem, Israel; 3) Service de Psychiatrie d'adultes, Hôpital Henri Mondor et Albert Chenevier, AP-HP, Creteil, France; 4) Sevice de Psychopathologie de l'enfant et de l'adolescent, Hôpital Robert Debre, Paris, France; 5) Research Laboratory, S. Herzog Memorial Hospital, Jerusalem, Israel.

A polymorphism in the coding region of the catechol-O-methyltransferase gene (COMT) was previously reported to be associated with Obsessive Compulsive Disorder (OCD), particularly in male probands[1]. That report was based on a case-control paradigm that examined OCD probands and an unrelated control sample matched for ethnicity. Because molecular genetic case-control studies can exhibit Type I error in the face of population stratification of alleles[2], we attempted to replicate the previous finding using a family-based design in a haplotype relative risk analysis (HRR)[3]. Fifty-six OCD probands and their parents were genotyped for the COMT locus using established methods[4]. Analysis of allele and genotype frequencies between the proband genotypes and the control (parental non-transmitted) genotypes gave no evidence of association. A further analysis of gender and COMT alleles in OCD probands also gave no evidence of association. These findings indicate that 1) COMT is probably not associated with OCD; and 2) caution is necessary in the design and interpretation of molecular genetic association studies that use a case-control paradigm.

Program Nr: 1465 from the 1999 ASHG Annual Meeting

Genetic prediction of antipsychotic response. *M.J. Arranz[1], J. Munro[1], J. Birkett[1], A. Bolonna[1], D. Mancama[1], M. Sodhi[1], K.P. Lesch[2], J.F.W. Meyer[2], P. Sham[1], D.A. Collier[1], R.M. Murray[1], R.W. Kerwin[1]*. 1) Dept Psychological Med, Inst Psychiatry, London, England; 2) Department of Psychiatry, University of Wuerzburg, Germany.

Prediction of clinical response to pharmacological treatments through pharmacogenomic analysis of selected targets may lead to the direct selection of the most beneficial treatment for each individual. In previous studies we hypothesised that response to antipsychotics may be influenced by mutations in the targeted neurotransmitter receptors. In support of this hypothesis, we found associations between polymorphisms in the serotonin 2A (5-HT2A) and 2C (5-HT2C) receptor genes and response to the potent antipsychotic clozapine. However, these polymorphisms could not fully explain the individual's variation in response to clozapine treatment. We have now investigated 19 genetic variants in neurotransmitter receptors targeted by clozapine and in the serotonin transporter (5-HTT) in a sample of 200 schizophrenic patients treated with the drug. A combination of 6 of the polymorphisms studied in 4 different loci (5-HT2A, 5-HT2C, 5-HTT and Histamine type 2) results in 76.7% success in the prediction of clozapine response (p= 0.0001). These results constitute the first report of the use of pharmacogenetics for the individualisation of psychiatric treatment and will form the basis for a simple test to enhance the usefulness of clozapine.

Program Nr: 1466 from the 1999 ASHG Annual Meeting

The role of protein misfolding in the neurodegenerative disease, Spinal and bulbar muscular atrophy. *C.K. Bailey[1,2], D.E. Merry[2]*. 1) Univ. of Pennsylvania, Neuroscience Graduate Group, Philadelphia, PA; 2) Thomas Jefferson Univ., Dept. of Biochemistry and Molecular Pharmacology, Philadelphia, PA.

Spinal and bulbar muscular atrophy (SBMA) is a neurodegenerative disease caused by expansion of a polyglutamine repeat within the androgen receptor (AR). A common feature of polyglutamine repeat diseases is protein misfolding, as evidenced by the presence of ubiquitinated neuronal intranuclear inclusions, containing the mutated protein. Analysis of such inclusions in motor neurons of SBMA patients reveals the presence of only amino-terminal AR epitopes, suggesting that the amino terminus of expanded repeat AR is pathogenic. Consistent with this, we have shown that an amino-terminal portion of the expanded repeat AR is more toxic to Cos cells than full length AR. Using this *in vitro* system, we have shown altered metabolism for expanded repeat AR, including aggregation and proteolytic processing in a repeat length-dependent manner. Our finding of co-localization of the molecular chaperones, Hsp70 and Hsp40, with AR inclusions supports the idea of protein misfolding in this disease.

Molecular chaperones are known to bind to misfolded proteins in order to refold the proteins and to prevent aggregation. Since co-chaperones of the Hsp40 family may be present in cells in limited amounts, we overexpressed an Hsp40 family member, HDJ-2/HSDJ, in our *in vitro* system to study the effects on AR protein metabolism. Co-expression of HDJ-2/HSDJ with truncated, expanded repeat AR resulted in a significant, although modest, decrease in aggregate formation, in both Cos and HEK293T cells. HDJ-2/HSDJ J domain mutants showed a similar decrease in aggregation, indicating that this effect is not J domain dependent. We are currently investigating the effect of HDJ-2/HSDJ over-expression on the cellular toxicity caused by expanded repeat AR.

These studies suggest that abnormally folded expanded polyglutamine repeat AR may overwhelm the cell's molecular chaperone systems, thus leading to aggregation. Our current studies will allow us to determine if the process of protein misfolding contributes to cell death.

Program Nr: 1467 from the 1999 ASHG Annual Meeting

Increased Prevelance of Alzheimer Disease in an Arab-Israeli Community. *C.T. Baldwin[1], A. Bowirrat[4], A. Korczyn[4], C. Adams[1], L. Farrer[2], R. Friedland[3]*. 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Genetics Program, Dept of Medicine, Boston Univ Sch Medicine, Boston, MA; 3) Department of Neurology, Case Western Reserve Univ, Cleaveland, OH; 4) Department of Neurology, University of Tel-Aviv, Israel.

In a population-based study of Alzheimer disease (AD), we screened all elderly residents (855 individuals) of an Arab community in northern Israel. Fourteen families (hamulas) founded this community several hundred years ago and consanguinity is commonly practiced. In those over the age of 60, we observed an unusually high prevalence of AD (20.5% of those > 60; 60.5% of those > 85). This prevalence is 2-4 fold higher than reported for any other population, even after adjustment for age, education and gender. The frequency of APOE e4 alleles was low in this population, 3.5% for non-demented elderly controls and 4.5% for AD cases. Thus, the increased frequency of AD is not due to APOE e4. The occurrence of AD in this community appears to be clustered in families; more than one-third of the 168 prevalent cases occur in one hamula (#13). We hypothesize that this is may be due to a founder effect in this genetic isolate as well as a result of consanguinity. A 10 cM genome wide scan was conducted in 5 cases and 5 non-demented control samples from hamula #13. We expect that an AD predisposing gene would be identical by descent in affected members of this family and excessive allele sharing, or homozygosity among affected individuals would be found. Five chromosomal regions were identified that show a significant association with AD (Fishers Exact $p < 0.05$). One chromosomal location near the presenilin-2 gene on chromosome 1 and the second near a potential locus reported by Kehoe et al., 1999. In summary, the study of AD in this unique genetic isolate has the potential to identify new AD genes, particularly those that are inherited in a recessive fashion.

Program Nr: 1468 from the 1999 ASHG Annual Meeting

Multiple Functional Variations In COL6A1 Coding Region Modulate Risk of Congenital Heart Defects in Down Syndrome. *M.J. Baptista[1], U.L. Fairbrother[1], G.E. Davies[1], D. Trikka[2], T. Davis[1], C. Baldock[3], C.M. Kielty[3], A.M. Kessling[1]*. 1) Medical and Community Genetics, Imperial College, , Harrow, Middlesex, England; 2) Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, Texas; 3) School of Biological Sciences, Manchester University, 2.02 Stopford Building, Oxford Road, Manchester, M13 9PT.

Down syndrome (DS) is associated with a much higher incidence of congenital heart defects (CHD) than is seen for the general population (40% compared to 0.8% euploid individuals). The COL6A1-A2 locus on chromosome 21q22.3 is included in the critical region for CHD associated with DS. Variation in the COL6A1 region is associated with CHD.

We have used SSCP and direct sequencing methods to analyse each of the globular regions encoding exons of COL6A1. To date we have found twelve novel polymorphisms and functional variations in the 3' end of the coding sequence. The distribution of these variants has been studied in 97 families having a child with DS with or without a heart defect.

Individuals with DS not having mostly wild type haplotypes found in COL6A1 for the SSCP or the RFLP data confers a relative risk of 5.1 and an odds ration of 11.25 (p=0.008 Fishers exact test) for having a CHD.

In 33 UK/Irish families there are eleven unequivocal haplotypes and eight probable unique haplotypes, many seen in only a single individual. All of these haplotypes appear to be functional in the diploid state since they exist in euploid parents who do not have CHDs.

We propose a disease mechanism whereby the expression of more than two haplotypes disrupts the stoichiometry of the collagen VI molecule. This may lead to the modification of the tertiary structure of the collagen VI "beaded filaments." The resulting disturbance in function of collagen VI (relative to the euploid state) would lead to the failure of the endocardial cushions to fuse, resulting in a CHD.

Program Nr: 1469 from the 1999 ASHG Annual Meeting

Assessment of the methylenetetrahydrofolate reductase (MTHFR) C677T genotype and neural tube defect risk in a south Texas Hispanic population. *R.C. Barber[1], B.S. Joggerst[2], S.L. Shalat[2], R.H. Finnell[1]*. 1) Center for Molecular Genetics, University of Nebraska Medical Center, Omaha, NE; 2) Environmental and Occupational Health Sciences Institute, UMDNJ, Rutgers, Piscataway, NJ.

Intracellular methionine and homocysteine metabolism are controlled primarily by the folate-dependent enzyme, 5,10-methylenetetrahydrofolate reductase (MTHFR). Although methionine synthase catalyzes the final reaction, MTHFR is responsible for the rate limiting step in the cycle that converts homocysteine to methionine. A mutant MTHFR allele (C677T) that encodes a thermolabile variant of the protein with reduced activity, has been linked to elevated serum homocysteine levels in TT homozygous individuals. Although studies of Dutch and Irish populations have reported an association between homozygosity for this mutation and elevated neural tube defect (NTD) risk, other studies have either found no, or a much smaller association. The MTHFR C677T genotype was determined in a case-control sample collected from El Paso, Webb and Hidalgo counties in the Rio Grande valley of Texas. This population was specifically investigated because NTD prevalence is known to be generally greater among Hispanic than non-Hispanic Caucasians, and because a cluster of NTDs was detected in this region in 1991, with increased NTD rates being observed again in 1998. Crude odds ratios and 95% confidence intervals were computed using SAS, and exact probabilities were calculated using Fisher's Exact Test. Allele frequencies in different populations were compared by Chi-square. Although no significant association was observed between any genotype and NTD risk, genotype frequencies in the overall sample population were significantly different from those reported for Irish or Hispanic populations. In addition, the frequency of the T allele (0.4892) was higher in this study than has been previously reported. The observations presented here as well as conflicting reports from the literature illustrate the complexity of the relationship between the MTHFR C677T polymorphism and NTD risk. Accordingly, the impact of this polymorphism on NTD etiology is far from being resolved. Funding for this study was provided by NIH grant ES06650.

Program Nr: 1470 from the 1999 ASHG Annual Meeting

Positive association of nonsyndromic cleft palate only (CPO) and aryl hydrocarbon receptor nuclear translocator 2 (*ARNT2*). . *L.L. Barrow[1], M.E. Wines[2], P.A. Romitti[3], B.C. Holdener[2], J.C. Murray[3]*. 1) Otolaryngology, Univ. of Iowa, Iowa City, IA; 2) Biochemistry and Cell Biology, State Univ. of NY at Stony Brook, Stony Brook, NY; 3) Pediatrics, Univ. of Iowa, Iowa City, IA.

Nonsyndromic orofacial clefts have an incidence of 1/1000 live births. Population genetic and embryologic studies suggest that cleft palate only (CPO) may be a distinct clinical entity from cleft lip with or without cleft palate (CL/P). Clefts are thought to be multifactorial in etiology, with genetic, environmental, and developmental determinants all playing a role. Mice are valuable model systems to identify potential risk factors. The *c112k* mouse line demonstrates *ARNT2* deletion and a complex phenotype including CPO and thymic hypoplasia. *ARNT2* localizes to a conserved linkage group on mouse Chr 7 that is syntenic with human Chr 15q23-25. This chromosomal region was previously identified as a teratogen-induced clefting susceptibility locus in a genome-wide scan of AXB and BXA recombinant inbred mice. To determine whether *ARNT2* influences human craniofacial development, we identified the human *ARNT2* gene and conducted genomic structural analysis. Mutational screening was performed in infants with nonsyndromic CPO or CL/P identified by the Iowa Birth Defects Registry, an active population-based surveillance system. No obvious disease-causing mutations were detected by SSCP analysis. A microsatellite marker, *GATA89D04*, was identified within an intron of human *ARNT2*, and linkage disequilibrium of nonsyndromic CPO and CL/P parent-infant trios was conducted, following transmission of the 244 bp allele. AFBAC analysis (CPO=20; CL/P=37) demonstrated a positive association with CPO (c^2=11.90; $p<0.02$) but no association with CL/P (c^2=1.94; $p>0.05$). TDT analysis (CPO=28; CL/P=48) confirmed a positive association with CPO (c^2=6.26; $p<0.05$) but no association with CL/P (c^2=0.69; $p>0.05$). Future analyses include evaluation of further CPO parent-infant trios and assessment of environmental exposures. Of particular interest, the teratogen 2,3,7,8-tetrachlorodibenzo-p-dioxin acts through the aryl hydrocarbon receptor pathway to produce dose-dependent CPO and thymic wasting in mice exposed *in utero*.

Program Nr: 1471 from the 1999 ASHG Annual Meeting

Autistic Disorder and chromosome 7: Analysis of an inversion breakpoint in a multiplex family. *S. Basu[1], A. Ashley-Koch[1], C.M. Wolpert[1], M.M. Menold[1], N. Matsumoto[2], C.M. Powell[3], M.B. Qumsiyeh[1], M.L. Cuccaro[4], D.H. Ledbetter[2], E.D. Green[5], J.M. Vance[1], M.A. Pericak-Vance[1], J.R. Gilbert[1]*. 1) Department of Medicine, Duke University Medical Center, Durham, NC; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Department of Pediatrics, University of North Carolina, Chapel Hill, NC; 4) WS Hall Psychiatric Institute, University of South Carolina, Columbia, SC; 5) NHGRI, NIH, Bethesda, MD.

Autistic Disorder (AD) is a developmental affliction characterized both by severe impairments in reciprocal social interaction and communication, as well as by stereotyped patterns of behavior. Genomic screen results from several groups (IMGSAC, 1998; Bass et al., 1998; Philippe et al., 1999) indicate the presence of an AD susceptibility gene on the long arm of chromosome 7, in the region of 7q31-q35. Cytogenetic abnormalities associated with an autistic phenotype found to overlap the region of positive linkage have previously been reported (de la Barra et al., 1986; Sarda et al., 1988; Lopreiato et al., 1992) and can help to narrow the region of interest. We have identified a family (Duke 7543) with multiple affected members segregating for a paracentric inversion, inv(7)(q22q31.2), which overlaps our region of suggested linkage on chromosome 7 (Ashley-Koch et al., ASHG 1999). We postulate that the inversion is disrupting expression of the putative AD gene on 7q; we are therefore isolating and characterizing the inversion breakpoints. Using a series of 12 BAC clones for FISH analysis, we have narrowed the 7q31.2 breakpoint region to a 350 kb interval several centimorgans proximal to CFTR, and are in the process of constructing a physical map of the area. Pulse field mapping of the 350 kb region is in progress to identify CpG islands, indicative of candidate genes. In addition, we are constructing a cosmid library from an affected member of our pedigree to physically fine map and characterize both inversion breaks. Physical and gene mapping data, as well as a genomic contig of the candidate region, will be presented.

Program Nr: 1472 from the 1999 ASHG Annual Meeting

Quantitative fluorescence PCR (QF-PCR) of chromosome 11p15.5 markers in Beckwith-Wiedemann syndrome (BWS): Detection of microduplications and microsegmental uniparental disomy (UPD). *L.S. Beischel[1], M.M. Haag[1], D.H. Viskochil[2], S.M. Phillips[1], J.P. Johnson[1]*. 1) Medical Genetics, Shodair Hospital, Helena, MT; 2) Pediatrics/Genetics, U. of Utah, Salt Lake City, UT.

BWS, a childhood disorder of tissue overgrowth and cancer susceptibility, is associated with abnormalities of expression of imprinted genes at 11p15.5. Increased dosage of growth-promoting genes expressed from the chromosome of paternal origin, or decreased dosage of growth-suppressing genes expressed from the chromosome of maternal origin, or both, may cause this syndrome. About 1% of patients have visible chromosome rearrangements (translocation, inversions and duplications), 15% have paternal uniparental disomy (UPD, usually segmental and mosaic), and 20% are familial, with maternal inheritance. More than half of BWS patients lack a characterized genetic cause for their condition. We looked for paternal UPD using QF-PCR for 10 polymorphic DNA markers from 11p15.5 in five families with an affected child. In two patients, we found probable de-novo DNA duplications of paternal origin within the critical region of chromosome 11, predicting functional disomy for paternally expressed genes. The duplicated alleles had twice the peak areas of the single copy alleles. Mosaic segmental paternal UPD, while possible, is unlikely given identical 2:1 allele ratios in both patients. A third patient has a very small region lacking maternal alleles, probably due to microsegmental paternal UPD, again predicting disomy for paternally expressed genes. These anomalies were not visible by G-banded cytogenetic analysis of patients 1 and 3 (study pending on patient 2). We hypothesize that such microduplications and microsegmental loss of maternal alleles (probable paternal UPD) are more frequent than visible rearrangements of chromosome 11p, and have previously been undetected by cytogenetic and molecular techniques. QF-PCR, using polymorphic markers localized to the region of imprinted genes at 11p15.5, can potentially detect aberrations of gene copy number or parental origin at higher resolution than previously available. Results may be helpful in genetic counseling and in defining a molecular etiology of BWS.

Program Nr: 1473 from the 1999 ASHG Annual Meeting

Interleukin-1-induced Fas is not always nitric oxide dependent in mouse islet cells. *S. Bertera, A. Alexander, M. Crawford, M. Trucco.* Division of Immunogenetics, Department of Pediatrics, University of Pittsburgh School of Medicine, Rangos Research Center, Children's Hospital of Pittsburgh, Pittsburgh, PA.

Insulin dependent diabetes mellitus (IDDM) is an autoimmune disease characterized by the destruction of the insulin-producing beta cells of the islets of Langerhans in the pancreas. To understand the underlying basis of Type 1 diabetes pathogenesis, attention must be focused on the factors that permit or provoke this autoimmune attack. Interleukin-1 beta (IL-1b), a proinflammatory cytokine, is the major secreted form of IL-1 and related to tumor necrosis factor alpha (TNF-a). IL-1b has recently been shown to upregulate Fas on the surface of the insulin producing beta cells in the pancreas, priming them for destruction by the Fas (CD95/APO-1) dependent apoptotic cell death pathway. Nitric oxide (NO), which is derived from L-arginine, is thought by many to play an important role in the apoptotic cell death of pancreatic islets, resulting in IDDM. The NO radical, when present in moderate amounts, can function as a cellular signaling molecule or regulator of gene expression. During the insulitis process in humans, it has been reported that secretion of IL-1 by activated macrophages induces transcription and translation of the inducible nitric oxide synthase (iNOS) gene and produces NO in abundance. It was then hypothesized that the Fas mediated apoptosis pathway of human pancreatic islets is upregulated in response to NO production by the iNOS gene. However, we have evidence that the same may not be true for rodent beta cells. Our studies show, using islets from an iNOS knockout mouse model, through *in vitro* NO suppression with arginine analogs and arginine-free media, and flow cytometric analysis, that Fas can be upregulated on the surface of mouse islet cells in response to IL-1b without the presence of L-arginine, the iNOS gene or NO, suggesting that in mice the Fas mediated apoptotic cell death pathway is not necessarily nitric oxide dependent.

Program Nr: 1474 from the 1999 ASHG Annual Meeting

Investigation of polymorphisms in the NMDAR1 gene in association with schizophrenia. *A.A. BOLONNA, J. Munro, M.J. Arranz, A.J. Makoff, R.W. Kerwin.* psychological medicine, INSTITUTE OF PSYCHIATRY, LONDON, ENGLAND.

The glutamate system, mediating the majority of excitatory transmission, has been implicated in the complex aetiology of schizophrenia. An initial report of decreased glutamate concentrations in the cerebrospinal fluid of schizophrenic patients (Kim et al., 1980) was supported by observations that phencyclidine (PCP), a non-competitive NMDA antagonist, induces a psychotomimetic effect in normal subjects closely resembling that of schizophrenia (Domino and Luby, 1981). Additional suggestive evidence include alterations in receptor binding and messenger RNA expression levels of glutamate receptor subunits in the post-mortem brain of patients (Kerwin et al., 1990; Harrison et al., 1991). Therefore, the genes encoding the glutamate receptor family are candidates in the aetiology of the disorder. We have investigated whether variations in the NMDAR1 gene, the key subunit of the NMDA receptor, influences the genetic predisposition to schizophrenia.The NMDAR1 gene, 22 exons in length, was systematically screened for mutations, using single strand conformation polymorphic (SSCP) analysis, in 50 cases and an equal number of controls. The sample population included patients of British Caucasian origin (DSMIII/IVR classification) and ethnically matched controls.Two silent polymorphisms were identified in the coding region of the gene (exon 6-A/G and exon 7-A/G) and an additional five in non-coding regions (-855-G/C, Int10-G/A, Int11-A/G, Int12-del7 and Int14-C/T). The frequent polymorphisms were genotyped in cases and controls, but association was not detected with schizophrenia. However, haplotype analysis revealed that the polymorphisms were in strong linkage disequilibrium ($p<0.00001$) and particular haplotype combinations showed an association with schizophrenia ($p=0.01$).In conclusion, analysis of variations in the NMDAR1 gene in association with schizophrenia does not suggest a major role for this gene in conferring susceptibility to the disorder.

Program Nr: 1475 from the 1999 ASHG Annual Meeting

CFTR gene mutations in sarcoidosis patients. *C. Bombieri[1], F. Belpinati[1], M. Luisetti[2], L. Casali[2], P.F. Pignatti[1].* 1) Section of Biology and Genetics, DMIBG, Univ. Verona, Italy; 2) Inst. Respir. Dis., IRCCS, S. Matteo Hospital, Univ. Pavia, Italy.

Sarcoidosis is a multisystem immuno-mediated granulomatous disorder with unknown aetiology. The diagnosis of sarcoidosis depends on finding noncaseating granulomas in affected tissue, therefore infectious agents known to cause granulomatous inflammation have been investigated as potential aetiological agents. Ethnic variation in incidence and familial clustering of the disease suggest an inherited susceptibility. The relative risk in siblings patients is supposed to be approximately 2.0. Studies performed to determine risk factors remain inconclusive. During a CFTR gene mutation screening in pulmonary diseases, we found that 5/8 (62%) sarcoidosis patients had a mutations, as a serendipity finding (Hum. Genet. 103:718-22, 1998). This high incidence suggested us to analyse a second series of patients to confirm the data. 26 new patients and 65 control individuals were recruited. A DGGE analysis was performed on all exons and intronic flanking regions of the CFTR gene. At the writing of this abstract the analysis is completed for 19/26 patients and for all the controls. In 6/19 patients at least one mutation was found (31%). This increase is not statistically different from the mutations found in controls. The total number of CFTR mutation carriers in completely screened patients is 11/27 (41%), a significant increase over controls (11/65; Fisher's exact test p=0.017). One of the patients presented 3 mutations: R75Q, 186-13C/G, and 1898+3A/G (phase unknown). Moreover, 6 samesense mutations were found in patients, not statistically different from controls (9/65). In the remaining 7 patients, 18/27 exons have been screened: two mutations (exon 16, to be sequenced, and L997F), were found in 2 patients. In conclusion, the data obtained in an enlarged series of sarcoidosis patients shows an excess of CFTR gene mutations, which may indicate an involvement of the gene in disease etiopathogenesis and/or progression.

Program Nr: 1476 from the 1999 ASHG Annual Meeting

Association study of the dopa decarboxylase gene in bipolar affective disorder and schizophrenia. *A.D. Borglum[1], T.G. Bruun[2], M. Hampson[4], T.E. Kjeldsen[1], P. Lodge[4], H. Ewald[2], O. Mors[2], G. Kirov[3], W. Muir[4], V. Murray[4], C. Russ[3], B. Freeman[3], D. Blackwood[4], D.A. Collier[3], T.A. Kruse[5].* 1) Dept Human Genetics, Aarhus Univ, Aarhus, Denmark; 2) Dept Psychiatric Demography, Psychiatric Hospital in Aarhus, Denmark; 3) Institute of Psychiatry, London, United Kingdom; 4) Dept Psychiatry, Royal Edinburgh Hospital, Edinburgh, Scotland; 5) Dept Clinical Biochemistry and Genetics, Odense University Hospital, Denmark.

Dopa decarboxylase (DDC) is a regulated enzyme required in the synthesis of the monoaminergic neurotransmitters dopamine, noradrenalin, adrenalin, and serotonin. In addition, DDC is rate limiting in the production of trace amines such as 2-phenylethylamine (2-PE) which have neuromodulating capabilities. DDC is regarded as a candidate gene for predisposition to a variety of neuropsychiatric disorders including bipolar affective disorder (BPAD) and schizophrenia.

We identified two novel variants in the DDC gene: a 1-bp deletion in the neuronal promoter and a 4-bp deletion in the neuronal exon 1. Both deletions affect putative binding sites for known transcription factors, suggesting a possible functional impact at the level of expression. The two variants were applied in association studies of BPAD and schizophrenia. The BPAD study investigated 80 Danish and 112 English patients, and 223 Danish and 349 English controls. The schizophrenia study comprised 174 patients and 200 controls from Scotland. A significant association was found between the 1-bp deletion and BPAD with P-values of 0.037 (allelic) and 0.021 (genotypic). The frequency of the 1-bp deletion was 13.3% in patients and 9.4% in controls with a corresponding odds ratio of 1.48 (95% CI: 1.02-2.15). A replication study of this finding is currently in progress, analyzing 150 BPAD patients and 200 controls from Scotland.

No significant association was found between the DDC variants and schizophrenia.

The results presented suggest that DDC may act as a minor susceptibility gene for BPAD, whereas no support was found for the possible involvement of DDC in schizophrenia.

Program Nr: 1477 from the 1999 ASHG Annual Meeting

Systematic mutational analysis of the human metabotropic glutamate receptor 3 (mGluR3): association analysis in patients with schizophrenia and bipolar affecitve disorder. *S. Bort[1], S. Cichon[1], T. Schulze[2], D.J. Müller[2], M. Albus[3], E. Franzek[4], M. Knapp[5], M. Rietschel[2], P. Propping[1], M.M. Nöthen[1].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Psychiatry, University of Bonn; 3) Mental State Hospital, Haar; 4) Department of Psychiatry, University of Würzburg; 5) Institute of Medical Statistics, University of Bonn.

Glutamate is the major excitatory neurotransmitter in the mammalian central nervous system. Its actions are mediated by glutamate receptors which fall into ionotropic (iGluR) and metabotropic (mGluR) receptors. The ionotropic receptors are further subdivided into three groups: AMPA, kainate and NMDA receptor channels. The metabotropic receptors are coupled to G-proteins, and regulate the production of intracellular messengers. Several observations implicate brain glutamatergic abnormalities in the pathophysiology of schizophrenia. This evidence includes both human neurochemical and clinical pharmacologic data. In the present study, we have sought to identify mutations in the human metabotropic glutamate receptor 3 (mGluR3) gene by screening genomic DNA samples from 92 unrelated individuals (46 schizophrenic patients and 46 individuals with bipolar affective disorder) by means of single-strand conformation analysis (SSCA). We detected two rare silent sequence variants, namely 627C/T and 873C/T and a common silent variant, 1872C/T. The occurrence of the 1872C/T variant was studied in a large sample of bipolar and schizophrenic patients (n=283 and n=265, respectively) as well as controls (n= 227). We found a significant (P=0.0022) overrepresentation of the 1872T variant in schizophrenic patients when compared to controls. To test for the significance of this finding, we are currently studying the 1872C/T variant in an extended sample of schizophrenic patients and controls as well as in a schizophrenic trio sample using the transmission/disequilibrium test (TDT).

Program Nr: 1478 from the 1999 ASHG Annual Meeting

Skewed X-inactivation associated with abnormal methylation in ICF patients. *D. Bourc'his[1], M. Jeanpierre[2], E. Viegas-Pequignot[1]*. 1) INSERM U383, Hôpital Necker; 2) INSERM U129, CHU Cochin, Paris, FRANCE.

ICF syndrome is a rare autosomal recessive disorder characterized by variable Immunodeficiency, Centromeric instability and Facial dysmorphism. Only one chromosomal region (20q11-q13) has been identified for this pathology despite its heterogeneity. We initially showed that DNA undermethylation is a constitutional feature of ICF genomes and is associated with chromosomal rearrangements typical of the syndrome. The inactive X chromosome of female ICF patients exhibits also a global undermethylated profile which is variable among patients at the molecular level. Intronic CpG sites are systematically demethylated, but 5' CpG islands demethylation of X-repressed genes occurs only in half of the patients. Fonctionnally, the methylation defect does not disturb the major features of the inactivation process which is initiated and maintained in these patients.

We observed that the X chromosome undermethylation is related to a skewed pattern of inactivation. Using the HUMARA assay, skewing was over 90% in the class of ICF patients showing methylated CpG islands. In the second class of patients (demethylated CpG islands), we confirmed this result by the analysis of a XIST expressed polymorphism. The X inactivation skewing was not restricted to leukocytes, thus excluding a monoclonal proliferation of hematopoietic precursor cells or the implication of a specific tissular factor leading to this distorsion. As X chromosome rearrangements or deleterious mutations were not observed in these patients, the skewed X-inactivation is not the result of a secondary cellular selection by relative growth advantages, as usually described in families prediposed to a X inactivation bias. The skewed X inactivation of ICF patients appears as a primary defect in the chromosome choice at the onset of inactivation. The implication of an autosomal factor in this control is suggested by the cosegregation of the X inactivation skewing trait with the ICF phenotype in an autosomal recessive mode. Inasmuch the ICF gene is probably involved in the methylation reaction, the nature of this transacting factor could be related to epigenetic modifications.

Program Nr: 1479 from the 1999 ASHG Annual Meeting

Genetic Characterization of a Diabetes Susceptibility Locus on Mouse Chromosome 4. *T.C. Brodnicki[1,2], P. McClive[1], S. Couper[1,2], G. Morahan[1,2]*. 1) Genetics and Bioinformatics , The Walter & Eliza Hall Institute, Melbourne, Victoria, Australia; 2) The Cooperative Research Center for Discovery of Genes for Common Human Diseases, Melbourne, Victoria, Australia.

Insulin-dependent diabetes mellitus (IDDM) is a multigenic autoimmune disease. The reason(s) autoreactive T cells become activated and mediate destruction of insulin-producing beta cells are not fully understood, but insights may be gained from one of the best animal models for IDDM - the nonobese diabetic (NOD) mouse. We previously located a NOD diabetes susceptibility locus, designated Idd11, on mouse chromosome 4 by analyzing diabetic backcross mice produced after crossing NOD/Lt with the nondiabetic resistant C57BL/6 (B6) strain. In order to confirm Idd11 and further refine its location, three NOD congenic mouse strains with different B6-derived intervals within chromosome 4 were generated. Two of the congenic strains had a significant decrease in the cumulative incidence of diabetes compared to NOD/Lt control mice. The third NOD congenic strain, containing a B6 interval surrounding the Slc9a1 locus, was not protected against diabetes. Mouse chromosome 4 has also been linked to another autoimmune disease, systemic lupus erythematosus (SLE), in the New Zealand Black (NZB) mouse strain. In order to further characterize Idd11, a mouse strain was generated which contained one copy of the NZB interval for Idd11 on the NOD background. Analysis of this mouse strain demostrated that the NZB interval for Idd11, compared to the B6 interval, is unable to protect NOD mice from diabetes. These combined results define a new distal boundary for Idd11, eliminate the Slc9a1 gene as a candidate and suggest that the Idd11 locus may play a role in SLE development.

Program Nr: 1480 from the 1999 ASHG Annual Meeting

Identification of a new polymorphism in intron 6 of the human *NURR1* gene and investigation of association with Parkinson's disease and schizophrenia. *S. Buervenich[1], A. Carmine[1], F. Xiang[2], Z. Zhang[2], O. Sydow[3], E.G. Jonsson[4], G.C. Sedvall[4], M. Anvret[2,5], L. Olson[1]*. 1) Dept. of Neuroscience, Karolinska Institutet, Stockholm, Sweden; 2) Dept. of Clinical Genetics, Karolinska Institutet, Stockholm, Sweden; 3) Division of Neurology, Karolinska Institutet, Danderyd, Sweden; 4) Dept. of Clinical Neuroscience, Psychiatry Section, Karolinska Institutet, Stockholm, Sweden; 5) AstraZeneca R&D Sodertalje, Sodertalje, Sweden.

Schizophrenia and Parkinson's disease have in common that affected relatives constitute the largest epidemiological risk factor, but the mode of inheritance of susceptibility is complex and remains to be elucidated. A further common observation in both diseases is etiologic and/or therapeutic involvement of dopaminergic neurotransmission. Recently, a number of studies have pointed out the importance of retinoids and retinoid-related genes for midbrain dopamine neurons. Mice lacking the retinoid-related orphan receptor *Nurr1* fail to develop mesencephalic dopamine neurons. We therefore considered the *NURR1* gene a good candidate for the two diseases. We sequenced the entire coding region and parts of all introns in 10 Parkinson patients, 10 schizophrenic patients and 4 controls. We identified a new polymorphism in the sixth intron that deletes a cleavage site for the restriction enzyme BseRI. This polymorphism was found to be present at a frequency of 20 to 25 percent in larger (n=140 alleles for each group) samples of controls, Parkinson patients and schizophrenic patients from Sweden. No significant differences were found between any of the groups. We conclude that strong association between the identified polymorphism and any of the two diseases can be excluded. However, larger materials have to be looked at in order to exclude minor effects of the identified sequence change.

Program Nr: 1481 from the 1999 ASHG Annual Meeting

Fully expanded fragile X CGG repeats exhibit a length- and differentiation- dependent instability in cell hybrids that is independent of DNA methylation. *R.W. Burman[1], B.W. Popovich[1], P.A. Yates[2], P.B. Jacky[3], J.L. Schnell[1], M.S. Turker[1,2]*. 1) Dept of Molecular and Medical Genetics, Oregon Health Sciences University, Portland, OR; 2) Center for Research on Occupational and Environmental Toxicology, Oregon Health Sciences University, Portland, OR; 3) Cytogenetics Laboratory, Kaiser Permanente NW, Clackamas, OR.

The fragile X syndrome is characterized at the molecular level by expansion and methylation of a potentially unstable CGG trinucleotide repeat located within the *FMR1* locus. Somatic instability occurs in the large majority of full mutation carriers resulting in repeat length mosaicism, which is manifest as a complex smeared and multi-banded hybridization pattern when examined by Southern blot analysis. These mutational patterns tend to be well conserved among multiple tissues within individuals and can be conserved in monozygous twins. Moreover, typical methylated full mutation alleles are stable in cultured fibroblasts. These observations suggest that repeat instability is limited to a period during early embryogenesis. The specific conditions that exist in embryonic cells which are believed permissive to fluctuations in repeat number have not been described.

To study the behavior of full mutation alleles in mitotic cells, we have generated human x mouse somatic cell hybrids that carry both methylated and unmethylated full mutation fragile X alleles. We analyzed repeat dynamics in these hybrids as a function of DNA methylation, repeat length, and cellular differentiation. We find that both methylated and unmethylated full mutation alleles are unstable in the hybrids. Repeat stability in the hybrids is dependent on repeat length except in an undifferentiated cellular background where large alleles are maintained with a high degree of stability. This stability is lost when the cells undergo differentiation. These results indicate that the determinants of repeat stability are more complex than generally believed and suggest an unexpected role for cellular differentiation in repeat stability.

Program Nr: 1482 from the 1999 ASHG Annual Meeting

Ethnic-Specific Allele Frequency Differences in the Human Interleukin-4 Receptor Gene. *M. Caggana, K. Walker, A.A. Reilly, J.M. Conroy, S. Duva, A.C. Walsh.* Wadsworth Ctr, New York State Dept Health, Albany, NY.

Two functionally significant sequence variants in the interleukin-4 receptor gene (*IL-4R*) were recently reported. One variant, a G to A transition at nucleotide 1902, results in the substitution of arginine for glutamine (Gln551Arg) and acts dominantly. The Arg variant is associated with atopy. The second recessively acting variant is an A to G transition at nucleotide 398. This results in the substitution of valine for isoleucine (Ile50Val). The Ile variant is associated with atopy and atopic asthma. Because asthma prevalence varies in different ethnic groups, we sought to examine the allele frequencies of these mutations in four anonymous New York State newborn screening populations unselected for disease (N=855). These data show that Arg551 is most frequently found in African-Americans with an allele frequency of 68%. However, the Ile50 allele is most common in Caucasians (allele frequency, 87%). When both alleles are studied together as a haplotype, a higher proportion of African-Americans were homozygous for the "enhanced signaling" variants (Ile50/Arg551). In concert with other signals, IL-4 binding to its receptor induces isotype switching in B cells from mu to epsilon and is therefore associated with increased IgE production. Therefore, our data suggest that the African-American population may be at increased risk for diseases, including asthma, which are associated with increased IgE production. In addition, these data emphasize the importance of determining the frequencies of single nucleotide polymorphisms (SNPs) in different populations before attempting to draw conclusions regarding allele association studies, since the background allele frequencies may be widely disparate between different populations. Studies to characterize two additional (*IL-4R*) sequence variants that result in amino acid substitutions in these same specimens and a cohort of phenotypically characterized unrelated asthmatics are underway.

Program Nr: 1483 from the 1999 ASHG Annual Meeting

Numerous Point Mutations in the Mitochondrially-Encoded Cytochrome c Oxidase Genes Detected by Single Strand Conformational Polymorphism Analysis of Brain Samples from Patients with Alzheimer's Disesase. *F.J. Castora, N.S. Hamblet, B. Ragland, M. Ali.* Dept Physiological Sciences, Eastern Virginia Med Sch, Norfolk, VA.

A “ mitochondrial hypothesis ” of late onset Alzheimer's Disease (AD) has been proposed based on studies that establish altered oxidative phosphorylation (OXPHOS) in AD tissue. Biochemical studies have indicated that there is a significant decrease in cytochrome c oxidase (COX) activity as well as perturbed COX I and COX III mRNA levels in platelets and in brain tissue from Alzheimer's patients. We have examined the mitochondrial-encoded COX subunits (COX I, II, and III) by single strand conformation polymorphism (SSCP) and DNA sequencing. The efficiency of SSCP in detecting mutations in the COX subunits was estimated to be 80 per cent. Twenty one mtDNA point mutations were identified. Seventeen of the mutations are new variants of the mitochondrial genome. One missense mutation in COX III at nucleotide position 9861 which was observed in four of thirty three autopsy-confirmed AD patients results in the alteration of a moderately conserved phenylalanine to a leucine. This 9861 mutation was absent in 26 control brains and is absent in a GENBANK search of 130 human mtDNA sequences examined. Measurements of cytochrome c oxidase activity in extracts from frozen brain samples indicated that there was a 31 per cent decrease in COX activity in AD brains compared to age-matched control brain samples, which agrees with previously published observations. COX activity in one of the AD brain samples carrying the 9861 mutation was decreased by 61 per cent relative to the activity obtained from control brain samples. These results suggest that this mutation may be linked to AD and that its phenotypic expression results in reduced respiratory complex IV activity.

Program Nr: 1484 from the 1999 ASHG Annual Meeting

Decreased frequency of a neutral sequence variant of the RET proto-oncogene in sporadic Hirschsprung disease.

I. Ceccherini[1], P. Griseri[1], M. Sancandi[1], G. Patrone[1], R. Bocciardi[1], R. Hofstra[2], R. Ravazzolo[1,3], G. Romeo[3,4], M. Devoto[3]. 1) Lab Genetica Molecolare, Ist G. Gaslini, 16148 Genova, Italy; 2) Dept Medical Genetics, University of Groningen, The Netherlands; 3) Dept Oncologia,Biologia e Genetica, Universita' di Genova, Italy; 4) Genetic Cancer Susceptibility Unit, IARC, Lyon, France.

Hirschsprung (HSCR) disease is an inherited disorder characterized by absence of intrinsic ganglion cells in the distal gastrointestinal tract. Genetic mapping in humans and knock-out studies in mice have clearly shown that different susceptibility genes, involved in either the RET or the endothelin signalling pathways, contribute to HSCR phenotype. Interestingly, alterations of these genes are detected in only 30-50% of all HSCR patients, suggesting the involvement of modifier genes and/or additional genetic or environmental risk factors. We have analyzed about 300 HSCR patients confirming that a wide range of mutations of the RET proto-oncogene accounts for the highest proportion of cases. In addition to causative nucleotide changes, we have identified rare sequence variants and neutral substitutions which might act as susceptibility alleles conferring an altered disease risk. To test this hypothesis, we have retrospectively compared the frequencies of RET alleles detected in 52 Italian sporadic HSCR patients with respect to those found in 92 population-matched unaffected individuals, finding that a C2508T transition in exon 14 of the RET gene (S836S) is clearly less frequent in HSCR patients than in controls and the difference is statistically significant (Fisher exact test p=0.004). In agreement with a recent report (Gimm et al.,1999), we found the same variant is over-represented in patients with sporadic medullary thyroid carcinomas (MTC). These observations suggest that codon S836 may play an important role on normal RET function, inducing opposite functional effects when/if its sequence is altered. So far, we have excluded a role of the C2508T variant in RNA processing and DNA-protein interaction, while a possible linkage disequilibrium with another RET alteration or an effect on RNA translation are currently under investigation.

Program Nr: 1485 from the 1999 ASHG Annual Meeting

Genes on human chromosome 18q21 identified using exon trapping: towards the determination of bipolar susceptibility loci. *H. Chen[1], D. DePaulo, Jr.[1], G.N. Rochino[1], Y. Huo[1], T. Swift-Scanlan[1], C.A. Ross[1,2], M.G. McInnis[1], P. Sklar[3]*. 1) Department of Psychiatry & Behavioral Sciences; 2) Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21287, U.S.A; 3) Massachusetts General Hospital, Boston, MA.

The region between D18S41 and D18S60 in the q21 band on chromosome 18 (HC18) has been linked to bipolar disorder (Stine et al, 1995; McMahon et al, 1997). In order to identify genes systematically in this region we performed exon trapping on cosmids which had been isolated from an HC18-specific cosmid library (LL18NC02) using 47 STSs from the interval as hybridization probes. A total of 285 unique sequences (exons) were obtained. Homology searching of the databases using NCBI's BLAST algorithms revealed that 32 exons show identity to known genes and/or ESTs, 29 have significant homologies to genes from human and other species, and 19 sequences are homologous to ALU or other repeats. There are 205 sequences (72%) with no homology to entries in public databases. Of these exons, 34 were selected at random for mapping back to chromosome 18. Twenty-nine of 34 exons tested were mapped back to chromosome 18 using PCR amplification of the Genebridge4 radiation hybrid panel. Sixteen exons localized to the 18q21 region. We performed cDNA library screening and RT-PCR analysis to test whether the exons are expressed. Three pools of 6 exons each identified over 120 cDNA clones from a human fetal brain library. RT-PCR products from fetal brain RNA were obtained from 26 of the 34 exons (76%). The majority of the exons are being mapped to chromosome 18. We are developing full length cDNAs according to the trapped exons localized to the region and single nucleotide polymorphisms for association studies in bipolar families. A comprehensive transcript map in the region will provide valuable tool for the identification of susceptibility genes for bipolar illness and other disorders that map to the chromosome.

Program Nr: 1486 from the 1999 ASHG Annual Meeting

Association of gene markers on chromosome 5q and 11q with asthma in a Chinese population. *H. Chen[1,2], Y.Zh. Chen[2], L.P. Hu[3], J. Fu[2], H.Q. Zhang[2].* 1) Molecular Biochemistry, Basic Medical Science, Beijing, P.R.China; 2) Capital Insitute of Pediatrics, Beijing, China; 3) Academic Medical Science of Armyä.

We investigated linkages of asthma phenotypes to the markers on chromosome 5q31-33 and 11q13 in order to accumulate data on the related loci in the Chinese population. Thirty-two families with 192 samples were collected from 3 villages in the Fujian province of Southern China which has the highest morbidity (5%) of asthma reported from a recent epidemiological study. Each family was selected through the proband, a child with symptomatic asthma. The polymorphic markers D5S436 and D5S393 at chromosome 5q31-33 were genotyped. Sib-pair analysis showed evidence for linkage of asthma with D5S436 (IBD t=2.714, P<0.05, IBS t=2.313, P<0.05) but not D5S393. No significant linkage to total serum IgE was observed with either marker. Multiallelic TDTs was performed using the program ETDT. Transmission for individual alleles revealed the strongest association of asthma with particular allele of D5S436 (allele 236bp, ratio of transmitted: not transmitted 42:20, P=0.0052). Allele 236 of D5S436 was also found to be transmitted more frequently to offspring with high total serum IgE (20:7, P=0.0124). A coding variant of E237G and two RsaI polymorphic sites in the non-coding region of the FceRI-b gene (chromosome 11q13) were conducted. The allele frequencies for three FceRI-b gene polymorphisms in the Chinese population were markedly different from the published results of Caucasians and Japanese. The MIXED procedure by SAS system was used to evaluate differences in several factors-specific means for total serum IgE. The only significant difference was found between genotype of RsaI polymorphic site in intron 2 and total serum IgE levels. Further analysis of association between A allele of intron 2 polymorphism and elevated total serum IgE was also significant (Fish exact P=0.039, RR=1.316, 95%CI=1.028-1.803, P=0.038). However, biallelic TDT showed strong evidence for linkage disequilibrium between allele G of E237G and asthma (c^2td=10.24, P<0.01). These findings suggest that chromosome 5q31-33 and 11q13 may still be very attractive candidates for further investigation in the Chinese population.

Program Nr: 1487 from the 1999 ASHG Annual Meeting

Enzymatic and NMR spectral evidence of hairpin stability in DNA triple repeats: a possible mechanism for initiating the repeat expansion. *S.-H. Chen[1], C.R. Scott[1], S.-H. Chou[2]*. 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Institute of Biochemistry, National Chung Hsing University, Taichung, Taiwan, ROC.

Hairpin formation of single strand trinucleotide DNA repeats during meiosis has been suggested to be an event that possibly leads to the repeat expansion being associated with specific neurological diseases. We have synthesized pure CGG, CCG, CAG, CTG tandem repeats, and repeats with specific interruptions. The following experiments were performed: 1) Analysis of homoduplex and hairpin formation of the oligonucleotide repeats, 2) Hairpin stability test by an enzymatic assay (T4 DNA polymerase) of the repeats, and 3) Secondary structure stability analysis of the repeats by NMR imino proton spectra. We found that 1) Both hairpin and self-complimentary structures were detected for the CGG repeat under different conditions,while only hairpin was observed for the CGG, CAG and CTG up to 9 pure repeats. 2) T4 DNA polymerase studies showed that hairpin structures of $(CGG)_7$ and $(CCG)_7$ repeats were stable, while the repeats with interruptions were not. 3). NMR spectra revealed that the temperatures for imino proton "melting" of the $(CCG)_7$ and $(CGG)_7$ tandem repeats were greater than 50° C, while those for the $(CGG)_5\underline{T}CGCCG$ and $(CGG)_3\underline{A}GG(CGG)_3$ interrupted repeats were less than 40° C. These results suggest that a stable hairpin structure might be the initiating step enabling the expansion of the repeats.

Program Nr: 1488 from the 1999 ASHG Annual Meeting

A novel 2 bp deletion in Cytochrome C oxidase subunit II (COX II). *T. Chen[1], W. Fan[1], M. Lipson[2], M. Sifry-Platt[2], A. Grix[2], L. Wong[1]*. 1) Inst. for Mol & Human Genetics, Georgetown University, Washington, DC; 2) Kaiser Permanente Genetics Dept. 1650 Response Road Sacramento, CA 95815.

Most cytochrome oxidase (COX) deficiencies are autosomal recessive disorders associated with a variety of syndromes including Leigh and fetal infantile myopathy. COX deficiency has also been found in mitochondrial DNA (mtDNA) disorders with point mutations in tRNAs or large mtDNA deletions. Mutations in mitochondrial mRNA encoding COX subunits have only been reported once in COXIII (an inframe deletion of 15 bp) and once in COX II (mutation at initiation codon). We report here, for the first time, a 2 bp deletion in COX II, resulting in frame shift, truncated COX II mutant subunit. The mutation was found in a newborn male died at 12 days of age following a course of apnea and bradycardia, and 2 days of metabolic deterioration with significant lactic acidosis (serum lactate: 54 mmol/L; normal: 0.5-2.2 mmol/L). A twin brother also decompensated around the same time and expired. Family history was remarkable for a maternal half sibling died at 2 months of age following a DPT vaccination. The heteroplasmic mutation was first detected in a skeletal muscle autopsy by Temporal Temperature Gradient Gel Electrophoresis (TTGE). DNA sequencing analysis revealed a 2 bp deletion at 8042-8043 del AT (or 8043-8044 del TA). This mutation results in an alteration of three amino acids followed by a premature stop codon. The mutant COX II is 68 amino acids shorter than the wide type protein. Subsequent PCR/ASO analysis demonstrated that same heteroplasmic mutation was present in the autopsy tissues of heart muscle and liver, as well as in the tissue cultures of skin and lung, but absent in the mother blood sample.

Program Nr: 1489 from the 1999 ASHG Annual Meeting

Mutation analysis of spinocerebellar ataxia type 1 gene in Taiwanese schizophrenic patients. *Y.H. Chen[1], C.H. Chen[1,2]*. 1) Institute of Human Genetics, Tzu-Chi Medical College, Hualien, Taiwan; 2) Department of Psychiatry, Tzu-Chi General Hospital, Hualien City, Taiwan.

Schizophrenic is a devastating, chronic mental disorder with genetic component in its etiology. Previous linkage study suggested chromosome 6p22-24 may harbor important gene(s) for schizophrenia. Spinocerebellar ataxia type 1 (SCA1) gene was mapped to this region and was considered as a putative candidate gene for schizophrenia. In addition, the SCA1 gene contains polymorphic CAG repeats in its coding sequences, and evidence of linkage disequilibrium between schizophrenia and SCA1 CAG repeat was also reported by researchers, suggesting the possible important role of SCA1 gene in schizophrenia. Recently, Pujana and his colleagues reported identification of a serine to cysteine at codon 186 (S186C) in a schizophrenic from Spain (Hum Genet 1997;99:772-775), which added further support that SCA1 gene may play a role in the pathology of schizophrenia. To test if the SCA1 gene also involves in the pathogenesis of schizophrenia in our population, we first determined the CAG repeats number in a cohort of 115 schizophrenic patients and 87 non-psychiatric controls. The CAG repeats range from 21 to 34 in both groups, neither abnormal expansion of CAG repeats was observed in our patient, nor significant different CAG genotypes distributions was observed between patients and controls. We further systematically searched for the mutations in the protein coding sequences of SCA1 gene in 63 Chinese schizophrenic patients with positive family history. Currently we identified two polymorphisms of SCA1 gene in our population, including 1865T/C and 2150A/G, which were already reported in literature. However, we did not identify any other mutation of SCA1 gene in this cohort, including the S186C mutation. Hence, we suggest that SCA1 gene may not play a major role in the pathogenesis of schizophrenia in our population.

Program Nr: 1490 from the 1999 ASHG Annual Meeting

Determination of microsatellite total allele content differences between DNA pools: applications to association and population studies. *H.E Collins[1], S.E. Inda[1], C.M. Phillips[1], J. Tuomilehto[2], M.F. Seldin[1]*. 1) Rowe Program,UC Davis, Davis, CA 95616; 2) Nat. Public Health Inst. Helsinki, Finland.

DNA pooling is a potential tool for genome wide association studies or population comparisons. A simple method for measuring total allele differences in comparisons between two pools containing large numbers of DNA samples is presented. The method compares relative peak height differences between electrophoretigrams for each allele of a microsatellite. The method was evaluated by analysis of eleven microsatellites utilizing pooled sample sizes of 50, 100 and 200 individual DNA samples. Calculated pool differences were compared with real total allele differences determined by individual genotyping. Together > 200 comparisons demonstrated a correlation coefficient of 0.96. This method can provide a rapid screen for total allele differences of greater than 5-10%, a threshold that should be applicable to detecting low relative risk genes in common diseases. The validity of this method for association screens was verified by comparing a pool of 200 Finnish probands with rheumatoid arthritis to 200 Finnish controls. A strong positive signal was obtained for three MHC linked microsatellites, and allele specific differences were consistent with those anticipated for the DRB1 shared epitope. The applicability of the method to population comparisons was demonstrated by comparing microsatellite allele frequencies for an array of microsatellites between 5 ethnic pools, each with ³300 individuals. For analysis of >50 markers, the mean intrapool difference was 5.7%. In contrast, differences >20% were found for 50% of the markers between European Americans (EA) and Africans and 30% of the markers between EA and African Americans (AA), but only 8% of markers between EA and Hispanic Americans (HA). These findings demonstrate larger EA admixture in the HA than AA ethnicity. In conclusion, these studies suggest that DNA pooling can be a powerful tool in association studies for the determination of candidate regions for a range of complex genetic diseases, and in population screens to determine evolutionary divergence or to screen for markers useful for mapping by admixture disequilibrium.

Program Nr: 1491 from the 1999 ASHG Annual Meeting

Parent-of-Origin Effects in the Disequilibrium Mapping of Quantitative Traits. *W.O.C. Cookson, G.R. Abecasis, L.R. Cardon.* Wellcome Trust Center for Human Genetics, University of Oxford, OX3 7BN, United Kingdom.

Gene expression is the end result of complex and diverse regulatory mechanisms. It has been observed that for some genes expression of maternally and paternally inherited copies is differentially regulated, and it is likely that some of the genes underlying complex disease may be subject to parent-of-origin effects, such as methylation mediated imprinting. When the effect of maternal and paternal alleles is not modeled separately, traditional methods of association and linkage mapping can be inefficient in locating imprinted genes. For family-based association analysis of quantitative traits, we describe how imprinting effects can be modeled and distinguished from maternal effects and population stratification, and how the difference between the effects of maternal and paternal alleles on a particular trait can be evaluated.

For a range of effect sizes and allele frequencies, we examine the power to detect significant differences between models that allow for parent-of-origin effects and those that do not. We show that when the effect of maternal and paternal alleles differs greatly, models that do not allow for parent-of-origin effects may be unable to locate imprinted genes at all. Modeling the effect of maternally and paternally inherited alleles separately can significantly increase power. Allele frequencies appear to be especially important for di-allelic markers, as the parental origin of the inherited alleles may often be ambiguous. We show that, in sets of di-allelic markers, power can be greatly increased when haplotypes are used to resolve cases of ambiguity between maternal and paternal inheritance. These results and methodology may be of general value in the dissection of complex human disease.

Program Nr: 1492 from the 1999 ASHG Annual Meeting

Glaucoma phenotype associated with the GLC1A Gln368STOP mutation from the Glaucoma Inheritance Study in Tasmania. . *J.E Craig[1, 3], D.A. Mackey[1,3], P. Baird[1], A.I. McNaught[1,3], J.L. Dickinson[3], J.L. Rait[1], M.A. Coote[1], D.L. Healey[1], J.H. Fingert[2], E.M. Stone[2]*. 1) CERA, Melbourne University, East Melbourne, Victoria, Australia; 2) Department of Ophthalmology,University of Iowa,Iowa City; 3) Menzies Centre, University of Tasmania, Hobart, Australia.

Purpose: To investigate the age-related penetrance and phenotypic variability of Primary Open Angle Glaucoma (POAG) in Australian families with the GLC1A mutation Gln368STOP. Methods: Pedigrees with the Gln368STOP mutation in the myocilin gene (MYOC) at the GLC1A locus were identified from 1900 cases of POAG in Tasmania. Individuals positive for the Gln368STOP mutation were identified and examined along with available family members. Results: Gln368STOP is the commonest glaucoma mutation identified in our population to date. Incomplete penetrance was observed. Family history of POAG on both maternal and paternal sides, and phenocopies were frequently observed. Conclusions: The Gln368STOP mutation is associated with POAG of variable age of onset. Other factors, as yet uncharacterised, may be involved in expression of the POAG phenotype in Gln368STOP pedigrees.

Program Nr: 1493 from the 1999 ASHG Annual Meeting

Novel repeat structures identified in African-Americans represent a new mechanism leading to fragile X CGG repeat instability. *D.C. Crawford[1], C.E. Schwartz[2], S.T. Warren[1,3], S.L. Sherman[1].* 1) Department of Genetics, Emory University, Atlanta, GA; 2) P.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC; 3) Howard Hughes Medical Institute, Atlanta, GA.

The fragile X syndrome is caused by an unstable CGG repeat in the 5' UTR of FMR-1. To date, a number of factors have been identified which may influence repeat instability including number and position of interspersed AGGs, length of the 3' pure CGG repeat, and haplotype. However, nearly all such data were derived from studies of Caucasian populations (CC). Here we examine the African-American population (AA) by haplotyping a large, unaffected (n=643) and fragile X (n=63) AA population and sequenced the CGG repeat array in a subset of these chromosomes (n=125). Compared with the established CC data, the unaffected AA population had a significantly decreased frequency of intermediate alleles (IA; 41-60 repeats) yet the same prevalence of the syndrome. Furthermore, there was no association of haplotype background with these IAs in contrast to that observed among CCs. Sequencing data show that the frequency of alleles with >24 pure repeats at the 3'end of the repeat in the AA population (0.03) was similar to that shown in CCs. Therefore, although there was a decreased frequency of IAs in the AA population, the frequency of susceptible repeat structures was similar to the CC population. Among the fragile X AA, we identified a unique haplotype background not yet observed in the unaffected CC population. Also, this haplotype background was rare in the unaffected AA population and was not found among the IAs. Sequencing of these alleles revealed the lack of a 5' AGG but the retention of a 3' AGG. These data suggest that the lack of a 5' CGG repeat may be a factor for repeat instability. We propose that these repeat structures increase the risk for either 1) loss of the 3' AGG leading to an allele of >24 pure repeats or 2) expansion of the number of 5' CGG repeats. Either result may lead to rapid expansion to the premutation. To distinguish between the two possible mechanisms, premutation alleles of this haplotype background are being sequenced to determine the presence or absence of a 3' AGG.

Program Nr: 1494 from the 1999 ASHG Annual Meeting

A low enzyme activity haplotype at DBH associates with cocaine-induced paranoia. *J.F. Cubells[1,2], H.R. Kranzler[3], E. McCance-Katz[1], G.M. Anderson[4], R.T. Malison[1], L.H. Price[1], J. Gelernter[1,2].* 1) Dept Psychiatry, Yale Univ Sch Med, New Haven, CT; 2) VACHS, West Haven, CT; 3) Dept. Psychiatry, Univ. Conn. Health Center, Farmington, CT; 4) Yale Child Study Center, New Haven, CT.

Low levels of dopamine b-hydroxylase (DbH) protein in the serum or cerebrospinal fluid (CSF) are associated with greater vulnerability to positive psychotic symptoms across several diagnostic groups. DbH level is a stable, genetically controlled trait. The locus encoding DbH protein, DBH, is the major quantitative trait locus controlling plasma and CSF DbH levels. We therefore hypothesized that DBH variants associated with low levels of DbH in the plasma would also associate with greater vulnerability to cocaine-induced paranoia (CIP).

To test this hypothesis, we first showed that a di-allelic variant, DBH5'-ins/del, located approximately 3 kb 5' to the DBH transcriptional start site, significantly associates with plasma DbH activity in European-Americans (EAs; N = 66). Linkage disequilibrium (LD) analysis of that polymorphism and DBH444g/a, another di-allelic variant associated with DbH activity, demonstrated that alleles of similar association to DbH levels are in positive LD. We then estimated DBH haplotype frequencies in cocaine-dependent EAs rated for cocaine-induced paranoia (N = 45). As predicted, the low-DbH-associated haplotype, Del-a, was significantly more frequent ($p = 0.0005$) in subjects endorsing CIP (N = 29) than in those denying CIP (N = 16). Comparison to haplotype frequencies in control EAs (N = 170) showed that the association predominantly reflected under-representation of Del-a haplotypes in those denying CIP.

We conclude that (a) the two DBH polymorphisms we studied are associated with DbH activity; (b) those two polymorphic systems are in significant LD in EAs, with alleles of similar association to DbH levels in positive LD, and (c) the haplotype associated with low DbH activity is associated with CIP.

Program Nr: 1495 from the 1999 ASHG Annual Meeting

Identification of six mutations in the *Caspase-8* gene in non-obese diabetic (NOD) mice. *A. Davoodi-Semiromi, M. Marron, E. Leung, C-Y. Wang, J-X. She.* Department of Pathology, University of Florida, Gainesville, FL. USA, 32610.

Apoptosis is a major form of cell death characterized initially by a series of morphological changes. This process appears to play an important role in the development of diabetes in the non-obese diabetic mice (NOD). Key elements that initiate and eventually execute the apoptotic program are members of the caspase family of cystein protease whose activation is believed to be essential for virtually all forms of apoptosis. Here we report the identification and characterization of six mutations in the caspase-8 gene in mice. Total RNA was extracted and converted to the cDNA by reverse-transcription and amplified by polymerase chain reaction (RT-PCR). The whole coding sequence and parts of the 3' and 5' end of the gene were amplified and subjected to direct sequencing. We sequenced the gene for NOD and six other strains and we found the same mutations in NOD, MRL and Balb/c. These mutations, however, were not present in B6, C3H, CBA and NZW. An A to G at position -23 and an Ala96Val along with four silent mutations at codons 48, 92, 188, and 317 were found. Of six mutations identified in this study, the A to G transition at position -23 and a missense mutation at codon 96 (Ala96Val) might be pathological mutations. Our data show that these mutations, however, are not specific for NOD mice since they are found in other strains as well. Functional significance of these mutations and their potential role in IDDM remains to be elucidated.

Program Nr: 1496 from the 1999 ASHG Annual Meeting

Molecular characterization of four endogenous retroviral related sequences identified by Representational Difference Analysis from three sets of monozygotic twins discordant for schizophrenia. *P. Deb-Rinker[1], P.P. McDonald[1], M.J. Lewis[1], R.L. O'Reilly[2], S.M. Singh[1]*. 1) Molecular Genetics Unit (Zoology), University of Western Ontario, London, Ontario, Canada; 2) Psychiatry, University of Western Ontario, London, Ontario, Canada.

A significant proportion of the human genome consists of sequences with a retroviral origin, some with the capacity to transpose. Such human endogenous retroviral sequences could cause mutations by insertions as well as provide a basis for the evolution of the human genome. Despite the notable representation of retrovirus-like sequences in the human genome, relatively little is known about their organization, distribution and significance. We have isolated four retroviral-related sequences from human genomic DNA representing three sets of monozygotic twins discordant for schizophrenia by Representational Difference Analysis. Southern blot analysis has identified one of them (MSRV-like gb AF009668) to be present in multiple copies (15-20) while the other three (with no significant database match) are single copy sequences. The mutlicopy MSRV-like sequence was FISH mapped to at least six different chromosomal locations, suggesting that HERVs have a dispersed pattern in the human genome with few chromosomal sites favoring integrations. The origin of these sequences was assessed with a Zooblot. All four sequences were limited to humans and rhesus monkey lanes suggesting a primate lineage. It is interesting that three of these sequences showed weak positive signals in the Bovine lane, indicating a related retroviral element in this species. Further, when used as probes on Northern blots, two of these sequences identify 7-9kb RNA transcripts in the human placenta. The other two sequences also identify RNA transcripts in a few adult tissues. These results on retroviral elements bring out the potential of these and related sequences in the human genome as causative agents for insertional mutagenesis during development and differentiation. Such mechanisms could cause significant pathological effects and contribute to discordance of monozygotic twins for complex multifactorial diseases including schizophrenia.

Program Nr: 1497 from the 1999 ASHG Annual Meeting

A common substitution (C-514T) in the human hepatic lipase gene promoter decreases its transcriptional activity. *S.S. Deeb.* Dept Genetics/Medicine, Univ Washington, Seattle, WA.

Hepatic lipase catalyzes the hydrolysis of triglycerides and phospholipids in plasma high-density lipoprotein (HDL) and low-density lipoprotein (LDL) particles. Four polymorphisms exist in the proximal promoter of the human hepatic lipase gene (LIPC). They are in almost complete linkage disequilibrium. The less common haplotype, which occurs at a frequency of between 0.15-0.21 among Caucasians, is associated with decreased postheparin plasma hepatic lipase activity, increased plasma HDL cholesterol (particularly the phopholipid-rich HDL2 particles) and increased bouyancy of circulating LDL particles. Decreased HDL cholesterol and prevalence of small dense LDL particles constitute a risk factor for atherosclerosis. We investigated whether any of the four LIPC promoter polymorphisms influences transcriptional activity of proximal promoter constructs (-639/+29) as measured by transient transfection of the murine heptocyte cell line ML12. We observed that the C-514T substitution resulted in approximately a 30 per cent decrease in promoter activity ($P<0.0001$). On the other hand, the G-250A substitution had no effect on activity of promoters with either T or C at position -514. Interestingly, the substitution at position -514 lies within a potential binding site for a transcription factor (upstream-stimulatory factor)that has been shown to mediate insulin action on gene transcription. In conclusion, we postulate that the C-514T substitution contributes significantly to the decrease in levels of plasma hepatic lipase activity, which in turn results in higher levels of phospholipid-rich HDL2 and large bouyant LDL particles.

Program Nr: 1498 from the 1999 ASHG Annual Meeting

Association between schizophrenia and the UFD1L promoter polymorphism - 277A/G. *A. De Luca[1], A. Botta[1], F. Amati[1], E. Conti[1], A. Pasini[2], F. Macciardi[3], N. King[3], G. Spalletta[2], B. Dallapiccola[1,4], G. Novelli[1]*. 1) Department of Biopathology and Diagn. Imaging, Tor Vergata University and CSS Mendel Institute, Rome,Italy; 2) Department of Psychiatry, Tor Vergata University, Rome,Italy; 3) Neurogenetic Section, Clarke Institute of Psychiatry, University of Toronto, Ontario, Canada; 4) IRCCS,CSS,S.Giovanni Rotondo, Italy.

Haploinsufficiency resulting from deletion of a gene or a number of genes at 22q11.2 has been associated with a variety of clinical disorders, including DiGeorge syndrome (DGS) and velocardiofacial syndrome (VCFS). Hemizygosity of 22q11.2 has been also associated with schizophrenia or schizoaffective disorders. To identify the schizophrenia susceptibility gene(s) in this region, we evaluated a novel single nucleotide polymorphism mapped within a region with functional promoter activity of the Ubiquitin Fusion Degradation Protein-1 (UFD1L) gene. UFD1L gene is considered a candidate for schizophrenia, since it is expressed during development in the medial telencephalon that forms hippocampus and is deleted in DGS/VCFS patients most of which develop psychiatric disorder by adult age. Sixty-one individuals with DSM-IV--SCID-P schizophrenia and 70 ethinically matched controls were genotyped for the -277A/G UFD1L promoter polymorphism. A significant increase in the frequency of the -277A variant allele of the UFD1L promoter polymorphism was found in schizophrenic patients (0.54) compared to matched controls (0.35) ($P<0.003$). The difference in genotype distribution was also significant ($P<0.02$).To elucidate the role of this gene in the pathogenesis of schizophrenia expression and protein localization in the human brain were investigated. Northern and western blot analyses using mRNA and protein extracted from different areas of adult human brain, confirmed the presence of the UFD1L transcript and protein in the brain expecially in the cerebellum, cerebral cortex, and thalamus. These results support the presence of a susceptibility locus for schizophrenia in chromosome 22. Work supported by a grant from Italian Ministry of Health and Telethon (N. E 723 and 264/bi).

Program Nr: 1499 from the 1999 ASHG Annual Meeting

Maternal Multivitamin Use, Genetic Variation in Folate Metabolism and Risk of Oral Clefts. *S.R. Diehl, M.H. Khoshnevisan, D.F. Wyszynski, T. Wu, A. Miller-Chisholm.* Craniofacial Epidemiology and Genetics Branch, NIDCR/NIH, Bethesda, MD, USA.

The purpose of this study was to evaluate the association between SNPs at the MTHFR gene, maternal multivitamin consumption and risk of nonsyndromic cleft lip with or without cleft palate in a Caucasian population. We studied 234 families with one or more CL/P affected members. Two SNPs in the MTHFR gene (C677T and A1298C) were assayed by standard PCR-RFLP techniques. We performed a transmission disequilibrium test and a case-only analysis to evaluate linkage disequilibrium (association) and interactions with maternal multivitamin consumption. Without considering multivitamin consumption, we found significant (1) < 0.05) evidence of disequilibrium with risk of cleft lip for the C677T SNP, but no association with the A1298C polymorphism for all subjects. However, when we incorporated multivitamin consumption into our analyses, we found a much stronger association of CL/P risk for the C677T MTHFR SNP for mothers who did use multivitamins during their first trimester of pregnancy ($p < 0.005$). We also found a weak association with the A1298T MTHFR SNP for mothers who did not use multivitamins. These findings indicate the presence of a strong gene by environment interaction for MTHFR SNPs and maternal multivitamin consumption.

Program Nr: 1500 from the 1999 ASHG Annual Meeting

FMRP is a phosphoprotein and a substrate of the Fes non-receptor tryosine kinase. *S.P. DiMarco, S. Ceman, E. Torre, S.T. Warren.* Howard Hughes Medical Institute and Departments of Biochemistry, Pediatrics and Genetics, Emory University School of Medicine, Atlanta, GA 30322.

Fragile X syndrome, a common form of mental retardation is caused by the absence of FMRP, the encoded protein of FMR1. FMRP is an RNA binding protein and shuttles between the cytoplasm and nucleus. Phosphorylation of certain proteins has been shown to modulate RNA binding and cellular localization, therefore, we decided to investigate the phosphorylation status of FMRP. Here we describe FMRP as a serine, threonine and tyrosine phosphoprotein. We have pursued the tyrosine phosphorylation of FMRP and identified the Fes kinase as responsible for the tyrosine phosphorylation of FMRP in vivo and in vitro. The tyrosines phosphorylated by Fes were identified by CNBr cleavage and 2-dimensional peptide mapping of Fes phosphorylated FMRP. Three tyrosine residues within an 8kDa CNBr fragment of FMRP, adjacent to the nuclear export signal, were found to be phosphorylated. These tyrosines were mutated to phenylalanines and the protein was no longer able to be phosphorylated by Fes in vivo. Similar to other substrates of Fes, FMRP was found associated with Fes in immunoprecipitations. NIH 3T3 cells, transiently expressing Fes, were labeled with 32P-orthophosphate, nuclear and cytoplasmic lysates were made and immunoprecipitated with an anti-FMRP antibody. Using phosphoamino acid analysis, FMRP was found to be tyrosine phosphorylated only in the nucleus. Nuclear FMRP only accounts for 4-5% of cellular FMRP, which correlates with the amount of FMRP found to be tyrosine phosphorylated in normal lymphoblastoid cells. The three tyrosines phosphorylated by Fes may play a role in RNA binding, mRNP assembly, or nuclear transport of FMRP.

Program Nr: 1501 from the 1999 ASHG Annual Meeting

The subcellular distribution of HTm4, a hematopoietic specific protein and a canditade gene for atopy. Identification of the CDK-associated phosphatase KAP as an interacting protein. *J.L. Donato, H.B. Cai, C.N. Adra.* Beth Israel Deaconess Med Ctr, Harvard Medical School, Boston, MA.

HTm4 is a four transmembrane protein expressed specifically in hematopoietic cell lineages. This protein is 214 amino acids in length, with a predicted molecular weight of 25 kDa and is significantly (28%) homologous to CD20 and FceRIb. The HTm4 gene is organized into 7 exons and 6 introns, whose structure is reminiscent of the FceRIb and is localized to chromosome region 11q13.1, closely clustered with CD20 and FceRIb. We have identified two independent loci for atopic asthma on 11q13.1. One is for atopy (high IgE levels) and lies in a region that includes FceRIb and HTm4 genes, the other is for asthma per se (wheeze and labile airway obstruction) and lies close to D11S480. HTm4 is expressed in G0 hematopoietic stem cells, and in cells committed to differentiate into myeloid and B lymphocyte cell lineages. The gene is "shut off" in non-quiescent stem cells that are undergoing proliferation and differentiation. We used a specific polyclonal antibody to study the cell localization and protein interactions first detected by the yeast-two hybrid assay. Flow cytometry and immunohistochemistry analysis using the anti-HTm4 antibody showed an intracellular localization of HTm4 in U937 cells. A prominent immunofluorescent staining was seen around the nuclei. After U937 nuclei purification and Western blotting analysis, strong HTm4 signals were obtained in both total cell lysate and membrane fractions, but no significant reaction was observed in the nuclei enriched fraction, demonstrating that HTm4 is mainly located in the ER membranes. The yeast assay revealed that HTm4 specifically binds KAP (CDK-Associated Phosphatase). This interaction was confirmed by Western blotting analysis showing that HTm4 co-immunoprecipitates with KAP in total cell lysates incubated with anti-KAP antibody. Since KAP modulates the activity of the cyclin dependent kinases cdk2 and cdc2, our results emphasize the importance of HTm4 gene in hematopoietic cells and open the possibility that this molecule participates in the cell cycle events and in the maintenance of cells of the immune system.

Program Nr: 1502 from the 1999 ASHG Annual Meeting

Analysis of C. elegans transgenic for HD gene constructs with an expanded repeat. *J.C. Dorsman[1], H.G.A.M. van Luenen[3], M.A. Smoor[1], B. Pepers[1], M. Bremmer-Bout[1], J.T. den Dunnen[1], R.H.A. Plasterk[3], R.A.C. Roos[2], G.J.B. van Ommen[1]*. 1) Department of Human Genetics, LUMC, Leiden, The Netherlands; 2) Department of Neurology, LUMC, Leiden, The Netherlands; 3) The Netherlands Cancer Institute, Division of Molecular Biology, Amsterdam, The Netherlands.

Huntington's disease (HD) is a neurodegenerative disorder with a midlife onset. The disease is caused by expansion of a CAG (gln) repeat within the coding region of the HD gene. We are studying the effects of expanded huntingtin repeats in the nematode C. elegans, an inexpensive model animal, of which the neuroanatomy, differentiation and genetics are well-defined. We have generated nematodes transgenic for exon1 or exon1-7 of the HD gene, with (CAG)17, (CAG)73 or (CAG)140 repeats. The transgenes are present either as an extra-chromosomal array or integrated into the genome. Expression of the transgenes is driven by the HSP promotor which is regulated by heatshock. After heatshock induction a clear expression of the transgenes can be detected. Expression of the 140 HD transgene could only be detected with a monoclonal antibody specifically recognizing expanded gln repeats and with polyclonal antibody CAG53B which recognizes exon1 sequences. An extensive survey of transgenic worms containing the transgenes on extrachromasomal arrays revealed that a single heat shock of either eggs or L1 larvae has no effect on the percentage of transgenic offspring. Preliminary experiments suggest that expression of long gln repeats decreases the lifespan considerably. Transgenic animal and cell-model studies for HD have been hampered by the intrinsic instability of long CAG-repeat sequences in sub-cloning experiments. We have now shown that this stability problem can be reduced by the interruption of the perfect repeat at the DNA level by an alternative trinucleotide sequence encoding the same amino acid, i.e. a mixed repeat consisting of CAG and CAA triplets. We will use these larger repeat sequences (e.g. 300 gln) to accelerate the disease process and/or to cause more severe (lethal) phenotypes facilitating, e.g., high throughput drug-testing studies.

Program Nr: 1503 from the 1999 ASHG Annual Meeting

Genome-wide linkage analysis in a New Zealand family with familial Vesicoureteric Reflux. *M.R. Eccles[1], G.J. Jacobs[1], K.L. Choi[1], M. French[1], L. McNoe[1], J. Goodwin[1], S. Edwards[2], P. Tomlinson[2], G.D. Abbott[3]*. 1) Dept Biochemistry, Univ Otago, Dunedin Otago, New Zealand; 2) Dept Paediatrics, Univ Otago, Dunedin Otago, New Zealand; 3) Dept Paediatrics, Christchurch School of Medicine, Univ Otago Christchurch, New Zealand.

Vesicoureteric reflux (VUR) is very common in children, with an estimated incidence of between 0.4% and 9% of the general population. Approximately 15% of end-stage renal failure in children is caused by VUR making it one of the commonest causes of end-stage renal failure. The strong familial association of VUR and associated reflux nephropathy suggests that VUR may have a genetic component. Previous studies have suggested (one) dominantly inherited locus of major effect. PAX2 mutations cause VUR in a quarter of individuals with renal-coloboma syndrome, however PAX2 mutations are absent in patients with primary familial VUR. We have now carried out genome-wide linkage analysis in a 4-generation New Zealand family with familial VUR, in which 7 of 35 individuals were affected. Parametric and non-parametric programmes were used to analyse 226 markers evenly spread over the genome. Six regions were obtained on chromosomes 2, 4, 5, 8 and 12 with LOD scores >1.0. A maximum multipoint LOD score of 2.4 was obtained on chromosome 12. No linkage was found on chromosome 6p, or at the PAX2 locus on chromosome 10, both of which have been previously suggested might have a role in VUR. Further analysis of each of these chromosomal regions in 15 smaller New Zealand families with VUR failed to add significantly to the LOD scores. These data suggest that either VUR is caused by several genes in the population, or that there are several loci of major effect contributing to the disease.

Program Nr: 1504 from the 1999 ASHG Annual Meeting

High-throughput sequencing of candidate genes for alcohol-related QTLs. *M.A. Ehringer[1], J. Thompson[1], O. Conroy[1], Y. Xu[1], F. Yang[1], J. Canniff[1], M. Beeson[2], L. Gordon[2], B. Bennett[2], T.E. Johnson[2], J.M. Sikela[1]*. 1) Dept Pharmacology, Univ Colorado Health Sci Ctr, Denver, CO; 2) Institute for Behavioral Genetics, Univ Colorado, Boulder, CO.

We have developed a high-throughput automated gene sequencing approach to examine candidate genes within QTLs (Quantitative Trait Loci) related to alcohol action. Our efforts to date have focused on the four QTLs associated with inbred lines of mice which differ in their initial sensitivity to alcohol, inbred short-sleep (ISS) and inbred long-sleep (ILS). Using the rapidly evolving human and mouse gene maps, we have identified genes that fall within these QTLs and ranked them as possible candidate genes based on several criteria. Brain RNA isolated from appropriate animals is used to make cDNA, which is amplified using overlapping pairs of PCR primers specific for the coding regions of candidate genes. DNA sequences of PCR products are determined using ABI fluorescent automated sequencers, and the data is analyzed using a UNIX sequencing software package which includes Phred, Phrap, and Consed. Direct comparison of sequences obtained for each animal allows us to immediately determine if a DNA difference corresponds to a change in an amino acid. Thus far, a primary search of the four Lores has been completed. For example, approximately 123 genes within Lore2 have been evaluated and ranked using the latest data from the human gene map. Presently, the coding regions of eighty candidate genes have been comparatively sequenced and analyzed, either in whole or in part. We have identified five genes with DNA changes corresponding to amino acid differences between ISS and ILS mice, representing all four QTLs. This work is supported by grants AA11853 and AA03527.

Program Nr: 1505 from the 1999 ASHG Annual Meeting

Fragile X Mental Retardation in Syndrome in Saudi Arabia. *M.F. El-Hazmi.* Med Biochem, King Khalid Hosp, King Saud Univ, Riyadh, Saudi Arabia.

Mental retardation is a cognitive disorder frequently associated with various forms of disability. In a National survey, we identified 298 cases of mental retardation among 5,000 subjects, where mental retardation accounted for 10% of the disabilities. The aetiology of mental retardation is complex and several monogenic, polygenic and chromosomal abnormalities play a role in the development of mental retardation. One of the genetic causative factors of mental retardation is fragile X syndrome, a condition related to increased number of a polymorphic triple repeat sequence, (CGG), at a folate-sensitive fragile site, Xq27.3 (FRAXA). The number of the repeat sequence, located at the 5'-untranslated regions of FMR-1, is related to the mental disability. Males, due to their hemizygous state of X-chromosome, suffer more frequently from a mentally sub-normal state in patients with the number of repeats ranging from 54 to 200 (premutation), and mental retardation in patients with an increase in the repeat number more than 200. Normal men carrying a premutated allele are called `normal transmitting males (NTM) and have a high risk of having affected grandsons. Some affected individuals have premutations and full mutations and present mosaicism. A sample of forty two Saudi patients diagnosed as mentally retarded, and 800 cases with other disabilities were investigated using PCR amplification of DNA with primers flanking the trinucleotide repeats. Of the 42 mentally retarded group, 15 cases of full mutation and 8 cases of premutation were identified. The rest had normal PCR product pattern ruling out fragile X syndrome. Premutation pattern was also identified in the group with other disabilities including speech defects, learning disabilities. This paper will present an overview of diagnostic value of fragile X-syndrome in mental retardation, speech and learning disability.

Program Nr: 1506 from the 1999 ASHG Annual Meeting

Gene Dose Effect in Psoriatics Homozygous for HLA-Cw6. *C. Enerback[1], F. Enlund[2], A. Inerot[1], L. Samuelsson[2], J. Wahlstrom[2], G. Swanbeck[1], T. Martinsson[2].* 1) Dept Dermatology, Univ Gothenburg, Gothenburg, Sweden; 2) Dept Clin Genet, Univ Gothenburg, Sahlgrenska Univ Hosp, Gothenburg, Sweden.

Psoriasis is a common inflammatory skin disease with a heterogenous genetic background. The existence of a gene in the HLA region on 6p was suggested from association studies which in recent years has been confirmed by linkage studies. The purpose of this study was to study the Cw6 allele and its contribution to disease susceptibility in a patient material consisting of 104 families with at least two affected siblings. We have set up a sequencing method to examine the two exons that build up the antigen binding site of the C-locus receptor. Patients homozygous for Cw6 based on haplotype information was sequenced which confirmed the identity of the Cw6 allele in an affected individual with the consensus sequence. We screened the material for psoriasis patients homozygous for Cw6. Eleven individuals with a mean age at onset of 16,1 years was found, that in comparison with the mean age of 18,45 for the Cw6 heterozygotes and 22.36 for Cw6 negatives, points towards a gene dose effect. The method was also used to decide the genotype for the parents in order to perform a Transmission Disequilibrium Test on the Cw6 allele per se, used as a biallelic marker. This analysis resulted in a C^2 of 70,21 ($p= 5x10^{-17}$). This widely exceeds our previous results of TDT in this region, including microsatellite markers and SNPs in the coding part of the S gene (corneodesmosin). Also the maximum NPL value is reached using Cw6 as a marker. We conclude that Cw6 is the allele which show the highest degree of association to psoriasis in our material and we propose that it influences directly the age at onset of the disease rather than increasing the genetic load in accordance with a polygenic theory.

Program Nr: 1507 from the 1999 ASHG Annual Meeting

The alpha-synuclein-associated protein, synphilin-1: Gene structure and localization, and presence of synphilin-1 protein in Lewy bodies. *S. Engelender[1], K. Wakabayashi[2], T. Wanner[1], Z. Kaminsky[1], J.J. Kleiderlein[1], R.L. Margolis[1], S. Tsuji[2], H. Takahashi[2], C.A. Ross[1]*. 1) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) Brain Research Institute, Niigata University, Japan.

Parkinsons disease (PD) is a common neurodegenerative disease characterized by motor signs including tremor, bradykinesia and rigidity. Pathologically, there is loss of neurons in substantia nigra and the surviving neurons develop cytoplasmic inclusions termed Lewy bodies. Alpha-synuclein mutations cause some familial forms of PD, and alpha-synuclein protein is also present in Lewy bodies of patients with sporadic disease. Alpha-synuclein interacts *in vivo*with a novel protein we have called synphilin-1 (Engelender et al., Nature Genet. 22: 110-114, 1999). When synphilin-1 was co-transfected into mammalian cells with the NAC portion of alpha-synuclein we observed the formation of eosinophilic inclusions resembling Lewy bodies. We now find that synphilin-1 is present in some Lewy bodies of patients with PD and DLB. The staining of Lewy bodies with synphilin-1 is specific, since no staining is observed when the antibody is pre-absorbed with recombinant synphilin-1. We now have also cloned the human synphilin-1 gene, determined the organization of its10 exons and localized it to chromosome 5q23.1-23.3. Mutation analysis of synphilin-1 may further clarify the role of synphilin-1 in the pathogenesis of genetic PD. Furthermore, in sporadic PD, synphilin-1 could modulate alpha-synuclein aggregation.

Program Nr: 1508 from the 1999 ASHG Annual Meeting

Expression of the myotonic dystrophy locus genes in neonatal and adult tissues, and during muscle regeneration - indicators of possible pathological mechanisms. *M. Eriksson[1,2], T. Ansved[1], L. Edström[1], D. Wells[3], D. Watt[3], M. Anvret[1], N. Carey[4].* 1) Dept Neurology, Clinical Neuroscience, Stockholm, Sweden; 2) Dept Mol Med, Clin genetics unit, Karolinska Hospital, Stockholm, Sweden; 3) Division of Neurosciences,Imperial College School of Medicine,London,UK; 4) Division of Surgery, Imperial College School of Medicine,London,UK.

Myotonic dystrophy (DM) is a multisystemic disorder caused by the expansion of a CTG trinucleotide repeat, but the mechanism(s)by which this repeat leads to the very complex symptomatology remains controversial. One hypothesis is that the expansion disrupts the expression of the genes in its immediate vicinity - *DMPK*, *DMWD* and *Six5*. The pathological consequences of this phenomenon may vary between tissues, depending on the normal expression patterns of the DM locus genes. However, there have been no systematic, genuinely quantitative studies addressing the issue of relative expression levels of the genes at different time points in clinically significant tissues. It is also possible that the normal expression of the genes may be differentially regulated depending upon the physiological status of certain tissues. For example, we have already published data showing that *DMPK* expression increases in the muscles of patients with non-DM myopathies,and we hypothesise that this may be a consequence of increased muscle regeneration. We are using murine model systems to address these issues. Using highly sensitive and reproducible real-time fluorescence RT-PCR technologies the precise expression levels of the DM locus genes (relative to a house-keeping standard, TATA-binding protein) have been analysed in clinically relevant tissues from neonatal and adult C57Bl/10 mice. An *in vivo* system for stimulating skeletal muscle regeneration in the mice has also been employed for assessment of the effects of this process on expression of the genes. Our data provide essential baseline information on the expression of the DM locus genes, which is vital for selecting candidates for specific aspects of the pathology in this disease.

Program Nr: 1509 from the 1999 ASHG Annual Meeting

mtDNA mutation A1555G and progressive deafness: modifying factors of a common mutation causing late onset deafness. *X. Estivill[1], N. López-Bigas[1], R. Rabionet[1], O. Bravo[2], J. Girons[2], M.L. Arbonés[1].* 1) Medical & Molecular Genetics Center, Barcelona, Spain; 2) Otolaryngology Service, Bellvitge Hospital, Barcelona, Catalonia, Spain.

Late onset deafness is likely the result of complex interactions between genetic susceptibility factors and the environment. The A1555G mutation in the mitochondrial 12S rRNA has been associated with aminoglycoside-induced and non-syndromic sensorineural deafness. We have previously described 19 families with maternally transmitted deafness that have the A1555G mutation and we have analyzed the relationship of this mutation with the treatment with aminoglycosides. We have identified 66 new families with sensorineural hearing loss and have tested them for mutation A1555G. We have found the A1555G mutation in 11 of these families. By combining the families presented here with those described previously, we have identified 30 families with the A1555G mutation, representing 22% of all the deafness families that we have studied. Considering the 30 families with mutation A1555G, deafness was diagnosed in 214 of 429 subjects with the mutation, with a penetrance for A1555G of 50% by the age of 30 years and 90% by the age of 65. Interestingly, only 46 of 230 (20%) subjects with deafness of the 30 families with A1555G were treated with aminoglycosides prior to their hearing loss, indicating the strong role of factors as yet unknown in the development of deafness. This further confirms that the A1555G mutation is a major susceptibility factor for progressive deafness and that its penetrance can be enhanced by treatment with aminoglycosides. The identification of other factors involved in deafness due to A1555G should facilitate the understanding of the complex interactions between environmental and genetic factors in hearing loss. We are currently studying the relationship between A1555G and other deafness mutations in the mtDNA, specially mutation A7445G affecting the tRNA Ser(UCN), and mutations in the connexin 26 gene, for which a high carrier frequency have been described in the Mediterranean population. Mutations in these genes may enhance the development of deafness in patients that carry A1555G.

Program Nr: 1510 from the 1999 ASHG Annual Meeting

Search for imprinting effects in the hereditary paraganglioma critical region on chromosome band 11q23: allelic expression analysis of *PPP2R1B, POU2AF1,* D11S966E and methylation analysis of two *Not*I sites associated with novel genes. *J.E. Farr[1], J.R. Goss[2], P. Taschner[3], P. Devilee[3], U. Surti[4], B. Devlin[1], B.E. Baysal[1].* 1) Dept Psychiatry, Univ Pittsburgh Med. Ctr., Pittsburgh, PA; 2) Dept Neurology, Univ Pittsburgh Med. Ctr., Pittsburgh, PA; 3) Dept of Human Genetics Leiden Univ Med Ctr., The Netherlands; 4) Dept of Genetics, Magee Women's Hospital,Pittsburgh, PA.

Pedigrees with hereditary non-chromaffin paragangliomas (PGL, glomus tumors, MIM#168000) display features consistent with genomic imprinting: disease transmission through affected mothers has yet to be demonstrated whereas the disease phenotype segregates as autosomal dominant when transmitted through fathers. In accord genomic with imprinting, allelic imbalance patterns in PGL tumors display strong bias for the loss of normal, maternal allele. However, there are no other parent-of-origin effects described on chromosome band 11q23. *PGL1* has been confined to a 1.5 Mb critical interval. We evaluate allelic expression in three regional genes, *PPP2R1B* (encoding the beta isoform of PP2A-A subunit), *POU2AF1* (*Bob1*, *OBF1*, encoding Oct- binding factor 1) and D11S966E. For *PPP2R1B*, we obtain novel 3'-untranslated region sequence, which is compatible with the 5.0 kb transcript size in Northern analysis, and identify a new (CA/GT)n simple tandem repeat polymorphism (STRP) therein. Several fetal and adult tissues including brain, kidney, lung, chorionic villi, decidua and lymphoblastoid cell lines (LCL) show bi-allelic expression. For *POU2AF1* and D11S966E, we have tested an expressed (CCTT)n STRP and a single nucleotide polymorphism, respectively. Both genes show bi-allelic expression in LCL. We also capture two *Not*I sites associated with two novel genes in the *PGL1* critical region. Both *Not*I sites are completely de-methylated in LCL. Bi-allelic expression and de-methylation patterns are not altered in LCL from PGL affected and imprinted carrier individuals. The physical locations of the tested genes and *Not*I sites yield an even coverage of the critical region. These results provide the first direct evidence against domain-wide imprinting effects in the *PGL1* critical region.

Program Nr: 1511 from the 1999 ASHG Annual Meeting

A common in-frame deletion in the a_{2C}adrenergic receptor (a_{2C}AR): possible association with cocaine abuse. *J. Feng[1], J. Zheng[1], J. Gelernter[2], H. Kranzler[3], E. Cook[4], N. Craddock[5], D. Goldman[1], L.L. Heston[1], W.P. Bennett[1], S.S. Sommer[1]*. 1) Dept Molecular Genetics, City of Hope Natl Medical Ctr, Duarte, CA; 2) Dept Psychiatry, Yale University, West Haven, CT; 3) Dept Psychiatry, University Conn., Farmington, CN; 4) Dept Psychiatry, University Chicago, Chicago, IL; 5) Dept Psychiatry, Univ. Birmingham, Birmingham, UK.

All $a_2$adrenergic receptors (a_2ARs) are activated by adrenaline and noradrenaline, and three subtypes, termed A,B,C, are defined by differential affinities for antagonists including yohimbine and rauwolscine. All subtypes are expressed in major organ systems, and they bind common medications including antihypertensives, diuretics, antiemetics, sedatives, anxiolytics and neuroleptics. Compared to other subtypes, a_{2C}AR expression predominates in heart, lung, aorta, spleen, kidney, adrenal gland, cerebral cortex and cerebellum. Because the a_{2C}AR binds avidly to clozapine, which is used for treatment-resistant schizophrenia, we tested the hypothesis that a_{2C}AR polymorphisms predispose to schizophrenia or a behavior disorder. The coding regions of a_{2C}AR were scanned for polymorphisms using DOVAM-S in 100 schizophrenics and at least 25 patients in each of the following groups: autism, puerperal psychosis, alcoholism, cocaine abuse, and attention deficit/hyperactivity disorder. This analysis discovered three silent polymorphisms at codons 136, 148, and 388 (allele frequencies [AF] of 0.6-6.7%) plus a 12-base, in-frame deletion of codons 322-325 (Gly-Pro-Gly-Ala), which is the second of two homologous repeats. Del322-325 occurred commonly in African-American schizophrenics (11/28 subjects, AF 39%) and controls (AF 44%) and less commonly in 85 Caucasian schizophrenics of western European descent (AF 3.5%). Initial studies of behavior disorders suggest an association (p=0.029, Fisher's Exact Test) with Caucasian cocaine abusers (AF 8/80, 10%) compared to unrelated controls (AF 6/198, 3.0%). However, population stratification remains an issue and analyses continue. Since Del322-325 occurs within the third intracytoplasmic loop, it could plausibly alter the effects of therapeutic or recreational compounds.

Program Nr: 1512 from the 1999 ASHG Annual Meeting

The genetics of ischemic heart disease in the French-Canadian population: an association study. *C. Fournier[1], G. Turecki[1], C. Scali[1], C. Marineau[1], J. Grégoire[2], S. Bujold[2], P. Théroux[2], G.A. Rouleau[1]*. 1) Centre for Research in Neuroscience, McGill University and Montreal General Hospital Research Institute, Montreal, Canada; 2) Montreal Cardiology Institute, Montreal, Canada.

Cardiovascular diseases (CVD) are the leading cause of death in industrialized countries where 51% of deaths are related to ischemic heart disease (IHD). IHD is a complex disorder which is influenced by both environmental and genetic factors. As part of an ongoing study looking for genetic risk factors for IHD we conducted an association study in the French-Canadian population, where a significant founder effect has occurred. This population is especially well suited for the genetic study of complex traits due to a limited number of ancestral chromosomes resulting in decreased genetic heterogeneity. We studied 6 polymorphisms which have previously been implicated in the development of IHD: angiotensinogen (M235T), angiotensin-converting enzyme (287 bp I/D), plasminogen activator inhibitor-1 (4G/5G), apolipoprotein E, stromelysin-1 (5A/6A), and methylenetetrahydrofolate reductase (C677T). We investigated 165 French-Canadians with IHD aged 64.9+/-8.1 years (mean+/-SD) for the presence of the 6 genotypes listed above. The control group consisted of 85 French-Canadians, free of CVD, aged 64.0+/-7.6 years (mean+/-SD). We compared genotype frequencies between cases and controls using a chi-square test. There was no significant difference between cases and controls for all six genotypes. Moreover, no statistically significant differences were found when the analysis was repeated with the case and control groups segregated by gender. So far, the data from this study indicates that these polymorphisms do not contribute to the development of IHD in the French-Canadian population. A more stringent definition of the case and control groups as well as a more segregated analysis with respect to CVD risk factors might be needed to observe the possible effects of these genes.

Program Nr: 1513 from the 1999 ASHG Annual Meeting

Origin of Uniparental Disomy 15 in Prader-Willi and Angelman syndromes. *C. Fridman, C.P. Koiffmann.* Dept. of Biology, University of Sao Paulo, Sao Paulo, SP., Brazil.

Maternal uniparental disomy (UPD) accounts for ~25% of Prader-Willi syndrome (PWS) and paternal UPD for about 2-5% of Angelman syndrome (AS). These findings and the parental origin of deletions are evidences of genomic imprinting involvement in the PWS and AS aethiology. The PWS (neonatal hypotonia,hyperphagia,severe obesity,short stature,mental retardation)results from the loss of paternally expressed genes. The AS (ataxia, seizures, sleep disorder, hyperactivity, severe mental retardation with lack of speech, happy disposition) originates through the failure of maternally expressed gene(s). In a total of 34 PWS patients we disclosed 8 with maternal UPD and among 26 AS patients, 4 with paternal UPD. Analysing 10 microsatellite loci (CA repeats) spanning 15q (D15S541, D15S542, D15S11, D15S113, GABRB3, CYP19, D15S117, D15S131, D15S984, D15S115) we identified the meiotic origin of nondisjunction (ND) in all cases but two (1PWS and 1AS), and also the numbers of transitions (=observed changes in marker state between heterodisomy and isodisomy)in each case. A mitotic error was considered if all markers throughout the chromosome showed reduction to homozygosity. So, we disclosed 6 PWS heterodisomies originating from maternal meiosis I (MI) ND (3 showed heterodisomy throughout the entire chromosome with no evidence of recombination), 1 AS isodisomy (MII paternal error),3 isodisomies resulting from mitotic errors (1PWS,2AS). The maternal age was increased in our UPD samples; the mean age of PWS patients's mothers involving MI errors which showed no transitions from hetero to isodisomy was lower than of those showing one or more observable transitions (30,7 versus 41,5). These results confirm that the majority of maternal ND events resulting in UPD15 PWS are associated with MI errors, rare cases are MII or due to postzygotic errors, whereas most paternal UPD15 are MII or postzygotic events. The postzygotic errors are associated with an increased maternal age since the primary event is the maternal ND followed by fertilization of a nullosomic egg with a normal sperm and posterior duplication of the paternal chromosome in the zygote. Supported by: FAPESP.

Program Nr: 1514 from the 1999 ASHG Annual Meeting

Genome screening in human systemic lupus erythematosus: results from a second Minnesota cohort and combined analysis of 187 sib-pair families. *P.M. Gaffney[1], W.A. Ortmann[1], S.A. Selby[1], K.B. Shark[1], T.C. Ockenden[1], K.E. Rohlf[1], N. Walgrave[1], W. Boyum[1], M. Malmgren[1], G.M. Kearns[2], R.P. Messner[1], R.A. King[1], S.S. Rich[3], T.W. Behrens[1]*. 1) University of Minnesota Medical School, Minneapolis, MN; 2) University College, Dublin 7, Ireland; 3) Wake Forest University School of Medicine, Winston-Salem, NC.

Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by a loss of immunologic tolerance to a multitude of self-antigens. Epidemiologic data suggests an important role for genes in the etiology of lupus, and previous genetic studies have implicated the HLA locus, complement genes and low affinity IgG (Fcg) receptors in SLE pathogenesis. In an effort to identify new susceptibility loci for SLE, we recently reported the results of a genome-wide microsatellite marker screen in 105 SLE sib-pair families (PNAS, 95:14875, 1998). We found strong evidence for linkage in four intervals: 6p11-21 (near the HLA), 16q13, 14q21-23, and 20p12.3, and weaker evidence (lod scores 1.0 and 2.6) in another 9 regions. We now report the results of a second complete genome screen in a new cohort of 82 SLE sib-pair families. In the Cohort 2 screen, the four best intervals were 7p22 (lod=2.87), 7q21 (lod=2.40), 10p13 (lod=2.24), and 7q36 (lod=2.17). Seven additional intervals were identified with lod scores ranging from 1.00 to 1.67. A combined analysis of MN Cohorts 1 and 2 (187 sib-pair families) showed that markers in 6p11-p21 (D6S426, lod=4.19) and 16q13 (D16S415, lod=3.85) met criteria for significant linkage. Three intervals (2p15, 1q42, and 7q36) have lod scores ranging from 1.92 to 2.06, and another thirteen intervals show lod scores ranging from 1.00 to 1.78 in the combined sample. These data, together with other available gene mapping results in SLE, are beginning to allow a prioritization of genomic intervals for gene discovery efforts in human SLE.

Program Nr: 1515 from the 1999 ASHG Annual Meeting

Mutation analysis of the a**7 nicotinic acetylcholine receptor gene and its partial duplication in schizophrenia patients.** *J.M. Gault[1], J. Logel[1,3], C. Drebing[1], R. Berger[1], J. Hopkins[3], A. Olincy[1], B. Sullivan[1], M. Short[3], K. Walton[1], M. Robinson[1], M. Maslak[3], J. Meriwether[3], L. Baldermann[1], S. Jacobs[3], R. Freedman[1,2,3], S. Leonard[1,2,3].* 1) Department of Psychiatry, Univ Colorado Health Sci Ctr, Denver, CO; 2) Department of Pharmacology, Univ Colorado Health Sci Ctr, Denver, CO; 3) Veterans Affairs Medical Center, Denver, CO.

Results from linkage analyses of pedigrees with schizophrenic members suggest that an auditory gating deficit and schizophrenia is linked to the 15q13-q14 region. The a7 neuronal nicotinic acetylcholine receptor (a7 nAChR) gene maps to the 15q13-q14 region and pharmacological investigation of the a7 receptor supports the hypothesis that it is involved in the auditory gating pathway that is disrupted in many schizophrenics. Exons 5-10 are proximally duplicated and are about 99% identical at the nucleotide level to the full-length a7 gene. Mutation analysis of both the a7 nAChR gene and its partial duplication in schizophrenics is presented. Southern blot, single strand conformation polymorphism (SSCP) and sequence analyses were used to identify variants in and flanking exons 1-10 of the full-length a7 gene. Four variants have been identified in or flanking exons 1-4. Eight variants have been identified in or flanking exons 5-10. Both genes are expressed with unique 5' ends allowing variants identified in exons 5-10 to be mapped to either the full-length a7 gene or its partial duplication by RT-PCR analysis using RNA isolated from either postmortem hippocampal brain or cycloheximide treated immortalized lymphocytes. Variants in the coding region that would obviously disrupt the function of the full-length a7 gene were not found and there is no evidence for gene conversion. Southern analysis using exon 5 as a probe detected 5 schizophrenics and one family member with the gating deficit that appear to be missing both copies of the duplicated a7 gene. The duplicated a7 gene message was not detected using RTPCR analysis of RNA isolated from three of these samples, supporting the hypothesis that these individuals are missing the duplicated a7 gene. The extent of the potential deletion of this region remains to be determined.

Program Nr: 1516 from the 1999 ASHG Annual Meeting

Identification of tumor necrosis factor receptor 2 (TNFRSF1B) as a novel mediator of insulin resistance traits in familial combined hyperlipidemia. *J.M.W. Geurts[1], C.J.H. van der Kallen[1], M.M.J. van Greevenbroek[1], R.G.J.H. Janssen[1], B.E. Aouizerat[2], H. Allayee[2], R.M. Cantor[3], A.J. Lusis[2], J.I. Rotter[3], T.W.A. de Bruin[1].* 1) Department of Internal Medicine, Maastricht University, the Netherlands; 2) Department of Microbiology and Molecular Genetics, University of California, Los Angeles, CA90095; 3) Department of Medicine and Human Genetics, University of California, Los Angeles, CA90095.

Familial combined hyperlipidemia (FCHL) is a common familial lipid disorder characterized by a variable pattern of elevated levels of plasma cholesterol and/or triglycerides, present in approximately 10 percent of patients with premature coronary artery disease. The genetic etiology of the disease is still largely unclear. Using a panel of Dutch FCHL families, a 10 cM genome screen was performed to identify chromosomal regions linked to genes contributing to this complex disorder. One of the loci identified by LOD score exhibited suggestive, but not significant, evidence for linkage to FCHL. After reviewing the genes in this region (chromosome 1p36.2), the TNFRSF1B gene was chosen as a possible candidate gene. A CA-polymorphism located within intron 4 of the TNFRSF1B gene was used as a marker to detect possible relationships between this gene and several clinical and biological variables related to the FCHL phenotype. Genotyping of this repeat in the families demonstrated the presence of 6 alleles (CA10, CA13, CA14, CA15, CA16 and CA17; of which 2 were hitherto unreported (CA10 and CA17). Alleles CA13, CA15 and CA16 were used for statistical analyses. Allelic distribution studies showed a significant enrichment of individuals homozygous for allele CA13 in the normoliplidemic relatives and a significant enrichment of individuals homozygous for allele CA15 in the hyperlipidemic subgroup. Furthermore, significant associations were demonstrated between these 3 alleles and several insulin resistance traits such as blood pressure, BMI, glucose, leptin, LDL-size, free fatty acids, soluble TNFRSF1B, waist and waist-hip ratio. Using this CA-repeat in additional two-point linkage analyses showed significant linkage to FCHL.

Program Nr: 1517 from the 1999 ASHG Annual Meeting

Normal human sperm exhibit greater mitochondrial DNA (mtDNA) heteroplasmy than ova. *C.D. Gocke[1], F.A. Benko[1], W. Dodson[2], P.K. Rogan[3]*. 1) Pathology, Penn State Coll Med, Hershey PA; 2) Obstetrics & Gynecology, Penn State Coll Med; 3) Medical Genetics & Mol Med, Children's Mercy Hospital, Kansas City, MO.

Background: We previously reported mtDNA heteroplasmy in 2.5% of normal mother-offspring pairs and marked genotype shifts, which were consistent with an estimated 252 to 505 mtDNA genomes segregating in oocytes. To test this, we assayed the D loop region of single oocytes for heteroplasmy, using single spermatids as controls. Materials and methods: Unfertilized oocytes discarded from IVF procedures on 5 women (12, 9, 7, 3, and 3 ova) were harvested, washed, lysed and amplified with D loop region primers. Donor sperm from 2 men (50 and 29 sperm) were counted by cytometry, diluted to a concentration of a single cell/tube, and similarly amplified. Lymphocyte DNA was available only from the women. Heteroplasmic variants were identified in PCR products by single strand conformational polymorphism analysis, sequenced and, if possible, confirmed by restriction digestion. Results: Three heteroplasmic loci were found in ova from 2 women. Spermatids had a higher frequency of heteroplasmy and polymorphism than oocytes. Polymorphisms were detected at 3 different loci in 29 sperm from one donor and at 19 loci in 50 sperm from the other. Conclusions: This study provides direct evidence of a bottleneck in mtDNA segregation during oogenesis. Genotype switching in oocytes was more frequent than we previously found in mother-offspring pairs, raising the possibility of either a post-meiotic bottleneck or of oocyte selection during IVF. Since identical variants are found in corresponding oocyte and lymphocyte mtDNA, heteroplasmy was inherited and not the result of mutations in ova. The inconsistent pattern of segregation of oocyte mtDNA may confound genetic counseling for mitochondrial disorders. By contrast, the presence of a variant in more than one sperm suggests that mutations arise early in spermatogenesis. The high frequency of homoplasmy for different variants in sperm from the same individual suggests that the population of segregating mtDNA species is smaller in sperm than in oocytes. This is consistent with a decreased population of mitochondrial genomes during sperm cell maturation.

Program Nr: 1518 from the 1999 ASHG Annual Meeting

Molecular genetic study of patients with hypertrophic cardiomyopathy. *M.V. Goloubenko[1], V.P. Puzgrev[1], K.V. Puzyrev[2], V.B. Salukov[1]*. 1) Population genetics laboratory, Institute of Medical Genetics, Tomsk, Russia; 2) Institute of Cardiology, Tomsk, Russia.

Idiopathic hypertrophic cardiomyopathy (HCM) is cardiac muscle disease caused in most cases by mutations in sarcomere proteins genes. Moreover, some mutations in mitochondrial DNA may also be cause for this disease. For investigation of genetic background of idiopathic HCM, the group of patients with HCM has been formed, consisting of 6 familial and 10 sporadic cases. Genomic DNA has been extracted to date from blood samples of 12 patients, as well as of some their relatives. Also, DNA will be obtained in near future from remaining 4 individuals and members of their families. Clinical assessment included medical history, echocardiography, and coronarography and allowed to exclude atherosclerosis and arterial hypertension as cause for hypertrophy. As the first stage of molecular genetic analysis, this sample was screened by RFLP analysis for the presence of A3243G mutation which is known as MELAS mutation but also may present in other diseases, including HCM. There were no patients who has this mutation, at least at the level detectable by routine electrophoresis. Further ascertainment of genetic basis of HCM in these patients will include sequencing of beta-myosine heavy chain gene which is responsible for about 50% cases of HCM.

Program Nr: 1519 from the 1999 ASHG Annual Meeting

Distance Between Marker and Trait-Affecting Loci in Linkage Disequilibrium Found in the General Population in Three Major Races: The Alzheimer's Disease, Hypertension, and Osteoporosis Genes. *G. Gong[1], J. Mordeson[2], S.-C. Cheng[2], N.C. Fong[2], R.R. Recker[1]*. 1) Osteoporosis Center, Creighton Univ, Omaha, NE; 2) Dept of Mathematics and Computer Science, Creighton Univ, Omaha, NE.

Alzheimer's disease (AD) is associated with the e4 allele at the apolipoprotein E (APOE) gene. It is possible that a mutation may have initially occurred somewhere close to, but not at, the APOE locus. The two loci may be in linkage disequilibrium, which is detected by association studies. The distance between the putative mutant and the APOE loci is mainly (under certain circumstances) a function of the degree of linkage disequilibrium and the number of generations past since the mutation. We developed a method to estimate the distance. The degree of disequilibrium was derived from published data. The age of the mutation was assumed to be 5000 generations. The assumption is based on the fact that the AD-e4 association is found in the general population in the three major races, which suggests that the putative linkage disequilibrium had existed before the divergence of the three races 100,000 years ago. The calculated distance was 35 ± 5 kb, which tends to be overestimated. Genetic heterogeneity and/or environmental factors (or their interactions) do not affect the estimation with our method. The two loci are so close that it is likely that the AD-predisposing mutation (or variation) falls within the span of the candidate APOE gene. The nature and the exact location(s) of the mutation(s) within the APOE gene still need to be determined. With a different approach, we also estimated the distance between marker (at the angiotensinogen gene and vitamin D receptor gene) and quantitative trait (blood pressure and bone mineral density) loci in association found in the general population in the three major races. The mean distances were less than 100 kb. We conclude that a well-established association between a marker and a trait (or disease) found in the general population in the three major races is likely to suggest that a mutation(s) is located within the span of the candidate gene, such as those in which certain polymorphisms are associated with AD, hypertension and osteoporosis.

Program Nr: 1520 from the 1999 ASHG Annual Meeting

Delineation of a 6p25 syndrome. *D.B. Gould[1], M.S. Jaafar[2], M.K. Addison[2], C.M. Powell[2], M.E. Walker[2], F.L. Munier[2], R. Ritch[2], I.M. MacDonald[1], M.A. Walter[1].* 1) Deptartment of Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) See poster for affiliated institution.

Our purpose is to further describe the phenotypes of patients with the 6p25 deletion syndrome and establish a genotype/phenotype correlation. Peripheral blood samples or cell lines were collected from patients with reported deletions of chromosome 6. PCR of polymorphic markers was used to establish copy number of alleles. FISH analysis has been initiated on available cell lines. Three patients have maximum deletions of 6.4cM, 27.2cM and 13.9cM. The fourth and fifth patients have a cytogenetic deletion at 6p25.1 and a ring(6) with breakpoints at 6p25q27 respectively, that have not yet been confirmed by molecular analysis. This could reflect a lack of markers in the region or the unreported presence of a translocation in the first case and mosaicism in the second. Three additional patients studied are deleted as the result of unbalanced translocations. Only one, a 2;6 translocation, has been confirmed by molecular analysis to have a maximum deletion of 6.4cM. The two remaining patients, with an unbalanced 6;8 translocation, and an unbalanced 4;6 translocation respectively, are currently being analyzed with polymorphic markers. Mutations resulting in haploinsufficiency of the FKHL7 gene at 6p25 have been shown to cause Axenfeld Rieger eye malformations. We suggest that haploinsufficiency of FKHL7 and other developmental control genes including FREAC2, BMP6 and AP2, also located at 6p24-6p25, are responsible for the 6p25 syndrome. The roles of these genes are under investigation. This work is supported by grants from the University of Alberta, Glaucoma Research Foundation, and the MRC.

Program Nr: 1521 from the 1999 ASHG Annual Meeting

TYPE I ALLERGY - A TOTAL GENOME SCANNING FOR CANDIDATE REGIONS AND TEST OF CANDIDATE GENES. *A. Haagerup[1], T. Bjerke[2], P.O. Schiøtz[4], R. Dahl[3], H.G. Binderup[1], T.A. Kruse[5]*. 1) Institute of Human Genetics, Aarhus University, Aarhus , Aarhus C, Denmark; 2) ASTRA Draco AB, Lund, Sweden; 3) Department of Respiratory Diseases, University Hospital of Aarhus, Aarhus, Denmark; 4) Department of Pediatrics, University Hospital of Aarhus, Aarhus, Denmark; 5) Clinical Institute, University of Odense, Odense, Denmark.

To identify genetic risk factors for atopic disease we collected 100 nuclear families containing at least two affected full siblings and both their parents. All family members, a total of 419 individuals, went through clinical investigation, questionnaire evaluation, and measurements of total and specific IgE. Two distinct strategies are used for DNA analysis: 1. A genome scanning with anonymous markers in an affected sib-pair design to identify candidate regions harbouring atopy candidate genes. 2. Test of specific candidate genes in a case-control design. 1. Genome scanning: Fifty families containing two sibs with type I allergy are being analysed with 500 micro satellite-markers evenly located through out the genome. The data is used for nonparametric linkage analysis. 2. Candidate genes: Variations in three candidate genes were analysed in all 100 families. A possible association between the variations and five different atopy phenotypes was tested using trio-families with internal controls. Il4R: We developed a simple PCR-based method to test genomic DNA for the Q576R polymorphism in the interleukine-4 receptor a subunit (chromosome 16p12). CCR-5: The delta 32 mutation in chemokine receptor five gene (3q21-24). CC16: The A38G variation in the Clara cell secretory protein (11q13). We did not find significant association between the tested genetic polymorphisms and type I allergy phenotypes.

Program Nr: 1522 from the 1999 ASHG Annual Meeting

Glucokinase gene is associated with Gestational Diabetes Mellitus in Chinese population. *H. Han[1], S. Wang[1], L. Ji[2], X. Han[2].* 1) Department of Obstetrics and Gynecology; 2) Department of Endocrinology and Metabolism, People's Hospital, Beijing Medical University, Beijing, P.R.China.

Gestational Diabetes Mellitus(GDM) is a status of impaired glucose tolerance during gestation and the individuals affected with GDM has a very high risk of developing Non-insulin dependent diabetes mellitus(NIDDM) later in their life. Early studies on glucokinase(GCK) gene had found several cases of NIDDM patients with history of GDM carried mutation in GCK gene. To test the hypothesis that the defect in GCK gene contribute to the genetic susceptibility to the GDM in Chinese population. We carried out a case-control study to investigate the allele distribution of two microsatellites, GCK1 and GCK2, in 40 women with history of GDM and 43 women without history of GDM and family history of NIDDM. Result: 1). 4 allele (A.B.C.D) of GCK1 and 4 alleles(1,2,3,4) of GCK2 were identified in both case and control groups. 2). There were not difference in the allele distribution of GCK1 in case and control groups. 3). The frequency of allele 3 of GCK2 was significantly increased in GDM group as comparing with that in the control group(31.3% vs 17.4%, P=0.035). 4). Further more, in GDM group, after stratifying 17 individuals who had developed NIDDM at time of this study by the alleles of GCK2, individuals carrying allele 3 (9 individuals) had a significant higher level of fasting plasma glucose and 2 hour plasma glucose in the OGTT test than that of those (7 individuals) carrying other alleles(9.9+ 3.7 mmol/l vs 6.3+ 0.6 mmol/l, p=0.019 and 15.9+ 4.4 mmol/l vs 11.2+ 2.2 mmol/l, p=0.020, respectively) . In addition, individuals carrying allele 3 had significantly decreased 2 and 3 hour insulin level in the OGTT test than that of those carrying other alleles (45.8+27.4 pmol/L vs 112.5+ 66.1 pmol/L, p=0.015 and 18.7+16.3 pmol/L vs 75.2+46.1 pmol/L, p=0.017, respectively). In conclusion, data from this study suggesting that the GCK gene is associated with GDM in Chinese population and allele 3 of GCK2 probably is in linkage disequilibrium with the genetic defects in GCK gene.

Program Nr: 1523 from the 1999 ASHG Annual Meeting

Methylation of the *UBE3A* CpG island does not mediate transcriptional repression of the paternal allele in brain.

M.K. Han[1], M.G. Butler[2], J.S. Sutcliffe[1]. 1) Program in Human Genetics, Dept of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Dept of Medical Genetics and Molecular Medicine, Children's Mercy Hospital, Kansas City, MO.

Angelman syndrome (AS) is a severe neurological phenotype involving profound mental retardation with absent speech, seizures, abnormal EEG, a movement disorder, happy disposition, and other features. AS results from deficiencies of imprinted gene expression of the E6-AP ubiquitin-protein ligase (*UBE3A*) gene, caused by common maternal deletion of human chromosome 15q11-q13, paternal uniparental disomy, imprinting defects, and discreet mutations in the *UBE3A* gene. Imprinted, maternal-specific expression of *UBE3A* and its mouse ortholog is restricted to the brain, with data from the mouse showing tight imprinted repression of the paternal allele in hippocampal and cerebellar Purkinje neurons. In peripheral tissues, such as leukocytes, *UBE3A* is expressed biallelically. DNA methylation is typically associated with transcriptional silencing of inactive alleles of imprinted genes; this includes the *SNRPN* gene, which is located within the adjacent, oppositely imprinted Prader-Willi syndrome critical region. *SNRPN* is associated with a 5' CpG island, which is heavily methylated on the transcriptionally silent maternal homolog. Unlike *UBE3A*, *SNRPN* is imprinted in all adult tissues, and displays allele-specific methylation accordingly. *UBE3A* is similarly associated with a 5' CpG island. To determine whether methylation of the *UBE3A* CpG island is associated with its brain-specific imprinting, we performed Southern blot analysis to test for methylation in brain and other tissues. Analysis of DNA from normal human hippocampus, cortex and leukocytes, using methylation-sensitive enzymes and probes spanning the CpG island, revealed no methylation in any of these tissue types. Similarly in mouse, analysis of DNA from tissue including hippocampus, cortex, and liver revealed no methylation of this CpG island, indicating that allele-specific methylation of this CpG island, in contrast to other CpG island-associated imprinted genes, such as *SNRPN* and *H19*, is not correlated with cell type-specific imprinting.

Program Nr: 1524 from the 1999 ASHG Annual Meeting

Gly40Ser Mutation of the Glucagon Receptor Gene is not a major determinant of genetic susceptibility to Non-insulin Diabetes Mellitus(NIDDM) in Chinese population. *X. Han, L. Ji.* Endocrinology and Metabolism, People's Hospital, Beijing Medical University, Beijing, P.R.China.

Recent studies had shown that a G123A mutation which causing a Gly40Ser substitution in exon 2 of the human glucagon receptor gene(GCG-R) was associated and linked with non-insulin-dependent diabetes mellitus (NIDDM) in France , Sardinia as well as Finnish population., but not with NIDDM in Japan , Russia as well as Utah of U.S.A, suggesting genetic heterogeneity of NIDDM in different ethnic groups. To investigate whether this mutation is contribute to genetic susceptibility to NIDDM in Chinese population, 150 NIDDM patients with family history of NIDDM were genotyped by using PCR-RFLP technique to screen for G 123 A mutation in GCG-R gene. As an result, none of the subjects studied showed this mutation. Our result suggested that Gly40Ser mutation of GCG-R gene is not associated with NIDDM in Chinese population. Thus, the Gly40Ser mutation does not play an important role in the pathogenethesis of NIDDM in Chinese population.

Program Nr: 1525 from the 1999 ASHG Annual Meeting

Maternal uniparental disomy of chromosome 7 (matUPD7) is confined to cases of Silver-Russel syndrome in children with growth retardation of unknown etiology. *K. Hannula[1], M. Lipsanen-Nyman[2], P. Höglund[1,3], C. Holmberg[2], J. Kere[1,4].* 1) Dept Medical Genetics, Univ Helsinki, Finland; 2) Hospital for Children and Adolescents, Helsinki Univ Central Hospital, Finland; 3) Jorvi Hospital, Dept Pediatrics, Espoo, Finland; 4) Finnish Genome Center, Univ Helsinki, Finland.

Maternal uniparental disomy of chromosome 7 (matUPD7) is observed in approximately 10% of Silver-Russel syndrome (SRS) patients. SRS patients are characterized by severe growth retardation and variable dysmorphic features, including hemihypertrophy, clinodactyly of the fifth digits, frontal bossing, and a triangular face. In order to ascertain if matUPD7 occurs in other growth-retarded patients in addition to SRS, we have studied DNA samples from 195 children with growth retardation of unknown etiology from the outpatient clinic for growth disorders at the Hospital for Children and Adolescents, Helsinki University Central Hospital. The patients formed three distinct groups by the following criteria: 1. Silver-Russel syndrome, 2. severe pre- and postnatal growth retardation exceeding -2.5 SD and 3. severe postnatal growth retardation exceeding -2.5 SD. Patients with endocrine abnormalities, abnormal karyotypes, chronic illnesses or any other known causes for growth retardation were excluded from study. MatUPD7 cases were screened for by genotyping DNA samples from each patient, mother and father with 14 chromosome 7 specific polymorphic microsatellite markers and an automated sequencer (ABI). Paternity for matUPD7 cases was confirmed by genotyping 12 non-chromosome 7 markers. Altogether four matUPD7 cases were observed among 33 SRS cases (12%). No matUPD7 cases were found in any other patient groups. The fact that matUPD7 cases are confined to patients with SRS strengthens the suggestion that multiple maternally imprinted genes may account for the various dysmorphic features in SRS patients that are not distinguished in other patient groups. It is nevertheless possible that disruption of imprinting of a gene/genes responsible solely for growth regulation would be the cause of growth retardation in other patient groups lacking dysmorphic features of SRS.

Program Nr: 1526 from the 1999 ASHG Annual Meeting

mRNA Differential Display Identifies Novel Strain Specific Ethanol Responsive (SSER) cDNAs Involved in Alcohol Preference. *M.L. Harrison, K.R. Uddin, J. Treadwell, B.C. Murphy, S.M. Singh.* Molecular Genetics Unit, University of Western Ontario, London, Ontario, Canada.

Alcohol preference is a well recognized contributor to the etiology of alcoholism, a complex disease known to run in families. A measure of alcohol preference is voluntary alcohol consumption (VAC), particularly in animal models (e.g. mice). Established genetic strains of mice are classified as alcohol preferer with high VACs (e.g. C57BL/6J) and avoiders with low VACs (e.g. A/J, DBA/2J and BALB/cJ). Despite extensive efforts over four decades, the search for VAC genes using traditional genetic approaches have not identified a single causitive gene. It is however, known that ethanol effects gene expression, possibly in a strain specific manner. Further such strain specific ethanol responsive (SSER) genes are expected to play a role in the determination of this complex phenotype. Also, it offers an opportunity to apply novel technologies such as mRNA differential display towards identification of SSER cDNAs.

Using the above approach, we have identified 10 brain specific SSER cDNAs. GenBank searches following sequencing of these bands permit one to classify them into two groups; a) no match in GenBank sequences and b) genes of known function. The sequences with no match in the GenBank database are of particular interest as they have the potential to represent still uncharacterized, novel genes. We are using GenomeWalker to obtain complete sequences towards the characterization of such genes and assess their significance in ethanol preference using segregation analysis including recombinant inbred (RI) lines. Identification and characterization of genes involved in murine alcohol preference will be a positive step in understanding the etiology of human alcoholism.

Program Nr: 1527 from the 1999 ASHG Annual Meeting

Single cell analysis of somatic mosaicism of CAG repeats in DRPLA brain. *H. Hashida[1,2], J. Goto[1,2], T. Suzuki[1], S.-Y. Jeong[1], N. Masuda[1,2], N. Hazeki[1], I.. Kanazawa[1,2].* 1) CREST, Japan Science and Technology Corporation, Tokyo, Japan; 2) Department of Neurology, University of Tokyo, Tokyo, Japan.

We report the analysis of somatic mosaicism of human triplet repeat gene using single cell isolated from human postmortem materials. We developed a system for RT-PCR analysis of single neuron isolated from autopsied human brain using laser microdissector. The single cells were dissected from unfixed brain specimen of the patients with dentatorubral-pallidoluysian atrophy (DRPLA) with laser microdissector after stained with toluidine blue. We demonstrate the transcripts of the normal and expanded alleles of CAG repeats by nested RT-PCR. Cell to cell difference was demonstrated in the length of CAG repeats of the expanded allele by the analysis of single cerebellar Purkinje cells isolated from autopsy materials of DRPLA.

Program Nr: 1528 from the 1999 ASHG Annual Meeting

Comprehensive Analysis of Gene Expression in Intracranial Aneurysm. *E. Heidrich-O'Hare[1], A. Kassam[2], H. Yonas[2], R. Ferrell[1], A. Brufsky[3], D. Peters[1].* 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Neurosurgery, University of Pittsburgh, Pittsburgh, PA; 3) Hematology/Oncology, University of Pittsburgh, PA.

Each year in the U.S., more than 25,000 people suffer a ruptured intracranial aneurysm (ICA). Among these, 50% die at the time of rupture or shortly thereafter and 25% suffer permanent disability, including paralysis, loss of speech, vision and motor coordination. The remaining 25% are at increased risk of stroke, recurrent bleeding or other complications. In contrast, operative repair of an unruptured aneurysm has a mortality of <2.5 % and morbidity of <6%. Despite their high frequency, the catastrophic consequences of a ruptured ICA and the difficulty and expense of operative surgical repair, almost nothing is known regarding the molecular pathology/pathogenesis of this disease. We have utilized a modified SAGE strategy ("SAGE-Lite") to compare gene expression patterns in a sample of unruptured ICA with a superficial temporal artery (STA) sample from the same individual, a two year old female who underwent elective craniotomy to resect multiple unruptured giant aneurysms in the middle cerebral artery. Analysis of the first 10,000 SAGE tags from each sample revealed marked differences at the level of transcription between normal and aneurysmal artery. Patterns of transcription are consistent with a pathological profile that involves extensive tissue remodeling and a significant inflammatory response. In summary, 31 % of the 100 most highly expressed genes in ICA are differentially regulated with a >5-fold change in expression relative to STA. Of these 100 genes, 22 % are not listed in GenBank. So far we have verified expression of 4,924 different genes in the ICA. Similarly, 29 % of the 100 most highly expressed genes in STA are differentially regulated with a >5-fold change in expression relative to ICA. Of these 100 genes, 25 % are not listed in GenBank. So far we have verified expression of 3,552 different genes in the STA.

Program Nr: 1529 from the 1999 ASHG Annual Meeting

Mutations in the UBE3A gene are only a minor cause for Angelman syndrome (AS). *H.C. Hennies[1], J. Bürger[2], K. Sperling[2], A. Reis[1,2].* 1) Molecular Genetics, Max-Delbrueck Center, Berlin, Germany; 2) Human Genetics, Charité, HU Berlin, Germany.

Angelman syndrome (AS) is a severe neurogenetic disorder with a complex mode of inheritance. Clinically, AS is characterized by mental retardation, ataxia, and lack of speech. AS is caused by loss of function of an only maternally expressed gene. Around 70 % of AS patients show *de novo* maternal deletions at 15q11-q13, a few cases have a paternal UPD, and about 5 % have imprinting defects.

Mutations in the UBE3A gene, which encodes E6-AP and is paternally imprinted in brain, have been shown in non-deletion, non-UPD, non-imprinting-defect patients with AS. Until now, we have investigated 219 patients with a clinical diagnosis of AS for mutations in UBE3A by SSCP analysis of twelve translated exons representing the various open reading frames of the gene. Sequencing of conspicuous exons revealed eight different mutations in eight unrelated patients. All the mutations are insertions or deletions of two to 18 bases, five of these in-frame deletions and three frameshift mutations leading to premature stop codons. One two-residue deletion has been identified in three affected sisters and their unaffected mother, and one frameshift mutation is also of maternal origin. Six mutations are *de novo* ones. All alterations are compatible with paternal imprinting in AS and represent most presumably true mutations. Furthermore, five exonic polymorphisms were discovered in UBE3A.

Even considering that some of the patients might turn out to be misdiagnosed, our findings reveal a huge discrepancy between the number of mutations identified in UBE3A and the number of patients analyzed. In contrast to other studies with highly selected groups of patients, we can show that the disease is not due to mutations in UBE3A in the clear majority of non-deletion, non-UPD, non-imprinting-defect AS patients. Mutation analysis is still valuable in these patients for verification of the clinical diagnosis and genetic counseling. A further gene, however, or yet another mechanism must be conceived in the etiology of AS.

Program Nr: 1530 from the 1999 ASHG Annual Meeting

PARTICIPATION OF HLA DQA1 AND DQB1 LOCI IN THE INTRA-FAMILIAL HbA1 VARIATION OF FAMILIES WITH TYPE 1 DIABETES MELLITUS.. *R.M. Hermosillo-B[1], C. Ramos[2], F.J. Perea[1], F. Rivas[1], M. Casas-Catañeda[1], A.L. Camacho[1], Y.J. Sánchez[1], C. Gorodezky[3], B. Ibarra[1].* 1) Div. Genética, CIBO-IMSS, Guadalajara, Jal; 2) Hosp. Especialidades, CMNO-IMSS, Guadalajara, Jal; 3) INDRE-SSA, México, D.F. México.

In healthy individuals, variations in HbA1 level have been attributed to biological differences, or associated with several risk factors to develop diabetes. DQA1 and DQB1 genes are a major contributing risk factor in the pathogenesis of Type 1 Diabetes Mellitus (DM-1). Present work aims to analyze participation DQA1 and DQB1 alleles in the intrafamily variation of HbA1. We studied 20 families with DM-1 (115 individuals) and 19 control families (100 individuals). HbA1 values were analyzed among healthy members of DM-1 and control families to determine the intrafamily variation coefficient of HbA1 (ivc-HbA1). Molecular analysis of DQA1 and DQB1 alleles was performed by PCR-SSO and PCR-SSP. The average value of ivc-HbA1 was similar in both groups (11.98.0 and 9.84.5%). ivc-HbA1 of more than 10% was observed in 10 families of each group, whose average was similar except at ANOVA (17.66.9% and 14.03.3% respectively). Susceptibility (S) and Protection (P) DQA1 and DQB1alleles were analyzed in both groups considering independent chromosomes, parents of families with Normal ivc-HbA1 (less than 10%, DN and CN for parents of DM-1 and control families), as well as those with High ivc-HbA1 (DH and CH). Significant differences of allelic distribution were found for DQA1 and DQB1. For DQA1 differences were found among all groups except DH-CH and CH-CN. For DQB1 differences were found among all groups except DH-DN. The analysis of the total count of S and P alleles at both loci showed a main proportion of S alleles in the DH group, followed by DN, CH, and CN groups. We investigated the Relative Risk between all subgroups, the higher numbers were observed for DQA1 *0501 allele between DH-CN groups (7.18) and for DQB1 *0201 between DN-CH groups (7.22), The chi-square with Yates correction for both comparative groups was significant ($p< 0.02$ and 0.05 respectively). This data suggests the participation of both DQA1 and DQB1 loci at intrafamily variability of HbA1 levels.

Program Nr: 1531 from the 1999 ASHG Annual Meeting

A genealogical study of Parkinson's Disease in Iceland: Further evidence for a genetic component in late-onset disease. *A. Hicks[1], T. Jonsson[1], H. Petursson[1], S. Sveinbjornsdottir[2], J. Gulcher[1], K. Stefansson[1].* 1) DeCode Genetics, Reykjavik, Iceland; 2) National Hospital of Iceland, Reykjavik, Iceland.

Over recent years, the role of genetics in some forms of Parkinson's Disease (PD) has been clearly established. Mutations in the a-synuclein gene are involved in a small subset of autosomal dominant early-onset PD (< 50 years old), while mutations in the parkin gene have been identified as the primary cause of autosomal recessive juvenile parkinsonism. For the majority of late-onset PD (> 50 years old), both in kindreds and sporadic cases, mutations in these genes have been excluded. Furthermore, several cross-sectional twin studies have reported similar concordance between monozygotic (MZ) and dizygotic (DZ) twins, and have thus favored the influence of environmental factors over direct genetic effects. A recent longitudinal PET study of twins has reopened the debate with its findings of a strong genetic component in sporadic PD. To further examine the role of genetic components in the majority of PD cases, and to attempt their characterization, we are using a population-based genetic approach. Data from two epidemiological studies in Iceland, one in the 1960s and another from the 1980's onward, have succeeded in identifying over 750 PD patients born within the last 120 years (representing a large proportion of the total number of PD cases). We have compiled an extensive genealogical database of over 580 000 records dating back to the settlement of Iceland a thousand years ago. With this database we have used a number of statistical tools, including the newly developed Minimum Founder Test alongside kinship coefficient and relative risk calculations, to examine the relationships among these PD patients and to compare these with those among matched control groups in the general population. Our data demonstrate that in Iceland, there is a clear genetic component in all forms of PD examined.

Program Nr: 1532 from the 1999 ASHG Annual Meeting

***De novo* tandem duplication of 7p11.2-p12 in a patient with Silver-Russell syndrome and asynchronous replication timing further implicates *GRB10*as a candidate gene.** *M.P. Hitchins[1], D. Monk[1], E.L. Wakeling[1], V. Proud[2], P. Stanier[1], M.A. Preece[3], G.E. Moore[1].* 1) Paediatrics, Obstetrics & Gynaecology, Imperial College School of Medicine, Queen Charlotte and Chelsea Hospital, London, UK; 2) Daughters, 601 Childrens Lane, Norfolk, Virginia 23507-1921, USA; 3) Biochemistry, Endocrinology & Metabolism, Institute of Child Health, London, UK.

Silver-Russell syndrome (SRS) is a congenital disorder, characterised primarily by intrauterine growth restriction and lateral asymmetry. The aetiology of the syndrome is heterogeneous, but maternal uniparental disomy for chromosome 7 (mUPD7) has been demonstrated in 7% of patients. Consistent heterodisomy for the entire chromosome 7 in several mUPD7 cases provides strong evidence that one or more imprinted genes on chromosome 7 may be involved in the pathogenesis of this syndrome. Human 7p11.2-12 is syntenic to the imprinted region of proximal mouse chromosome 11, and mice with maternal disomy for this region demonstrate a growth-restricted phenotype.

We describe a *de novo*cytogenetic duplication of 7p11.2-12 in a SRS patient. Fluorescent *in situ* hybridisation (FISH) confirmed the presence of a tandem duplication encompassing the genes for the insulin-like growth factor binding proteins 1 and 3 (*IGFBP1* and *IGFBP3*), and the growth factor-receptor bound protein 10 gene (*GRB10*), but not the epidermal growth factor receptor gene. FISH analysis using PAC clones from 7p11.2-14 indicated that the duplication extends at least 8cM. The duplication was shown to have arisen on the maternally derived homologue, through dosage analysis of microsatellite markers. Biallelic expression of *IGFBP1* and *IGFBP3* has been observed during fetal development, making their involvment in SRS unlikely. Murine *Grb10*, which maps to proximal 11, was identified as a maternally expressed imprinted gene. Human *GRB10* is the prime candidate for SRS. We have used interphase FISH to investigate the replication timing of the region surrounding *GRB10*. Asynchronous replication was observed, which is a hallmark of imprinted genes, suggesting human *GRB10* may also be subject to genomic imprinting.

Program Nr: 1533 from the 1999 ASHG Annual Meeting

Improved screening methods for the polyglutamine $(CAG)_n$ tract length of the human androgen receptor gene.

L.M. Hoffman, E. Moan. Epicentre Technologies, Madison, WI.

The length of the polymorphic CAG (polyglutamine encoding) repeat in exon 1 of the human androgen receptor (AR) gene is inversely related to the degree of transcriptional activation by the AR. Individuals with X-linked spinal and bulbal muscular atrophy have 40 or more CAG repeats. Increased AR repeat length has been associated with decreased prostate cancer risk in men or increased breast cancer risk in women with disease-associated germline BRCA1 mutations. We describe improved methods of sample preparation, amplification and initial size screening of the AR gene CAG repeat. The sizing may be performed nonradioactively and without fluorescent labeling using standard molecular biology laboratory equipment. DNA samples from noninvasive buccal (cheek) swabs can be used for PCR amplification of repeats with high G+C contents. In previous studies, amplification of the AR gene CAG repeat was inconsistent or required two rounds of PCR amplification. Detection often required radiolabeled PCR primers and/or extraction of the PCR product from an agarose gel prior to sequencing. We amplified buccal cell DNA under conditions optimized for the AR gene amplicon. Unlabeled PCR products were digested with restriction endonuclease PstI that generated a constant internal reference DNA fragment and a CAG repeat-containing fragment of variable length. The size of the repeat fragment in relation to the internal reference fragment was used to estimate the length of the short tandem repeat (STR). Samples containing repeats near the mean length of (CAG)21 can be easily recognized. Sequence analysis of selected amplicons showed that the gel migration of the constant fragment was slightly faster than the median length STR fragment, and that STR fragments differing by three nucleotides may be separated using a minigel apparatus. Amplicons containing STR's differing significantly from the median length can be selected for sequencing or more accurate sizing, avoiding the use of these costly procedures for all samples. The improvements in the process of G+C-rich repeat screening are applicable not only to the AR gene but also to a large number of STR amplicons.

Program Nr: 1534 from the 1999 ASHG Annual Meeting

Significant association of a single nucleotide polymorphism in the tumor necrosis factor-alpha gene promoter with human narcolepsy. *H. Hohjoh[1], T. Nakayama[1], J. Ohashi[1], T. Miyagawa[1], H. Tanaka[3], T. Akaza[3], Y. Honda[2], T. Juji[3], K. Tokunaga[1]*. 1) Human Gen,Sch Internatl Health, Univ Tokyo, Tokyo, Japan; 2) Seiwa Hospital, Tokyo, Japan; 3) Japanese Red Cross Central Blood Center, Tokyo, Japan.

Narcolepsy is a sleep disorder in which multiple factors including environmental and genetic factors are involved. A genetic factor strongly associated with the disorder has been found in the human leukocyte antigen (HLA) region: the DRB1*1501-DQB1*0602 haplotype predisposes to narcolepsy. No susceptibility genes other than the HLA-haplotype have been found. In this study, we performed an association study of tumor necrosis factor-alpha (TNF-a) gene with human narcolepsy, in which we examined the known single-nucleotide polymorphisms (SNPs) in the promoter region in 49 Japanese narcoleptic patients, who were all positive for DRB1*1501, and 111 healthy controls. The results indicated that the frequency of the genotype at position -857 (-857SNP) was significantly different between the patients and controls, and the allele frequencies of -857SNP revealed that the frequency of -857T was significantly increased in the patients compared with that in the controls: P = 0.0068. In addition, haplotypes presumed from HLA-DRB1, -857SNP and HLA-B loci suggested that -857T was mainly associated with DRB1 alleles other than DRB1*1501. This led the interpretation that the significant increase in frequency of -857T in the patients was not caused by allelic association with DRB1*1501. Thus, it is conceivable that the TNF-a with -857T was associated with narcolepsy independently of the strong association of DRB1*1501 with the disorder. To further examine the relationship between -857T and DRB1*1501, we investigated several Japanese narcolepsy families. From the haplotype analyses of the family members, both cis- and trans-associations between them were observed. It might be that the -857T-DRB1*1501 haplotype confers a strong predisposition to narcolepsy, although it is a minor haplotype in the healthy population. Altogether, these observations lead us to propose that TNF-a could be a new susceptibility gene in human narcolepsy.

Program Nr: 1535 from the 1999 ASHG Annual Meeting

Studies of the CAG repeat in the spinocerebellar ataxia type 7 gene in Taiwan. *M. Hsieh[1], S.J. Lin[4], J.F. Chen[2], H.M. Lin[1], K.M. Hsiao[3], C. Li[1], S.Y. Li[3]*. 1) Institute of Medicine; 2) School of Medical Technology; 3) Department of Life Sciences, Chung Shan Medical & Dental College, Taichung; 4) Department of Pediatrics, National Cheng Kung Univ.,Tainan,Taiwan, R.O.C.

Spinocerebellar ataxia type 7 (SCA 7) is an autosomal dominant disorder characterized by neural loss, mainly in the cerebellum and regions of the brainstem and particularly, the inferior olivary complex. This neurodegeneration disease is associated with expansion of unstable CAG repeats within the 5'-translated region of the SCA7 gene, located on chromosome 3p. We conducted a local survey of the normal population and candidate patients to analyze the distribution of the CAG repeat units in the SCA 7 gene in Taiwan by using the radioactive genomic polymerase chain reaction (PCR). The CAG repeat number ranged from 6 to 17 in the normal population, with the more common being around 8-13 repeats. The range is relatively narrow compared to that reported for other ethnic groups (7 to 35 CAGs). Meanwhile, by the use of a combination of PCR and southern blot analysis, one SCA7 family was identified and reported in this study. A marked instability of the CAG repeat number during transmission from father to son (41 vs. 100) was observed in the SCA7 family. Clinical anticipation is also significant in this family including an infantile case, whose age of disease onset is one month old. Up to date, the SCA7 mutation was detected in one out of 73 families with ADCA phenotypes, which is about 1.4 % of the ataxia families referred to us, compared to SCA1 (1.4%), SCA2 (9.6%) and SCA3/ MJD (27.3%) in our collection. In summary, we demonstrated that the PCR-based Southern blot analysis, with the advantages of sensitivity of PCR and specificity of Southern blot, is the most reliable diagnosis method for the SCA7 mutation screening. The molecular analysis technique makes possible the quick and accurate diagnosis of SCA7 patients and hopefully, in the future, applies to prenatal screening for SCA 7 families.

Program Nr: 1536 from the 1999 ASHG Annual Meeting

Fragile site at the myotonic dystrophy locus. *H.E. Hughes[1], E.E. Newman[2], J. Myring[1], P. Thompson[1], S.H. Roberts[1], E.A. Pickering[1], J.D. Brook[2]*. 1) Inst Medical Genetics, Univ Hosp of Wales, Cardiff, Wales; 2) Dept of Genetics, Queen's Medical Centre, University of Nottingham, Nottingham, UK.

Myotonic dystrophy is a progressive neuromuscular disorder caused by expansion of a CTG trinucleotide repeat within the 3untranslated region of the protein kinase gene, DMPK. We present the first known example of a fragile site at the DM locus in a patient with an expanded CTG repeat. The 10 year old female proband was investigated because of learning difficulties and confirmed myotonic dystrophy in her mother and other maternal relatives. Haplotype analysis on maternal relatives was carried out and the affected chromosome traced through the pedigree. DNA of the patient did not show an expanded CTG repeat on the maternal high risk chromosome that she had inherited. This raised the possibility that there had been a region of DNA deleted from the maternal chromosome or that an inter-allelic gene conversion event had occurred resulting in the apparent duplication of the paternal chromosome. Analysis using additional markers within the DM locus failed to resolve the situation as the patient was either heterozygous or uninformative for each of these markers. However, a Southern blot analysis performed on the DNA obtained from a lymphoblastoid cell line showed the presence of a paternal allele together with the maternally-derived expanded allele. Cytogenetic investigation of peripheral blood showed a fragile site at 19q13.32/3 in 12.7%. FISH studies with the probe F18894 showed that the fragile site mapped to the DM locus. Neither parental karyotype demonstrated a fragile site and the position of the chromosome 19 centromeric heterochromatin indicated that the chromosome containing the fragile site was maternally inherited. It is not clear why the original Southern blot failed to demonstrate the expansion in blood and if this failure can be directly related to the presence of the fragile site within the DM gene. It is has not been possible to test other tissues such as muscle. The increased sensitivity of the test in the lymphoblastoid cell line could be related to a number of enriched sub-populations of lymphocytes leading to an enhanced chance of detection.

Program Nr: 1537 from the 1999 ASHG Annual Meeting

Changes in the levels of heteroplasmy in cultured LHON cells. *K. Huoponen[1,2], V. Juvonen[1], E. Nikoskelainen[3], M. Penttinen[4], M-L. Savontaus[1,2].* 1) Medical Genetics; 2) Biology; 3) Ophthalmology; 4) Clinical Genetics Unit, University of Turku, Finland.

Heteroplasmy, the coexistence of wild type and mutant mtDNA in an individual, has been detected in about 14% of LHON families with the primary mutations. At present we have only a limited amount of knowledge of the mechanisms involved in segregation and distribution of heteroplasmic mtDNA. This poses problems in understanding the etiopathogenesis of the disease and genetic counselling of the heteroplasmic families since the transmission of the mutant mtDNA cannot be predicted. In order to study the behaviour of heteroplasmic LHON cells in long-term cultures, we established EVB transformed lymphoblastoid cell lines from five LHON patients having the ND4/11778 mutation. The percentage of wild type mtDNA in patients' blood was 6.2%, 11.4%, 36.0%, 62.5% and 65.8%, respectively. Using an accurate and sensitive minisequencing method, we quantified the levels of heteroplasmy in cell cultures at several points in time during 200-300 days. Our studies suggest that the initial proportions of wild type and mutant mtDNAs influence on which mtDNA type becomes ultimately fixed. If the proportion of one mtDNA type, mutant or wild type, is high enough, it eventually becomes fixed, and the other type is eliminated. The cells with 6.2% of wild type mtDNA became homoplasmic for mutant mtDNA, and the cells with 62.5% and 65.8% of wild type mtDNA shifted towards fixation of wild type mtDNA. There seemed to be a transition zone where either of the mtDNA types could become fixed or increase its proportion, as the behaviour of the cells with 11.4% of wild type mtDNA demonstrated: one cell line reached homoplasmy for the mutant mtDNA, while in the other cell line the amount of mutant mtDNA increased but did not reach homoplasmy. In the cells with 36% of wild type mtDNA the changes in the levels of heteroplasmy were slow, although generally towards increasing the amount of wild type mtDNA. Our observations suggest that neither of the mtDNA types have a replicative advantage, but the changes can be explained by non selective replication of both types of mtDNA molecules.

Program Nr: 1538 from the 1999 ASHG Annual Meeting

Mitochondrial DNA mutations in the tRNA$^{Ser(UCN)}$ gene causing maternally inherited hearing impairment. *T.P. Hutchin[1], M.J. Parker[3,4], I.D. Young[4], A. Davis[3], R.F. Mueller[2].* 1) Molecular Medicine Unit, St James's University Hospital, Leeds, U.K; 2) Department of Clinical Genetics, St James's University Hospital, Leeds, U.K; 3) MRC Institute of Hearing Research, University Park, Nottingham, U.K; 4) Department of Clinical Genetics, City Hospital, Nottingham, U.K.

Sensorineural hearing loss is the most common feature of mitochondrial diseases, often occurring in the presence of other clinical features. To date three point mutations in the mtDNA have been reported in cases of non-syndromic maternally inherited hearing impairment (MIHI); A7445G and 7472insC, both in the tRNASer(UCN) gene and A1555G in the 12S rRNA gene which also causes hypersensitivity to aminoglycoside antibiotics.

We describe two families from the U.K. with non-syndromic MIHI, one with the A7445G mutation and the other with a novel T to C mutation at position 7510, also in the tRNASer(UCN) gene. The T7510C mutation, which creates a Hin fI site, was not present in over 660 controls and will disrupt a highly conserved base pair in the acceptor stem of the tRNA.

Both mutations, although homoplasmic affect only the inner ear in these two families. Hearing loss is typically progressive but varies in age of onset and severity, although almost all family members with either mutation are affected. That three of the four mtDNA mutations currently identified in non-syndromic hearing impairment are in the tRNASer(UCN) gene may be coincidental or indicate a common mechanism for the pathology of these mutations, perhaps related to the processing of the tRNASer(UCN) in the cochlea.

The increasing number of reports of families with hearing impairment such as those here, highlights the importance of mtDNA mutations as a cause of non-syndromic hearing loss. mtDNA mutations may be more common than previously thought in non-syndromic hearing loss and should be screened for in all families compatible with maternal inheritance of deafness.

Program Nr: 1539 from the 1999 ASHG Annual Meeting

Polymorphisms in the TNF gene cluster are not associated to asthma in a German/ Swedish study sample. *T. Immervoll, M. Wjst.* Institute of Epidemiology, GSF Research Center, Neuherberg, Germany.

Recently a genome wide screen in an affected sib pair study of a mixed German/ Swedish sample including 97 families and 156 sib pairs was finished. Microsatellite typing with a panel of 351 markers evenly spaced over the genome with about 10 cM distance yielded 4 chromosomal regions with suggestive linkage for asthma. Chromosome 6 around the marker D6S291 showed a p-value of 0.008 (Wjst et al., 1999) The surrounding region of this marker contains the asthma candidate genes tumour necrosis factor (TNF) and lymphotoxin (LT). Two already known single nucleotide polymorphism were screened. The first (LTaNcoI 1/*2) is located in the second intron of LT and creates a new NcoI site. The second (TNF-308*1/*2), which has been analyzed by sequence specific oligonucleotide (SSO) probing, is located in the promoter region of TNF. Both polymorphisms do not show significant association with asthma in the described population. Wjst, M., Fischer, G., Immervoll, T., et al., (1999), Genomics, 58:1-8. A genome wide search for linkage of asthma.

Program Nr: 1540 from the 1999 ASHG Annual Meeting

Abnormal expression of a**1A-voltage-dependent calcium channel protein in brains of spinocerebellar ataxia type 6 (SCA6).** *K. Ishikawa[1,3], H. Fujigasaki[1,2,3], H. Saegusa[2,3], N. Ohkoshi[4], S. Shoji[4], T. Tanabe[2,3], H. Mizusawa[1,3].* 1) Dept Neurology, Tokyo Medical & Dental Univ, Tokyo, Japan; 2) Dept Pharmacology, Tokyo Medical & Dental Univ. Tokyo, Japan; 3) CREST, Japan Science and Technology Corporation, Saitama, Japan; 4) Dept Neurology, Inst. Clinical Medicine, The Univ. of Tsukuba, Tsukuba, Ibaraki, Japan.

Spinocerebellar ataxia type 6 (SCA6) is one of at least eight neurodegenerative disorders caused by expansion of trinucleotide CAG repeat in the a1A-voltage-dependent calcium channel gene (CACNA1A). Neuropathology show predominant neuronal loss of the Purkinje cell in the cerebellar cortex. To clarify the pathophysiology in SCA6, we analyzed the expression of a1A-calcium channel protein in normal and SCA6 brains using two polyclonal antibodies raised against synthetic peptides corresponding two different portions of the channel protein. Of note is that one of these antibodies recognizes only the extended C-terminal region of the channel protein, containing polyglutamine tract. Immunohistochemically, a variety of neurons throughout the normal human brain were immunoreactive with both of the antibodies. However, the Purkinje cell showed the most intense immunoreaction, indicating that the channel protein is most abundantly expressed in this type of neuron. In SCA6 brains, aggregation of the channel protein was seen in the cytoplasm of Purkinje cells. This cytoplasmic inclusion was specific to SCA6 Purkinje cells, since similar inclusion was not seen in any other neurons of the SCA6 brains, nor in brains affected with other CAG repeat/polyglutamine diseases. In addition to the aggregation formation, reduced immunoreactivity against the calcium channel antibody was seen in the molecular layer and dentate nucleus, which may suggest altered distribution or reduced expression of the a1A-calcium channel protein in the cerebellum. There were no obvious changes in immunoreactivities in all other regions of the SCA6 brains. We conclude that formation of aggregation and altered expression of channel protein could be strongly related to the pathophysiology of SCA6.

Program Nr: 1541 from the 1999 ASHG Annual Meeting

The mitochondrial C3303T mutation is highly segregated in ragged-red fibers. *R. Iwanaga, Y. Koga, Y. Akita, S. Yano, T. Matsuishi, H. Kato.* Department of Pediatrics and Child Health, Kurume University School of Medicine.

A C3303T mutation in the mitochondrial tRNALeu(UUR) gene was reported as the family with maternal inherited cardiomyopathy. However, there is no described information about the relationship between pathological, biochemical, and genetical findings on this C3303T point mutation. In our case, we analyzed the percentage of this mutation in various autopsied tissues to evaluate the correlation between pathology and heteroplasmic condition, and also we performed the single fiber analysis by PCR/RFLP method to evaluate the distribution of this mutation in the single fiber tissue. Five months old Japanese girl was admitted to our hospital showing generalized muscle weakness, hepatomegaly, and cardiomegaly with lactic acidosis and died at six months of age. Skeletal muscle showed severe degenerating myopathy shown as full of ragged-red fibers, increased numbers of lipid droplets, and severe COX deficiency. Microscopically hepatocytes showed massive accumulation of lipid droplets and heart muscle showed network pattern suggesting metabolic cardiomyopathy. Activities of respiratory chain enzyme complex I plus IV in the skeletal were 23.4% and 5.0% of the control value, significantly decreased. The percentages of C3303T mutation in the patient tissues are quite variable, range from 25% in pancreas to 99% in spinal cord. By the single fiber analysis the percentage of C3303T mutation in RRFs with COX negative (Group1) (42.4+7.0) and in RRFs with COX positive (Group2)(58.2+5.8) were significantly higher than that in non RRFs with normal COX staining (Group3) (10.7+6.3) ($p>0.001$). Although the pathological abnormality in Group1 was much severe than in Group 2, the percentage of mutant DNA in Group 1 was significantly lower than in Group 2($p>0.05$). Our patient showed fatal infantile from of encephalopathy, myopathy and cardiomyopathy associated with widely distributed C3303T mutation in all of her somatic cells. Since her skeletal muscles showed severe pathological changes but the percentage of mutation in her muscle were only 67%, this mutation may have more potent biological abnormality than that in A3243G mutation.

Program Nr: 1542 from the 1999 ASHG Annual Meeting

Limited expression of SCA8 is consistent with cerebellar pathogenesis and toxic gain of function RNA model.
M.A. Janzen, M.L. Moseley, K.A. Benzow, J.W. Day, M.D. Koob, L.P.W. Ranum. Genet Cell Biol & Devel, Inst Hum Genet, Neurol, Univ of MN, Mpls, MN.

It is intriguing to consider how untranslated CTG expansions cause diseases as distinct as spinocerebellar ataxia type 8 (SCA8) and chromosome 19 myotonic dystrophy (DM1). DM1 has been distinct among the triplet repeat disorders both in terms of the transcribed repeat motif (CTG) and its location in the 3' untranslated region of this gene. We recently isolated a second example of a pathogenic CTG expansion in SCA8. As in DM1, the SCA8 mutation is an untranslated CUG expansion at the 3' end of an RNA. This is the first dominant spinocerebellar ataxia not caused by an expanded CAG repeat translated as a polyglutamine tract. Affected individuals develop spastic and ataxic dysarthria and limb movements. However, systemic features of DM are absent in SCA8. There is no predilection for cardiac arrhythmias, cataracts, glucose intolerance, or gonadal failure, nor do SCA8 patients have clinical or electrical myotonia or myopathic weakness. The expanded CUG transcripts in SCA8 and DM1 might share a common toxic RNA mechanism at the cellular level. To evaluate if the SCA8 tissue distribution correlates with clinically affected tissues, Northern and multiple tissue blots were probed. Only weak hybridization signals were detected in various brain tissues. RT-PCR analysis confirmed that SCA8 is expressed primarily in the brain. SCA8 PCR analysis of normalized first-strand cDNA from mRNA extracted from eight human tissues was performed. PCR products were detected in brain and very weakly in lung but not in heart, placenta, liver, skeletal muscle, kidney and pancreas. Additional RT-PCR experiments detected transcripts in cerebellum but not in skeletal muscle and blood. The limited expression of SCA8 correlates with the cerebellar atrophy. We hypothesize that the disease mechanisms for SCA8 and DM1 are similar, and that the clinical differences between these diseases are due to the different expression profiles of the SCA8 and DM1 transcripts. We are testing this hypothesis by further characterizing SCA8 gene expression and by developing a mouse model of the disease (also see Koob et al.).

Program Nr: 1543 from the 1999 ASHG Annual Meeting

Paraoxonase May Contribute to Vascular Disease Through an Effect on LDL Density. *G.P. Jarvik, T.S. Hatsukami, A. Chait, C.E. Furlong.* Dept. Medicine, U. Washington, Seattle.

Paraoxonase (PON1) is a high density lipoprotein (HDL)-associated enzyme that has been suggested to protect low density lipoprotein (LDL) from oxidative modification. The $PON1_{Q/R192}$ polymorphism results in an amino acid 192 substitution (Gln/Arg). The R allele has been predictive of vascular disease (CVD) in several, but not all, studies and is carried by over half of Caucasians. We evaluated the relationship of PON1 and another atherogenic LDL feature, dense LDL, in 105 Caucasians with carotid artery disease (over 80 percent stenosis by angiogram). The subjects were US military Veterans, mean age 69 yr (range 49-83 yr); 103 were male, 67 hypertensive, 21 diabetic, 87 former and 39 current smokers. LDL flotation rate (LDL-Rf), a quantitative measure of LDL density, was determined using non-equilibrium density gradient ultracentrifugation.

$PON1_{192}$ genotype was predictive of LDL-Rf (p=.01), with the RR genotype being associated with denser LDL (LDL-Rf was not normally distributed, thus a Kruskal-Wallace Mean Rank test was used; mean ranks of QQ, QR, and RR genotype subjects were 55, 56, and 22; mean LDL-Rfs were .268, .265, and .228, respectively). Adjustment of LDL-Rf for LDL oxidative susceptibility using 3 measures of copper-mediated oxidation of LDL did not eliminate the significant $PON1_{192}$--LDL-Rf relationship. The $PON1_{55}$ polymorphism did not add additional information about LDL density once $PON1_{192}$ genotype is considered, but PON1 enzyme activity for the hydrolysis of paraoxon and diazoxon did add information about LDL density.

Thus, $PON1_{192}$ genotype predicts variation in LDL density in these vascular disease subjects. Of interest, this sample has multiple CVD risk factors and genetic factors may have been expected to play less of a role. Gene by environment interactions may exist. Although LDL density has been associated with LDL oxidative susceptibility, an independent PON1-LDL-Rf relationship is suggested by the significance of PON1 predictive power on oxidative status-adjusted LDL-Rf. This may represent a previously undescribed biologic mechanism for the reported role of the $PON1_{192}$ polymorphism in CVD.

Program Nr: 1544 from the 1999 ASHG Annual Meeting

Analysis of Affected Sibling Pairs with Rheumatoid Arthritis: The North American Rheumatoid Arthritis Consortium. *D. Jawaheer[1,4], T. Costello[2,4], C. Amos[2,4], J. Monteiro[1,4], M. Seldin[3,4], L. Criswell[4], SL. Bridges[4], H. Schroeder[4], D. Pisetsky[4], D. Kastner[4], R. Wilder[4], R. Pope[4], D. Clegg[4], R. Ward[4], S. Albani[4], JL. Nelson[4], M. Wener[4], L. Callahan[4], T. Pincus[4], PK. Gregersen[1,4].* 1) Dept Biol & Human Genetics, North Shore Univ Hosp, Manhasset, NY; 2) MD Anderson, Houston, TX; 3) UC Davis, Davis, CA; 4) The North American Rheumatoid Arthritis Consortium.

The North American Rheumatoid Arhtiris Consortium (NARAC) has, to date, identified 491 families with one or more sibling pairs affected with rheumatoid arthritis. At least one affected sibling in each family is required to have erosions on hand X-rays. Affected siblings have also been evaluated upon examination using a modified joint alignment and mobility score (JAMS). 77% of the affected siblings are female and 23% are male. The mean age of disease onset was 37 and 41 for females and males, respectively, with mean disease duration of 17(+/- 11.7) years. 82% of patients are RF+ and 92% have erosions in both hands. The mean JAM score is 27.8 (range 0-117). These data indicate that the selection criteria for NARAC have resulted in a collection of RA sibling pairs with relatively early onset, longstanding and severe disease. A genome-wide screen using microsatellite markers from the Marshfield set 8A is currently being performed on the first 158 families. In addition, 4 markers within the HLA region (D6S265, D6S1629, D6S273 and D6S291) have been used to evaluate whether linkage can be detected with this current data set. Analysis of the HLA data from 184 affected sib pairs, using Sibpal from the S.A.G.E ver 3.1 package, showed significant linkage with disease, especially for markers D6S265 and D6S273 (p=0.001). Haplotyping with GENEHUNTER of HLA loci led to an estimate of 15% of sib pairs sharing 0 alleles i.b.d. which yields a 1.7-fold relative risk estimate associated with HLA.

Program Nr: 1545 from the 1999 ASHG Annual Meeting

DRD2 not associated with obesity in Pima Indians. *C.P. Jenkinson, K. Cray, R. Hanson, C. Wiedrich, C. Bogardus, L. Baier.* PECRB, NIH/NIDDK, Phoenix, AZ.

The gene for the type 2 dopamine receptor, DRD2, has been associated with various addictive, impulsive disorders, including alcoholism, schizophrenia and obesity (Noble et al., Int. J. Eat. Disord. 15:205-217, 1994; Noble, Alcohol, 16:33-45, 1998). In an autosomal genomic scan for genetic markers linked to obesity and type 2 diabetes in Pima Indians, the region most strongly linked to obesity was on chromosome 11q22-24 (Hanson et al., Am. J. Hum Genet. 63:1130-1138, 1998; lod = 3.6 for BMI). This complex disease gene localization has subsequently been partially replicated in a Caucasian population (Jaquish et al., Am. J. Hum Genet. 63:A329, 1998; lod = 3.2 for BMI). The fact that DRD2 maps to this locus makes it a strong positional candidate for susceptibility to obesity. To further investigate this possibility we analyzed single nucleotide polymorphisms (SNPs) within the DRD2 gene for association with BMI. The SNPs (Ser311Cys, a C®G transversion and TaqAI, a T®C transition) were genotyped in the same group of 1200 subjects which had provided evidence for linkage in the Pima population. Ser311Cys is a coding sequence mutation which severely reduces dopamine signal transduction through DRD2. TaqAI, located in the 3 non-coding region, has provided evidence for association with obesity in other populations. All analyses were performed on the residual of the log-transformed maximal BMI, adjusting for age, sex, birth year, and nuclear family membership. Among full-heritage Pimas, individuals with a heterozygous CG genotype at Ser311Cys had a slightly higher BMI than those with CC homozygosity (36.7 vs. 35.5 kg/m2, p=0.03), although a test of the overall null hypothesis that all three genotypes are equal was not significant (p=0.08, 2 df). The T®C change at the TaqAI site was not significantly associated with BMI. Adjustment for these polymorphisms had no significant effect on linkage for BMI. Thus DRD2 does not appear to be the putative major gene for BMI on chromosome 11.

Program Nr: 1546 from the 1999 ASHG Annual Meeting

Nuclear receptor co-activator (ACTR), a candidate gene for type 2 diabetes identified by fine mapping of 20q13.1: results of mutation analysis. *L. Ji[1,2], T. Klupa[1,2], A. Antonellis[1], M. Malecki[1,2], J.H. Warram[1], A.S. Krolewski[1,2]*. 1) Dept Genetics & Epidemiology, Joslin Diabetes Ctr, Boston, MA; 2) Department of Medicine, Harvard Medical School.

Our study provided strong evidence for a novel susceptibility gene for type 2 diabetes located on 20q13.1, most likely in a critical region defined by markers D20s178 and D20s197. Several other family studies have also provided evidence pointing to these markers. To facilitate the identification and cloning of diabetes susceptibility genes in this region, we constructed a contig covering the chromosomal region that includes D20s178 and D20s197. We used STSes and ESTs on GeneMap '99 to construct the contig from four PAC sequences (Sanger Center) and 5 BAC clones identified either electronically or manually. In addition to 10 ESTs, one gene named nuclear receptor co-activator (ACTR) was mapped to the contig. ACTR is a histone acetyltransferase that plays a central role in DNA transcription by forming a multimeric activation complex with P/CAF and CBP/p300. Because of its presumed role in insulin gene transcription and the recent successes in identifying diabetes genes that are involved in insulin transcription, we were prompted to test whether a genetic defect in the ACTR gene might be responsible for type 2 diabetes that is linked with Chromosome 20. We screened the coding sequence of the ACTR gene in the probands of each of seven families with type 2 diabetes linked with 20q and found mutations in three of them. Two mutations did not segregate with diabetes while one, a missense mutation Tyr469Ser, segregated with type 2 diabetes in one family. A further search for mutations in the promoter region of the ACTR gene is being made in the 6 remaining families.

Program Nr: 1547 from the 1999 ASHG Annual Meeting

Kinetics of mitochondrial iron turnover in Friedreich ataxia cells. *S. Jiralerspong[1], L. Montermini[1], M. Pandolfo[1,2]*. 1) Dept. of Neurology, Centre Hospitalier de l'Université de Montréal, Montréal, Canada; 2) Dept. of Neurology and Neurosurgery, McGill Univ., Montréal, Canada.

Studies in yeast suggest that *YFH1*, the gene encoding a homologue for the Friedreich ataxia (FRDA) protein frataxin, is important for maintaining mitochondrial iron homeostasis. Moreover, human fibroblasts from FRDA patients show increases in steady-state mitochondrial iron levels by direct measurement. These increases have been fairly subtle and have failed to convincingly validate the yeast model for frataxin function as applied to mammalian systems, especially in light of the absence of iron accumulation in bacteria deficient for the frataxin homologue *CYAY*. Consequently, we hoped to clarify this issue and detail the dynamics of mitochondrial iron cycling by performing pulse-chase analysis on fibroblasts. We have observed significant differences in the kinetics of mitochondrial iron turnover between FRDA and control cells, even in cells with only marginal decreases in frataxin expression. Control cells preloaded with iron rapidly accumulate and export additional iron, while patient cells show steady, modest increases in iron over the same time period. Our results confirm that mitochondrial iron cycling is altered in FRDA cells as in yeast cells. Further studies to define the pathways directly influenced by loss of frataxin function are underway.

Program Nr: 1548 from the 1999 ASHG Annual Meeting

Multiple Autoimmune Disease Regulatory Loci Cluster on Rat Chromosome 10 and Homologous Mouse and Human Chromosomes. *B. Joe[1], E.F. Remmers[1], M.M. Griffiths[2], R.L. Wilder[1]*. 1) Arthritis and Rheumatism Branch, NIAMS,NIH,Bethesda,MD 20892; 2) Research Service Veterans Affairs Medical Center and Department of Medicine/Rheumatology, University of Utah, Salt Lake City, UT 84132.

Infection and immunity are biologically inter-linked processes. Dysfunctional regulation of immune responses to infectious agents may lead to autoimmune diseases. Among several factors that affect susceptibility to infectious diseases and autoimmune responses, genetic factors are being identified using animal models of infectious and autoimmune diseases, respectively. Evidence from several genetic mapping studies indicates that regulatory loci for susceptibility to infectious and autoimmune disease traits cluster on rat chromosome 10 and homologous regions on mouse and human chromosomes. We have identified two regulatory loci, Cia5 and Ciaa2, that regulate severity of collagen-induced arthritis (CIA) and levels of autoantibody production, on rat chromosome 10. Cia5 not only overlaps with regulatory loci for oil-induced arthritis (Oia2) and carrageenan induced inflammatory exudate volume in rats, but also with regulatory loci for leishmaniasis (Scl1) and autoantibody production in mice, and loci for psoriasis (PS) and multiple sclerosis (MS) in humans. Ciaa2 overlaps with Eae7, Idd4 and Orch3, which are loci on mouse chromosome 11 regulating experimental autoimmune encephalomyelitis (EAE), insulin dependent diabetes mellitus (IDDM) and orchitis, respectively and with MS in humans. In addition to Cia5 and Ciaa2, rat chromosome 10 additionally harbors a third cluster of loci that regulates susceptibility to experimental autoimmune uveitis (EAU) and EAE, onset of diabetes and levels of IgE. These loci include the IL-3, IL-4 and IL-5 regions at rat chromosome 10 (25-50cM). Homologous regions bear susceptibility loci for lupus linked traits (Lbw8, Nba), EAE (Eae6), S. typhi infections and IL-12 responsiveness (Tpm1) in mice and a regulatory locus for IgE levels in humans. Overlapping of regulatory loci on rat chromosome 10 and its homologous regions in other species suggests that rat chromosome 10 contains genes controlling susceptibility to infections and autoimmune responses.

Program Nr: 1549 from the 1999 ASHG Annual Meeting

The interaction of transcriptional regulatory proteins with huntingtin: implications for Huntington's disease aetiology. *L. Jones[1], P. Thomas[1], L. Elliston[1], P.S. Harper[1], J.W. Neal[2]*. 1) Institute of Medical Genetics and; 2) Dept of Pathology, University of Wales College of Medicine, Cardiff, Wales, UK.

Huntington's disease (HD) is an autosomal dominant neurodegeneration associated with an expanded CAG repeat at the 5' end of a large gene, which upon translation gives an expanded polyglutamine tract at the N-terminus of the protein, huntingtin. We previously isolated a transcriptional repressor protein, the nuclear receptor co-repressor (N-CoR) which interacts specifically with the polyglutamine-bearing N-terminus of huntingtin. The strength of interaction is modulated by repeat length; longer repeats have a stronger interaction with huntingtin. There appears to be no interaction with other proteins carrying polyglutamine repeats. We have followed up this finding in human HD and control postmortem brain tissue, examining the distribution of N-CoR and other proteins known to interact with it in the formation of repression complexes. N-CoR itself is detected in control brain, localised in the neuronal cytoplasm and also the nuclei of cortical neurons, particularly in layers V and VI. In HD brain cortical neurons, however, N-CoR immunoreactivity is localised in the cytoplasm and the nuclear localisation appears to be abolished. N-CoR immunoreactivity was not localised to the characteristic intranuclear inclusions of HD brain. However, other proteins which interact with N-CoR within the repression complex, are found to localise to the NII of HD brain. mSin3 and HDAC1 were both detected localised to a subset of inclusions in Grade III and IV HD brain. This study is currently being extended to Grade I and II HD brain. Further *in vitro* experiments have also indicated changes in the transcription of reporter genes in the presence of N-terminal huntingtin, implying that the repression complex may be recruited by huntingtin through its interaction with N-CoR. These experiments indicate that the interaction of huntingtin with N-CoR may have consequences for transcription of sets of genes under the control of N-CoR which may contribute to the pathology of HD.

Program Nr: 1550 from the 1999 ASHG Annual Meeting

Allelic Variants of Candidate Genes TGFA, TGFB3, and MSX1 and Orofacial Clefting in Norway: A Case-Parent Triad Approach. *A. JUGESSUR[1,2,3], R.T. LIE[2], A. WILCOX[4], F. ÅBYHOLM[5], H. VINDENES[5], J.C. MURRAY[3]*. 1) Center for Molecular Medicine, Haukeland Hospital, Bergen, Norway; 2) Division for Medical Statistics, Univ. of Bergen, Bergen, Norway; 3) Dept Pediatrics, Univ Iowa, Iowa City, IA; 4) Epidemiology Branch, NIEHS, Research Triangle Park, NC; 5) Norwegian Radium Hospital, Oslo, Norway.

Orofacial clefts are common congenital malformations occurring in approximately 2/1000 live births. Past studies have suggested multifactorial causation, with both genetic and environmental origins. The most studied allele associated with facial clefts has been transforming growth factor alpha, TGFA, although results are not consistent across studies. More recent reports have suggested additional associations of facial clefts with transforming growth factor beta 3, TGFB3, and MSX1 (a member of the family of Drosophila Msh, muscle segment homeobox). New candidate genes have been proposed, including genes for growth and signaling factors, and extracellular matrix proteins. The present study was based on DNA collected from case-parent triads, which eliminates possible bias from population admixture. A linkage disequilibrium-based analysis was used to detect non-Mendelian transmission of TGFA, TGFB3, RARA and MSX1 alleles in a total of 126 Norwegian nuclear triads. To date, we have completed the genotyping for TGFB3 and MSX1 using CA-repeat markers. The results indicate no formal statistical interaction between these two genes and either isolated cleft lip (NSCLO) or isolated cleft lip and palate (NSCL/P). However for MSX1, a similar pattern of allele representation was observed as in a previous study in Caucasian CL/P patients ($p = 0.07$). To investigate this further, another polymorphic variant of MSX1, MSX1-1.3, is currently being genotyped in our case-parent triads. Prospective analyses include screening a subset of the cases for variants in the RARA gene, and investigating environmental interactions such as smoking and folic acid metabolism in the etiology of clefts.

Program Nr: 1551 from the 1999 ASHG Annual Meeting

Agenesis of the corpus callosum associated with a chromosome (4;14) translocation. *D. Kamnasaran[1], M. Muenke[2], P.C.M. O'Brien[3], M.A. Ferguson-Smith[3], D.W. Cox[1].* 1) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Children's Hospital of Philadelphia and MBG, NHGRI, NIH, Bethesda, MD, U.S.A; 3) Clinical Veterinary Medicine,Centre for Veterinary Science,Cambridge, U.K.

Disorders such as holoprosencephaly and autosomal dominant and recessive deafness syndromes are associated with the chromosome 14q12-q13 cytogenetic region. We report a proband with a 46,XY,t(4;14)(q25;q13) karyotype who has agenesis of the corpus callosum, microcephaly, low set ears, feeding problems and failure to thrive. We have mapped the proband's translocation breakpoint between the markers AFM200ZH4 and D14S306 on chromosome 14 and between the markers D4S2449 and D4S3167 on chromosome 4 by PCR analysis of flow sorted chromosomes. We have assembled a 3 Mb YAC contig that spans the translocation breakpoint on chromosome 14 by selecting CEPH YAC clones that are positive for markers localized to the interval. This was done in order to map, by PCR, all known genes that have been binned to the 14q13 region and to analyze potential candidate genes. Six known genes, PAX9, TTF1, HNF3A, SEC23, SDK3 and RPS14 mapped onto the YAC contig. Of the genes mapped at the 14q13 translocation breakpoint, TTF1 is a potential candidate for the agenesis of the corpus callosum observed in the proband. We have also analyzed PITX2 at the chromosome 4q25 region as another potential candidate gene for agenesis of the corpus callosum. PITX2 is the gene for Rieger syndrome. A putative deletion within PITX2 was found by PCR analysis of flow sorted chromosomes with primer pairs that amplified different exons of the gene. PITX2 was physically estimated to map at least 1.2 Mb proximal to the translocation breakpoint on chromosome 4 by mapping on CEPH YAC clones binned to 4q25. The presence of two breaks at 4q25 implies a possible inversion at this region.

Program Nr: 1552 from the 1999 ASHG Annual Meeting

A putative *Drosophila* homolog of the *Huntington disease* gene. *C.A. Karlovich[1], Z. Li[1], M.P. Fish[2], M.P. Scott[2], R.M. Myers[1]*. 1) Dept. of Genetics, Stanford University, Stanford, CA; 2) Dept. of Genetics and Developmental Biology, Stanford University, Stanford, Stanford, CA.

The *Huntington disease (HD)* gene encodes a protein, huntingtin, with no known function and no detectable sequence similarity to other proteins in current databases. To gain insight into the normal biological role of huntingtin, we isolated and sequenced a cDNA encoding a protein that is a likely homolog of the HD gene product in *Drosophila melanogaster*. We also determined the complete sequence of 43,125 contiguous base pairs of genomic DNA that encompasses the *Drosophila HD* gene, allowing the intron-exon structure and 5' and 3' flanking regions to be delineated. The predicted *Drosophila* huntingtin protein has 3,583 amino acids, which is several hundred amino acids larger than any other previously-characterized member of the HD family. Analysis of the genomic and cDNA sequences indicates that *Drosophila HD* has 29 exons, compared to the 67 exons present in vertebrate *HD* genes, and that *Drosophila* huntingtin lacks the polyglutamine and polyproline stretches present in its mammalian counterparts.

We have generated antibodies against several peptide regions from Drosophila HD. Using these antibodies, we find that the Drosophila HD protein is expressed in a broad range of developmental stages and in the adult. The *Drosophila HD* mRNA is similarly expressed. Thus, the temporal pattern of expression of both protein and mRNA in the fly is similar to that observed for mammalian huntingtins.

In contrast to vertebrate huntingtins, which have a high degree of sequence similarity to one another, the Drosophila HD protein shows only low overall similarity to other members of the HD family. This low sequence conservation makes it possible to discern five regions of relatively high similarity from multiple sequence alignments between *Drosophila* and vertebrate huntingtins. These regions may define functionally important domains within the protein.

Program Nr: 1553 from the 1999 ASHG Annual Meeting

Trinucleotide repeat for SCA8 on 13q21: super expansion in psychosis individuals unaffected by ataxia. *J.L. Kennedy[1], M.L. Neves-Pereira[1], A.D. Paterson[1], E. Yamamoto[1], S.V. Parikh[1], F. Macciardi[1], A. Petronis[1], J.B Vincent[1,2].* 1) Neurogenetics Section, Clarke Inst, Toronto, ON, Canada; 2) Dept. Genetics, Hospital for Sick Children, Toronto, ON, Canada.

Increased frequency of large CAG/CTG trinucleotide repeat tracts in individuals affected with schizophrenia (SCZ) and bipolar affective disorder (BPAD) has previously been reported. Studies of two unstable CAG/CTG repeats (SEF1-2B and ERDA1) indicate that the majority of individuals with large repeats (detected by RED) have large repeat alleles at these loci, but that there is no association of large alleles with either BPAD or SCZ. Using RED, we have identified from amongst our sample a BPAD individual with a very large (>690bp) trinucleotide repeat tract at a third site. From this individual s DNA, we have cloned a new highly polymorphic trinucleotide repeat, TGC13-7a, comprised of [TAC]n [TGC]n, which isexpanded (~1800bp) in this patient. The repeat region localizes to chromosome 13q21, and has recently been shown to be the cause of spinocerebellar ataxia type 8, where alleles with greater than ~107 repeats are thought to be pathogenic. We observed no significant differences in allele distribution between 100 BPAD patients and 100 matched controls (p=0.06), and no transmission disequilibrium in 93 BPAD trios (p=0.49) or 54 SCZ trios (p=0.46). We have now identified a number of other individuals with very large expansions at TGC13-7a/SCA8: a SCZ individual with ~550 repeats, a SCZ individual with 115 repeats and unaffected father with ~700 repeats, none of whom are affected by spinocerebellar ataxia. Whilst these expansions are relatively rare (~0.5% of all individuals tested), it is clearly much more common than the frequency of all spinocerebellar ataxia cases (0.01%), let alone SCA8. Super expansions at TGC13-7a/SCA8 may be allelic variants that predispose psychosis via a different molecular mechanism to the more modest expansion alleles reported for SCA8, or may be completely unrelated to disease.

Program Nr: 1554 from the 1999 ASHG Annual Meeting

Using 2D gel analysis of wildtype and *Fmr1* knockout mouse hippocampus to identify differentially expressed proteins. *L.L. Kirkpatrick, D.L. Nelson.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Fragile X syndrome results from mutations in the X-linked *FMR1* gene. The most common mutation is expansion and hypermethylation of a CGG repeat in the 5UTR of *FMR1* which blocks transcription and results in the loss of FMR1 protein (FMRP). FMRP has two KH domains and an RGG box, protein motifs thought to mediate RNA binding, and studies have shown that FMRP binds RNA in vitro. This suggests that FMRP may be involved in some aspect of RNA metabolism, perhaps in targeting, transport, or translation regulation. A necessary first step towards understanding how the absence of FMRP leads to mental retardation is the identification of mRNAs and/or proteins with which FMRP interacts. We have used 2D gel analysis in an effort to identify proteins whose expression levels are changed in the absence of FMRP. Wildtype and *Fmr1* knockout mouse hippocampus samples were subjected to 2D SDS-PAGE and differences in protein spots were then identified using a computerized comparison. The spots were cut from the gels and subjected to mass spectroscopy fingerprinting for identification. Using this method, we have identified NFL and TOAD64 as being increased in knockout hippocampus, and HSC70 as increased in wildtype hippocampus. Northern blot, western blot, and immunocytochemical analyses are being used to validate the 2D gel results.

Program Nr: 1555 from the 1999 ASHG Annual Meeting

CAG/CTG repeats in auotimmune disease: a possible role in rheumatoid arthritis? *W. Klitz[1], L. Barcellos[2], Q-p. Yuan[3], K. Lindblad[3], M. Schalling[3], L. Field[4], M. Sheldin[5]*. 1) Sch Public Health, Univ California, Berkeley, CA; 2) Dept Neurology, Univ California, San Francisco, CA; 3) Cntr Molecular Medicine, Karolinska Hosp, Stockholm, Sweden; 4) Dept Medical Genetics, Univ Calgary, Calgary, Canada; 5) Rowe Program in Genetics, Univ California, Davis, CA.

Spontaneous expansions of trinucleotide repeats have now been shown to be responsible for at least a dozen diseases, many of them involving genes affecting the nervous system. In many of these disorders, anticipation, an increased severity and earlier age of onset from one generation to the next, is seen. Because the discovery of non-HLA genetic components of autoimmune disease has been frustratingly slow, a non-calssical genetic mechanism seemed worth pursuing as an underlying biological contributor to autoimmune disease. We examined individuals scored for CAG/CTG exapnded repeat size (³120nt) sampled from three autoimmune diseases--insulin dependent diabetes mellitus (IDDM), multiple sclerosis (MS), and rheumatoid arthritis (RA)--and compared them to a control sample.

Repeat sizes of two known locations of CAG/CTG expansions (ERDA1 and CTG18.1) were phenotyped by PCR and all expansions phenotyped by the repeat expansion detection method. None of the the three diseases differed in phenotype frequencies of expanded repeats compared to the controls. Age of onset and HLA DR typing information was also examined for each disease. The IDDM and MS samples showed no effects with these two variables, but for the RA sample earlier age of onset ($p = 0.019$) and absence of the predisposing shared DR epitope ($p = 0.036$) were each associated with increased frequency of CAG/CTG expansions. These observations suggest that trinucleotide repeat expansions may play a role in rheumatoid arthritis, and await confirmation in an independent RA patient sample.

Program Nr: 1556 from the 1999 ASHG Annual Meeting

Tissue specificity in the mitochondrial tRNA processing implicates the clinical heterogeneity in mitochondrial disorders. *Y. Koga, Y. Akita, R. Iwanaga, H. Kato.* Dept Pediatrics & Child Health, Kurume Univ Sch Medicine, Kurume, Fukuoka, Japan.

In order to know the pathological meaning of tissue specific processing at the mitochondrial tRNALeu(UUR) boundary in mitochondrial myopathy, we analyzed the percentage of processing intermediates. Total RNAs were isolated from various human tissues from 8 normal individuals, and from 5 patients. Three patients have been diagnosed MELAS having A3243G mutation, one patient diagnosed Leigh disease having A3243G mutation, and one patient diagnosed mitochondrial encephalomyopathy and cardiomyopathy having T3303C mutation in the mitochondrial tRNALeu(UUR) gene. We analyzed the percentage of point mutation in RNA 19 fraction in RNAs from muscles, using rTth reverse transcriptase PCR-RFLP methods. We also analyzed the 5'- or 3'-end of tRNALeu(UUR) by primer-extension or S1-digestion method. The RNA 19 is recognized in normal human tissues including muscle, heart, brain, kidney, liver, spleen and uterus, ranging 3.5%, 11.6%, 13.6%, 8.4%, 4.2%, 1.7% and 6.5% of their total ND 1 signal, respectively. 3'-end of tRNALeu(UUR) portion is processed much earlier than 5'-end in most of the human tissues, while in the fibroblasts, 5'-end of tRNALeu(UUR) portion is processed much earlier than 3'-end. In patients, we observed significantly increased levels of RNA 19 in muscles from all patients examined ; 3 MELAS (5 - 8 times more than that of the control), Leigh (8 times) and T3303C (, which is well harmonized with the percentage of mutation analyzed in their mitochondrial DNA from muscles. The proportion of mutated RNA in RNA19 fraction always higher than that in DNA fraction, suggesting that these point mutations located in the tRNALeu(UUR) gene exhibited dominant negative effects on the mitochondrial RNA processing events, resulting in the accumulation of RNA 19 transcripts in these patients. This accumulation of RNA 19 seems to be specific for the tRNALeu(UUR) mutation and related to the pathogenic mechanism of MELAS.

Program Nr: 1557 from the 1999 ASHG Annual Meeting

Sequence-specific and non-specific nucleotide binding activities of the ORF1 protein from mouse LINE-1. *V.O. Kolosha, S.L. Martin.* Dept. of Cellular and Structural Biology, University of Colorado School of Medicine, Denver, CO.

LINE elements and other non-LTR retrotransposons are widely dispersed in nature. In humans, transposition of LINE elements in germ cells or early embryos can disrupt essential genes, leading to heritable disease. Mammalian LINE-1 encodes two proteins that are required for transposition. The ORF1 gene product is a nucleic acid binding protein. It appears to "coat" the L1 RNA forming a ribonucleoprotein particle, although its exact role in transposition remains to be elucidated. Contradictory data establishes the human protein as a sequence-specific RNA binding protein, whereas the mouse homolog is a sequence non-specific, single-stranded nucleic acid binding protein. In this study, the mouse L1 ORF1 protein is purified in soluable form from both insect cells and *E. coli* to apparent homogeneity. The results obtained from several independent assays confirm our earlier observations that the ORF1 protein binds single-stranded nucleic acids non-specifically. In addition, these studies extend those observations to demonstrate the presence of a single, relatively high-affinity site for a specific sequence within the mouse L1 RNA. Both baculo- and bacterially-expressed ORF1 proteins coimmunoprecipitate a specific 38 nucleotide fragment from several, overlapping RNAase T1-digested, L1 *in vitro* transcripts. This analysis allows the unambiguous identification of the bound fragment. The sequence is U-rich (U-content 42% in L1Md-A2), and lies just 3' of the AUG codon at the beginning of the ORF2 coding sequence, homologous to one of two high-affinity sites identified for the human ORF1 protein in human L1 RNA. The fact that the structure of this short region of the ~7kb L1 RNA is sufficient to be recognized by the ORF1 protein is supported by co-immunoprecipitation of a 43 nucleotide transcript containing this region. The high-affinity interaction of ORF1 protein with the L1 RNA may nucleate the coating of L1 RNA by ORF1 protein. Once the first molecule of ORF1p is bound, the lower affinity, non-specific interactions and protein-protein interactions would allow the RNA to be covered by ORF1p, forming the ribonucleoprotein particle.

Program Nr: 1558 from the 1999 ASHG Annual Meeting

Differential display analysis of inducible N2a cells stably expressing huntingtin exon 1 with normal and expanded polyglutamine region . *S.E. Kotliarova, G.H. Wang, Y. Kamide, M.A. Zemskova, N. Nukina.* Lab.for CAG repeat diseases, Brain Science Institute, RIKEN, Wako-shi, Saitama, Japan.

Huntington disease is caused by expansion of CAG repeats in huntingtin exon 1 that results in abnormal protein with expanded polyglutamine (pQ) tract. This triggers the chain of events resulting in formation of nuclear inclusions and neuronal cell death.

To study the factors, which may be involved in mechanism of Huntington disease, we have established the new model system of this disease inducible stable cell lines of mouse neuroblastoma HD16Q-23 (16pQ) and HD150Q-28 (150 pQ). The constructs containing fusion protein of Huntingtin exon 1 and GFP were used to generate these cell lines.

mRNA isolated from these cell lines was analysed by Differential Display (DD) technique . Several differentially expressed bands were detected in mRNA extracted on the third day after differentiation and induction, when the majority of HD150Q-28 cells were dying. Among differentially expressed cDNA several apoptosis-related genes were identified. The difference in expression for these genes was confirmed by semi-quantitive RT-PCR and TaqMan assay in cells harvested on the third day.

In addition we compared the pattern of expression level change for several genes during time course from 0 to 3 days in 0.5 day increments in cells expressing normal and expanded pQ .

Our data suggest that genes participating in programmed cell death are probably involved in the mechanism of cell death triggered by expanded pQ of huntingtin.

Program Nr: 1559 from the 1999 ASHG Annual Meeting

Linkage analysis of 3 novel *CD4* promoter polymorphisms in Danish IDDM multiplex families. *O.P. Kristiansen, F. Pociot, J. Johannesen, A.E. Karlsen, J. Nerup, T. Mandrup-Poulsen, DSGD, DIEGG.* Steno Diabetes Center, Gentofte, Denmark.

Recently, evidence for linkage between IDDM and the A4 (113bp) allele of a CTTTT-repeat in the *CD4* promoter was reported. The **aims** of the present study were to screen the *CD4* promoter for novel polymorphisms and to investigate for linkage between novel *CD4* polymorphisms and IDDM in the Danish population. **Methods and material**: SSCP screening of the *CD4* promoter (position 386®1523bp; M86525) was performed in 20 IDDM and 10 healthy subjects. The allelic variants in the SSCP polymorphic sites were identified by cycle sequencing. Linkage was investigated by the transmission disequilibrium test (TDT) in 146 sibpair and 103 parent-offspring IDDM families. Transmission to 418 affected and 249 non-affected offspring was observed. **Polymorphism screening**: Three novel polymorphisms were found: 1) a T®C substitution in pos. 474 bp, 2) a G®C substitution in pos. 1003 bp, and 3) a C®G substitution in pos. 1343bp. PCR based ([1]*BslI* RFLP, [2]*MspI* RFLP and [3]a mutagenically separated (MS)) assays for the polymorphisms were established. **Linkage analysis**: The G-allele of the *BslI* (pos. 474 bp) polymorphism was in complete linkage disequilibrium with allele A8 (88bp) of the *CD4* (CTTTT)-repeat, known not to be linked to IDDM. Both the *MspI* (pos. 1003 bp) and the *BsaXI* (pos. 1343 bp) alleles showed random transmission to the IDDM offspring, but a non-significant tendency to skewed transmission was observed for both polymorphisms: 80 (55%) G- and 66 (45%) C-alleles (P_{tdt}=0.25) and 160 (54%) C- and 134 (46%) G-alleles (P_{tdt}=0.13) were transmitted, respectively. A *MspI-BsaXI* haplotype was established. Transmission of the 3 identified haplotypes G-C, C-G and G-G were 55% (164/300; P_{tdt}=0.11), 43% (65/151; P_{tdt}=0.09) and 48% (113/233; P_{tdt}=0.6). In **conclusion**, we have identified 3 novel polymorphisms in the *CD4* promoter. None of the found polymorphisms or the resulting *MspI-BsaXI* haplotype were significantly linked to IDDM in the Danish population. Thus, it is less likely that any of the novel polymorphisms confer susceptibility to IDDM, although the region is linked (*CD4* (CTTTT)-repeat) to IDDM.

Program Nr: 1560 from the 1999 ASHG Annual Meeting

A novel 4.4kb mtDNA deletion underscores clinical heterogeneity in mitochondrial DNA deletion disorders. *F.L. Lacbawan[1], C.J. Tifft[2], M. Amaya[2], M. Pennybacker[3], S. Weinstein[4], L.C. Wong[3].* 1) NHGRI,NIH, Bethesda, MD; 2) Dept of Medical Genetics, Children's National Medical Center, Washington DC; 3) Institute for Molecular and Human Genetics, Georgetown University, Washington DC; 4) Dept of Neurology,Children's National Medical Center, Washington DC.

Among the mitochondrial DNA deletion (mtDNA del) disorders, chronic progressive external ophthalmophlegia (CPEO), Kearne-Sayre syndrome (KSS), Pearson marrow-pancreas syndrome, diabetes insipidus, diabetes mellitus, optic atrophy, and deafness(DIDMOAD)and cyclic vomiting syndrome are relatively well-defined clinically. However with more reported cases, it is evident that a whole spectrum of disease severity can be associated with similar deletions of mtDNA and there is no correlation of phenotype to the size of mtDNA deletion. We report an 8 yo Hispanic girl with short stature, ataxia, dysphagia, and aphasia who had transfusion-dependent macrocytic anemia during infancy and early childhood and recurrent bacterial and fungal infections. Extensive hematologic and immunologic work-up were unrevealing. Therapeutic trials of folate, folinic, and vitamin B12 were unsuccessful however her anemia apparently resolved after 2 years. Later, gait problems, exercise intolerance and chronic episodic vomiting were also noted. A lactate/pyruvate ratio was normal but MRI-spectroscopy revealed a large lactate peak. A cranial computed tomography scan showed bilateral basal ganglia calcifications and extensive frontal lobe white matter changes. Ragged red fibers were present on muscle biopsy. A 4.4 kb deletion was identified by Southern blot analysis of muscle mtDNA. Subsequent PCR and sequencing analyses localized the deletion to be between nucleotides 10559 and 14981. The same heteroplasmic deletion was demonstrated in blood, buccal cells and hair follicles. Although large deletions are usually sporadic, analysis of maternal DNA is in progress. The constellation of clinical features in this patient does not point to a single mtDNA del syndrome. This case further illustrates the clinical heterogeneity with mitochondrial disorders, and encourages physicians to maintain a high index of suspicion in patients with atypical findings.

Program Nr: 1561 from the 1999 ASHG Annual Meeting

Is the myotonic dystrophy protein kinase (DMPK) a muscle-specific protein? *L.T. Lam, Y.N.C. Pham*, N.T. Man, G.E. Morris.* MRIC Biochemistry Group, North East Wales Institute, WREXHAM, UK.

Myotonic dystrophy (DM) is a multi-systemic disorder caused by a triplet repeat expansion which affects three different genes, DMPK, Six5 (or DMAHP) and gene 59. The cell and tissue distribution of their protein products may help us to understand their different roles in DM pathogenesis. Unfortunately, many antibodies raised against DMPK are subject to cross-reactions which have lead to confusion over its size (72-80kD or 52-55kD) and localisation.
In an earlier study (Pham et al, Hum. Mol. Genet. 7 (1999) 1957), a new panel of ten monoclonal antibodies (mAbs) was used to show that a 72-80kD protein is the main product of the human DMPK gene. Only one mAb, MANDM1, recognised rabbit or mouse DMPK and this was used to show a 72-80kD protein in all rabbit tissues tested, including brain and lung. Using human tissues, however, we now show that most mAbs against DMPK do not react with any protein on Western blots of brain, lung or skin fibroblasts, though they all recognise the same DMPK band in skeletal and cardiac muscle. This suggests that DMPK is expressed at high levels only in skeletal and cardiac muscle, a result which is consistent with in situ hybridisation studies of DMPK mRNA (Jansen et al, Nat. Genet. 13 (1996) 316). The misleading results obtained with mAb MANDM1 may result from cross-reaction with a protein of similar size, possibly a related protein kinase.
A subset of 6 mAbs from the original panel has now been identified which recognise a DMPK band only in skeletal and cardiac muscle and these mAbs recognise different epitopes in both the catalytic and coil domains.
Supported by the Muscular Dystrophy Campaign..

Program Nr: 1562 from the 1999 ASHG Annual Meeting

Haplotype and AGG-interspersion analysis of *FMR1* $(CGG)_n$ alleles in the Danish population: implications for multiple mutational pathways towards fragile X alleles. *L.A. Larsen[1], J.S.M. Armstrong[2], K. Grønskov[2], H. Hjalgrim[2], J. Macpherson[3], K. Brøndum-Nielsen[2], L. Hasholt[4], B. Nørgaard-Pedersen[1], J. Vuust[1]*. 1) Department of Clinical Biochemistry, Statens Serum Institut, Artillerivej 5, DK-2300 Copenhagen, Denmark; 2) Department of Medical Genetics, The Department of Medical Genetics, The John F. Kennedy Institute, 7. Gl. Landevej, DK-2600 Glostrup, Denmark; 3) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, Wiltshire SP2 8BJ, United Kingdom; 4) Institute of Medical Biochemistry and Genetics, University of Copenhagen, The Panum Institute, Blegdamsvej 3, DK-2200 Copenhagen, Denmark.

The AGG interspersion pattern and flanking microsatellite markers and their association with instability of the *FMR1* $(CGG)_n$ repeat, involved in the fragile X syndrome, were analyzed in DNA from filter-paper blood spots randomly collected from the Danish newborn population. Comparison of DXS548-FRAXAC1 haplotype frequencies in the normal population and among fragile X patients suggested strong linkage disequilibrium between normal alleles and haplotype 7-3 and between fragile X alleles and haplotype 2-1 and 6-4. Comparison of the AGG interspersion pattern in 143 $(CGG)_n$ alleles, ranging from 34-62 CGG in size, and their associated haplotypes, indicates the existence of at least three mutational pathways from normal alleles towards fragile X alleles in the Danish population. Two subgroups of normal alleles, with internal sequences of $(CGG)_9AGG(CGG)_{20}$ and $(CGG)_9AGG(CGG)_{12}AGG(CGG)_9$, possibly predisposed for expansion, were identified in the data set. When alleles larger than 34 CGG were investigated, comparing the lengths of 3 uninterrupted CGG triplets (uCGG), we found that alleles associated with haplotype 2-1 and 6-4 contains significantly longer stretches of uCGG than alleles associated with haplotype 7-3. Thus the data support that $(CGG)_n$ instability is correlated to the length of uCGG.

Program Nr: 1563 from the 1999 ASHG Annual Meeting

Effect of mutations on cytochrome P4501B1 (CYP1B1), the protein responsible for Primary Congenital Glaucoma. *F. Abou-Zahr, B.A. Bejjani, F.A.E. Kruyt, R.A. Lewis, J.R. Lupski, H. Youssoufian.* Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

CYP1B1 is a dioxin-inducible member of the cytochrome P450 gene superfamily with an as yet undefined role in ocular development. CYP1B1 and other drug-metabolizing enzymes seem to regulate the steady state of biologically active molecules (e.g. hormones) that affect growth and differentiation. Previous studies have shown that mutations in *CYP1B1* cause primary congenital glaucoma. We developed cell culture and in vitro assays to evaluate the effect of patient-derived mutations on the expression, localization and function of CYP1B1. In vitro-generated mutants (5 missense mutations and one 10-bp deletion) were cloned in the mammalian expression vector pcDNA3. Similar to wild-type CYP1B1, the missense mutations encode full-length proteins that are localized to microsomes in the cytoplasm. By contrast, the 10 bp deletion produced an undetectable protein. Cell lysates were prepared and incubated with varying amounts of Estradiol (E2), a known substrate for CYP1B1 enzymatic action. Conversion of E2 to 4 OH-E2 is being analyzed by GC/MS. Interactions of CYP1B1 with other enzymes involved in xenobiotic metabolism are currently being investigated. An understanding of the mechanism of CYP1B1 function provides insights into the effects of endogenous morphogens or xenobiotics on ocular development.

Program Nr: 1564 from the 1999 ASHG Annual Meeting

A novel mutation in ATP7A deletes the di-leucine targeting motif in a family with occipital horn syndrome. *A.N. Adam, S.L. Dagenais, J.W. Innis, T.W. Glover.* Pediatrics and Human Genetics, University of Michigan, Ann Arbor, MI.

Occipital horn syndrome (OHS) is an X-linked recessive disorder of copper metabolism allelic to the more severe Menkes syndrome. Both syndromes result from mutations in a P-type ATPase known as ATP7A. Affected OHS males are deficient in the cuproenzyme lysyl oxidase, an enzyme which initiates cross-linking of collagen and elastin. The resulting phenotype involves primarily connective tissue, and leads to characteristics such as hyperelastic skin, hypermobile digital joints, bony abnormalities including protuberances from the occiput, bladder diverticulae and inguinal herniae. Based on radiographic examinations, serum copper levels and phenotypic manifestations, we have identified a family in which two brothers and their maternal uncle are affected with OHS. RT-PCR analysis did not reveal aberrant splicing, and Northern analysis of fibroblast mRNA did not show differences in ATP7A levels in affected individuals. Sequence analysis at the genomic level revealed a single base deletion in exon 23 of the two affected siblings and their carrier mother, while the unaffected brother and a control subject had no deletion. The deletion causes a frameshift which is of interest for several reasons. Conceptual translation of the mutant message produces a truncated form of the ATP7A protein which is missing the di-leucine L1487L1488, recently reported to be a motif necessary for steady state localization of ATP7A to the *trans*-Golgi network (TGN). Loss of this motif in artificial ATP7A constructs results in the accumulation of ATP7A on the plasma membrane due to loss of the proteins ability to recycle back to the Golgi. Of interest is the fact that this loss produces the relatively mild phenotype of OHS rather than a more severe phenotype. Previously we localized ATP7A to the TGN using antibodies generated against the first four metal binding domains of ATP7A. Similar examination of cells from OHS family members should reveal whether this mutation causes a shift in steady state localization of ATP7A from the TGN to the plasma membrane. These studies will further our understanding of di-leucine targeting motifs and how their function is manifested phenotypically.

Program Nr: 1565 from the 1999 ASHG Annual Meeting

Novel mutations in the duplicated region of the Polycystic Kidney Disease 1 (PKD1) gene reveals supporting evidence for the gene conversion theory in this gene. *A.R. Afzal[1], R.N. Florêncio[2], A. Saggar-Malik[1], R. Taylor[1], S. Jeffery[1]*. 1) Dept. of Medical Genetics, St. Georges Hospital Medical School, London, United Kingdom; 2) Ribeirao Preto Medical School, University of São Paulo, Brazil.

Autosomal Dominant Polycystic Kidney Disease (ADPKD) is one of the most common single-gene disorders of humans, and is the most common frequent inherited form of cystic kidney disease. It is estimated that ~85% of ADPKD is due to mutations in the PKD1 gene, that is located on chromosome 16p13.3. Mutation analysis in the PKD1 gene is difficult because more than two thirds of the gene is reiterated several times on chromosome 16p13.1. In this study, mutation screening in 90 ADPKD1 patients was carried out on exons in the duplicated region of the PKD1 gene (23-34) using genomic long range PCR followed by nested PCR and SSCP, and finally cycle sequencing. Two novel non-conservative missense mutations were detected in exons 25 and 31. Moreover, 4 conservative mutations were found in exons 24, 25, 29, and 33, that in exon 25 having been reported previously. Furthermore, one splicing mutation which is expected to cause skipping of exon 30 was detected in one case. In 14 cases polymorphisms G>C9406 and T>C9407 reported by Watnick et al., 1997, were also found. Comparison between some of these changes and published sequences from the homologous genes on 16p13.1 revealed supporting evidence for the gene conversion theory as a mechanism responsible for mutation in PKD1.

Program Nr: 1566 from the 1999 ASHG Annual Meeting

Genetic heterogeneity in autosomal dominant recurrent fevers. *E. Aganna[1], M.F. McDermott[1], D. Booth[2], B.W. Ogunkolade[1], G.A. Hitman[1], P.N. Hawkins[2]*. 1) Medical Unit, Royal London Hospital, London, UK; 2) Immunological Medicine, Hammersmith Hospital, London, UK.

TNFR1 associated periodic syndromes (TRAPS) have been described in a number of different ethnic groups, the majority of which are Northern European in origin. The TRAPS phenotype, inherited as an autosomal dominant trait, is characterised by recurrent attacks of fever associated with variable manifestations of abdominal pain, and synovial and cutaneous inflammation. A multiplex Indian family that includes at least 8 living family members suffering from intermittent episodes of fevers lasting >1 week, limb pains, rashes, peri-orbital oedema and serositis was studied. In addition 4 members of this family have documented systemic AA amyloidosis. As this phenotype strongly resembles TRAPS we used an informative microsatellite marker from the first intron of TNFR1 in addition to D12S99 and D12S77 which flank this locus to genotype all available members, both affected and unaffected. Two-point and multipoint lod scores definitively excluded linkage to TNFR1 and a haplotype study confirmed these findings. Sequencing of exons 1-9 and flanking sequences of TNFR1 revealed no mutations. To further exclude the possibility of pseudo-dominant familial Mediterranean fever (FMF) we also used markers flanking the MEFV locus on chromosome 16p13.3, and linkage was also definitively excluded. Thus there is evidence of genetic heterogeneity within the spectrum of autosomal dominant recurrent fevers as disease in this family is not linked to either TNFR1 or MEFV.

Program Nr: 1567 from the 1999 ASHG Annual Meeting

Functional analysis and identification of the DNA binding site of the *Hairless* gene product. *V.M. Aita[1], H. Uyttendaele[2], P.B. Cserhalmi-Friedman[2], T.C. Gilliam[1,3], A.M. Christiano[1,2]*. 1) Department of Genetics & Development, Columbia University, New York, NY; 2) Department of Dermatology, Columbia University, New York, NY; 3) Columbia Genome Center, Columbia University, New York, NY.

Investigations into the relationship between the structure and function of the *hairless* (*hr*) gene provide valuable insight into the specific nature of the transcriptional regulation mediated by this gene. *Hr* is an essential regulator of the hair cycle and has been implicated in a form of congenital atrichia in both humans (OMIM#209500) and hairless and rhino mice. In humans, distinct mutations in the *hr* gene have been observed in families from diverse ethnic origins including Pakistani, Irish, Arab Palestinian, Japanese and Polish. Of particular interest, the mutation in the Polish family is a missense mutation changing the invariant third cysteine residue of the zinc-finger binding domain to a glycine. In rhino mice, we have identified four distinct nonsense mutations leading to an absense of functional protein, which results in a dysregulation of apoptosis at the first catagen phase of the adult hair cycle and subsequent destruction of the hair follicle. *Hr* has been identified as a putative transcription factor with structural homology to the GATA family of transcription factors since it contains a single zinc-finger domain with high homology to the type found in GATA transcription factor family members. We demonstrate *Hr* binds DNA by western blot analysis of proteins captured via their binding to DNA-cepharose beads incubated with total protein lysates from 293T cells overexpressing the *hr* gene. Binding site selection assays such as the CASTing method will elucidate the specific DNA binding sequence bound by *Hr* protein, which will be confirmed by gel shift assay. The recapitulation of the Polish family zinc-finger mutation by site-directed mutagenesis will be used to investigate a putative loss of DNA binding activity as the molecular basis for congenital atrichia in this family and facilitate a better understanding of *hr* gene function and genotype-phenotype correlations in humans and mice with this disorder.

Program Nr: 1568 from the 1999 ASHG Annual Meeting

Uroporphyrinogen III Synthase: Identification/Characterization of An Erythroid-Specific Promoter and Mutations Therein Causing Congenital Erythropoietic Porphyria. *G.I. Aizencang, C. Solis-Villa, L. Cunha, D.F. Bishop, K.H. Astrin, R.J. Desnick.* Department of Human Genetics, Mount Sinai School Medicine, New York, NY.

Mutations in the gene encoding the heme biosynthetic enzyme uroporphyrinogen III synthase (UROS) cause congenital erythropoietic porphyria (CEP). This autosomal recessive porphyria has a variable phenotype ranging from non-immune hydrops fetalis to a mild adult-onset form with only cutaneous lessions. To date, a common severe (C73R) and 17 other (mostly private) mutations causing CEP have been reported; however, ~15% of mutant alleles remain undetected. Thus, the human UROS genomic structure was determined revealing alternative promoters and two alternative 5'untranslated and nine coding exons which generated housekeeping and erythroid-specific transcripts. Sequencing of the erythroid-specific promoter of CEP patients with undefined alleles revealed three mutations in four patients: 1) a -70 T to C transversion altering a GATA-1 consensus sequence, 2) a -86 C to A transversion and 3) a -90 C to A transversion, the latter two mutations in a putative erythroid regulatory element. Luciferase reporter constructs with the -70C, -86A and -90A mutations transfected in K562 cells expressed 8.5, 49 and 13% of the normal promoter construct, respectively. Genotype/phenotype correlations were consistent with the *in vitro*expression of the patients' other alleles in *E. coli:* a fetus prenatally diagnosed with the -70C/C73R genotype had severe transfusion-dependent disease and was terminated; two unrelated adult women with the mild -86A lesion had moderate or only mild cutaneous disease, consistent with the severity of their other alleles, C73R or IVS2 $^{+1}$, respectively; and a male with the -90A/G225S genotype had moderately severe disease. Thus, discovery of an erythroid-specific promoter and lesions in the GATA-1 element and a novel regulatory element provide further understanding of the regulation of heme biosynthesis and the molecular pathology of CEP. The first two authors contributed equally to this work.

Program Nr: 1569 from the 1999 ASHG Annual Meeting

Multiple synostosis type 2 (SYNS2) maps to 20q11.2 and caused by a missense mutation in the growth/ differentiation factor 5 (GDF5). *A.N. Akarsu[1], T. Rezaie[2], M. Demirtas[1], D.D Farhud[3], M. Sarfarazi[4]*. 1) (TUBITAK) DNA/Cell Bank & Gene Research Lab, Child Hlth Inst/Hacettepe Univ, Ankara, Turkey; 2) Mehryad Medical Clinic, Tehran, Iran; 3) Department of Human Genetics, School of Public Health, Tehran University, Tehran, Iran; 4) Surgical Research Center, Department of Surgery, University of Connecticut Health Center, Farmington,CT.

GDF5 and Noggin are two important factors for proper skeletal development and joint formation. Mutations in these genes result in disruption of proper cartilage condensation and joint formation in several disorders such as chondrodysplasias and brachydactyly type C (GDF5) as well as symphalangism and multiple synostosis syndrome (Noggin). Herein, we report identification, ascertainment, mapping and mutation screening of a large autosomal dominant Iranian family (150 subjects; 61 affected) with clinical manifestation of tarsal-carpal coalition, humero-radial synostosis, brachydactyly and proximal symphalangism. These findings are mainly consistent with the Pearlman syndrome, but considerable overlaps also persist with other types of multiple synostosis syndromes. By using 38 informative meioses (21-phase known), the Noggin gene on 17q22 and many other candidate genes were first excluded. Eventually, significant linkage was obtained with DNA markers on 20q11.2. The highest LOD score was observed with D20S200 (Z=13.58 at theta=0.0), followed by D20S106 (Z=12.37) and D20S890 (Z=10.46). Affected crossovers positioned the disease gene between D20S844 and D20S478, a region that contained the GDF5 gene. Mutation screening of the proband identified a heterozygous missense mutation in a highly conserved region of GDF5 (S475N) that is co-segregated with the SYNS2 phenotype in 39 affected and 27 normal members. This mutation has not been detected in 182 unrelated control chromosomes. In conclusion, our result maps a new locus for SYNS2, identifies mutation in the GDF5 gene and further rejects a previous assumption that various types of SYNSs are due to the same genetic defect. Furthermore, this provides an opportunity for re-classification of these phenotypes using the existing molecular evidence.

Program Nr: 1570 from the 1999 ASHG Annual Meeting

TNF receptor associated periodic fever syndromes (TRAPS): novel TNFR1 mutations and early experience with etanercept therapy. *I. Aksentijevich[1], J. Galon[1], MF. McDermott[2], R. Ortman[1], JJ. O'Shea[1], DL. Kastner[1].* 1) ARB/NIAMS, NIH, Bethesda, MD; 2) Royal London Hospital, UK.

Mutations in the extracellular domains of the 55 kDa TNF receptor (TNFR1) define a family of autoinflammatory syndromes (TRAPS, TNF receptor-associated periodic syndromes) that are characterized by prolonged (>1 wk) periodic fevers, sterile peritonitis, pleurisy, arthritis, skin rash, and/or conjunctivitis; some patients also develop systemic AA amyloidosis. We have previously described 6 disease-associated TNFR1 mutations, 5 of which disrupt extracellular cysteines involved in disulfide bonds (Cell 97:133). For patients with the C52F mutation, there is diminished TNFR1 cleavage following cellular activation, with a commensurate reduction in levels of potentially antagonistic soluble receptor, thereby possibly explaining the autoinflammatory phenotype. In a survey of additional patients with periodic fevers, we have identified 4 new TNFR1 mutations: c.193-14G > A, H22T, C30S, and C33G. The first mutation has been found in two families of different ethnic background and the latter 2 mutations occur at residues at which we had already identified other missense mutations (C30R and C33Y). Another family had a T50M mutation, which we had previously seen in 2 other families. Of the 10 known mutations, c.193-14G>A and T50M are the only ones we have seen in more than 1 family. Functional analyses of leukocytes from two C33G patients indicated the same defect in TNFR1 shedding that had been observed in the C52F family. In 3 families and 4 sporadic cases with compatible clinical presentations, we have not yet identified TNFR1 mutations, despite genomic sequencing of the exons encoding the extracellular domains. Based on the proposed mechanism of disease, we have begun treatment of 3 members of the family bearing the C52F mutation with soluble p75 TNF receptor: Fc fusion protein (etanercept). In the one patient for whom followup clinical and laboratory data are available, there has been marked improvement, both in subjective measures and in a panel of acute phase reactants.

Program Nr: 1571 from the 1999 ASHG Annual Meeting

Construction of a sequence-ready 1.5 Mb PAC contig covering the whole OPA1 candidate region on chromosome 3q28-q29. *C. Alexander[1], G. Auburger[2]*. 1) Neurogenetics Lab, Dept. Neurology, University Hospital, Duesseldorf, Germany; 2) NIH, Bethesda, MD.

Autosomal dominant optic atrophy (Kjers type) is the most common form of all inherited optic atrophies with a prevalence of 1: 12.000 in certain regions. Patients suffer from a variable degree of visual loss ranging from subjectively unnoticed to legally blind. Histopathological findings point to a degeneration of retinal ganglion cells. Linkage analysis in various families affected by Kjers type optic atrophy has defined the microsatellites D3S3669 and D3S3562 as flanking markers for the disease critical region on chromosome 3q28-q29 of 1-2 cM. Building upon a previously constructed YAC contig we have established a 1.5 Mb sequence-ready PAC contig. It was constructed by an initial hybridisation screening of a high-density spotted genomic PAC library using STSs and probes derived from the YAC contig and subsequent filling of gaps by chromosomal walking. The clone order was defined by STS-PAC-Mapping and confirmed by Alu-fingerprint-PCR. The minimal tiling path covering the whole OPA1 candidate region comprises 11 PACs and the minimum depth is 3 PACs. The ends of all 120 PACs contained in the contig were sequenced and analysed by the BLAST software package. 75 new PCR-able STSs were developed leading to the very high STS-density of 1 STS every 18 kb on average throughout the whole contig. 7 ESTs/THCs were finemapped into the disease critical interval. We believe that the construction of this PAC contig is an important step in facilitating the cloning of the OPA1 gene and in the identification of further genes within this genetic interval.

Program Nr: 1572 from the 1999 ASHG Annual Meeting

Tuberous sclerosis 1 (*TSC1*) gene mutation screening by Denaturing High-Performance Liquid Chromatography (DHPLC). *A. Allavena, S. Padovan, L. Longa, S. Polidoro, A. Brusco, N. Migone.* Dept. of Genetics, Biology and Biochemistry, Univ. Torino; CNR-CIOS, Torino, Italy.

Mutation screening of the *TSC1* and *TSC2* genes responsible for tuberous sclerosis is a time-consuming challenge (overall, 62 exons) that has been so far accomplished by sequential, multi-method strategies, with a combined detection rate generally below 75%, even in presence of positive linkage to either locus. Recently, looking for an automated method we shifted to DHPLC, a technique which should be able to separate homo and heteroduplex DNA on alkilated non-porous particles under partial denaturing conditions. First, 23 samples known to carry *TSC1* or *TSC2* mutations (8 single nt substitutions, 1 nt insertion, 7 micro deletions) or polymorphisms (7) as previously shown by PTT, heteroduplex-polyacrylamide analysis (HD) or fluorescence assisted mismatch analysis (FAMA), were all confirmed by DHPLC, suggesting a sensitivity threshold equal or superior to standard methods. At present, we have set up the conditions for *TSC1* (23 amplicons, 7 of which requiring two different temperatures), and screened 41 patients who a) did not show major rearrangement in either gene at southern, and b) were *TSC2*-negative at PTT, and *TSC1*-negative at HD. This sample included 2 *TSC1*-assigned patients: 1 by linkage and 1 by LOH found in a giant astrocytoma. Briefly, two novel, de novo mutations and one polymorphism were found in *TSC1*. The rarity of *TSC1* involvement in this sample is not unexpected since the prevalence of *TSC1* mutations in unselected, i.e. mostly sporadic, patients is about 10%. Interestingly, one of the two mutations is a missense (L72P) in a conserved position in drosophila and rat. All 93 *TSC1* defects known so far are frameshifs mutations. The full screening of *TSC2* and the re-analysis of a few *TSC1* exons at different temperatures are under way in this patient in order to exclude additional defects in either locus. *Work supported by the "Associazione E. and E. Rulfo per la Genetica Medica" and by Telethon, Italy (project E.730).*

Program Nr: 1573 from the 1999 ASHG Annual Meeting

Molecular analysis of the P/Q type Ca $^{2+}$ channel a1-subunit gene in patients with progressive cerebellar ataxia. *I. Alonso[1], M.C. Moreira[1], P. Mendonça[1], L. Jardim[2], J. Barros[3], P. Coutinho[4], J. Sequeiros[1], I. Silveira[1].* 1) UnIGENe, IBMC- Univ. Porto, Portugal; 2) Serv. Genética Médica, Hosp. Clínicas Porto Alegre, Brazil; 3) Serv. Neurologia, HGSA, Porto, Portugal; 4) Serv. Neurologia, Hosp. S.Sebastião, Feira, Portugal.

The CACNL1A4 is a brain-specific P/Q type Ca^{2+} channel a1-subunit gene with 47 exons spanning 300 kb. This gene has been implicated in familial hemiplegic migraine (FHM), episodic ataxia type-2 (EA-2), and in a autosomal dominant form of spinocerebellar ataxia (SCA) named SCA6. Six different missense mutations in exons 4, 6, 16, 17 and 36 were found in families with FHM; two EA-2 families have shown mutations in exons 22 and 24 while SCA6 is caused by a $(CAG)_n$ expansion in the 3'-UTR of this channel gene. In order to improve the knowledge about the molecular basis leading to neurodegeneration, we have screened our ataxia families that did not present any of the other known (CAG)n expansions (SCA1-2,7,8, MJD and DRPLA) for CACNL1A a1-subunit mutations. We have ascertained 78 unrelated individuals, representing 26 autosomal dominant families, 9 apparently recessive kindreds and 43 isolated cases; 63 were of Portuguese origin, while 15 were from Brazil. They all have been clinically diagnosed with progressive ataxia with or without other associated features. Polymorphism detection was performed by PCR amplification, single strand conformational polymorphism (SSCP) analysis and sequencing. Expansions of the $(CAG)_n$ repeat were assessed by comparing migratian relative to an M13 sequencing ladder. Mutations in exons 6, 16, 17, 36, 22 and 24 were completely excluded from all our families as well as the presence of a $(CAG)_n$ repeat expansion. In 5 individuals we found a conformational polymorphism in exon 4; we are still sequencing this exon and begun screening the remaining 40 exons. In conclusion, the SCA6 trinucleotide expansion in the CACNL1A4 gene as well as the point mutations already studied are not present among our Portuguese and Brazilian ataxia families. The remaining exons still need to be studied.

Program Nr: 1574 from the 1999 ASHG Annual Meeting

Elucidation of the cDNA sequence and genomic structure of a conserved gene on 7q36 and assessment as a candidate gene for pigmentary glaucoma. *J.S. Andersen[1], E.A. DelBono[1], K. Damji[2], M. Gorin[3], J.S. Schuman[1], C. Mattox[1], J. Haines[4], J.L. Wiggs[1,5].* 1) Dept Ophthalmology, New England Medical Ctr, Boston, MA; 2) University of Ottawa Eye Institute, Ottawa, Ont; 3) University of Pittsburgh, Pittsburgh, PA; 4) Vanderbilt University, TN; 5) Tufts University School of Medicine, Div of Genetics, Boston, MA.

Pigmentary glaucoma is a blinding ocular disorder for which loci have been mapped to 7q36 and 18q. Fine mapping of the critical interval on 7q36 has identified a 1 to 2 cM linked region containing a number of ESTs including SHGC30207, which was derived from a retinal cDNA library and shows similarity to genes of unknown function in C. elegans and Fugu. With expression in the eye and location within the critical interval, this gene is considered a good candidate for pigmentary glaucoma. A combination of database searches, hybridization, and direct sequencing was used to assemble a full-length cDNA. BAC sequencing, inverse PCR, and comparison to genomic sequences was used to elucidate the genomic structure of this gene. A partial cDNA clone was used to generate expression data by Northern blotting and primers were designed to flank the exons for use in screening individuals affected with pigmentary glaucoma. The gene comprises 17 exons spread over 81 kb of genomic DNA. The full-length cDNA is 3.5 kb and encodes a predicted protein of 491 amino acids containing nine predicted transmembrane domains. The putative protein is over 60% similar to the Fugu predicted protein and over 40% similar to that in C. elegans. Expression of the gene in mouse was found in the eye and more strongly in the epididymus and submaxillary gland. Human expression of the gene was also found in the heart, skeletal muscle, liver and kidney. There was no evidence of developmental upregulation at embryonic stages tested. Screening of this gene in affected individuals will allow us to assess this gene in the context of pigmentary glaucoma.

Program Nr: 1575 from the 1999 ASHG Annual Meeting

Familial hypertrophic cardiomyopathy mutations in the regulatory myosin light chain are not necessarily associated with midventricular hypertrophy. *P. Andersen[1], O. Havndrup[2], L.A. Larsen[1], H. Bundgaard[2], J. Vuust[1], K. Kjeldsen[2], M. Christiansen[1]*. 1) Dept Clinical Biochemistry, Statens Serum Inst, Copenhagen, Denmark; 2) Department of Medicine B, The Heart Center, Rigshospitalet, University of Copenhagen, DENMARK.

Familial hypertrophic cardiomyopathy (FHC) is an autosomal dominant heart disease of the cardiac sarcomere. Until now more than 125 mutations have been found in seven different genes encoding sarcomere proteins. Mutations in the two myosin light chains have been characterized to be associated with a special rare type of FHC with midventricular hypertrophy (MVH). In a study of 50 probands with classical FHC and three with MVH FHC we investigated the *MYL2* and *MYL3* genes encoding the regulatory and the essential myosin light chain, respectively. One proband with classical FHC was compound heterozygote for two novel mutations (K102E and IVS6 -1). Another proband had a known A13T mutation. This proband also had the classical form of FHC unlike a previous report where an A13T mutation was associated with a MVH phenotype (Poetter et al., 1997). Only in one of the three probands with MVH we identified a N47K mutation in *MYL2*. We did not identify any *MYL3* mutations among the 53 probands. Concluding the analysis we find that a MVH phenotype is not necessarily associated with a myosin light chain mutation. Reference: Poetter, K. et al. 1997. Nat. Genet. 13:63-69.

Program Nr: 1576 from the 1999 ASHG Annual Meeting

The survival motor neuron (SMN) protein is developmentally regulated and upregulated by NMDA receptor stimulation in cultured cerebellar granule cells. *C. Andreassi[1], A.L. Patrizi[2], M.L. Eboli[1], C. Brahe[2]*. 1) Institute of General Pathology; 2) Institute of Medical Genetics, Catholic University, Rome, Italy.

Spinal muscular atrophy (SMA) is a common autosomal recessive neuromuscular disorder characterized by the degeneration of alpha motor neurons of the spinal cord and weakness of limb and trunk muscles. The disease is caused by absence or mutation in the survival motor neuron (*SMN*) gene. SMN plays an essential role in pre-mRNA splicing and is localized in the cytoplasm and the nucleus where it is concentrated in dot-like structures, termed gems. To investigate whether SMN could be specifically involved in neuronal cell development and function, we studied the expression of SMN in rat cerebellar granule cells during differentiation *in vitro*. Immunofluorescence analysis showed a marked variation in the number of cells with gems during the maturational stages with highest immunoreactivity during the phase of neuronal cell clustering and a marked decrease in nuclear staining in the adult stage of cerebellar neurons. These findings suggest that the appearance of gems is developmentally regulated and support the suggestion that SMN is highly required during the embryo-fetal neuronal development. Since granule cells exhibit a glutamate receptor phenotype similar to that of motor neurons, we also studied SMN expression in response to NMDA receptor stimulation. Exposure to NMDA caused a transient increase in gems and SMN mRNA. To our knowledge, this is the first evidence that SMN expression can be modulated by receptor activation.

Mutation analysis of the GJB2 gene by DGGE in Greek patients with sensorineural deafness. *T. Antoniadi[1], A. Pampanos[2], M. Petersen[1,2]*. 1) Dept Genetics & Molec Biol, Mitera Maternity Hosp, Athens, Greece; 2) Dept Genetics Institute of Child Health, Athens, Greece.

Congenital deafness or hearing impairment affects about 1 in 1000 children and 50% of this hearing loss is genetic. Nonsyndromic recessive deafness accounts for approximately 80% of genetic hearing loss. The first locus defined for recessive deafness, DFNB1, is located on chromosome 13q11. It accounts for a large proportion of cases, due to mutations in the GJB2 gene, which encodes the gap junction protein connexin 26. A major mutation has been identified: a deletion of a G within a stretch of 6 Gs at position 30-35 of the GJB2 cDNA which leads to a premature stop codon at nucleotide 38 and accounts for the vast majority of mutant alleles. In the Greek population we have determined the carrier frequency of this mutation to 3.5%. Since there is still need for identifying the rest of the pathological alleles we developed a DGGE method for screening the entire coding region and surrounding regions. In order to amplify the entire GJB2 coding region we selected the optimal location of primers using the WinMelt program, and GC-clamps were optimized by analyzing the placement effect on the DNA melting profile. The GJB2 cDNA sequence and the surrounding areas (nt -103 to nt 681+320) were divided in 3 amplifiable segments. Using this approach, we started screening 66 chromosomes (33 patients) with prelingual, sensorineural deafness, where syndromic forms and environmental causes of deafness had been excluded. Until now, in addition to 20 alleles with the 35delG mutation (Pampanos et al, abstract this meeting), we have identified 11 candidate mutants in the 5 and 3 segment of the gene, which are currently analyzed by sequencing.

Program Nr: 1578 from the 1999 ASHG Annual Meeting

Progress towards developing a mouse model of Hereditary Haemorrhagic Telangiectasia. *H.M Arthur[1], D.I Wilson[1], E. Torsney[1], G. Renforth[1], A.G. Diamond[2], J. Burn[1].* 1) Human Genetics, University of Newcastle, UK; 2) SMIVS,University of Newcastle, UK.

Endoglin (CD105) is a transmembrane glycoprotein expressed by mammalian endothelial cells. It binds TGFbeta isoforms 1 and 3 and modulates TGFbeta1 signalling. Humans, heterozygous for deleterious mutations in the endoglin gene, develop the disease Hereditary Haemorrhagic Telangiectasia Type 1 (HHT1), which is characterised by bleeding from vascular malformations. In order to study the role of endoglin in vivo and to develop an animal model of HHT1, we have derived mice that carry a targeted nonsense mutation in the endoglin gene. Embryos homozygous for this mutation show severe deficiencies in haematopoiesis, vasculogenesis and angiogenesis in the yolk sac and fail to progress beyond 10.5 days post coitum. This phenotype is remarkably similar to that of both TGFbeta receptor II and TGFbeta1 knockout mice, indicating that endoglin is needed in vivo for TGFbeta1 signalling during formation of the extra-embryonic vasculature. We have also observed abnormal cardiac development in homozygous endoglin-deficient embryos suggesting a particular role for endoglin in cardiogenesis. Recently, we have made significant progress towards the development of an animal model of HHT. Some animals, heterozygous for the endoglin mutation, develop extensive abnormally dilated and weak-walled vessels typical of the vascular lesions seen in HHT patients.

Program Nr: 1579 from the 1999 ASHG Annual Meeting

The Fanconi anemia gene *FANCG*: spectrum of mutations and phenotype correlations. *A.D. Auerbach[1], J. Greenbaum[1], S.D. Batish[1], P.F. Giampietro[2], P.C. Verlander[1]*. 1) Rockefeller Univ; 2) Cornell Medical College., New York, NY.

Fanconi anemia (FA) is a genetically heterogeneous autosomal recessive syndrome associated with chromosomal instability, hypersensitivity to DNA cross-linking agents, and predisposition to malignancy. The gene for FA complementation group G (*FANCG*) has recently been cloned by functional complementation and is identical with human *XRCC9*, which maps to 9p13. The cDNA is predicted to encode a polypeptide of 622 amino acids, with no homology to any known protein that might suggest a function for *FANCG*. We have used SSCP analysis and direct sequencing to screen genomic DNA from a panel of 262 racially and ethnically diverse unrelated FA patients from the International Fanconi Anemia Registry (IFAR) for mutations in *FANCG*. IFAR patients with known mutations in *FANCA* (138 probands) and *FANCC* (53 probands) were excluded. When a sequence variant was identified, additional family members, additional probands of similar ethnicity, and normal individuals were screened to determine if the variant was associated with the FA phenotype. Conservation of sequence in human, mouse and Chinese hamster was also considered in determining pathogenicity. A total of 23 variants were detected, 18 of which are likely to be pathogenic mutations. 43 patients (34 probands) are in FA complementation group G (FA-G), based on the detection of at least one pathogenic mutation in *FANCG*. We estimate that FA-G accounts for ~10% of all FA. The most frequent pathogenic mutations found in the IFAR population are: IVS3+1G>C (Korean/Japanese); IVS8-2A>G (Brazil); IVS11+1G>C (French Canadian); 1184-1194del (N. Eur.); 1794-1803del (N. Eur.). Recurring normal variants include 890C/T (297T/I), 1538G/A (513R/Q) and 1133C/T (378S/L; African Amer.). Most *FANCG* mutations were associated with a severe phenotype, while patients with amino acid substitutions usually displayed a mild phenotype with few major congenital malformations (CM) and a later onset of hematologic abnormalites (HA). Mean number of major CM was 1.8; median age on onset of HA was 4.8 years. Identification of mutant alleles in FA patients will aid in prediction of clinical outcome and in decision-making regarding therapeutic modalities.

Program Nr: 1580 from the 1999 ASHG Annual Meeting

Homozygosity mapping identifies the chromosomal location of a rare congenital contracture gene. *S.J. Bale[1], G.R. Rogers[1], R. Bailey[1], F. Austin[1], J.C. Marini[2], W.A. Cabral[2], J.G. Compton[1], W. Paton[3].* 1) NIAMS, NIH, Bethesda, MD; 2) NICHD, NIH, Bethesda, MD; 3) Alaska Native Med Cntr, Anchorage AK.

The first description of Kuskokwim Syndrome (KS) was published in 1969 (Wright DG), and the first identified case was born in 1922. Patients with this autosomal recessive disease have congenital contractures of large joints and other skeletal anomalies including absent, small, or displaced patellae, spinal and foot defects. In severe cases, knees become fully flexed and patients ambulate by walking on their knees or "duck walking". KS has been reported only in Yup'ik Eskimos of the Yukon-Kuskokwim river delta of SW Alaska. We traveled to 8 Yup'ik villages and 2 towns to ascertain 12 families, including 16 affected KS individuals, 6 probable affecteds, and 47 unaffected 1°relatives. Using homozygosity mapping on pooled DNA from the first 8 families, we evaluated > 300 markers. All 11 affected individuals were homozygous for a single KRT9 allele on 17q12-q21. Further studies revealed a conserved haplotype ("4-1-4") of 3 markers (KRT9-D17S846-D17S800), spanning ~26cM. In the 2nd group of 6 "probable KS" patients, 3 were homozygous 4-1-4, 2 carried one 4-1-4 haplotype and one 4-1-3, and one was heterozygous for the 4-1-4 haplotype but homozygous at D17S846. The 4-1-4 haplotype had a frequency of 92% in affecteds. Analysis of 49 normal controls showed that 4-1-4 occurs with a maximum frequency of 3% in the Yup'ik population. Detailed examinations of 6 KS patients revealed new observations: hx of multiple fractures; horizontal sacrum, superior angulation of transverse processes of lower lumbar vertebrae, highly attenuated patellar/triceps tendons. Clinical features suggest that a gene involved in bone or tendon development may underlie KS. Using radiation hybrids, we are fine mapping COL1A1, which may be a candidate gene for this disorder, and had been located to 17q22. Electrophoresis on SDS-urea-PAGE of type I procollagen from KS fibroblasts showed a slight migration delay of the a1 (I) collagen chain (derived from pro a1(I) by endogenous processing enzymes), suggesting a possible mutation in the C- or N- terminus. Mutation analysis of the N- terminal region was negative.

Program Nr: 1581 from the 1999 ASHG Annual Meeting

Presence of defective and normal LCD40 cDNAs in a patient with X-linked hyper IgM syndrome. *R.M. Barbouche, D.M. Fathallah, M. Bejaoui, Y. Boukhdir, K. Dellagi.* Dept of Immunology, Institute Pasteur de Tunis, Tunisia.

The X-linked form of hyper IgM syndrome is a rare hereditary immunodeficiency characterized by impaired immunoglobulin class switching from IgM to IgG, IgA or IgE. Affected individuals have a defective interaction between the CD40 molecule expressed by B cells and its ligand (LCD40) expressed on the surface of T cells. Several mutations in the LCD40 gene underlying the disease have been reported. The diagnosis of a severe form of X-linked hyperIgM syndrome was established in a Tunisian boy, by serum immunoglobulin measurement and confirmed by the lack of LCD40 expression on the surface of the patient peripheral blood lymphocytes as assessed by flow cytometry analysis using a chimeric human CD40-murin Fc IgG2a recombinant fusion protein. To investigate the molecular basis of the LCD40 expression defect in our patient, we have used specific primers to amplify by RT/PCR the LCD40 cDNA. Experiments have yielded repeatdly two cDNA fragments of different sizes. One with the expected 760bp full length coding region and the second beong approximatively 100 bp shorter. These results were confirmed by several experiments using different sets of primers. DNA sequencing has shown that both fragments were LCD40 cDNA specific. Interestingly, the smaller fragment has an in frame deletion that leads to exon 3 skipping while the sequence of the large fragment was normal. This peculiar pattern of the cDNA expression of an X-linked gene raises different hypothesis among which a possible gene duplication with defective expression, an alternative erroneous splicing or cellular mosaicism. These possibilities are currently under investigation.

Program Nr: 1582 from the 1999 ASHG Annual Meeting

ATM gene expression patterns during early mouse development. *S.G. Becker-Catania[1], H.I. Kornblum[2], R.K. Iyer[1], R.A. Gatti[1]*. 1) Department of Pathology, UCLA School of Medicine, Los Angeles, CA. 90095-1732; 2) Department of Molecular and Medical Pharmacology, UCLA School of Medicine, Los Angeles, CA. 90095.

Ataxia-telangiectasia (A-T) is an autosomal recessive disease characterized by progressive ataxia, telangiectasia, radiosensitivity, increased cancer susceptiblity, and immunodeficiency. The neuropathogenesis of A-T is marked by neuronal loss in the cerebellum (Purkinje cells, granule cells) as well as by demyelination and gliosis in the brain and spinal cord. Extensive immunohistologic studies of patient cerebellums have shown abnormal dendritic arborization and axonal degeneration of the Purkinje cells but have not elucidated the central lesion which leads to the neurodegeneration. ATM knockout mice, although not presenting with ataxia or significant cerebellar changes, have exhibited a loss of dopaminergic neurons in the corpus striatum. We have used in situ hybridization to analyze the expression of the ATM gene in the central nervous system during development, with an emphasis on the midbrain and cerebellar regions. We designed a riboprobe to the mouse atm gene and examined expression at embryonic days 12, 15.5, and 17 in sagittal and coronal sections from C57Bl mouse embryos. At embryonic day 12, we see ubiquitous expression throughout the central nervous system; expression is seen in proliferating neuroepithelial cells lining the ventricles, a subpopulation of which will become the cerebellar primordium as well as the midbrain. Expression in embryonic days 15.5 and 17 are currently being analyzed. The localization of the ATM message in the neuroepithelium may provide insight into which of these neuronal cell precursors may contribute to the ultimate Purkinje cell loss, and which neural stem cell populations would be most appropriate to attempt to replace by neural stem cell transplantation.*in situ*.

Program Nr: 1583 from the 1999 ASHG Annual Meeting

GTP-Cyclohydrolase 1 mutations in autosomal dominant dopamine responsive dystonia and autosomal recessive hyperphenylalaninemia. *H.M. Bedford[1,2], C.A. Rupar[1,2,3], J.M. Gillett[3], R. Casey[4]*. 1) Biochemical Genetics Laboratory, CPRI; 2) Dept Paediatrics; 3) Dept Biochemistry, University of Western Ontario, London, Canada; 4) Dept Paediatrics, University of Saskatchewan, Saskatoon, Canada.

Hereditary progressive dystonia with marked diurnal fluctuation (HPD) or dopa-responsive dystonia (DRD) is an autosomal dominant, childhood onset postural dystonia characterized by diurnal fluctuation and response to dopamine therapy. GTP-cyclohydrolase 1 (GCH1), maps to chromosome 14q and is the first and rate limiting step in the synthesis of tetrahydrobiopterin (BH4). Complete GCH1 deficiency, which is autosomal recessively inherited, results in a rare form of hyperphenylalaninemia. As an approach to understanding how these clinically and genetically disparate disorders could be due to mutations in the same gene, we have characterized causative mutations in a child with HPD/DRD and one with BH4 deficiency hyperphenylalaninemia. Analysis of sequences generated from PCR amplification of the GCH1 promoter and exons including exon/intron junctions revealed a novel point mutation in a sporadic case of HPD/DRD who presented with childhood-onset oromandibular dystonia. The G->A mutation in exon 6 at nucleotide 722 of the coding sequence results in an Arg to Gln substitution at amino acid 241 (Arg241Gln) and the loss of an AvaI restriction enzyme cleavage site. The child with hyperphenylalaninemia is a compound heterozygote for 2 novel mutations; C->T in exon 1 at position 276 resulting in a Leu92Phe substitution and C->G in exon 1 at nucleotide 312 resulting in a Phe104Leu substitution. The parents are heterozygous with no clinical evidence of neurologic sequelae. Neither mutation has been reported in patients with HPD/DRD. Mutations in the GCH1 gene in patients with HPD/DRD are scattered throughout the GCH1 gene with none prevalent. Mutations in the GCH1 gene which result in hyperphenylalaninemia have been described exons 1, 5, and 6 and located closely to DRD mutations. There are no mutations common to HPD/DRD and hyperphenylalaninemia. Establishing genotype/phenotype correlations between these two very distinct disorders will require further analysis of protein structure.

Program Nr: 1584 from the 1999 ASHG Annual Meeting

INVOLVEMENT OF THE HLXB9 GENE IN CURRARINO SYNDROME. *E. Belloni[1], G. Martucciello[3], D. Verderio[1], E. Ponti[1], M. Seri[3], V. Jasonni[3], M. Torre[3], M. Ferrari[1], L.-C. Tsui[2], S.W. Scherer[2].* 1) Unitá di Genetica e Diag Molec, DIBIT-HSR, Milano,Italy; 2) Dept. of Genetics, The Hospital for Sick Children Toronto, ON, Canada; 3) Giannina Gaslini Insitute, University of Genoa, Italy.

Anorectal malformations (ARMs) account for 1/4 of digestive malformations that require neonatal surgery. ARMs have been found in association with sacral anomalies in about 29% of cases. Caudal Regression Syndrome (CRS) is a multisystemic disorder with an overall incidence of 1/7500 live born, presenting total or partial sacrococcygeal agenesis, anorectal malformations, neural changes and urogenital malformations. A peculiar form of CRS is the Currarino Syndrome (CS), characterised by hemisacrum, ARMs and presacral mass (anterior meningocele, teratoma and/or rectal duplication). This syndrome, defined as autosomal dominant, presents high phenotypic variability, but true CS patients always show the typical hemisacrum with intact first sacral vertebra. Recently, the involvement of the HLXB9 homeogene with sacral malformations has been demonstrated: in order to precisely evaluate its role in the development of different sacral phenotypes, we performed Double Gradient-DGGE (DG-DGGE) mutation analysis and DNA sequencing on a total of 27 cases. Patients were divided into 3 groupings, according to strict clinical criteria. Group 1: patients affected by CS; group 2: patients affected by CRS along with ARMs and sacral hypodevelopment; group 3: patients affected by total sacral agenesis along with ARMs. We analysed a total of 1720 bp, including the complete HLXB9 coding region (3 exons) and the intron-exon boundaries. We identified mutations in 4 CS patients (2 missense, 1 frameshift, and 1 splicing). In 3 more CS patients, we identified the presence of deletions of HLXB9, suggesting that haploinsufficiency for this gene is the cause of the disease. We didn't identify any alteration in any of the remaining 17 patients examined. Our results suggest a specific involvement of the HLXB9 homeogene in Currarino Syndrome and possibly not in other sacral malformations.

Program Nr: 1585 from the 1999 ASHG Annual Meeting

A Fibroblast Growth Factor Receptor 3 (FGFR3) Lys650Asn Mutation Causes Hypochondroplasia. *G.A. Bellus[1], P.W. Speiser[2], M.K. Webster[3], D.J. Donoghue[3], C.A. Francomano[4].* 1) Dept Dermatology, B-153, Univ Colorado Health Sci Ctr, Denver, CO; 2) Dept Pediatrics, N Shore Univ Hosp, New York Univ School of Med, Manhasset, NY; 3) Dept Chemistry & Biochemistry, Univ California, San Diego, Lajolla, CA; 4) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Hypochondroplasia is a relatively common autosomal dominant skeletal dysplasia with a phenotype that is similar to, but milder than, achondroplasia. Previous studies have shown that the majority of cases (approximately 50% - 75%) are caused by one of two point mutations (C1620A or C1620G) in the FGFR3 gene resulting in an Asn540Lys substitution in the intracellular tyrosine kinase domain. However, substantial proportions of patients with clinical diagnoses of hypochondroplasia do not have FGFR3 Asn540Lys mutations. Using PCR techniques, we have screened a large group of patients with clinical features of hypochondroplasia who do not have FGFR3 Asn540Lys mutations looking for other FGFR3 mutations. Two patients were found to have lost a *Bbs-1* restriction site in exon 15 and direct sequencing demonstrated that both patients were heterozygous for a G1950T transversion leading to a Lys650Asn substitution. Evaluation of DNA from the parents of these patients revealed that this mutation occurred sporadically in one patient and was inherited from the other patient's father (who also showed skeletal disproportion and mild short stature). These results demonstrate that 3 different amino acid substitutions at the FGFR3 Lys650 codon can result in 3 distinct genetic syndromes. A cDNA construct of this mutation was made and expressed by transient transfection in NIH 3T3 cells. FGFR3 immunoprecipitation and autophosphorylation assays demonstrated the Lys650Asn mutation results in ligand-independent constitutive activation of the FGFR3 tyrosine kinase domain but to a lesser degree than the thanatophoric dysplasia, type 2 FGFR3 Lys650Glu or the SADDAN FGFR3 Lys650Met mutations. These results support the hypothesis that, in FGFR3 related skeletal dysplasias, the severity of the skeletal findings correlates with the level of constitutive FGFR3 tyrosine kinase activity and highlight the importance of the Lys650 codon in FGFR3 function.

Program Nr: 1586 from the 1999 ASHG Annual Meeting

Mutations of the ATPase7B gene in Tunisian patients with Wilson Disease. *M. BenFadhel[1], M.D. Fathallah[1], M. Ben Hariz[1], F. Amri[1], K. Dellagi[1], A. Bobba[2], V. Petrogall[2], E. Marra[2], S. Giannatasio[2].* 1) Immunology, Institute Pasteur Tunis, Tunis, Tunisia; 2) CNR-Centro di Studio sui Mitocondri e Metabolismo Energitico, Bari -Italy.

Wilson disease (WD) is an autosomal recessive genetic disorder characterized by impaired copper transport. Accumulation of the copper in the liver and secondarily in the brain , kidney and cornea results in different clinical manifestations of the disease (hepatic, neurologic or combined form). The gene responsible for WD encodes for a copper transporting P-type ATPase (ATP7B) highly homologous to that of the X-linked copper transport defect : Menkes disease. We have investigated the mutations affecting the ATP7B gene in 8 patients from Tunisia (North Africa) affected by Wilson disease. All these patients were born off first degree consanguineous marriages and belonged to six unrelated families. Four patients had the hepatic form while two had the neurologic one and two had mixed symptoms. We have used SSCP to screen the entire ATP7B coding sequence as well as the exon-intron junctions. The mutations were identified by automated DNA sequencing of the shifted fragments. We characterized five missense mutations, one was already reported (Arg832Lys,exon 10) and the remaining four are newly described (Ser744Pro,exon8;Leu813Ile,exon9;Lys787Ile,Exon9; Val1140Asp, exon16). All the detected mutations affected structurally important regions of the ATP7B molecule which might explain the severe phenotype of our patients. We noticed the absence of the His1069Gln, the most common mutation in European and North Mediterranean population. We have also observed several silent mutations in the ATP7B gene of the patients studied probably associated to polymorphism of the gene in the Tunisian population. Our results suggest that the spectrum of mutations causing Wilson disease in North African populations would be different from the other populations of the northern Mediterranean basin.These data will help providing an early or prenatal diagnosis.

Program Nr: 1587 from the 1999 ASHG Annual Meeting

Mutation screening of the Tuberous Sclerosis gene 1 (TSC1) by protein truncation test. *P. Benit, A. Kara-Mostefa, S. Hadj-Rabia, A. Munnich, J.-P. Bonnefont.* Unité de Recherches sur les Handicaps Génétiques de l'Enfant, INSERM U393, Hôpital Necker, Paris, France.

Tuberous Sclerosis (TSC) is caused by mutations in either the TSC1 gene (9q34) or the TSC2 gene (16p13). More than 90% of TSC1 mutations are predicted to truncate Hamartin, the TSC1 gene product. Taking advantage of these data, we devised a protein truncation test (PTT) to analyze the entire coding sequence of the TSC1 gene in four overlaping fragments. A total of 12 sporadic cases and 3 familial cases linked to 9q34 were studied using a combination of PTT and SSCP analysis. While PTT detected 4/15 mutations (1250+1 G®A, 1473 del C, 1491 del AG, Q743X), SSCP picked up one missense mutation (L72P) and two small deletions (1473 delC, 1491 del AG) but failed to detect two truncating mutations (1250+1 G®A, Q743X) identified by PTT. TSC1 mutation was identified in all three familial cases but in two of the 12 sporadic cases only. Our results emphasize the interest of PTT as a rapid, easy and efficient method for mutation detection in TSC.

Program Nr: 1588 from the 1999 ASHG Annual Meeting

An X-linked T-cell Activation Syndrome characterized by Diarrhea, Respiratory Infections and Autoimmune Disease, harbors rare mutation of the Wiskott-Aldrich Syndrome gene alternate promoter. *C.L Bennett[1], R. Yoshioka[4], H. Kiyosawa[4], D. Barker[3], P. Fain[2], A. Shigeoka[3], I. Blair[1], P.F Chance[1]*. 1) Pediatrics, University of Washington, Seattle, WA 98117; 2) University of Colorado in Denver, Denver, CO 80933; 3) University of Utah, Salt Lake City, UT 84112; 4) Fukushima Medical College, Fukushima-Ken, Japan, 960-12.

We describe an X-linked syndrome with polyendocrinopathy, immune dysfunction & diarrhea (XPID), that commonly results in death during infancy. In this pedigree of 20 affected males, there are two survivors, aged eight and 30 years. Cyclosporin A treatment has produced clinical improvement in diarrhea, and resolution of autoimmune hemolytic anemia and arthritis. Linkage analysis mapped the gene to a 30-cM interval defined by the markers DXS8083 and DXS441 on Xp11.23-11.22, encompassing the gene for Wiskott-Aldrich Syndrome (WAS) and X-linked thrombocytopenia (XLT). The maximum LOD score was 3.81 (theta=0) at DXS255 which is closely linked to WAS. Mutations in the WAS gene have been found in patients with WAS and in patients with the related disorder XLT, indicating that XLT and WAS are allelic variants. To explore the possibility of further allelic heterogeneity in WAS gene mutations, we investigated mutations in XPID. The clinical features of XPID are similar to those of WAS and the XPID gene has been mapped to a region on the X chromosome which contains the WAS locus. Northern blot analysis detected the same relative amount and same-sized WAS gene message in XPID patients and in a normal control. However, in addition to the predicted coding regions we also sequenced the recently identified alternate promoter and untranslated upstream first exon. We identified a C-T transition within the first 8-bp of the alternate translation start site that generates an ATG translation start codon that once spliced into the mRNA transcript, predicts a frameshift mutation. A Nla III restriction fragment length polymorphism generated by this C-T transition segregated with the disease in this family. We propose that the XPID disorder may represent further heterogeneity of clinical manifestations resulting from mutations in the WAS gene.

Program Nr: 1589 from the 1999 ASHG Annual Meeting

CMT1A-REPs based PCR strategies to identify duplications/deletions in Charcot-Marie-Tooth type 1A (CMT1A) and Hereditary Neuropathies with liability to Pressure Palsies (HNPP). *R.B. Bernard[1], A. Navarro[1,2], J. Pouget[3], C. Desnuelle[4], N. Philip[1,2], M. Fontés[2], N. Lévy[1,2]*. 1) Département de Génétique Médicale, Hôpital d'enfants de la Timone, Marseille, France; 2) Inserm U491 "Génétique médicale et Développement" Faculté de Médecine, Marseille, France; 3) Clinique des maladies Neuromusculaires, Hôpital Timone, Marseille, France; 4) Service de reeducation fonctionnelle, Hôpital l'Archet, Nice, France.

CMT1A and HNPP are usually caused by a 1.5 Mb duplication or deletion respectively. These rearrangements occur by unequal meiotic recombination between homologous sequences flanking the 1.5 Mb region (distal and proximal CMT1A-REPs). Reiter et al. (1996), identified a recombination "hotspot" between the CMT1A-REPs and developed a Southern blot approach to detect a 3.2 Kb (EcoRI/SacI) or 1.7 Kb (EcoRI/NsiI) junction fragment in 75% of CMT1A duplicated patients; or a 7.8 Kb (EcoRI/EcoRI) junction fragment in the same proportion of HNPP deleted patients. CMT1A/HNPP diagnosis is technically challenging, time consuming, costly and require isotopic labelled probes. To identify CMT1A duplications, we used a set of primers surrounding EcoRI (distal REP) and SacI (Proximal REP) restriction sites. An EcoRI+NsiI digestion of the PCR products identified a 1.7 Kb junction fragment only in patients for whom duplication resulted from a recombination within the "hotspot". To rapidly detect the HNPP deletions, a PCR assay was designed, using primers flanking the EcoRI and NsiI sites. Prior to the PCR assay, DNAs were digested with EcoRI and NsiI to avoid amplification of the normal REPs. Only the HNPP specific recombinant fragments were amplified. 70 CMT1A and 30 HNPP patients, all presenting a known duplication/deletion by recombination within the "hotspot", were analyzed and identified (100%). In addition, we used a microsatellite analysis to detect the CMT1A duplications/HNPP deletions due to recombination outside the hotspot. Our strategy rapidly identifies almost the entire set of duplications/deletions. It should become a key approach for genetic counselling and prenatal diagnosis of these peripheral neuropathies. Different methods from other groups will be compared.

Program Nr: 1590 from the 1999 ASHG Annual Meeting

Universal Mutation Database (UMD): Software and database for the analysis of mutations in human genes. *C. Béroud[1], G. Collod-ô[1], C. Gallou[1], C. Boileau[1], T. Soussi[2], C. Junien[1].* 1) INSERM U383, Hôpital Necker Enfants malades, PARIS CEDEX 15, FRANCE; 2) Institut Curie, CNRS UMR 218, PARIS CEDEX 05, FRANCE.

With the development of our knowledge of genes alterations involved in human diseases, it has become clear that the identification of mutations plays a critical role not only for diagnosis and prognostic but also for research. The Universal Mutation Database software (UMD) was developed as generic software to create locus specific databases (LSDB). It was developed with the 4th Dimension® package from ACI. It runs on Macintosh or compatible computers and also on IBM PC and compatibles. Since September 1997, it was also used to create the UMD Web site (http://www.umd.necker.fr) which includes today the APC, FBN1, LDLR, MEN1, p53, SUR1, VHL and WT1 LSDB. It has been queried more than 300 000 times. UMD Databases are comprehensive LSDB that contains all reported mutations localized in the coding sequence and splice site mutations of a specific gene. Specific clinical data can also be included depending of each gene/disease (available for FBN1, LDLR, MEN1, SUR1, VHL, WT1). Each data is checked by curators. The UMD software is freely available (ftp.umd.necker.fr) and includes many tools to analyze data. These tools includes routines to: identify preferential mutation sites; indicate mutational events; study the relative distribution of mutations at all sites and sort them according to their frequency; display the distribution of mutations in each exon and evaluate the significance of the differences between observed and expected mutations; search for repetitive sequences involved in the mutational event; study mutated pyrimidine dimers on both strands; study mutations accordingly to their phylogenic conservation ; align repeated domains and compare the distribution of mutations in these domains ; study the mutational event either at the nucleotide or at the amino acid level. A graphical display is available for these routines. The use of optimized searching and sorting tools to select records from any fields gives access to a large range of analyses. They are particularly useful for phenotype/genotype correlation and molecular epidemiology studies.

Program Nr: 1591 from the 1999 ASHG Annual Meeting

Mutational Spectrum of Pallister-Hall Syndrome. *L.G. Biesecker[1], J.M. Graham[2], T. Grebe[3], G. Neri[4], R. Pagon[5], C. Bonneman[5], M. Partington[5], C. Killoran[1].* 1) Genetic Dis Res Branch, LGDR/NHGRI/NIH, Bethesda, MD; 2) UCLA, Cedars-Sinai Medical Center; 3) University of Arizona, Phoenix; 4) Universita Cattolica, Rome, Italy; 5) Other Institutions.

Pallister-Hall syndrome is a human developmental anomaly syndrome that includes hypothalamic hamartoma, polydactyly, bifid epiglottis, and visceral malformations. It is inherited in an autosomal dominant pattern and has been shown to be caused by mutations in the Gli3 zinc finger transcription factor gene. Here we report 11 mutations that cause PHS in addition to the originally described two mutations. These newly reported mutations have been found in sporadic (eight cases) and familial (three cases) occurrences of the disorder. In all cases, the mutation predicts a premature truncation of the GLI3 protein due to 1-19 bp deletions (seven cases), insertions (1 case) or nonsense mutations (three cases). There are no substitutions known to cause PHS. The position of the mutations within the gene ranges from cDNA bp 2146 to 3324, all of which are 3' to the zinc finger encoding domains. These mutations overlap with some truncation mutations that have been associated with apparantly isolated post-axial polydactyly type A (PAP-A). We will review these mutations in light of the molecular models of GLI3 activity and correlate the mutations with the phenotypes of the affected members of the pedigrees.

Program Nr: 1592 from the 1999 ASHG Annual Meeting

Gamma Crystallin and the Congenital Aculeiform Cataract. *G.D. Billingsley[1], M.K. Priston[1], D.F. Schorderet[4], F.L. Munier[4,5], E. Héon[1,2,3].* 1) Eye Research Institute of Canada; 2) University of Toronto, Department of Ophthalmology; 3) The Hospital for Sick Children Research Institute, Toronto, Ontario, Canada; 4) Unit of Oculogenetics and Division of Medical Genetics, CHUV; 5) Hôpital Ophtalmique Jules Gonin; Lausanne, Switzerland.

Aculeiform cataract is an autosomal dominant cataract characterized by fiberglass-like or needle-like crystals projecting in different directions. The underlying molecular cause is unknown. A 7 cM disease-gene interval was recently identified on chromosome 2q33-36. Further analyses were performed to identify the underlying genetic defect. Mutational analysis of the gamma-crystallin genes cluster was performed in three unrelated European families by direct sequencing. Direct cycle sequencing of crystallin gamma B, C, D, and E was performed. Observed sequence variations were sequenced in both directions and compared to the sequence of a control population without lens opacification. Several polymorphic sequence changes were identified in gamma B, C, D and E. A missense mutation identified in exon 2 of gamma D cosegregated perfectly with the disease phenotype and was not seen in 210 controls, nor in 44 patients affected with age-related cataracts and 39 patients with sporadic congenital cataracts of various subtypes. The sequence change is likely to impair the folding of the protein.The aculeiform cataract phenotype appears to be due to sequence changes in gamma D crystallin. This is the second association of gamma D crystallin with a congenital cataract phenotype. The identification of cataract-related genes is critical to the better understanding of normal lens development and the biology of cataract formation and progression.

.

Program Nr: 1593 from the 1999 ASHG Annual Meeting

Autosomal dominant hyperopia and strabismus in patients from 3-generation family associated with mutation in LIM-domain interacting factor CLIM2 gene. *P. Bitoun[1], E. Semina[2], J. Gaudelus[1], J.C. Murray[2].* 1) Dept Genetique Medicale & Pediatrie, C.H.U Paris-Nord, Hopital Jean Verdier, BONDY, 93143 cedex France; 2) Dpt of Pediatrics & Biological Sciences, U of Iowa, IOWA CITY, IA 52242.

Accomodative esotropia (AE) associated with congenital hyperopia and early strabismus has autosomal dominant transmission in some families (Drack et al; P.Bitoun, unpublished). Early diagnosis is of importance since appropriate correction may help prevent strabismus surgery and since AE often is complicated by secondary glaucoma in the 4th and 5th decade. We identified 5 families with autosomal dominant AE in 2 or 3 generations and performed a mutation search in several genes involved in ocular development which may cause abnormal eye size involved in AE:-PITX2, PITX3, CLIM2 and CLIM1. Screening was performed by SSCP analysis of PCR products obtained with gene-specific primers. The products that showed abnormal mobility of the SSCP gel were sequenced and compared with the normal sequence. An abnormal variant was identified in exon 2 of the CLIM2 gene in a 9 year-old female patient and affected sib with dominant AE from a three-generation family with AE transmitted from father and paternal grand-father. Sequencing identified that this mutation is predicted to cause R231H change in the CLIM2 protein. The mutation affects a highly conserved region of the protein that is immediately adjacent to the LIM- and PITX- interacting domains. Both LIM-domain and PITX genes were shown to be involved in ocular development. Comparison with other CLIM2 proteins isolated from different species identified that this position is occupied by arginine in all known CLIM2 proteins identified for drosophila, chicken, xenopus and mouse. The mutation was not found in 250 control chromosomes. Screening of the rest of the family for segregation of the mutation with the disorder as well as other families with autosomal dominant AE is ongoing. The human CLIM2 gene was localised on 10q24-q25 by Genebridge 4 radiation hybrid panel.

Program Nr: 1594 from the 1999 ASHG Annual Meeting

Clinal and molecular analysis of vitreoretinopathies which map to the proximal long arm of chromosome 5. *G.M. Black[1,2], R. Parveen[1], N. Hart-Holden[1], H.G. Brunner[3], D. McLeod[2].* 1) University Department of Medical Genetics and Regional Genetic Service, St Mary's Hospital, Manchester,UK; 2) University Department of Ophthalmology, Manchester Royal Eye Hospital, Manchester,UK; 3) Department of Human Genetics, Nijmegan University Hospital, Nijmegan, Netherlands.

Wagner syndrome is an autosomal dominant condition which is not associated with systemic stigmata. The ocular findings include an optically empty vitreous, chorioretinal atrophy, cataract and rhegmatogenous retinal detachment secondary to abnormal vitreoretinal adhesion. The condition is heterogeneous and genetic mapping has identified a locus on chromosome 5q13-q14. This region is also implicated in the related condition, erosive vitreoretinopathy which is characterised by abnormal vitreous gel structure, retinal pigment epithelial and electroretinographic abnormalities. We have analysed further families with vitreoretinopathies linked to this region and describe a spectrum of ocular pathologies including defects of early ocular development such as microphthalmia, cataract, persistent hyperplastic primary vitreous, anterior segment dysgenesis and congenital glaucoma. None of the families has extra-ocular manifestations. Genetic mapping presented here in our families reduces the critical region to approximately 2cM and have developed a genomic contig across the region. Subsequent refinement of the physical map allows ordering of known polymorphic microsatellites and excludes CRTL1 as a candidate. CSPG2 lies within the critical region. However mutation analysis of the gene in 15 families reveals no clear evidence that it is the gene underlying WGN1.

Program Nr: 1595 from the 1999 ASHG Annual Meeting

A positional cloning strategy to identify the gene for an autosomal dominant juvenile ALS on chromosome 9q34.

I.P. Blair[1], C.L. Bennett[1], G.D.J. Watts[1], B. Rabin[2], D.R. Cornblath[2], J. Griffin[2], P.F. Chance[1]. 1) Pediatrics, University of Washington, Seattle, WA; 2) School of Med, Johns Hopkins University, Baltimore, MD.

Amyotrophic lateral sclerosis (ALS) denotes a heterogeneous group of progressive neurological disorders associated with degeneration of motor neurons in the cerebral cortex, brain stem, and spinal cord. Youth onset forms of familial ALS have been described and termed "juvenile ALS". We recently described linkage mapping of a locus for an autosomal dominant juvenile ALS to chromosome 9q34 (ALS4). In order to refine the locus and ultimately identify the disease gene, we have undertaken a positional cloning/candidate strategy utilizing the resources of the Human Genome Project. Additional linkage and recombinant haplotype analysis in a large ALS4 family using a dense collection of microsatellite markers from the originally defined candidate interval has significantly redefined the critical interval to 2-5 Mb. Efforts to establish a complete physical map of the interval are underway. A cosmid contig developed as part of cloning the TSC1 gene is being utilized, in addition to CEPH YAC clones. PAC clones are being identified with view to bridging regions not covered by these clones. Using the "Genemap" EST databases, we have identified over 50 genes in the form of ESTs that localize within the critical interval. Extensive EST sequence contigs have been established for most of these genes by screening EST databases with each mapped EST sequence. Database comparisons with these extended sequences has identified several transcripts whose predicted function suggests that they are candidate genes for ALS4. Expression analysis and fine scale mapping has been used to investigate and prioritize transcripts prior to mutation analysis. This has allowed us to exclude the candidate genes SYT7, GRIN1, STXBPI, and kinesin related gene ATSV. Extensive mutation analysis is underway with several strong candidate genes using the techniques of dideoxy fingerprinting and direct sequencing. Genes under investigation include a homolog of the RING3 gene which has been shown to be induced in neurons undergoing cell death.

Program Nr: 1596 from the 1999 ASHG Annual Meeting

Screening for mutations of *PMP22, MPZ, EGR2, SCIP*and *EGR1*in CMT patients without the CMT1A duplication or *Cx32*mutations. *C.F. Boerkoel, K. Dalakishvili, J.R. Lupski.* Baylor College of Medicine, Department of Molecular and Human Genetics, Houston, TX.

Charcot-Marie-Tooth disease (CMT) is the most common inherited disorder of the peripheral nervous system affecting approximately 1 in 2500 individuals. It is a heterogeneous disorder that has been divided into two major groups: CMT type 1 (CMT1) and CMT type 2 (CMT2). CMT1 is characterized by demyelination with severely reduced motor nerve conduction velocities (NCV); whereas, CMT2 is characterized by axonal loss and normal or mildly reduced NCVs. The CMT1A duplication and *Cx32* mutations account for approximately 70% and 5% of familial and sporadic CMT1 respectively. In the remaining 25% of patients with CMT1, some 80% do not have an identifiable mutation in the coding region of other CMT “disease genes”: *PMP22, MPZ*and *EGR2. EGR2*encodes a transcription factor essential for myelin differentiation. Based on a candidate gene approach, we screened two additional transcription factor genes expressed during myelin differentiation: *SCIP/OCT-6*and *EGR1*. The *SCIP*knockout mouse has severe congenital dysmyelination that improves over time in a manner reminiscent of some forms of human congenital hypomyelination. *EGR1*belongs to the same class of transcription factors as *EGR2*, is expressed in early myelin differentiation, and maps to a locus (5q23-q33) associated with a recessive form of CMT. We report the distribution of mutations among *PMP22, MPZ, EGR2, SCIP*and *EGR1*in more than 100 patients without the CMT1A duplication or *Cx32*mutations.

Program Nr: 1597 from the 1999 ASHG Annual Meeting

Heterogeneous rearrangements of the PLP genomic region in Pelizaeus-Merzbacher Disease: genotype-phenotype correlation in 41 patients. *O. Boespflug-Tanguy[1], G. Giraud[1], C. Mimault[1], V. Isabelle[1], D. Pham Dinh[2], European Network on Brain Dysmyelinating Diseases[1].* 1) Inserm U384, Faculte de Medecine, Clermont-Ferrand, France; 2) UMR CNRS 7624, Universite Pierre et Marie Curie, Paris, France.

Pelizaeus-Merzbacher disease (PMD) is an X-linked developmental defect of brain myelination due to proteolipoprotein (PLP) gene mutations. Using a quantitative fluorescent multiplex PCR technique in 104 PMD affected families, we shown that duplication of the entire PLP gene is the most frequent mutation accounting for 50% of all PMD affected families and 64% of all PLP identified mutations. Furthermore, we found a large PLP gene deletion in a spastic paraplegia 2 family. Clinical evaluation of the 84 PLP-duplicated patients revealed a large range of disease severity with patients able to walk with support in the mildest form to patients with no motor achievment in the most severe form. An intrafamilial homogeneity was observed in the 14 familial forms analysed. The extend of the genomic duplication was further determined in 41 families by using a multiplex PCR with 10 pairs of primers chosen along the Xq22 region encompassing the PLP locus and by pulse field gel electrophoresis. Size of the duplications were greatly variable (40kb<to>1000kb) and not correlated to the clinical severity of the disaese. The two patients with the most severe form had PCR ratio compatible with a PLP triplication. For two patients the telomeric end of the duplication was localised inside the 20 kb end of the cosmid cV698D2 containing the PLP gene. Southern blot and sequencing analysis of the two breakpoint regions have demonstrated distinct rearrangements. Finally in PLP-related diseases, severity is correlated to the number of PLP copies and not to the size of the duplication. Existence of both duplication and deletion events associated with a large male mutation imbalance for duplications (C. Mimault, in press) suggest a mechanism of unequal sister chromatid exchange, as in the demyelinating neuropathies related to PMP22 mutations (CMT1 and HNPP). However, the large diversity found in the break points of PLP duplications suggests a more complex mechanism leading to the great genomic instability of the xq22 region.

Program Nr: 1598 from the 1999 ASHG Annual Meeting

Identification of complex genetic rearrangements in the iduronate-2-sulfatase (IDS) gene causing the Hunter syndrome (MPSII). *M-L. Bondeson[1], S.L. Karsten[1], B-M. Carlberg[1], W.J. Kleijer[2], K. Lagerstedt[1]*. 1) Dept of Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Dept of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

The Hunter syndrome (or mucopolysaccharidosis type II) is an X-linked recessive lysosomal storage disorder caused by a deficiency in the enzyme iduronate-2-sulfatase (IDS). Clinically, a wide spectrum of phenotypes has been observed ranging from severe to mild. The IDS locus is localised at the boundary between Xq27.3 and q28 and several novel genes have been found in the proximity of the IDS gene including an IDS-related gene with a pseudo-gene like structure (IDS-2). A large number of mutations have been identified as the primary genetic defect causing the Hunter syndrome. Most of the mutations represent point mutations or minor alterations. However, in about 20% of the patients major structural aberrations such as deletions of the entire gene or rearrangements have been identified. In order to gain insights into the mechanisms generating these structural aberrations we have analysed two unrelated patients by Southern blot analysis, PCR and DNA sequencing. In the first patient, an intragenic deletion of exons 5 and 6 in the IDS gene was identified. Sequencing of the deletion junction revealed a complex genetic rearrangement involving duplications and inversions. The second patient suffer from a large deletion of 43.6 kb spanning exons 1-7 of the IDS gene, the IDS-2 locus and exons 3-5 of the gene W. An interesting finding was the identification of a small deletion consensus motif, TG(A/G)(A/G)(G/T)(A/C), in both the 5' and 3' donor sequences. This motif is very similar to motifs found in the immunoglobulin switch regions and also to putative DNA polymerase alpha arrest sites. The location of this consensus sequence in both the 5' and 3' donor sequences spanning the deletion junction, strongly suggests that it contributes to the mutational process resulting in a large deletion. Based on DNA sequence analysis of the two deletions described here, we propose models for how the deletions might be generated by illegitimate recombination during the meiosis.

Program Nr: 1599 from the 1999 ASHG Annual Meeting

The Yemenite deaf-blind hypopigmentation syndrome revisited: SOX10 dysfunction causes different neurocristopathies. *N. Bondurand[1], K. Kuhlbrodt[2], V. Pingault[1], J. Enderich[2], M. Sajus[1], N. Tommerup[3], M. Warburg*[3], R.CM. Hennekam[4], AP. Read[5], M. Wegner[2], M. Goossens[1]*. 1) Inserm U468,hopital Henri Mondor, Creteil, France; 2) Zentrum fur Molekulare Neurobiologie, Universitat Hamburg, Germany; 3) Department of Medical Genetics, Institute of Medical Biochemistry and Genetics, Panum Institute, University of Copenhagen, Denmark *Center for Disabled Children, The Eye Clinic, Copenhagen, Gentofte, Denmark; 4) Department of Pediatrics and Clinical Genetics, AMC, Amsterdam, The Netherlands; 5) University Department of Medical Genetics, St Mary's Hospital, Manchester M13, UK.

Neurocristopathies are disorders characterized by a defect of neural crest development. We previously showed that heterozygous mutations in the sry-related *SOX10* gene are encountered in some cases of Shah-Waardenburg syndrome, a neurocristopathy characterized by the association of Hirschsprung disease (intestinal aganglionosis) and Waardenburg syndrome (pigmentation defects and sensorineural deafness). Moreover, *Sox10*/*SOX10* expression in rodents and human is consistent with a function in neural crest development. We therefore extended the mutation screening to other neurocristopathies. The Yemenite deaf-blind hypopigmentation syndrome was first observed in a Yemenite sister and brother showing cutaneous hypopigmented and hyperpigmented spots and patches, microcornea, coloboma, and severe hearing loss. A second case, observed in a girl with similar skin symptoms and hearing loss but without microcornea or coloboma, was reported as a mild form of this syndrome. Here we show that a *SOX10* missense mutation is responsible for the mild form, resulting in a loss of DNA binding of this transcription factor. In contrast, no *SOX10* alteration could be found in the other, severe case of the Yemenite deaf-blind hypopigmentation syndrome. Based on genetic, clinical, molecular and functional data, we suggest that these two cases represent two different syndromes. These results show that *SOX10* mutations cause various types of neurocristopathies.

Program Nr: 1600 from the 1999 ASHG Annual Meeting

Mutations in the RP1 gene causing autosomal dominant retinitis pigmentosa. *S.J. Bowne[1], S.P. Daiger[1], C.F. Inglehearn[2], M.M. Sohocki[1], K.A. Malone[1], J.R. Heckenlively[3], D.R. Birch[4], S.S. Bhattacharya[5], A. Bird[5], M.M. Hims[2], A.B. McKie[2], L.S. Sullivan[1]*. 1) Human Genetics Ctr, The University of Texas-Houston; 2) Leeds University, Leeds, UK; 3) Jules Stein Eye Institute, UCLA; 4) Retina Foundation of the Southwest, Dallas; 5) Institute of Ophthalmology, London, UK.

Recently we identified the gene responsible for the RP1 form of autosomal dominant retinitis pigmentosa (adRP) and found two different nonsense mutations in 3 families previously mapped to chromosome 8q. The RP1 gene encodes a protein 2,156 amino acids in length, but is comprised of four exons only. In order to determine the frequency and range of mutations in RP1 we screened probands from 56 large adRP families for mutations in the entire gene. After preliminary results indicated that mutations seem to cluster in a 442-nucleotide segment of exon 4, an additional 603 probands with a wide range of degenerative retinal diseases were tested for mutations in this region alone. In addition to the two nonsense mutations originally identified in RP1, we have now identified 7 more disease-associated mutations in 17 unrelated families and two rare missense changes in two additional families. All of the disease-associated mutations lead to a severely truncated protein. We also identified one new polymorphic amino acid substitution, one silent substitution and a rare variant in the 5' untranslated region that is not associated with disease. Based on this study, mutations in RP1 appear to cause 5 to 10% of adRP. A 5bp deletion of nucleotides 2383-2387 and the Arg677stop mutation account for over 50% of these mutations. Further studies will determine if missense changes in certain regions of the RP1 gene are associated with disease and if the background variation on either the mutated or wildtype RP1 allele plays a role in the disease phenotype.

Supported by NEI-NIH grant EY07142 and grants from the Foundation Fighting Blindness, the Hermann Eye Fund, the British RP Society and the Wellcome Trust.

Program Nr: 1601 from the 1999 ASHG Annual Meeting

Incomplete X-linked congenital stationary night blindness: Clinical variability among patients with the L1045insC founder mutation in *CACNA1F* and the search for genetic modifiers. *K.M. Boycott[1], W.G. Pearce[2], N.T. Bech-Hansen[1]*. 1) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Department of Ophthalmology, University of Alberta, Edmonton, AB, Canada.

Incomplete X-linked congenital stationary night blindness (iCSNB) is a non-progressive retinal disorder characterized by impaired night vision, decreased visual acuity, myopia, nystagmus, and strabismus. Mutation analysis of the *CACNA1F* gene, which codes for a retina-specific L-type calcium channel a_1-subunit protein (a_1F), in patients with iCSNB has identified a total of 17 different mutations seen in 36 families. One of these mutations, L1045insC, is seen in 15 families of Mennonite ancestry from Western Canada. Clinical variability was examined in 66 patients from these families in terms of night blindness, visual acuity, myopia, nystagmus, and strabismus. In 80% of the patients at least one of the main features of CSNB (night blindness, myopia, nystagmus) was absent. The only clinical feature present in all 66 patients was impaired visual acuity. The variability seen in clinical expression among these patients who share the L1045insC mutation suggests the presence of genetic modifiers.

There is increasing evidence that the manifestations of many genetic disorders are influenced by modifying genes distinct from the disease locus. Of the 66 iCSNB patients examined, 40% have nystagmus as one of the manifestations of the disease. Loci in Xq26, 6p12, and Xp11.4 identified as playing a role in the pathophysiology of congenital motor nystagmus were evaulated as candidate regions for modification of the nystagmus phenotype in iCSNB, and excluded as having a major effect. Similar investigations are currently being performed using candidate regions implicated in the pathophysiology of myopia. Identification of genetic modifiers that affect clinical expression in iCSNB will be important for understanding the disease process and may provide attractive targets for therapy.

This research was supported in part by the RP Research Foundation (Canada), the Alberta Heritage Foundation for Medical Research and the Roy Allen Endowment.

Program Nr: 1602 from the 1999 ASHG Annual Meeting

Detection of the survival motor neuron (*SMN*) genes by FISH: further evidence for a role of *SMN2* in the modulation of disease severity in SMA patients. *C. Brahe, T. Vitali, V. Sossi, S. Zappata, F. Tiziano, G. Neri.* Institute of Medical Genetics, Catholic University, Rome, Italy.

Spinal muscular atrophy (SMA) is a common autosomal recessive neuromuscular disorder characterized by the degeneration of spinal cord anterior horn cells and weakness of limb and trunk muscles. On the basis of age of onset and severity of the clinical course, three forms of childhood-onset SMA (types I-III) and one adult-onset form (type IV) can be distinguished. SMA is caused by the homozygous absence of the survival motor neuron (*SMN1*) gene due to deletion, gene conversion or mutation. *SMN1* and a nearly identical copy (*SMN2*) are located in a duplicated region at 5q13 and encode identical proteins.

The genetic basis for the clinical variability of SMA remains unclear. Data obtained by quantitative PCR assays have previously suggested a correlation between the number of *SMN2* gene copies and disease severity. However, the exact number of genes is difficult to estimate by this method. We have developed fluorescence in situ hybridization (FISH) conditions suitable for visualizing the *SMN* genes. We used as probe a mixture of PCR amplified DNA fragments specific of the *SMN* gene together with a reference probe, located outside of the duplicated SMA region, in order to establish the phase of the cell cycle in interphase nuclei. All patients had at least two *SMN2* genes suggesting that the presence of a single *SMN2* gene is very rare. We found 2 or 3 copies of *SMN2* in type I patients, 3 copies in type II and 3 to 4 copies in type III patients. One individual with very mild adult-onset SMA had 8 copies of *SMN2*. No alterations of the genes were detected by Southern blot and sequence analysis suggesting that all gene copies of *SMN2* were intact. These data provide further evidence that the *SMN2* genes modulate the disease severity but also supports the suggestion that not all *SMN2* genes are functionally equivalent.

Program Nr: 1603 from the 1999 ASHG Annual Meeting

Mutation analysis of PEX7 in patients with rhizomelic chondrodysplasia punctata (RCDP). *N.E. Braverman[1], P. Lin[2], G. Steel[2], C. Obie[2], H. Moser[3], A. Moser[3], D. Valle[1,2].* 1) Dept Pediatrics, Johns Hopkins University, Baltimore, MD; 2) Howard Hughes Medical Institute, Baltimore, MD; 3) Kennedy Krieger Institute, Baltimore, MD.

RCDP is a peroxisome biogenesis disorder characterized by rhizomelia, epiphyseal calcifications, cataracts and profound growth and developmental delay. Although most patients have this classical phenotype, milder variants are recognized. We have previously shown that RCDP is caused by mutations in PEX7, which encodes the receptor (Pex7p) for peroxisomal matrix proteins containing a PTS2 targeting sequence. Pex7p is a WD40 repeat protein. We have now completed a mutation survey in 51 RCDP patients. Using SSCP we found 17 unique alleles, accounting for 88%. There 14 missense (6 unique), 56 nonsense (7 unique, 50 are L292X), 18 splice site changes (3 unique, 14 are IVS9+1G>C), 1 deletion and 1 insertion allele. We performed ASO analysis for most mutations; none are population polymorphisms. Using 5 polymorphic markers in the PEX7 gene we show that L292X originated on a single chromosome in the Caucasian population. Preliminary evidence shows that the frequent IVS9+1G>C allele arose several times on different haplotypes.

Suprisingly, overexpression of exon 1 missense alleles (S25F, H39P and G41V) in RCDP null cells revealed they could mediate PTS2 protein import. Molecular modeling of Pex7p on the crystal structure of another WD40 repeat protein, b transducin, reveals that these changes are located in the coiled-coil N-terminus, which is not involved in the b-propeller structure. Of 6 patients with mild phenotypes, one, who has cataracts only, has an N-terminal missense mutation. Another, who has an adult Refsum disease phenotype, likely generates a Pex7p lacking an internal WD40 repeat. Our mild variants have high residual plasmalogen levels, but phytanoyl-CoA alpha-hydroxylase activity remains low. These results indicate that PEX7 alleles with residual function are associated with phenotypes outside the familiar and that specific changes in the b-propeller structure or N-terminus may influence PTS2 ligand binding or transport.

Program Nr: 1604 from the 1999 ASHG Annual Meeting

Tenascin-X (TN-X) deficiency in five patients with Ehlers-Danlos Syndrome (EDS). *S.M. Burridge[1], J. Schalkwijk[2], G. Taylor[1], P.M. Steijlen[2], W.L. Miller[1], J. Bristow[1].* 1) Pediatrics, UCSF, San Francisco, CA; 2) Dermatology, University Hospital, Nijmegen, Netherlands.

The tenascin family of extracellular matrix proteins consists of three members named TN-C (cytoactin, tenascin), TN-R (restrictin) and TN-X. Studies of the expression of TN-C and TN-R suggest important functions during development but TN-C and TN-R knockout mice have minimal neurological abnormalities and no other apparent phenotype. TN-X is associated with collagen fibrils and is highly expressed in connective tissues, but its function is unclear. The TN-X gene overlaps the CYP21 gene for steroid 21-hydroxylase that causes congenital adrenal hyperplasia (CAH) on the opposite strand of DNA on chrom 6p21.3. We previously reported a patient with a contiguous gene syndrome of EDS and CAH who was heterozygous for a 30kb deletion which deletes CYP21 and part of TN-X. We now report the identification of a similar unrelated patient with this contiguous gene syndrome. As in the index case, TN-X is absent from western blots of fibroblast conditioned medium while collagen V secretion is normal. Also like the index case, this patient is heterozygous for the CYP21/TN-X deletion. Protein truncation tests confirmed the presence of this deletion. Both patients appear to carry as yet unidentified inactivating mutations on their second TN-X alleles. This finding suggested that inactivating TN-X mutations might be found without mutations in CYP21 and that TN-X deficiency could be a cause of EDS independant of CAH. We have now identified 3 such patients with mild classical EDS and complete TN-X deficiency. All have typical skin findings, and hyperextensible joints. One patient has spina bifida, one has a dilated aortic root, and one has poorly characterized neuromuscular disease. PCR showed that only one isolated EDS patient carries the 30kb deletion, and he is heterozygous. Microsatellite analysis suggests that the 30kb deletion has occured independently in each patient. This work supports our hypothesis that TN-X deficiency can cause classical EDS in patients who do not also have CAH. Mutational analysis to identify inactivating mutations in non-deleted TN-X alleles is now underway.

Program Nr: 1605 from the 1999 ASHG Annual Meeting

X chromosome inactivation studies in families with Prader-Willi syndrome. *M.G. Butler, J.D. Eskew, L.D. Wilcox, P.K. Rogan.* Section Medical Genetics, Children's Mercy Hosp, Kansas City, MO.

In normal human females one of the two X chromosomes in each somatic cell becomes inactivated in early embryonic development. The inactivation process is thought to be random in any particular somatic cell. However, a subset of female biased X inactivation may occur leading to preferential methylation of X linked genes on either the paternal or maternal X chromosome, for example, in X chromosome rearrangements and certain X linked diseases. Nonrandom X inactivation is increased in fetuses and newborns that are associated with confined placental mosaicism of an autosomal trisomy. This could conceivably result from a reduction in the size of the early embryonic cell pool due to poor growth or selection against trisomic cells. Extremely skewed X inactivation patterns have been reported in Prader-Willi syndrome (PWS) females with upd(15)mat (Lau et al., 1997), which frequently results from postzygotic missegregation in a trisomic conceptus. X inactivation status was assayed using methylation-specific polymerase chain reaction of a polymorphic sequence in the androgen receptor gene (Kubota et al., 1999). We have extended this observation by evaluating PWS families and have found 4 of 13 upd(15)mat females with significant X inactivation, i.e., close to 100% inactivation of one particular allele. Two female individuals and their mothers appeared to show identical X inactivation patterns, consistent with the possibility of hereditary X inactivation in these individuals. However, we also found skewed methylation of the maternally derived allele in one of three deletion PWS females and her mother. As an additional control, we evaluated the pattern of X inactivation in 13 different tissues from a 20-week gestation non-PWS female fetus, which showed tissue-specific skewing of X chromosome methylation. Biased X inactivation may not be more common in subjects with upd(15)mat than in unaffected individuals; however, additional studies are warranted.

Program Nr: 1606 from the 1999 ASHG Annual Meeting

Cell-specific processing of mutant type I collagen in three probands with Osteogenesis Imperfecta. *W.A. Cabral, J.C. Marini.* Sec Connective Tissue Disorder, NICHD/NIH, Bethesda, MD.

In previous comparisons of collagen synthesis by OI osteoblasts and fibroblasts, we reported that the proportion of overmodified alpha chains, as well as their relative electrophoretic delay, was greater in osteoblasts than fibroblasts (Hum Mut 11:395(1998)). Further comparisons of mutant collagen metabolism were conducted in paired primary osteoblasts and fibroblasts to determine the bases of the differences in cell-specific processing. For intracellular processing and secretion studies, we selected cases of non-lethal OI in which normal and mutant type I chains from fibroblasts and osteoblasts were electrophoretically well-resolved. Mutations were identified using RNase A digestion of RNA hybrids, then subcloning and sequencing. We identified point mutations resulting in glycine substitutions: a2(I) gly703®arg (GGA®AGA) and gly922®ser (GGT®AGT), and a1(I) gly997®ser (GGT®AGT). For each proband, the products of steady-state and continuous pulse labelling of osteoblast and fibroblast collagen were compared electrophoretically. For steady-state labelling, the intracellular and secreted proportion of electrophoretically delayed alpha chains was greater in osteoblasts than fibroblasts. Continuous pulse-labelling showed overmodified chains appear rapidly in osteoblasts, about 2 hours sooner than in fibroblasts. Overmodified collagen chains are present in higher proportion and with greater electrophoretic delay than in fibroblasts. Further, the overmodified chains in osteoblast samples have a gradually increasing electrophoretic delay with time, attaining the steady-state pattern in about 4 hours. The proportion of secreted mutant chains was greater in osteoblasts than fibroblasts, where only a low proportion of overmodified form is detected in media samples. In these OI cases, osteoblasts are more permissive than fibroblasts for intracellular survival and secretion of mutant collagen. Although OI is a generalized disorder of connective tissue, the predominant symptoms occur in bone. Cell-specific differences between fibroblasts and osteoblasts in processing and secretion of collagen may be a crucial part of the pathophysiology of OI.

Program Nr: 1607 from the 1999 ASHG Annual Meeting

A newly identified transcript and SPG7, the spastic paraplegia gene, are homologous and are separated by 500kb at 16q24.3. *D.F. Callen[1], S.A. Whitmore[1], M. d'Apolito[2], A. Savoia[2], A. Gardner[1], G. Kremmidiotis[1].* 1) Dept Cytogenetics/Molec Gen, Women's and Children's Hosp, South Australia, Australia; 2) Servizio di Genetica Medica, IRCCS-Ospedale CSS, San Giovanni, Italy.

The gene, SPG7, has recently been shown to be mutated in a recessive form of spastic paraplegia (Casari et al 1998). Exon trapping analyses of cosmid clones 500kb distal to the SPG7 gene on chromosome 16 indicated the presence of a homologous transcript. However, analysis of human EST clones revealed a transcript without a clear open reading frame (ORF). Complete genomic sequencing of 70kb in the region showed the presence of a complex intronic repeat which resulted in mis-alignment and mis-identification of human ESTs. Mouse ESTs which were identified in the region allowed the exons and the ORF of the human gene to be clearly delineated and this was confirmed by RT-PCR experiments. BLASTP searches show that the predicted protein is highly homologous to yeast mitochondrial ATPases as is Paraplegin which is the protein mutated in recessive spastic paraplegia. The newly characterised gene shows 52% identity to Paraplegin. We hypothesise that the close physical proximity is consistent with a duplication event and that this newly identified transcript may be mutated in some patients with this disease.

Program Nr: 1608 from the 1999 ASHG Annual Meeting

Identification of Survival Motor Neuron-interacting proteins, including a novel RNA helicase, by yeast-two-hybrid screening. *L. Campbell, K. Hunter, P. Mohaghegh, Y. Chan, K.E. Davies.* Department of Human Anatomy and Genetics, University of Oxford, Oxford, UK.

Spinal muscular atrophy (SMA) is a common neurodegenerative disease in which reduced levels of the survival motor neuron (SMN) protein results in loss of spinal motor neurons and associated proximal muscle weakness. The SMN protein is ubiquitously expressed. The high levels of SMN normally present in the motor neurons are greatly reduced in type I SMA patients. Proteins interacting with SMN have been identified in previously reported yeast-two-hybrid screens using HeLa and thymus cell cDNA libraries (1,2).

We screened a mouse brain cDNA library in an attempt to identify protein interactions relevant to the specific nature of the motor neuron degeneration characteristic of SMA. As previously reported by other investigators, interactions with prey clones encoding SMN (itself) and SIP1 were identified (1,3). Several additional interactors were also identified, two of which (LK1 and LK2) encoded previously unidentified genes. A consensus sequence for LK1 was obtained from 10 independent clones. Northern analysis showed that LK1 encodes for an mRNA of approximately 6kb, which is highly expressed in muscle and kidney. LK2 (5 clones) encodes a 3kb mRNA which is ubiquitously expressed, with highest levels in testis. Developmental mouse northern analysis indicated high levels of expression as early as embryonic day 7. Database analysis of the coding sequence identified LK2 as a novel member of the RNA helicase family. The significance of this interaction is as yet unknown, but such helicase proteins participate in most cellular RNA metabolic processes, including splicing, in which SMN plays an important role (4).

In vitro co-localisation studies and characterisation of LK1 and LK2 specific antibodies are in progress.

Program Nr: 1609 from the 1999 ASHG Annual Meeting

Identification and characterization of a candidate gene highly expressed in hippocampus for X-Linked Mental Retardation in Xp22.1-21.3. *A. Carrie[1], L. Jun[2], T. Bienvenu[1], M.C. Vinet[1], S. Frints[2, 3], B. Hamel[4], C. Moraine[5], J.P. Fryns[3], C. Beldjord[1], P. Marynen[2], J. Chelly[1].* 1) INSERM U129, ICGM, Paris, France; 2) The Flanders Interuniversity Institute for Biotechnology, UZ Gasthuiberg, Leuven, Belgium; 3) Center for Human Genetics, Clinical Genetics University, UZ Gasthuiberg, Leuven, Belgium; 4) University Hospital Nijmegen, Department of Human Genetics, Nijmegen, The Netherlands; 5) Centre Hospitalier de Tours, service de Genetique, Hopital Bretonneau, Tours, Franceé.

The Xp22.1-21.3 region, distal to the DMD gene is a region of interest for non specific X-linked mental retardation (XLMR). A confirmation of a potential XLMR locus was obtained through the detection of two inherited overlapping microdeletions associated exclusively with nonspecific mental retardation. In order to refine the MRX gene locus, we constructed cosmid and PAC contigs encompassing approximately 550 kb and covering the smallest deletion. This PAC contig was used by the Sanger Centre (Cambridge, UK) for large scale sequencing of the critical region. With the availability of the genomic sequence, we combined the computational sequence analysis with the screening of cDNA libraries, 5 and 3 rapid amplification of cDNA ends-PCR (RACE-PCR) and RT-PCR procedures to isolate and characterise a unique candidate gene which maps within the critical region. The transcript produced by this gene is highly expressed in the hippocampus including the dentate gyrus, the primary olfactory cortex, the entorhinal cortex, the perirhinal cortex, and occipito-parietal cortices. The combination of mapping data and its particular expression pattern strongly implicate this gene as a candidate for mental retardation in the Xp22.1-21.3 region. Mutations screening in mentaly retarded families which maps in the region and validation of this gene are in progress.

Program Nr: 1610 from the 1999 ASHG Annual Meeting

An in frame deletion of BRCA1 exon 20 in a family with early onset breast cancer and ovarian cancer. *N. Carson, C. Gilpin, A. Hunter, J. Allanson, H. Aubry.* Dept of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada.

The BRCA1 gene was cloned in 1994 and since then over 300 different mutations resulting in an increased risk of developing breast and ovarian cancer have been described. Most of these mutations are frameshift or nonsense mutations however a number are missense mutations. Recently large genomic rearrangements have also been characterized. All rearrangements described to date have been out of frame alterations leading to premature stop codons. We describe a family with early onset breast and ovarian cancer that has an in frame deletion of exon 20.

The proband developed breast cancer at the age of 40. She has one sister who developed breast cancer at 34 and another who died of breast cancer which developed at 44 years of age. Their mother died of ovarian cancer. Analysis of RNA using the protein truncation test for the region defined by exons 14 to 24 of the BRCA1 gene revealed a truncated protein approximately 4 kDa shorter than normal suggesting a mutation at the end of exon 23 or in exon 24. Sequence analysis of the cDNA revealed a deletion of all of exon 20 suggesting a possible splice site mutation, however, no mutation could be identified. Southern blot analysis of genomic DNA probed with exon 14- 24 cDNA revealed junction fragments for both HindIII and EcoRI digests while the BglII digest showed reduced intensity for the exon 20 specific fragment. These results support the presence of a large genomic deletion encompassing all of exon 20. Long range PCR using primers that flank the deleted region has shown that the deletion is approximately 4 kb in size.

This rearrangement is of interest as it is an in frame deletion resulting in the loss of 28 amino acids from the carboxyl end of the BRCA1 protein. In order to provide evidence for this mutation being the cause of breast cancer in this family, DNA will be analysed from the proband's affected relatives. Assuming this deletion segregates with breast cancer in this family, this is the first example of a large in frame deletion of BRCA1 leading to the development of breast and ovarian cancer.

Program Nr: 1611 from the 1999 ASHG Annual Meeting

Laron dwarfism mutation in a Chilean family with a probable Mediterranean ancestor. *M.P. Carvallo[1], C. Espinosa[1], M. Sjoberg[1], A. Rodriguez[1], T. Salazar[2], F. Cassorla[2], V. Mericq[2]*. 1) Human Genetics Program, ICBM, Faculty of Medicine, Universidad de Chile; 2) IDIMI,Universidad de Chile.Santiago, Chile.

Laron-type dwarfism is a rare autosomal recessive disorder caused by an insensibility to growth hormone. Several mutations in the growth hormone receptor gene (GHR), involving splice site, nonsense, and missense mutations have been described. One of these mutations creates a new splice site in exon 6 (E180splice), and has been detected in a cohort of 55 patients from south Ecuador and one oriental Jewish patient. It has been shown that this mutation is associated with a specific haplotype (I) within the GHR gene, which is also the most frequent Mediterranean haplotype (52%), suggesting a common Mediterranean ancestor for all these patients. We studied a Chilean family in which the parents were consanguineous and two of the seven children were affected from Laron syndrome. This family lives in the south of Chile in a region where a high aborigine admixture has been detected. We studied all family members through clinical and molecular analysis. Through SSCP and sequence analysis we found the same mutation described above, E180splice, in both patients. Both parents were heterozygous for this mutation, as well as four non affected siblings. Interestingly heterozygous members of the family show normal values in the clinical and phenotype evaluation. Only homozygous affected members have IGF-1 and its respective binding protein IGFBP-3 levels below normal, as well as low stature (-5.5 and -4.7 SDS). Since this is the third time that this mutation has been detected in world patients, we found interesting to perform the haplotype analysis in this family. We found an association of haplotype I with the mutated locus in the family, being this haplotype heterozygous in both parents. The frequency determination of the seven haplotypes in a Chilean population (60 chromosomes) revealed a very low frequency for haplotype I (0.07) being haplotypes II, III and IV, the most frequent ones (0.6, 0.16 and 0.22. These results strongly support the hypothesis that the E180splice mutation in the GHR receptor has a common Mediterranean ancestor. (supported by FONDECYT 197-0276).

Program Nr: 1612 from the 1999 ASHG Annual Meeting

Yeast and mouse models of Friedreich's ataxia. *P. Cavadini[1], S.S. Branda[1], C. Lesnick[1], F. Taroni[2], J. van Deursen[1], G. Isaya[1]*. 1) Pediatric & Adolescent Medicine, Mayo Clinic and Foundation, Rochester, MN; 2) Unit of Cellular Pathology, Department of Neurobiology, Istituto Nazionale Neurologico "C. Besta", Milan, Italy.

Friedreich`s ataxia (FRDA) is an autosomal recessive neurodegenerative disease caused by deficiency of the mitochondrial protein frataxin. Most patients are homozygous for GAA trinucleotide repeat expansions in the first intron of the frataxin gene, while ~4% of cases are compound heterozygous for a GAA expansion and a point mutation. The GAA expansion has been shown to lead to frataxin deficiency which in turn results in mitochondrial iron overload, but the functional consequences of the point mutations remain undefined. To carry out a mutational analysis of frataxin, we have expressed the human protein in a S. cerevisiae strain (yfh1D) lacking the endogenous yeast frataxin homologue (Yfh1p). In this system, the human frataxin precursor is efficiently imported and processed via an intermediate to the mature form. In vitro processing assays show that both cleavages are carried out by the yeast mitochondrial processing peptidase (MPP) and that the mature form of human frataxin is produced by cleavage at or near valine 55. The processed protein restores the respiratory competence of yfh1D indicating that the yeast mitochondrial protein import machinery produces a functional form of human frataxin. Yeast therefore represents an expression system suitable to study the functional consequences of point mutations identified in FRDA patients. To address the effects of reduced levels of frataxin in a mammalian system, we are also developing mutant mouse lines in which the frataxin gene carries a targeted insertion of a hygromycin B-poly(A) cassette in the first intron, which is predicted to produce heterozygous and homozygous mice with graded expression of frataxin. A genomic clone of ~18 kb containing exons 1-3 of the mouse frataxin gene has been isolated and restriction sites for construction of the targeting vector have been identified. This work is supported by the Muscular Dystrophy Association and the National Institute on Aging. P.C. is supported by the P. and L. Mariani Foundation, Milan, Italy.

Program Nr: 1613 from the 1999 ASHG Annual Meeting

Novel prion protein sequence variant associated with familial encephalopathy. *L. Cervenakova[1], C. Buetefisch[1], H-S. Lee[1], I. Taller[1], G. Stone[1], C.J. Gibbs, Jr.[1], P. Brown[1], M. Hallett[1], P. Gambetti[2], L.G. Goldfarb[1]*. 1) National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD 20892; 2) Case Western Reserve University, Cleveland, OH 44106.

Hereditary spongiform encephalopathies (hSE) are associated with mutations in the PRNP (prion protein) gene on chromosome 20p12-pter. We report a four-generation family, in which seven patients developed limb and truncal ataxia, dysarthria, myoclonic jerks and cognitive decline. The pattern of inheritance was autosomal dominant. The age of onset in the 30s, 40s or 50s, prolonged disease duration, cerebellar atrophy on imaging and the presence of synchronic periodic discharges on EEG suggested a familial encephalopathy resembling Gerstmann-Straussler-Scheinker disease. PrP deposits with laminar distribution in the cerebral cortex were identified in a biopsy sample obtained from one of the patients. A previously unknown A-to-G transition in codon 187 changing the codon sequence from CAC to CGC and resulting in a predicted histidine to arginine (H187R) substitution was detected in affected, but not in unaffected family members or 49 unrelated control individuals, suggesting a pathogenic role for this mutation. This novel H187R mutation is located within the third alpha-helical segment of the prion protein, in which other pathogenic mutations causing hSE have been identified.

Program Nr: 1614 from the 1999 ASHG Annual Meeting

Mutation analysis of prion gene in Chinese schizophrenic patients from Taiwan. *C.H. Chen[1,2], M.T. Tsai[2]*. 1) Department of Psychiatry, Tzu-Chi General Hosp, Hualien City, Taiwan; 2) Institute of Human Genetics, Tzu-CHi Medical College, Hualien City, Taiwan.

Prion disease may present as inherited, infectious and sporadic neurodegenerative disorders,resulting from aberrant prion protein conformation. These disorders, characterized by spongiform encephalopathy in the cerebral cortex, include Creutzfeldt-Jakob disease (CJD), kuru, Gerstmann-Straussler disease(GSD) and familial fatal insomnia (FFI). Recently, a new variant of CJD (vCJD) was observed. The psychiatric manifestations in the initial presentation in these cases raised the possibility that prion gene mutation may be associated with serious psychiatric disorders. In fact, Samaia and colleagues recently reported an asparagine to serine mutation at codon 171 (N171S) of prion gene in a family with serious psychiatric disorder (Nature 1997;390:214). Prompted by this finding, we first systematically sequenced the protein coding sequences of prion gene in 60 Chinese schizophrenic patients with family history from Taiwan. We identified two polymorphisms of prion gene in this cohort. However, no other mutation including N171S was identified. These two polymorphisms include methionine/valine at codon 129 (M129V) (allele frequencies: Met 96%, Val 4%) and glutamic acid/lysine at codon 219 (E219K) (allele frequencies: Glu 96%, Lys 4%). The M129V was found in both Caucasians and Orientals, while E219K was only found in Japan, not in Caucasians. Our data add further support that E219K may only occur in Orientals. Furthermore, genotype distributions and allele frequencies of these two polymorphisms were determined in 235 schizophrenic patients and 100 non-psychiatric controls. No significant difference was found between two groups. We further compared the estimated haplotype frequencies of these two polymorphisms between patients and controls. Similarly, no significant difference was identified. In conclusion, our study demonstrated that prion gene mutation may not play a major role in the pathogenesis of schizophrenia in Chinese population.
.

Program Nr: 1615 from the 1999 ASHG Annual Meeting

The Familial Mediterranean Fever protein interacts and colocalizes with a putative Golgi transporter. *X. Chen, Y. Bykhovskaya, M. Hamon, Z. Bercovitz, O. Spirina, N. Fischel-Ghodsian.* Ahmanson Department of Pediatrics, Steven Spielberg Pediatric Research Center, Medical Genetics Birth Defects Center, Cedars-Sinai Medical Center and UCLA School of Medicine, Los Angeles, CA.

The biological function of pyrin, the protein mutated in Familial Mediterranean fever (FMF), has not been elucidated. Based on sequence homology, a transcription factor activity was proposed for this neutrophil specific protein. In a yeast two hybrid assay, neither transcription activation activity nor any self interaction was detected for pyrin. Screening of an expression cDNA library of peripheral blood leukocytes using as bait the carboxyl portion of pyrin (amino acids 557-781) which contains most of the FMF mutations, led to the identification of P/M-IP1 (pyrin/marenostrin interacting protein 1). A splice variant of P/M-IP1, GTC-90, had previously been described as a component of the 13 S hetero-oligomeric protein complex that stimulates in vitro Golgi transport. We have now shown that P/M-IP1 colocalizes with pyrin in the perinuclear cytoplasm of Cos-7 cells, and that the interaction between these two proteins is impaired by FMF causing mutations in pyrin. These data suggest that, at some stage of its functional pathway, pyrin resides in the cytoplasm and might be involved in, or impacted by, cellular protein sorting by the Golgi apparatus. The data also imply that P/M-IP1 may be involved in the abnormal inflammatory response which occurs in patients with FMF.

Program Nr: 1616 from the 1999 ASHG Annual Meeting

Association between changes with time in the level of aberrantly spliced CFTR mRNA and CF lung disease severity. *O. Chiba-Falek[1], E. Kerem[2], M. Nissim-Raffinia[1], A. Tal[3], M. Aviram[3], A. Augarten[4], B. Kerem[1].* 1) Dept Genetics, Hebrew Univ, Jerusalem, Israel; 2) Dept Pediatrics and CF Center Shaare Zedek Medical Center, Hebrew Univ Medical School, Jerusalem, Israel; 3) Dept Pediatrics and CF Clinic, Soroka Medical Center, Ben Gurion Univ, Beer Sheva, Israel; 4) Dept Pediatrics and CF Clinic, Chaim Sheba Medical Center, Tel Hashomer, Israel.

The disease severity of cystic fibrosis patients carrying splicing mutations correlates with the level of aberrantly spliced CFTR transcripts. The aim of this research was to investigate if there are changes with time in the level of aberrantly spliced transcripts and if such changes might be associated with changes in disease severity. We analyzed the levels of aberrantly spliced RNA transcribed from the splicing mutation 3849+10kb C®T, in nasal epithelial cells from five CF patients at two time points, 1-4 years apart. Semi-quantitative non-differential RT-PCR of the samples, revealed considerable variability in the levels of the aberrantly spliced mRNA among the patients (0-28%). These levels correlated with the lung disease severity of the patients ($r=0.94$, $p=0.015$). Comparison of the levels of aberrantly spliced CFTR mRNA transcribed from the 3849+10kb C®T alleles at the two different time points, showed that changes in lung disease severity were associated with changes in the level of aberrantly spliced CFTR mRNA. Higher levels of aberrantly spliced CFTR mRNA in the second analysis were associated with declines in pulmonary functions. Lower levels of aberrantly spliced CFTR mRNA at the second time point were associated with lung function improvement. Normal lung function at both time points was associated with the presence of normal CFTR transcripts only. Thus, the regulation of alternative splice site selection may be an important mechanism underlying changes with time in CF disease severity in patients carrying splicing mutations. The same mechanism might underlie changes overtime in disease severity observed in other human genetic diseases caused by splicing mutations.

Program Nr: 1617 from the 1999 ASHG Annual Meeting

Activating Mutations in Fgfr3 are Responsible for Decreased Receptor Degradation. *Y. Cho[1,2], W.A. Horton[2]*. 1) Dept of Mol & Medical Genetics, Oregon Health Sciences Univ., Portland, OR; 2) Research Dept, Shriners Hospital for Children, Portland, OR.

Fibroblast growth factor receptor 3 (Fgfr3) is an important regulator of endochondral bone growth and mutations in Fgfr3 are responsible for the chondrodysplasia class of dwarfing conditions in humans. The pathogenesis of Fgfr3 mutations in inhibiting bone growth has been attributed in part to constitutive activation of the receptor, which in turn activates other signaling pathways such as STAT1/p21, the MAP kinases, and PLC-gamma. Here we propose an additional means by which mutations in Fgfr3 enhance signaling. We show that activating mutations in Fgfr3 lead to an accumulation of FGFR3 protein within the cell, in comparison to cells expressing wild type receptors. The accumulation of mutant proteins occurs despite similar RNA levels, suggesting the activated mutant Fgfr3 is not being degraded properly. This may be due to a problem with the processing of the receptor through the proteasome machinery or perhaps an accumulation of the mutant receptor in the ER/Golgi apparatus. To determine the role of the proteasome pathway in the degradation of FGFR3, we have studied the effects of proteasome inhibitors (lactacystin) and enhacers (geldanamycin, genestein, herbimycin) on cells transfected with mutant or wt Fgfr3. As well, we have generated a fusion protein in which the C-terminus of FGFR3 has been tagged with EGFP (Fgfr3-EGFP). We show the EGFP fusion does not affect the signaling properties of FGFR3 nor does FGFR3 affect the fluorescent properties of the EGFP. Using confocal microscopy, we have visualized an accumulation of FGFR3-EGFP in certain subcellular compartments.

Program Nr: 1618 from the 1999 ASHG Annual Meeting

Long QT syndrome: Genotype-phenotype relationship and relation to Sudden infant death syndrome (SIDS). *M. Christiansen[1], L.A. Larsen[1], I. Fosdal[2], I.H. Svendsen[3], P.S. Andersen[1], J.K. Kanters[4], J. Vuust[1], G. Wettrell[5].* 1) Dept Clinical Biochemistry, Statens Serum Inst, Copenhagen, Denmark; 2) Dept Pediatrics, Visby Hospital, Visby Gotland, Sweden; 3) Dept Medicine B, State University Hospital, Rigshopitalet, Copenhagen, Denmark; 4) Dept of Medical Physiology, University of Copenhagen, Denmark; 5) Dept of pediatric Cardiology, Lund University Hospital, Lund, Sweden.

Long QT syndrome (LQTS) is a genetic disease of the heart characterized by a prolonged QT interval on the ECG and a propensity for tachyarrhythmias, causing syncopes and sudden cardiac death. Recently, mutations in the genes KVLQT1, HERG, SCN5A, KCNE1, and MIRP1, coding for subunits of cardiac ion channels have been found to cause LQTS. In 12 Scandinavian families with LQTS we found seven different missense mutations and one trinucleotide duplication in HERG. In SCN5A we found one splice-site mutation, and in KVLQT1 we found one splice-site, one nonsense, and 3 missense mutations. No mutations were found in neither KCNE1 nor MIRP1. In 10 families the clinical picture was classical Romano-Ward syndrome with variable penetrance, but in two families LQTS exhibited recessive inheritance. At present there is no evidence of a founder effect, and the mutations causing LQTS seem to be private. Mutations in HERG seemed to have a worse prognosis than mutations in other genes. In two families with SIDS we found mutations in the PAS domain of the HERG K-channel. A pilot-study in 120 patients dying from SIDS revealed no pore-associated mutations in neither KVLQT1 nor HERG, or mutations in the c-terminus of KVLQT1, or in KCNE1. We suggest that the documented association between a pro-longed QT-interval on the ECG in newborns and the risk of SIDS could be caused by mutations in regulatory domains of the HERG ion channel. .

Program Nr: 1619 from the 1999 ASHG Annual Meeting

Graduated strategy for the molecular diagnosis of craniosynostosis syndromes. *K.M. Chun[1], A. Teebi[2], S. Kennedy[2], C.R. Forrest[3], P.N. Ray[1]*. 1) Depts. of Genetics and Pediatric Lab Medicine; 2) Dept. of Pediatrics; 3) Dept. of Surgery, Hospital for Sick Children, Toronto, Canada.

Craniosynostosis is the premature fusion of calvarial bones leading to an abnormal head shape. The craniosynostosis syndromes are clinically heterogeneous with overlapping features, which make an accurate diagnosis very difficult. Although accurate diagnosis, namely the clarification of a genetic lesion, does not have a direct impact on patient management in a lot of these cases, there is a significant benefit with accurate prenatal diagnosis. Genetic counsellors are able to offer better risk estimates of recurrences to non-manifesting carriers and their extended family members and for affected patients of reproductive age. Recent advances in gene discovery have shown that these craniosynostosis syndromes, with the exception of Apert syndrome, are genetically heterogeneous. Apert patients have a missense mutation in exon IIIa of the fibroblast growth factor receptor 2 (*FGFR2*) gene that affects codons 252 and 253. Crouzon and Pfeiffer patients have been shown to carry a variety of mutations in and around exons IIIa and IIIc of *FGFR2*, and mutations in *TWIST* have been shown to be the underlying defect in a number of Saethre-Chotzen patients. The recently defined non-syndromic craniosynostosis syndrome generally is due to a recurrent P250R mutation in *FGFR3*. However, this mutation has also been found in patients who were initially clinically diagnosed with Crouzon, Pfeiffer or Saethre-Chotzen syndrome. A recurrent mutation in *FGFR1* accounts for the familial cases of Pfeiffer syndrome. We surveyed 91 craniosynostosis patients at the molecular level and have found mutations in approximately half of them. Of note are two novel Pfeiffer mutations, both of which affect the 5' splice site of exon IIIc of *FGFR2*. They are 952-1G®A and 952-3del10insACC. In studying these 91 patients, a diagnostic strategy for craniosynostosis testing became apparent, where sequential analysis of recurrent mutations is followed by selective sequencing. This algorithm makes testing of craniosynostosis syndromes more efficient and cost-effective for the diagnostic laboratory.

Program Nr: 1620 from the 1999 ASHG Annual Meeting

Restricted distribution of loss-of-function mutations within the LMX1B genes of nail patella syndrome patients.
M.V. Clough, J.D. Hamlington, I. McIntosh. Institute of Genetic Medicine, Johns Hopkins Univ., Baltimore, MD.

Nail patella syndrome (NPS) is a pleiotropic condition characterized by dysplasia of the nails, hypoplasia of the patellae, elbow dysplasia and progressive kidney disease. The syndrome is inherited in an autosomal dominant manner and has been shown to result from mutations in the LIM-homeodomain encoding LMX1B gene. The LMX1B transcription factor plays a role in defining the development of dorsal specific structures during limb development; its role in other organs is unclear. The identification of 29 mutations published previously suggests that NPS is the result of haploinsufficiency for LMX1B (AJHG 63:1651, 1998). A further 39 mutations have been identified comprising 14 missense, 9 nonsense, 8 small insertions/deletions, 4 putative splice mutations and 4 larger deletions. Each of 22 missense mutations identified to date involves substitution of a conserved residue in either the LIM or homeodomains. All of 33 nonsense and frameshift mutations which would be predicted to prevent synthesis of full length polypeptides are also concentrated in and around these functional domains. No NPS mutations have been observed within the carboxy-terminal third of the coding sequence suggesting that mutations in this region are not inactivating or, at least, do not prevent LMX1B acting to dorsalize the developing limb. Any other phenotype resulting from mutation of this domain remains to be identified. The function of the C-terminal glutamine-rich region is under investigation. These findings support the hypothesis that NPS results from a 50% reduction in LMX1B function via a reduction in synthesis, disruption of secondary structure or failure to bind DNA.

Program Nr: 1621 from the 1999 ASHG Annual Meeting

***Jagged1* Mutations in Alagille Syndrome Patients and Their Families.** *R.P. Colliton[1,2], A. Genin[1,2], L. Bason[1,2], D.A. Piccoli[1,3], I.D. Krantz[1,2], N.B. Spinner[1,2].* 1) The Children's Hospital of Philadelphia, Phila, PA; 2) Div. Human Genetics; 3) Div. of Gastroenterology.

Alagille syndrome(AGS)is a dominant multisystem developmental disorder previously shown to result from mutations in Jagged1(JAG1),a ligand in the Notch signaling pathway.Clinically,AGS is characterized by bile duct paucity in combination with heart defects,ocular anomalies,vertebral anomalies and characteristic facial features.As part of our interest in understanding the full spectrum of JAG1 mutations associated with this disorder,and the clinical features associated with mutations in JAG1,we have studied a large cohort of patients with Alagille syndrome,and their family members,to identify mutations in JAG1.This study reports our current experience.To date,we have completely screened 127 probands for mutations in JAG1,by SSCP and identified 75 mutations(59%).Most of the mutations(72%)are protein truncating with 8%caused by splicing mutations,12%missense mutations and 4%total gene deletions.The mutations occur throughout the coding sequence of JAG1,within the evolutionarily conserved protein motifs. Very few of the mutations were seen in more than one unrelated patient,the exceptions being 2 small deletions in exons 16(2 pts.)and 17(3 pts.)and a small insertion in exon 9(3 pts.)all of which occurred where there were repeated sequences within the gene.The 9 missense mutations occurred at 6 different amino acids within the extracellular portion of JAG1.Parental samples were available for screening in 40 cases, and in 16 (40%)the mutations were inherited (8 maternal and 8 paternal).In the families in which there was an inherited mutation,a total of 38 JAG1 mutation carriers were identified. Clinical features in these individuals ranged from very mild to full blown AGS,with most individuals not meeting clinical criteria for the disorder.To identify the cause of disease in the 40%of AGS patients screened,in whom no mutation could be found,we are currently screening JAG1 cDNA using conformational strand gel electrophoresis(CSGE).This an alternative electrophoretic technique which has proven to be highly sensitive in studies of other genes.Results of these studies will be reported.

Program Nr: 1622 from the 1999 ASHG Annual Meeting

A novel mutation (Phe383Cys) in a patient with Achondroplasia carrying a classic Gly380Arg mutation. *D. Concolino[1], M. Baldi[2], M. Baffico[2], S. De Seta[1], T. Viscomi[1], G. Camera[3], P. Strisciuglio[1]*. 1) Dept. of Pediatrics, University of Catanzaro, Italy, MD; 2) Lab. of Human Genetics, Hospital "Galliera" of Genoa, Italy, PhD; 3) Surgical Center of Hand, Savona, Italy, MD.

Achondroplasia, the commonest form of non lethal osteochondrodysplasias, is inherited as autosomal dominant trait and is derived from a defective endochondral ossification which leads to a delayed growth of long bones with disharmonic dwarfism. This condition is usually sporadic and is associated with advanced paternal age. The achondroplasia gene, mapped to chromosome 4p16.3, encodes fibroblast growth factor receptor 3. Recently, several mutation have been identified, 95% of which result in a glycine to arginine substitution at codon 380 (Gly380Arg). Less common mutations are Gly375Cys and Gly346Glu. We present a case of achondroplasia with the classic Gly380Arg mutation on the paternal allele and a novel mutation Phe383Cys on the maternal allele. At admission in our hospital, the 3 days old patient showed rhizomelic shortness of limbs, large cutaneous folds of arms, craniofacial deformities such as macrocephaly, prominent forehead, flattened nasal root. Skeletal X rays confirmed the diagnosis of achondroplasia. Molecular analysis showed a point mutation T®G at the nucleotide 1148 (Phe383Cys) in additin to the classic mutation Gly380Arg. The same mutation Phe383Cys was detected in the asymptomatic mother. The point mutation T®C at the nucleotide 1350 (Phe384Leu) is found in 0.04% of achondroplasic patients, and it is considered a polymorfism, because its presence in normal population. This mutation leads to substitution from phenylalanine to cysteine, either neutral and hydrofobic aminoacids, that may explain absence of disease in the carrier. On the other hand, the mutation Phe383Cys, never reported previously, results in the substitution of a neutral hydrofobic aminoacid in a neutral polar one, so that may produce an alterated protein. Further reports are necessary to understand the consequences of this mutation.

Program Nr: 1623 from the 1999 ASHG Annual Meeting

ULTRASTRUCTURE OF CORNEAL EPITHELIUM FROM A PATIENT WITH MEESMANN'S CORNEAL DYSTROPHY AND NOVEL MUTATIONS IN KERATIN 12. *L.D. Corden[1], C.M. Coleman[1], A.D. Irvine[2], O. Swensson[3], B. Swensson[4], R. Rochels[4], G.C.M. Black[5], W.H.I. McLean[1]*. 1) Epithelial Genetics Group, Dundee, UK; 2) Dermatology, Belfast, UK; 3) Dermatology, Kiel, Germany; 4) Ophthalmology, Kiel, Germany; 5) Clinical Genetics, Manchester, UK.

Recently, we identified the first mutations in corneal keratins K3 and K12 in kindreds with Meesmann's corneal dystrophy (MCD). Here, we report 6 further K12 mutations and ultrastructural analysis of MCD cornea. Mutation 428G>C was identified in a German family, predicting amino acid change R135T. This mutation represents an ancestral German mutation. In another German kindred, we detected novel mutation 413A>C, predicting amino acid substitution Q130P. A novel mutation was detected in an American kindred, 410T>C, which predicts the amino acid substitution M129T. The other three novel mutations found were: 451G>T (V143L) in a kindred from Saudi Arabia; 423T>G (N135K) in an English kindred and 1300A>G (I426V) in a second American kindred. The mutations were found to co-segregate with MCD in the families and were excluded from 100 normal chromosomes by restriction enzyme analysis. All 6 mutations occur in the helix boundary motifs which are highly conserved between intermediate filament proteins. Mutations in these regions in other keratins have previously been shown to severely compromise cytoskeletal function, leading to phenotypes characterised by epithelial fragility. A total of thirteen mutations have now been reported in the K12 gene. In addition to the genetic analysis, ultrastructural examination was performed on corneal tissue from one MCD patient carrying the N135K mutation. This revealed perinuclear vacuolation, basement membrane abnormalities and cellular degeneration. In addition, thickened, shortened and clumped filamentous structures were seen, highly analogous to the keratin filament aggregates in the skin disease epidermolysis bullosa simplex, caused by mutations in the basal cell keratins K5 and K14. Thus, these abnormal subcellular structures were recognised for the first time as keratin filament aggregates, providing further evidence for the pathologic relevance of keratin mutations in MCD.

Program Nr: 1624 from the 1999 ASHG Annual Meeting

Characterization of candidate genes for Microphthalmia with Linear Skin Defects (MLS) through generation of targeted deletions in the mouse. *T.A. Cormier[1], I.B. Van den Veyver[1], S.K. Prakash[1], A. McCall[1], B. Wu[1], H.Y. Zoghbi[1,2]*. 1) Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Houston, TX.

MLS is a disorder caused by a dominant, male lethal deletion of Xpter to Xp22.3. Heterozygous females have microphthalmia, skin lesions on the head and neck, agenesis of the corpus callosum and mental retardation. We propose that the loss of function of one or more previously isolated genes (*ARHGAP6*, *HCCS* and *MID1*) from the 450 Kb candidate region causes MLS. Because MLS is caused by deletions, mutation analysis of candidate genes in patients is not possible. Therefore, to understand the contribution of each gene, we set out to generate inactivating mutations in *arhgap6*, *hccs* and *mid1*, and to engineer targeted deletions of the homologous region in the mouse. We targeted each gene in ES cells with selectable markers and one *lox*P site (using either replacement or insertion vectors). The markers and *lox*P sites were oriented to generate specific deletions in the region using Cre recombinase.

We replaced *61b3r* (the homologue of a human 5' UTR exon of *MID1* at the telomeric boundary of the region) with exons 3-9 of HPRT. *61b3r* was also replaced in an ES cell line previously targeted at the *arhgap6* locus (at the centromeric boundary of the region). Both $61b3r^{-}$ and $61b3r^{+/-}$/$arhgap6^{+/-}$ animals are apparently unaffected by the replacements. $61b3r^{+/-}$/$arhgap6^{+/-}$ females are being mated to males transgenic for Cre recombinase under an EIIa promoter which then drives expression in the zygote. The offspring of this mating are expected to be models for human MLS.

A vector with exons 3-9 of HPRT was inserted into exon 1 of the *mid1* gene. We have generated a $mid1^{ins/+}$/$arhgap6^{+/-}$ mouse which will be used to generate a deletion larger than *61b3r*/*arhgap6*. Characterization of these mice will establish the role of *MID1* in the MLS phenotype.

Program Nr: 1625 from the 1999 ASHG Annual Meeting

Friedreich ataxia mouse models. *M. Cossee, H. Puccio, H. Koutnikova, V. Campuzano, K. Fischbeck, J.L. Mandel, M. Koenig.* Inst Genetics, Illkirch Strasbourg, Illkirch, France.

Friedreich ataxia is caused by the loss of function of frataxin, a mitochondrial protein conserved through evolution. Yeast knock-out models, histological and biochemical data from heart biopsies or autopsies from patients suggest that frataxin may play a role in mitochondrial iron transport or in iron-sulfur proteins assembly. Affected human tissues are rarely available to test this hypothesis. We generated a mouse model by inactivation of the frataxin gene homologue. The gene disruption was obtained by deletion of exon 4, which causes a frame-shift. The genotype of surviving offsprings from heterozygote intercrosses was either wild-type or heterozygous; no mouse was homozygous for the deleted allele. We are analysing embryos to investigate the stage of embryonic lethality and the mechanism of degeneration, with a particular emphasis on iron accumulation. To circumvent embryonic lethality, we are generating a conditional knock-out model, based on the Cre-lox system in which exon 4 will be deleted under temporal and tissue specific control, and a knock-in mouse model by insertion of the H180R missense mutation found in a typical Friedreich ataxia patient (H183R). These models will allow to investigate the mechanism of the disease and to test anti-oxidant therapies.

Program Nr: 1626 from the 1999 ASHG Annual Meeting

Severe mutations in the *ABCR* gene are associated with a clinical subtype of autosomal recessive retinitis pigmentosa. *F. Cremers[1], A. Maugeri[1], J. Klevering[2], S.L. Go[2], A. Wagner[3], H. Brunner[1], C. Hoyng[2].* 1) Dept Human Genetics, Univ Hosp Nijmegen, Nijmegen, Netherlands; 2) Dept Ophthalmology, Univ Hosp Nijmegen, Nijmegen, Netherlands; 3) Dept Clinical Genetics, Erasmus Univ, Rotterdam, Netherlands.

Mutations in the retina specific ATP-binding cassette transporter (*ABCR*) gene are associated with Stargardt disease (STGD) and an as yet unknown fraction of autosomal recessive (ar) retinitis pigmentosa (RP) and cone-rod dystrophy (CRD). In addition, heterozygous ABCR mutations increase the risk for age-related macular degeneration (AMD). Our studies have shown that *ABCR* mutations can be grouped in different classes of severity and that the severity of the retinal disease is inversely correlated with the remaining activity of the ABCR protein. In patients with the most severe phenotype, RP, both *ABCR* genes carry null mutations.

Clinically, RP patients with *ABCR* mutations can be distinguished from other RP patients because they show a more severe visual loss due to an early macular degeneration. Based on our model we estimated that *ABCR* mutations might account for a sizeable fraction (10-15%) of arRP. In this study, we have selected a group of 15 sporadic and two novel familial cases with RP which show the typical early macular involvement. Upon SSCP screening of approximately one-third of the *ABCR* gene, we identified *ABCR* mutations in at least 3 patients with RP. In a family in which patients with RP and STGD are second counsins and the father of the RP patient shows AMD, a homozygous splice site mutation (768G®T) was found in the RP patient, whereas the STGD patient carries the same splice site mutation and a mild 2588G®C founder mutation. Another sporadic RP patient was also shown to be homozygous for the 768G®T mutation. A sporadic patient with RP shows a deletion of exons 20-22 on one allele and a splice site mutation (IVS28-2A®G) in the other allele. In conclusion, this study confirms a relatively frequent involvement of the *ABCR* gene in arRP, in particular in patients with an early macular involvement.

Program Nr: 1627 from the 1999 ASHG Annual Meeting

An approach for screening of Hereditary Hyperferritinemia Cataract Syndrome (HHCS) by a new DG-DGGE method for rapid mutational scanning in ferritin L-chain IRE. *L. Cremonesi[1], A. Fumagalli[1], N. Soriani[1], M. Ferrari[1], E. Tinazzi[2], M. Camparini[3], R. Aldigeri[3], D. Girelli[2], P. Arosio[4], S. Levi[5].* 1) Unit of Genetics and Molecular Diagnostics, IRCCS, H. San Raffaele, Milan, Italy; 2) Department of Clinical and Experimental Medicine, University of Verona, Italy; 3) Institute of Ophthalmology, University of Parma, Italy; 4) Chair of Chemistry, University of Brescia, Spedali Civili, Brescia, Italy; 5) Protein Engineering, IRCCS, H. San Raffaele, Milan, Italy.

HHCS is an autosomal dominant disorder characterized by elevated serum ferritin levels, unrelated to iron status, and early onset bilateral cataract. The disease is caused by heterogenous mutations on the iron responsive element (IRE) sequence in the noncoding region of L-ferritin. The IRE mutations so far reported have been identified by DNA sequencing. We developed double-gradient denaturing gradient gel electrophoresis (DG-DGGE) conditions to easily identify sequence alterations. By this method we analyzed seven known mutations (G41C, A40G, C39T, G32A, T22G/C18T, D10-38, G51C), representing the majority of the mutations so far described. All mutations displayed an altered electrophoretic pattern. Thus, the optimized DG-DGGE technique appears a powerful and rapid method for scanning L-ferritin IRE and study the prevalence of the mutations in hyperferritinemias and juvenile cataracts, and to evaluate the presence of asymptomatic polymorphisms in the sequence region. In collaboration with an Ophthalmologycal center, where more than 2,000 cataract operations (mostly age-related) are performed per year, we started a pilot study to evaluate the frequency of HHCS in cataracts. We selected 50 cases including "unexplained" juvenile cataract (mean age 33.4), senile cataracts and age-matched controls. All samples were negative for IRE mutations. The work has been extended to a selected population of 20 cases with juvenile cataract and hyperferritinemia (more than 400 mg/L). We are planning an approach to screen for HHCS mutations in a large population of blood donors and subjects with hyperferritinemia (more than 500 mg/L), with cataract. (Partially supported by a grant of Telethon-Italy).

Program Nr: 1628 from the 1999 ASHG Annual Meeting

Correlation of sarcospan and sarcoglycan expression in patients with muscular dystrophies. *R.H. Crosbie[1], H. Collin[2], S. Moore[3], F.M.S. Tomé[2], M. Fardeau[2], K.P. Campbell[1].* 1) Howard Hughes Medical Institute, Dept. of Physiology & Biophysics, Dept. of Neurology, University of Iowa College of Medicine, Iowa City, IA; 2) INSERM 523, Institut de Myologie, Hôpital de la Salpêtrière, Paris; 3) Dept. of Pathology, University of Iowa College of Medicine, Iowa City, IA.

We recently identified a unique member of the dystrophin-associated glycoprotein complex, which we have named sarcospan based on its multiple sarcolemma-spanning domains (Crosbie et al.,1997). The gene encoding sarcospan is localized to human chromosome 12p11.2 and to date, no mutations in this gene have been found to cause muscle-related disorders. In order to assess the potential role of sarcospan in disease pathogenesis and to further probe the molecular associations of sarcospan with other proteins of the dystrophin-glycoprotein complex, we examined sarcospan expression in muscle from a panel of sarcoglycan-deficient limb-girdle muscular dystrophy patients. Primary mutations in a, b,g, or d-sarcoglycan disrupt the structural organization of the sarcoglycan complex and consequently result in LGMD-2D, 2E, 2C and 2F, respectively. In summary, we demonstrate that sarcospan expression is correlated with the level of sarcoglycan expression in muscle from LGMD patients. Sarcospan is dramatically reduced in all sarcoglycan-deficient patients examined. We show that sarcospan is tightly associated with the sarcoglycan complex and that membrane targeting and localization of sarcospan is dependent on the sarcoglycan complex. In order to determine if primary mutations in sarcospan are associated with human disease, we have developed a PCR-based screening assay and have identified intragenic polymorphic markers that are important for linkage analysis. Our data provide important implications about sarcospan's involvement in as yet uncharacterized forms of muscular dystrophy.

Program Nr: 1629 from the 1999 ASHG Annual Meeting

Aberrant splicing in the presenilin-1 intron 4 mutation causes presenile Alzheimers disease by increased ab**42 secretion.** *M. Cruts[1], C. De Jonghe[1], E.A. Rogaeva[2], C. Tysoe[3], A. Singleton[3], H. Vanderstichele[4], W. Meschino[2], B. Dermaut[1], I. Vanderhoeven[1], H. Backhovens[1], E. Vanmechelen[4], C.M. Morris[3], J. Hardy[5], D.C. Rubinsztein[3], P.H. St.George-Hyslop[2], C. Van Broeckhoven[1].* 1) Flanders Interuniversity Institute for Biotechnology (VIB), Born-Bunge Foundation (BBS), University of Antwerp (UIA), Department of Biochemistry, Antwerpen, Belgium; 2) Centre for Research in Neurodegenerative Disease, University of Toronto and North York General Hospital, Ontario, Canada; 3) Cambridge Institute for Medical research, Wellcome/MRC Building, Addenbrookes Hospital, Cambridge and MRC Neurochemical Pathology Unit, Newcastle General Hospital, Newcastle upon Tyne, UK; 4) Innogenetics Inc., Zwijnaarde, Belgium; 5) Neurogenetics Laboratory, Mayo Clinic Jacksonville, Florida, USA.

We previously described a splice donor site mutation in intron 4 of presenilin-1 (PSEN1) in 2 autopsy-confirmed patients with early-onset Alzheimer's disease (AD). Since then, we identified 4 additional AD cases. The mutation segregates in an autosomal dominant manner and genotype analysis of markers located near PSEN1 indicated that all cases have one common ancestor. The mutation involves a deletion of the first nucleotide of intron 4 destroying the spice donor consensus sequence and produces 3 different transcripts due to aberrant splicing: 2 deletion transcripts (D4 and $D4_{cryptic}$) and 1 insertion transcript (ins_{TAC}). The deletion transcripts result in the formation of C-truncated PSEN1 proteins while the insertion transcript produces full-length PSEN1 with one extra amino acid (Thr) inserted between codons 113 and 114 (PSEN1 T113-114ins). *In vivo*, the truncated proteins were not detectable in brain homogenates or lymphoblast lysates of mutation carriers. *In vitro*, HEK-293 cells overexpressing D4, $D4_{cryptic}$ or ins_{TAC} PSEN1 cDNAs showed increased Ab42 secretion (~3.4 times) only for the insertion cDNA construct. Increased Ab42 production was also observed in brain homogenates. Our data indicate that in case of the intron 4 mutation, the AD pathophysiology results from the presence of the PSEN1 T113-114ins protein comparable to cases carrying PSEN1 missense mutations.

Program Nr: 1630 from the 1999 ASHG Annual Meeting

The TaqI(B) Polymorphism in the CETP Gene is Associated with Variation in High Density Lipoprotein. *L.A. Cupples[1], J.M. Ordovas[2], P.W.F. Wilson[3,4], E.J. Schaefer[2].* 1) Dept Epid/Biostatistics, Boston Univ Sch Public Health, Boston, MA; 2) Tufts University, Boston, MA; 3) Boston Univ Sch Medicine, Boston, MA; 4) Framingham Heart Study, NIH/NHLBI, Framingham, MA.

High levels of high density lipoprotein cholesterol (HDL-C) are known to be protective against the development of coronary heart disease while low levels are known to be a risk factor. Cholesteryl ester transfer protein (CETP) facilitates the exchange of triglycerides and cholesteryl ester between lipoprotein particles. The CETP gene has been localized to 16q21 and encompasses 16 exons. CETP deficiency is associated with hyperalphalipoproteinemia, primarily due to an increase of cholesteryl ester-enriched large-sized HDL. The TaqI(B) polymorphism (RFLP) in the CETP gene was typed in 2916 subjects from the Framingham Offspring Study with the goal of examining its relationship to a variety of lipid measures, including total cholesterol (TC), HDL-C, LDL-C and triglycerides. The B2 allele at this site has been previously associated with increased HDL-C levels. To evaluate its relationship to a variety of lipid measures, we performed measured genotype analyses with this polymorphism, classifying subjects as B1B1, B1B2 or B2B2. These analyses were performed using the variance component approach implemented in SOLAR adjusting for gender, age, body mass index, smoking, alcohol intake, use of beta blockers, apolipoprotein E, menopausal status and estrogen replacements in women. The results of this analysis indicate an increasing gradient in HDL-C levels with an increase in the number of B2 alleles ($p < 0.0001$). A similar result is found for HDL-C subfractions, HDL2 and HDL3. The TC/HDL-C ratio shows a corresponding decreasing gradient with an increase in the number of B2 alleles. A genome scan of 1535 subjects in 236 Framingham families revealed no lod scores above 0.5 in this region on chromosome 16. Since the estimated proportion of variation in HDL-C in our measured genotype analysis due to the TaqI(B) polymorphism is approximately 1 percent, we conclude that identification of genes need to be tackled with both candidate gene and linkage approaches.

Program Nr: 1631 from the 1999 ASHG Annual Meeting

Characterization of SMN hybrid genes in Spanish SMA patients: evidence of *de novo* and compound heterozygous cases. *I. Cusco[1], M.J. Barcelo[1], E. Bussaglia[2], M. Baiget[1], E. Tizzano[1]*. 1) Genetics, Hospital Sant Pau, Barcelona, Spain; 2) Pathology,Hospital Sant Pau, Barcelona, Spain.

Spinal muscular atrophy (SMA) is classified in type I (severe form), type II (intermediate form) and type III (mild/moderate form) and is caused by mutations in the Survival Motor Neuron telomeric (SMNt) gene. A centromeric functional copy of this gene (SMNc) is deleted in 10% of the control Spanish population. Approximately in 85% of the Spanish SMA patients, a homozygous deletion of exon 7 and 8 of the SMNt gene is detected regardless of the phenotype. In addition 5% of the cases have only a deletion of exon 7. We analyzed 14 unrelated cases with this mutation to characterize centromeric-telomeric hybrid genes. We have studied a possible phenotype-genotype correlation comparing the different structures of the hybrid alleles, the presence or absence of NAIP and the origin of the mutation in their parents. Twelve patients showed a CCT structure (Cent intron 6-Cent exon 7- Tel exon 8) characteristic of a gene conversion event. However one case showed concomitantly a homozygous deletion of the centromeric exon 8, indicating that an intrachromosomal deletion was involved. Two cases were type I, 7 type II and 3 type III. Nine patients retained at least one copy of NAIP exon 5 (being present in the 3 type III cases). All but one CCT case were inherited. The exemption was probably a *de novo* case although germinal mosaicism could not be excluded. Another type II patient showed the hybrid structure TCT (Tel intron 6-Cent exon 7- Tel exon 8) with deletion of NAIP and the remaining case was a very mild affected woman with a CCT structure in one chromosome and a TCT in the other with presence of NAIP. We conclude that: 1) in all type III cases at least one copy of NAIP 5 was detected, while this gene was absent only in types I and II hybrid chromosomes; 2) no association with the paternal or maternal origin of the mutation was found 3) *de novo* hybrid genes may account for a small but still important proportion of the cases; 4) the presence of two chromosomes with gene conversions may be associated with the presence of a very mild phenotype.
Supported by FIS 98-556 and Telemarato TV3.

Program Nr: 1632 from the 1999 ASHG Annual Meeting

Mapping of the Fried syndrome gene through a maternally inherited Xp deletion to Xpter-DXS987. *M.J. Dasouki[1], C. Cohick[1], C. Vnencak-Jones[2], V.G. Dev[3].* 1) Sect Medical Gen & Molec Med, Children's Mercy Hosp, Kansas City, MO; 2) Department of Pathology, Vanderbilt University, Nashville, TN; 3) Genetics Associates, Nashville, TN.

Fried syndrome is an X-linked mental retardation (XLMR) syndrome with hydrocephalus, and mild facial dysmorphism. It has considerable similarity to the MASA syndrome which results from mutations in the L1CAM gene in Xq28. Previous molecular studies indicated that this gene lies within the interval KAL-DXS989 in Xp22. Here, we report a maternally inherited Xpter-22.3 deletion found in an 18-year old G1P1 woman and her female infant. Prenatal ultrasonographic examination of the daughter showed massive hydrocephalus due to aqueductal stenosis while her mother had short stature only. FISH analysis using X-WCP (Whole Chromosome Paint) failed to reveal any evidence of a cryptic translocation in either mother or child. In both individuals, the steroid sulfatase and Kallman syndrome gene specific probes were found to be deleted by FISH analysis.X-chromosome inactivation studies performed on peripheral blood lymphocytes using cytogenetic techniques demonstrated that in both mother and daughter, 20/20 cells showed the deleted X-chromosome to be inactive. However, peripheral blood DNA analysis at the HUMARA locus showed exclusive inactivation of the deleted X-chromosome in the mother while the daughter had exclusive inactivation of her normal X-chromosome. Genotyping using fluorescently labeled microsatellite markers that map to the interval DXS6807-DXS6789 (distal 100 cM on Xp) showed biallelic inheritance except for the most distal marker DXS6807. These results indicate that the entire X-chromosome pseudo-autosomal region including the SHOX gene was deleted and that the Fried syndrome gene maps to the distal 13.8 cM of Xp. Additional studies using FISH and microsatellite gentoyping are underway to narrow the deleted region. Further X-chromosome inactivation studies in other tissues may provide a better explanation for the difference in phenotypes and X-inactivation patterns between mother and child.

Program Nr: 1633 from the 1999 ASHG Annual Meeting

Cardioferlin, a novel dysferlin family member and potential modifier of muscular dystrophy. *D.B. Davis[1], E.M. McNally[2]*. 1) Department of Pathology, University of Chicago, Chicago, IL; 2) Department of Medicine, Section of Cardiology, University of Chicago, IL.

Dysferlin was recently identified as the gene mutated in Limb Girdle Muscular Dystrophy type 2B and Miyoshi myopathy (Bashir, et al., Nat Genet 1998 Sep;20(1):37-42 and Liu, et al., Nat Genet 1998 Sep;20(1):31-6). These two muscle disorders vary considerably in phenotypic severity, and the type of mutation found in dysferlin cannot account for these differences. This suggests that additional genetic loci may modify phenotypic severity. Through homology searches, we have identified and cloned a novel cDNA that codes for a protein we have termed cardioferlin. Cardioferlin has been localized to human chromosome 10q24. Cardioferlin, like dysferlin, encodes a 7.5 kb mRNA with an open reading frame encoding a protein of at least 2087 amino acids. The two proteins are 58% identical and 75% similar at the amino acid level. Both proteins contain four C2 domains, which are involved in membrane fusion events. Cardioferlin also contains a unique SH3 domain, implying other protein-protein interactions. Northern blot analysis shows that cardioferlin mRNA is expressed in all tissues, with an eight-fold higher expression level in heart than in skeletal muscle. We have also developed a polyclonal antibody specific for cardioferlin. Cardioferlin is a 230 kD protein found in membrane fractions of heart and skeletal muscle. Due to the high level of similarity between dysferlin and cardioferlin, it is possible that cardioferlin may be able to perform a partial rescue of the loss of dysferlin in LGMD 2B and Miyoshi myopathy explaining the milder spectrum of these muscular dystrophies. Due to the presence of C2 domains in this family of proteins, it is likely that they play a role in membrane repair. We have also demonstrated upregulation of cardioferlin in skeletal muscle membranes from mdx mice lacking dystrophin. Upregulation of cardioferlin may play an important role in the repair of membrane damage seen in some forms of muscular dystrophy. Due to its expression pattern, cardioferlin is a promising candidate as a primary or secondary effector in muscular dystrophy or cardiomyopathy.

Program Nr: 1634 from the 1999 ASHG Annual Meeting

Towards identification of the gene responsible for Acadian Usher Syndrome on 11p. *M. DeAngelis[1,2], S. Savas[2], C. Donaldson[2], L. Buckley[2], J. Doucet[3], C. Visser[2], Z. Den[2], M. Pelias[2], P. Deininger[4], B. Keats[1,2], M. Batzer[1,2].* 1) Neuroscience Ctr., LSU Med Ctr., New Orleans, LA; 2) Dept. of Biometry and Genetics, LSU Med Ctr., New Orleans, LA; 3) Dept. of Biological Sciences, Nicholls State Univ., Thibodaux, LA; 4) Tulane Cancer Ctr., New Orleans, LA.

The Usher syndromes are a group of autosomal recessive disorders characterized by congenital sensorineural hearing impairment and progressive retinitis pigmentosa usually resulting in blindness. Three types of Usher Syndrome have been described and chromosomal locations of nine genetic loci reported, with only two of the genes identified to date. Usher syndrome Type 1, the most severe form, is distinguishable from Usher syndromes types II and III by a severe to profound deafness, absence of vestibular function and an earlier onset of retinal degeneration. Type I Usher syndrome occurs in populations throughout the world, including a small Southwestern Louisiana population descended from French speaking emigrants exiled from Acadia. Our studies focus on the 11p locus for type 1c Usher syndrome (USH1C) in families of Acadian ancestry. Previously, we constructed a contiguous sequnce-ready physical map of bacterial artificial chromosomes (BACs) containing the USH1C critical region using 17 genetic markers. These genetic markers allowed us to refine the critical region by haplotype analysis to a physical distance of less than 400 kb between genetic markers D11S1397 and D11S1890. Sequencing to a 5X coverage of one 150 kb BAC from this region followed by computer-aided analysis yielded 3 genes, that are excellent USH1C candidates. At present we are using RT-PCR and northern blot analysis in order to study the expression pattern of these genes. These genes will then be used for mutational analysis in affected patients in order to identify the gene responsible for USH1C.

Program Nr: 1635 from the 1999 ASHG Annual Meeting

Familial case of Frasier Syndrome indicates that the WT1 KTS donor splice site mutation does not affect ovarian development and function. *L.A. Demmer[1], W.A. Primack[1,2], V. Loik[3], R.S. Brown[1], N. Therville[4], K. McElreavey[4].* 1) Dept Pediatrics, Univ Massachusetts Memorial Health Care, Worcester, MA; 2) Fallon Clinic, Worcester, MA; 3) Department of Obstetrics, Baystate Medical Center, Springfield, MA; 4) Department of Human Immunogenetics, Institut Pasteur, Paris, France.

The description of Frasier syndrome until now has been restricted to XY females with gonadal dysgenesis, progressive glomerulopathy and significant risk of gonadoblastoma. Mutations in the donor splice site in intron 9 of the Wilms' tumor (WT1) gene have been shown to cause Frasier syndrome and are distinct from WT1 exon mutations associated with Denys Drash syndrome. The WT1 gene, which is essential for normal kidney and gonadal development, encodes a zinc finger transcription factor. The intron 9 alternatve splice donor site mutation seen in Frasier syndrome leads to loss of three amino acids (+KTS isoform), thus disrupting the ratio of the +KTS/-KTS isoforms critical for proper gonadal and renal development.

Here we report two sisters with identical intron 9 mutations (cytosine-thymidine transition at position +4 of the donor splice site). The proband carries a classic diagnosis of Frasier syndrome with focal segmental glomerulosclerosis (FSGS) and 46,XY gonadal dysgenesis while her sister has the progressive glomerulopathy but a 46,XX karyotype and normal female development. This demonstrates that the proper WT1 isoform ratio is critical for renal and testicular development, but does not affect either ovarian development or function.

We propose that the clinical definition of Frasier syndrome should be broadened to include 46,XX females with normal genital development and FSGS associated with a WT1 intron 9 donor splice site mutation. The risk for gonadal malignancy in these patients as well as the risk for kidney disease and gonadal dysgenesis in their offspring needs to be considered.

Program Nr: 1636 from the 1999 ASHG Annual Meeting

A truncation mutation (L126Z) of SOD1 gene leads to ALS-like phenotype in transgenic mice. *H-X. Deng, R. Fu, H. Zhai, T. Siddique.* Neurology Dept, Northwestern Univ, Chicago, IL.

Amyotrophic lateral sclerosis (ALS) is a paralytic disorder caused by degeneration of motor neurons in the brain and spinal cord. Mutations in SOD1 gene account for approximately 20% of familial ALS cases. The SOD1-knockout mice develop normally and the transgenic mice expressing several missense mutations of SOD1 gene develop ALS-like phenotype, suggesting a gain of toxic function mechanism underlines the disease. How mutations in SOD1 gene cause Familial ALS and which portion of SOD1 polypeptide is responsible for its toxicity are unknown. We previously described a familial ALS patient with a truncation mutation in SOD1 (L126Z), i.e. a stop codon replaced codon for Leu at 126, truncating the other 28 amino acids at C-terminus. The truncated SOD1 is not detectable in the erythrocytes and lymphoblastoid cells of the patient. To identify the selective expression of truncated SOD1 and further investigate the pathogenesis using this unique mutation, we have developed a transgenic mouse model that expresses this truncated SOD1. These transgenic mice develop an ALS-like phenotype. The symptoms are detectable around 280~320 days and the aniamls die 2~3 weeks later. These results provide proof of principle that a merely shortened version of the SOD1 protein is sufficient to cause disease and indicate that 1) the full length SOD1 is not a requirement for the development of ALS; 2) the C-terminal portion (28 amino acids) is not involved in the toxicity; 3) the N-terminal portion (125 amino acids) is responsible for the toxicity that causes motor neuron death in ALS. Further characterization of this mouse model may provide clues to the pathogenesis of this fatal disease.

Program Nr: 1637 from the 1999 ASHG Annual Meeting

Phenotypic Variability in a Large Aniridia Pedigree with a Novel *PAX6* 1410delC Mutation. *J.L. Dickinson[1], J.E. Craig[2], M. Sale[1], S. Nicholls[1], J. Love[3], I. Hanson[3], S.J. Matthews[2], D.A. Mackey[1,2].* 1) Menzies Centre, University of Tasmania, Australia; 2) Centre for Eye Research Australia, University of Melbourne, Australia; 3) MRC Human Genetics Unit, Edinburgh, Scotland.

Purpose: To investigate phenotypic variability with a mutation in the *PAX6* gene. **Methods:** 11 affected individuals in a 3 generation pedigree were examined. Anterior segment and fundus photographs, automated perimetry and IOP measurement were performed. **Results:** Mutation analysis revealed a single base deletion 1410delC in the *PAX6* gene. Affected individuals ranged from total aniridia to minimal anterior segment findings. Other findings included keratitis, cataract, glaucoma, disc anomalies and foveal hypopolasia. **Conclusions:** A novel mutation in the *PAX6* gene is associated with considerable phenotypic variation. Pedigrees such as this may be useful to identify other genes responsible for anterior segment development.

Program Nr: 1638 from the 1999 ASHG Annual Meeting

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) : familial report with thymidine phosphorylase mutation. *V. Dideberg[1], A. Verloes[1], B. Sadzot[2], M. Reznik[3], A. Rotig[4], I. Nishino[5], M. Hirano[5]*. 1) Human Genetics, Liege University Hospital, Liege, Belgium; 2) Department of Neurology, Liege University Hospital, Liege, Belgium; 3) Department of Neuropathology, Liege University Hospital, Liege, Belgium; 4) Research Unit on Children's Genetic Handicaps, Hopital Necker-Enfants-Malades, Paris, France; 5) Dept of Neurology, Columbia-Presbyterian Medical Center, New York, USA.

Our proband, born to remotely related parents, was a 30 year-old woman who was initially diagnosed as HSMN type I. Because of probable Guillain-Barr syndrome, she was referred to the University Hospital. She was 172 tall for 42 kg. She presented with severe amyotrophy, abolished reflexes, external ophthalmoplegia, pes cavus, and chronic diarrhea. Investigations showed slow conduction velocities, high frequency deafness, delayed somesthetic EP, and generalized leucoencephalopathy without intellectual impairment. Nerve biopsy confirmed demyelinization. Muscular mtDNA revealed heteroplasmic deletion of about 9 kB, and normal respiratory chain function, allowing a firm diagnosis of mitochondrial neurogastrointestinal encephalomyopathy (MNGIE). A brother of our proband was similarly affected. MNGIE (or POLIP syndrome) is a disorder characterized by chronic intestinal pseudo-obstruction, ophthalmoplegia, demyelinating sensori-motor neuropathy, leucodystrophy, and abnormal muscle (abnormal mitochondria and/or ragged red fibers) associated with mitochondrial dysfunction (complex 4 and/or complex 1 defect) and usually multiple mtDNA deletions (Hirano, Neurology 1994,44,721-727). Surprisingly, MNGIE was shown to be a genetically homogeneous, recessively inherited disorder mapping to 22q13.32-qter (Hirano, AJHG 1998,63,526-533), due to mutations in the thymidine phosphorylase gene (Nishino, Science 1999,283,689-692). In our proband, a homozygous A3371C (E289A) missense mutation in a highly conserved glutamic acid was found in the 7th exon. This appears to be a recurrent mutation, already observed in patients of British, European American and Ashkenazi origin.

Program Nr: 1639 from the 1999 ASHG Annual Meeting

Genetic analysis of tauopathies: corticobasal degeneration shares the same genetic background with progressive sopranuclear palsy. *E. Di Maria[1], T. Vigo[1], M. Tabaton[2], E. Bellone[1], R. Marchese[2], P. Montagna[3], D. Munoz[4], P. Pramstaller[5], G.L. Zanusso[5], N. Rizzuto[5], F. Ajmar[1], P. Mandich[1]*. 1) Dept. of Oncology, Biology and Genetics, Univ. of Genova, Italy; 2) Dept. of Neurological Sciences, Univ. of Genova; 3) Univ. of Bologna, Italy; 4) Univ. of Ontario, Canada; 5) Univ. of Verona, Italy.

Corticobasal degeneration is a rare disease involving cerebral cortex as well as extrapyramidal structures, with clinical signs as apraxia, tremor and rigidity. CBD is included in a group of neurodegenerative diseases characterised by abnormal deposits of protein tau (microtubule associated protein tau, MAPT). This group, named "tauopathies", comprises CBD, progressive supranuclear palsy (PSP), and some forms of frontotemporal dementia (FTD). Missense mutations of MAPT gene were reported in familial cases of FTD; conversely, an association between PSP and the A0 allele of a dinucleotide polymorphism in the intron 9 of the gene was found in several series of patients. When seen at the ultrastructural level, CBD and PSP share the same features of the tau deposits, thus differing from FTD. We recruited to date twenty-two patients affected with CBD and fourteen with FTD. Mutation analysis of MAPT gene coding region did not reveal any mutation; five single nucleotide polymorphisms (SNP) of exon 9 were detected both in patients and controls. In order to characterise the genetic background underlying CBD, fourteen cases were genotyped for the dinucleotide polymorphism in the intron 9: 82% of CBD cases carry the A0 allele, compared to 67% in controls. The association study was therefore extended to a panel of polymorphisms lying in the critical region of tau. A haplotype, resembling the one reported for PSP, is over-represented in CBD, compared with controls as well as with FTD ($p<0.05$). Based on this result, we could conclude that, besides similar clinical and neuropathological features, CBD and PSP share the same genetic background and therefore appear to be the same entity, quite distinct from FTD. Further studies are in progress to investigate the specific genetic defect underlying corticobasal degeneration.

Program Nr: 1640 from the 1999 ASHG Annual Meeting

Heterogeneity within subgroups of the autosomal recessive limb girdle muscular dystrophy in Turkey. *P. Dincer[1], Z. Akcoren[2], E. Demir[2], I. Richard[4], O. Sancak[1], G. Kale[2], S. Ozme[2], E. Tan[3], J.A. Urtizberea[5], J.S. Beckmann[4], H. Topaloglu[2].* 1) Medical Biology, Hacettepe University,, Ankara, TURKEY; 2) Children's Hospital; 3) Neurology; 4) Genethon, Evry, France; 5) Institute de Myology-AFM,Groupe Hospitalier Pitie-Salpetriere, Paris,France.

Autosomal recessive limb girdle muscular dystrophies (LGMD2) represent a heterogeneous group of diseases. A broad range of clinical and genetic entities is observed, ranging from very mild to severe forms and from LGMD2A to LGMD2H subgroups. Eight genes were mapped for AR-LGMD2s; they are LGMD2A (CAPN3) at 15q, LGMD2B (dysferlin) at 2p, LGMD2C (g-SG) at 13q, LGMD2D (a-SG) at 17q, LGMD2E (b-SG) at 4q, LGMD2F (d-SG) at 5q, LGMD2G at 17q and LGMD2H at 9q. We have evaluated 38 LGMD2 families with 65 cases by linkage analysis for known loci of LGMD2A to LGMD2F, and protein studies. All families are Turkish. Consanguinity was present in 37 of them. The classification of the families according to the combined data of linkage and protein analysis was as follows; calpainopathy 7, dysferlinopathy 3, g-sarcoglycan deficiency 5, a-sarcoglycan deficiency 2, b-sarcoglycan deficiency 7, d-sarcoglycan deficiency 1 and merosinopathy 2. There were two families showing an Emery-Dreifuss phenotype with normal staining of Emerin and 9 showing no linkage to the LGMD2A to F loci, and they had normal sarcoglycans. There is extreme heterogeneity in the clinical presentation. g-sarcoglycan deficiency seems to be the most severe group as a whole, whereas dysferlinopathy is the mildest. In sarcoglycan deficiencies, sarcoglycans other than the primary ones may also be reduced severely, however this may not reflect to the phenotype. Many cases of primary g-sarcoglycan deficiency stained normal or only mildly abnormal d-sarcoglycan staining. Calf hypertrophy is a cardinal feature of sarcoglycan deficiencies. Interfamilial variability of symptoms was a common finding in most groups. Cardiomyopathy was not present in any of the families during evolution. Scapular winging and selective wasting of hamstrings is peculiar for calpainopathy. Support: TUBITAK (SBAG-1774), Turkey and AFM, France.

Program Nr: 1641 from the 1999 ASHG Annual Meeting

Gene discovery in Acadian Usher Syndrome. *J.P. Doucet[1], A.R. Clement[1], L.C. Ledet[1], S.S. Robichaux[1], J.R. Landry[1], S.M. Robichaux[1], M.M. DeAngelis[2], B.J.B. Keats[3], M.A. Batzer[4], P.L. Deininger[5].* 1) Molecular Genetics Section, Biological Sciences, Nicholls State University, Thibodaux, LA; 2) LSU Neuroscience Center, New Orleans, LA; 3) Department of Biometry and Genetics, LSU Medical Center, New Orleans, LA; 4) Department of Pathology, LSU Medical Center, New Orleans, LA; 5) Tulane University Cancer Center, New Orleans, LA.

The Usher Syndromes are the most common multisensory deficits known. Type I Usher Syndrome, characterized by profound deafness, vestibular dysfunction, and retinal degeneration, segregates in a small population of Acadian descendants deriving from southwestern Louisiana. Of the nine loci linked to the Usher Syndromes, only 11p14.2-15.1 is linked to the Acadian population. In an effort to discover the causative gene in Acadian Usher Syndrome (USH1C), we have obtained partial nucleotide sequence of our previously reported bacterial artificial chromosome contig (DeAngelis, et al., Biochim Biophys Acta 1407 [1998]). Through nucleotide similarity analyses, we have identified several putative exons that map to the USH1C critical region. Using primers designed to the internal aspects of these putative exons, we have determined by amplification the existence of these exons in various cDNA sources and have identified one exon that appears in retinal cDNA. Using the RACE (Rapid Amplification of cDNA Ends) technique, we have derived a 3-kb gene fragment from this retinal exon that presumable contains the full 5 end of its coding sequence. This cDNA is unique from others our group has discovered. The discovery of a retinally-expressed sequence in the USH1C critical region makes its gene a prime candidate for the USH1C gene.

Program Nr: 1642 from the 1999 ASHG Annual Meeting

Real-time quantitation of the relative levels of Dp260 mRNA expression in mouse tissues reveals an abundance in eye as compared to brain, heart and skeletal muscle. *S.J. Dwinnell[1], N.M. Duncan[2], S.A. Tokarz[1], P. Pattee[2], D.M. Pillers[1,2]*. 1) Dept Molecular & Medical Gen, Oregon Health Sci Univ, Portland, OR; 2) Dept Pediatrics, Oregon Health Sci Univ, Portland, OR.

Purpose: Duchenne muscular dystrophy (DMD) results from mutations within the X-linked *DMD* gene. In addition to skeletal myopathy, patients may exhibit non-muscle manifestations such as cognitive dysfunction, cardiomyopathy, and abnormalities of retinal electrophysiology. The *DMD* gene encodes full-length dystrophin (Dp427) and four smaller isoforms that all conserve the carboxyl terminus of Dp427: Dp260, Dp140, Dp116, and Dp71. Dp260 was first identified in retina and genotype/phenotype correlation studies in DMD/BMD patients and *dmd* mouse models show that mutations disrupting Dp260 result in abnormal retinal electrophysiology. We hypothesized that *DMD* gene defects which alter Dp260 expression in retina, heart and brain may cause non-muscle manifestations of DMD/BMD, and sought to determine the relative extent of Dp260 mRNA expression in mouse. **Methods:** The TaqMan and ABI 7700 system (Perkin Elmer) was used to measure Dp260 transcript levels relative to that of the housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) in each tissue by real-time quantitative RT-PCR. PCR primers and fluorogenically labeled probes for mouse Dp260 and GAPDH cDNA sequences were designed using Primer Express software (Perkin Elmer). mRNA was isolated from brain, eye, heart and skeletal muscle of C57BL/6J mice and cDNA was synthesized using sequence-specific reverse PCR primers. PCR reactions were performed on the ABI 7700 sequence detection/thermocycler. Relative levels of Dp260 fluorescence emission were determined in real-time and compared to GAPDH for each tissue. **Results:** The ratio of Dp260/GAPDH was approximately equal in brain, heart and skeletal muscle, but was significantly increased in eye as compared to the other tissues. **Conclusion:** The finding that Dp260 is more highly expressed in eye than in skeletal muscle and other non-muscle tissues is consistent with the genotype/phenotype correlation studies that implicate Dp260 as playing a crucial role in normal retinal electrophysiology in the mouse.

Program Nr: 1643 from the 1999 ASHG Annual Meeting

Isolation and characterization of a novel candidate gene, SMT7, in the facioscapulohumeral muscular dystrophy (FSHD) gene region. *J.T. Ehmsen[1], J.D. Forrester[2], J.E. Hewitt[3], D.A. Figlewicz[2], S.T. Winokur[1]*. 1) University of California , Irvine, CA; 2) University of Rochester, Rochester, NY; 3) Nottingham University, Nottingham, UK.

Facioscapulohumeral muscular dystrophy (FSHD) is the third most common form of inherited muscle disease following Duchenne and myotonic dystrophy. FSHD is initially characterized by an asymmetric, progressive weakness of the facial and pectoral girdle muscles. The disorder is inherited in an autosomal dominant fashion with nearly complete penetrance and results from a deletion of integral copies of a heterochromatic 3.3 kb tandem repeat unit on the long arm of chromosome 4 (D4Z4). A "short" EcoR1 fragment (< 35 kb) containing D4Z4 segregates with the disease, while the size of this polymorphic locus in the normal population ranges between 35 and 300 kb. The specific gene(s) responsible for FSHD have not been identified. However, integral deletions of the heterochromatic D4Z4 repeat appear to disrupt the normal expression of genes proximal to D4Z4, a phenomenon akin to position effect variegation in Drosophila and telomere silencing in yeast. We have cloned and characterized a novel gene which maps to the FSHD gene region. This gene, SMT7, was initially identified in the Unigene '97 EST database as mapping to distal 4q. We have refined its map position within 4q35 through a radiation hybrid minipanel and determined that it maps proximal to the D4Z4 repeat array adjacent to the skeletal muscle specific gene ALP. SMT7 is expressed in adult skeletal muscle, as determined by RT-PCR. Interestingly, expression of SMT7 gene is increased in FSHD muscle tissue compared to control muscle, suggesting a position effect involving this gene in FSHD. Using 20 ng of muscle cDNA per sample, we carried out RT-PCR on 8 control samples and 10 FSHD samples. The gene was expressed, on average, 3X higher in FSHD muscle samples than controls. Sequence analysis on 950 bp of this transcript reveals no significant homologies to known genes. We are currently sequencing two skeletal muscle cDNA clones which span an additional 2.5 kb of the SMT7 transcript. Studies are also underway to map and isolate the mouse homolog.

Program Nr: 1644 from the 1999 ASHG Annual Meeting

Mutation screening for the calcium channel beta subunit gene *CACNB4* in familial ataxia and epilepsy. *A. Escayg[1], D.D. Lee[1], R. Baloh[2], T. Sander[3], M.H. Meisler[1]*. 1) Dept Human Genetics, Univ Michigan, Ann Arbor 48109-0618, MI; 2) Dept Neurology, UCLA, Los Angeles; 3) Dept Neurology, U. Hospital Charite, Humboldt U., Berlin.

Four paralogous mammalian genes encode the cytoplasmic beta subunits of the voltage gated calcium channel. A loss-of-function mutation in the beta 4 subunit, *CACNB4*, was identified in 1997 in the mouse neurological mutant *lethargic*. Homozygous *lethargic* mice exhibit ataxic gait and seizures, suggesting that *CACNB4* may be considered a candidate gene for the corresponding human disorders. To test this possibility, we determined the exon/intron structure of human *CACNB4* (Genomics 50:14) and designed PCR primers to amplify the exons from genomic DNA. The genomic PCR products are screened for mutations by SSCP and conformation sensitive gel electrophoresis (CSGE). Mobility variants are gel purified and manually sequenced. Two patient populations are being analyzed. Families with seizures were ascertained through members with childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), or juvenile myoclonic epilepsy (JME) (Epilepsy Res. 29:115). The second group of patients exhibit hereditary episodic ataxia. DNA samples from 255 controls are also being tested. Two potential disease mutations are under investigation. Eight silent SNPs with frequencies between 0.001 and 0.026 have also been identified. Allele specific oligonucleotides (ASOs) and diagnostic restriction digests have been developed for analysis of these SNPs in association and linkage studies.

Program Nr: 1645 from the 1999 ASHG Annual Meeting

Variability in the PS deficient phenotype associated with *PROS1* allelic heterogeneity. *Y. Espinosa-Parrilla[1], M. Morell[1], M. Borrell[2], J.C. Souto[2], J. Fontcuberta[2], X. Estivill[1], N. Sala[1].* 1) Departament de Genètica Molecular, I.R.O, Barcelona, Spain; 2) Unitat d'Hemostasia i Trombosis, Hospital de Sant Pau, Barcelona, Spain.

Anticoagulant protein S (PS) deficiency is a cause of thrombophilia. To study the molecular basis of its phenotypic heterogeneity, the results of *PROS1* gene and mutation analysis were compared to the PS values in 54 families with different types of PS deficiency and thrombosis. Type I PS deficiency (reduction of total and free PS antigen) was found in 18 families and all but one family that segregated the rare P460 allele of the S/P460 variant, had a cosegregating mutation. Type III deficiency (only free PS antigen is reduced) was found in 23 families in which the unique *PROS1* alteration was the presence of 3 rare allele variants in 3 families and the P460 allele in 11 families (47.8%), though it did not always segregate with the deficiency. Finally, 13 families were classified as type I/III since both phenotypes coexisted in these families. Six of them carried a cosegregating mutation, 2 had a non cosegregating variant and 3 segregated the P460 allele. Mean free PS levels in type III individuals were significantly higher ($p<0.0001$, unpaired t-test) than those in type I, and mean total PS levels in type III individuals were significantly lower ($p<0.0001$) than those in normal relatives. In the pedigrees segregating the S/P460 variant, not only free but also mean total PS levels were found significantly lower in the SP460 heterozygotes than in the SS460 homozygotes. This, together with the finding of a P460 homozygote with type I deficiency, suggests a role for this PS variant in the deficient phenotype. Besides, in vitro expression analysis, performed with 6 *PROS1* missense mutants, showed differential secretion of these mutants causing phenotypic heterogeneity in PS deficiency. All together indicating that while type I is a quantitative PS deficiency, essentially due to different detrimental *PROS1* mutations, type III deficiency is a milder quantitative deficiet phenotype caused by some functional *PROS1* variants and other genetic and/or environmental factors that determine variability in PS levels.

Program Nr: 1646 from the 1999 ASHG Annual Meeting

New mutations in the voltage-gated calcium channel gene CACNA1A in british families with episodic ataxia type 2. *L.H. Eunson[1], A. Jouvenceau[1], V. Ramesh[2], S.M. Zuberi[3], A. Nairne[4], N. Hyman[4], N.W. Wood[1], A. Spauschus[1], D.M. Kullmann[1], M.G. Hanna[1]*. 1) Clinical Neurology, Institute of Neurology, Queen Square London, England; 2) Newcastle General Hospital; 3) Royal Hospital for Sick Children, Glasgow; 4) Battle Hospital, Reading.

Episodic ataxia type 2 (EA2) is an autosomal dominant disorder caused by mutations in the voltage-gated calcium channel gene, CACNA1A, on chromosome 19q. We have identified fifteen new families with the EA2 phenotype. We have analysed exons 4,6,16,17,22,24 and 36 that have previously been reported to harbour pathogenic mutations, and have also analysed exons 2,3,7,11,12,25,26,28,30,31,38,41,42 and 43 by SSCP and DNA sequencing. We have determined the length of the CAG repeat using fluorescent PCR techniques. They were normal in all cases. None of the EA2 probands harboured any of the previously reported mutations in these exons. In two families we identified novel pathogenic mutations. The proband in family 1 exhibited typical attacks of EA2, but in addition had absence epilepsy and learning difficulties. He was unresponsive to acetazolamide. We identified a heterozygous C to T transition at nucleotide 5733 in exon 36 (CGA to TGA resulting in R1820stop). This predicts the introduction of a premature stop codon at the beginning of the C terminus of the alpha 1A subunit. Affected members of family 2 exhibited typical acetazolamide-responsive EA2. We identified a heterozygous intronic 4 base pair deletion at +3 of intron 41. This mutation is predicted to disrupt channel function either by causing exon skipping or alternative splicing. Both mutations were not detected in over 100 control chromosomes, have not been reported previously, and are likely to be pathogenic. The R1820stop mutation is the most distal truncation mutation identified in CACNA1A and suggests that loss of the C terminal region may be the important functional consequence of other truncation mutations described. An intronic deletion mutation has not been reported previously in CACNA1A and suggests a new mutational mechanism. The absence of known mutations in the other families suggests further genetic heterogeneity associated with the EA2 phenotype.

Program Nr: 1647 from the 1999 ASHG Annual Meeting

Additional *CDMP1* mutations suggest that brachydactyly type C is locus homogeneous and incompletely penetrant. *D.B. Everman[1], A. Polinkovsky[1], C.A. Francomano[2], J.M. Graham, Jr.[3], F.R. Goodman[4], G. Neri[5], S. Morrison[1], N.H. Robin[1], M.L. Warman[1]*. 1) Case Western Reserve Univ and Univ Hospitals, Cleveland, OH; 2) NHGRI, NIH, Bethesda, MD; 3) Cedars Sinai Medical Center, Los Angeles, CA; 4) Institute of Child Health, London, UK; 5) Univ Cattolica, Rome, Italy.

We have previously reported that mutations in the TGF-b superfamily member *CDMP1* can cause autosomal dominant brachydactyly type C (BDC). Herein we describe additional *CDMP1* mutations confirming that *CDMP1*, on human chromosome 20, is the major BDC locus and that the most common mechanism of mutational effect is functional haploinsufficiency. Also, in two separate kindreds, we detected mutation carriers who lacked findings of BDC, indicating that functional haploinsufficiency mutations may be non-penetrant. In an English kindred, an affected mother transmitted a mutant *CDMP1* allele to two of her children; her daughter has typical BDC while her son appears clinically unaffected and radiologically has a normal metacarpal-phalangeal profile. This mutation co-segregates with the disease phenotype in the mother's extended family. In an American kindred, an unaffected (clinically and radiographically) mother, whose son has typical features of BDC, was also found to have a *CDMP1* mutation; we have not yet determined whether the mother's mutation was inherited, or arose *de novo*, in which case somatic mosaicism could explain her non-penetrance. Interestingly, both families have the same mutation, an insertion G at nucleotide residue 206 of the coding sequence which creates a reading frame shift beginning at amino acid residue 69 and causes premature termination 25 amino acid residues downstream. This mutation has not been detected in over 100 control alleles. We have also identified a *CDMP1* mutation in the kindred with BDC that was originally described by Haws; linkage analysis in this kindred had suggested the existence of a second BDC locus on human chromosome 12q. However, we found a 23 bp insertion within the *CDMP1* coding sequence that co-segregates with the family's phenotype. This indicates that BDC is most likely locus homogeneous and that prior linkage to chromosome 12q can be attributed to type I error.

Program Nr: 1648 from the 1999 ASHG Annual Meeting

Search for X-Chromosomal Microdeletions in Rett Syndrome. *F. Fan[1], R.E. Amir[3], X. Zhang[2], E.J. Dahle[3,4], H. Zoghbi[3,4], U. Francke[1,2]*. 1) Dept. of Genetics; 2) Howard Hughes Medical Institute, Stanford Univ Sch of Med, Stanford, CA; 3) Dept. of Pediatrics and Molecular and Human Genetics; 4) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX.

Rett Syndrome (RTT) is a neurodevelopmental disorder that affects mostly females. Symptoms first appear at 6-18 months of age with progressive loss of acquired language and fine motor skills and development of stereotypical hand movements. Severe mental impairment is usually present. The estimated prevalence of 1 in 15,000 females makes it one of the more common causes of mental disability. The majority of the cases are sporadic, presumably due to independent new mutations. In an effort to delineate the genetic basis of RTT, we tested the hypothesis that RTT may be caused by recurrent microdeletions of the X chromosome which are not readily detected by cytogenetic studies. Such microdeletions could be mediated by region-specific duplications leading to non-homologous recombination events, analogous to the autosomal Williams and Prader-Willi/Angelman syndromes. We studied a panel of somatic cell hybrids from 7 affected RTT females representing 5 independent mutational events. Either the maternal or the paternal X chromosome, but not both, was retained in these hybrid cell lines. Therefore, we were able to assay STS markers by PCR. We also included cells from a severely affected male carrying a familial Rett mutation (Schanen and Francke, AJHG 63:267,1998). Our deletion survey covered about 35Mb of the X chromosome that were not excluded from carrying the RTT gene at the time we initiated our study. PCR assays were established for a total of 425 mapped STS/EST markers. For the Xp22 region DXS85-DXS1053, 50 markers were tested for an average inter-marker distance of 142kb. This region was subsequently excluded by family studies. On the long arm, for region DXS1206-DXS1227 (Xq25-q27) 238 markers were tested and for region DXS998-DXS7062 (Xq27-q28) there were 137 markers, with the average distance between the long arm markers being 75 kb. No microdeletions were found in our test panel. We conclude that a microdeletion of 100kb or larger is not likely to be a common mutational mechanism for RTT.

Program Nr: 1649 from the 1999 ASHG Annual Meeting

Linkage exclusion in nine families with probable Parkinson's disease. *M.J. Farrer[1], A. Destée[2], E. Becquet[2], F. Wavrant-De Vriéze[1, 3], V. Mouroux[3], F. Richard[3], L. Defebvre[3], S. Lincoln[1], J. Hardy[1], P. Amouyel[3], M-C. Chartier-Harlin[3].* 1) Neurogenetics, Mayo Clinic Jacksonville, Jacksonville, FL; 2) Clinique Neurologique, CHRU, 59037 Lille Cedex France; 3) INSERM 508, Institut Pasteur de Lille, 59019 Lille Cedex, France.

We have analyzed the segregation of genetic markers spanning chromosomal regions 2p13, 4p14-15, 4q21-23, 6q25-27 and 17q21 in nine French families affected by autosomal dominant probable Parkinsons disease. These regions have been linked/associated with familial Parkinsons disease or parkinsonism. Multipoint linkage and haplotype analysis excluded 2p13 and 4p14-15 loci in 4/9 and 5/9 kindreds respectively. For four families, which were equivocal for linkage to 4p14-15 (D4S405), the ubiquitin carboxy-terminal hydrolase gene (UCH-L1) was sequenced. In one family, a novel UCH-L1 M124L mutation that did not segregate with early-onset disease was identified. This suggests that rare variants in this gene may not be pathogenic. In 7/9 families, it could be inferred that affected individuals did not share 4q21-23 (alpha-synuclein) haplotypes. All families were unequivocally excluded, by haplotype analysis, from the parkin locus on 6q25-27. Finally, the 17q21 region was excluded in 5/9 kindreds and no mutation in the tau gene was identified in the four remaining families. Findings from this study confirm and extend the observation that familial parkinsonism is genetically heterogeneous.

Program Nr: 1650 from the 1999 ASHG Annual Meeting

Neonatal diagnosis of Cystic Fibrosis: Application of the Elucigene™CF20 test using blood spots samples. *D. Feldmann, C. Magnier, L. Vallat, C. Houdayer, M. Tredano, M. Pressac, P. Aymard.* Service de Biochimie, Hopital Trousseau, Paris, France.

DNA analysis of neonatal samples for CF is becomming more widespread and there is a need for a cost-effective method wich can detect many mutations and is suitable for blood spots. ARMS (Amplification Refractory Mutation System) technology has been applied for mutation detection. We evaluated a newly developped multiplex ARMS test wich detects 20 mutations in the CFTR gene to assess its suitability for routine analysis of blood spots samples in a clinical laboratory. 26 samples with elevated immunoreactive trypsinogen levels were selected for DNA analysis. DNA was extracted from the blood spots samples by a rapid alkali lysis method and directly added to 3 multiplex ARMS reactions. Following PCR amplification, the products of each reaction were analysed by agarose gel electrophoresis. All DNA were successfully amplified using the test including samples stored fot a period of up to one year or more. We detected mutations in 6 of the 26 samples analysed. The test results were concrdant with data obtained using other mutation detection methods according to the limitation of the test (homozygosity information for DF508 only). Results could be obtained in one day. We conclude that the test is a simple and rapid screening method for molecular analysis of the CFTR gene in neonates.

Program Nr: 1651 from the 1999 ASHG Annual Meeting

Identification of the gene responsible for non-type I cystinuria, *SLC7A9*. *L. Feliubadaló[1,5], The Cystinuria Consortium[1,2,3,4,5]*. 1) Dpt. Genètica Molecular, IRO, L'Hospitalet Ll, Barcelona, Spain; 2) Dpt. Medicine C, Sheba Medical Center, Tel Hashomer, Israel; 3) SGM, Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; 4) TIGEM, San Raffaele Biomedical Science Park, Italy; 5) Dpt. Bioquímica i Biologia Molecular, Fac. Biologia, Universitat de Barcelona, Spain.

Cystinuria (OMIM 220100) is a common recessive disorder of renal and intestinal re-absorption of cystine and dibasic aminoacids. Mutations in *SLC3A1*, encoding rBAT, produce cystinuria type I. A gene causing non-type I cystinuria has been assigned by linkage analysis to 19q12-13.1. We have identified a kidney cDNA (*SLC7A9*) of the family of the light subunits of amino acid transporters, expressed in kidney, liver, small intestine and placenta, and its gene is localized to the non type I cystinuria 19q locus. Cotransfection of the SLC7A9, encoding $b^{o,+}$AT, and *SLC3A1* brings the latter to the plasma membrane and results in the expression of L-arginine uptake in COS cells. We have found *SLC7A9* mutations in Libyan-Jewish, North American, Italian and Spanish non type I cystinuria patients. The Lybian-Jewish patients are homozygous for a founder mutation which abolishes $b^{o,+}$AT amino acid uptake activity when cotransfected with rBAT in COS cells. Four missense, two in homozygous state, and two frameshift mutations were identified in other patients. Our data establish that mutations in *SLC7A9* cause non-type I cystinuria, and strongly suggest that $b^{o,+}$AT is the light subunit of rBAT.

Program Nr: 1652 from the 1999 ASHG Annual Meeting

An explanation for the origin and pathogenic role of the hereditary pancreatitis-associated N21I mutation in the cationic trypsinogen gene. *C. Ferec, J.M. Chen.* Centre de Biogenetique, Universite, Hopital, ETSBO, Brest, France.

Hereditary pancreatitis (HP) is an autosomal dominant disease. Two missense mutations-an R117H in exon 3 and an N21I in exon 2 of the cationic trypsinogen gene have been associated with HP. While the R117H mutation could be explained by disrupting an important "self-destruct" mechanism, why and how the N21I substitution could cause a "gain of function" of the cationic trypsin remains one of the most important but unanswered questions. We address this issue by pursuing the origin of this missense mutation in the context of the human trypsinogen gene family and then unify the current available knowledge to explain its pathogenic role in HP. There is strong evidence suggesting that the N21I substitution arose as a gene conversion event in which the wild-type functional anionic trypsinogen gene acted as the donor sequence: the only presence of Ile at residue 21 of the anionic trypsinogen gene amongst the several trypsinogen genes; a high overall sequence homology between the cationic and anionic genes; a single unbroken tract of nucleotides of up to 113 bp flanking the I21 residue in the anionic gene; a chi-like sequence present in the 5' proximity and a perfect seven nucleotide inverted repeat split by an asymmetric 21 bp sequence located in the 3' proximity of the mutation. A multiple alignment of the partial sequences around residue 21 of vertebrate trypsins further indicated that N21 and I21 represent rare mutations of the two functional human trypsinogen genes, positively selected by evolution to somehow endow an as yet unknown advantageous effect on their respective protein's structure and function. Thus, a non-reciprocal genetic information exchange between them at this position could be disastrous. In support of this, the physico-chemical properties of Ile are quite different from Asn and a structural difference of this substitution has been suggested by different affinity constants of a monoclonal antibody towards the two trypsinogens and by computer prediction analysis. These observations, taken together, enabled us to complement a working model for the N21I mutation, which highlights an indirect impairment on the "self-destruct" mechanism.

Program Nr: 1653 from the 1999 ASHG Annual Meeting

Russell-Silver syndrome: Identification of a candidate region on the short arm of chromosome 7. *B.A. Fernandez[1], I. Teshima[1], K. Nakabayashi[1], V. Proud[2], R. Weksberg[1], S.W. Scherer[1].* 1) Dept. of Genetics, Hosp Sick Children, Univ Toronto, Toronto, ON, Canada; 2) Valley Children's Hosp, Madera, CA.

Russell-Silver syndrome (RSS) is a form of dwarfism characterized by IUGR, triangular facies and 5th finger clinodactyly. Ten percent of sporadic cases are associated with maternal uniparental disomy for chromosome 7 (matUPD7), suggesting that the etiology in some patients is an alteration in one or more imprinted genes on chromosome 7.

Two RSS patients were identified, each with a cytogenetic rearrangement of 7p. Patient 1 had a partial duplication of 7p [46,XX,dup(7)(p12p14)]. Patient 2 had a paracentric inversion, with the proximal inversion breakpoint at 7p14 [46,XY,inv(7)(p14p21)]. We hypothesized that the RSS phenotype in both patients might be due to alteration in an imprinted gene or region on 7p. Also, given the previous matUPD7 data, we hypothesized that patient 1's duplication was carried on her maternal chromosome 7.

The first hypothesis was tested by fluorescence *in situ* hybridization (FISH) mapping. Metaphase FISH experiments using YACs and PACs for the 7p region were performed. Results indicate that patient 1's duplication extends from 7p12 into 7p14. In patient 2, a YAC that spans the proximal (7p14) inversion breakpoint, is also duplicated in patient 1. Thus, a common region of involvement (1 Mb in size) on 7p14 has been identified, and we propose this as a possible RSS candidate region.

In patient 1, the parent-of-origin of the chromosome carrying the duplication was determined by typing 8 fluorescent short tandem repeats (STRs) in the patient and her parents (5 STRs from within the duplicated region and 3 STRs from the flanking regions). Five quantitative multiplex PCR reactions have confirmed that patient 1's duplication is carried on her maternal chromosome 7. This finding suggests that RSS in patients with matUPD7 is due to excess of a maternally expressed growth-suppressing gene, rather than due to deficiency of a paternally expressed growth-promoting gene.

Program Nr: 1654 from the 1999 ASHG Annual Meeting

Quantitative Analysis of 4q35 Genes. *J. Forrester[1], R. Morsch[1], J.E. Sowden[1], R.C. Griggs[1], R. Tawil[1], D.A. Figlewicz[1,2].* 1) Neurology, University Rochester, Rochester, NY; 2) Neurobiology and Anatomy, University of Rochester, Rochester, NY.

Facioscapulohumeral muscular dystrophy (FSHD) is the third most common form of muscular dystrophy, resulting from deletions of integral copies of a 3.3Kb repeated element, known as D4Z4, on chromosome 4q35. However, no transcripts have been isolated from D4Z4, or from the distal subtelomeric DNA. Current experimental work is centered around a hypothetical mechanism: disruption of gene expression at 4q35 may result from telomeric chromatin reorganization due to these deletions. We are using quantitative competitive RTPCR to determine expression levels of genes which lie centromeric to D4Z4: adenine nucleotide translocator gene (ANT1), actin associated LIM protein (ALP), factor eleven (FXI), plasma prekallikrein (KLK3), and FSHD related gene 1 (FRG1), using muscle tissue from normal control individuals, and from FSHD patients. To date, we have examined expression of ALP and ANT1 in ten unrelated FSHD patient muscle biopsies, and ten normal control muscle samples. We have found a three fold increase in expression of ALP in patients ($p=0.006$) and a four fold increase in expression in ANT1 ($p=0.001$), with the competitive RTPCR approach. Using RTPCR with comparison to housekeeping genes, we have found an increase in expression of FRG1 in four unrelated FSHD patients compared to four unrelated normal controls. Expression levels of KLK3 and FXI have not been quantitated, because they are not consistently expressed in muscle tissue. KLK3 was expressed in four of ten FSHD muscle samples and one of nine normal muscle samples, while FXI was expressed in five of eight FSHD muscle samples and three of seven normal control samples. These results suggest that deletions of the D4Z4 repeats affect expression of genes lying closest to the D4Z4 locus. We are continuing our evaluation of expression at 4q35 by looking at expression levels of these genes in non-FSHD disease muscle controls, as well as investigating expression of non-4q35 housekeeping genes in FSHD muscle and normal control muscle. Supported in part by grants from the FSH Society, MDA-USA,and New York State Dept. of Education.

Program Nr: 1655 from the 1999 ASHG Annual Meeting

***CRX* mutation analysis in age-related macular degeneration (AMD).** *C.L. Freund[1], A. Huang[1], Y. Liu[2], B. Muskat[1], S.G. Jacobson[3], J. Seddon[4], D.J. Zack[2], R.R. McInnes[1]*. 1) Hospital for Sick Children, Toronto, ON; 2) Johns Hopkins Medical School, Baltimore, MD; 3) University of Pennsylvania, Philadelphia, PA; 4) Massachusetts Eye and Ear Infirmary, Boston, MA.

The CRX homeodomain protein is expressed specifically in photoreceptors and pinealocytes, and activates the transcription of photoreceptor outer segment genes, including rhodopsin. Mutations in *CRX* are associated with cone rod dystrophy, and other retinal degeneration phenotypes that affect photoreceptor cells. These findings led to the hypothesis that *CRX* mutations may cause AMD, a photoreceptor degeneration with complex genetics and environmental risk factors. We screened the *CRX* gene in 214 AMD patients (156 atrophic form, 58 neovascular form). One patient with atrophic AMD was found to be heterozygous for a putative pathogenic mutation, P184L. We also identified three benign sequence variants (S34S, S199S, G209G) in other patients. The P184L change (CCG->CTG) is not polymorphic; it is absent from 1018 other *CRX* genes (62 normals, 447 retinal disease patients). Pro 184 is embedded in a '-gly-pro-ser-' context, which is predicted to cause a 180^{o} hairpin turn in the CRX polypeptide. Substitution of this Pro by Leu is predicted to remove the hairpin and create a hydrophobic patch which may promote aggregation of CRX monomers. Initial biochemical studies of the P184L-CRX protein suggest that this allele leads to a loss-of-function: i) in transient transfection studies with a rhodpsin reporter construct P184L-CRX has reduced transactivation activity; ii) the ability of the P184L-CRX mutant to associate with CRX-interacting proteins in yeast two hybrid assays is reduced two to nine fold. These results indicate that i) *CRX* mutations may be a rare cause of AMD, ii) the diminished transcriptional activity and protein:protein interactions of P184L-CRX result from loss of its secondary structure, and iii) demonstration of the pathogenicity of P184L-CRX would confirm that failure to maintain the photoreceptor outer segment can lead to AMD.

Program Nr: 1656 from the 1999 ASHG Annual Meeting

A new locus for late-onset, progressive, hereditary hearing loss (DFNA20) maps to 17q25. *K.H. Friderici[1], R.J. Morell[2], S. Wei[1], J.L. Elfenbein[1], S. Levine[1], T.B. Friedman[2], R.A. Fisher[1].* 1) Depts of Microbiology, Pediatrics and Human Development and Audiology and Speech Sciences, Michigan State Univ, East Lansing, MI; 2) Laboratory of Molecular Genetics, NIDCD, NIH, Rockville, MD 20850.

Progressive hearing loss is a significant problem in the aging population. By age 80 nearly 50% of individuals have hearing loss that impairs their ability to communicate easily. Late-onset hearing loss can be caused by genes or environmental factors such as exposure to noise or otoxic drugs, or by the interaction of genes and environment. The proportion of late-onset hearing loss that is attributable to heredity is unknown. Here we report the localization of DFNA20, a gene causing dominant, non-syndromic, progressive hearing loss in a 3-generation Midwestern family. Affected family members show a bilateral, sloping, progressive, sensorineural hearing loss, first evident at 6,000 and 8,000 Hz, that can be identified in some family members in the early teens and is clearly evident by the early twenties. As age increases, the degree of hearing loss increases with threshold shifts seen at all frequencies. A sloping configuration is maintained. No dysmorphology is observed and vestibular function is normal by neurological exam. After linkage to known dominant and recessive loci was excluded, a genome-wide screen was initiated using the Weber version 8A marker panel. Positive linkage to markers at 17q25 was found with a maximum two point LOD score of 6.62 to marker D17S784 (q = 0). Informative recombinants refined the DFNA20 critical region to 12 cM between D17S1806 and D17S668. Several candidate genes expressed in the ear and reported to map to the region were considered and eliminated. In summary, the DFNA20 locus was identified and mapped 17q25 in an interval of less than 133.7 cR10,000 on the RH map, which corresponds to ~ 2.5 to 3.3 megabases, assuming 1 cR10,000 ~ 25 kbp. Since the progression of early hearing loss in the family resembles that which is associated with old age in the general population (presbycusis), the identification of the DFNA20 gene may provide insight into the etiology of presbycusis and suggest strategies to ameliorate progressive hearing loss.

Program Nr: 1657 from the 1999 ASHG Annual Meeting

D1152H: A common CFTR mutation associated with highly variable disease expression. *K.J. Friedman[1], W.E. Highsmith, Jr.[3], Z. Zhou[1], P.G. Noone[2], A. Spock[4], J.A. Cohn[5], L.M. Silverman[1], M.R. Knowles[2].* 1) Dep't of Pathology & Lab Medicine, Univ North Carolina, Chapel Hill, NC; 2) Dep't of Medicine, Univ North Carolina, Chapel Hill, NC; 3) Dep't of Pathology, Univ Maryland, Baltimore; 4) Dep't of Pediatrics, Duke Univ, Durham, NC; 5) Dep't of Medicine, Duke Univ, Durham, NC.

D1152H is a CFTR missense mutation associated with reduced chloride currents upon heterologous expression. Commonly associated with isolated CBAVD, we report the D1152H/G542X genotype in three siblings with atypically mild CF surviving into the 7th and 8th decade. One developed a cough and "bronchitis" with mucoid P. aeruginosa infection in early adolescence. Although her sweat chlorides were normal (27 mEq/L), she showed reduced chloride conductance across her nasal epithelium (Cl- diffusion PD, +2 mV). She died of respiratory failure at 65 yrs. Her two brothers had atypically mild disease for years, marked by cough, "bronchitis", "asthma" and/or sinusitis. Both grew mucoid P. aeruginosa in their sputum, had normal sweat chlorides (15 and 29 mEq/L), and one had reduced chloride conductance similar to his sister (+1 mV). Neither brother had fathered children, supported by abnormal semen analysis in one. The oldest brother had an episode of acute pancreatitis at 64 yrs. Each has survived into their 70's despite histories of heavy smoking. Subsequently we have identified a further 17 patients (11 families) with D1152H. Six are male (avg. age ~44 yrs) and eleven are female (avg. age ~30 yrs). Presenting symptoms are variable, although most have normal sweat chlorides. Bronchitis, bronchiectasis, hemoptysis and nasal polyps are typical pulmonary manifestations and respiratory infections include P. aeruginosa, S. aureus, and M. avium. All but one are pancreatic sufficient and four have pancreatitis. Ongoing investigations of these individuals are characterizing their disease and quantitating the epithelial ion transport dysfunction associated with this mutation. In summary, D1152H is associated not only with CBAVD, but also with mild, late onset lung disease and pancreatitis in conjunction with normal sweat chlorides, in this family & others.

Program Nr: 1658 from the 1999 ASHG Annual Meeting

Investigating the underlying genetic causes of idiopathic male infertility in an Irish population. *A.M. Friel[1,2,3], M. Maher[2], M. Glennon[2], A. Nolan[3], J.A. Houghton[1]*. 1) Microbiology Department, National University of Ireland, Galway, Ireland; 2) National Diagnostics Centre, BioResearch Ireland, National University of Ireland, Galway, Ireland; 3) Fertility Unit, University College Hospital, Galway, Ireland.

Purpose: Infertility is a common health problem affecting 15-20% of all couples of reproductive age. Men who are infertile account for about half of these cases. Genetic abnormalities are now thought to account for many cases of idiopathic male infertility. Three different approaches are currently in use here to study the underlying genetic causes of male infertility.

Methods: 1. Several genes on the long arm of the Y chromosome contribute to spermatogenesis, and microdeletions in this region have been associated with infertility. A Polymerase Chain Reaction-based approach has been set up to screen the Azoospermia Factor region of the Y chromosome (AZF region) for the presence of microdeletions. To date, 50 azoospermic/oligozoospermic men have been screened using 18 primers which span the AZF region. The aim of this study is to establish the frequency of microdeletions in an Irish male population, and also to assess the potential fertility of male offspring born using current IVF treatments. **2.** Reverse transcriptase-PCR and Northern blots are being used in this study to determine whether infertile men with an intact AZF region are expressing the candidate genes at the expected level. **3.** Mitochondrial DNA deletions in spermatozoa have been associated with male reproductive disorders. A 'Pure Sperm' gradient/Long Range PCR technique has been developed here to investigate if mitochondrial DNA deletions are associated with the decline of motility in spermatozoa.

Results: No deletions have been detected in our 50 patients. Further primers are now being used to expand the screening area. A 4-5 kb region of mitochondrial DNA has been found deleted in some fractions in 8/11 patient sperm samples. This region is currently being cloned and sequenced to see if it correlates with the previously described 'common' 4977 bp deletion. A normal control study is also in progress here.

Program Nr: 1659 from the 1999 ASHG Annual Meeting

Disruption of mouse SMN exon 7 results in early embryonic lethality. *T. Frugier, F. Tiziano, P. Miniou, N. Roblot, A. Dierich, M. Le Meur, J. Melki.* IGBMC, BP 163 Illkirch (Strasbourg) France.

Spinal muscular atrophy (SMA) is an autosomal recessive disorder characterized by degeneration of lower motor neurons and caused by SMN gene mutations. In order to elucidate the pathophysiology underlying SMA, a conditional mutagenesis of the mouse SMN gene has been undertaken using the Cre-LoxP system. We inserted two loxP sites flanking SMN exon 7 (SMNF7) through homologous recombination in order to delete SMN exon 7, the most frequent mutation found in SMA patients. Heterozygous SMNF7 mice were intercrossed and (SMNF7/F7) mice appear similar in size and morphology to wild type mice. In order to delete SMN exon 7 in all cell types, (SMNF7) mice were crossed with a transgenic line expressing Cre recombinase under the control of CMV promoter (CMV-Cre). Offspring carrying both the SMNF7 allele and CMV-Cre transgene were selected. In the progeny, heterozygous deletion of SMN exon 7 (SMND7/+) was detected in one to two offspring lacking CMV-Cre transgene. (SMND7/+) mice remained indistinguishable from wild type littermate to date (12 months). To validate the construct, RT-PCR amplification of RNA extracted from various tissues of mice carrying SMND7, SMNF7 or wild type alleles was performed. In addition to the full length transcript, a shorter product was generated in (SMND7/+) mice. Sequence analysis revealed transcript lacking exon 7, resulting in a putative protein with a different C-terminal end. (SMND7/+) mice were intercrossed but no live (SMND7/D7) mice were produced among 50 newborns. To determine the timing of the (SMND7/D7) lethality, embryos were analyzed during gestation. At 9.5 d.p.c., a total of 53 embryos were analyzed and 13 of them were shown to be completely resorbed. All resorbed embryos were homozygous for the SMND7 mutation, indicating that homozygous deletion of SMN exon 7 in all cell types results in embryonic lethality during early development. To overcome the problem of embryonic lethality, we generated trangenic line expressing Cre recombinase under the control of neuronal promoter in order to induce SMN exon 7 deletion restricted to neurons, the target cells in SMA.

Program Nr: 1660 from the 1999 ASHG Annual Meeting

Clinical characterization of DFNA15 genetic hearing loss caused by a mutation in the POU4F3 transcription factor. *M. Frydman[1,2], S. Vreugde[2], B.I. Nageris[3], S. Weiss[2], K.B. Avraham[2]*. 1) Genetics Institute, Haim Sheba Medical Center, Tel Hashomer, Israel; 2) Department of Human Genetics and Molecular Medicine, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Department of Otolaryngology-Head and Neck Surgery and Department of Audiology, Rabin Medical Center, Petah Tiqwa, Israel.

The genetic heterogeneity of inherited deafness has made it difficult to make correlations between clinical symptoms and particular loci, though with the recent cloning of several genes for non-syndromic hearing loss, genotype-phenotype correlations are now possible. The locus DFNA15 defines autosomal dominant progressive hearing loss in a large extended family from Israel, Family H. Sensorineural hearing loss is associated with a mutation in the transcription factor POU4F3, in which case it is fully penetrant. We studied the audiological parameters of Family H members harboring the POU4F3 8-bp deletion. Hearing was measured by pure-tone audiometry and speech audiometry on all participating relatives of Family H. Immittance testing (tympanometry and acoustic reflexes), auditory brainstem response (ABR), and otoacoustic emissions were done in a selected patient population. Audiological characteristics, such as configuration of audiogram (low, mid, high frequency), shape of slope, severity, and age of onset, were found to be variable. Our results indicate that POU4F3 mutation-associated deafness cannot be identified strictly through clinical evaluation, but only through molecular analysis. Intrafamilial variability suggests that other genetic or environmental factors may modify the age of onset and rate of progression.

Program Nr: 1661 from the 1999 ASHG Annual Meeting

Identification of 4 novel mutations in the CFTR gene, including one de novo mutation. *H. Frye-Boukhriss, K. Rommel, T. Doerk, M. Stuhrmann.* Inst Humangenetik, Med Hochschule Hannover, Hannover, Germany.

By June 1999, more than 800 mutations have been identified in the CFTR gene. Some of these mutations are reaching high frequencies, while most mutations are found in very few families or in even one family, only. We assumed that some of the latter mutations may have arisen de novo. Only 4 de novo CFTR mutations have been reported to date, all of which were novel. To identify novel mutations in the CFTR gene, we performed SSCP and heteroduplex-analysis on DNA samples from 100 patients with typical or atypical CF, who carried only one or none of 20 different CFTR mutations, which we screened routinely for CF diagnostics. Among several known mutations and novel base substitutions, we identified 3 novel frameshift mutations and one complex deletion/insertion: 836delT (exon 6a), 1212delA (exon 7), 1366delG (exon 9) and 1492del24ins9 (exon 9). In accordance with their genotypes, three of the compound heterozygous patients (836delT/DF508, 1366delG/G542X, 1492del24ins9/DF508) were affected with typical CF and inherited the novel mutation from one of their parents and the already known mutation from the other. One patient, however, who was heterozygous for both mutations DF508 and 1212delA, presented with very mild pulmonary but severe gastrointestinal symptoms. Testing of the parents of this 5 years old female patient revealed presence of DF508 in the mother but absence of 1212delA in both parents. Paternity testing with 13 different microsatellites was performed after informed consent and false paternity was excluded. We conclude that in case of a novel mutation in the CFTR gene, both parents should be investigated to determine whether this mutation is de novo, which will result in a decreased recurrence risk for CF in further offspring.

Program Nr: 1662 from the 1999 ASHG Annual Meeting

Overexpression of glutathione peroxidase has no effect on ALS-like phenotype of mutant SOD1 transgenic mice.
R. Fu, H-X. Deng, T. Siddique. Neurology, Northwestern University, Chicago, IL.

Mutations in SOD1 gene are associated with about 20% of familial amytrophic lateral sclerosis (FALS). Transgenic mice expressing FALS-linked mutations develop FALS-like phenotype. The mechanisms by which mutations in SOD1 gene cause FALS are not known. Some lines of evidence support that increased levels of free radicals or reactive oxygen species are involved in the pathogenesis. For example, dietary supplementation with vitamin E delays onset of clinical disease and slows progression in the mutant SOD1 transgenic mice although it does not prolong survival; it has also been reported that glutathione peroxidase (PE) activity is significantly reduced in precentral gyrus (a region affected in ALS) in sporadic ALS. Glutathione peroxidase is an antioxidant enzyme that scavenges hydroperoxides by using GSH as an electron donor. To test whether PE has a protective role in ALS and to explore if this enzyme can be used as a therapeutic agent, we cross-bred the transgenic mice overexpressing PE and mutant SOD1 transgenic mice. Even though the PE activity was 4-fold higher in brain in PE transgenic mice, the phenotype of the double transgenic mice that overexpress both PE and mutant SOD1 is not significantly different from mutant SOD1-alone mice. These results indicate that PE has no effect on ALS-phenotype of SOD1 transgenic mice, suggesting that hydroperoxides is not involved in the pathogenesis.

Program Nr: 1663 from the 1999 ASHG Annual Meeting

A point mutation in exon 1 of the telomeric survival motor neuron (*SMNt*) gene in a child with progressive spinal muscular atrophy. *V.L. Funanage[1,3], M. Scavina[1], S.M. Kumar[1], J. Johnston[1], M. Chopra[1], H.G. Marks[2].* 1) Department of Medical Research, Alfred I. duPont Hospital for Children, Wilmington, DE; 2) Nemours Children's Clinic, Fort Myers, FL; 3) Department of Pediatrics, Thomas Jefferson University, Philadelphia, PA.

Three genes have been identified in the spinal muscular atrophy (SMA) region: survival motor neuron (*SMN*), neuronal apoptosis inhibitory protein (*NAIP*), and *p44*. The *SMN* gene exists in two nearly identical copies: telomeric SMN (*SMNt*) and centromeric SMN (*SMNc*). Absence of the *SMNt* gene has been observed in approximately 95% of SMA patients. Parsons et al. (Am. J. Hum. Genet. **63**: 1712-1723, 1998) have recently described a novel point mutation in exon 1 of the *SMNt* gene in three unrelated SMA patients. We found a similar type of mutation in a nine-year-old black male with a progressive form of SMA. DW was evaluated at age three because of abnormal gait and absent reflexes. EMG and muscle biopsy were neurogenic. DW was diagnosed with SMA type III and was seen in our clinic at age six because of progressive weakness. He is now nine and non-ambulatory. DNA analysis revealed one copy of the *SMNt* gene and at least a single gene copy of *NAIP*. Sequencing of the *SMN* gene in DW demonstrated a point mutation (A2G) in the *SMNt* gene. A second change was a C®T polymorphism in the 5' UTR of the *SMNt* gene. The mother of DW also carried the A2G mutation as well as the C®T polymorphism. This polymorphism was frequent in the black population (6/12 non-related individuals tested), but was not found in 28 individuals of non-African heritage. Our results indicate that a point mutation in exon 1 of the *SMNt* may correlate with a milder phenotype that can be progressive in nature. In patients with a clear clinical picture of motor neuron disease who do not have a *SMNt* deletion, sequencing should be carried out to look for known or novel point mutations. We are currently determining whether the A2G mutation reduces the association of the encoded SMN protein with SIP1 (SMN interacting protein 1).

Program Nr: 1664 from the 1999 ASHG Annual Meeting

Identification of dosage sensitive genes on 22q11 associated with congenital anomaly disorders. *B. Funke, R. Pandita, F. Grimmer, L. Edelmann, N. McCain, E. Spiteri, A. Shanske, R. Goldberg, A. Skoultchi, R. Kucherlapati, T. Van De Water, B. Morrow.* Albert Einstein College of Medicine, Bronx, NY.

Three congenital disorders, cat-eye syndrome (CES), der(22) syndrome and velo-cardio-facial syndrome/DiGeorge syndrome (VCFS/DGS), result from tetrasomy, trisomy and monosomy, respectively, of part of 22q11. Our goal is to determine the molecular basis of these disorders. A 1.5 Mb region on 22q11, containing over 20 genes, is shared among the three syndromes and is conserved on mouse chromosome 16. We hypothesize that this interval contains dosage sensitive genes required for normal embryonic development. To address this hypothesis, we are taking a genetic approach using the mouse as a model organism. Using the cre/loxP system, the syntenic region on mouse chromosome 16 can be deleted. Transgenic mice carrying subsets of genes from the deleted interval can then be used for genetic complementation, thereby identifying genes which are susceptible to decreased dosage (VCFS/DGS). In addition, the genomic transgenics themselves might reveal phenotypes caused by genes that are susceptible to increased dosage (der(22) syndrome and CES). Towards this goal, we have generated 12 lines of transgenic mice for three different human BACs from the distal half of the 1.5 Mb region. Together, they contain 10 genes including *UFD1L*, *TBX1* and *COMT*. All mice are viable and fertile. Preliminary findings show a behavioral anomaly in one of the lines caused by defects in the vestibular system. In most lines, the BACs appear to be intact as determined by STS content analysis. Quantitative Southern hybridization analysis revealed different BAC copy numbers per line which further increases the range of gene dosages that can be analyzed. We found that the human transgenes are expressed in most of the lines by RT-PCR analysis. The spatial expression of most of the human genes mirrored that of their mouse counterparts, indicating that they may be properly regulated. The mice we generated provide a tool to scan a large region on 22q11 for dosage sensitive genes without any a priori knowledge about their function and might help to understand the molecular etiology of VCFS/DGS, der(22) syndrome and CES.

Program Nr: 1665 from the 1999 ASHG Annual Meeting

Differences in complexity of the isolated brachydactyly type c phenotype can not be attributed to locus heterogeneity alone. *R.J.H Galjaard[1], L.I van der Ham[2], N. Posch[2], P.F. Dijkstra[3,4], B.A. Oostra[1], S.E.R. Hovius[2], G.J. Sonneveld[2], A.J.M. Hoogeboom[1], P. Heutink[1]*. 1) Clinical Genetics, University Hospital Dijkzigt, Rotterdam, Netherlands; 2) Plastic and Reconstructive Surgery, University Hospital Dijkzigt, Rotterdam, Netherlands; 3) Radiology, Jan van Breemen Institute, Amsterdam, Netherlands; 4) Radiology, Academic Medical Centre, Amsterdam, Netherlands.

The inherited brachydactyly type C (bdC) phenotype (OMIM 113100), occuring as an isolated malformation, mostly follows an autosomal dominant pattern of inheritance with a marked variability in expression. This phenotype has been mapped to 3 different loci on chromosomes 12p, 12q24, and 20q11.2. The latter locus contains the cartilage derived morphogenetic protein (CDMP)1 gene. A null mutation in this gene has been found in patients with bdC, showing malformations of only the upper extremities. It has been suggested that the gene defect causes anomalies during a very restricted time in embryonic development; the development of the upper limbs are 1-2 days ahead of the lower limbs. Since a more complex bdC phenotype was mapped to chromosome 12q24, it has been hypothesized that the differences in complexity of these phenotypes could be attributed to locus heterogeneity. The editors of OMIM suggest clinical subtyping of the bdC phenotype, based on the degree of complexity. We present two families with patients with bdC, showing considerable intra- and interfamilial variability in expression of the phenotype. We show, using haplotype analysis, that the disease phenotype in both families segregates with markers on chromosome 20q11.2. We found a disease causing mutation in patients of both our families, thereby showing that mutations of the CDMP1 gene can also cause a complex phenotype. We therefore reject both hypotheses mentioned and can not find a justification for clinical subtyping of this phenotype based on the genetic defect. We attribute differences in complexity of the bdC phenotype to variation in expression not due to locus heterogeneity, but to genetic modifiers and/or environmental factors.

Program Nr: 1666 from the 1999 ASHG Annual Meeting

PFGE analysis of 4qter-10qter subtelomeric exchanges in normal and FSHD affected individuals: implications for the molecular diagnosis and genetic counseling of the disease. *G. Galluzzi[1,2], L. Colantoni[2], E. Bonifazi[1], G. Deidda[1], S. Cacurri[1], F. Mangiola[2], E. Ricci[3], L. Felicetti[1]*. 1) Inst of Cell Biology, CNR, Rome, Italy; 2) Centre for Neuromuscular diseases.UILDM-Rome section; 3) Institute of Neurology-Catholic University.Rome.

Interchromosomal exchanges within the subtelomeric regions from 4q and 10q reach high frequency (about 30%) in the normal population and result in the displacement of BlnI-resistant and BlnI-sensitive KpnI repeats from one chromosome to the other, with the appearance of atypical PFGE pattern of p13E-11 alleles.The exchanges may affect the whole set of BlnI-sensitive or BlnI-resistant repeat units or may be only partial: in the latter case hybridization with cloned KpnI repeats is required to identify these types of rearrangement. We tried to verify to what extent interchromosomal exchanges affect the reliability of molecular diagnosis in a group of FSHD families (more than 180) submitted to DNA analysis. In 95% of FSHD patients one of the 4q alleles is small (10 to 30 kb) whereas the other is in the normal range (30 to 200 kb) and both are resistant to BlnI digestion. After PFGE analysis, we observed variation in the number of BlnI-resistant alleles in five patients: 3 trisomic and 1 tetrasomic showed extra-alleles ranging between 35 and 120 kb in size.One patient showed only three EcoRI alleles suggesting a deletion spanning p13E-11 and KpnI sequences and maintained only one 35 kb BlnI-resistant fragment (monosomic). In addition we found three patients showing a pair of small BlnI-resistant fragments, either of similar or different size (22 and 23 kb, 24 and 14 kb, 22 and 19 kb). It is likely that only one of the fragments is involved in the disease, while the other derives from a 10qter chromosome carrying BlnI-resistant repeats. In two of the three cases, family studies allowed us to attribute the pathogenic effect to one of the small fragments. Our results suggest that one must be cautious, at least in a few cases, in the interpretation of molecular data for the diagnosis and genetic counseling of FSHD.

Program Nr: 1667 from the 1999 ASHG Annual Meeting

The human and mouse homologues of the epilepsy gene, EPM2A: Isolation and characterization of full-length transcripts and mutation detection in Lafora disease families. *S. Ganesh[1], K. Shoda[1], K. Amano[1], A. Uchiyama[2], S. Kumada[2], A.V. Delgado-Escueta[3], K. Yamakawa[1]*. 1) Neurogenetics Laboratory, RIKEN Brain Science Institute, Wako-shi, Japan; 2) Tokyo Metropolitan Medical Center for Severely Handicapped, Tokyo, Japan; 3) Comprehensive Epilepsy Program, UCLA School of Medicine, Los Angeles.

The progressive myoclonus epilepsy of the Lafora type (LD) is a rare but lethal autosomal recessive disorder, characterized by the presence of intracellular inclusion bodies. LD usually manifests as epileptic seizures during adolescence followed by a rapid and progressive dementia. Recently, mutations in the novel gene EPM2A, coding for a protein-tyrosine phosphatase, has been identified in a number of LD families but the isolated cDNA was a partial clone and therefore the complete coding region of EPM2A is not known. We have cloned and analyzed the expression of a full-length and an alternatively spliced transcript for the EPM2A gene. Sequence analyses of the full-length clone predicted four exons and is expected to code for 351 amino acids with a protein-tyrosine phosphatase domain. Northern analyses revealed that the size and expression profile of the full-length clone is distinct from the abundantly transcribed transcripts. The alternate transcript is a partial cDNA clone but showed an unique 5 coding sequence suggesting the presence of more than one promoter for EPM2A regulation. We have screened LD families for sequence variations in the coding region of EPM2A and identified polymorphism and mutations, including a microdeletion. In addition, we have cloned and characterized the mouse homologue, named Epm2a, which showed 86% identity at the nucleotide level and 89% identity and 94% similarity at the amino acid level to the human EPM2A. In mouse, Epm2a is located on the proximal end of chromosome 10 and expressed ubiquitously.

Program Nr: 1668 from the 1999 ASHG Annual Meeting

The L392V mutation of Presenilin 1 associated with autosomal dominant early-onset Alzheimers disease alters the secondary structure of the hydrophilic loop. *R. Gantier[1, 2], C. Dumanchin[1], D. Campion[1], C. Loutelier[3], C. Lange[3], J. Gagnon[4], D. Davoust[2], F. Toma[2], T. Frebourg[1]*. 1) INSERM EPI 9906, Faculté de Médecine et de Pharmacie, IFRMP, Rouen; 2) Laboratoire de RMN, UPRES A CNRS 6014, IFRMP, Mont Saint-Aignan; 3) Laboratoire de spectrométrie de masse bioorganique, UPRES A CNRS 6014, IFRMP, Mont Saint-Aignan; 4) Institut de Biologie Structurale, Grenoble, France.

Autosomal dominant early-onset Alzheimers disease results mainly from mutations of the presenilin 1 (PSEN1) gene, which codes for an integral membrane protein of 467 amino-acids. The hydrophilic loop (amino-acids 263-407) of PSEN1, in which many pathogenic mutations have been localized, appears to be crucial for the protein function since it includes the binding domains to different PSEN1 partners. Using circular dichroism (CD), we analyzed the structural effects of the pathogenic L392V mutation that we previously identified in a family including 38 affected subjects, and compared them to those of the E318G substitution. This study revealed that, the L392V mutation, in a phospholipidic medium which mimics the in vivo membrane environment, reduces the a helix content of the PSEN1 loop, whereas the E318G substitution, considered as a polymorphism, does not. These results suggest that the pathogenic effect of some PSEN1 mutations within the hydrophilic loop could be the alteration of the interaction to the different binding proteins through a disruption of the secondary structure.

Program Nr: 1669 from the 1999 ASHG Annual Meeting

***CBP* mutation detection of the Rubinstein-Taybi syndrome for diagnostic purposes.** *R.H. Giles[1], J.G. Dauwerse[1], R.I. Blough[2], A.M. Rus[1], G.J.B. van Ommen[1], D.J.M. Peters[1], M.H. Breuning[1], F. Petrij[1,3]*. 1) Dept Human and Clinical Genetics, Leiden Univ Medical Center, Leiden, The Netherlands; 2) Cincinnati Center for Developmental Disorders, Children's Hospital Medical Center, Cincinnati, OH; 3) Dept Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

The Rubinstein-Taybi syndrome (RTS) is a malformation syndrome characterized by facial abnormalities, broad thumbs, broad big toes and mental retardation. In a subset of RTS patients, microdeletions, translocations, and inversions involving chromosome band 16p13.3 can be detected. We have previously shown that disruption of the gene encoding the CREB-binding protein (*CREBBP*, or *CBP*), either by these gross chromosomal rearrangements or by point mutations, leads to RTS. CBP is a large nuclear protein involved in transcriptional regulation, chromatin remodeling, and the integration of several different signal transduction pathways. Here we report *CBP* diagnostic analysis in a series of 197 RTS patients. In one case the mother is also suspect for having RTS. Analysis of the entire *CBP* transcript in 37 RTS patients by the protein truncation test revealed 3 (8%) truncating mutations: two point mutations, and one 11 bp deletion. Screening *CBP* for larger deletions, using different cosmid probes in FISH, we found 14/171 (8%) microdeletions. In a systematic and unbiased study of a subset of these patients using 5 cosmid probes covering the entire gene, we found 8/89 (9%) microdeletions. It is of interest to note that 4 of these 8 microdeletions (50%) affected 5' or interstitial sequences of *CBP* and would not have been detected using the commonly used 3' probe RT1. These data demonstrate the necessity of using all 5 probes in FISH screening of RTS patients.

Program Nr: 1670 from the 1999 ASHG Annual Meeting

***G530S* in *COL5A1* is responsible for intrafamilial variability in a three-generation family with the classical type of Ehlers-Danlos syndrome due to a *G1489D* mutation.** *C. Giunta, B. Steinmann.* Dept. Metabolic & Molecular Diseases, University Children's Hospital, Zurich, Switzerland.

The classical type of EDS is an autosomal dominantly inherited connective tissue disorder characterised by skin hyperelasticity, tissue fragility, and joint hypermobility. We investigated the molecular defect of EDS in a three-generation family. Cultured dermal fibroblasts from the proband and his affected daughter produced abnormal a1(V) and a2(V) collagen chains. Mutation analysis revealed the presence of a heterozygous *G1489D* mutation in the *COL5A1* gene, which represents the first report of a glycine substitution in the main triple-helical region of a1(V) collagen. In the proband, the unaffected daughter and mother we identified a further newly recognised *G530S* substitution in the NH_2-terminal domain, which did not co-segregate with the EDS phenotype and was found in only one of 51 unrelated control individuals. The question now arises whether we should consider this a functional mutation or a rare polymorphism. Since the NH_2-terminal domain plays a crucial role in modulating fibril formation, the *G530S* substitution may alter the structure and function of this region and consequently the formation of collagen fibrils. Indeed, indirect evidence supports our hypothesis: (1) the EDS phenotype in the compound heterozygous proband is more severe than in his affected daughter with the *G1489D* mutation only; (2) his unaffected daughter and mother with the *G530S* substitution present with thin skin and delayed wound healing; (3) as did the control individual with the same substitution unlike his mother and sister without *G530S* (the father was not available). Thus, in the compound heterozygous proband the EDS phenotype is caused by the *G1489D* mutation and aggravated by the *G530S* substitution. This represents one of the few examples of intrafamilial variability of heritable disorders of connective tissue caused by a single additional factor. It remains to be studied whether in selected individuals of a large control population or in members of different ethnic groups with somewhat weak connective tissues the *G530S* substitution is more prevalent and predisposes to soft skin.

Program Nr: 1671 from the 1999 ASHG Annual Meeting

Association of specific mutations and severe mental retardation in Duchenne Patients. *R.R Gomes[1], A.F.B. Torres[1], M. Vainzof[1,2], A.M. Cerqueira[1], M.R. Passos-Bueno[1], M. Zatz[1].* 1) Centro de Estudos do Genoma Humano, Departamento de Biologia,IB-USP; 2) Dept. of Neurology, FMUSP, Universidade de Sao Paulo, SP, Brazil.

Duchenne muscular dystrophy (DMD), a lethal X-linked disorder is caused by a defective gene at Xp 21. The DMD gene has 79 exons spanning over 2,4 Mb. About 60-70% of DMD are caused by deletions, 6-8% by duplications and the remaining by point mutations. Several dystrophins isoforms are expressed in different tissues. Dp 140, a 7.5 Kb transcript which encodes a 140 kDa protein is expressed in the CNS and is transcribed from a promoter in the dystrophin locus upstream to exon 45, with its first initiation codon in exon 51; Dp 116 (an intermediate dystrophin gene product of 116 kDa) is expressed in the Schwann cells of the peripheral nerves ; and Dp 71(a protein of 75 kDa expressed in a wide variety of tissues), the major transcript in adult brain arise from a promoter localized within intron 63 of the human DMD gene. About 30-50% of DMD patients have severe to mild MI. It is still unclear whether or how defects in brain dystrophin isoforms are responsible for MI seen in DMD. In order to assess if there is an association between MI in DMD and specific mutations we are currently screening DMD patients with MI for point mutations in the exons involved with the dystrophin brain isoforms, that is: 44,45,49-54,69,70, and 79. Among 143 patients with MI screened for exons 44, 45, 50 and 51 we observed 27 changes: 8 polymorphisms (or rare neutral mutations) and 19 pathogenic mutations. Interestingly, 5 patients with severe MI had novel point mutations in exon 70, which were not observed in 166 patients with normal intelectual capacity. According to Human Gene Mutation Database a total of 216 mutations have been reported in the dystrophin gene. These mutations are distributed along the entire gene with no " hot spots" for specific mutations. Therefore these results suggest that mutations in the exons involved with brain dystrophin isoforms may be more often associated with MR. Supported by FAPESP, CNPq, PRONEX.

Program Nr: 1672 from the 1999 ASHG Annual Meeting

Mutation and polymorphism analysis in the human EPM2 gene in Lafora disease patients. *P. Gomez-Garre[1], Y. Sanz[1], S. Rodriguez de Cordoba[2,3], J.M. Serratosa[1].* 1) Servicio de Neurologia, Fundacion Jimenez Diaz, Madrid, Spain; 2) Unidad de Patologia Molecular, Fundacion Jimenez Diaz, Madrid, Spain; 3) Departamento de Inmunologia, Centro de Investigaciones Biologicas, Consejo Superior de Investigaciones Cientificas, Madrid, Spain.

Progressive myoclonus epilepsy of the Lafora type or Lafora disease (EPM2) is an autosomal recessive disease characterized by epilepsy, myoclonus, dementia, and periodic acid-Schiff-positive intracellular inclusion bodies. We have recently cloned the gene responsible for chromosome 6q-linked Lafora disease (EPM2) and characterized the corresponding product, a putative protein tyrosine phosphatase (LAFPTPase). We now report haplotype and mutational analysis of the EPM2 gene in 74 chromosomes from 37 affected individuals. Ten novel mutations were found: four missense mutations (F84L, R108C, G240K, and P301L), one nonsense (Y86stop), three <50 bp microdeletions (K91fs, Ex1-32bpdel, and Ex1-33bpdel), and two >3 kb deletions affecting exon 2. Including eight mutations previously communicated by our group, to date a total of 18 mutations have been found in our family set. We have also characterized five simple sequence repeats (SSRs) and two simple nucleotide polymorphisms (SNPs) within or adjacent to the EPM2 gene. Haplotypes were constructed and analyzed in order to determine haplotypic associations between EPM2 polymorphisms and EPM2 mutations. R241stop, the predominant mutation in the Spanish population was found in 16 chromosomes. The variability of the haplotypes associated with the R241stop mutation supports the idea that R241stop is a recurrent mutation with several phylogenetic origins. G279S, the second most common mutation, was found in four chromosomes carrying three different haplotypes, a finding that also supports several origins for G279S. All other mutations were found in three or less chromosomes. We conclude that a remarkable genetic allelic heterogeneity is present in chromosome 6q-linked Lafora disease and that even the most common mutations have several phylogenetic origins.

Program Nr: 1673 from the 1999 ASHG Annual Meeting

Wolframin mutations in Spanish families with Wolfram syndrome. *M. Gomez-Zaera[1], T. Strom[2], T. Meitinger[2], V. Nunes[1]*. 1) Molecular Genetics Dept., Institut de Recerca Oncològica, Barcelona, Spain; 2) Abteilung Medizinesche Genetik, Klinikum Innenstadt, München, Germany.

Wolfram syndrome (WS) is an autosomal recessive disorder mainly characterized by familial diabetes mellitus and optic atrophy. WS patients frequently show other clinical features such as diabetes insipidus, renal abnormalities, psychiatric disorders and a variety of neurologic symptoms: deafness, ataxia, peripheral neuropathy. Prevalence reported to date ranges from 1/770,000 to 1/100,000. Our group demonstrated mitochondrial implication in some Wolfram families by linkage analysis taking the presence of mtDNA deletions as a marker. 7 out of 15 families showed deletions (5 multiple deletions, 2 single deletions). A gene mutated in Wolfram patients has been recently located in 4p16. Subsequently named wolframin, this gene encompasses 33.4 kb and it is composed of 8 exons. We have looked for wolframin mutations in 12 of these 15 Wolfram pedigrees. Mutations in 8 families have been detected in exons 4 and 8. Some polymorphisms are also found in exons 2, 3 and 8. A 16 pb-insertion in exon 4 is present in 4 families, thus being the most frequent among the studied families. We could not find mutations in 4 families, and this fact can have at least two explanations: i) mutations are located in wolframin regions not yet analyzed such as exon I or the promoter region; ii) the gene responsible for WS in these families is not the wolframin gene. This option would support the idea of WS as a genetically heterogenic disease. Considering the presence of wolframin mutations and the presence of mtDNA deletions (multiple or single), our families can be classified under 6 categories. We do not yet have an explanation for these various situations. The knowledge of wolframin protein function would clarify how mitochondrial and nuclear genomes contribute to WS.

Program Nr: 1674 from the 1999 ASHG Annual Meeting

Screening of the Pro250Arg mutation in the FGFR3 gene in patients with isolated coronal craniosynostosis. *A. Gonzalez-del Angel, A. Rasmussen, L. Orozco.* Human Genetics Department, Instituto Nacional de Pediatria, Mexico city, Mexico.

Background: The main clinical feature of craniosynostosis syndromes is the premature fusion of one or more of the cranial sutures. It has recently been discovered that several of these syndromes are due to mutations in the Fibroblast Growth Factor Receptor (FGFRs) genes. In the case of isolated coronal craniosynostosis, a number of patients carry the Pro250Arg mutation in the FGFR3 gene which is a substitution of Proline for Arginine at position 250. This condition has been termed Muenke syndrome and has an autosomal dominant inheritance pattern. **Objective**: The purpose of the present study was to determine the presence of the Pro250Arg mutation in the FGFR3 gene in 16 families with isolated coronal craniosynostosis with the aim of delivering an adequate genetic counseling in the positive families. **Methods**: Genomic DNA was obtained from peripheral blood samples of the 16 index cases and their first degree relatives. Exon 7 of the FGFR3 gene was amplified by PCR and the products were cut with the NciI restriction enzyme. **Results**: Of the 16 screened families, only one carried the Pro250Arg mutation. The propositus and his father were heterozygous, with a mutant allele, while his mother and brother were homozygous for the normal allele. The father had been previously considered unaffected, however after a cautious clinical evaluation, he presented only few signs of the disease. After having obtained the molecular diagnosis a risk of recurrence of 50% for future pregnancies was given to this couple who would possibly have been counseled with a much lower recurrence risk otherwise. **Conclusions**: The detection of Pro250Arg mutation in the FGFR3 gene makes it possible to distinguish sporadic cases from those that are familial. In our family with the Pro250Arg mutation there was variable expressivity and its detection showed the importance of the molecular analysis in a family case that previously was not diagnosed by the clinical study.

Program Nr: 1675 from the 1999 ASHG Annual Meeting

Haploinsufficiency for *HOXD8-HOXD13* and *EVX2* causes atypical synpolydactyly. *F.R. Goodman[1], F. Majewski[2], R.M. Winter[1], P.J. Scambler[1]*. 1) Molecular Medicine & Clinical Genetics Units, Institute of Child Health, London, UK; 2) Institute of Human Genetics, University of Düsseldorf, Düsseldorf, Germany.

The critical role of the 5'*HOXD* genes in limb and genital bud development suggests that haploinsufficiency for these genes may cause severe limb and genital malformations. Two children with monodactylous limbs and penoscrotal hypoplasia were indeed recently shown to have chromosome 2q31 deletions that include the entire *HOXD* cluster. In mice, however, hemizygosity for single and multiple 5'*HoxD* genes produces only very minor limb defects. Here we report the phenotype caused by haploinsufficiency for the six most 5' human *HOXD* genes and *EVX2*. Our proband had bilateral 3rd finger duplication, broad halluces, 2nd metatarsal duplication and middle phalanx hypoplasia in both feet; her father had only 3/4 syndactyly in the hands, but an identical foot phenotype. Haplotype analysis with polymorphic markers in and around the *HOXD* cluster revealed that a 2q31 microdeletion had arisen *de novo* in the father and been transmitted to the proband but not to her two unaffected sisters. FISH studies with cosmids mapping to the region, followed by Southern blot analysis, showed that the deletion's centromeric end lay between *EVX2* and *DLX2*, while the telomeric end lay between *HOXD8* and *HOXD4*. These patients are therefore haploinsufficient for *HOXD8-13* and *EVX2*, but for no other gene in the region. Their phenotype closely resembles synpolydactyly (SPD) resulting from expansion or deletion mutations in *HOXD13*, believed to act as dominant negatives and functional nulls respectively. The effects of haploinsufficiency for *HOXD8-12* and *EVX2* thus appear to be slight. An SPD-related malformation also occurs in mice lacking *Hoxd11-13*, but only in homozygotes, implying that the consequences of altered *HOX* gene dosage differ in mice and humans. The limb malformations associated with large 2q31 deletions are therefore due to haploinsufficiency not for the 5'*HOXD* genes, but for a nearby gene(s). Moreover, haploinsufficiency for the nearby gene(s) must mask the SPD caused by haploinsufficiency for the 5'*HOXD* genes, suggesting that the nearby gene(s) interacts with the 5'*HOXD* genes in autopod development.

Program Nr: 1676 from the 1999 ASHG Annual Meeting

The identification of a probable IMPDH pseudogene within the critical region of the X-linked COD-1 locus and theidentification of unique IMPDH-like transcripts within the human retina. *M.B. Gorin[1,2], F.Y.K. Demirci[1,2], B.W. Rigatti[1], N. White[3], J.H. Riley[3], J. Lamb[4]*. 1) Dept. of Ophthalmololgy, The Eye and Ear Institute, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Physical Mapping Unit, UK Molecular Genetics, Glaxo Wellcome, England; 4) Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, England.

Inosine 5'-monophosphate dehydrogenase (IMPDH) is the rate-limiting enzyme in de novo guanine nucleotide biosynthesis and is responsible for an X-linked ocular mutant, raspberry in Drosophila. In our search for the gene responsible for X-linked COD-1, we identified sequences from a PAC within our contig that corresponded to the coding region of an IMPDH-like EST . We screened a retina cDNA library (Stratagene) with a hybridization probe that was inclusive of the IMPDH-like sequence from the X-chromosome PAC and which would cross-hybridize with IMPDH-1. Three rare and unique cDNA clones containing inserts of 3936, 951, and 4400 basepairs were isolated. All demonstrated portions of their coding region with strong similarity to IMPDH-1. Fifty-five percent, 57.5%, and 50.1% of the total transcripts for clones 1, 2, and 3, respectively could be closely aligned with human IMPDH-1 with similarities of 90%, 92%, and 88% within the regions of alignment (MacVectors ClustalW algorithm, default parameters). Each of these cDNA clones contained coding regions that were completely unlike the known IMPDH transcripts. We designed specific primers flanking the junctional portions of these cDNAs and confirmed the presence of these unique transcripts in another retina library (Clontech), thus ruling out a simple cloning artifact. Nearly complete sequencing of the PAC has demonstrated the entire coding sequence for an IMPDH transcript without any evidence of introns or homologies to the P2 promoter region of IMPDH-1, strongly suggesting that this is a pseudogene. We are currently identifying the chromosomal locations of these new IMPDH-like genes, testing their expression in other tissues, and confirming that the sequences on the X chromosome represent an IMPDH-like pseudogene.

Program Nr: 1677 from the 1999 ASHG Annual Meeting

Original COFS syndrome Manitoba aboriginal kindred has a mutation in the Cockayne syndrome group B (CSB) gene. *J.M. Graham, Jr.[1], L.B. Meira[2], C.R. Greenberg[3], N.G.J. Jaspers[4], D. Busch[5], D.M. Coleman[5], D.W. Ziffer[5], E.C. Friedberg[2]*. 1) Medical Genetics Birth Defects Cntr, Cedars-Sinai Medical Cntr, Los Angeles, CA; 2) Laboratory of Molecular Pathology, Dept of Pathology, Univ of Texas Southwestern Medical Cntr, Dallas, TX; 3) Children's Hospital, Univ of Manitoba, Winnipeg, Manitoba; 4) Dept Cell Biol & Genetics, Erasmus Univ, Rotterdam, The Netherlands; 5) Dept of Environ and Toxicol Pathol, AFIP, Washington, DC.

Cerebro-Oculo-Facio-Skeletal (COFS) syndrome is a rapidly progressive neurologic disorder leading to brain atrophy with calcifications, cataracts, microcornea, optic atrophy, progressive joint contractures, and growth failure. Cockayne syndrome (CS) is a recessively inherited neurodegenerative disorder characterized by low to normal birth weight, growth failure, brain dysmyelination with calcium deposits, cutaneous photosensitivity, pigmentary retinopathy and/or cataracts, and sensorineural hearing loss. Cultured CS cells are hypersensitive to UV, due to impaired nucleotide excision repair (NER) of UV-induced damage in actively transcribed DNA, whereas global genome NER is unaffected. The abnormalities are caused by mutated CSA or CSB genes. Herein we present evidence that two children related to the Manitoba Aboriginal population group within which COFS syndrome was originally reported by Pena and Shokeir in 1974, have cellular phenotypes that are essentially identical to those previously described for CS. Additionally the identical mutation was detected in the CSB gene from both individuals. Sequence analysis of CSA and CSB cDNAs prepared by RT-PCR failed to identify mutations in the CSA open reading frame. However, in cells from both Manitoba patients we detected the identical deletion of 2 nucleotides at nucleotide position 3794 of the CSB open reading frame. This deletion generates the nonsense codon TGA at codon position 1240 and is therefore expected to result in a truncated polypeptide missing the C-terminal 254 amino acids. Identical heterozygous mutations have been identified in both parents of one of these patients. These results suggest that CS and COFS syndrome share a common pathogenesis.

Program Nr: 1678 from the 1999 ASHG Annual Meeting

Mutations affecting different functional motifs of GLI3 associated with Greig cephalopolysyndactyly syndrome.
K.-H. Grzeschik, M. Kalff-Suske, M. Wessling, D. Bornholdt, H. Engel, H. Heuer. Medical Center for Human Genetics, Philipps-Universitaet, Marburg, Germany.

Greig cephalopolysyndactyly syndrome characterized by craniofacial and limb anomalies (GCPS, MIM 175700), has previously been demonstrated by our group to be associated with translocations as well as point mutations affecting one allele of the zinc finger gene GLI3. Other polydactyly syndromes such as Pallister-Hall syndrome (PHS, MIM 146510) and postaxial polydactyly type A (PAP-A, MIM 174200) are caused by GLI3 mutations. In order to gain more insight into the mutational spectrum associated with a single phenotype, we report here the extension of the GLI3 mutation analysis to more than 24 new GCPS cases. We report the identification of over 15 novel mutations present in one of the patient's GLI3 alleles. The mutations map throughout the coding gene regions affecting different functional motifs. The majority are truncating mutations (9 of 15) that engender prematurely terminated protein products mostly but not exclusively N-terminally to or within the central region encoding the DNA-binding domain. Missense and splicing mutations mapping within the zinc fingers motifs are shown experimentally to interfere with DNA-binding. The five mutations identified within the protein regions C-terminal to the zinc fingers putatively affect additional functional properties of GLI3. In cell transfection experiments using fusions of the DNA-binding domain of yeast GAL4 to different segments of GLI3, transactivating capacity was assigned to two adjacent independent domains (TA1 and TA2) in the C-terminal third of GLI3. Since these are the only functional motifs affected by three C-terminally truncating mutations, we postulate that GCPS may be due either to haploinsufficiency resulting from the complete loss of one gene copy or to functional haploinsufficiency related to compromised properties of this transcription factor such as DNA-binding and transactivation. Comparison of human GLI3 with the homologous Ci (Cubitus interruptus) protein from Drosophila guides to prediction of the functional impact of GLI3 mutations in GCPS which can be tested experimentally.

Program Nr: 1679 from the 1999 ASHG Annual Meeting

Improvement in clinical genetic testing for SCA-7: Development of a Southern to detect extremely large expansions. *P.H. Gunaratne[1], A. Gannavarapu[1], S. Palmer[2], C.S. Richards[1].* 1) Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Univ Texas Health Sci Ctr, San Antonio, TX.

Spinocerebellar ataxia type 7 (SCA-7) is a dominantly inherited neurodegenerative disorder involving clinical ataxia due to specific neuronal cell death in the cerebellum. Clinical symptoms include ataxia, ophthalmoplegia, loss of vision, dysarthria, pyramidal and extrapyramidal signs, deep sensory loss or dementia. While a distinguishing feature of SCA-7 from other SCA types is retinal degeneration, the clinical diagnosis is often difficult in the absence of molecular analysis. The expansion of an unstable CAG repeat in the SCA7 gene, which maps to chromosome 3p12-13, is responsible for disease. Normal individuals have 17 or fewer repeats, while SCA-7 patients have expansions of 38 repeats or greater. Anticipation with a prevalence for expansion during paternal transmission has been described in SCA-7 families, and extremely large expansions of over 100 repeats have been reported. While molecular analysis of SCA-7 is available in a number of clinical laboratories (see the GeneTest database), the quality of testing may vary from laboratory to laboratory. The standard clinical laboratory analysis is based upon PCR across the CAG repeat to determine the number of repeats in the normal and expanded alleles. We have now tested over 382 patients for expansions in SCA7. We have identified 37% with two normal-sized alleles, 62% with only one normal-sized allele, and 4% with expansions in the SCA7 gene. However, in patients having only one allele identified by PCR, it is difficult to rule out an extremely large expansion that is not detected by PCR. In addition, primer site polymorphism would also result in failure of a second allele to amplify. To address these concerns, we have developed a Southern-based assay to detect extremely large expansions and thus, rule out possible errors of molecular analysis. We recommend that clinical molecular genetic laboratories providing testing for SCA-7 utilize both PCR and Southern analysis.

Program Nr: 1680 from the 1999 ASHG Annual Meeting

Muscle degeneration without mechanical injury in sarcoglycan-deficiency. *A.A. Hack[1], D.I. Shoturma[2], L. Cordier[2], M.Y. Lam[3], H.L. Sweeney[2], E.M. McNally[3].* 1) Dept. of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL; 2) Dept. of Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Dept. of Medicine, Sect. of Cardiology, University of Chicago, Chicago, IL.

In humans, mutations in the genes encoding components of the dystrophin-glycoprotein complex cause muscular dystrophy. Specifically, primary mutations in the genes encoding a-, b-, g-, and d-sarcoglycan have been identified in humans with Limb Girdle Muscular Dystrophy (LGMD) types 2D, E, C and F, respectively. Sarcoglycan is also absent in Duchenne Muscular Dystrophy (DMD) as a secondary consequence of the loss of dystrophin. In order to further study the molecular and physiologic basis of LGMD and DMD we have generated mice deficient for g-sarcoglycan (Hack et al., *J. Cell Biol.* 142:1279). We have shown that mice lacking g-sarcoglycan develop progressive muscular dystrophy similar to human muscular dystrophy. Without g-sarcoglycan, the expression and localization of a-, b- and d-sarcoglycans is compromised. However, the expression and localization of dystrophin, dystroglycan and laminin-a2, a mechanical link between the actin cytoskeleton and the extracellular matrix, appears unaffected by the loss of sarcoglycan. In order to assess the functional integrity of this mechanical link we have subjected sarcoglycan-deficient muscle to isolated muscle mechanics as well as an extended regimen of strenuous exercise. We report that isolated muscles lacking g-sarcoglycan showed normal resistance to mechanical strain induced by eccentric muscle contraction. In addition, sarcoglycan-deficient muscles also showed normal peak isometric and tetanic force generation. Furthermore, there was no evidence for contraction-induced injury in mice lacking g-sarcoglycan that were subjected to an extended, rigorous exercise regimen. These data demonstrate that mechanical weakness and contraction-induced muscle injury are not required for muscle degeneration and the dystrophic process. Thus, a nonmechanical mechanism, perhaps involving some unknown signaling function, is likely responsible for muscular dystrophy where sarcoglycan is deficient.

Program Nr: 1681 from the 1999 ASHG Annual Meeting

Huntingtin interacting protein-1 (HIP-1) associated neuronal death is accompanied by activation of the caspase and JNK pathways. *A.S. Hackam[1], A.S. Yassa[1], J. Vaillancourt[2], M. Metzler[1], L. Gan[1], D.W. Nicholson[2], M.R. Hayden[1]*. 1) CMMT, University of British Columbia, Vancouver, BC; 2) Dept. Biochem. and Molecular Biology, Merck Frosst, Montreal, PQ.

Recent studies on Huntington disease (HD) suggest that events in the cytoplasm occurring prior to aggregate formation and degeneration may be responsible for disease initiation. Mutant huntingtin has significantly reduced interaction with the cytoplasmic protein HIP-1. We have previously demonstrated that HIP-1 promotes cell death and huntingtin aggregate formation in transfected cells. In this study we investigate the molecular basis of HIP-1 toxicity. Transfection of HIP-1 into neuronal NT2 cells resulted in more death than control transfections ($p<0.01$, $n=5$). A cell permeable caspase 3 inhibitor and inhibitors of the stress-kinase JNK both reduced cell death to the level of control, implicating stress kinase and caspase pathways in HIP-1 initiated cell death. A domain within the N-terminus of HIP-1 was identified with homology to proteins known to be involved in apoptosis. Substitution of a conserved hydrophobic residue within this domain with a nonpolar residue (HIP-1/F300G) reduced toxicity to the level of control, whereas substitution to a different hydrophobic residue (HIP-1/F300Y) or alteration of the adjacent amino acid (HIP-1/E299G) did not change toxicity ($n=3$). Also, expression of just this domain alone resulted in toxicity indistinguishable from HIP-1. Our data suggest that HIP-1, unbound to mutant huntingtin, can precipitate neuronal death in HD. Indeed, co-expression of a huntingtin fragment capable of binding HIP-1 significantly reduced cell death, compared with co-expression of HIP-1 with a control protein ($p<0.05$, $n=6$). Therefore, HIP-1 toxicity is likely mediated by the N-terminal domain through activation of caspases and JNK, suggesting that interfering with signaling pathways initiated by excess HIP-1 may be an effective therapeutic strategy.

Program Nr: 1682 from the 1999 ASHG Annual Meeting

A transcript map of the ALS2 candidate locus on human chromosome 2q33-q34, and exclusion of usurpin, caspase-10, and caspase-8 as candidate genes for ALS2.*ALS2*. *S. Hadano[1,2,3], N. Nichol[3], K. Fichter[3], J. Huizenga[4], J. Skaug[4], J. Nasir[3], D. Martindale[5], B.F. Koop[5], D.W. Nicholson[6], S.W. Scherer[4], G.A. Rouleau[7], J.-E. Ikeda[1,2], M.R. Hayden[3]*. 1) The Inst. of Med.Sci., Tokai. Univ., Kanagawa, Japan; 2) NeuroGenes, ICORP/JST, Japan; 3) CMMT/Dept. of Med. Genet., Univ. of British Columbia, Vancouver, Canada; 4) Dept. of Genet., The Hospital of Sick Children, Canada; 5) Center for Environ. Health, Dept. of Biol., Univ. of Victoria, Canada; 6) Dept. of Biochem. And Mol. Biol., Merck Frosst Centre for Therap. Res., Canada; 7) Centre for Res. In Neurosci., McGill Univ., Canada.

The autosomal recessive form of juvenile amyotrophic lateral sclerosis (ALS2) has previously been mapped to the 1.7 cM interval flanked by D2S116 and D2S2237 on human chromosome 2q33-q34. Based on our yeast artificial chromosome (YAC) contig map (Hadano et al. Genomics 55, 106-112, 1999), this interval spans approximately 3 Mb region of the ALS2 candidate region. To understand the molecular mechanism for the pathogenesis of ALS2, we have sought to generate a transcript map of the ALS2 locus as a first step of the identification of of the ALS2 gene. So far, we have mapped 67 transcribed DNA sequences including 9 known genes (hORC2L, usurpin, caspase-10, caspase-8, Sentrin, CTLA-4, CD28, ArgBP1, and BMPR2), 3 novel full-length transcripts (CALS-C, CALS-7, and CALS-21) and 55 expressed sequenced tags (ESTs) within this interval. In this report, we further focused on mutation search in three known genes, usurpin, caspase-10, and caspase-8. First, we have defined structures of exon/intron organizations of these genes. The human usurpin, caspase-10, and caspase-8 genes were found to contain 14, 11, and 13 exons, respectively. Then, we have designed primer sets that allow to amplify each exon and exon/intron boundaries, amplified DNA from patients with ALS2 and normal controls, determined each DNA sequence, and compared DNA sequences between patients and normal controls. As a result, no mutation has been found in all exons analyzed. These studies indicate that neither usurpin, caspase-10, nor caspase-8 gene has mutation and/or sequence alterations that associated with ALS2, excluding usurpin, caspase-10 and caspase-8 genes as candidates for ALS2 gene.

Program Nr: 1683 from the 1999 ASHG Annual Meeting

Correlation between genotype and phenotype in Korean patients with spinal muscular atrophy. *S.H. Hahn, S.Y. Won, E.H. Lee, K.N. Cho, S.H. Kim, C.H. Hong.* Dept Pediatrics, Ajou Univ Col Medicine, Suwon, Kyunggi do, Korea.

Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disorder with a large phenotypic variability. The disease can be classified into three clinical types based on age of onset and degree of severity. The genes associated with SMA were mapped to chromosome 5q13 where large scale deletion have been reported encompassing several genes, the p44 gene, neuronal apoptosis inhibitory protein (NAIP) gene and the survival mortor neuron (SMN) gene. 90% of patients with type 1 have defects in exon7 and 8 of telomeric survival motor neuron (SMNtel) gene, while 67% and 45% of type I patients have defects of NAIP and p44 gene, respectively. So far, no strict correlation between genotype and phenotype has been established. We have screened for the SMN, NAIP and p44 gene deletions in 9 Korean patients with type 1 and 2 with type II. Six of nine type I (66.7%) and one of two type II patients, 10 year-old girl had deletions of above all three genes. The rest of type I and type II patients had the deleted SMN gene only. It appeared that there was no significant correlation between the size of deletion and severity in Korean patients with SMA. In one particular case, the patient was confirmed to have exon 8 of SMNtel gene, but had the deletion of exon 7. The telomeric exon 7 in this patient was converted by centromeric exon 7. We also analysed Ag1-CA and C212 microsatellite markers in order to find the relationship between copy numbers of marker and severity in SMA patients but no significant relationship was revealed. In screening of one hundred normal individuals, two of them showed deletion of SMNcen gene suggesting the frequent rearrangements in the region. Despite the limited number of subjects in this study, gene conversion appears to account for the significant number of Korean patients with SMA and no relationship between genotype and phenotype was suspected. It is conceivable that other unknown factors may play an important role in the pathogenesis of SMA and are also responsible for the severity of the phenotype.

Program Nr: 1684 from the 1999 ASHG Annual Meeting

Highly homologous human anion transporter genes, CLD and DTDST, have partially overlapping expression in colon epithelium. *S.P. Haila[1], P. Höglund[1], U. Saarialho-Kere[2], M.-L. Karjalainen-Lindsberg[3], J. Hästbacka[1], J. Kere[1, 4].* 1) Dept Medical Genetics, Univ Helsinki, Finland; 2) Dept Dermatology, Helsinki Univ Central Hospital, Finland; 3) Dept Pathology, Univ Helsinki, Finland; 4) Finnish Genome Center, Univ Helsinki, Finland.

Congenital chloride diarrhea (CLD) is an autosomal recessive disorder. It manifests as a lifetime watery diarrhea with a high chloride content and is caused by mutations in the DRA/CLD gene. The CLD protein is highly homologous to two other known human anion transporters, namely the proteins encoded by the diastrophic dysplasia sulfate transporter gene (DTDST) and the Pendred syndrome gene (PDS). Mutations in the human DTDST gene cause diastrophic dysplasia (DTD), atelosteogenesis type II, and achondrogenesis type IB. These proteins share common features like their suggested transmembrane topology and function as anion transporters. In vitro functional studies have demonstrated that both CLD and DTDST mediate the transport of sulfate that is inhibited by extracellular chloride. CLD mRNA is expressed in the mature surface epithelium, especially in brush border cells of normal colon. By Northern analysis, DTDST is expressed in a wide variety of human tissues including colon, whereas Northern analysis with the rat dtdst have suggested a more restricted expression profile limited to cartilage and intestine only. Colon expression of DTDST was studied using radioactive mRNA in situ hybridization and compared with that of CLD in colon. The human DTDST gene demonstrated strong colon expression in the top one-third of the crypt and lack of signal both at the surface level and in the bases of the crypts. The localization was partially overlapping with but distinct from that of CLD. Clinical abnormalities known in DTD are restricted to cartilage and bone and no intestinal manifestations are known. In physiological circumstances, CLD has been shown to transport preferentially chloride but it transports also sulfate, whereas the loss of sulfate transport has a major role in the pathogenesis of cartilage growth defects in DTD. Clinical significance of the colon expression of DTDST remains to be evaluated in DTD patients.

Program Nr: 1685 from the 1999 ASHG Annual Meeting

Effects of mutation on Notch function and implications for CADASIL. *T. Haritunians[1], A. Gu[1], C. Hicks[2], J. Boulter[3], G. Weinmaster[2], N.C. Schanen[1].* 1) Human Genetics, U.C.L.A., Los Angeles, CA; 2) Biological Chemistry, U.C.L.A., Los Angeles, CA; 3) Psychiatry and Biobehavioral Sciences, U.C.L.A., Los Angeles, CA.

CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy) is an inherited vascular dementia that occurs in young people lacking risk factors for stroke. Pathologically, there is replacement of the vascular smooth muscle cells of the tunica media of small and medium sized arterioles by an amorphous substance. The loss of integrity of the vessel wall leads to multiple ischemic strokes in the deep white matter, resulting in progressive dementia. CADASIL is caused by missense mutations in the extracellular EGF-like repeat domains of the transmembrane receptor, Notch3. Notch3 is a member of a family of evolutionarily conserved cell surface receptors with known function in cell fate determination during embryonic development. To understand the molecular pathogenesis of CADASIL, we have cloned and sequenced rat Notch3, revealing a 93% and 85% homology to mouse and human Notch3, respectively. Using site-directed mutagenesis, we introduced four point mutations in rat Notch1 and Notch3, which are analogous to those observed in CADASIL patients. Functional characterization of these mutants in transiently-transfected cells allows in vitro analysis of the effect of these mutations on both ligand binding and signal transduction. Cotransfection with CBF1-luciferase reporter plasmids allows scrutiny of the CBF1 dependent pathways that have been shown to be involved in Notch signaling. These investigations provide preliminary evidence for the mechanism of dominance of the mutations (dominant negative versus activating mutations).

Program Nr: 1686 from the 1999 ASHG Annual Meeting

Structural and Functional Analysis of Human Acid Sphingomyelinase: Insights from Niemann-Pick Disease Mutations. *X. He[1], S. Miranda[1], A. Butler[1], E. Mehler[2], M. McGovern[1], E. Schuchman[1].* 1) Dept Human Genetics, Mt Sinai Sch Medicine, New York, NY; 2) Dept Physiology and Biophysics, Mt Sinai Sch Medicine, New York, NY.

Human acid sphingomyelinase (ASM) is the lysosomal enzyme required for the hydrolysis of sphingomyelin to ceramide and phosphocholine. An inherited deficiency of ASM activity leads to Types A and B Niemann-Pick disease (NPD). To investigate the nature of phenotype variation in this disorder, the clinical, biochemical and molecular abnormalities in individual NPD patients was studied. Several new ASM mutations were identified and expressed, but no correlations could be made between phenotypic severity, the location of the ASM mutations within the primary protein sequence, or the residual ASM activity in cultured cells. In the absence of crystallographic data, a 3D molecular model of human ASM was created based in part on the known 3D structures of Saposin and b-Glucuronidase. ASM consists of a saposin domain (residues 82-97) hinging a phosphodiesterase domain (199-464) with a proline-rich domain (182-197). Four Zn+2 binding sites also were identified, and a substrate binding motif (354-388) was predicted based on homologies with lysenin, a sphingomyelin-specific binding protein. Notably, many of the NPD patient mutations occurred at or near the putative zinc or substrate binding sites. His430 also was predicted as an important residue in the ASM active site based on conservation between ASMs from human, mouse and C. elegans, as well as various phospholipase C sequences. The validity of the molecular model was tested by expressing several ASM mutations at sites predicted to be critical for ASM function and demonstrating loss of activity. These results demonstrate that a reliable model of a complex enzyme such as ASM can be created in the absence of crystallographic information and suggests that such models may be useful for predicting the severity of individual disease-causing mutations.

Program Nr: 1687 from the 1999 ASHG Annual Meeting

Dyskerin localises to the nucleolus and mislocalisation is not involved in the pathogenesis of dyskeratosis congenita. *N. Heiss[1], A. Girod[2], R. Salowsky[1], S. Wiemann[1], R. Pepperkok[2], A. Poustka[1]*. 1) Department of Molecular Genome Analysis, Deutsches Krebsforschungszentrum (DKFZ), Heidelberg, Germany; 2) Cell Biophysics, EMBL, Heidelberg, Germany.

The gene responsible for causing the X-linked recessive form of dyskeratosis congenita (DKC, OMIM 305000), DKC1, has been positionally cloned. The early stage of DKC is characterised by nail dystrophy, mucosal leukoplakias, and reticulate skin hyperpigmentation. Patients develop progressive bone marrow failure and this is the major cause of premature death. An increased risk of developing a range of malignancies also exists. To date, 14 different missense mutations, a putative splice site mutation, and a deletion of the last exon, exon 15, have been identified. There are mutation hot spots in the exons 3, 4, and 11. The peptide dyskerin is highly conserved to the rat NAP57, yeast Cbf5p, and Drosophila Nop60B nucleolar proteins which are involved both in the pseudouridylation and in the cleavage of pre-rRNA. We confirmed the nucleolar localisation of dyskerin by microinjecting mammalian cell lines with constructs expressing dyskerin fused to the enhanced green fluorescent protein (EGFP). Staining with the p80coilin antibody showed that EGFP-dyskerin co-localises with the coiled bodies which are functionally linked with the nucleoli. A series of deletion constructs and mutant constructs containing amino acid substitutions introduced by in vitro mutagenesis were generated. This facilitated the delineation of sequences involved in targeting dyskerin to the nucleus and the nucleolus. Further, we demonstrated that EGFP fusions containing mutations detected in patients do not cause dyskerin to mislocalise. In order to quantitatively and qualitatively examine the endogenous localisation of dyskerin in patient cell lines, we are currently characterising monoclonal antibodies. Since a number of functional connections have been made between the nucleolus and aging, it is of interest that some features of DKC have been likened to those of a pre-mature aging syndrome. To address these functional aspects, we are in the process of generating a murine model for the disease.

Program Nr: 1688 from the 1999 ASHG Annual Meeting

Intragenic localisation of Tau mutations correlates with distinct FTD phenotypes. *P. Heutink[1], P. Rizzu[1], S. Rosso[2], M. Joosse[1], R. Ravid[3], W. Kamphorst[4], JC. van Swieten[2].* 1) Dept. Clinical Genetics, Erasmus University, Rotterdam, Netherlands; 2) Dept. Neurology, Erasmus University Rotterdam; 3) Dutch Brain Bank, Amsterdam; 4) Dept.Pathology, Vrije Universiteit, Amsterdam.

Fronto-temporal dementia's (FTD) are a group of presenile dementia's with progressive behavioral changes and often frontal and temporal atrophy. Approximately 40% of cases are familial. Mutations in the microtubule associated protein tau are associated with familial FTD. Patients can roughly be divided in three groups based on localisation of the mutation in the tau gene: 1. Missense mutations within the first two microtubule binding domains. 2. Missense mutations affecting the C-terminus of tau. 3. Mutations increasing the alternative splicing of exon 10. We have compared clinical and pathological characteristics of multiple families with mutations for each of these three groups (6 large Dutch families supplemented with published data). Group 1 show little variation in age at onset and duration of disease. Disinhibition and initiative loss are characteristic. Tau pathology consists of pretangles in neurons and Glia cells consisting mostly of 4-repeat tau isoforms. Group 2 shows a relatively late age at onset and long duration of disease, memory loss early in the disease. Tau pathology consists of pretangles in neurons only, consisting of all 6 tau isoforms. Group 3 Shows large intrafamilial differences in age at onset and duration of disease.Parkinsonian symptoms are prominent. Tau pathology consist of pretangles in neurons and glial cells consisting of 4-repeat tau isoforms. Functional assays of the different mutations in the tau protein offer a partial explanation for the found correlations. Most missense mutation show a (partial) loss of microtubule binding function and an increased capacity for self assembly into insoluble aggregates. Mutations in the C-terminus of tau have a less dramatic effect on microtubule binding and self assembly providing a possible explaining the late onset and duration of disease. Mutations increasing incorporation of exon 10 result in overexpression of 4-repeat tau isoforms consistent with pathology findings.

Program Nr: 1689 from the 1999 ASHG Annual Meeting

Use of Denaturing High Performance Liquid Chromatography (DHPLC) for connexin 26 gene mutation screening. *P. Hilbert, C. Kint, L. Van Maldergem, Y. Gillerot.* Dept Molecular Biol, Inst Pathologie et Genetique, Loverval, Belgium.

Recent progress in the genetics of deafness has shown that mutations in the connexin 26 (GJB2) gene are responsible for a significant proportion of non-syndromic recessive form of deafness. More than 40 mutations have been described but one (30delG) accounts for the majority of those described so far. The carrier frequency of the 30delG mutation varies from 2 % in the USA to 4 % in Italy. In order to estimate the frequency of the different Cx26 mutations in our population (Southern part Belgium), we developped a rapid screening test based on the DHPLC technology. This method based on the automated separation and detection of homo- and heteroduplexes allows the detection of mutations/polymorphisms in a PCR fragment in less than 10 minutes. The optimization of the DHPLC conditions was established on samples with previously sequenced mutations. Interestingly, the 30delG mutation showed a typical pattern. The carriers mutation screening was realised on 367 individuals of whom 35 (9.5 %) showed a modified elution profile and were subsequently sequenced. The 30delG mutation was identified in 16 subjects. It represents a carrier frequency of 4.35 %, one of the highest described so far. For all of them but one (with a second I128I polymorphism) the mutation was already identified from the elution profile before sequencing. Known polymorphisms and mutations were found in 14 other cases: 3 V37I (0.8 %), 9 M34T (2.4 %) , 1 G160S (0.2 %) and 1 R127H (0.2 %). This result confirms the high frequency of the M34T polymorphic variant. Three new variants were detected: V153I corresponding to a G-A transition at position 457 (4 cases - 1 %), G12V due to a G-T transition at position 35 (1 case - 0.2 %) and I128I due to a C to T transition at position 384 (1 case - 0.2 %). If I128I can probably be considered as a polymorphism, the impact of the two other nucleotide changes remains to be elucidated. This study confirms that the DHPLC is a powerful technology for the screening of mutations in connexin 26 gene and allows the rapid identification of the 30delG mutation without the need of sequencing.

Program Nr: 1690 from the 1999 ASHG Annual Meeting

Mutations in non-coding regions of the proteolipid protein (*PLP*) gene in patients with Pelizaeus Merzbacher disease (PMD) and PMD-like disorders. *G.M. Hobson[1], A. Davis[2], N. Stowell[3], E.H. Kolodny[4], V.L. Funanage[1], H.G. Marks[5]*. 1) Department of Research, A I du Pont Hosp for Children, Wilmington, DE; 2) Jefferson Medical College, Thomas Jefferson University, Philadelphia, PA; 3) DuPont Pharmaceuticals Co, Wilmington, DE; 4) School of Medicine, New York University Medical Center, New York, NY; 5) Department of Pediatrics, Nemours Children's Clinic, Fort Myers, FL.

Pelizaeus Merzbacher disease (PMD) is a dysmyelinating disorder of the central nervous system. Duplications or point mutations in exons of the proteolipid protein (*PLP*) gene have been found in most patients with PMD. Direct sequence analysis of the *PLP* gene of 43 patients with either PMD or a clinically similar disorder revealed four mutations in non-coding regions. One patient was normal at birth and developed head oscillations at four months, and ataxia, which has remained stable, at eight months. At two years of age, he has developed spasticity of the lower limbs. A C to T transition was found in this patient at +37 in the 3'UTR of the *PLP* gene. Since an unaffected male member of the family also has the mutation, it is probably a polymorphism. In two brothers with a connatal form of PMD, we found a G to T transversion at IVS6 +3, which caused skipping of exon 6 in RNA prepared from cultured fibroblasts. An eight-year old who developed nystagmus at 16 months and progressive spastic ataxia at 18 months was found to have a 19-base deletion of a G-rich region near the 5' end of intron 3. A very low level of the mutation was detected in peripheral blood lymphocytes of the maternal great-grandmother, indicating that she is probably a somatic mosaic and the mutation arose in her. Another patient had the classical form of PMD. He was found to have a T to C transition at IVS3 +2. This, like the 19-base deletion, is in intron 3, which is involved in *PLP/DM20* alternative splice site selection. These findings indicate that in the evaluation of patients suspected of having PMD or a PMD-like disorder, one needs to look for mutations in introns in addition to looking for duplications or mutations in exons of the *PLP* gene.

Program Nr: 1691 from the 1999 ASHG Annual Meeting

Characterization of H4F5, a candidate modifying gene for spinal muscular atrophy (SMA). *Y. Hofmann[1], F.I. Sieprath[1], C.L Lorson[2], E.J. Androphy[2], B. Wirth[1].* 1) Inst. of Human Genetics, Bonn, Germany; 2) TUFTS-University, Boston, MA, USA.

Spinal muscular atrophy (SMA) is a common autosomal recessive neuromuscular disorder with variable phenotype caused by mutations in the survival motor neuron gene SMN1 and phenotypically modulated by SMN2 copies. Recently, it has been shown that a single nucleotide exchange in SMN2 attenuates the activity of an exonic enhancer and leads to alternative splicing of exon 7 which is the molecular defect that causes SMA. Neighboring genes may also influence the transcription and function of SMN. H4F5, a duplicated gene ($H5F5^T$ and $H4F5^C$), is localized only 6.5 kb upstream from SMN and shows a strong correlation between frequency of deletions and severity of the disease.

Therefore, it has been proposed as a candidate modifying gene for SMA (Scharf et al., Nature Genet, 1998, 20:83-86). To find out whether the two H4F5 copies are identical, we sequenced the coding region of 10 SMA patients who retained only $SMN2/H4F5^C$ and 10 controls who retained only $SMN1/H4F5^T$. No sequence difference was found. Two isoforms of H4F5 ($H4F5_S$ and $H4F5_L$), each containing 3 exons have been reported. The two isoforms vary by the third exon. We identified an additional splicing within exon 3b in both H4F5 copies. Due to a cryptic site, 182 bp of exon 3b were alternatively spliced, producing an additional isoform. Furthermore, we identified a non-transcribed pseudogene of H4F5.

Both $H4F5_S$ and $H4F5_L$ are predicted to form helix-turn-helix proteins, indicating a role in nucleic acid binding. Since snRNPs consist of RNA and are components of the cellular splicing machinery, binding of H4F5 to RNA and thus an effect on SMN splicing as modifyer is of great interest. We have begun the molecular characterization of H4F5 including RNA- and DNA binding, SMN protein association, and affects upon SMN mRNA processing.

Program Nr: 1692 from the 1999 ASHG Annual Meeting

COMP gene mutations result in abnormal collagen fibril morphology. *P. Holden[1], W. Newman[1], C.J.P. Jones[2], M.E. Grant[1], M.D. Briggs[1].* 1) Wellcome Trust Centre for Cell-Matrix Research, School of Biological Sciences; 2) Academic Unit of Obstetrics and Gynaecology, University of Manchester, Manchester, M13 9PT, England.

Cartilage oligomeric matrix protein (COMP) is found in cartilage, tendon and ligament and functions as a large multidomain pentameric glycoprotein. Mutations in COMP result in pseudoachondroplasia (PSACH) and multiple epiphyseal dysplasia (MED), two autosomal dominant skeletal dysplasias characterised by delayed ossification and joint laxity. Electron microscopy of transverse sections of labrum ligament from a patient with PSACH shows irregular collagen fibril morphology; longitudinal sections show abnormal tissue architecture with disruption of collagen fibril orientation, suggesting an important role for COMP in collagen fibril assembly. Using primary cell lines, established from ligament of both affected and normal adults, we are looking at the role of the C-terminal domain of COMP in the development of the extracellular matrix and particularly its role in collagen fibril assembly. In addition, solid phase binding assays using native COMP purified from articular cartilage and recombinant C-terminal COMP expressed in bacterial and mammalian cells, are being used to identify interactions between COMP and various constituent collagens of ligament and cartilage. Cell attachment/spreading assays are also being performed with these proteins. Furthermore, a series of mutant proteins representing the known mutations within the C-terminal domain have been expressed and are currently being studied to determine their effects on the function of this domain. We have shown that native COMP specifically interacts with primary ligament cells and preliminary evidence indicates that C-terminal COMP can interact with type I collagen, suggesting an important role for this protein in the development of the extracellular matrix and subsequent tissue morphology. This work will undoubtedly provide a clearer illustration of the complex matrix of these tissues and lead to a more complete understanding of disease pathology. (This work is supported by the Arthritis Research Campaign and The Wellcome Trust).

Program Nr: 1693 from the 1999 ASHG Annual Meeting

Application of bisulphite genomic modification to determine the methylation status of a 1.2 kb region of neurofibromatosis type 1 (NF1) promoter sequence in benign neurofibromas from 10 unrelated NF1 patients.
M.P. Horan, M. Upadhyaya. Institute of Medical Genetics, Univ Wales College of Medicine, Cardiff, U.K.

Neurofibromatosis type 1 (NF1) is a common autosomal dominant disorder. The NF1 gene product, neurofibromin, has a GAP related domain (GRD) that is involved in the down regulation of p21ras oncogene activity. The NF1 gene is therefore considered to function as a tumour suppressor gene. Loss of functional activity of tumour suppressor genes is a key factor in tumorigenesis. Inactivating mutations within the coding region of the NF1 gene lead to development of disease expression and tumour formation. An alternative method of tumour suppressor gene inactivation is hypermethylation of CpG dinucleotides within promoter sequences resulting in a significant reduction in protein expression, and is now recognised as an important epimutational mechanism. In practical terms, hypermethylation represents the second hit (somatic) mutation. We have investigated whether such hypermethylation of the NF1 promoter may also be associated with tumorigenesis in NF1-related tumours. The study group comprised DNA samples derived from 10 benign neurofibromas (9 dermal and 1 plexiform), peripheral blood lymphocytes (PBL) DNA from unrelated NF1 patients and suitable control individuals. Molecular analysis of 70 CpG sites encompassed within the 5' end of the NF1 gene sequence was carried out by bisulphite genomic sequencing. Analysis was confined to a 1.2 kb region containing upstream and downstream sequences from the transcription start site (-674 -> +533) which also encompassed the first 50 bases of exon 1. Tumour-associated hypermethylation of 3 separate CpG sites has been identified at position -609 (both alleles in 6 tumours and 1 allele in 2 tumours), at position -406 (1 allele in 3 tumours), and position -383 (1 allele in 2 tumours) upstream from the transcription start site. All other CpG sites remained hypomethylated. These results suggest that hypermethylation of CpG sites within the NF1 promoter is not a common causative factor for benign neurofibroma formation, and indicates that hypermethylation of the NF1 gene promoter is unlikely to be associated with tumorigenesis in these tumours.

Program Nr: 1694 from the 1999 ASHG Annual Meeting

Ataxia with Isolated Vitamin E Deficiencfy: A Novel Mutation in the a-**Tocopherol Transfer Protein Gene.** *W. Hung[1], H. Jiang[1], H.X. Deng[1], S. Wharton[2], T. Siddique[1].* 1) Dept Neurology, Northwestern Univ Medical Sch, Chicago, IL; 2) Seratoga Springs, NY.

Ataxia with isolated vitamin E deficiency (AVED), transmitted as an autosomal recessive trait, is a progressive neurological disease characterized by cerebellar ataxia and symptoms of central and peripheral axonopathy resembling Friedreichs ataxia. The underlying biochemical defect is the failure of a-tocopherol incorporation into very low density lipoprotein (VLDL) in liver cells. a-Tocopherol transfer protein (a-TTP) enhances the transfer of the a-tocopherol form of vitamin E between membrances. The gene for this protein is located on chromosome 8q13. Its mutation has been shown to cause AVED. To date, sixteen different mutations of aTTP have been identified in AVED patients in North Africa, Europe, North America and Japan. We now report a new AVED case with compound mutation in aTTP gene; one mutation occurs in exon 3 as previously reported, which involves a deletion of T at codon 162 and the other mutation involves a substitution of AA with C at codon 72 in exon 2, that leads to a frameshift and premature stop of aTTP synthesis with additional 10 amino acids downstream.

Program Nr: 1695 from the 1999 ASHG Annual Meeting

Nuclear localization, aggregation or ubiquitination of ataxin-2 are not necessary for SCA2 pathogenesis in human or mouse. *D.P. Huynh[1], M.R. Del Bigio[2], K. Figueroa[1], N. Hoang[1], T. Ho[1], S.M. Pulst[1]*. 1) Medicine, Cedars-Sinai Medical Ctr, Los Angeles, CA.90048; 2) Pathology, University of Manitoba, Winipeg, Canada.

Introduction: Instability of CAG DNA trinucleotide repeats is the mutational mechanism of several neurodegenerative diseases resulting in the expansion of a polyglutamine (polyQ) tract. Proteins with long polyQ tracts have an increased tendency to aggregate, often forming intranuclear inclusion bodies. We investigated whether intranuclear aggregate formation or even diffuse intranuclear localization was necessary for SCA2 pathogenesis using cultured cells, human brains, and SCA2 transgenic mouse lines. Methods: To determine the cellular differences between the normal Q22 and the diseased Q58 ataxin-2, full-length SCA2 cDNA containing either 22 or 58 CAG repeats was ligated in-frame into the pEGFPC1 vector, and transiently transfected into COS1 cells. Transfected cells were imaged using a Zeis LSM 310 confocal microscope. To make a transgenic SCA2 construct expressing predominantly in Purkinje neurons, we placed the full-length SCA2 cDNA under the regulation of the Purkinje cell specific promoter (Pcp2). Transgenic and wild type mice were analyzed using a mouse rotarod apparatus to test motor balance and coordination, and immunohistochemical staining using ataxin-2 and calbindin28K antibodies to determine anatomical abnormality caused by the polyQ expansion. Results:In COS1 cells transfected with Q58 or Q22 GFP-ataxin-2 expression constructs and in SCA2 human brains, cytoplasmic but not nuclear aggregates were found. Mice expressing ataxin-2 with Q58 showed progressive functional deficits accompanied by loss of calbindin-28K labeling and subsequent degeneration of Purkinje cell dendritic aborization, but no intranuclear aggregates in Purkinje neurons. Conclusion:These observations suggest that intranuclear localization or ubiquitination is not a shared feature of polyQ diseases, and point to cytoplasmic factors in neurodegeneration. **IntroductionMethodsResultsConclusion**.

Program Nr: 1696 from the 1999 ASHG Annual Meeting

Spinocerebellar ataxia type 8; clinical and molecular studies in Japan. *Y. Ikeda, M. Shizuka, M. Watanabe, K. Okamoto, M. Shoji.* Department of Neurology, Gunma University School of Medicine, 3-39-22 Showa-machi, Maebashi 371-8511, Japan.

Spinocerebellar ataxia type 8 (SCA8) is the first example of hereditary ataxia caused by a dynamic mutation of the untranslated CTG trinucleotide repeat. We examined the clinical and molecular characteristics of Japanese SCA8 patients and also investigated the frequency of the CTG repeat length in Japanese normal elderly controls aged more than 79 years. The numbers of the combined CTA/CTG repeats of six affected SCA8 alleles and normal elderly controls were 106.3 +/- 24.4 ranging from 89 to 155 and 24.3 +/- 4.4 (n=104 alleles) ranging from 15 to 34, respectively. The mean age at onset of our SCA8 cases was 53.8 +/- 19.7 years, with a range from 20 to 73. One father-daughter pair in an SCA8 family showed remarkable clinical and genetic paternal anticipation, which is a rare phenomenon in SCA8. The number increased from father to daughter of the family was +16 CTG repeats with an acceleration of age at onset, resulting in -31 years (from 73 to 42 years). These SCA8 cases chiefly showed symptoms and signs derived from disturbance of the cerebellar system, and the MRI findings demonstrated significant atrophy of the cerebellar vermis and hemispheres. The severity of cerebellar atrophy on MRI was much greater for SCA8 in comparison with SCA6, another example classified as autosomal dominant cerebellar ataxia type III.

Program Nr: 1697 from the 1999 ASHG Annual Meeting

Darier's disease - a dominant skin disorder with a neuropsychiatric component. *N.J.O. Jacobsen[1], I. Lyons[1], B. Hoogendoorn[1], S. Burge[2], P.Y. Kwok[3], M.C. O'Donovan[1], N.J. Craddock[4], M.J. Owen[1].* 1) Psychological Medicine, Neuropsychiatric Genetics, Cardiff, Wales, Great Britain; 2) Department of Dermatology, Churchill Hospital, Oxford OX3 7LJ; 3) Washington University School of Medicine, 660 S. Euclid Ave, Box 8123 St. Louis, MO 63110 USA; 4) Division of Neuroscience, University of Birmingham, Queen Elizabeth Psychiatric Hospital, Birmingham, B15 2QZ.

Darier's disease (DD - OMIM 124200), is a rare, dominantly inherited disorder that affects the skin producing a variety of types of lesion. Close examination of lesional DD skin shows the presence of the abnormal keratinisation (epidermal differentiation) and acantholysis (loss of cohesion) of keratinocytes. A number of clinical studies have described the co-occurrence of various neurological and psychiatric symptoms with DD, including major affective disorder, psychosis, epilepsy, mental retardation, and a slowly progressive encephalopathy. A single locus for DD has been mapped to chromosome 12q23-q24.1 and a variety of missense, nonsense, frameshift, and splicing mutations in the ATP2A2 gene have recently been described in families with DD by Sakuntabhai et al (1999). This gene encodes the sarcoplasmic/endoplasmic reticulum calcium pumping ATPase SERCA2, which has a central role in intracellular calcium signalling. In this study a sample of patients suffering from DD and varying neuropsychiatric phenotypes were analysed for mutations in ATP2A2. The mutations identified were then compared to mutations found in patients with DD only. In neuropsychiatric cases of DD mutations were found to cluster significantly within exons 13-19 of ATP2A2 compared to DD patients where mutations occurred throughout the gene ($p=0.011$), and were found to be predominantly missense mutations (70% versus 35% in DD patients). This suggests that specific mutations in ATP2A2 elicit pleiotropic effects in brain. Subsequent studies of these mutations may provide simple models for complex neuropsychiatric disorders.

Program Nr: 1698 from the 1999 ASHG Annual Meeting

Towards the gene for Lethal Congenital Contracture Syndrome. *N.A. Jarvinen[1,2], P. Makela-Bengs[1], L. Chen[2], K. Vuopala[3,4], L. Peltonen[2]*. 1) 1Department of Human Molecular Genetics, National Public Health Institute, and Department of Medical Genetics, University of Helsinki; 2) Department of Human Genetics, University of California, Los Angeles; 3) Department of Pathology, Lapland Central Hospital, Rovaniemi, Finland; 4) Department of Pathology, University of Oulu, Oulu, Finland.

LCCS is an autosomal recessive syndrome reported so far only in the genetically isolated population of Finland. The incidence in Finland is 1 in 19000. LCCS leads to prenatal death of the fetus before 32 weeks of gestation. The affected fetuses have hypoplastic lungs, hydrops, marked skeletal muscle hypoplasia and contractures of the extremities. The hallmark of the syndrome is the early onset degeneration of the anterior horn motoneurons and the descending tracts, whereas the sensory neurons of the ascending tracts are preserved. We have previously assigned the locus for LCCS to chromosome 9q34.1 by linkage analysis and restricted the region to under 100kb in the vicinity of marker D9 S61 using linkage disequilibrium and monitoring for shared ancestral haplotype. We have built a physical map of BACs with a 10x coverage over the region between markers D9 S904 and D9 S752 which encompasses the marker D9 S61. With the aid of BAC end sequences used as probes for in silico cloning we have located several EST contigs in the critical DNA region. Known interesting positional candidate genes in the region, include Dynamin-1, SPTAN, and glutamine transaminase K. Analyses of these regional candidate genes are ongoing. Sequencing of this region by genome centers at MIT and the Sanger Centre is also close to completion. Identification of the gene defect will form the basis for understanding the pathogenesis of LCCS and will provide novel insight into the normal and disturbed development of motoneurons.

Program Nr: 1699 from the 1999 ASHG Annual Meeting

Molecular genetics of Thalassemia and G6PD Deficiency in Bahrain. *N.A. Jassim[1], S.S. Al Arrayed[1], T. Merghoub[2], R. Krishnamoorthy[2]*. 1) Genetic dep., Salmaniya Medical Centre., Manama, Bahrain; 2) Inserm U458,Jopital R Debre,Paris,France.

Bahrain is an archipelago in the Arabian Gulf with a population estimate of 700,000 inhabitants. Previous phenotype analysis in this country revealed high frequency of Thalassemias ($\alpha$and $\Beta$)and G6PD deficiency, By using a variety of molecular techniques (PCR-RFLP,PCR-DGGE,RDB,differential PCR amplification and DNA sequencing) here we are reporting the precise molecular spectrum of these disorders in the population of Bahrain. For $\Beta$ thalassemia a total of 13 different mutations were identified, of which four mutations (IVSI,3^{1} end (-25bp);Cd39(C$rightarrow$T);IVSI,5(G$rightarrow$C)and IVSII.1(G$rightarrow$A)account for 80%of all βthal alleles.Concerning α thalassemia , five different α thal determinants have been identified. The most common $alpha$ allele is Saudi type poly A signal mutation (AATAAA$rightarrow$AATAAG)followed by the rightward deletion(-$\alpha$$^{3.7}$)and the pentanucleotide deletion(GGTGAGG>GG)in itron1 of α globin gene. Two less frequent alleles (leftward deletion (-$\alpha$$^{4.2}$)and the Turkish type polyA signal mutation (AATAAA>AATGAA) were identified . For G6PD deficiency, our results showed that G6PD Mediterranean variant (nt563C$rightarrow$;188 Ser$rightarrow$Phe) is the most frequent allele in this country. These data allowed us to tailor a cost -effective molecular diagnosis approaches for screening, diagnosis and genetic counselling purposes.

Program Nr: 1700 from the 1999 ASHG Annual Meeting

Mutations in the NKCC2 gene in a large cohort of Bartter's patients. *N. Jeck[1], R. Ruf[2], R. Vargas[3], C. Chauve[5], M. Konrad[1], M. Vollmer[2], L. Guay-Woodford[4], N. Knoers[4], C. Antignac[3], F. Hildebrandt[2], H.W. Seyberth[1], G. Deschênes[5], D. Feldmann[5]*. 1) Dept of Pediatrics, Philips University, Marburg, Germany; 2) Dept of Pediatrics, Freiburg university, Freiburg, Germany; 3) Inserm U423, Hopital Necker, Paris, Frace ê; 4) Dept of Medecine and Pediatrics, Alabama University, Birmingham, USA, Dept of Human genetics, Nijmegen, NL; 5) Dept of Biochemistry and Dept of Nephrology, Hopital Trousseau,Paris, France.

Bartter's syndrome comprises a set of rare inherited tubular disorders. Recent molecular studies have shown that the antenatal form is caused by loss of function mutations in either NKCC2 gene coding for the bumetanide-sensitive Na-K-2Cl cotransporter or in the gene coding for the K channel ROMK1. Furthermore, mutations in the gene encoding the Cl channel CLCKb have been described in patients with a late onset form of Bartter's syndrome called Bartter III or classic Bartter. But, the classification of the Bartter's phenotypes are still in debate and studies on phenotype-genotype correlations need to be performed. We have studied a large cohort of Bartter's patients from different European countries. After previous analysis of ROMK1 and CLCKb genes, 40 families were selected for NKCC2 screening. Molecular analysis were performed by SSCP and sequencing. Fifty percent of the coding region have been analysed. Six new mutations consistent with a loss of function of NKCC2 and four variations are described. Mutations consist of two insertions (1206insT, 1058insTGTG), one nonsens mutation (W192X) and three missens mutations (L196P, C461R, G478R). All the missens mutations involved conserved aminoacids. A frequent polymorphism in exon 10 have been identified (Q484H). This highly informative biallelic intragenic polymorphism can be useful for molecular studies. The different phenotypes corresponding to the new mutations will be discussed.

Program Nr: 1701 from the 1999 ASHG Annual Meeting

Nonsense-Mediated mRNA Decay- useful to the geneticist as well as to the cell? *D. Jeganathan[1], M.F. Fox[1], J.M Young[1], J.R.W Yates[2], J.P Osborne[3], S. Povey[1].* 1) MRC Human Biochemical Genetics Unit, University College London, London, U.K; 2) Department of Medical Genetics, University of Cambridge, Cambridge, U.K; 3) Bath Unit for Research into Paediatrics, Royal United Hospital, Bath, U.K.

Many mutations predicted to truncate the protein product are associated with decreased levels of mutant transcript. This phenomenon, known as nonsense mediated decay (NMD), is an enigmatic surveillance mechanism that may offer the cell some protection against "dominant-negative" nonsense mutations. We explored the implications of NMD in relation to Tuberous Sclerosis (TSC), an autosomal dominant disorder, with mutations in either of two genes, TSC1 or TSC2. Currently, mutation detection requires comprehensive screening of both genes. However, virtually all TSC1 mutations are predicted to truncate the protein product, thus providing a model system to explore NMD. We used polymorphisms in the coding and 3'untranslated region of the gene to investigate imbalance between allelic transcripts in TSC1 patients. This approach allowed us to identify five out of seven TSC1 patients tested blind from a panel of TSC1 and TSC2 patients, with no false positives. Treatment of cells with puromycin, an inhibitor of translation appears to increase the relative amount of mutant message, which may prove useful for RNA-based mutation screening methods. The other aspect to this work has been concerned with addressing the problem of clinical variability in TSC which can even occur within the same family. Here, similar levels of reduction of the mutant transcript were seen in family members and two unrelated patients with the same mutation. We deduce that intra-familial variation is unlikely to result from variabilty in NMD. However, our results do suggest a possible rapid screen to distinguish TSC1 from TSC2 patients by examining frequent polymorphisms in the mRNA. Another intriguing possibility is that a dense single nucleotide polymorphism (SNP) map of transcribed regions might encourage a similar approach to the assessment of candidate genes for diseases whose cause is still unknown.

Program Nr: 1702 from the 1999 ASHG Annual Meeting

Three sisters with XY gonadal dysgenesis and sex reversal - a new variant? *W. Just[1], A. Sinkus[2], L. Andriuskeviciute[2], L. Jurkeniene[2], C. Geerkens[1], I. Reisert[3], W. Vogel[1], A. Baumstark[1]*. 1) Dept Medical Genetics, Univ Ulm, Ulm, Germany; 2) Dept Biology, Kaunas Medical Academy, Kaunas, Lithuania; 3) Dept Anatomy and Cell Biology, Univ Ulm, Ulm, Germany.

Gonadal dysgenesis in females with an XY karyotype may be the consequence of mutations in *SRY*. Since the discovery of *SRY*, mutations in other genes and deletions of defined chromosomal regions have been reported which also may lead to XY sex reversal.

We report on a family with three sisters, all XY females. Histological examination of their gonads showed only ovarian tissues. It consisted of hypoplastic ovarian stroma with degenerated primary and secondary follicles. No testicular structures were apparent. The presence of *SRY* was confirmed by PCR. A sequence analysis of the coding region did not reveal any mutation. Loss of heterozygosity was studied for markers in distal 9p, a region where deletions also contribute to gonadal dysgenesis. From the marker analyses it was apparent that all sisters had two alleles and all inherited the same allele from their father. This may indicate a mutation in a gene (*DMT1*?) from this chromosomal region.

Since the pedigree suggests an X-chromosomal mode of inheritance, we studied the dosage of genes from Xp21 - the DSS region (dosage-sensitive sex reversal). By quantitative Southern blot a double dosage of the *DAX1* gene from this interval was excluded. With a total of 28 microsatellite markers from the X chromosome we screened for co-segregation of the disorder with these markers. They had in common a 15.65 Mb interval ranging from DXS1202 (Xp21.3-p21.2) to DXS1003 (Xp11.3) including the DSS region.

Genetic studies on mutations/deletions of *WT1* and *SOX9* were not considered, because the sisters did not show symptoms of Campomelic dysplasia (*SOX9*) or kidney cancer (*WT1*).

We conclude that mutations rather than dosage differences in a gene(s) from distal 9p or from a region around DSS may be responsible for the XY sex reversal.

Program Nr: 1703 from the 1999 ASHG Annual Meeting

Genetic Analysis of Hearing Loss in Palestinian Kindreds. *M.N. Kanaan[1], H. Shahen[1,2], J. Morrow[3], T. Sobe[2], M.-C. King[3], K.B. Avraham[2], E.D. Lynch[1]*. 1) Department of Life Sciences, Bethlehem University, Bethlehem, Palestine; 2) Department of Human Genetics and Molecular Medicine, Tel Aviv University, Tel Aviv, Isreal; 3) Department of Medicine and Genetics, University of Washington, Seattle WA.

In Palestine, the prevalence of inherited prelingual profound deafness is among the highest in the world, affecting 5-10% of children in some geographic areas. We have initiated a comprehensive study of genetic causes of hearing loss in the Palestinian population. A pilot survey of probands with prelingual bilateral nonsyndromic hearing loss (NSHL) indicates that mutations in connexin 26 (GJB2) account for 30% (8/27) of cases, all of whom were from multiply-affected families. Homozygosity for three connexin 26 mutations was observed: 30delG, 229T to C, and 167delT. One case was a compound heterozygote for 167delT and 233delC. Comparative haplotype analysis of Jewish and Palestinian kindreds indicates that the 167delT mutation probably occurred independently, perhaps multiple times. In four large Palestinian consanguineous kindreds with congenital profound bilateral hearing loss, all known deafness loci (DFNA and DFNB) were excluded by linkage analysis as the cause of inherited hearing loss. Genome wide analysis of linkage is in progress in these four families and should reveal novel hearing-related genes.

Program Nr: 1704 from the 1999 ASHG Annual Meeting

Exclusion of AR-CHED from the chromosome 20 region containing the PPMD and AD-CHED loci. *A.B. Kanis[1], A.A. Al-Rajhi[2], C.M. Taylor[1], W.D. Mathers[1], R. Folberg[1], D.Y. Nishimura[1], V.C. Sheffield[1], E.M. Stone[1]*. 1) University of Iowa, Iowa City, IA; 2) King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia.

Congenital hereditary endothelial dystrophy (CHED) is a disorder of the corneal endothelium and has been recognized to segregate in families with both autosomal dominant (AD) and autosomal recessive (AR) modes of transmission. AD-CHED has been previously linked to the pericentric region of chromosome 20. Posterior polymorphous dystrophy (PPMD), a corneal endothelial disorder showing phenotypic overlap with CHED has also been previously genetically mapped to this region. The genetic interval containing AD-CHED is within the larger genetic interval containing the PPMD locus. This study sought to determine whether AR-CHED segregating in a consanguineous Saudi pedigree is linked to the previously mapped and overlapping loci for AD-CHED and PPMD on the pericentric region of chromosome 20.

Forty members of a consanguineous Saudi Arabian pedigree segregating AR-CHED were ascertained. Short tandem repeat polymorphic markers from the 20 cM interval on chromosome 20 containing both the PPMD and AD-CHED loci were used to genotype these individuals. LOD score analysis of the genotype data using the MENDEL software package utilizing a model of autosomal recessive inheritance with complete penetrance showed exclusion of CHED from the entire PPMD / AD-CHED interval by utilizing overlapping intervals of LOD scores of at least -2.

The results obtained demonstrate that AR-CHED is not allelic to either AD-CHED, nor to PPMD, although it has been proposed that AD-CHED may be allelic to PPMD. This shows that there are at least 2 genes responsible for CHED and PPMD.

Program Nr: 1705 from the 1999 ASHG Annual Meeting

Small mutations and polymorphisms in the dystrophin coding region in Japanese patients with Duchenne muscular dystrophy. *J. Kawamura[1], T. Ishihara[1], S. Kato[2], K. Yatabe[1], T. Shigeyama[1]*. 1) Dept. Internal Medicine, National Higashisaitama Hospital, Hasuda, Saitama, Japan; 2) Dept. of Microbiology, School of Medicine, Keio University, Tokyo,Japan.

Duchenne muscular dystrophy (DMD) is a severe X-linked lethal myopathy with an incidence of approximately 1 in 3500 male births. The primary biochemical defect in DMD is dystrophin deficiency. The dystrophin gene, which spans approximately 2.4Mb of Xp, has a high mutation rate. About 60% of DMD patients has a deletion mutation and 10% has duplication mutation. Remaining one third of patients with DMD have no gross rearrangements in the dystrophin gene identifiable by Southern blot analysis or multiplex PCR. These Southern-negative cases presumably resulted from small mutations that cannot be detected by current diagnostic screening strategies. We sequenced the entire coding region of dystrophin gene for detection of small mutations in 38 DMD patients without large deletions or duplications by using reverse transcription PCR and direct sequencing, and identified 25 nonsense mutations or small deletions/insertions, 4 intronic mutations and 2 exon skippings, all of which were unique to single patients. There was no clustering of small mutations in contrast to gross deletions and duplications. Whether the abnormality of the dystrophin gene was a small mutation or a gross deletion/duplication containing exons was not associated with specific phenotypes. We also identified 19 different nucleotide substitutions in the coding sequence. The frequency of small mutations in Southern blot-negative patients with DMD in this study was significantly higher than those of previous studies, which may be ascribed to the high efficiency and accuracy of our strategy of using RT-PCR and direct sequencing. Structural analysis of small genetic disorders relevant to DMD by the present method will contribute the molecular pathogenesis of DMD and extend the scope of carrier diagnosis.

Program Nr: 1706 from the 1999 ASHG Annual Meeting

Pathological missense mutations affecting neural cell adhesion molecule L1 disrupt binding to different ligands.

S.J. Kenwrick[1], E. De Angelis[1], A. Watkins[1], G. Yeo[1], F.G. Rathjen[2], T. Brümmendorf[2]. 1) Cambridge Institute for Medical Research and Univ Cambridge Dept Medicine, Addenbrooke's Hospital, Cambridge, CB2 2XY UK; 2) Max Delbrück Center for Molecular Medicine, 13092 Berlin, FRG.

Neural cell adhesion molecules (CAMs) of the immunoglobulin (Ig) superfamily are multi-domain cell surface glycoproteins that interact with overlapping repertoires of ligands, cell surface partners and signalling molecules. *in vitro* and *in vivo* studies implicate these proteins in a variety of processes during nervous system development including; axon growth, fasciculation, neuronal cell migration and adhesion. We have shown that mutations affecting one of these CAMs, L1, are responsible for the development of an X-linked recessive disorder that involves congenital hydrocephalus, developmental delay, spasticity and adducted thumbs (X-linked hydrocephalus or MASA syndrome). Over 100 different mutations have been described. Almost one half of these alter single amino acids and may highlight important residues for L1, structure, ligand interaction or downstream activity. The vast majority of missense mutations affect the extracellular Ig and fibronecin type III (FNIII)-like domans that are involved in ligand binding. To examine whether these mutations are capable of affecting ligand binding or affect the ability of L1 to reach the cell surface we have used mammalian expression systems to generate mutated L1. Purified, soluble versions of these proteins are used in FACs-based adhesion assays. Using 20 different mutated constructs we have shown that most pathological missense mutations allow cell surface expression but affect L1 binding either to itself or heterophilic ligands F11 and axonin-1. Whilst many mutations disrupt binding to several ligands, a few have selective effects indicating that patient pathology may be due to more than one type of L1 malfunction. Furthermore, these structure:function studies allow us to propose models for L1 homophilic and heterophilic interaction that involve both Ig and FNIII domains. Finally, the morbidity of individual mutations is related to the consequences of the amino acid change for protein structure and ligand binding.

Program Nr: 1707 from the 1999 ASHG Annual Meeting

The congenital chloride diarrhea (CLD) gene is expressed in eccrine sweat gland epithelium. *J.K. Kere[1, 2], S. Haila[1], U. Saarialho-Kere[3], M.-L. Karjalainen-Lindsberg[4], H. Lohi[1], P. Höglund[1]*. 1) Dept Medical Genetics, Univ Helsinki, Finland; 2) Finnish Genome Center, Univ Helsinki, Finland; 3) Dept Dermatology, Helsinki Univ Central Hospital, Finland; 4) Dept Pathology, Univ Helsinki, Finland.

Clinical abnormalities known in CLD are restricted to the intestine and the most prominent clinical feature is a lifelong watery diarrhea rich in chloride. Other tissues are not known to be affected. CLD is caused by mutations in the anion transporter protein encoded by the CLD, or DRA, gene. The CLD protein acts mainly as a Na+ -independent Cl-/OH- exchanger, but it transports also other anions, such as sulfate and oxalate. CLD has been shown to be expressed in the mature surface epithelium, especially in brush border cells of normal ileum and colon. Its expression profile has been shown to be very restricted and limited only to the intestine and seminal vesicle. Characterisation of other tissues and specific cell types that express CLD in vivo is important in elucidating its physiological function.

Immunohistochemistry with the peroxidase-antiperoxidase technique using polyclonal anti-CLD antibodies was performed to study the expression of CLD in normal epithelial tissues from various organs. Among multiple glandular tissues studied, only eccrine sweat glands, in addition to the seminal vesicle, showed CLD protein expression. Abundant immunoreactivity was detected on the luminal side and in intercellular canaliculi of epithelial cells in the coiled secretory part of the eccrine sweat gland epithelium.

Main electrolytes of primary sweat are of sodium, chloride, potassium, and bicarbonate. The mechanisms of electrolyte transportation across cellular borders and to the sweat gland lumen are not clear but complex co-operation of multiple electrolyte transporters have been proposed. Localisation of the CLD protein to the coiled secretory part of the eccrine sweat gland suggests that it may be one of the mediators of electrolyte transportation involved in primary sweat formation.

Program Nr: 1708 from the 1999 ASHG Annual Meeting

Somatic mutations of *PIG-A* in Korean patients with paroxysmal nocturnal hemoglobinuria : Identification of 4 novel mutations. *J.Y. Kim[1,2], S.S. Park[1], Y.W. Chang[1], J.H. Yoon[1], H.R. Moon[2], H.I. Cho[1]*. 1) Dept. of Clinical Pathology, Seoul National University College of Medicine, Seoul, Korea; 2) Green Cross Reference Laboratory, Seoul, Korea.

Paroxysmal nocturnal hemoglobinuria (PNH) is a hematopoietic stem cell disorder due to the somatic mutation of *PIG-A* gene. *PIG-A* mutations result in the formation of clonal blood cells that are deficient in the surface expression of glycophosphatidylinositol (GPI) anchored protein, and those blood cells present various clinical manifestations including hemolysis and thrombosis. Mutation analysis in different countries is an effective tool to elucidate racial or geographical differences, and possible environmental or genetic causes of somatic mutations. We analyzed *PIG-A* in leukocytes of 18 Korean patients with PNH, using dideoxy fingerprinting and sequencing for the exons and their exon-intron boundaries. We found 12 kinds of mutations including four novel ones in 12 cases : 6 deletion (del) or insertions (ins) [del CT at codon (CD) 139, del 22 bp at CDs 165-172, ins A at CD 248, del G at CD 282, del T at CD 316, del 25 bp at CDs 409-417], 6 base substitutions [GGC->GTC at CD 48, TCA->TGA at CD 127, GGA->TGA at CD 302, G->A at 5' splice site in intron 4, G->A at 5' splice site in intron 5, G->A at 3' splice site in intron 5]. The rate of base substitutions (6/12) is almost the same as in Japan (8/16), and more than in Thai (2/14). All but one case (missense GGC->GTC at CD 48) are frameshift or nonsense mutations causing early truncation of protein, and splicing mutation. These findings suggest that absence of GPI is the major cause of PNH rather than abnormal protein.

Program Nr: 1709 from the 1999 ASHG Annual Meeting

Identification of Mutations in CACNL1A3 in Korean Patients with Hypokalemic Periodic Paralysis ; De novo Arg528His mutations. *S.H. Kim[1], K.W Chung[2], S.J. Kim[3], Y. Namkoong[4], D.J. Kim[5], C.C. Lee[1].* 1) Biology, Seoul National Univ., Seoul, Korea; 2) Biology, Kongju National Univ., Kongju, Korea; 3) Biology, Cheju National Univ., Cheju, Korea; 4) Biology, Kangnung National Univ., Kangnung, Korea; 5) Medicine, Samsung Medical Center, Seoul, Korea.

Hypokalemic periodic paralysis (hypoPP) is an autosomal dominant disorder involving the abnormal function of ion channels and is characterized by attacks of paralysis of varying severity, accompanied by a fall in blood potassium levels. Linkage analysis showed that the candidate locus responsible for the hypoPP was localized to chromosome 1q31-32, and this locus encoded the muscle DHP-sensitive calcium channel a1-subunit (CACNL1A3). So far, three different mutations in CACNL1A3 gene were identified in patients with hypoPP: Arg528His, Arg1239His, and Arg1239Gly. In this study, we screened for the CACNL1A3 gene in four Korean families with hypoPP using PCR-based restriction and SSCP analysis. Arg528His mutation was detected in three families and one family has no known mutations. Moreover, for the first time, we detected de novo Arg528His mutations in two out of the three families with hypoPP. Haplotype analysis with three microsatellite makers (D1S1726, CACNL1A3, D1S1723) and CfoI RFLP suggested the evidence of de novo Arg528His mutations in two of three families with Arg528His. These results imply that de novo mutation, in addition to nonpenetrance, is one of the genetic mechanisms which can explain the previous clinical observation that hypoPP occurs sporadically without familial history.

Program Nr: 1710 from the 1999 ASHG Annual Meeting

Novel Mutations of the PKD1 Gene in Korean patients with Autosomal Dominant Polycystic Kidney Disease.

U.K. Kim[1], J.H. Shin[2], J.A. Shin[1], K.W. Chung[3], S.J. Kim[4], C.C. Lee[2], Y. Namkoong[5]. 1) Molecular Biology, Seoul National University, Seoul,Korea; 2) Biology, Seoul National University, Seoul, Korea; 3) Biology, Kongju National Univ., Kongju, Korea; 4) Biology, Cheju National Univ., Cheju, Korea; 5) Biology, Kangnung National Univ., Kangnung, Korea.

The gene for the most common form of autosomal dominant polycystic kidney disease (ADPKD), PKD1, has recently been characterized and shown to encode an integral membrane protein, polycystin-1, which is involved in cell-cell and cell-matrix interactions. Until now, approximately 30 mutations of the 3' single copy region of the PKD1 gene have been reported in European and American populations. However, there is no report of mutation in the Korean population. Using the polymerase chain reaction and single-strand conformation polymorphism analysis, 91 Korean patients with ADPKD were screened for mutation in the 3' single copy region of the PKD1 gene. As a result, we have identified and characterized six mutations : three frameshift mutations (11548del8bp, 11674insG, 12722delT), a nonsense mutation (Q4010X), and two missense mutations (R3752W, D3814N). Five mutations except for Q4010X are reported here for the first time. Our findings also indicate that many different mutations are likely to be responsible for ADPKD in the Korean population. The detection of additional disease-causing PKD1 mutations will help in identifying the location of the important functional regions of polycystin-1 and help us to better understand the pathophysiology of ADPKD.

Program Nr: 1711 from the 1999 ASHG Annual Meeting

Analysis of the R402Q polymorphism associated with OCA1B. *R.A. King, J.E. Pietsch, J.P. Fryer, W.S. Oetting.* Department of Medicine, Division of Genetics, Univ of Minnesota, Minneapolis, MN.

Mutations of the tyrosinase gene are responsible for type 1 oculocutaneous albinism (OCA1). The 'classic' form (OCA1A) is associated with lifelong absence of melanin pigment in the eyes, hair and skin, resulting from mutations that produce inactive enzyme. Many individuals with tyrosinase gene mutations have no pigment at birth but eventually develop skin, hair and eye melanin (OCA1B). We and others have shown that this is caused by leaky mutations of the tyrosinase gene that encode enzyme with residual catalytic activity, allowing for some biosynthesis of melanin pigment. One particular tyrosinase gene mutation, an amino acid substitution of arginine by glutamic acid at codon 402 (R402Q) has been reported to be associated with normal enzymatic activity at 31C and markedly reduced activity at 37C. This mutation also represents a common polymorphism with an allele frequency of 85% for the arginine allele (CGA) and 15% for the glutamine allele (CAA). It has been suggested that individuals with the CAA allele on one chromosome and a null activity mutation on the homologous chromosome can also have OCA1B, indicating that this common polymorphism is also pathologic. To analyze this possibility, we have performed haplotype analysis for a large number of OCA1 families utilizing polymorphic changes in the tyrosinase gene at positions 301bp, 199bp, codon 192, and codon 402. We have identified seven families in which an unaffected parent and an affected child have a pathologic mutation on one allele and the CAA allele at codon 402 on the homologous allele. There was no evidence of hypopigmentation or ocular changes of albinism in the parent. We conclude that the R402Q polymorphism is not involved in OCA1.

Program Nr: 1712 from the 1999 ASHG Annual Meeting

Motor and cognitive changes among presymptomatic Huntington disease gene carriers. *S.C. Kirkwood, E. Siemers, M.E. Hodes, P.M. Conneally, J.C. Christian, T. Foroud.* Dept Med & Molec Genetics, Indiana Univ Sch Medicine, Indianapolis, IN.

Although typically diagnosed following the onset of manifest chorea, Huntington disease (HD) is characterized by variable onset of progressive motor, cognitive, and emotional signs. We previously demonstrated subtle differences in several cognitive[1] and motor[2] measures in presymptomatic gene carriers (PSGC) in a subset of the current study sample. In order to further characterize these changes in presymptomatic at-risk individuals, we examined the entire sample of 585 individuals, gene carriers (n=171) and nongene carriers (NGC) (n=414), who were gene tested anonymously and could not be given a clinical diagnosis of HD. A neurologic rating scale, physiological tests measuring speed of movement and reaction time, and the Wechsler Adult Intelligence Scale-Revised (WAIS-R) were administered. On neurologic examination, the PSGC exhibited significantly greater definite or possible abnormality than the NGC for several oculomotor measures, including saccades accuracy, saccades velocity, optokinetic nystagmus, and overall oculomotor function and for functional motor measures that included gait and station stability, rapid alternating movement, and muscle stretch reflexes. Although no gene carriers given a definite diagnosis of HD on clinical examination were included, the PSGC demonstrated more definite or possible abnormality for chorea of the extremities, trunk, and face. PSGC had significantly slower performance for auditory reaction time, visual reaction time with decision, movement time with and without decision, and button-tapping time. Scores on the WAIS-R subtests, Picture Arrangement and Digit Symbol, and Arithmetic were worse for the PSGC. These results suggest that subtle worsening of speed of movement, reaction time, oculomotor, functional motor, and psychomotor performance occurs prior to the onset of signs sufficient to make a clinical diagnosis in HD gene carriers.

Program Nr: 1713 from the 1999 ASHG Annual Meeting

X-linked retinitis pigmentosa 3 (RP3): identification of a retina-specific *RPGR* transcript and gene targeting of the mouse orthologue. *R. Kirschner[1], C. Zeitz[1], K.-P. Knobeloch[2], K. Rüther[3], E. Rohde[2], K. Hoffmann[3], J. Grosse[4], I. Horak[2], R. Roepman[5], T. Rosenberg[6], F.P.M. Cremers[5], H.-H. Ropers[1,5], W. Berger[1]*. 1) Max-Planck-Institut für molekulare Genetik, Berlin, Germany; 2) Forschungsinstitut für molekulare Pharmakologie, Berlin, Germany; 3) Augenklinik der Charité, Berlin, Germany; 4) Anatomisches Institut der Technischen Universitaet Muenchen, Germany; 5) Department of Human Genetics, University of Nijmegen, The Netherlands; 6) National Eye Clinic for the Visually Impaired, Hellerup, Denmark.

Retinitis pigmentosa (RP) is a heterogeneous group of retinal dystrophies characterised by progressive degeneration of the photoreceptor cells. Mutations in the RP3 gene (*RPGR*, retinitis pigmentosa GTPase regulator) were detected in 20% of all X-linked RP families although linkage data suggest that 60% are due to mutations at this locus. To search for additional coding sequences as putative mutation targets we analysed *RPGR* expression in various organs from mouse and man. These studies revealed at least 12 alternatively spliced isoforms. Some of the transcripts are tissue-specific and contain novel exons, which elongate or truncate the previously reported ORF. One of the newly identified exons is exclusively expressed in the human retina and mouse eye and contains a premature stop codon. Moreover, this exon was found to be deleted in a family with XLRP. As alternative splicing often requires regulatory elements in intronic sequences we are now studying adjacent *RPGR* introns by comparative sequence analysis in man and mouse. In order to examine the mechanisms leading to premature photoreceptor cell death we established a mouse model for RP3. Targeted mice harbour an in-frame deletion of exon 4 and show a reduced expression of the *mRpgr* mRNA. Exon 4 codes for 21 amino acids which are identical in man and mouse. Hemizygous male mice carrying the targeted allele are viable and fertile. Up to 4 month of age, no characteristic changes were observed by electroretinography and conventional histology of retina sections. Phenotype analysis of older mice will reveal whether this exon 4 deletion results in photoreceptor degeneration.

Program Nr: 1714 from the 1999 ASHG Annual Meeting

A novel mutation in the troponin I gene is associated with sudden cardiac death in familial hypertrophic cardiomyopathy. *I.C. Klausen[1], J. Mogensen[1,2], H. Egeblad[1], U. Baandrup[4], A.D. Borglum[3]*. 1) Department of Cardiology, Skejby University Hospital, Aarhus, Denmark; 2) Research Unit for Molecular Medicine, Skejby University Hospital, Denmark; 3) Institute of Human Genetics, University of Aarhus, Denmark; 4) Department of Pathology, Aarhus University Hospital, Denmark.

Background: Familial hypertrophic cardiomyopathy (FHC) is inherited as an autosomal dominant disease. Mutations have been identified in 8 different genes all encoding sarcomeric polypeptides. FHC is a major cause of sudden cardiac death among young otherwise healthy individuals. Methods: We made clinical and genetic investigations of a large FHC pedigree. Individuals were considered to have FHC if they had hypertrophy of the myocardium (>13mm), hypertrophy in the ECG or Q-waves/major ST-segment changes in at least 2 ECG leads. Genetic investigations included pairwise and multipoint linkage analyses and mutation analyses of the troponin I gene (TNNI3). Results: Two out of 9 affected family members died suddenly in their fifties. They had both suffered from dyspnoea, angina, and palpitations. The remaining affected family members had symptoms of varying severity due to either dysfunction of the left ventricle or arrhythmia, except a 21 years old asymptomatic woman. The hypertrophy observed was primarily localized at the apex. Linkage analyses of all the known FHC loci appointed TNNI3 as the probable disease gene. Subsequent mutation analyses identified a ser199asn mutation in exon 8. The ser199 is a phylogenetically conserved amino acid, and the nucleotide substitution was not observed in 140 control chromosomes. Conclusion: We describe the first TNNI3 mutation associated with sudden cardiac death in the first Caucasian family ever reported to carry mutations in TNNI3. The mutation appeared highly penetrant and was associated with relatively high morbidity and mortality in the pedigree investigated.

Program Nr: 1715 from the 1999 ASHG Annual Meeting

Cataract due to crystal deposits of 37R>S mutated gamma-D-crystalline. *S. Kmoch[1], B. Asfaw[1], K. Bezouska[3], J. Brynda[4], J. Sedlacek[4], M. Filipec[2], M. Elleder[1].* 1) Inst Inherited Metabolic Dis, Charles Univ 1st Sch Medicine,Prague Prague 2, Czech Republic; 2) Dept Ophthalmology, Charles Univ 1st Sch Medicine, General Faculty Hospital, Prague; 3) Dept Biochemistry, Faculty of Science, Charles University, Prague; 4) Dept of Gene Manipulation, Academy of Science, Prague, Czech Republic.

We found a crystal cataract in an five years old boy suffering from impaired vision. The crystals ranging in size up to 1 mm were mechanically isolated from the extracted lenses, purified and analysed using an SDS-PAGE. Single protein band of molecular mass of 21kDa was subsequently identified as the gamma-D-crystalline (CRGD) using Edman microsequencing. Direct sequencing of CRDG gene showed that the patient is heterozygous for a C>A transversion resulting in a 37R>S substitution in the CRDG protein. The mutation was not found in the mother and two older siblings with normal vision. The father whose vision was reported to be normal, died and no DNA was available for investigation. These findings allow us to conclude that the patient mutation most probably arose de-novo. This is the first case of a human cataract caused by deposition of crystals of CRDG protein and the second case of an cataract associated with mutation of this lens protein. To learn more about the mechanism underlying the crystal formation in this pathological condition, the crystals were subjected to x-ray diffraction analysis. Data have been collected to 2.2A resolution (ESRF, ID 14 EH3). Preliminary results have shown that the substitution of an Arg residue in the Arg37Ser mutant is essential for the observed intermolecular contacts between adjacent crystalline molecules.

Program Nr: 1716 from the 1999 ASHG Annual Meeting

Three novel SALL1 mutations extend the mutational spectrum in Townes-Brocks syndrome. *J. Kohlhase[1], C. Blanck[1], S. Engels[1], P. Burfeind[1], A. Bottani[2], M. Patel[3], W. Engel[1], H.Y. Kroes[4], J.M. Cobben[4].* 1) Institute for Human Genetics, University of Goettingen, Goettingen, Germany; 2) Division of Medical Genetics, University of Geneva, Geneva, Switzerland; 3) Department of Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 4) Department of Medical Genetics, University of Groningen, Groningen, The Netherlands.

Townes-Brocks syndrome (TBS) is an autosomal dominantly inherited malformation syndrome characterized by anal, renal, limb, and ear anomalies. TBS is caused by mutations in the putative zinc finger transcription factor gene SALL1 related to spalt of Drosophila. All mutations identified so far are truncating mutations (nonsense mutations or short deletions), which are located 5' of the first double zinc finger encoding region. This led to the suggestion that only SALL1 mutations which remove all double zinc finger domains result in TBS. Here we present three novel mutations of SALL1, one single base pair deletion, one nonsense mutation, and one intronic mutation. While the short deletion is located within the previously described hotspot region, the nonsense mutation is positioned 3' of the region encoding the first double zinc finger. The intronic mutation creates a aberrant splice site and is predicted to result in a protein in which all but the most carboxyterminal zinc finger domains are intact. Based on these findings, we suggest that all double zinc finger domains of SALL1 are required for SALL1 function, and that truncating mutations removing one or more of these domains from the SALL1 protein result in the same phenotype.

Program Nr: 1717 from the 1999 ASHG Annual Meeting

Novel Mutations and Genotype-Phenotype Relationships in 107 families with Fukuyama-type Congenital Muscular Dystrophy (FCMD). *E. Kondo-Iida[1,3], K. Kobayashi[1], M. Watanabe[1], J. Sasaki[1], Y. Nakamura[2], T. Toda[1].* 1) Lab Genome Med,Hum Genome Ctr, Inst Med Sci, Univ Tokyo , Tokyo, Japan; 2) Lab Molecular Med, Hum Genome Ctr, Inst Med Sci, Univ Tokyo, Tokyo, Japan; 3) Dept Pediatrics, Tokyo Women's Med Univ, School of Med, Tokyo, Japan.

Fukuyama-type congenital muscular dystrophy (FCMD), one of the most common autosomal recessive disorders in the Japanese population, is characterized by congenital muscular dystrophy in combination with cortical dysgenesis. Recently we identified on chromosome 9q31 the gene responsible for FCMD, which encodes a novel 461-amino-acid protein we have termed fukutin. Most FCMD-bearing chromosomes examined to date (87%) have been derived from a single ancestral founder, whose mutation consisted of a 3kb retrotransposal insertion in the 3' non-cording region of the fukutin gene. Two independent point mutations (nonsense and frameshift) in this gene have also been found on chromosomes carrying the non-founder haplotype. FCMD is the first human disease known to be caused primarily by an ancient retrotransposal integration. We undertook a systematic analysis of the FCMD gene in 107 unrelated patients, and identified four novel non-founder mutations in five of them: one missense, one nonsense, one L1 insertion, and a 1-bp insertion. The 1-bp insertion was the first de novo alteration ever confirmed in FCMD. Moreover, we evaluated all the mutations observed so far to look for correlation between genotype and phenotype. The frequency of severe phenotypes, including WWS-like manifestations such as hydrocephalus and microphthalmia, was significantly higher among probands who were compound heterozygotes carrying a point mutation on one allele and the founder mutation on the other, than it was among probands who were homozygous for the 3-kb retrotransposon. Remarkably, we detected no FCMD patients with non-founder (point) mutations on both alleles of the gene, and suggest that such cases might be embryonic-lethal. Our results provided strong evidence that loss of function of fukutin is the major cause of FCMD, and appeared to shed some light on the mechanism responsible for the broad clinical spectrum seen in this disease.

Program Nr: 1718 from the 1999 ASHG Annual Meeting

Mutation analysis of the CFTR and CT genes in patients with idiopathic pancreatitis. *A. Korte[1], J. Ockenga[2], T. Doerk[1], N. Teich[4], M. Ballmann[3], V. Keim[4], M.P. Manns[2], M. Stuhrmann[1]*. 1) Inst Humangenetik; 2) Abt Gastroenterologie und Hepatologie; 3) Kinderklinik, Medizinische Hochschule, Hannover, Germany; 4) Medizinische Klinik II, Universitaet Leipzig, Germany.

Mutations in the cystic fibrosis transmembrane conductance regulatory (CFTR) gene seem to confer susceptibility to chronic pancreatitis in some patients. In addition, autosomal dominant hereditary chronic pancreatitis is frequently caused by mutations in the cationic trypsinogen (CT) gene. We investigated whether mutations in the CFTR or the CT genes are associated with idiopathic non-familial (sporadic) pancreatitis. We screened the CFTR gene from 13 unrelated patients with idiopathic pancreatitis for the presence of 28 mutations and the 5T allele in intron 8 of the CFTR gene. This procedure has been proven to detect > 90% of all CF alleles in the German population. The CT gene was screened by restriction digestion or a mutation specific PCR and additionally by sequencing of exons 1, 2, 3. Patients with a CFTR mutation were further investigated by assessment of the transepithelial nasal potential difference and by intestinal current meassurement. No mutation could be identified in the CT gene. Heterozygosity for the CFTR mutations Y1092X or I336K was present in one male and one female patient, respectively. I336K was present in the healthy mother and sister of the patient, too. With intragenic markers we proved that the sister inherited a different paternal allele. In addition, one female patient carried a 5T allele. Two of these three patients had nasal polyps, but none of them showed any abnormal electrophysiological values. The allele frequency of CFTR mutations is almost twice as high among our patient group (7.7%) than among the general population (4%), while the allele frequency of the 5T allele (3.8%) is not different from the expected frequency (5%). These results are in accordance with two recent studies showing an association between mutations in the CFTR gene and chronic pancreatitis. In contrast to autosomal dominant chronic pancreatitis, mutations in the CT gene do not seem to be a significant factor in the pathogenesis of sporadic pancreatitis.

Program Nr: 1719 from the 1999 ASHG Annual Meeting

DNA binding analysis of PITX2 mutations found in IGDS and ARS patients. *K. Kozlowski[1], M. Walter[1,2]*. 1) Ophthalmology, University of Alberta, Edmonton, Alberta, Canada; 2) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

The autosomal-dominant disorders Iridigoniodysgenesis Syndrome (IGDS) and Axenfeld-Rieger Syndrome (ARS) are characterized by maldevelopment of the anterior segment of the eye, associated with an increased risk of early-onset glaucoma. IGDS and ARS both result from mutation of the paired-bicoid class transcription factor PITX2, indicating that they are allelic disorders. We have used an in vitro coupled transcription/translation system to express PITX2 protein. DNA-PITX2 interactions were examined using gel mobility shift assays. Recombinant PITX2 protein was tested in DNA-binding assays with an oligonucleotide containing the CE-3 binding site of Pitx1. Pitx1 and PITX2 have 97% identity within their DNA-binding homeodomains and are thus expected to bind similar DNA sequences. We have demonstrated that wildtype PITX2 can bind the CE-3 oligonucleotide. Mutations identified in IGDS patients (Arg69His; Arg84Trp) were introduced into recombinant PITX2 by site-directed mutagenesis. Preliminary results demonstrate reduced DNA-binding by the mutant proteins, suggesting that diminished DNA-binding by PITX2 is the etiological mechanism of IGDS. We are currently using a mammalian expression vector for PITX2 production to confirm our results, and to investigate the binding ability of ARS-associated mutations of PITX2. As ARS is a more severe phenotype than IGDS, we hypothesize that ARS-mutant PITX2 protein will exhibit an even greater reduction in DNA-binding ability. These experiments will allow correlation between the IGDS and ARS PITX2 mutations and PITX2 protein function, and, hopefully, further elucidate the etiological mechanisms of both disorders.

Program Nr: 1720 from the 1999 ASHG Annual Meeting

DNA microarray-based profiling of global gene expression changes in myotonic dystrophy (DM). *R. Krahe[1], J. Palatini[1], T. Ashizawa[2], K. Virtaneva[1]*. 1) Div. of Human Cancer Genetics, Comp. Cancer Ctr., Ohio State Univ., Columbus, OH; 2) Dept. of Neurology, Baylor Coll. Med. and VA Med. Ctr., Houston, TX.

Myotonic dystrophy (DM) is an autosomal dominant neuromuscular disease with highly variable multisystemic manifestations. The mutation underlying DM is an unstable (CTG)n expansion in the 3' untranslated region of the myotonic dystrophy protein kinase gene (*DMPK*). However, the pathophysiological mechanism(s) of the expanded (CTG)n repeat remains unclear. Various effects have been proposed, most recently a gain-of-function for mutant DMPK transcripts which results in a generalized RNA metabolism defect, mediated through one or several *trans*-acting proteins involved in RNA processing, and in turn leads to the loss-of-function of multiple genes by qualitatively and/or quantitatively affecting post-transcriptional RNA processing, splicing and/or nuclear export of their transcripts. To test these hypotheses we examined global mRNA expression changes between DM patients and normal controls by comprehensively and simultaneously profiling >6,800 human genes with oligo-based GeneChip microarrays (Affymetrix). Total, nuclear and cytoplasmic RNA fractions of DM patient lymphoblastoid cell lines (four adult-onset, one congenital) as well as primary undifferentiated myoblasts and differentiated myotubes (one adult-onset, one congenital) were profiled. In culture DM myoblasts showed a markedly reduced differentiation rate to myotubes and a tendency to dedifferentiate, suggesting a general block in or reprogramming of differentiation. Expression profiles of DM cell lines differed considerably from controls. Between the different DM cell lines profiled, many of the >6,800 genes assayed showed dysregulation, both down and up. Moreover, comparison of nuclear and cytoplasmic fractions suggested a defect in the nuclear export of some processed transcripts. Interestingly, the number of genes dysregulated and the degree of dysregulation correlated with expansion size. Functions of the dysregulated genes were highly varied. In conclusion, DNA microarray expression profiling identified several novel DM effector candidate genes which may explain the complex pathogenesis of DM.

Program Nr: 1721 from the 1999 ASHG Annual Meeting

The Cornelia de Lange syndrome; Cytogenetic and molecular analysis, with exclusion of linkage to chromosome 3q in some familial cases. *I.D. Krantz[1], E. Tonkin[2], M. Hofreiter[1], M. Smith[2], L. Jukofsky[1], B.P. Conti[1], C. Simpson[2], V. Abraham[1], A.D. Kline[3], T. Strachan[2], L. Jackson[4].* 1) Division of Human Genetics and Molecular Biology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Human Genetics Unit, University of Newcastle upon Tyne, UK; 3) Department of Pediatrics, Sinai Hospital of Baltimore, Baltimore, MD; 4) The Division of Medical Genetics, Jefferson Medical College, Philadelphia, PA.

The Cornelia de Lange Syndrome (CdLS) is a complex developmental disorder consisting of upper extremity abnormalities, growth and neurodevelopmental retardation, characteristic facial features, and other anomalies. Most cases of CdLS appear sporadic. Familial cases are rare and demonstrate autosomal dominant inheritance. Partial phenotypic overlap between CdLS patients and patients with duplications of chromosome 3q has been noted. Ireland et al (J. Med. Genet. 28:639-640, 1991) described a patient with classic CdLS and a de novo, apparently balanced, 3;17 translocation with a breakpoint within the dup3q critical region. It has been postulated that a gene within the duplicated region on chromosome 3q is deleted or mutated in patients with CdLS and results in a different but mildly overlapping phenotype. To evaluate the involvement of chromosome 3q in the pathogenesis of CdLS we have studied this region in a large cohort of patients. These studies include; 1) Linkage analysis to the critical region for the dup3q syndrome in 10 familial cases of CdLS, 2) High-resolution chromosome and FISH analysis, with a YAC that crosses the t(3;17) breakpoint, on 30 probands, and 3) Chromosomal analysis of fibroblasts in 9 probands (to evaluate the possibility of a mosaic alteration, not present in lymphocytes). All cytogenetic studies have been within normal limits. Linkage analysis revealed that in 4/10 families haplotypes from 3q were not shared from either parent in the affected individuals, while in 6 families at least one parental haplotype was shared. This implies that this region on 3q26-27 is associated with, at most, a subset of CdLS cases, indicating that this may be a genetically heterogeneous disorder.

Program Nr: 1722 from the 1999 ASHG Annual Meeting

Characterization of a novel autosomal dominant bleeding disorder in a large kindred from East Texas. *S. Kuang[1], M. Phillips[2], Y. Wan[1], P. Thiagrajan[1], D.M. Milewicz[1]*. 1) Int Med Univ of TX Med School Houston, Houston, TX; 2) Centeon Corporation, USA.

A large Texas family with autosomal dominant inheritance of a novel bleeding disorder has been identified. The disorder is characterized clinically by life-threatening bleeding with trauma or surgery and excessive bruising, along with menorrhagia in affected women. Laboratory studies demonstrated prolongation of the PT or aPTT, or both in affected individuals. Paradoxically, assays of known coagulation factors are all within normal limits. To determine the molecular basis of this disease, we undertook a candidate gene linkage analysis in this kindred. Three generations of the family participated in the research. There were 16 affected and 13 unaffected individuals. We initially hypothesized that the cause of the disease in this family could be an antithrombin III mutation that resulted in a constitutively active antithrombin III in the absence of heparin binding. Linkage studies using DNA from the family and an intragenic polymorphic marker within the AT3 gene showed that the disease mapped to this locus on 1q23-25. The coding and intron/exon junctions of the AT3 gene were sequenced using the proband's DNA, but this analysis failed to identify a mutation. Further family members were recruited for the study and 16 polymorphic markers around the AT3 gene were analyzed. Using 2 recombinants, we have narrowed the critical interval for the defective gene to approximately 2 cM. The factor V gene mapped into the disease interval, therefore this gene was sequenced even though factor V activity assays were within the normal range. An alteration was identified in exon 13 of the factor V gene (Ser^{756}), which was present in all affected individuals from this family. This alteration falls within the "B" or hinge region of factor V and is thought to be a private polymorphism in this family. Further studies will determine the genetic defect causing the bleeding disorder in this family and may reveal a novel protein involved in the coagulation cascade.

Program Nr: 1723 from the 1999 ASHG Annual Meeting

Complete mutation screening of the EYA1 gene, genotype-phenotype correlation and genetic heterogeneity associated with Branchio-oto-renal syndrome. *S. Kumar[1], R.J.H. Smith[2], C.W.R.J. Cremers[3], W.J. Kimberling[1]*. 1) Department of Genetics, Boys Town National Research Hospital, Omaha, NE; 2) Department of Otolaryngology, University of Iowa Hospitals & Clinics, Iowa, IA; 3) Department of Otolaryngology, University Hospital Nijmegen, The Netherlands.

Autosomal dominant branchial anomalies associated with hearing loss and renal anomalies affect at least 2% of profoundly deaf children and have estimated prevalence of 1 in 40,000. The clinical features of Branchio-oto-renal syndrome (BOR) consist of external, middle and inner ear malformations, branchial cleft sinuses, cervical fistulas, mixed hearing loss and renal anomalies. The phenotypic expression of BOR can be quite variable even within the same family. The BOR gene has been localized to chromosome 8q13. Recently, a candidate gene EYA1, the human homologue of Drosophila eyes absent gene, was identified and mutations have been reported. In order to evaluate the extent to which mutation in the EYA1 gene contribute to BOR syndrome, we have performed mutation analysis on more than fifty BOR families by heteroduplex followed by sequence analysis of sixteen EYA1 exons. To date, using this approach, we have identified twelve novel mutations. At least 60% of our families, investigated so far, have not shown mutations in the EYA1 gene. Therefore, in the present study, we have also performed genetic linkage analysis on multigenerational BOR type families with 8q markers. Three large BOR type families did not show linkage with 8q markers suggesting the involvement of more than one gene. These families are currently being subjected to genome search. The present results demonstrate genetic heterogeneity. The clinical features of the BOR individuals were also compared to see whether the nature of the mutation correlates with the type and severity of the clinical symptoms. There were no distinct relationships observed between the nature of the mutations and variable clinical features associated with BOR syndrome. These results provide the basis for a molecular-genetic testing that will help the clinical evaluation and genetic counseling of members of BOR families. (Supported by NIH/NIDCD grant #P01 DC01813).

Program Nr: 1724 from the 1999 ASHG Annual Meeting

Identification of 14 new FBN1 mutations in Marfan syndrome and overlapping phenotypes using SSCP and heteroduplex analysis. *M. Lackmy-Port-Lys[1], G. Collod-Beroud[1], G. Jondeau[2], M. Mathieu[3], Y. Maingourd[4], M. Coulon[1], M. Guillotel[1], C. Junien[1,5], C. Boileau[1,5].* 1) INSERM U383, Hopital Necker-Enfants Malades, Paris, France; 2) Service de cardiologie, Hopital Ambroise Pare, Boulogne, France; 3) Centre de Genetique Clinique, CHU d'Amiens, Hopital Nord, Amiens, France; 4) Unite de Cardiologie Pediatrique, CHU d'Amiens, Hopital Nord, Amiens, France; 5) Laboratoire central de Biochimie, d'Hormonologie et de Genetique moleculaire, Hopital Ambroise Pare, Boulogne, France.

Marfan syndrome (MFS) is a dominantly inherited disease of connective tissue. Cardinal manifestations involve the eye, skeleton and cardiovascular systems. The disorder is characterized by considerable variation in the distribution and severity of organ system involvement between families that lead to the definition of diagnostic criteria listed first in the Berlin nosology and subsequently revised in the Ghent nosology. Mutations in the FBN1 gene (15q21.1), encoding fibrillin-1, have been demonstrated to result in MFS and associated phenotypes. We performed molecular analyses of the FBN1 gene in two groups of patients. The first one comprises patients presenting with MFS according to the Berlin criteria. The second group contains patients in which the diagnosis of MFS could not be made with the same criteria but for whom fibrillin implication have been proven by protein analysis, or suspected by segregation of FBN1 markers and exclusion with FBN2 and regional MFS2 markers. Screening of the available gene sequence for further causal mutations has been carried out by searching for single stranded conformational polymorphisms (SSCP) and heteroduplexes on PCR amplified fibrillin DNA isolated from fresh blood lymphocytes. We identified 14 new mutations. Nine are associated with complete forms of MFS [Y1186C, Y1101C, E1158A, 737-1 G->A, T101A, Y1266F, C68R 2, Y458S, G214S], C1081G is associated with neonatal MFS, and 1464-5G->A is associated with an incomplete form of MFS (only ocular and cardiovascular abnormalities). The last one, the G985E mutation, is the first mosaicism identified in a phenotype overlapping MFS (only cardiovascular and skeletal abnormalities).

Program Nr: 1725 from the 1999 ASHG Annual Meeting

Leukodystrophy and oculocutaneous albinism in a child with a 11q14 deletion identified by FISH. *D. Lacombe[1], C. Goizet[1], I. Coupry[1], P. Verin[2], B. Mortemousque[2], L. Taine[1], B. Arveiler[1].* 1) Department of Medical Genetics, Pellegrin University Hospital, Bordeaux Cedex, France; 2) Ophtalmology Department, CHU Bordeaux, France.

The leukodystrophies are a heterogeneous group of rare hereditary diseases affecting the central nervous system (CNS). They dysplay a heredo-degenerative involvement mostly in the white matter and leading to diffuse demyelination of the CNS. In 30% of all leukodystrophies, the causis is unknown and no specific biochemical or genetic abnormality can be identified.

We report a *de novo* chromosomal microdeletion identified by fluorescence in situ hybridization (FISH) in a patient with an unspecified leukodystrophy associated with oculocutaneous albinism (OCA). The patient is the third son of non-consanguineous French parents with unremarkable family history. OCA was noted at birth with total depigmentation of skin, hair and iris associated with nystagmus. Walking and speech were delayed. The visual deficit was evident in early childhood. At the age of 15, generalised epileptic episodes occured with slow activity and paroxysms on EEG. Brain MRI showed white matter lesions typical of leukodystrophy. At age 18, mental retardation was moderate (IQ=51). Metabolic screening was normal. Tyrosinase (TYR) activity was negative in hair roots, leading to classify OCA as tyrosinase-negative. Karyotype on lymphocytes was normal.

A FISH study using a TYR gene probe revealed a heterozygous microdeletion of chromosome 11q14. FISH of both parents was normal confirming the *de novo* aspect of this microdeletion. The 11q14 deletion inactivates one of the two TYR alleles. Sequencing the coding part of the TYR gene revealed a heterozygous mutation of the other allele. This mutation was a previously reported deletion of two bases (G,T) in codon 244/5 producing a stop codon inherited from his father.

These results suggest the localization at chromosome 11q14 of a new type of dominant leukodystrophy. We are now mapping the 11q14 microdeletion using loss of heterozygosity and FISH in order to identify the gene involved in this undetermined leukodystrophy.

Program Nr: 1726 from the 1999 ASHG Annual Meeting

***De novo* mutations in EGF-like repeats of Jagged1 in Alagille syndrome patients.** *P.S. Lai, F.S.H. Cheah, M.H. Liew, M.M. Aw, S.H. Quak.* Dept Pediatrics, National Univ of Singapore, Singapore, Singapore.

Alagille syndrome (AGS) is an autosomal dominant disorder with multisystem involvement. There is variable expressivity of clinical features from apparently normal phenotype to severe cases where liver failure requires transplantation. We have studied five unrelated probands and family members. Three novel mutations were identified within *Jagged1* confirming the involvement of this gene in our patients. All three mutations (1213delC, 2884insA, 2638delCAGT) were present in heterozygous form and occur in the EGF-like repeats of Jagged1. These two frameshifts and one nonsense mutations are predicted to result in truncated protein products without the cystein-rich and transmembrane domains. Mutations in these evolutionary conserved EGF-like motifs of Jagged1 protein is likely to severely affect interaction with the Notch receptor resulting in AGS phenotype in these three patients. Screening of parental samples indicate *de novo* origin of mutations in all three cases. In two of these cases, parents of the probands did not have any clinical features consistent with a diagnosis of AGS while in one, the mother was diagnosed with features of an AGS microform. In the remaining two probands, no truncating mutations could be identified despite screening of all coding exons and flanking introns of *Jagged1*. However, two polymorphisms (1178C®T, 2627A®C) were observed but did not lead to any altered amino acid residues. These sequence alterations were also observed in unaffected family members and show mendellian segregation. It is likely that other unidentified mutations are responsible for the AGS phenotype in these patients.

Program Nr: 1727 from the 1999 ASHG Annual Meeting

Diagnosis of X-linked Myotubular Myopathy by detection of the implicated protein (myotubularin), and genotype/phenotype correlation in mild cases. *j. laporte, f. blondeau, a. buj-bello, c. kretz, j.-l. mandel.* Institut de Genetique et de Biologie Molculaire et Cellulaire (IGBMC), CNRS/INSERM/ULP, 1, rue Laurent Fries, B.P. 163, 67404 ILLKIRCH Cedex, FRANCE.

X-linked Myotubular Myopathy (XLMTM) is a severe congenital muscular disorder characterized by generalized muscle weakness leading in most cases to early postnatal death. The gene (MTM1) responsible for the disease has been isolated and found mutated in most patients (Laporte et al., Nat. Genet. 96). It is about 100 kb in length and composed of 15 exons. It encodes a novel protein named myotubularin that contains the consensus active site of tyrosine phosphatases (PTP). It has been recently reported that myotubularin interacts with several proteins containing the SET domain that are implicated in epigenetic mechanisms of gene regulation (Cui et al., Nat. Genet. 98).

We and others have shown that myotubularin displays a dual specificity phosphatase (DSP) activity. By searching in sequence databases and screening cDNA libraries, we have identified novel members of the MTM1 gene family in different species. We have found 8 MTM-related genes in the human genome and determined the chromosomal localization and expression pattern for most of them. This represents the largest DSP family described so far. A subclass of MTM-related genes lacks the DSP active site and could act as anti-phosphatases. Most missense mutations found in patients affect residues that are conserved in the homologous Drosophila protein. We have obtained antibodies against myotubularin and have used them to detect myotubularin by immunoprecipitation followed by western blot. 90% of the XLMTM patients have no detectable level of myotubularin. This technique could be used for diagnosis and these results confirm that XLMTM is due to a lack of myotubularin activity. Furthermore, we present the identification of novel mutations in the MTM1 gene in patients with severe and mild XLMTM by SSCP and sequencing. Our results implicate mutations in the MTM1 gene in patients with a milder phenotype compared to the typical severe form of XLMTM.

Program Nr: 1728 from the 1999 ASHG Annual Meeting

Gene Therapy for Motor Neuron Diseases by Adenoviral Gene Transfer. *G. Acsadi[1,3], J. Jani[2], R. Anguelov[1], M. Shy[2,3]*. 1) Department of Pediatrics; 2) Department of Neurology; 3) Center for Molecular Medicine and Genetics, Wayne State Univ. Med. School, Detroit, MI 48201.

Spinal muscular atrophy [SMA] and amyotrophic lateral scleroisis [ALS] are caused by a degeneration of motor neurons (MN). Although, the genetic and biochemical background of both diseases has been identified, there is no effective therapy available. Various neurotrophic factors (e.g. GDNF) have the potential to prevent motor neuron degeneration but for an effective treatment, these factors have to be delivered directly to the MN. We have utilized adenovirus vectors (AV) expressing beta-galactosidase (LacZ; as a reporter gene) or GDNF to study the gene transfer into MNs in mice by means of intramuscular or intrathecal delivery. The gene expression was analyzed by histochemical and ELISA techniques. We demonstrate that both LacZ and GDNF genes can be efficiently transferred and expressed in MNs of spinal cord and brainstem by both delivery. After intramuscular administration of AV, the viral genome is transported retrogradely to the MNs as shown by PCR amplification of AV-DNA. The level of gene expression in MN is higher in newborn or immunocompromised mice (FK506 treated, beta2-microglobulin deficient and SCID) compared to control adult mice. Although, at a lower level, the non-immunosuppressed mice are able to maintain significant gene expression (GDNF and LacZ) in the spinal cord or brainstem for at least two month when AV is given intramuscularly. In contrast, after the intrathecally administered AV, the gene expression is lost by one month. In conclusion, AV-mediated gene transfer into skeletal muscles appears a feasible technique to deliver nerve growth factors to MN in spinal cord and brainstem and study the direct effect of these factors in animal models for motor neuron diseases such as SMA or ALS. Supported by Muscular Dystrophy Association of USA.

Program Nr: 1729 from the 1999 ASHG Annual Meeting

Functional analyses of SMN/SMNc gene expression : therapeutic implications in Spinal Muscular Atrophy. *P. Burlet, S. Bertrandy, E. Vial, L. Viollet, A. Munnich, S. Lefebvre.* INSERM U393, IFREM, Hopital Necker Enfant, Paris, France.

Spinal Muscular Atrophy (SMA) is an autosomal recessive disorder characterized by degeneration of motor neurons in the spinal cord and muscular atrophy. SMA is subdivided into three forms according to age of onset and milestones of development. The disease results from alterations of the telomeric copy of Survival Motor Neuron (SMN) gene located in an unstable region of chromosome 5q13 containing a highly homologous copy gene SMNc. SMN is absent in the majority of patients (>95%) and the remaining patients carry intragenic mutations. The SMNc is present in all patients, but absent from about 5%; of control individuals without phenotypic manifestations. A tight correlation between clinical severity of the disease and SMNc protein level was found in tissues and cell cultures derived from SMA fetuses and patients. These findings suggested that the SMNc protein has some active role and pharmacological stimulation of the SMNc gene could represent a therapeutic strategy in SMA. Sequence analyses revealed that SMN and SMNc promoters are identical and that they contain binding sites for several transcription factors. The abundance of binding sites for potential regulatory proteins within the SMN/SMNc minimal promoter suggests that they may be subject to various level of control and regulation in different cellular contexts. Notable among these are responsive elements for cAMP, retinoic acid, mineralocorticoids, hormones, and several cytokines. Since expression of a gene can be greatly influenced by its position in the genome, we investigated directly the SMN protein expression by immunodetection upon stimulation of different cell types. Treatment of lymphoblastoid and fibroblast cell cultures from SMA patients and control individuals with forskolin, INF-b, INF-g, retinoic acid (9-cis and all trans) did not significantly increase the SMN/SMNc protein level. Other stimuli are currently under investigations and will be presented. This approach should identify the key regulators of the SMN/SMNc promoter activity and the pathways responsible for the activation in different cells. Hopefully, these studies may contribute to identify a pharmaceutical agent for SMA.

Program Nr: 1730 from the 1999 ASHG Annual Meeting

Improvement of growth and intelligence in individuals with deletions of 18q treated with growth hormone. *J.D. Cody[1], D.E. Hale[1], M. Semrud-Clikeman[2], P.D. Ghidoni[1], R.L. Schaub[1], N.M. Thompson[4], C.I. Kaye[1], R.J. Leach[1,3]*. 1) Department of Pediatrics, UT Health Science Center, San Antonio, TX; 2) Department of Educational Psychology, University of Texas, Austin, TX; 3) Department of Cellular and Structural Biology, UT Health Science Center, San Antonio, TX; 4) Department of Psychiatry and Behavioral Health Sciences, University of Washington, Seattle, WA.

Most individuals with deletions of 18q have growth failure and mental retardation. We evaluated 60 individuals with 18q deletions and found only 2 with completely normal growth parameters. The remaining individuals had some degree of growth failure. Growth failure due to growth hormone (gh) deficiency severe enough to qualify for gh therapy was found in 66%. We evaluated both gh treated and untreated individuals longitudinally for changes in growth and IQ and have data on the first 14. The period of time between evaluations averaged 30.7 months (range = 14 - 54 months). The height of the participants was compared by determining the number of standard deviations (SD) from the mean for a normal population of the same age. The average height SD of the untreated group (n = 6) was -2.1 and the change in height over the observation period was -0.25 SD. The average height SD for the gh treated group (n = 8) was -3.3 and the change in height SD was +1.8. This demonstrates that the treated children experienced significant catch-up growth while the untreated children maintained a slightly slower than normal growth rate. Over this period of time, the untreated group had IQ changes of between -2 and +6, which are well within the standard error measure for cognitive tests. Performance IQ scores were used since many of these children are hearing impaired and the verbal IQ would underestimate their skills. The treated group had IQ changes of between 0 and +47 points with an average increase of 23 IQ points. An increase of this magnitude is highly significant. The treated individual whose IQ did not increase was the oldest child and had the largest deletion. Future studies will focus on age related responses to treatment as well as on genotypic correlation with response.

Program Nr: 1731 from the 1999 ASHG Annual Meeting

The effects of potential therapeutic agents on ALS-transgenic mice. *N.A Cole, R. Fu, G. Deng, T. Siddique.*
Neurology, Northwestern University Medical School, Chicago, IL 60611.

Transgenic mice over-expressing mutations in SOD1 gene (G1H)develop disease similar to ALS (amyotrophic lateral sclerosis) in humans. Therapeutics can be rapidly screened in this animal model. The thiol lipoate and especially its reduced form dihydrolipoate (DHLA) are potent antioxidants in brain and peripheral nerves. Recently, we administered lipoic acid to our ALS-mice and onset of disease was delayed in females by 13 days. This represents the first observation in ALS transgenic mice of a gender difference which reflects the gender difference in the epidemiology of ALS in humans (1:1.6). Lipoic acid is therefore, another drug that delays the onset of disease in ALS-mice and may provide new insights into the pathogenesis of ALS.

Program Nr: 1732 from the 1999 ASHG Annual Meeting

Application of mutation specific hammerhead ribozymes as gene therapy tools for skin diseases. *P.B. Cserhalmi-Friedman[1], H.C. Dietz[2], A.M. Christiano[1].* 1) Department of Dermatology, Columbia University, New York, NY; 2) Howard Hughes Medical Institute, Johns Hopkins University School of Medicine, Baltimore, MD.

We investigated the feasibility of using target specific hammerhead ribozymes to eliminate selected mRNAs as a possible method of gene therapy in skin conditions. As an experimental model, we used an HPV immortalized human keratinocyte cell line, carrying a 16 bp deletion on one allele of the COL7A1 gene. This mutation leads to the in frame skipping of a 69 bp exon (Cserhalmi-Friedman et al. Lab Invest 1998, 78:1483-1492). We synthesized target specific hammerhead ribozymes to recognize only the mRNA and pre-mRNA transcribed from the mutant allele. The ribozymes were incubated with total RNA extracted from the cells carrying the mutation, and the efficiency and selectivity of the ribozyme action was determined using quantitative RT-PCR to compare the level of the wild-type versus mutant messages. We achieved over 85% selective reduction of the mutant mRNA. To assess the ribozyme activity in cells, we stably transfected the keratinocytes carrying the mutation with the ribozyme expression constructs using a retroviral vector. Then total RNA was extracted, and the ribozyme action was evaluated using the same quantitative RT-PCR system and Northern blot analysis. To prepare for in vivo application, we compared direct liposome mediated delivery, retroviral transduction, and application of naked DNA constructs to express Enhanced Green Fluorescence Protein (EGFP) in mouse skin. For liposome delivery, we used in vitro synthesized EGFP mRNA, for retroviral transduction and for naked DNA uptake we used a construct containing CMV promoter and the EGFP gene. Skin biopsies were taken and analyzed for the expression of EGFP 24-72 hours after the application. Our results demonstrate the feasibility of using hammerhead ribozymes to specifically reduce the level of selected mRNA in the skin.

Program Nr: 1733 from the 1999 ASHG Annual Meeting

Intracellular enhancement of a**-galactosidase A activity in 31 Fabry lymphoblasts and fibroblasts by 1-deoxy-galactonojirimycin.** *J.-Q. Fan[1, 4], S. Nakao[2], C.R. Kaneski[3], R.O. Brady[3], R.J. Desnick[1], Y. Suzuki[4], S. Ishii[5].* 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY, USA; 2) Faculty of Medicine, Kagoshima Univ., Kagoshima, JAPAN; 3) DMNB, NIH, Bethesda, MD, USA; 4) Tokyo Metropolitan Institute of Medical Science, Tokyo, JAPAN; 5) Usuki Bio-Research Center, Oita, JAPAN.

Fabry disease is a genetic disorder of glycosphingolipid metabolism caused by deficiency of lysosomal a-galactosidase A (a-Gal A). This disorder is classified according to clinical manifestations into two groups: 1) classic form with generalized vasculopathy, and 2) cardiac variant of late-onset form with clinical manifestations limited to the heart. Recently, we reported (1) that 1-deoxy-galactonojirimycin (DGJ), a potent competitive inhibitor of a-Gal A, effectively enhanced the enzyme activity in lymphoblasts of a late-onset Fabry patient by cultivation of the cells with DGJ at concentrations lower than normally required to inhibit the intracellular enzyme activity. Oral administration of DGJ to transgenic mice overexpressing a mutant a-Gal A substantially elevated the enzyme activity in major organs. DGJ appeared to accelerate the transport and maturation of the mutant enzyme resulting in increased intracellular enzyme activity. In order to evaluate this strategy with other genotypes and phenotypes, we tested DGJ with 31 strains of Fabry lymphoblasts and fibroblasts that exhibit residual a-Gal A activity. The cells were cultured with 20 mM DGJ at 37°C for 5 days. After washing the cells twice with phosphate-buffered saline, homogenates of the cells were assayed for a-Gal A activity. Among them, 19 cell lines responded to DGJ treatment. Intracellular enzyme activity was elevated from 1.8 - 53 % of normal to 25 - 97 % of normal. The genotypes of these mutations were E59K, E66Q, I91T, A97V, R112H, F113L, N215S, Q279E, M296I, M296V, R301Q and R356W. Most of the patients were diagnosed as the cardiac late-onset Fabry disease. Administration of DGJ may be considered as a therapeutic possibility for patients with the late-onset form of Fabry disease. Program Nr: 1734 from the 1999 ASHG Annual Meeting

Inhibitors of 4-OH phenylpyruvate dioxygenase and adenoviral gene therapy for the treatment of murine alkaptonuria. *J.M. Fernandez-Canon, K. Manning, M. Al-Dhalimy, M. Grompe.* Molecular and Medical Genetics, Oregon Health Sci. University, Portland, OR.

Alkaptonuria is a inborn error of metabolism caused by deficiency of homogentisic acid dioxygenase (HGD) an enzyme in tyrosine catabolism. The disease phenotype has a late onset and is characterized by degenerative arthritis caused by accumulation of homogentisic acid (HGA) metabolites (ochronosis). To date therapeutic interventions such as tyrosine restriction have not been successful in preventing disease progression. Recently, a new class of compounds consisting of electrophilic benzoyl derivatives of 1,3 cyclohexane dione has been identified. These drugs are potent inhibitors of 4-OH phenylpyruvate dioxygenase, the enzyme upstream of HGD in tyrosine metabolism. We have tested 2 such compounds, 2-(2-nitro-4-trifluoromethylbenzoyl)-cyclohexane dione (NTBC) and 2-(2-chloro-4-methanesulfonylbenzoyl)-cyclohexane dione (CMBC), as therapeutic drugs in a murine model of alkaptonuria. HGD deficient mice were given different doses of NTBC or CMBC in their drinking water and their urine HGA and blood tyrosine levels were measured. While excretion of urinary HGA could be completely eliminated by this approach, blood tyrosine levels became elevated. Therefore treatment of alkaptonuria with blockers of 4-OH phenylpyruvate dioxygenase represents a trade-off between high blood tyrosine levels and the accumulation of arthritis-causing HGA metabolites.

For this reason liver directed gene transfer of HGD may be a more attractive approach to the treatment of HGD. We have generated a first generation adenoviral vector expressing the human HGD and are currently testing this vector in vivo in our murine model. The 2 approaches to the treatment of alkaptonuria will be compared.

Program Nr: 1735 from the 1999 ASHG Annual Meeting

Adeno-associated virus mediated gene therapy for the neurological disorder of mucopolysaccharidosis III B using a knock-out mouse model. *H. Fu[1], T.J. McCown[2,3], R.J. Samulski[3], J. Muenzer[1].* 1) Department of Pediatrics, University of North Carolina, Chapel Hill, NC; 2) Department of Psychiatry, University of North Carolina, Chapel Hill, NC; 3) Gene Therapy Center, University of North Carolina, Chapel Hill, NC.

Mucopolysaccharidosis type III B (Sanfilippo syndrome type B, MPS III B) is due to the deficiency of the lysosomal enzyme a-N-acetylglucosaminidase (NaGlu). MPS III B is characterized by severe central nervous system (CNS) involvement, but with only mild somatic disease. Correction of lysosomal storage in CNS is critical for the successful treatment of the MPS III B patient. A MPS III B knock-out mouse model (Li et al, AJHG 63: A15, 1998, obtained from Dr. EF Neufeld, UCLA) was used in this study to investigate the feasibility of adeno-associated virus (AAV) mediated gene therapy for treating the CNS diseases in MPS III B patients. Two therapeutic AAV vectors were constructed, containing the human NaGlu cDNA, driven by a human cytomegalovirus (CMV) promoter or the neuron specific enolase (NSE) promoter. In vitro experiments showed that AAV-CMV-NaGlu could mediate NaGlu expression in both Hela and MPS III B fibroblast cell lines, where the recombinant NaGlu was secretory. The AAV vectors were delivered into 4 brain structures of a MPS III B knock-out mouse model by direct microinjection (10^6 viral particles/site). Efficient expression of functional NaGlu was detected in inferior colliculus, hippocampus, hypothalamus and cortex for up to 12 weeks. Our data demonstrates that AAV-mediated gene delivery can result in enzyme expression in different brain structures of MPS III B mice, which may be sufficient for correction of lysosomal storage in these areas. (This project was supported by a grant from The Children's Medical Research Foundation, Inc., Western Springs, IL).

Program Nr: 1736 from the 1999 ASHG Annual Meeting

Cessation of Enzyme Replacement Therapy (ERT) in Gaucher Disease Type 1. *E.D. Geller, K.A. Grinzaid, L.J. Elsas.* Division of Medical Genetics, Dept of Pediatrics, Emory Univ, Atlanta, GA.

Intravenous replacement of mannans-engineered b-glucosidase is an expensive but effective treatment for Gaucher disease. There are few reports regarding the effect of discontinuing ERT. Because ERT is expensive and time consuming, four of our patients who experienced clinical improvement during their initial treatment with ERT chose to discontinue ERT under careful observation for 1 or more years.

Genotype	N370S/L444P	N370S/L444P	K79N/K79N	N370S/N370S
Age@dx/trt(yrs)	5/6	5/13	19/49	35/51
On/Off trt-yrs	On-3/Off-1/On-1	On-2/Off-1.5/On-1	On-2/Off-2/On-1	On-1.5/Off-3
Liver/%D/yr	-16/ +25/ -8	-8/ +3/ -16	-22/ +7/ -16	-10/ +2
Platelets/%D/yr	+26/ -23/ -7	+4/ -8 / +10	+35/ -21/ +55	+82/ -12
MRI index/%D/yr	not available	+25/ -5/ n/a	+101/ -15/ n/a	+10/ +9

All patients improved on ERT, and when ERT was interrupted all had progressive decline in clinical status. The patient with the genotype N370S/N370S declined very slowly over the 3 year period. His spine bone density was decreasing on and off ERT , but is responding to Fosamax off ERT. The other three patients were restarted on ERT within 2 years of cessation. Resumption of ERT resulted in improvement of visceral and hematological parameters within one year. We conclude that cessation of ERT results in slow decline of visceral and hematological parameters, but that reinstitution of ERT corrects these losses. There is a positive correlation between severity of disease(based on genotype and age of diagnosis)and response to cessation of ERT.

Program Nr: 1737 from the 1999 ASHG Annual Meeting

Cooperability of SP1 and GABP transcription factors in activating the Utrophin promoter : Implications for functional substitution therapy of Duchenne muscular dystrophy (DMD). *M. Gyrd-Hansen[1], T. Krag[1], J. Shang[2], A. Rosmarin[2], T. Khurana[1]*. 1) Clin. Biochemistry, Glostrup Hospital, Denmark; 2) Div. Hematology, Miriam Hospital, Providence, USA.

Utrophin functional substitution is a strategy designed to circumvent problems associated with gene therapy in DMD and relies on using trans-acting factors to activate the utrophin promoter and the ability of high levels of utrophin to functionally substitute and rescue dystrophin-deficient muscle. Recently we had demonstrated that the utrophin promoter could be activated by the GABP transcription factor complex via heregulin mediated ERK activation. However, the magnitude of increase in utrophin expression using these methods (2.4X) is modest. Here we demonstrate that the transcription factor SP1 activates the utrophin promoter. Activation is an order of magnitude greater than previously observed. We have defined two regions of the promoter that are putative SP1 sites based on structural predictions, gel and super-shift assays as well as DNAse hypersensitivity. Using site-directed mutagenesis and reporter assays we have analyzed the relative contribution of the proximal and distal sites. Co-transfection using both GABP and SP1 reveal that these transcription factors cooperate and activate the utrophin promoter to a greater extent than ascribable to a simple summation of each factor's individual contribution. Our results suggest that cooperability of GABP and SP1 are major determinants in transcription factor mediated recognition, recruitment and remodeling of the utrophin gene promoter that modulates utrophin expression in muscle and methods that stabelize this interaction in vivo, may be utelized to achieve high levels of utrophin expression in DMD patients.

Program Nr: 1738 from the 1999 ASHG Annual Meeting

Cell Lines for Production of Gutted Adenovirus. *D.J. Hartigan-O'Connor[1,3], C. Barjot[2,3], J.S. Chamberlain[1,2,3].* 1) Program in Cellular and Molecular Biology; 2) Department of Human Genetics; 3) Center for Gene Therapy, University of Michigan, Ann Arbor, MI.

Gutted, or helper-dependent, adenoviral vectors offer some advantages over conventional Ad vectors. Because gutted viruses contain no viral genes, their cloning capacity is much larger than that of conventional vectors and the possibility of a harmful host immune response is reduced. Unfortunately, these vectors have proven difficult to grow and purify. We report progress in our efforts to develop cell lines that facilitate production of gutted Ad vectors. C7 cells are 293 cells that stably express both adenovirus DNA polymerase and preterminal protein. We have previously shown that C7 cells plaque suboptimal Ad genomes with increased efficiency, which leads to increased yield of gutted virus. We now show that modified versions of the C7 line plaque adenovirus with still higher efficiency and we suggest applications for such cell lines. We find that C7 cells expressing Cre recombinase, when used in combination with helper viruses containing "floxed" packaging signals, provide a significant increase in gutted viral yield and purity at each serial passage. At early growth stages, a single passage on C7 Cre cells provided an average 20-fold increase in both gutted viral yield and purity. We created a helper virus that contains a mutation in the Ad polymerase gene in addition to a "floxed" packaging signal. Use of this virus increases the purity of gutted viral preparations but reduces yield somewhat when compared with pol-positive helpers. This floxed, E2B-deleted helper should reduce the danger of an immune response directed against residual helper virus. Comparison of a variety of Cre lines reveals significant variation in Cre levels and excision efficiency, a factor that may be important for rapid production of gutted virus.

Program Nr: 1739 from the 1999 ASHG Annual Meeting

Gene therapy for twitcher mouse using retrovirus vector. *K. Inui, C. Kokubu, T. Nishigaki, T. Muramatsu, H. Tsukamoto, N. Sakai, S. Okada.* Develpomental Medicine (Pediatrics), Graduate School of Medical Science, Osaka Univ, Osaka, Japan.

Krabbe disease (globoid cell leukodystrophy) is an autosomal recessive neurodegenerative disorder that affects both the central and peripheral nervous systems due to an enzymatic defect of galactocerebrosidase (GALC). Twitcher mouse (TW), naturally occurring mouse model for Krabbe disease, provides an excellent experimental model for gene therapy. In this study to examine the effectiveness of gene therapy using retrovirus vector targeted to bone marrow (BM) cells, recombinant retrovirus vector containing human GALC cDNA was constructed. The normalization of GALC metabolism was confirmed in transfected cultured skin fibroblasts from Krabbe disease and TW. Then, TW bone marrow cells were transfected ex vivo and they were transplanted intraperitoneally into twitcher neonates at 2 postnatal days. This treatment significantly increased body weight at 26 days and 35 days compared to untreated, busulfan treated and busulfan+BM transplantation from TW groups. Human GALC cDNA was not detected in bone marrow cells but sciatic nerve, and the GALC activities were significantly increased in sciatic nerves around 40 postnatal days. However, survival length did not change. The transduction efficiency was about 20 % in hematopoietic colonies. The low efficiency of transduction and pretreatment of BM using busulfan were not enough to extend the survival, but differentiated macrophages from stem cells infiltrated into demyelinating sciatic nerve and stayed there as tissue macrophages. This is the first report of gene therapy for TW using retrovirus vector. There is a possibility to improve the survival of TW by increasing transduction efficiency and using high expression vectors.

Program Nr: 1740 from the 1999 ASHG Annual Meeting

Clinical accessment of therapeutic response to enzyme replacement therapy in 16 Korean Gaucher pts. *H.J. Kim[1], M.J. Ha[1], J.H. Cho[1], B.S. Kim[1], M.K. Kim[1], S.H. Kim[1], H.S. Kim[1], J.S. Kim[1], Y.A. Lim[1], Y.J. Lee[1], H.W. Yoo[2], C.H. Park[1]*. 1) Ajou Univ. School of Medicine, Suwon, Korea; 2) Ulsan Univ. College of Medicine, Seoul, Korea.

16 Korean Gaucher dis. pt.(9 type 1 and 7 type 3), aged 1 to 25 yrs old, began on Enzyme Replacement Therapy (ERT) using Cerezyme with starting dosage of 30u/kg/2wks since May 1998, except 3pts. of type 1, previously on Ceredase from 1 to 3yrs, switched to CZ. Clinical accessment is made on general growth parameters, hematologic parameters of Hb. platelet count, liver function test and acid phosphatase, viceral involvements of hepatosplenomegaly by MRI, skeletal involvements by plain X-ray and MRI and neurologic evaluation with EEG prior to and every 6 m. after ERT (for 1 to 5 yrs follow up). 2 pts. developed antibody against CZ; 1 y.o. pt. developed generalized urticaria after 3 m. Rx. with CZ, massive hepatosplenomegaly and pancytopenia, requiring splenectomy and switched to CD. The other 2 y.o. tolerated the CZ Rx. without clinically adverse reaction. All but 3pts. have responded well and maintained on initial dosage of 30u/kg/2wks regimen; 2 type 3B, required 30u/kg/wk regimen and 1 type 1, to 60u/kg/2wks after recurrent femur Fx. In addition to most freq. finding of subjective "feeling of well being, ", the most consistant finding was the linear growth, evident in all prepubertal children, esp 6 with short stature (Ht.<3%), with growth spurt following 6 m. of Rx., althrough the radiologic bone improvement was not evident yet. Changes of Hb and and platelet count are not informative in 10 splenectomized pts. but acid phosphatase level fell down 20% in 6 m., and 30-50% in 1yr. The reduction of spleen and liver size was most evident in 6 month (-30%) but subsequent reduction was not big as the 1st yr. 5 type 3A pts. responded well on ERT with no further progression in CNS S//S except a 16 y.o. female who had progressive myoclonic seizures since 13 y.o. requiring BMT. With high dosage and high frequency regimen (30u/kg/wk), two type 3B pts. responded well for failure to thrive, massive splenohepatomegaly and other hematologic abnormalities, but abnormal ocular movements have not changed yet.

Program Nr: 1741 from the 1999 ASHG Annual Meeting

Recombinant AAV vectors integrate as single copies even in the presence of wt-AAV. *M.J. Landrum, G.R. Cutting.* Dept Human Genetics, Johns Hopkins Univ, Baltimore, MD.

Wild-type AAV (wt-AAV), a potential gene therapy vector, has the unique property of integration into a specific region of human chromosome 19 termed AAVS1. The integrated provirus is usually found in multiple tandem copies in head-to-tail fashion. Although the precise mechanism of site-specific integration is unknown, the wt-AAV Rep protein plays a major role. Rep^- recombinant AAV (rAAV) vectors integrate to non-19 sites and adding back Rep protein as a plasmid can restore targeting. To study Rep- and non-Rep-mediated integration, we infected cells with both wt-AAV and rAAV or with rAAV alone to test the hypothesis that the presence of Rep protein provided by wt-AAV allows rep^- rAAV to integrate in a manner similar to wt-AAV. Cells were infected either with AAV-GFP, which contains the green fluorescent protein (GFP) and neo-resistance (neo) genes, or with both wt-AAV and AAV-GFP. Colonies were selected for GFP expression and G418 resistance. One single infection clone and two from the dual infection were chosen for extensive Southern blot analysis of the AAV-GFP integrations. Digestion with Hind III which does not cut AAV-GFP and hybridizing with an AAVS1 probe showed that none of the clones has an integration disrupting AAVS1. Five restriction enzymes and three AAV-GFP probes confirmed that an intact viral genome is present. Novel hybridizing bands representing the flanking sequences were used to construct a restriction map of the flanking DNA. The maps confirmed that each clone contains a single copy of integrated AAV-GFP, regardless of the presence of wt-AAV. Fourteen more dual infected clones were characterized. Hind III digestion and hybridizing with AAVS1 confirmed that none of the AAV-GFP integrations disrupt AAVS1. Digestion with an enzyme that yields neo and 3' flanking sequence on a single fragment shows that 13 of 14 clones have a single copy of AAV-GFP integrated at a unique site. These results indicate that in contrast to wt-AAV, rAAV vectors do not specifically target chromosome 19 and integrate as single copies, suggesting that rAAV uses a different non-Rep mediated mechanism of integration, even in the presence of wt-AAV.

Program Nr: 1742 from the 1999 ASHG Annual Meeting

Correction of the metabolic defect in Fabry mice through genetic modification of depot organs. *C. Li[1], R. Ziegler[1], M. Cherry[1], P. Berthelette[1], H. Romanczuk[1], R.J. Desnick[2], Y.A. Ioannou[2], N.S. Yew[1], S.H. Cheng[1]*. 1) Genzyme, Framingham, MA; 2) Mt. Sinai Sch. Med., NYC, NY.

Fabry disease is caused by a deficiency of the lysosomal enzyme a-galactosidase A (a-Gal) resulting in deposition of globotriaosylceramide (GL-3) in vascular lysosomes. Normally, a portion of the enzyme is secreted into circulation which can be recaptured by distant cells through specific receptors. Therefore genetic modification of a depot organ such as liver or lung may suffice to produce corrective levels of the deficient enzyme. Previously, we demonstrated the efficacy of systemic administration of an adenovirus vector encoding a-Gal in Fabry mice. Injection of 10^{11} particles of Ad2/CMVHIagal resulted in high levels of a-Gal in all organs examined, reducing GL-3 to near normal levels. However, associated with administration of this dose of recombinant virus was a robust host immune response which obviated readministration and attenuated expression. We showed transient immunosuppression using the antibody MR1 or deoxyspergualin could overcome this block to readministration and facilitated greater persistence of expression. An alternative to intravenous administration is delivery to the lung. This mode offers the advantage of localized delivery and perhaps greater ease of immunosuppression. Pulmonary instillation of 10^{10} particles of Ad2CMVHIagal into BALB/c mice resulted in expression of a-Gal in the lung, liver, spleen, kidney and plasma. The observation of enzyme outside of the lung suggests that it could cross the blood-air barrier, enter systemic circulation and be internalized by distal tissues. However, expression was transient and undetectable after 3 weeks. The loss of expression was likely due in part to an immune response to the adenovirus and transgene product. Fabry mice have been treated to determine whether this low level of enzyme is sufficient to reduce accumulated GL-3. In addition, an AAV vector encoding the hydrolase has been constructed as this vector purportedly facilitates greater longevity of expression. Comparative studies of these two vector systems will aid in our selection of the most appropriate vehicle for use in gene therapy of Fabry disease.

Program Nr: 1743 from the 1999 ASHG Annual Meeting

Phenotypic correction of feline lipoprotein lipase (LPL) deficiency by adenoviral gene transfer. *G. Liu[1,3], K.J.D. Ashbourne Excoffon[1,3], J.E. Wilson[2,3], B.M. McManus[2,3], L. Miao[1,3], M.E.S. Lewis[1,3], M.R. Hayden[1,3].* 1) Dept. of Medical Genetics; 2) Dept. of Pathology; 3) University of British Columbia, Vancouver, B.C. Canada, V6T 1Z4.

Previous studies have revealed that adenovirus-mediated ectopic liver expression of human LPL (huLPL) can efficiently mediate plasma triacylglycerol (TG) catabolism in mice despite its native expression in adipose and muscle tissue. We aimed to explore the feasibility of liver-directed gene transfer and enzyme replacement for human LPL deficiency using a larger, naturally occurring feline animal model of complete LPL deficiency, remarkably similar in phenotype to the human disorder. A cohort of LPL-deficient (LPL -/-) cats were given iv 8x109 pfu of a CMV promoter/enhancer-driven, E1/E3-deleted adenoviral vector containing a 1.36 kb huLPL cDNA (Ad-LPL) or reporter alkaline phosphatase gene (Ad-AP). Active circulatory huLPL was readily released after iv heparin injection resulting in a ten-fold reduction in plasma TGs, disappearance upon FPLC of the plasma VLDL/chylomicron carriers of TG and enhanced clearance of an excess iv fat load. Antibody against huLPL protein was detected at Day 14 with adenovirus-specific neutralizing antibody present 7 days post gene transfer in both cat cohorts. Tissue-specific expression of the huLPL transgene relative to controls was confirmed by RT-PCR. While huLPL expression was greatest in the liver, other tissues including spleen and lung expressed huLPL message, in direct correlation with histopathological evidence of increased Oil red O positive neutral lipid influx. In contrast, intravenous LPL enzyme replacement therapy (ERT) lead to rapid disappearance of 900 mU/kg of active bovine LPL enzyme from the circulation, with T1/2 occurring at < 10 min in 2 LPL -/- cats. Heparin injection one hour later released < 10% of the original bovine LPL, further indicating its rapid systemic clearance, inactivation or degradation as well as its ineffectiveness as a viable therapeutic alternative for complete LPL deficiency.

Program Nr: 1744 from the 1999 ASHG Annual Meeting

In vivo gene therapy of Pompe disease using an adenoviral vector. *E. Martin-Touaux[1], K. Azibi[1], J.P. Puech[1], D. Chateau[2], E. Kremer[3], N. Raben[4], M. Fardeau[2], A. Kahn[1], L. Poenaru[1].* 1) Laboratoire de Genetique, INSERM U129, CHU Cochin, Paris, France; 2) U153, Pitie-Salpetriere, Paris, France; 3) Genethon, Evry, France; 4) NIH, Bethesda, USA.

Pompe disease (glycogen storage disease type II or GSD II) is an autosomal recessive disorder caused by a deficiency of the lysosomal acid a-glucosidase (GAA). Patients with GSD II accumulate glycogen in lysosomes resulting in three clinical phenotypes: infantile, with severe cardiomyopathy leading to death before 2 years of life, juvenile and adult with a progressive skeletal muscle weakness affecting also the diaphragm causing respiratory failure. No treatment was available for this disease so far. Recently, different therapeutic approaches have been considered such as enzyme replacement and gene therapy. M. Nicolino *et al* in our laboratory have obtained a first generation recombinant adenoviral vector containing the GAA cDNA under the control of the cytomegalovirus promoter (AdGAA). This vector was able to transduce fibroblasts, myoblasts and myotubes of GSD II patients, to provide a high level expression of the GAA and to correct glycogen accumulation. In the present study, we aim to demonstrate the efficiency of the GAA adenoviral vector in vivo in a mouse model of the disease. Previously, we demonstrate the ability of a control adenoviral vector encoding the b-galactosidase, to transduce efficiently the injected muscle by intramuscular injection, and the liver but also the heart and a few skeletal muscle fibers after intravenous injection. The expression is still present 2 months later. The GAA adenoviral vector was administered in newborn mice in the same targeted tissues. Acid a-glucosidase activity was measured 15 days or 2 months after injection and the clearance of intracellular glycogen was evaluated by direct assay and histological analysis, especially electron microscopy. The AdGAA vector permits to restore the GAA activity in liver and muscle. The activity seems to be sufficient to hydrolyse the intralysosomal glycogen. These results are the first step in the evaluation of the feasibility of gene therapy in Pompe disease using a specific recombinant adenoviral vector.

Program Nr: 1745 from the 1999 ASHG Annual Meeting

A family with autosomal dominant polyposis coli and Cowden disease unlinked to the APC, PTEN, and HMPS loci : A new cancer syndrome. *H. Mehenni[1], R. Chergui[2], M.A Brundler[3], S.E Antonarakis[1], M.A Morris[1]*. 1) Medical Genetics, Centre Med Univ, Geneva, Switzerland; 2) Service de gastroenterologie, clinique D. Rahmouni, CHU Algiers, Algeria; 3) Division of Pathology, department of Internal medecine, Cantonal University Hospital of Geneva, Geneva, Switzerland.

Various inherited polyposis syndromes predispose to the development of colonic polyps and colorectal cancer; the elucidation of the molecular pathogenesis of these syndromes is furthermore of great value in understanding mechanisms of sporadic tumorigenesis. We studied a four-generation family of 28 individuals, eight of whom were affected by adenomatous polyposis coli. At colonoscopy, there were more than 100 polyps, which were adenomatous. There were no extra-colonic symptoms except CHRPE in one case. Five individuals developed cancer (three colorectal and one small intestinal and one nasopharynx cancer) and among them four died. A further family member presented with hamartomatous polyps plus cutaneous hamartomas and a thyroid tumor (Cowden disease). Seven family members were unaffected, and twelve of unknown status. The transmission of the polyposis was apparently autosomal dominant. Genetic linkage analysis using microsatellites tightly linked to three genes mutated in polyposis coli, APC, PTEN, and HMPS, showed significant negative Lod scores compatible with exclusion of linkage of the phenotype in this family to these loci. The clinical and genetic data in this family suggest that this syndrome (Cowden/FAP association) has a new genetic etiology. We term this family's disease Hereditary Associated Polyposis Syndrome (HAPS). The main characteristic of this syndrome is the high occurrence of cancer. A genome-wide search in this family will provide the mapping position of the locus and help in the cloning of the gene.

Program Nr: 1746 from the 1999 ASHG Annual Meeting

Incidence and functional consequences of microsatellite instability in a population series of young endometrial cancer patients. *A.L. Millar[1], C. Luceri[1], E. Holowaty[2], S. Gallinger[1], M. Redston[1], B. Bapat[1]*. 1) Center for Cancer Genetics, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 2) Cancer Care Ontario, Toronto, ON, Canada.

Endometrial adenocarcinoma (EC) is the most common noncolorectal cancer in women with familial cancer syndrome, HNPCC. The frequency of HNPCC in the population varies widely, possibly due to incomplete penetrance of the disease, variable phenotype and empirically established clinical criteria (the Amsterdam criteria); which do not account for extra-colonic cancers including EC. Cancers arising in HNPCC patients display microsatellite instability (MSI), caused by genetic defects in mismatch repair (MMR) genes. Germline defects in two MMR genes, MSH2 and MLH1, account for 70% of known HNPCC families. Based on the extent of instability in colon cancers, three classes of MSI are recognized; MSI-H (high, >40% instability), MSI-L (low, <40%) and MSS (stable). We have undertaken a molecular genetic and epidemiologic study of the population incidence of HNPCC-associated EC, using the Ontario Cancer Registry (OCR). All incident cases of young (<50 yrs) EC within the geographical region of Central-East Ontario during 1989-1993 are identified using OCR (n=185). Hematoxyline & Eosin stained sections (5 micron) from all EC cases are reviewed and areas of >75% neoplastic cellularity are selected for microdissection. Matched normal and tumor DNA is screened for MSI using a panel of 5 microsatellite loci (D2S123, D5S346, D17S250, BAT25, BAT 26) and MSI positive cases subjected to immunohistochemical analysis of MSH2 and MLH1 expression, in order to identify underlying mismatch repair gene defect. Of 118 cases analyzed to date, 36 (30.5%) were MSI-H, 13 (11%) were MSI-L and 69 (59%) were MSS. BAT 26 was identified to be the most useful marker for MSI analysis of EC and exhibited 88% sensitivity and 95% specificity.

Program Nr: 1747 from the 1999 ASHG Annual Meeting

A model database for the cataloging of APC mutations and clinical features: Providing a global forum for accurate genetic information. *G.A. Miller, A. Whetsell, M. Wright, R.J. Pomponio.* Molecular Profiling Laboratory, Genzyme, Framingham, MA.

The HUGO Database Initiative has made recommendations for standardized mutation nomenclature, formation of locus-specific and ethnic/national mutation databases, and advocated the creation of peer-reviewed "electronic journals" for mutation reports. Additionally they have been strong proponents of bioinformatics software development and have offered a forum for the discussion and showcasing of new curatorial programs. Recently the paper "Guidelines and recommendations for content,structure, and deployment of mutation databases" (Scriver et al. 1999 Hum Mutat 13:344-350) was published as a compilation of these discussions. In addition to the research utility of such databases it is clear that future genetic testing programs will require accurate, user friendly and up-to-date sources of clinical genetic information.

Consistent with these recommendations, we have developed a model database for the accessioning and reporting of mutations within the Adenomatous Polyposis Coli gene (APC) using the commercially available FileMaker Pro software package (FileMaker, Inc. Santa Clara, CA). The database allows for a more complete "event-based" record of both the molecular and phenotypic data associated with each mutation either reported in the literature or through web-based submission to the site. Unique allelic variants are assigned a permanent accessioning number allowing for efficient searches and sorting of related data. The database can seamlessly integrate data from disparate sources and can be linked to a number of currently existing generalized information databases such as OMIM, GenBank and GDB.

We are currently inviting a dialogue between individuals and institutions working with APC towards creating an APC Consortium for the open reporting and discussion of mutations in this gene. The ultimate goal of this effort is to provide an open, robust, accurate resource for the research and genetic testing communities.

.

Program Nr: 1748 from the 1999 ASHG Annual Meeting

Nipple Aspiration Fluid(NAF): A "Pap Smear" for the Breast in *BRCA* 1/2 Carriers? *G. Mitchell[1,2], P.A. Trott[2], N. Coleman[3], L. Morris[3], E. Sauter[4], R.A. Eeles[1,2].* 1) Institute of Cancer Research, Sutton, Surrey, UK; 2) Royal Marsden Hospital, London, SW2,UK; 3) Addenbrookes Hospital,Cambridge, CB2 2QQ,UK; 4) Thomas Jefferson University, Philadelphia 19107.

Mammographic breast cancer screening is advised for *BRCA*1/2 mutation carriers, but concerns remain as to reduced premenopausal mammographic sensitivity and radiation exposure. An alternative technique is desirable. NAF is produced by ductal epithelial cells, cells which undergo malignant transformation, and contains exfoliated epithelial cells and other cell types. NAF analysis is not new, but an historically poor aspiration rate of ≤60% rendered this technique an unsuitable screening method. **Purpose** To assess the aspiration success rate and normal NAF cellular profile from serial aspiration in non-carriers prior to the start of a NAF screening study for *BRCA*1/2 mutation carriers. **Methods** 15 healthy premenopausal female volunteers had NAF taken from both breasts weekly for 2 menstrual cycles. NAF preparations were stained with H&E and Pap stains, epithelial membrane antigen (EMA) and CD68 (macrophage marker). Cellular proliferative activity was assessed in cycle 2 using an antibody against minichromosome maintenance protein-2 (Mcm-2), a member of the pre-replication complex. **Results** A successful aspiration rate of 88%(247/280 breasts). Of 189/247 specimens available for cytology 92% were cellular, 47% contained epithelial cells and all cellular specimens contained foam cells. Foam cells expressed EMA and CD68 suggesting a heterogeneous population with epithelial and macrophage differentiation. Cellular content did not show menstrual variation or reduce on serial sampling. In 24/104(23%) of samples foam cells expressed Mcm-2 and in 3/24 Mcm2 was also expressed in epithelial cells. Positive cases were from 6 women. No consistent menstrual cycle correlation of Mcm-2 was detected. **Conclusions** NAF cytology maybe useful as a breast cancer screening method similar to the Pap smear, particularly if a subset of foam cells demonstrate epithelial origin. The sensitivity of this method maybe increased by the use of proliferation markers as suggested for cervical Pap smears. Funding by Breast Cancer Campaign.

Program Nr: 1749 from the 1999 ASHG Annual Meeting

Androgen receptor gene mutation R726L is associated with prostate cancer in Finland. *N. Mononen[1], P.A. Koivisto[1], J. Schleutker[1], M. Matikainen[1], T. Tammela[1], J. Trapman[2], O-P. Kallioniemi[3].* 1) Lab. Cancer Genetics, Inst. of Medical Technology, Tampere, Finland; 2) Dept. of Pathology, Erasmus University, Rotterdam, the Netherlands; 3) Cancer Genetics Branch, NHGRI, NIH, USA.

Due to the importance of androgen signaling in prostate cancer, the role of androgen receptor has been extensively studied as a risk factor for prostate cancer. However, only few germ-line androgen receptor mutations have so far been found, none of which have been conclusively linked with the disease. We found a recurrent germline mutation at codon 726 of the androgen receptor gene (AR) in Finnish prostate cancer patients. This missense mutation (G>T) replaces arginine with leucine in the hormone-binding domain of the receptor, and has previously been shown to alter transactivational properties of the receptor (Elo et al, J Clin Endocrinol Metab. 1995 Dec;80(12):3494-500). To explore the disease association of R726L, we performed ASO-analysis of 417 consecutive prostate cancer patients and 562 healthy male and female blood donors (altogether 684 AR alleles) collected at the Tampere University Hospital, as well as 107 Finnish prostate cancer families. R726L was significantly more common among unselected prostate cancer patients (8/417, 1.9%; p=0.025, RR=4.4) than the carrier frequency in blood donors (3/684, 0.4%). Interestingly, R726L was also present in three prostate cancer families (2.8%; p=0.038, RR=6.2). In two of these families, segregation of R726L with disease could be demonstrated. In conclusion, R726L is associated with prostate cancer and present in up to 2%; of Finnish prostate cancer patients, as well as a subset of prostate cancer families. R726L and other similar functional AR SNPs require further attention as predisposing or modifier loci for human prostate cancer.

Program Nr: 1750 from the 1999 ASHG Annual Meeting

A New Insertional Mutation and Differentially Spliced mRNAs in the BRCA1 Gene. *M. Munnes, I. Zuther, B. Schmitz, W. Doerfler.* Inst Genetics, Univ Cologne, Koeln, Germany.

In breast cancer, one of the most frequent cancer forms in women, one major risk factor besides progressing age and late pregnancy is a family history of breast and/or ovarian cancer. Among familial breast cancer patients, early onset (<30 years), bilateral disease as well as joint occurrence with ovarian cancer are more frequent compared to the general population. Two major candidate genes, the BRCA1 (17q21) and BRCA2 (13q12.3) have been identified. Numerous mutations in the 24 exons of the BRCA1 gene that spans a genomic region of 100 kbp have been found in patients. We have identified a family with several cases of breast/ovarian or other forms of cancer in three generations and an index patient with breast cancer diagnosed at age 26. DNA and mRNA from peripheral white blood cells have been isolated and all PCR amplified exons have been subjected to automated DNA sequencing. Within the coding sequence we found two polymorphic nucleotide exchanges in exons 11 and 16 which seemed unrelated to the disease. More importantly, we detected a so far undescribed 10 bp heterozygous insertion in exon 6 of the BRCA1 gene. This insertion alters and truncates the BRCA1 protein after 86 amino acids. The cDNA sequences obtained by RT-PCR displayed biallelic expression of the BRCA1 gene. By protein truncation tests (PTT), we also confirmed the truncation of the BRCA1 protein due to the insertion of a premature stop codon in the DNA sequence in this woman. Haplotype analyses and DNA sequencing revealed the transmission of the 10 bp insertion from the patient's mother who had also been treated for breast cancer. In studies on the transcription patterns of the BRCA1 gene, we have noted several splice variants in the 5'-part of the gene affecting exons 3, 5 and 8. In about 50 % of all transcripts the first codon of exon 8, coding for glutamine, was absent. The complete or partial loss of exon 3 or 5 led to the disruption of the RING finger motif in the c-terminal part of the BRCA1 protein. PTT analyses have confirmed truncated or size-reduced forms of the BRCA1 protein. The splice variants were not specific for the breast cancer patients analyzed.

Program Nr: 1751 from the 1999 ASHG Annual Meeting

Structural and functional evidence for the presence of a tumor suppressor gene in human non-small cell lung cancers on chromosomal region 11q23.2. *Y.S. Murakami[1], T. Nobukuni[1], Y. Sugiyama[1], M. Kuramochi[1], H. Fukuhara[1], T. Maruyama[1], T. Sekiya[1], M. Pletcher[2], R.H. Reeves[2]*. 1) Oncogene Div, Natl Cancer Ctr Research Inst, Tokyo, Japan; 2) Dept of Physiology, Johns Hopkins Univ. Schl. Med, Baltimore, MD.

Loss of heterozygosity (LOH) for the loci on chromosome 11q22-23 is observed at high frequency in human non-small cell lung cancers (NSCLCs). We recently reported that by spheroplast fusiong of YAC clones incorporating 1,100 kb of DNA from 11q23.2 into a human NSCLC cell line, A549, can completely suppress the tumorigenic phenotype of these cells. A nested deletion carrying 800kb of this YAC gives partial suppression. These findings provide functional evidence for the presence of a tumor suppressor gene(s) on 11q23.2. To identify this tumor suppressor gene, a contig map of the 1,100 kb region was constructed by screening human BAC and PAC libraries. Six polymorphic markers were mapped to high resolution on this contig. These markers were used to refine the localization of breakpoints in a subset of NSCLCs that showed LOH around this region. This allowed the commonly deleted NSCLC region to be narrowed to 1.0 Mb between the markers, 86CA and D11S1885. This region completely contains the entire 800 kb fragment with tumor suppresssor activity, providing independent confirmation of the presence of a tumor suppressor gene(s) in this region. To further refine the location of the tumor suppressor gene, PAC clones into A549 cells. The PAC vector includes the blasticidine-S-methylase gene, allowing selection of transfected cells with blasticidine. Resistant clones were screened by hybridization to detect the human sequences from the transferred PAC. Twelve transfected A549 cell lines were characterized by Southern blotting, demonstrating the presenece of one to ten copies of the insert DNA in various A549 cell lines. These lines are being tested to determine whether the included fragments suppress tumorigenicity of the parental A549 cells, providing a fucntional assay to localize this NSCLC tumor suppresor gene(s).

Program Nr: 1752 from the 1999 ASHG Annual Meeting

Cytogenetic analysis of two histopathological types of schistosome-related bladder tumors using comparative genomic hybridization. *M.T. Muscheck[1,2,4], H. Abol-Enein[3], K. Chew[1], P. Alken[2], P. Carroll[4], F. Waldman[1]*. 1) Cancer Genetics Program, UCSF Cancer Center, San Francisco, CA; 2) Department of Urology, Uni-Klinikum Mannheim gGmbH, Mannheim, Germany; 3) Urology & Nephrology Center, University of Mansoura, Mansoura, Egypt; 4) Department of Urology, UCSF, San Francisco, CA.

Schistosome-related bladder cancer shows different clinical and pathological features compared to non-schistosome-related bladder cancer. In this study, we used molecular cytogenetics to characterize regional differences in DNA sequence copy number in two histopathological types of schistosome-related bladder cancers from Egypt. Schistosome-related primary bladder tumors from 54 Egyptian patients with invasive disease (pT2-4) were analysed. Tumors were classified as squamous cell carcinomas (SCC; n=26) and transitional cell carcinomas (TCC; n=28. Genomic DNA was extracted after micro-dissection, amplified by DOP-PCR, followed by nick-translation and CGH. The mean number of alterations per specimen was significantly higher in TCC tumors (14.4) compared to SCC tumors (8.2, $p<0.001$). Most prevalent genetic alterations were 8p-, 8q+, and 18q- for both tumor types, 5q-, 9p-, 10q-, 11p-, and 11q- for TCC tumors, and 17p-, and 18p- for SCC tumors. After statistical correction of p-values, chi-square tests showed significantly different losses for chromosome arms 11p ($p=0.01$), 17p ($p=0.001$), 18p ($p=0.03$), and 21q ($p=0.03$). High level amplifications (green to red ratio > 1.5) of small chromosome regions were found in 15 TCC tumors and 8 SCC tumors. Amplification sites were 1q21-q23 (2), 6p22 (2), 8q21-q23 (3), 11q13 (3) for TCC tumors, and 1p21 (1), 1p31 (1), 8q22-q23 (2), and 11q13 (1) for SCC tumors. This study represents the first analysis of schistosome-related bladder cancer by CGH, and it confirms the presence of previously known aberrations and highlights new quantitative abnormalities and sequence amplifications. It strengthens the supposition that different tumor subgroups of the urinary bladder are characterized by distinct patterns of chromosomal alterations, which might explain differences in clinical behavior. Supported by: NCI CA 47537.

Program Nr: 1753 from the 1999 ASHG Annual Meeting

Loss of heterozygosity in different areas within high-grade diffuse astrocytoma. *A. Mutirangura[1], Sh. Shuangshoti[2], Y. Navalitloha[3], V. Kasantikul[2], S. Shuangshoti[2].* 1) Genetics Unit, Dept Anatomy, Fac Medicine, Chulalongkorn Univ, Bangkok, Thailand; 2) Department of Pathology, Fac Medicine, Chulalongkorn Univ, Bangkok, Thailand; 3) Department of Surgery, Fac Medicine, Chulalongkorn Univ, Bangkok, Thailand.

The primary objective of this study was to determine loss of heterozygosity (LOH) in various portions of 9 high-grade diffuse astrocytomas, 8 glioblastomas and 1 anaplastic astrocytoma. LOH was observed on chromosomes 9, 10, 17 and 19 in 8, 3, 4 and 2 cases, respectively. Genetic heterogeneity and a multistep process were identified in 4 glioblastomas explaining the diverse morphological characteristics, a common feature of diffuse astrocytomas. In 2, 2, 3 and 1 cases, the allele losses were found within part of grade IV astrocytomas but not grades II or III, on chromosomes 9, 10, 17 and 19, respectively. In one of these, while genetic heterogeneity was observed on chromosome 17 between the area of grade II and grade IV, 9pLOH was found within both areas and occurred on the same allele. The other 5 cases did not demonstrate genetic heterogeneity and the LOH was on the same allele, irrespective of grade, suggesting clonal origin. In conclusion, at the molecular level, the diverse morphological features of astrocytoma develops by a multistep mechanism of genetic alterations from one cell via low-grade and more malignant tumors towards glioblastoma.

Program Nr: 1754 from the 1999 ASHG Annual Meeting

Prostate cancer risk and repeat (CAG and GGN) polymorphism of the androgen receptor gene in an Australian population. *N.T Nassif, C. Kok, G.P Lobo, G.A Nicholson.* Molecular Medicine Laboratory, Department of Medicine, Sydney University, Clinical Sciences Building, Concord Hospital, Concord, NSW 2139, Australia.

Prostate cancer is the most commonly-diagnosed male malignancy and the second most common cause of male cancer death in the Western world. Androgens play an essential role in the growth of normal and malignant prostate cells. Androgen action within target cells is mediated by the androgen receptor (AR) which binds dihydrotestosterone and stimulates the transcription of androgen-responsive genes. Because of this association, it has been proposed that the AR might be one genetic predictor of an individual's susceptibility to prostate cancer. The transactivation activity of the AR resides in the amino-terminal domain of the protein encoded in exon 1 of the gene. Exon 1 contains in-frame polymorphic $(CAG)_{9\text{-}33}$ and $(GGN)_{8\text{-}17}$ trinucleotide repeats. The transactivation activity of the receptor has been shown to be inversely proportional to (CAG)n repeat length. Shorter CAG alleles cause a more active growth of prostate cells which, in turn, elevates the risk of prostate cancer since target cell proliferation is known to promote tumorigenesis. Our aim was to determine whether germline CAG and GGN repeat polymorphisms within the AR gene are associated with the development of prostate cancer. We have determined the CAG and GGN allele sizes of prostate cancer patients (n=360) and age-matched unaffected individuals (n=302). We have found that the prostate cancer patients had a mean CAG repeat size (21.68) that was smaller than that of the control (22.2) group (two sided $P<0.05$). No such difference in mean (GGN)n repeat number was observed between cases and controls. Further analyses revealed an increased risk in men with less than the median number of CAG repeats (<22) and who had an affected first degree relative. Men with shorter (n£16) GGN repeats also had elevated risk estimates. The subset of men with two short repeats (CAG<22 and GGN £16) had a 2-fold elevation in risk.

Program Nr: 1755 from the 1999 ASHG Annual Meeting

p53 mutation spectrum in non-small cell lung cancer: results from a prospective study. *H.H. Nelson[1], J.K. Wiencke[2], D.C. Christiani[1,3], E.J. Mark[3], J.C. Wain[3], K.T. Kelsey[1].* 1) Cancer Cell Biology, Occupational Health Program, Harvard School Public Health, Boston, MA; 2) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA; 3) Departments of Medicine, Pathology, and Surgery, Massachusettes General Hospital, Boston, MA.

p53 mutations were assessed in a large case-series of surgically resected lung tumors from a predominantly smoking population (n=354). The prevalence of mutation was 28%, and did not significantly differ by histology or gender. p53 mutations occurred with a similar frequency in current and former smokers (28%), and were less common in never smokers (18%). Previous studies, using meta-analysis and retrospective case designs, have established that transversion mutations (in particular G:C to T:A substitutions) are the dominant mutation event in lung tumors from smokers. Analysis of spectra in the current study revealed a strikingly low prevalence of G:C to T:A mutations (16.8%). C:G to T:A substitutions were the most common type of mutation (28.7%), with the majority of these occurring at non-CpG sites (70%). In addition, the prevalence of transitions, transversions, and specific base substitutions did not differ when the population was stratified on pack-years smoked. Finally, analysis of the distribution of mutations by codon did not reveal any hotspots. Comparison of our spectra data with the IARC database reveals significant differences in both the distribution of mutations along the gene, and the frequency of mutation types. These differences may reflect recent changes in the lung cancer epidemic.

Program Nr: 1756 from the 1999 ASHG Annual Meeting

Characterization of common BRCA1 and BRCA2 missense mutations. *S.L. Neuhausen[1], M. Hoffman[1], A. Deffenbaugh[2], S. Manley[2], T.S. Frank[2], B.E. Ward[2].* 1) Dept Medical Informatics, Univ Utah, Salt Lake City, UT; 2) Myriad Genetic Laboratories Inc, Salt Lake City, UT.

Over 1000 individual mutations have been identified in BRCA1 and BRCA2, genes responsible for inherited predisposition to breast and ovarian cancers. The functional significance, and therefore clinical significance, of many of the missense mutations has not been established. Some of these missense mutations have been observed repeatedly. No assay to test the function of missense mutations is available. Observations which suggest that a missense mutation is not causal are: 1) it is observed in a control group in equal or greater prevalence to an at-risk group; 2) it is not in a putative functional domain; 3) there is not cosegregation of the variant and disease in a family with significant disease; 4) the missense change results in replacement of a similar amino acid to the wild-type; and 5) there is not conservation of the wild-type amino acid between human, mouse, and dog BRCA1 or BRCA2 proteins.

The aim of this study was to characterize the clinical significance of 8 missense mutations that have been reported in multiple unrelated women who have undergone clinical testing for BRCA1 and BRCA2. Of the 8 mutations, none occurred in putative functional domains, 6 had dissimilar and 2 had similar amino changes, 5 were conserved and 3 were not conserved in human and mouse, and 6 were observed in individuals with a truncating mutation in the same gene. A control population, of 154 Caucasians of Northern European ancestry unaffected with cancer, was used to determine population frequencies of the mutations. Frequencies in the control population ranged from 0% to 3.3%. Based on the criteria described above, the BRCA1 S1512I and M1652I and BRCA2 A2951T mutations are polymorphisms, the BRCA1 R1347G and BRCA2 D1420Y and V2728I mutations are likely polymorphisms, and the BRCA2 T598A and R2034C mutations remain missense mutations of unknown significance. Additional control samples are being examined for the more rare mutations, such as T598A. Cosegregation of mutations within families also needs further exploration.

Program Nr: 1757 from the 1999 ASHG Annual Meeting

Expression analysis of candidate endometrial tumor suppressor genes from 10q25.3. *F.C. Noonan[1], D.G. Mutch[2], P.J. Goodfellow[1]*. 1) Surgery, Washington University, St. Louis, MO; 2) Obstetrics and Gynecology, Washington University, St. Louis, MO.

LOH studies in endometrial tumors have mapped a tumor suppressor gene to a minimum deletion interval of 300 kb on chromosome 10q25.3. Genomic sequence for the region has facilitated our sequence-based approach to candidate gene isolation. We have identified multiple cDNAs in the region by EST mapping. Northern and dot blot analysis undertaken to prioritize candidates has revealed four apparantly independent transcripts with expression patterns consistent with a potential role in tumorigenesis. All four candidates are expressed highly in normal uterus. We have begun to isolate full length cDNAs corresponding to these ESTs. The first candidate, F1, is expressed in three tissues: uterus, kidney and brain, and detects a transcript of 3 kb. F1 shows evolutionary conservation by Southern hybridization to rodent genomic DNA and sequence homology to two mouse ESTs [88% identity over 258 bp]. In addition, F1 contains part of the coding sequence of the second candidate, the homeobox gene *EMX2*. *EMX2* detects a ubiquitous 5 kb transcript, and an abundant 3 kb transcript in the uterus. We are attempting to clarify the relationship between these two transcripts by isolating both uterus and kidney cDNAs. The third candidate, F5C, has an expression pattern similar to F1; it is expressed highly in the uterus, kidney and brain. However, F5C detects an 8 kb transcript. Screening three cDNA libraries has yielded four clones, the longest of which is only 1 kb. RACE is being used to isolate a more complete sequence for this large transcript. The fourth transcript, F4 is expressed only in the uterus. The localization of these genes in a relatively small genomic interval and the expression patterns suggests that this may be a gene complex involved in uterine development and/or morphogenesis. Sequence analysis of the partial cDNAs (with the exception of *EMX2*) indicates that all correspond to novel genes. *In situ* hybridization analysis has been initiated in endometrial tissues at different stages of proliferation to learn more about the temporal and spatial expression patterns of these transcripts.

Program Nr: 1758 from the 1999 ASHG Annual Meeting

t(8;12) Induces Aberrant *HMGIC* Expression In Aggressive Angiomyxoma Of The Vulva. *M.R. Nucci[1,2,4], S. Weremowicz[2,4], G. Tallini[5], K. Sornberger[2], C.C. Morton[2,3,4], B.J. Quade[1,2,4].* 1) Div. of Women's and Perinatal Pathology; 2) Dept. of Pathology, and; 3) Dept. of OB/GYN, Brigham and Women's Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) Dept. of Pathology, Yale Medical School, New Haven, CT.

Background: Benign mesenchymal tumors associated with rearrangements of *HMGIC*, a DNA architectural factor gene mapping to 12q15, include cutaneous lipomas, uterine leiomyomas, pulmonary chondroid hamartomas, endometrial polyps, pleomorphic adenomas of the salivary gland, and breast fibroadenomas and hamartomas. Fusion gene formation predominates in lipomas and pleiomorphic adenomas. In contrast, rearrangements in leiomyomas result in *HMGIC* overexpression. Although *HMGIC* has also been implicated in the pathobiology of vulvar aggressive angiomyxoma (VAA), the molecular mechanism(s) pertaining to this neoplasm are unclear. **Design:** Tissue from a recurrent VAA was used for cytogenetic and FISH analysis and for RT-PCR or immunohistochemical analysis of *HMGIC*, HMGI(Y), or *G3PDH* expression. **Results:** The GTG-banded karyotype was 46,XX,t(8;12)(p12;q15). FISH with whole chromosome painting probes excluded additional occult rearrangement. The chromosome 12 breakpoint was mapped with two-color FISH using cosmid probes 5' (centromeric) and 3' (telomeric) to *HMGIC*. Signals for both cosmid probes showed hybridization on the normal chromosome 12 and der(12) chromosome, indicating that the breakpoint was 3' (telomeric) to the gene. RT-PCR revealed *HMGIC* expression in the tumor. Immunohistochemistry localized HMGIC expression to the tumor's spindle cells, but not to blood vessels. HMGI(Y) expression was not detected by immunostaining. **Conclusions:** Like numerous benign mesenchymal tumors, this locally aggressive tumor is associated with rearrangements of *HMGIC*. Our results show that chimeric gene formation is not required for tumorigenesis. Inappropriate expression of this DNA binding protein in the tumor's spindle cell component, however, is important in this tumor's pathobiology. Understanding the pathogenetic mechanism in VAA may also provide new insights into invasiveness in other tumors and in management of residual disease in VAA.

Program Nr: 1759 from the 1999 ASHG Annual Meeting

Cytogenetic and molecular genetic analysis of renal tumors in Singapore. *P.L. Ong[1], P.H. Tan[1], W.O. Lui[2], L.C. Lau[1], Y.Y. Chong[1], T.W. Chong[3], K.T. Foo[3], S.L. Tien[1]*. 1) Dept of Pathology, Cytogenetics Laboratory, Singapore General Hospital, Singapore; 2) Dept of Medical Oncology, Singapore General Hospital, Singapore; 3) Dept of Urology, Singapore General Hospital, Singapore.

In our study of 17 renal tumors in Singapore, 12 were clear cell RCC, 2 were papillary RCC, 1 had both clear cell and papillary foci and 2 were transitional cell carcinoma (TCC) of the renal pelvis. The patient cohort comprised 13 males and 4 females ranging from 44 to 73 years old. 13 were Chinese and 4 were Malay in ethnic origin. 10 clear cell RCCs had chromosome 3 aberrations; the eleventh had -8 while the twelfth had +21. 6 had -3 and 3 had t(3;5). The papillary RCCs had gains or losses of whole chromosomes. The TCCs had +3, -9 and -21 in common, one of which had a novel add(3)(q27). The retinoblastoma susceptibility 1 (RB1) gene at 13q14 was also deleted in this tumor. DNA was extracted from the renal tumors of these patients and PCR performed at the VHL locus. We identified 3 novel frameshift mutations in 3 clear cell RCCs. The mutations, 587delAC and 628insA in exon 2, and 691delGA in exon 3, result in stop codons downstream from the mutation site and will produce truncated proteins. On cytogenetic analysis, the structural integrity of the VHL gene of the 3 tumors with mutations characterized was maintained, suggesting that the karyotypes underestimated the extent of genetic loss. In conclusion, we have identified chromosomal aberrations in our 17 patients with renal tumors, some which have not been previously documented. This may indicate the emergence of new anomalies in patients of Asian origin. In addition, cytogenetic analysis, complemented with molecular techniques, will enhance the detection of genetic aberrations in renal tumors. Furthermore, mutation searches of proto-oncogenes or tumor suppressor genes known to be involved in RCC should be done to fully understand the genetics of such tumors.

Program Nr: 1760 from the 1999 ASHG Annual Meeting

Gene Expression Profiles of Ovarian Cancer Using T7 based RNA Amplification and cDNA Microarray Technology. *K. Ono[1], T. Tanaka[1], O. Kitahara[1], N. Shiraishi[1], C. Kihara[1], T. Seki[1], R. Yanagawa[1], H. Ogasawara[1], T. Okamoto[2], Y. Ohnishi[3], K. Kuzuya[4], T. Tsunoda[5], T. Takagi[5], Y. Nakamura[1]*. 1) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science University of Tokyo; 2) Dept.of Obstet. and Gynecol., Nagoya Univ. Sch. of Med; 3) Dept.of Obstet. and Gynecol., Kagoshima City Hospital; 4) Dept.of Gynecol., Aichi Cancer Center; 5) Laboratory of Genome Database, Human Genome Center, Institute of Medical Science, University of Tokyo.

The microarray hybridization technology enabled us to study the expression of a large number of genes simultaneously. However, since the RNA expression analysis of cells using the microarray requires a few micrograms of mRNA, we applied T7-based RNA amplification method to obtain sufficient quantities of RNA from limited materials. Total RNAs were isolated from fresh-frozen normal and tumor specimens from patients with ovarian cancer. Following RNA amplification with T7 RNA polymerase, we labeled cDNA probes by Cyanine dyes and hybridized to the microarrayed cDNAs of 4476 genes. Probes amplified from total RNA and those prepared from mRNA from the same material revealed a very similar expression profile, indicating that the limited quantities of RNA (from 1000 or more cells) can be used for microarray analysis. Furthermore, the microarray analysis showed that expression patterns of several genes in ovarian cancer were correlated with the features of pathological or clinical classification of the samples. Thus, cDNA microarray technology in combination with T7-based RNA amplification method will provide the useful information for the identification of genes involving in tumorgenesis as well as molecular targets for diagnosis and therapeutic intervention .

Program Nr: 1761 from the 1999 ASHG Annual Meeting

Cytochrome P450c17a **gene(CYP17) polymorphism is associated with risk for colorectal adenomas.** *E.C. Osth[1], R. Haile[1], H-J. Lenz[2], E.R. Lee[3], H. Frankel[4], G. Coetzee[5], S.A. Ingles[1]*. 1) Dept. of Preventative Medicine, University of Southern CA, Los Angeles, CA; 2) Dept. of Hematology and Oncology, University of Southern CA, Los Angeles, CA; 3) Division of Gastroenterology, Sunset Kaiser Permanente Medical Center, Los Angeles, CA; 4) Division of Gastroenterology Bellflower Kaiser Permanente Medical Center, Los Angeles, CA; 5) Dept. of Microbiology, University of Southern CA, Los Angeles, CA.

Recent findings on hormone replacement therapy (HRT), genetic control of estrogen levels, and age and sex differences in the incidence of colorectal cancer have motivated our hypothesis that genetically controlled variation in endogenous estrogen levels might influence risk of colorectal cancer in women. Epidemiologic data have shown that HRT is protective against colon cancer in women and polymorphism in the CYP17 gene has been associated with serum estradiol levels and with age of menarche. We conducted a case-control study of 230 colorectal adenoma cases and 241 controls. All subjects were members of a prepaid health plan in Los Angeles who underwent sigmoidoscopy in 1991-1993. We found that women carrying at least one copy of the CYP17 A2 allele were at increased risk of colorectal adenomas. Compared to women with the A1/A1 genotype, the odds ratios were 1.33 (CI: 0.80, 2.02) for women with genotype A1/A2 and 2.18 (CI: 1.19, 4.00) for women with genotype A2/A2. Issues regarding our results and findings that associate HRT and colorectal cancer will be discussed.

Program Nr: 1762 from the 1999 ASHG Annual Meeting

Identification of genes overexpressed in medulloblastoma by SAGE. *E. Oussoren[1], O. Wirths[2], A.L.M.A. ten Asbroek[1], E. Pauws[1], T. Pietsch[2], F. Baas[1].* 1) Neurozintuigen, Academic Medical Center, Amsterdam, Netherlands; 2) Department of Neuropathology, University of Bonn Medical Center, Bonn, Germany.

Medulloblastoma is a malignant primitive neuroectodermal tumor of the central nervous system, occurring predominantly in childhood and arising in the cerebellum. Five-year survival of these children is still poor (39-70%) despite very intensive therapy consisting of neurosurgery, radiotherapy and sometimes chemotherapy. SAGE was used to search for genes that play a role in development and growth of medulloblastomas. The gene expression pattern of a 24 week fetal brain was compared with that of a medulloblastoma. Here we report the identification of two tags (#17 and 18) which were significantly higher expressed in medulloblastoma compared to fetal brain. Tag #17,which was found 13/10,000 SAGE tags in a classic medulloblastoma, was expressed in all medulloblastomas (n=10) tested thus far. Tag #17 matched with multiple ESTs. Sequence analysis of new clones identified with this tag shows homology with the family of the IGF binding proteins. Tag #18 matched to OTX2, the human homolog of the Drosophila gene orthodenticle. Expression patterns of OTX2 were determined by Northern blot and semi-quantitative PCR. In total 42 medulloblastomas were analyzed (32 of classic, 10 of desmoplastic histology). 26 of the classic medulloblastomas but only 2 of desmoplastic tumors showed high OTX2 mRNA, whereas adult tissues, fetal and adult cerebellum had no or very low mRNA levels. In conclusion, two genes highly expresssed in medulloblastoma were identified by SAGE. Both are expressed in the majority of the medulloblastomas tested thus far and may serve as molecular markers for these malignant tumors.

Program Nr: 1763 from the 1999 ASHG Annual Meeting

A hospital-based study to determine the genetic basis of non-medullary thyroid cancer. *T. Pal[1,2], R. Tsang[3], J. Brierley[3], S.A. Narod[2]*. 1) Familial Cancer Clinic, Princess Margaret Hosp, Toronto, ON, Canada; 2) The Centre for Research in Women's Health, University of Toronto, ON, Canada; 3) Department of Radiation Oncology, Princess Margaret Hosp, Toronto, ON, Canada.

The non-medullary forms of thyroid cancer are not generally thought of as having a familial basis; however, epidemiologic and family studies suggest that a subset of these cancers may be due to an inherited predisposition. In order to determine how frequently non-medullary thyroid cancer is due to a hereditary factor, we conducted a hospital-based study at the Princess Margaret Hospital, Toronto, Canada. We obtained pedigrees on 184 patients diagnosed with non-medullary thyroid cancer . Family histories of cancer were obtained for all 1339 first-degree relatives of these patients; in addition, family history of thyroid cancer was obtained on second and third degree relatives . There were 13 families (7%) with 2 or more cases of non-medullary thyroid cancer in either first, second or third degree relatives. The observed cancer rate in the relatives was compared with the expected number, based on comparison with age-standardized provincial incidence rates in order to estimate relative risks. For thyroid cancer, there were 11 cancers observed in relatives, compared to the 3.0 cancers expected, giving a relative risk of 3.7 (95% confidence interval (CI): 1.9-6.7). Our findings suggest that a small proportion of non-medullary thyroid cancer has an inherited basis. Further molecular studies are needed to determine the genetic basis of cancer in these families.

Program Nr: 1764 from the 1999 ASHG Annual Meeting

Mutation detection in BRCA1 using real time PCR and melting curve analyses. *G. Pals[1], K. Pindolia[2], M.J. Worsham[2]*. 1) Inst Human Genetics, Free Univ, Amsterdam, Netherlands; 2) Cancer Genetics Research, Pathology, Henry Ford Health Systems, Detroit, MI.

The detection of two recurrent mutations in the hereditary breast/ovarian cancer associated BRCA1 gene was studied with real time PCR and melting curve analyses. Short PCR products were designed around the small deletion 185delAG in exon 2 (recurrent in the Ashkenazi Jewish population) and the single base substitution 2841GT in exon 11 (recurrent in the Dutch population). Hybridization probe sets were designed for both PCR products, with each probe overlapping the specific mutation. The exon 11 probe set also covered two other mutations, the 2809insA and the 2814insA also recurrent in the Dutch population. The 3'end of the 5' probe was labeled with FITC and the 5'end of the 3' probe with LightcyclerRed640. The 185del and the 2841G mutations were easily detected with the hybridization probes, resulting in dual peaks for heterozygotes in melting curve analyses. The differences in melting characteristics of the heteroduplexes in heterozygotes were not detectable with SYBRgreen. Not all mutations covered by the probes could be detected, indicating that the method is not suitable for unknown mutations. For known mutations, melting curve analysis using hybridization probes is highly sensitive, rapid and an efficient approach to mutation detection.

Program Nr: 1765 from the 1999 ASHG Annual Meeting

Identification and characterization of genes differentially expressed in a subset of Wilms tumors with non-functional WT1. *H. Pannu, V. Huff.* Department of Experimental Pediatrics, University of Texas MD Anderson Cancer Center, Houston, TX.

Wilms tumor is a childhood renal malignancy that occurs in both sporadic and familial forms. The disease is genetically heterogeneous, and studies have implicated loci at 11p13, 11p15, 1p, 7p, 16q, 17q and 19q in the development of Wilms tumor. Of these, the transcription factor WT1 at 11p13 is the only Wilms tumor gene cloned and characterized to date. To identify other cellular genes that are potentially important in the development of Wilms tumor, we performed differential display analysis, comparing gene expression in a panel of six Wilms tumors which had sustained inactivating mutations at the WT1 locus with two other childhood renal tumors, normal kidney, and fetal kidney. Using a set of 104 primer combinations for differential display RT-PCR, we identified sixteen bands representing genes that are differentially expressed in Wilms tumors as compared to control tissues. We repeated the analysis in an independent RT-PCR amplification using the primer sets that generated these differentially expressed bands and were able to confirm differential expression for eleven of these gene fragments. We used these eleven gene fragments to probe Northern blots and determined that three of these detect transcripts that are differentially expressed in Wilms tumors as compared to controls. These three have been subcloned and sequenced. We have used the initial sequence (~250-550 bp) to screen available sequence databases and have identified a few highly homologous ESTs. We have screened a fetal kidney cDNA library for full length clones and will determine the chromosomal location of these genes using a radiation hybrid panel. In a further effort to define the role of these genes in Wilms tumor, we are currently analyzing the expression of these genes in genetically defined subgroups of Wilms tumor and in a range of normal fetal and adult tissues.

Program Nr: 1766 from the 1999 ASHG Annual Meeting

Characterization of chromosomal aberrations in six Korean gastric carcinoma cell lines using chromosome painting. *S.H. Park, J.I. Kil, S.Y. Park, H. Kim, Y.H. Chun.* Institution of Human Genetics, Dept. of Anatomy, Korea University College of Medicine and Gradute School of Biotechnology, Korea University, Seoul, Korea.

Gastric cancer is the most prevalent form of cancer in east Asia, including Korea and Japan. It is difficult to culture the stomach cancer cells and to analyze the chromosome aberrations. The purpose of this study was to establish in detail karyotypes of Korean gastric cancer cell lines, using multiple chromosome paintings. Six Korea gastric carcinoma cell lines(SNU-484, SNU-601, SNU-620, SNU-638, SNU-668, SNU-719) were cultured and harvested for cytogenetic analysis. Routine karyotyping was performed. For complete analysis of chromosomal aberrations, human chromosome-specific painting probes were constructed from somatic hybrid cell DNAs and region specific painting probes were made by amplification of microdissected chromosome bands. The origins of the unidentified marker chromosomes were analyzed by FISH with these painting probes. Each cell lines had unique modal kayotypic characteristics and showed a variable number of numerical and structural clonal cytogenetic aberrations. SNU-484, -620, -668 had near triploidy and SNU-601, -638, -719 had near diploidy, and the number of marker chromosome of SNU-484, -620, -668, -601, -638, -719 was 13-15, 8, 25-27, 15-20, 6, 3-6, respectively. The origins of the marker chromosomes of these cell lines were identified by FISH with constructed painting probes. Especially rearrangement of chromosome 17 resulting in partial deletion of 17p(and/or partial gain of 17q) and centromere involved translocations were found in all six cell lines. The most frequent marker observed in these cell lines was a partial gain or deletion of chromosome 7 with the breakpoints in regions 7q22-q32.

Program Nr: 1767 from the 1999 ASHG Annual Meeting

NO EVIDENCE OF CORRELATION BETWEEN P53 CODON 72 POLYMORPHISM AND RISK OF HPV-16 ASSOCIATED CERVICAL CARCINOMAS IN KOREAN WOMEN. *Y.S. Park, M.Y. Kim, H.J. Lee, M.J. Oh, K.O. Lee.* Molecular Diagnosis, Seoul Medical Science Institute, SCL, Seoul, Korea.

Human papillomavirus (HPV)-16 and 18 encode E6 oncoprotein, which binds to and induces degradation of the cellular tumor suppressor protein p53. A common polymorphism of p53, encoding either proline or arginine at position 72, affects the susceptibility of p53 to E6-mediated degradation. A recent report suggested that the risk of HPV associated cervical carcinomas in Caucasian women is about seven time higher for those homozygous for the arginine allele than for those who are heterozygous. To examine whether arginine 72 could be a risk factor for HPV associated cervical carcinomas in the Korean population, we used the PCR-RFLP method to analyze p53 polymorphism of HPV-16 positive cervical carcinomas from 109 Korean women versus 111 control samples. The proportions of individuals homozygous for the arginine allele, homozygous for the proline allele, and heterozygous for the two alleles were 31%, 17%, and 52% among the control group; and 38%, 11%, and 51% in women with HPV-16 positive cervical carcinomas. As we detected no significant difference in the frequencies of proline or arginine alleles between the two groups, p53 polymorphism at residue 72 does not seem to be involved in the development of HPV associated cervical carcinomas in women of Korean ethnicity.

Program Nr: 1768 from the 1999 ASHG Annual Meeting

Spinal magnetic resonance (MR) imaging findings in neurofibromatosis 2 (NF2) and correlations with *NF2* germline mutations. *D.M. Parry[1], C.M. Bromley[1], N. Courcoutsakis[2], G.L. Katzman[2], M. MacCollin[3], N. Patronas[2].* 1) Genetic Epidemiology Br, National Cancer Inst, Bethesda, MD; 2) Clinical Center, National Institutes of Health, Bethesda, MD; 3) Massachusetts General Hospital, Boston, MA.

Neurofibromatosis 2 (NF2) is an autosomal dominant disorder characterized by bilateral vestibular schwannomas, other central and peripheral schwannomas, meningiomas and cataracts. Spinal tumors have been seen in 75-89% of patients who have had MR imaging of the entire spine. Based on histopathology, extramedullary tumors are usually schwannomas or meningiomas, and intramedullary tumors are usually ependymomas. The *NF2* gene has been cloned from 22q and germline mutations have been identified in many NF2 patients. Comparisons of genotypes with phenotypes suggest that, in general, nonsense and frameshift mutations are associated with earlier ages at onset and diagnosis, having symptoms before age 20, and higher percentages with and higher numbers of intracranial meningiomas, spinal tumors and skin tumors. The different types of spinal tumors have not been examined in conjunction with genotype. We reviewed spinal MR images from 49 NF2 patients from 26 unrelated families. The tumors were counted and extramedullary tumors were classified as being either nerve sheath tumors (NSTs) or meningiomas. Intramedullary, extramedullary, and both types of tumors occurred, respectively, in 53%, 55% and 45% of the patients. Genotypes were known for 37 patients from 19 families: 10 families had nonsense or frameshift mutations, 7 had splice site mutations, and a missense mutation and an in-frame deletion were each present in a single family. Statistical analysis that adjusted for intra-family correlation demonstrated that a higher proportion of patients with nonsense or frameshift mutations had intramedullary tumors ($P<.025$) compared to the group of patients with all other types of mutations. In unadjusted analyses, patients with nonsense or frameshift mutations also had higher mean numbers of intramedullary tumors ($P<.006$) and NSTs ($P<.0001$). These results suggest that the association between nonsense and frameshift mutations and severe NF2 may extend to specific categories of spinal tumors.

Program Nr: 1769 from the 1999 ASHG Annual Meeting

Analysis of the *TSC1* and *TSC2* Genes in Sporadic Glial and Glioneuronal Tumours. *L. Parry[1], J. Maynard[1], S.A. Price[1], A. Patel[1], S. Whittaker-Axon[1], A. Von Diemling[2], J.P. Cheadle[1], J.R. Sampson[1]*. 1) Institute of Medical Genetics, University of Wales College of Medicine, Cardiff, Wales, UK, CF4 4XN; 2) Institute of Neuropathology, Berlin.

We studied paired constitutional and tumour DNA samples from 91 patients with sporadic glial and glioneuronal tumours for loss of heterozygosity at the TSC loci using a combination of 7 previously reported and 7 novel polymorphic markers. A relatively high frequency of LOH was seen in gangliogliomas (2/7 tumours informative for *TSC1* markers and 3/11 tumours informative for *TSC2* markers). Lower levels of LOH were seen in other types of brain tumour - 1/16 astrocytomas informative at both loci and 4/15 ependyomas, 2/14 glioblastoma multiforme, 0/7 oligodendromas, 0/7 tumours of mixed oligodendrocytic/astrocytic histology and 2/11 pilocytic astrocytomas.

An SSCP exon screen of the *TSC1* gene on the tumours displaying LOH at that loci revealed no mutations within the conserved allele. Tumours displaying *TSC2* LOH are currently being SSCP exon screened for the gene. All gangliogliomas are being SSCP screened for all exons of the TSC genes.

Previous non-targeted LOH studies on these tumours revealed no LOH in the gangliogliomas. This higher incidence of TSC LOH in these tumours which are histologically the most similar to atypical tuberous sclerosis hamartomas of the brain, make further molecular studies important to assess any role the TSC genes may play in the development of these sporadic gangliogliomas.

Program Nr: 1770 from the 1999 ASHG Annual Meeting

THREE NOVEL MUTATIONS IN THE NF2 TUMOR SUPPRESSOR GENE. *C. Paz-y-Mino[1,2], J.C. Pérez[1], R. Burgos[1], V. Dávalos[1], M. Pérez[3], E. Hermida[4], P.E. Leone[1,2].* 1) Hum Mol Genet & Cytogen Lab. , Ecuadorian Catholic University, Quito, Ecuador; 2) Medicine Faculty, Ecuadorian Catholic University; 3) E. Espejo Hospital; 4) Social Security Hospital.

Neurofibromatosis Type 2 (NF2) is a dominantly inherited disorder characterized by a predisposition to multiple tumors of the central nervous system, particularly schwannomas and meningiomas. The NF2 tumor suppressor gene has been assigned to chromosome 22. Cytogenetic and LOH studies have suggested that the gene responsible for the development of schwannomas and meningiomas is located on chromosome 22q, and it has been proposed that some sporadic schwannomas and meningiomas and NF2 associated tumors may result from functional inactivation of the NF2 gene. We analyzed 57 tumors of the central nervous system for mutations in the NF2 and single-strand conformational polymorphism (SSCP) analysis was used to identify six tumors with an altered NF2 gene in four of the ten exons of the NF2 gene studied exons (2, 4, 5, 7, 8, 9, 10, 11, 12 and 15). Samples displaying mobility shifts were subjected to DNA sequencing. We describe three novel mutations, 2 in meningiomas and 1 in schwannomas. Mutations involved exons 9 and 12, and correspond to one missense, one splice acceptor and one polymorphism. This study is supported by the Project BID-111.

Program Nr: 1771 from the 1999 ASHG Annual Meeting

***MEST* (7q32) is imprinted in human breast tissue and biallelically expressed in infiltrating carcinomas of the breast.** *I.S. Pedersen[1], P.A. Dervan[1,2], D. Broderick[1], M. Harrison[2], N. Miller[3], E. Delany[1], D. O'Shea[1], A. McGoldrick[1], G. Keating[2], B. Tobin[2], A. McCann[1]*. 1) Department of Pathology, Biotechnology Centre, Lab.1, Dublin 4, Ireland; 2) Department of Histopathology, Mater Hospital, Dublin 7, Ireland; 3) National Centre for Medical Genetics, OLHSC, Crumlin, Dublin 12, Ireland.

Genomic imprinting refers to the mechanism by which selected genes throughout the genome are monoallelically expressed according to their parental origin. The paternally expressed gene *MEST* is the first imprinted gene to be identified on chromosome 7. The *MEST* gene is located in a chromosomal region harboring genetic alterations in a high proportion of invasive breast carcinomas. Altered imprinting is known to be involved in the progression of both embryonal and sporadic tumors. The aim of this study was to investigate the imprinting status of *MEST* in a series of 53 paired normal and breast tumor samples. Heterozygosity and allelic-usage was assessed using a transcribed *Afl*III restriction fragment length polymorphism. Of the 53 patients, 12 (23%) were informative. Only 1 tumor (a ductal carcinoma *in situ*) showed loss of heterozygosity (LOH). RNA analysis established that the lost allele was the inactive copy. Since LOH often is accompanied by a duplication of the retained allele, it is possible that the outcome of LOH in this case is equivalent to the outcome of LOI - 2 active gene copies. *MEST* RT-PCR products from 8 of the 11 patients with retained heterozygosity were analyzable. Seven of the tumor samples showed biallelic expression, whereas a functional imprint, evident by monoallelic expression, was in place in the adjacent normal tissue. All biallelic cases were infiltrating carcinomas. One sample (a case of atypical ductal hyperplasia) had maintained imprinting. Epigenetic changes in the form of re-activation of a normally silent/imprinted allele is a well-established mechanism for overexpression of growth-promoting genes in cancer. This is, however, the first study to show altered imprinting of *MEST* in cancer.

Program Nr: 1772 from the 1999 ASHG Annual Meeting

Mapping the Papillary Renal Cell Carcinoma Gene Between Loci D17S787 and D17S1799 on Chromosome 17q21.32. *T. Pesti[1], I. Balint[1], J. Fischer[1], B. Ljungberg[2], G. Kovacs[1].* 1) Dept. of Urology, Ruprecht-Karls-University, Heidelberg, Germany; 2) Dept. of Urology, University of Umea, Sweden.

Chromosome 17q is frequently duplicated in hereditary (HPRCT) and sporadic papillary renal cell tumors (RCT) and considered to be the initial genetic change. To determine the gene region we have first analysed 37 papillary RCTs by applying 25 polymorphic microsatellite markers and found an overlapping duplication including loci D17S1795 and D17S1306 on chromosome 17q21. This region was than analysed in additional 118 sporadic and hereditary papillary RCTs. Overlapping duplications at the chromosome 17q21.32 region localized the papillary RCT gene to an approximately 300 kb genomic sequences flanked by loci D17S787 and D17S1799. We found allelic duplication at this region in 100 of 112 sporadic and 42 of 43 hereditary cancers including small lesions of 2 mm in diameter. Altogether, 92% of the 155 papillary RCT showed allelic duplication at this region. We have included multiple papillary RCTs from three different individuals having no familial records or germ line mutation of the MET and from three families with HPRCT, two of them showing a germ line mutation of the MET. Duplication of both parental alleles in multiple tumors indicates that allelic changes at this region are somatic events. The hepatic leukemic factor (HLF) is localized within this region. In acute pro-B-leukemia showing the t(17;19) the E2A-HLF fusion gene inhibit the apoptosis suggesting that the chimeric protein contributes to leukemic transformation. We have analyzed the expression of HLF in distinct types of RCT by RT-PCR and did not find any changes that seems to be specific for papillary RCT. Therefore, alteration of another gene from the 300 kb region is responsible for development of hereditary and sporadic RCTs.

Program Nr: 1773 from the 1999 ASHG Annual Meeting

***APC* mutation in woman with multiple desmoids: A new syndrome or FAP variation?** *J.A. Peters[1,2], M.T. Lotze[2], L. Sproul[3], V. Pratt[4], W.S. Rubinstein[1,2]*. 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA; 2) University of Pittsburgh Cancer Institute; 3) Carlow College, Pittsburgh, PA; 4) Labcorp, Research Triangle Park, NC.

Desmoid tumors are proliferative, locally invasive, non-metastasizing fibromatous tumors resistant to treatment. Desmoids may occur sporadically, or as part of Familial Adenomatous Polyposis in about 10% of FAP families. We evaluated a 31 year old woman with multiple desmoid tumors who underwent initial resection at age 18 years. She had multiple additional tumors removed from her right back and neck, abdomen, and left flank. Surgery and chemotherapy failed to arrest tumor progression. Additional medical problems included seizures since infancy, becoming grand mal at puberty; protruding mandible and one supernumerary tooth; psoriasis; and probable mental delay, anxiety, depression, poor impulse control, immaturity, inability to live independently, and unusual personality and speech pattern. The patient has no history of colon polyps or tumors as evaluated by colonscopy. The family history is negative for desmoids, polyps, and colon tumors, but positive for possible mental illness in the paternal history. She has a son with developmental delay and a variety of behavioral problems, currently diagnosed as Tourette syndrome. Cytogenetic studies revealed that both mother and son have normal karyotypes. On molecular testing, our patient had a truncating APC mutation near codon 1694. APC studies on her son are pending. A frameshift APC mutation at codon 1924 has been reported in another family with multiple desmoids but minimal polyposis (Eccles et al., 1996, AJHG 59:1193-1201).

Our case raises a number of questions: How broad is FAP expressivity? Does this patient have an FAP variant such as Gardner syndrome in the absence of all colon symptoms and signs? Can the neuropsychiatric findings be accounted for on the basis of the APC mutation? What proportion of desmoid patients have a germline APC alteration? Does an APC mutation in this family predispose only to desmoids or also to polyposis? Do modifier genes play a role in phenotypic expression of APC alterations?

Program Nr: 1774 from the 1999 ASHG Annual Meeting

Familial aggregation of cancer at multiple sites in families of Ashkenazic Jewish non-carriers of the *BRCA1* mutation 185delAG. *L.E. Peterson[1], L.C. Friedman[2], S.E. Plon[3].* 1) Dept Medicine; 2) Dept Psychiatry & Behav. Sci; 3) Dept Pediatrics, Dept Mol. & Hum. Genet., Baylor College of Medicine, Houston, TX.

The goal of this investigation was to study familial aggregation of cancer at multiple sites in families of 244 (27 males, 217 females) Ashkenazi Jewish (AJ) counselands who tested negative for the *BRCA1* 185delAG mutation in a community-based study. The presence of familial aggregation of cancer at multiple sites among non-carrier AJ families may provide insight into genes that predispose to a variety of cancers. Reported histories of cancer identified 43 unconfirmed cases among female counselands (29 breast, 2-ovarian, 2-colon, 2-skin, 8-other), 72 male and 130 female unconfirmed cases among 1,322 first-degree relatives (624 males, 698 females), and 133 male and 191 female unconfirmed cases among 2,135 (1,085 males, 1,050 females) second-degree relatives (3,457 total). Poisson regression was used to test the hypothesis of equal cancer risk in first-and second-degree relatives, assuming independence of risk between relatives. For males, the relative risk (*RR*) of cancer among first-degree relatives (compared with second-degree relatives) was 2.87(95% CI, 2.13-3.86) for all cancers, 1.63(0.43-6.24) for stomach, 2.51(1.28-4.93) for colorectal, 2.90(0.95-8.90) for pancreatic, 2.92(1.28-6.67) for lung, 6.86(1.61-29.22) for skin, 5.00(2.63-9.51) for prostate, 2.81(0.18-44.88) for testicular, 5.54(1.32-23.26) for bladder, 2.90(0.92-9.12) for kidney, 2.13(0.21-21.86) for brain, 1.44(0.26-7.88) for Hodgkin's disease, and 1.47(0.29-7.50) for leukemia. Among females, *RR* was 3.61(2.89-4.50) for all cancers, 0.35(0.05-2.72) for stomach, 2.10(0.96-4.60) for colorectal, 1.82(0.36-9.29) for liver, 0.50(0.06-4.22) for pancreatic, 3.14(1.16-8.49) for lung, 21.65(2.62-178.56) for skin, 3.92(2.86-5.37) for breast, 2.05(0.40-10.43) for uterine, 8.84(3.46-22.59) for ovarian, 5.88(0.93-37.39) for bladder, 1.87(0.16-22.10) for kidney, 2.73(0.68-10.92) for Hodgkin's disease, and 2.10(0.35-12.67) for leukemia. Aside from possible sources of bias, cancer at sites for which *RR*>1 may be causally related to susceptibility genes expressed at multiple sites. (Supported by KO7-CA78199-01).

Program Nr: 1775 from the 1999 ASHG Annual Meeting

Genetic Counseling and Testing for Hereditary Breast/Ovarian Cancer: The Impact of Receiving Positive and Uninformative Results. *S.K. Peterson[1], E.R. Gritz[1], S.W. Vernon[2], S.K. Marani[1], P.T. Rieger[1], P.A. Ward[1], G.B. Mills[1]*. 1) UT MD Anderson Cancer Center, Houston, TX; 2) UT School of Public Health, Houston, TX.

We report data from an ongoing study regarding psychosocial aspects of genetic counseling and testing for hereditary breast and ovarian cancer (HBOC) in a clinical setting. Fifty two high-risk women (23 of whom had a prior breast or ovarian cancer diagnosis) underwent genetic counseling and testing for HBOC, and completed psychosocial measures before pre-test genetic counseling (baseline) and within 2 weeks of receiving their genetic test results. We compared differences in scores on these measures, from baseline to 2-week follow-up, among women who received positive (BRCA1/2 mutation was found) or uninformative (no mutation was found) results. After results disclosure, those with uninformative results reported a significantly lower perceived risk of HBOC compared with baseline. There were no significant changes at 2-week follow-up in global or cancer-specific distress scores among those with either positive or uninformative results. Women who received positive test results reported an increased commitment to screening, and those who received uninformative results maintained a similar commitment to screening compared with baseline. Following genetic counseling for results disclosure, participants correctly answered a significantly greater number of HBOC knowledge items (93%) compared with baseline (71%). Our findings indicate that disclosure of either positive or uninformative genetic test results does not increase psychological distress. Genetic counseling improved participants' knowledge of HBOC and may facilitate understanding of the importance of screening adherence. Although women who received uninformative results may inappropriately perceive their HBOC risk to be lowered, intention to continue screening did not decline. Our data show that additional counseling and education may be required to facilitate an accurate understanding of the meaning of uninformative test results, and that follow up also may be needed to determine whether perceptions of personal HBOC risk are modified over time.

Program Nr: 1776 from the 1999 ASHG Annual Meeting

The cell line W12 as a model for investigation of genomic events associated with the progression of cervical squamous cell carcinoma. *M.R. Pett[1], I.R. Roberts[1], M.A. Stanley[1], N. Coleman[1,2].* 1) Department of Pathology, University of Cambridge, Cambridge, United Kingdom; 2) Department of Histopathology, Addenbrooke's Hospital, Cambridge, United Kingdom.

Although the association of human papillomavirus (HPV) infection with cervical squamous cell carcinoma (SCC) is well recognised, the nature of any additional genomic abnormalities that occur during neoplastic progression remains uncertain. The cell line W12 has been generated from a low-grade squamous intra-epithelial lesion of the cervix (CIN1) and contains the HPV-16 genome in episomal form. At early passage W12 recapitulates a CIN1 phenotype when grafted onto nude mice but following long-term passage there is viral integration and development of a high-grade (CIN3) phenotype. W12 therefore represents a suitable cell line for the study of genomic events associated with progression of cervical SCC. We have used spectral karyotyping and comparative genomic hybridisation to identify genomic events that occur during long term passage of W12. Loss of 10p and gain of 10q and 20p are early events that are stably maintained. Loss of 3p, gain of 3q and amplification of 5p are later events that occur following long term passage and which correlate well with observations made using clinical material. We are currently investigating whether the development of thaese genomic changes correlates with specific alterations in the phenotype of W12.

Program Nr: 1777 from the 1999 ASHG Annual Meeting

10q LOH analysis and PTEN mutations in melanoma cell lines and tumours. *P.M. Pollock, G.J. Walker, N.C. Bloch, T. Que Noy, N.K. Hayward.* Cancer Unit, QIMR, Brisbane, Queensland, Australia.

Cytogenetic and loss of heterozygosity (LOH) studies have indicated that one or more tumour suppressor genes (TSGs) mapping to chromosome 10q may be involved in the development of sporadic melanoma. A recently identified TSG, PTEN, which maps to chromosome band 10q23 has been shown to be mutated/deleted in a wide range of tumours and cell lines including melanoma. To further characterise the role of PTEN in melanoma we screened 57 melanoma cell lines for homozygous deletions and mutations by a combination of genomic PCR, RT-PCR and sequencing. We also performed microsatellite analyses to detect regions of 10q hemizygosity in these cell lines. Five melanoma cell lines were found to carry exon specific homozygous deletions. One cell line demonstrated a larger fragment by RT-PCR, corresponding to a 52bp insertion between exons 2 and 3 causing premature truncation of PTEN. Direct sequencing revealed 8 missense mutations in seven cell lines. When the results of this study are combined with previous findings,overall, homozygous deletions and mutations in the PTEN gene have been detected in 27/144 (19%) and 18/144 (13%) melanoma cell lines respectively. To further assess the involvement of PTEN in melanoma tumours, detailed LOH analysis was performed using 14 microsatellite markers mapping to chromosome 10, and a panel of 33 melanoma tumours. 8/33 tumours demonstrated loss at all informative markers, while another 4 tumours had partial loss restricted to 10q. Exons 1-9 of PTEN were sequenced in all tumours demonstrating loss surrounding this locus. An 11bp deletion within exon 7 was detected in one tumour. In summary, while approximately half of the melanoma cell lines were hemizygous for 10q, only 23% were found to carry a mutation or deletion in the remaining PTEN allele and only 1/10 tumours showing LOH carried a mutation. This low frequency of mutations in both cell lines and tumours demonstrating hemizygous loss, combined with the presence of a minimal region of loss telomeric to PTEN in melanoma cell lines, supports the notion that an additional locus telomeric to PTEN is involved in melanoma progression.*PTEN*.

Program Nr: 1778 from the 1999 ASHG Annual Meeting

Comprehensive molecular analyses of the APC gene of FAP patients; Novel mutations and relation to phenotype.

R.J. Pomponio[1], A. Whetsell[1], C. Reeves[1], A. Schmitt[1], P. Conrad[2], B. Crawford[2], S. Syngal[3], J.P. Terdiman[2,4], G.A. Miller[1]. 1) Molecular Profiling Laboratory, Genzyme, Framingham, MA; 2) UCSF Stanford Health Care/Mount Zion Medical Center, San Francisco, CA; 3) Dana Farber Cancer Institute, Boston, MA; 4) University of California San Francisco, San Francisco, CA.

Colorectal cancer is one of the most common causes of cancer-related deaths worldwide. A small percentage of all colorectal cancers are due to Familial Adenomatous Polyposis Coli (FAP) which is an autosomal dominantly inherited syndrome. Mutations in and/or loss of expression of the APC gene on chromosome 5q21 predispose at-risk individuals by initiating polyp formation and progression to carcinogenesis. Genotype/phenotype correlations with FAP have been reported for extracolonic disease, most notably CHRPE and desmoid growth. As the vast majority of APC mutations reported to date are either nonsense or frameshift mutations which result in a truncated protein product, the Protein Truncation Test (PTT) is often employed in screening programs for FAP patients and at-risk family members.

A comprehensive study of the APC gene of FAP patients, was undertaken using PTT as the initial screening tool and Restriction Endonuclease Fingerprinting or Single Strand Conformation Analysis as secondary methods, followed by automated sequencing. Sixteen of the 25 mutations identified so far from individuals have been novel. Of these, a deletion mutation (5819-5823delTACCA, frame shift A1946X) is particularly interesting in that it was identified in a family with Hereditary Desmoid Disease and is outside of the region (codons1403-1924) of the APC gene commonly associated with extracolonic desmoid growth.

Our data suggest that complete mutation characterization including sequence verification within FAP patients offers more information for genetic counseling, in some cases offers some prediction of clinical outcome, and often encourages presymptomatic testing of at-risk family members.

Program Nr: 1779 from the 1999 ASHG Annual Meeting

Cloning and characterization of genes from Wilms' tumor candidate regions. *D. Prawitt[1], C. Spangenberg[1], G. Klemm[1], J. Truebenbach[1], B. Gaertner[1], T. Enklaar[1], M. Higgins[3], J. Pelletier[2], A. Winterpacht[1], B.U. Zabel[1].* 1) Molec Genetics Lab, Children's Hosp/ Univ Mainz, Mainz, Germany; 2) McGill Cancer Center, McGill University of Montreal, Canada; 3) Roswell Park Cancer Center, Buffalo, NY, USA.

Wilms'tumor (WT) or nephroblastoma is the predominant solid childhood tumor with an incidence of 1:10000. The genetic heterogeneity of this renal neoplasia is well established but up to now no more than one responsible gene (WT1 of chromosomal region 11p13) could be identified. Only 10-15% of WTs display functional WT1 mutations and the search for additional genes involved in tumorigenesis is still in progress. Several genomic candidate regions were identified by the detection of WT specific chromosomal abnormalities, such as loss of parts of chromosome 11p, 16q, 17q or gain of chromosome 1, 6, 7p and 12q (Mitelman et al., 1997, Cancer Res) as well as WT specific translocation breakpoints (Mitelman et al., Nature Genet 1998).

To detect and characterize genes with potential involvement in WT development and progression we used a positional cloning strategy and differential display analysis comparing adult and fetal kidney as well as WT tissues.

The genomic approach was based on tumor cell lines with specific translocations: RH16 [with t(11;22)(p15.5;q11.23)] and WT128 [with t(7;12)(p22;q22)]. We isolated breakpoint-spanning genomic clones which are tested for disrupted genes to identify candidate genes. Differential display experiments led to ESTs serving as starting points for further analysis. We used a chromosomal hybrid panel and FISH analysis in order to concentrate on clones mapping to regions associated with WT. Up to now we were able to identify three ESTs mapping to chromosome 1, one of them being a clone for the TM7SF1 gene. TM7SF1 codes for a putative seven pass transmembrane receptor, downregulated in the majority of tumors. The two other clones (10C2 and 6A2) were either highly expressed in normal kidney (10C2) or upregulated in WT (6A2). We are currently obtaining full length cDNA clones for the candidate ESTs.

Program Nr: 1780 from the 1999 ASHG Annual Meeting

Human *PTTG*: a new proto-oncogene family. *T.R. Prezant[1,2], P. Merkel[1], P. Kadioglu[1], A.P. Heaney[1], G. Horwitz[1], S. Melmed[1,2]*. 1) Dept Med, Div Endocrinology, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) UCLA School of Medicine, Los Angeles, CA.

We recently isolated human *PTTG* (Pituitary Tumor Transforming Gene). Overexpression of the 609 bp coding sequence transforms cells *in vitro*, causes tumors in athymic mice and induces the transcription of basic FGF, an angiogenic protein. These three functions depend on an intact P-X-X-P motif that can potentially bind to SH3 domains. Human *PTTG* expression is increased in pituitary tumors and in many types of cancer cell lines, and is highly expressed in normal testis. While localizing human *PTTG* to chr. 5q33 by radiation hybrid (RH) mapping, we discovered a second intronless *PTTG* gene on chr. 4p12. This location was confirmed by PCR and Southern blot analysis of DNA from a human/hamster hybrid cell line containing human chromosome 4. The existence of *PTTG2* suggested that the two genes might have differential expression in normal development and tumorigenesis. We tested this by PCR-ELISA and dideoxy fingerprint analyses of *PTTG* cDNAs from normal tissues, pituitary tumors, and cancer cell lines. *PTTG1* (the intron-containing gene) is the major species in normal cells, primary tumors and cancer cell lines. However, *PTTG2* is expressed in several normal tissues and has increased transcription in some pituitary tumors. Through sequence analysis of genomic DNA for the *PTTG2* studies, we found 37 homozygous sequence changes in a control. Primers specific to this new sequence were used to repeat RH mapping analysis, with the discovery of a third member of the *PTTG* family, which maps to chromosome 8 and, like *PTTG2*, is intronless in the coding region. While testing "common primers" designed for quantitative expression studies, we amplified three additional *PTTG*-related sequences from genomic DNA. *PTTG4L* is intronless, while the other two products are larger. Primer extension analysis has shown that *PTTG2* and *PTTG3* are expressed in normal colon, but that the large increase in *PTTG* expression in adjacent colon tumors is due to *PTTG1*. Thus, this family of proto-oncogenes appears to differentially participate in tumor-specific pathogenesis.

Program Nr: 1781 from the 1999 ASHG Annual Meeting

OVCA1, a novel tumor suppressor, is aberrantly expressed in ovarian carcinomas. *A.H. Prowse, W. Bruening, A.K Godwin.* Fox Chase Cancer Center, Philadelphia, PA.

We have identified a gene, *OVCA1*, within a region of minimal allelic loss in ovarian tumors at 17p13.3. *OVCA1*codes for a highly conserved protein with no known function. Previous northern and western blot studies have revealed that *OVCA1*mRNA and protein levels were down-regulated in ovarian tumors as compared to normal human ovarian surface epithelial cells. In addition, overexpressing OVCA1 in the ovarian cancer cell A2780 resulted in dramatically reduced rates of proliferation which correlated with an increased proportion of the cells in the G1 fraction of the cell cycle and decreased levels of cyclin D. Localization studies indicate that OVCA1 shuttles between the cytoplasm and nucleus in a cell cycle dependent manner. We have now performed immunohistochemistry on normal ovaries and benign and malignant ovarian tumors using antibodies derived to the N and C-termini of OVCA1. In normal ovaries and ovarian tumors of low malignant potential, strong nuclear and cytoplasmic staining in the epithelial cells was observed using both antibodies. In contrast, 90% (9/10) ovarian adenocarcinomas showed little or no cytoplasmic staining using the N-terminal antibody. However, varying intensities of nuclear staining (high/medium in 5/9 tumors and light staining in 4/9 tumors) was observed. Interestingly, no nuclear or cytoplasmic staining was observed with the C-terminal OVCA1 antibody in these sections. Furthermore, there was no apparent correlation with cellular proliferation (as determined by ki-67 expression) and OVCA1 expression in these carcinomas. Our results suggests that in ovarian adenocarcinomas, OVCA1 undergoes an aberrant post-translational modification (reflected by a loss in immunoreactivity of the C-terminal antibody) which results in the mislocalization of OVCA1 to the nucleas and exclusion from the cytoplasm.Studies are underway to determine the molecular mechanisms regulating OVCA1 expression and localization in both normal and tumor tissue. These data suggest that *OVCA1*may represent a novel class of tumor suppressor genes and altered expression and/or post-translational modification of OVCA1 contributes to the development of ovarian tumors.

Program Nr: 1782 from the 1999 ASHG Annual Meeting

Polymorphic Variation at the BAT-25 and BAT-26 Loci in Individuals of African Origin: Implications for Microsatellite Instability Testing. *R.E. Pyatt[1], R.B. Chadwick[2], C.K. Johnson[2], C. Adebamowo[3], A. de la Chapelle[2], T.W. Prior[1]*. 1) Pathology, Ohio State University, Columbus, OH; 2) Division of Human Cancer Genetics, Ohio State University, Columbus, OH; 3) Dept. of Surgery, University College Hospital , Ibadan, Nigeria.

Instability in the repeat size of microsatellite sequences has been described in both hereditary nonpolyposis and sporadic coloretcal cancers. Tumors expressing microsatellite instability are identified through the comparison of the repeat sizes at multiple microsatellite loci between tumor and matched normal tissue DNA. The use of a five marker panel including two mononucleotide repeat microsatellites, BAT-25 and BAT-26, has recently been suggested for the clinical determination of tumor microsatellite instability. The BAT-25 and BAT-26 loci included in this panel have both demonstrated sensitivity to microsatellite instability and normal quasi-monomorphic allelic patterns which has simplified the distinction between normal and unstable alleles. However in this study, we identified allelic variations in the size of the poly (A) tract at BAT-26 in 12.6% of 103 healthy African-Americans screened. In addition, 18.4% exhibited allelic size variations in the poly (T) tract at BAT-25. Finally, 2.9% showed variant alleles at both BAT-25 and BAT-26 loci. Screening a population of Nigerians confirmed the polymorphic nature of both loci and the ethnic origin of alleles not identified in other populations studied thus far. Our results dispute the quasi-monomorphic nature of both BAT-25 and BAT-26 in all populations and support the need for thorough population studies in order to define the different allelic profiles and frequencies at microsatellite loci. Additionally, we recommend that matched normal tissue DNA be required for the comparison of test results for all samples showing microsatellite sequences suggestive of microsatellite instability.

Program Nr: 1783 from the 1999 ASHG Annual Meeting

Exploring The Dysregulation of *HMGIC* In Uterine Leiomyomata with t(12;14). *B.J. Quade[1], M. Getman[2], T.-Y. Wang[1], S. Weremowicz[1], P. Dal Cin[1], C.C. Morton[1,2].* 1) Depts. of Pathology and; 2) OB/GYN, Brigham & Women's Hospital and Harvard Medical School, Boston, MA.

Uterine leiomyomata (UL) are one of several benign mesenchymal tumors characterized by frequent chromosomal rearrangements involving the DNA architectural factor *HMGIC* in 12q15. In UL, 12q15 is translocated with 14q23-24. It has recently been suggested that t(12;14) produces fusion gene products containing *HMGIC* and *RAD51B*, a recombination repair gene family member. We previously mapped the chromosome 12 breakpoints centromeric (5') to *HMGIC* in 83% of tumors and have shown that t(12;14) dysregulates *HMGIC*, resulting in expression of its full coding sequence. To explore the possibility that t(12;14) involves *RAD51B*, we designed a series of primer pairs to hypothetical fusion products containing *HMGIC* and *RAD51B* in both orientations, and analyzed a series of nine t(12;14) UL by RT-PCR. In almost all cases, RT-PCR with *RAD51B*-specific primer pairs produced the expected product, consistent with either the normal *RAD51B* transcript or a *RAD51B-HMGIC* fusion transcript 5' to the fusion. No transcripts containing the 5' portion of *RAD51B* fused to the 3' of *HMGIC* were detected. In only one case was a fusion product containing *HMGIC* exons 1-3 and *RAD51B* exons 8-11 detected. This tumor was unique because it was one of a minority (17%) with rearrangement in the 3' region of *HMGIC* by FISH analysis. mRNA from this tumor was also analyzed by 3' RACE using a *HMGIC*-specific 5' primer. A novel *HMGIC* fusion transcript was detected in which an ectopic 244 bp were fused to the 3' UTR of *HMGIC* at nt 1912. The 244 bp sequence was mapped to chromosome 14 using radiation hybrids. To understand better the two different fusion transcripts found in this tumor, we isolated the breakpoints from the der(12) and der(14) chromosomes and found that they corresponded to the junction in the fusion transcript with the 244 bp sequence. The predominance of breakpoints 5' to *HMGIC* in UL suggests that the primary mechanism may be "promoter swapping." In our series of UL, only rare breakpoints involving the 3' region of *HMGIC* may produce fusions with either anonymous sequences at the breakpoint or *RAD51B* and *HMGIC*.

Program Nr: 1784 from the 1999 ASHG Annual Meeting

HER-2/neu Amplification in Simple & Complex Endometrial Hyperplasias.. *M.R. Quddus, A.J. Tsai, C.J. Sung, M.M. Steinhoff, U. Tantravahi.* Departments of Pathology & Molecular Cytogenetics, Women & Infants' Hospital, Providence, RI.

Her-2/neu amplification has been shown to be predictive of poor prognosis in various gynecologic cancers including breast & endometrial cancers. Hyperplasia of the endometrium can progress from simple to complex histologic forms and eventually, to frank carcinoma. The identification of genetic changes in these precancerous states may help elucidate the pathogenesis of the disease. The current study evaluated Her-2/neu amplification as a possible early event in the loss of control of cell proliferation in endometrial hyperplasia.

Fifty-six archival paraffin embedded endometrial hyperplasia tissues, 20 simple (SH), 21 complex (CH) & 14 complex hyperpalsia with atypia (CHA), were obtained from the Department of Pathology, Women & Infants' Hospital. Fluorescent *In-situ* Hybridization (FISH) was performed on 4m tissue sections. A DNA probe (Oncor) assessing gene amplification rather than gene product was used. Hybridization signals were detected using Digoxigenin Rhodamine Detection Kit. A total of 50 cells were scored in a blinded fashion using a fluorescent microscope with triple band filter. Cells with >4 signals were considered to have Her-2/neu gene amplification. Small amplification was defined with >4 distinct signals & large with >>4 signals that could not be counted individually. Adjacent normal tissue area signals were counted as an internal control.

The results indicated that 85% SH, 87.7% CH & 92.9% CHA cases showed Her-2/neu amplification. Thirty percent SH, 47.6% CH & 57% CHA showed large amplification.

Our study revealed Her-2/neu amplification may be an important factor in endometrial cancer progression. The amplification may be one of the early events in transformation of normal to hyperplastic state.

Program Nr: 1785 from the 1999 ASHG Annual Meeting

Absence of evidence for a familial breast cancer susceptibility gene at chromosome 8p12-p22. *N. Rahman, D. Teare, J. Chang-Claude, D. Easton, D. Eccles, D. Goldgar, J. Mangion, H. Meijers, S. Seal, Y. Shugart, M. Stratton, D. Thompson, B. Weber.* The BRCA3 linkage consortium, Section of cancer genetics, Institute cancer research, Sutton, Surrey, England.

Several recent studies indicate that the majority of families with five or fewer cases of breast cancer and no case of ovarian cancer are not due to BRCA1 or BRCA2. It has been proposed that a further breast cancer susceptibility gene that may account for some of these families is located on chromosome 8p12-p22. We have identified 38 site-specific breast cancer families that have greater than 80% posterior probability of being due to genes other than BRCA1 and BRCA2. These families have been examined for linkage to 8p12-p22 using markers flanking the putative location of the gene. The overall multipoint LOD score is strongly negative across the whole 44cM. At marker D8S136 the LOD score is -9.43. The individual multipoint score is negative in 25 of the 38 families and only exceeds 0.5 in a single family, (with a multipoint lod of 1.22). The maximum heterogeneity lod score was 0.03 at marker D8S136 with estimated proportion linked (a) of 3% (95% confidence interval 0%-28%). These data do not lend support to the hypothesis that chromosome 8p12-p22 harbors a familial breast cancer susceptibility gene.

Program Nr: 1786 from the 1999 ASHG Annual Meeting

A FISH study of the variant Philadelphia rearrangements. *K.S. Reddy, V. Sulcova.* Dept Cytogenetics, Quest Diagnostics, Inc, San Juan Capist, CA.

A total of 39 variant Philadelphia (Ph) translocations were studied by fluorescence in situ hybridization (FISH) using MBCR/ABL, mBCR/ABL or DBCR/ABL probes. Seven cases did not have a BCR/ABL fusion signal. Out of a total of 32 fusion positive cases, 5 were simple variants involving chromosome 22 and another chromosome; 23 were complex variants involving chromosomes 22, 9 and a third chromosome (18 cases) or 22, 9, and two other chromosomes (4 cases). Masked Philadelphia rearrangements were detected in 4 cases. One case was a Philadelphia chromosome mimic. FISH has become a widely used method for studying Philadelphia rearrangements. The expected pattern for DBCR/ABL probe is one green ABL signal [1G] on the normal 9, one red BCR signal [1R] on the normal 22, and two fusion signals BCR/ABL and ABL/BCR [2F] on a derivative 22 and a derivative 9, respectively. Deviant patterns from 1G1R2F and sometimes 1G1R2F are indicative of a variant, as long as there is a fusion signal. However, in interphase analysis it is not possible to visualize a variant rearrangement and when a deviant pattern involving at least one fusion signal is observed the following possibilities should be contemplated. The different patterns observed in fifteen Ph variants studied with DBCR/ABL probe were 2G2R1F (40%), 1G1R2F (20%), 1G1R1F (20%), 1G2R1F (13.3%) and 2G1R1F (6.66%). A 2G2R1F, FISH pattern observed in 6 cases appears to involve a single concerted event of simultaneous breaks on the participating chromosomes followed by mismatched joining. Three cases with 1G1R2F most probably arose by two independent sequential events. The pattern of 1G1R1F suggests either the BCR and ABL breakpoints are different or there are deletions at the breakpoints since residual signals are not observed. Two independent events appear to be involved in 1G2R1F with a reverse cryptic 9,22 rearrangement as the first event. In one case 2G1R1F was observed and the plausible explanation for this pattern in our case is an insertion of ABL next to BCR and either a simultaneous or a sequential translocation with another chromosome.

Program Nr: 1787 from the 1999 ASHG Annual Meeting

Analysis of the human mismatch repair genes, hMSH2 & hMLH1 in an early onset colon cancer population. *C. Reeves[1], M. Hepburn[1], A. Schmitt[1], J.P. Terdiman[2], G.A. Miller[1]*. 1) Molecular Profiling Laboratory, Genzyme, Framingham, MA; 2) University of California San Francisco, San Francisco, CA.

Hereditary Non-Polyposis Colon Cancer(HNPCC) is characterized by the early onset of colorectal cancer(CRC), proximal colonic tumors, an increased frequency of multiple primaries and an autosomal dominant genetic transmission. The frequency of the disease ranges between 3 and 6% of all colorectal malignancies. HNPCC is thought to be related to abnormalities in any one of at least five genes that normally assist in repairing DNA damage. Of the mismatch repair(MMR) genes, mutations in hMSH2 and hMLH1 account for the majority of the reported cases.

Using Denaturing Gradient Gel Electrophoresis and Automated Fluorescence Sequencing our laboratory has developed a high through-put, cost effective means to screen for mutations within the MMR genes, hMSH2 and hMLH1. Individuals were selected for testing on the basis of family history, microsatellite instability status and the total number of known risk factors for HNPCC. These risk factors include: greater than 2 CRC in a family; earliest age of diagnosis being less than 40; endometrial cancer in the family and other HNPCC related cancers in the family. To date we have studied 33 families and found 17 unique mutations. 13 of 17 mutations resulted in either a stop codon or the alteration of a splice site. The remaining mutations were amino acid changes of unknown significance. These results agree with previous studies indicating the presence of mutations in the MMR genes in approximately 50% of the HNPCC cases.

Our results demonstrate that the careful selection of individuals for testing and the use of highly sensitive and accurate methods of detection can provide valuable information to individuals at risk for HNPCC.

.

Program Nr: 1788 from the 1999 ASHG Annual Meeting

Analysis of E-cadherin (*CDH1*) and transforming growth factor-b **type II receptor (*TGFBR2*) genes in genetic predisposition to early onset colorectal carcinoma.** *F.M. Richards[1], L. Verma[1], T.R. Porter[1], D.G.R. Evans[3], E.R. Maher[1,2]*. 1) Medical & Molecular Genetics Section, Division of Reproductive & Child Health,University of Birmingham, The Medical School, Edgbaston, Birmingham, B15 2TT, UK; 2) West Midlands Regional Clinical Genetics Service, Birmingham Women's Hospital, Edgbaston, Birmingham, B15 2TG, UK; 3) Department of Medical Genetics, St Mary's Hospital, Manchester, M13 0JH, UK.

Colorectal cancer susceptibility is genetically heterogeneous. In patients with HNPCC most Amsterdam positive cases have germline mismatch repair (MMR) gene mutations, usually in *MSH2* or *MLH1*. In addition, germline *MSH2* and *MLH1* mutations account for a small proportion of patients with non-familial early onset colorectal cancer (EOCC). However the absence of germline MMR mutations in some HNPCC families and most EOCC and non-Amsterdam criteria familial colorectal cancer kindreds is consistent with additional susceptibility genes. Recently we have suggested that germline E-cadherin (*CDH1*) gene mutations predispose to both early onset colorectal cancer and familial gastric cancer (Hum. Mol. Genet. 8: 607-610; 1999). In addition, germline transforming growth factor-b type II receptor (*TGFBR2*) gene mutations have been reported in atypical HNPCC kindreds. To investigate the role of germline *CDH1* and *TGFBR2* mutations in colorectal cancer susceptibility we analysed these two genes in (a) 23 cases of microsatellite stable (MSS) EOCC (<50 years) and (b) 21 HNPCC families without detectable *MSH2* or *MLH1* mutations. No germline *CDH1* mutations were identified in either group. Similarly no *TGFBR2* mutations were detected. These results suggest that germline *CDH1* and *TGFBR2* mutations are not a major cause of HNPCC or early onset MSS colorectal cancer.

Program Nr: 1789 from the 1999 ASHG Annual Meeting

Exon Deletions and Duplications in BRCA1 Detected by semi-quantitative Polymerase Chain Reaction. *M.D. Robinson[1], C.E. Chu[2], G. Turner[2], D.T. Bishop[3], G.R. Taylor[1]*. 1) Yorkshire DNA Laboratory, St James's Hosp, Leeds, England; 2) Clinical Genetics Service, St James's Hosp, Leeds; 3) ICRF Genetic Epidemiology Laboratory, St James's Hosp, Leeds.

The majority of mutations identified in the BRCA1 gene lead to the production of a truncated product . Most studies have performed mutation analysis on genomic DNA using PCR based techniques such as heteroduplex analysis and the protein truncation test (PTT). Several recent reports have described partial deletions and in one case a partial duplication of the BRCA1 gene. These rearrangements would have been missed by conventional PCR based methods and were detected either by reverse transcriptase PCR (RT-PCR) or Southern blotting. RT-PCR analysis has been shown to give variable amplification of mutant alleles, which could lead to rearrangements being missed if testing is by this method alone. A recent study concluded that Southern blot analysis was not sensitive enough to detect partial gene duplications unless they produced an abnormal restriction fragment pattern. We have developed a semi-quantitative polymerase chain based fluorescent assay for the detection of previously identified deletions. This assay was used to screen 44 cases from high-risk families within the Yorkshire Health Region. No deletions were detected but five cases (11%) with an apparent duplication of exon 13 in BRCA1 were identified.

Program Nr: 1790 from the 1999 ASHG Annual Meeting

Molecular genetics of recurrent pituitary neoplasia. *J. Rock[1], S. Mehra[2], K. Ho[2], W. Chandler[3], P. Mckeever[3], K. Pindolia[2], M.J. Worsham[2].* 1) Neurosurgery, Henry Ford Health Systems, Detroit, MI; 2) Cancer Genetics Research, Pathology, Henry Ford health Systems, Detroit, MI; 3) University of Michigan, Ann Arbor, MI.

Pituitary tumors are, in general, benign, slow growing neoplasms. Regrowth after treatment is not uncommon and predicting the biologic potential of a given tumor based on histologic appearance is unreliable. While the frequency of malignant transformation is very low in individual neoplasms, the lesions tend to recur locally. To better understand the underlying biological behavior of tumor progression/recurrence we studied a patient with a primary adenoma and three subsequent recurrences. In addition to cytogenetics, to explore at a subcellular level the molecular characteristics of the primary and the recurrent tumors, we evaluated the Her2/neu oncogene for gene amplification, status of p53 expression, and the 11q13 region for loss of heterozygosity (LOH) with markers in the vicinity of the MEN1 gene. Though many studies have demonstrated a prognostic role for Her2/neu gene amplification in breast, ovarian and colon cancers, its role in pituitary tumorigenesis is largely unknown. The patient was diagnosed with Cushing's Disease at age 33 and radiated. Subsequent progression led to three surgical resections over 12 years. Cytogenetic studies revealed an abnormal hypodiploid karyotype with several chromosomal rearrangements and losses, including both copies of chromosome 11. Fluorescent in situ hybridization with probes to the centromere of chromosome 17 and Her2/neu suggested a trend toward slightly increased copy number for the Her2/neu gene with an average ratio of 1.4 in the primary and recurrent adenomas as compared to the normal ration of 0.92. LOH results of four markers in the 11q13-11q23.2 region suggested instability of this region. Two of the four markers in the second and third recurrences indicated an allele pattern that was different from the normal pituitary cells and that of the primary adenoma. The latter suggests that instability of this region is important in the progression of pituitary adenomas.

Program Nr: 1791 from the 1999 ASHG Annual Meeting

Characterization of a novel member of the Dbl family of Oncogenes. *N.R. Rodrigues[1], A.M. Theodosiou[2], M.A. Nesbit[3], A.T. Tandle[4], D. Saranath[4], K.E. Davies[1]*. 1) Dept of Human Anatomy & Genetics, Univ Oxford, Oxford, England; 2) Section of Gene Function and Regulation, Institute of Cancer Research, London, England; 3) MRC Molecular Endocrinology Group, MRC Clinical Sciences Centre, Hammersmith Hospital, London, England; 4) Laboratory of Cancer Genes, Cancer Research Institute, Bombay India.

We have identified a novel member of the family of Dbl oncogenes, *Ngef* . Many members of this family have been shown to function as guanine nucleotide exchange factors (GEF) for the Rho-type GTPases. Unlike the other members which show a wider tissue distribution, including hematopoietic tissues, this gene shows predominant expression in brain, with the strongest signal in the caudate nucleus. This region is associated with the control of movement and undergoes specific degeneration in disorders such as Huntington's disease. *Ngef* contains a translated trinucleotide repeat, a polyglutamine stretch interrupted by a glycine. We have isolated both the human and mouse homologues of *Ngef*. We have localized *Ngef* in mouse and human. We have shown that *Ngef* has transforming activity in cell culture and is able to induce tumors in nude mice.

Program Nr: 1792 from the 1999 ASHG Annual Meeting

Complex rearrangement in *BRCA1* results in the in-frame loss of exons in the BRCT domain. *E.M. Rohlfs[1], Q. Yang[2], C. Skrzynia[2,3], M.L. Graham[2,3], L.M. Silverman[1]*. 1) Dept Pathology & Lab Medicine; 2) Lineberger Comp Cancer Center; 3) Dept Medicine, Univ of North Carolina, Chapel Hill, NC.

In a linkage study of *BRCA1* families it was estimated that as few as 63% of the *BRCA1* mutations were identified by techniques which study individual exons and intron/exon borders. Genomic rearrangements and promoter mutations may account for the remainder; one study has shown that 15% of the mutations in their breast/ovarian cancer families were genomic rearrangements. Most frequently, the rearrangements result from homologous recombination between *Alu* repeats resulting in deletion, duplication or inversion of genomic sequence. Protein truncation analysis of lymphocyte RNA from a woman with breast cancer (dx age 51) and a family history of breast and ovarian cancer in her mother (37, 41) and aunt (70, 83), identified a truncated protein within the segment which corresponds to exons 12 - 24. This resulted from a shortened RT-PCR product which sequencing showed lacked exons 17 - 20. Loss of these exons results in the deletion of 97 amino acids but maintains the reading frame. Sequence analysis of all exons did not identify a mutation in any splice junctions. By southern blot analysis it was determined that ~11.5kb of genomic DNA between exons 16 and 21 was deleted. Amplification of genomic DNA identified a junction fragment that also indicated an 11.5kb deletion. However, sequence analysis of this fragment identified an 8216 bp deletion with breakpoints within AluSp (Int 16) and AluSx (Int 19) repeats. An additional junction fragment between introns 19 and 20 has been isolated and appears to account for the remaining ~3.3kb deletion. These tandem deletions result in loss of exons 17 through 20 at the RNA level. The region of the BRCA1 protein that is encoded by these exons (amino acids 1663 to 1759) corresponds to a subregion of the BRCT domain that interacts with RNA helicase A and thereby RNA polymerase II (amino acids 1650 to 1800). The binding of these proteins are thought to be the basis of *BRCA1*'s transcriptional activation function. This is the first report of an in-frame deletion in a high-risk breast cancer individual that removes a putative functional domain of BRCA1.

Program Nr: 1793 from the 1999 ASHG Annual Meeting

Genetic changes in hereditary prostate cancers by comparative genomic hybridization. *A. Rokman[1], J. Schleutker[1,2], P. Koivisto[1], M. Matikainen[1], R. Karhu[1], O. Kallioniemi[1,2].* 1) Lab. Cancer Genetics, IMT, TAUH, Univ. Tampere, Tampere, Finland; 2) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD.

According to the Knudson's two hit hypothesis, cancer predisposing germline alterations are uncovered by somatic chromosomal losses that inactivate the wild-type alleles of recessive tumor suppressor genes. The search for deletions in tumor tissues from patients with an inherited predisposition may therefore highlight putative cancer susceptibility loci (Hemminki et al., 1997). Here, we used comparative genomic hybridization (CGH) to analyze chromosomal alterations in 21 primary prostate cancers from men belonging to Finnish prostate cancer families. The average number (± S.D.) of chromosomal alterations per tumor was 4.0 ± 1.9 with 2.0 ± 2.2 losses and 2.0 ± 2.1 gains. The most common losses were found at chromosomal regions 13q21-q22 (38%), 8p12-pter (31%), 6q14-q21 (19 %), 11q22-q23 (10%), 19p (10 %) and 21q (10%), and the most common gains at 7q11 (38%), 19p (25%), 8q (10%), 9q (10%) and 1p33-pter (10%). The comparison of these data with our previous studies of unselected primary prostate cancers (Visakorpi et al., 1995) indicates that genetic changes do not appear to be significantly different between hereditary and sporadic prostate cancers. Analysis of another tumor material from patients belonging to large families linked to the HPC1 and HPCX loci is in progress.

Program Nr: 1794 from the 1999 ASHG Annual Meeting

Near-triploidy in chronic myelogenous leukemia. *B. Roland.* University of Calgary, Calgary, AB, Canada.

This report describes a case of chronic myelogenous leukemia (CML) with a near-triploid karyotype, and reviews the literature on similar cases. A 58-year-old female was diagnosed with CML in chronic phase. The bone marrow karyotype at diagnosis was 46,XX,t(9;22)(q34;q11.2)[18]/46,XX[2]. Three years later, when the patient was in accelerated phase, progressing to blast crisis, the karyotype was 65~69,XX,-X,-3,-4,-5,+6,-7,+8,-9,t(9;22)(q34;q11.2),+11,-12,-17,+18,+19,+20,+21,der(22)t(9;22)x2,+der(22)t(9;22)[cp19]/46,XX,t(9;22)[16]. The patient died one month later.

Although hyperdiploidy is common in CML at the time of progression, the presence of a near-triploid karyotype is rare, with only 7 cases reported previously. Review of the clinical features of the 8 patients shows that all had the near-triploid karyotype at the time of accelerated phase or blast crisis. There does not appear to be any association with gender (5 female, 3 male), age (41-68 years), length of chronic phase (3-9 years), or morphology at transformation. Review of the cytogenetic features of the 8 cases shows chromosome counts ranging from 58 to 71, with 2-4 copies of each chromosome, and 2-4 copies of the derivative chromosome 22. The chromosomes that most frequently show relative gains are chromosomes 8, 13 and 19 (7/8 cases each), and 6, 14 and 21 (6/8 cases each). The chromosomes that are most frequently under-represented are chromosomes 17 (8/8 cases), and 4, 5, 7, 9, and 12 (6/8 cases each). One or more structural abnormalities in addition to t(9;22) are also reported in 6 of the 8 cases.

Thus, the cytogenetic features of near-triploid CML are similar to the changes in hyperdiploid blast crisis, with the gain of chromosome 8, 19, 21, and der(22), and with the loss of 17p. However, near-triploidy differs in the higher frequency of structual abnormalities other than t(9;22), and in many of the relative chromosome gains and losses.

Program Nr: 1795 from the 1999 ASHG Annual Meeting

Using spectral karyotyping (SKY) for analysis of structural instability of chromosomes in human ovarian carcinoma cell lines. *A.V. Roschke[1], G. Tonon[1], K. Nakahara[1], D.A. Scudiero[2], I.R. Kirsch[1]*. 1) Gen Dept, Div Clinical Sci, National Cancer Inst, Bethesda, MD; 2) FCRDC, National Cancer Inst, Frederick, MD.

Structural chromosome rearrangements can be a characteristic of primary tumor samples, short-term cultures and established tumor cell lines. Most attention has been paid to non-random chromosomal aberrations whose recurrent presence is suggestive of a role in tumor progression or etiology. Nonrecurrent chromosomal aberrations usually are considered as noise that may reflect an underlying mechanism of instability, but otherwise are not significant. In this study we attempted to assess overall structural chromosomal instability (as manifested by the presence of recurrent and nonrecurrent chromosomal aberrations and the persistence of each over time) in six ovarian carcinoma cell lines (OVCAR-3, OVCAR-4, OVCAR-5, OVCAR-8, SKOV-3 and IGROV-1) using spectral karyotyping, an advanced cytogenetic technique, which allows nonambiguous identification of each marker chromosome in each analyzed metaphase. Ovarian carcinoma cell lines used in our study had highly abnormal karyotypes with total numbers of marker chromosomes ranging from 15 to 56 per cell line. The origin of all marker chromosomes was defined and the frequency of their occurrence within distinct metaphases of the same cell line was estimated. As a measure of structural chromosomal instability we calculated for each ovarian cancer cell line a coefficient of structural instability equal to the proportion of rearranged chromosomes to the total number of chromosomes per cell, and a coefficient of marker instability equal to the proportion of variable versus consistent markers per cell. Our findings indicate that ovarian carcinoma cell lines had notable differences in both the frequency and ongoing rate of chromosomal instability.

Program Nr: 1796 from the 1999 ASHG Annual Meeting

Loss of heterozygosity analysis in the chromosome 6q region in adenoid cystic carcinoma. *S. Rutherford[1], R. Saadut[1], CR. Marshall[1], CA. Rumpel[1], HR. Frierson Jr[1], CA. Moskaluk[2].* 1) Department of Pathology, University of Virginia, Charlottesville, VA; 2) Departments of Pathology and Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA.

Adenoid cystic is one of the most common of malignancies that arise in the salivary gland. It is present in the submandibular and minor salivary glands to a much greater extent than in any other location. A high rate of local recurrence, perineural spread and late distant metastasis characterizes the tumor. Adenoid cystic carcinoma produces both abundant basement membrane material and glycosaminoglycans and may be linked to novel genetic mechanisms of differentiation. Previous chromosome transfer experiments indicating chromosome 6 involvement to suppress tumorigenic or metastatic activity of melanoma cell lines, provide support for the hypothesis of one or more tumor suppressor genes residing within the chromosome 6q region. Moreover, cytogenetic studies have identified chromosome 6 as a target for genetic deletion in adenoid cystic carcinoma with breakpoints being mapped to the 6q21-q25 region. The present study extends these findings by assaying for loss of heterozygosity using polymorphic microsatellite markers in paired tumor and normal samples of individuals. Results from PCR amplification of 16 markers in 23 specimens has found a 43% overall incidence of 6q loss within the 6q16.3-6q22.33 region. Our preliminary data suggests that there may be two non-overlapping regions of consensus deletion bounded between D6S292 and D6S287 and between D6S287 and D6S251 respectively. An apparent "hotspot" of deletion also appears to be occurring at the D6S287, D6S407 and D6S262 contiguous markers. The results of additional samples and markers within this region are currently being determined and will be presented.

Program Nr: 1797 from the 1999 ASHG Annual Meeting

Functional characterization of OVCA1, a putative tumor suppressor. *A.M Salicioni, W. Bruening, L. Vanderveer, A.K. Godwin.* Department of Medical Oncology, Fox Chase Cancer Center, Philadelphia, PA.

OVCA1 is a candidate tumor suppressor gene that maps to a highly conserved region on chromosome 17p13.3. Its loss of heterozygosity is a frequent event in breast and ovarian carcinomas. OVCA1 is highly conserved and exists in at least two forms, a 50 and an 85 kDa protein. Somatic mutations in *OVCA1* have been detected, but are rare. Two germline missense mutations have been found in breast cancer-prone women who have tested negative for a *BRCA1* and a *BRCA2* mutation. Attempts to create breast and ovarian cell lines that stably over-express OVCA1 have generally been unsuccessful. The clones that do express exogenous OVCA1 do so at very low levels, and have dramatically reduced rates of proliferation. This reduction in proliferation rate correlates with an increased proportion of the cells in the G1 fraction of the cell cycle, and decreased levels of cyclin D, which may be caused by an accelerated rate of cyclin D degradation. To help determine the function(s) of OVCA1, we used a two-hybrid screening approach to identify OVCA1-associating proteins. The most redundant clone, *BOV-1* (Binding to OVCA1-1), accounted alone for 30% of the total cDNA isolated, and encoded for an ORF of 221 amino acids of an unknown protein. The expression pattern of *BOV-1* mRNA was evaluated by multiple tissue Northern blotting; three major mRNA species were detected (~5.5 kb, ~3.2kb, ~1 kb). All three species encode for BOV-1, are the result of alternative splicing and are expressed in all tissues to varying degrees: the 1-kb transcript was most abundant in testis, heart, placenta, spleen, thymus, and lymphocytes. Like OVCA1, BOV-1 appears to be highly conserved evolutionarily. *S. pombe* and *C. elegans* encode hypothetical proteins with 48.8 % and 60.6% identity and 64.5% and 75.4% similarity at the amino acid level to BOV-1, respectively. This extensive sequence similarity makes it highly likely that the biochemical function of the BOV-1 homolog has been conserved from yeast and nematodes to humans. Experiments are currently underway to determine the biological significance of this interaction in the context of normal and abnormal cell growth.

Program Nr: 1798 from the 1999 ASHG Annual Meeting

Linkage of a pedigree drawing program and database to a program for determining *BRCA* mutation carrier probability. *S.R. Sand[1], D.S. DeRam[2], D.J. MacDonald[1], K.R. Blazer[1], J.N. Weitzel[1]*. 1) Clinical Cancer Genetics, City of Hope Cancer Center, Duarte, CA; 2) GDS, Southbend, IN.

Genetic testing for *BRCA* gene mutations is generally reserved for families where mutation probability exceeds a practical threshold. Tables for estimating the probability that a family carries a mutation have been developed from high risk clinic genotyping data (Couch *et al*., 1997, Frank *et al*., 1998). Key factors are age for breast cancer (BC) and ovarian cancer (OC) occurence. These models do not account for limitations in family structure or non-penetrance. BRCAPRO is a computer program that uses a Bayesian calculation to estimate the probability that either a *BRCA1* or *BRCA2* mutation is present in a family based on first and second degree family history of BC or OC (Parmigiani *et al*, 1998). Key variables include the prevalence of mutations and age-specific penetrance estimates. Data entry was difficult and slow in the beta version. A user-friendly data input vehicle was recently developed (CAGENE, Euhus *et al*) with a pedigree interface. However, the CAGENE database is not flexible and data input is limited to first and second-degree relatives. Progeny (Genetic Data Systems [GDS], South Bend, IN), is a flexible pedigree application tool with a built-in relational database. Our primary data includes extended family history (>3 generations) and medical history germane to studies. An export module was developed to transfer relational pedigree data directly from Progeny to the BRCAPRO program, circumventing the need for data entry into both the pedigree drawing and risk calculation programs. The export module was tested by comparing the BRCAPRO output from 20 extended pedigrees in our Progeny database to the same data entered manually into BRCAPRO and into CAGENE. The output data were concordant for all three methods. Manual data entry took 10 times longer than either alternative. Although the time required for CAGENE and Progeny was similar, there is no capability for comprehensive data storage in the former. The Progeny export filter allows us to use our primary data to determine *BRCA* mutation probabilities within 5 minutes, making it a practical cancer risk assessment tool.

Program Nr: 1799 from the 1999 ASHG Annual Meeting

Characteristic genetic abnormalities in ependymal tumours of different malignancy grades. *D. Sanoudou[1], K. Ichimura[1], M.A. Ferguson-Smith[2], V.P. Collins[1], N. Coleman[1]*. 1) Dept Pathology, Univ Cambridge, Cambridge, England; 2) Dept Veterinary Medicine,Univ Cambridge,Cambridge, England.

Ependymomas are glial in origin and comprise approximately 6% of all CNS tumours. They are believed to develop from the ependymal cell lining of the ventricular system. Three major ependymoma entities have been described : Sub-ependymomas (WHO grade I), Ependymomas (WHO grade II) and Anaplastic ependymomas (WHO grade III). Numerous ependymoma cases have been studied genetically and cytogenetically. However, the results have been contradictory and the mechanisms of pathogenesis remain unclear. In the present study comparative genomic hybridisation (CGH) and allelic imbalance analysis have been used for the investigation of abnormalities in 41 ependymomas (10 sub-ependymomas, 23 ependymomas grade II and 8 anaplastic ependymomas). Paediatric and adult cases were included in the analysis. Only 4 sub-ependymomas had chromosomal aberrations. These included loss on 1p, 6p and 6q, loss of chromosome 8, 19 and X, and gain of chromosome 7. All grade II ependymomas had chromosomal abnormalities. The most frequent aberrations were loss of chromosome 22 (54% of cases), followed by gain of 9p arm (45%), loss on 6q arm (41%) and gain of chromosome 5 (32%). Other anomalies involved gain of 1q and 8q arms, and chromosomes 4, 5, 7, 9, 12, 15, 16, 18, 20 and X. Losses of 1p arm and chromosomes 2, 3, 10, 11, 13, 14, 16, 17, 19, 20 and 21 were also seen. The most common aberrations in grade III ependymomas were gain of 1q arm (63% of cases) and loss of chromosome 22. Other frequent abnormalities included gain of chromosome 8 and loss of chromosomes 11, 16, 17 and 19. Gain was also seen in 1p and 4q arms, and chromosomes 2, 5, 9, 10, 12, 14, 15, 20 and X. Losses were also seen on 9q arm, and chromosomes 3, 5, 6, 7, 8, 10, 13, 14, 15, 18 and 21. Certain differences in chromosomal aberrations could be seen between paediatric and adult patients, and between tumours arising at different anatomical locations.

Program Nr: 1800 from the 1999 ASHG Annual Meeting

CA repeat stimulated recombination: The role of mismatch repair in an *E. coli* model. *M.F. Santibanez, R. Gangeswaran, J.M. Hancock.* MRC CSC, Hammersmith Hospital, London, U.K.

Tumours arising in patients with an inherited defect of the mismatch repair (MMR) pathway are karyotypically simple compared to MMR proficient tumours in equivalent locations. This correlates with a lower frequency of LOH, a process often involving recombination. Chromosomal instability behaves in a dominant manner when MMR proficient and deficient cells are fused [Nature 396:643-646;1998]. This suggests that tumours in HNPCC patients have a lower LOH frequency not only because they have mutator phenotype (obviating the requirement for other mutational mechanisms to achieve, for example, inactivation of tumour suppressor genes), but also because they lack a pathway promoting recombination as a consequence of the MMR defect. The MMR system itself could be responsible for the recombinogenic effect. Although a variety of structures could mediate such an effect, microsatellites seem attractive candidates because the dramatic increase in their mutation rate in cells lacking functional MMR indicates that these sequences are important physiological targets for this repair system, and it has been shown that such repeats can promote recombination. We tested the influence of CA microsatellites on recombination using two compatible plasmids in different *E. coli* strains. Each plasmid carried a kanamycin resistance gene inactivated by a frame shift mutation. The introduction of a $(CA)_{97}$ repeat 3 of the resistance marker in one of the plasmids produced a consistent increase (2-6 fold) in the recombination rate in MMR proficient strains. MMR deficient strains had a higher (5-13 fold) recombination rate for the non array carrying constructs as compared with the parental strains. However, the introduction of the repeat failed to increase the recombination rate in these strains. Our observations are consistent with a mechanism in which stimulation of recombination by CA repeats results from the creation of slippage products during replication. This leads to unpaired regions between parental and daughter strands, which can constitute substrates for mismatch repair. The action of the MMR system then produces secondary lesions that are repaired by recombination.

Program Nr: 1801 from the 1999 ASHG Annual Meeting

The cellular distribution of BLM, the Bloom's syndrome protein. *M.M. Sanz[1], M. Proytcheva[2], N.A. Ellis[3], W.K. Holloman[1], J. German[1]*. 1) Departments of Microbiology and Pediatrics, Cornell University Medical College, New York, NY; 2) Department of Pathology, Albert Einstein College of Medicine, New York, NY; 3) Department of Human Genetics, Memorial Hospital for Cancer and Allied Diseases, New York, NY.

The gene mutated in Bloom's syndrome (BS) encodes a 1,417 aa protein, BLM, which has DNA helicase activity and so is assumed in some way to manipulate DNA. A major question is, What is/are its role(s) in DNA replication, DNA repair, transcription, and, or, recombination, in somatic and, or, germ-line cells? BLM is absent from cells of most persons with BS, which leads to the conclusion that its activity impinges directly or indirectly on the maintenance of genomic stability. In order to obtain leads as to BLM's exact function(s), its distribution has been examined in cells in culture, synchronized and not, using BLM antibodies and immunofluorescence microscopy. In interphase cells, BLM is detected only in the nucleus. In early post-telophase cells it is barely visible. It then increases in amount throughout G1, being both diffuse and also concentrating in multiple (sometimes 20 or more) minute, punctate, brightly fluorescing centers. During S, several (often 10 or more) larger punctate accumulations of BLM become brightly fluorescent, distinctive in appearance from the minute accumulations; these often co-localize with the PML nuclear protein, and in a more transitory way with RPA (the single-strand-binding replication protein A). In addition to the discrete foci, larger but less intensively fluorescing, irregularly shaped aggregates of BLM form in many nuclei. At metaphase, the condensed chromosomes appear to be BLM-free, the BLM then being distributed throughout the entire cell where it fluoresces intensely. Because early G1 cells have so little BLM (above), the conclusion seems inevitable that this is another protein that is eliminated from the cell during late mitosis. These observations will be extended to search for other proteins that co-localize with BLM, and they are to be complemented by immuno- and straightforward biochemical analyses of BLM.

Program Nr: 1802 from the 1999 ASHG Annual Meeting

BRCA1 and BRCA2 families in Finland: haplotype and phenotype analysis and predominance of founder mutations. *L. Sarantaus[1], P. Huusko[2], H. Eerola[1], V. Launonen[2], P. Vehmanen[1], K. Rapakko[2], E. Gillanders[3], K. Syrjäkoski[3], T. Kainu[3], P. Vahteristo[1], K. Pääkkönen[4], J. Hartikainen[5], C. Blomqvist[1], T. Löppönen[2], K. Holli[3], A. Mannermaa[5], J. Kere[4], O.-P. Kallioniemi[3], R. Winqvist[2], H. Nevanlinna[1]*. 1) Dept. of Obstetrics and Gynecology, and Oncology, Helsinki Univ. Centr. Hospital, Finland; 2) Dept. of Clinical Genetics, Univ. of Oulu/Oulu Univ. Hospital, Finland; 3) Lab. of Cancer Genetics, Tampere Univ. Hospital, Finland, and Cancer Genetics Branch, NHGRI, NIH, USA; 4) Dept. of Medical Genetics and Finnish Genome Centre, Univ. of Helsinki, Finland; 5) Unit of Clinical Genetics of Dept. of Gynecology, Kuopio Univ. Hospital/Univ. of Kuopio, Finland.

The result of mutation analyses on the two major breast/ovarian cancer susceptibility genes, BRCA1 and BRCA2, have shown mutational clustering in the genetically isolated Finland. Haplotype analysis of 5 BRCA1 and 4 BRCA2 mutations recurrently found in our population revealed that all families carrying the same alteration have a common ancestor (about 18-80 generations ago, depending on the mutation). Some of the recurrent mutations have also been seen elsewhere in the world, while others are exclusively of Finnish origin. The clustering of the mutations in certain geographical regions gives us remarkable diagnostic advantages, enabeling targeted genetic tests for families from different parts of the country. In addition, almost all BRCA1 and BRCA2 families identified in Finland so far were included in the genotype-phenotype analysis, the results of which in large confirmed the previous observations of preferentially different phenotypic expression of mutations of the 5' and 3' ends of BRCA1, and the earlier onset of ovarian cancer in the families with BRCA1 mutations. In the present study the boundary for differential expression of the BRCA1 mutations in mainly ovarian or breast cancer appeared to be between exons 11 and 12. L. S. and P. H. contributed equally to this study, and H. N. and R. W. share the senior authorship.

Program Nr: 1803 from the 1999 ASHG Annual Meeting

Complete p53 mutation analysis, allelic loss and microsatellite instability in non-small cell lung cancer. *E. Saunders, R. Shipman.* Visible Genetics Inc., Toronto, Ontario, CANADA.

p53 gene mutations in primary cancers may have value as markers for treatment response and outcome. A protocol has been developed which permits routine mutation analysis of the entire p53 gene (exons 2-11) from genomic DNA in both clinical and archival specimens. 67% (18/27) of the primary, non-small cell lung cancers (NSCLCs) examined in this study harboured p53 gene mutations. Molecular genetic studies of primary NSCLC have identified regions of invariant allelic loss at many chromosomal loci. 63% (15/24) of the NSCLCs displayed allelic loss at one or more of the loci examined in this study. The frequent allelic deletion of these discrete chromosomal loci suggests that loss of genes within these regions may influence the development and progression of primary NSCLC. Microsatellite instability (MSI) has also been observed in NSCLC but the frequency of MSI is variable amongst the reported studies. 13% (3/24) of the NSCLCs in this study displayed MSI at one or more of the loci examined. The molecular genetic defects responsible for this instability may play a significant role in the development of some NSCLCs. In addition p53 mutations, allelic loss and MSI were examined for association with clinical and histopathological parameters including treatment response and survival.

Program Nr: 1804 from the 1999 ASHG Annual Meeting

Using Comparative Genomic Hybridization Data to Infer Tree Models of Oncogenesis. *A.A. Schaffer[1], R. Desper[2], F. Jiang[3], O.-P. Kallioniemi[4], C.H. Papadimitriou[5]*. 1) NCBI/NIH, Bethesda, MD; 2) Deutsches Krebsforschungzentrum, Heidelberg, Germany; 3) Institute of Pathology University of Basel, Basel, Switzerland; 4) Cancer Genetics Branch, NHGRI/NIH, Bethesda, MD; 5) Department of Elctrical Engineering and Computer Science, U. C. Berkeley, Berkeley, CA.

Comparative genome hybridization (CGH) is a laboratory method to measure gains and losses of chromosomal regions in tumor cells. It is believed that DNA gains and losses in tumor cells do not occur entirely at random, but partly through some flow of causality. Models that relate tumor progression to the occurrence of DNA gains and losses could be very useful in hunting cancer genes and in cancer diagnosis. We lay some mathematical foundations for inferring a model of tumor progression from a CGH data set. We consider a class of tree models that are more general than a path model that has been developed for colorectal cancer. We derive two tree model inference algorithms based on the ideas of (1) maximum-weight branching in a graph and (2) fitting a matrix of distances to a phylogenetic tree. We prove that under plausible assumptions our algorithms infer good trees. We have implemented our methods in software, and we illustrate with a CGH data set for renal cancer. Our tree models confirm the know role of losses on 3p, and suggest an important role for losses on 4q in renal cell carcinoma.

Program Nr: 1805 from the 1999 ASHG Annual Meeting

Frequency of *BRCA* mutations among a series of Ashkenazi Jewish men diagnosed with breast cancer. *L. Scheuer[1], M. Robson[1], H. Hampel[2], P. Borgen[1], L. Norton[1], D. McDermott[1], M. Pinto[1], J. Hull[1], R. Baum[1], K. Nafa[1], N. Ellis[1], A. Schluger[1], K. Offit[1]*. 1) Department of Human Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Arthur G. James Cancer Hospital and Research Institute, Ohio State University, Columbus, OH.

Emphasis has been focused on determining the frequency of three *BRCA* founder mutations (*BRCA1* 185delAG and 5382insC, *BRCA2* 6174delT) in Ashkenazi women with breast and/or ovarian cancer. The frequency of these three mutations in Ashkenazi males with breast cancer has not previously been examined. With informed consent, blood samples were collected from sixteen males at Memorial Sloan-Kettering Cancer Center diagnosed with breast cancer who identified themselves as being at least of 1/4 Jewish descent. All cases were analyzed for the presence of the three *BRCA* founder mutations listed above. In addition, full *BRCA2* sequencing was performed on eleven of the specimens. Six of the sixteen male breast cancer cases (37.5%) were observed to carry one of the three truncating mutations in *BRCA1* or *BRCA2*. Five of the participants had the *BRCA2* mutation, 6174delT and one had the *BRCA1* mutation, 185delAG. In addition, two of the eleven cases that underwent *BRCA2* sequencing (18.2%) were found to have genetic variants of uncertain significance. The mean age of diagnosis of participants with deleterious mutations (60.3 years) was not significantly different from that of noncarriers (59.4 years). Carriers were more likely to report a family history of breast or ovarian cancer in a maternal first-degree relative or a paternal first-or second-degree relative (83.3%) than noncarriers or those with genetic variants (50%). Our findings suggest a high frequency of *BRCA* mutations in Ashkenazi Jewish males diagnosed with breast cancer and provides a rationale for *BRCA1* and *BRCA2* gene testing in all Ashkenazi men with breast cancer, regardless of age of diagnosis and family history.

.

Program Nr: 1806 from the 1999 ASHG Annual Meeting

Novel alternatively spliced isoforms of the Neurofibromatosis 2 tumor suppressor demonstrate tissue-specific expression pattern and distinct subcellular localization. *B. Schmucker[1], Y. Tang[1], M. Kressel[2]*. 1) Inst of Human Genetics, Univ Erlangen, Erlangen, Germany; 2) Institute of Anatomy, Univ Erlangen, Erlangen, Germany.

The NF2 protein, merlin, belongs to the protein 4.1 superfamily, a group of closely related membrane-cytoskeleton linkers that regulate cell adhesion and cortical morphogenesis. So far, merlin and the recently cloned DAL-1 are the only members of the superfamily protein 4.1 to act as tumor suppressors. The functional diversity of the prototypical protein 4.1 has been shown to be due to post-translational modifications, usage of two translation initiation sites and an all above extraordinarily complex pattern of alternative splicing. As shown for other tumor suppressor genes as NF1, APC and WT1 tissue integrity appears to be dependent of the relative expression level of different alternatively spliced isoforms. Therefore, we looked at the expression of different splice variants of the NF2 gene in human adult and fetal cDNA panels as well as in non-tumor and tumor cell lines. Three novel full-length isoforms have been identified resulting in altered amino acid sequences. Database search of these amino acid sequences revealed no significant homology to other proteins. Additionally usage of cryptic splice sites has been identified. Furthermore RT-PCR analyses showed tissue- and development-specific expression of novel NF2 transcripts. Evidence for a stable expression of these isoforms on the protein level was found by western blot analyses using different antibodies. To examine the biological significance of these novel isoforms, we expressed epitope-tagged wild type NF2 and splice variants in NIH3T3 cells by using both nuclear microinjection and lipid mediated transfection. Transfection experiments and subsequent confocal laser scanning microscopy revealed targeting of the novel protein isoforms to yet unrecognized subcellular compartments pointing towards functional diversity of the NF2 isoforms. Supported by DFG grant.

Program Nr: 1807 from the 1999 ASHG Annual Meeting

Clonality studies in giant cell tumor of bone. *H.S. Schwartz[1], J.D. Eskew[2], M.G. Butler[2]*. 1) Orthopaedics & Rehabilitation , Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Section of Medical Genetics and Molecular Medicine, The Children's Mercy Hospitals and Clinics, Kansas City, MO.

Giant cell tumor of bone (GCT) is a solid, primary bone tumor composed of stromal mononuclear cells and large multinucleated cells which resemble osteoclasts. It represents 5% of skeletal neoplasms and has an unpredictable pattern of biological aggressiveness manifesting as local recurrences and infrequent benign pulmonary metastasis. Cytogenetic studies have demonstrated telomeric associations and other chromosome abnormalities, specifically rings and markers, in as many as 50% of tumor cells in the majority of patients. Telomerase activity and telomere reduction have been demonstrated in tumor cells from GCT patients. In addition, microsatellite instability and loss of heterozygosity (LOH) studies have been performed on cells from GCT patients using several polymorphic DNA markers and no instability or LOH were found. To assess whether the population of GCT cells is monoclonal or polyclonal in proliferation, DNA was isolated from fresh frozen tumor and normal tissue from GCT individuals. A polymerase chain reaction-based assay for methylation of the polymorphic X-linked human androgen receptor gene (HUMARA) was used to assess clonality following established protocols from other tumor studies. To date, we have analyzed six female GCT subjects ranging in age from 20 to 43 years and the androgen receptor gene data supports polyclonal proliferation in all cases. Polyclonal proliferation has also been found in giant cell tumor of tendon sheath which is a common soft tissue tumor of synovial cell origin. Our studies suggest that giant cell tumor of bone is also polyclonal and not neoplastic if one assumes that cells forming a neoplastic mass must demonstrate monoclonality to be classified as a neoplasm.

Program Nr: 1808 from the 1999 ASHG Annual Meeting

Human acid ceramidase located at 8p22 is overexpressed but not mutated in prostate cancer. *R.S. Seelan, C. Qian, A. Yokomizo, D.I. Smith, W. Liu.* Div. of Experimental Pathology, Mayo Clinic & Foundation, Rochester, MN.

The 8p22 region of the human chromosome is frequently deleted in a variety of tumors including prostate cancer, suggesting that a putative tumor suppressor gene (or genes) is located within this region. The human acid ceramidase gene, which causes Farber disease, is located in this region between microsatellite markers D8S258 and D8S261 based on overlapping YAC contigs that span these markers. Ceramidase catalyzes the hydrolysis of ceramide, a potent lipid second messenger that promotes apoptosis and inhibits cellular proliferation. The chromosomal localization and the functional characteristics of this gene make it a promising tumor suppressor for prostate cancer. We describe here the structural organization of the gene and its 5' flanking (putative promoter) region. This gene contains 14 exons spanning about 28 kb of the genome. Comparison of the promoter sequences between the mouse and human ceramidase genes suggests that these two genes diverged considerably during evolution. Northern blot analysis indicates that ceramidase is highly expressed in prostate and blood but poorly expressed in testis and thymus. Quantitative RT-PCR analysis indicates that this gene is overexpressed in prostate cancer tissue, especially in high-grade tumors, compared with matched normals. Mutation analysis of this gene by Southern blot analysis and Denaturing HPLC in 28 prostate cancer and 12 sets of matched normal/prostate tumor samples revealed no mutations except for 12 single nucleotide polymorphisms (SNPs). Two of them are coding SNPs, in exons 3 and 4, and 7 of them are clustered in exon 14 within a 142 bp stretch. Although these findings rule out a tumor suppressor role for this gene in prostate cancer, it is possible that other types of mutations in the non-coding region might exist. The information provided, herein, should prove useful for large-scale screening of patients suffering from Farber disease or from disorders resulting from altered ceramide levels.

Program Nr: 1809 from the 1999 ASHG Annual Meeting

Mosaicism in von Hippel-Lindau Disease: Two Kindreds Each with an Affected Mosaic Parent Whose Offspring Carry Germline Mutations. *M.T. Sgambati[1], C. Stolle[2], P.L. Choyke[3], M.M. Walther[1], B. Zbar[1], W.M. Linehan[1], G.M. Glenn[1]*. 1) National Cancer Institute,Bethesda MD; 2) Genetic Diagnostics Laboratory, University of Pennsylvania, Philadelphia, PA; 3) National Institutes of Health, Bethesda, MD.

VHL (MM# 193300)is a heritable autosomal dominant multiple neoplastic disorder characterized by brain and spinal cord hemangioblastomas, retinal angiomas, clear cell renal carcinoma, neuroendocrine tumors and cysts of the pancreas, pheochromocytomas, endolymphatic sac tumors, and papillary cystadenomas of the epididymis and broad ligament. While most index cases have a positive family history of VHL, some do not. Cases without a family history of VHL may or may not have a germline mutation in their VHL tumor suppressor gene. We present here two cases of VHL mosaicism. In each of two families, standard-testing methods (Southern Blot and direct sequencing) identified the germline mutation in the VHL gene of the offspring, but not in their clinically affected parent. Further analyses of the affected parents' blood detected the VHL gene mutation in a portion of their peripheral blood lymphocytes. Detection of the deleted allele in one case was by fluorescence in situ hybridization (FISH), and in the second case,the three base pair deletion was detected by conformational sensitive gel electrophoresis (CSGE) and DNA sequencing of cloned genomic DNA. Mosaicism in VHL is important to search for and recognize. Identification of mosaic individuals has implications for counseling families and screening for disease in the mosaic individual.

Program Nr: 1810 from the 1999 ASHG Annual Meeting

Prompt improvement of acute promyelocytic leukemia (FAB M3) by classic therapeutic regimen in a patient without chromosomal abnormality, yet exhibiting PML/RARA translocation by fluorescence in situ hybridization. *H.O. Shah[1, 2], J.H. Lin[1, 2], M. Chester[1], W. Aung[1], J. Siddiqui[1], M. Garrison[1, 2].* 1) Nassau County Medical Ctr, East Meadow, NY; 2) State University of New York SUNY, Stony Brook, NY.

This 25 year old Hispanic woman treated for an acute orbital cellulitis for two days. Laboratory tests showed WBC of 1.8k/mm3, RBC of 2.64 mil/mm3, Hb of 8.8 gm/dl, Hct 25%, and platelet count of 25k/mm3. The peripheral blood revealed 70% of myeloblasts and promyelocytes. Many promyelocytes were reniform and some contained coarse granules and/or Auers rods. The aPTT and PT were elevated; fibrinogen was 122 mg/dl. The marrow cellular morphology disclosed acute promyelocytic leukemia (FAB M3), yet the marrow chromosomal study expressed 46,XX with no structural abnormality. Fluorescence in situ hybridization studies revealed specific translocation i.e. t(15;17)(q22;q11) in 370 of 500 interphase cells, i.e. 46,XX. nuc ish 15q22 (PMLx2),17q12(RARAx2)(RARA con PMLx1) and the rest of the cells revealed a normal signal pattern nuc ish 15q22(PMLx2),17q11(RARAx2) negative for presence of clone with PML/RARA rearrangement by interphase. The patient was then treated with ALL Trans Retionic Acid (ATRA). The coagulation parameters improved immediately and returned to normal in seven days. On the 13th ATRA therapy day, the WBC was 13.0k/mm3 with 5% myeloblasts, 12% promyelocytes, and the chromosomal make-up remained 46,XX. Because of good clinical response, she was continued with ATRA. On the 20th day she was started with induction therapy with Daunorubicin and Cytosin Arabinoside. Additional three weeks later she was in complete hematological remission and recovery from the periorbital lesion. She then received two additional cycles of chemotherapy and remained in complete remission ten months after diagnosis clinically and molecular-cytogenetically.

Program Nr: 1811 from the 1999 ASHG Annual Meeting

Uptake of Free BRCA1/2 Testing in Women at Risk for BRCA1/2 Germline Mutations. *K.M. Shannon[1], M.L. Lubratovich[1], D. Finkelstein[2], W. Goggins[2], D.A. Haber[1], M.V. Seiden[1].* 1) Dept Hematology/Oncology, Massachusetts General Hosp, Boston, MA; 2) Dept Biostatistics, Massachusetts General Hosp, Boston, MA.

Barriers to genetic testing for BRCA1/2 mutations have been examined in various contexts. Cost of gene sequencing has been identified as a possible deterrent, given that many women would prefer to not involve their insurance companies and/or their insurer will not reimburse for testing. The recent availability of a novel BRCA1/2 detection system at our institution has allowed us to evaluate this question directly. From 4/97-1/99, 47 women undergoing genetic counseling at our institution were identified as having a family history suggestive of an altered BRCA1/2 gene. The women were offered genetic testing and declined, citing high cost as the primary factor. All indicated they would be interested if the cost were greatly reduced. In 1/99, the women were invited to participate in a research study through which BRCA1/2 testing would be offered at no cost. They were asked to return a survey and indicate if they remained interested in testing. 30 responded yes, 2 responded no and 15 did not return the survey. Of the 30 who responded yes, 2 declined prior to scheduling a pre-test education visit and 2 declined after pre-test education. We were interested in factors that may affect decisions to pursue (N=26) or not pursue (N=6)free testing. Probabilities of carrying a mutation in either BRCA1 or BRCA2 were calculated using BRCAPRO software. The mean risk for women who declined testing (0.54) was significantly higher than those who desired testing (0.21) with P=.025. Examination of other variables including elapsed time between the initial genetic counseling session, whether or not the woman had sisters or female children demonstrated no significant correlation with decision to pursue testing. The association between testing decision and having children was marginally significant (p=.10). Our study suggests that in a group of women who cite the high cost of BRCA1/2 testing as the primary deterrent to testing, removing this barrier prompts testing in only half the group. Further study of a larger cohort is required to identify other barriers to testing in this patient population.

Program Nr: 1812 from the 1999 ASHG Annual Meeting

Chromosome 7q22 is a likely site of a Tumor Suppressor Gene in Malignant Myeloid Diseases. *V. Shashi[1], M.J Pettenati[1], C. von Kap-Herr[1], D.W Bowden[2].* 1) Pediatrics; 2) Biochemistry, Wake Forest Univ Sch Med, Winston-Salem, NC.

Monosomy of chromosome 7 or partial deletion of 7q is seen in 10% of Myelodysplastic syndromes (MDS) and Acute Myeloid Leukemia (AML) and in as many as 50% of therapy related MDS/AML. Previous studies using FISH have reported 7q22, 7q32-q33 and 7q35-q36 as commonly deleted regions. This has led to the hypothesis that there are one or more tumor suppressor genes on 7q responsible for MDS/AML A specific tumor suppressor gene has not yet been identified.

We have performed FISH on 21 consecutive cases of MDS/AML cases with a cytogenetic deletion of 7q. Interstitial (n=11) and terminal deletions (n=10) occur equally frequently, as determined by FISH with the 7q telomere specific probe. Thirteen YACs spanning the long arm of chromosome 7 from band q11.23-q36 were used to further delineate the deletions. Terminal deletions are clustered proximally between q11.23-q22. In interstitial deletions, proximal breakpoints mostly occur at 7q22 (n=8/11). The distal breakpoints vary from 7q31.1-q35. Bands 7q22 and q31.1 are the most commonly deleted segments in both terminal and interstitial deletions. Unlike previous studies we did not find a significant number of distal deletions involving 7q35-36.

Our results indicate that terminal and interstitial 7q deletions occur roughly equally in MDS/AML. Although there is heterogeneity in breakpoints in 7q deletions there is a commonly deleted area involving 7q22 and 7q31.1 in both interstitial and terminal deletions. Further deletion mapping of the 7q22-q31.1 region by FISH using a YAC contig will be helpful in determining the location of a putative tumor suppressor gene.

.

Program Nr: 1813 from the 1999 ASHG Annual Meeting

Application of molecular cytogenetic analysis for clarification of unusual chromosome rearrangements in a child with acute myelogenous leukemia (AML). *S. Shekhter-Levin[1], S. Orlando[2], L.C. Contis[3], M.E. Sherer[1], X. Huang[1], S. Stanke[5], S.M. Gollin[1,2,4]*. 1) Human Genetics, Univ Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Pediatrics, Univ Pittsburgh School of Medicine; 3) Pathology, Univ Pittsburgh School of Medicine; 4) Univ Pittsburgh Cancer Institute; 5) Applied Imaging, Santa Clara, CA.

The patient is a 2-year-old female with a one week history of fever, leukocytosis, anemia, thrombocytopenia and blasts in her peripheral blood. Peripheral blood and bone marrow pathology studies, including flow cytometry, supported the diagnosis of AML, most likely of the M5a FAB subtype. Classical cytogenetic analysis of G-banded metaphase cells from unstimulated bone marrow aspirate cell cultures at diagnosis revealed the following mosaic abnormal karyotype: 46,XX,?add(8)(p11.2),inv(9)(p11q13),+?19,-?22[7]/46,idem,?add(17)(q25)[12]. The inv(9)(p11q13) is considered a common constitional variant. The interpretation of the other findings was unclear, but was essentially solved using molecular cytogenetics. FISH studies with the BCR/ABL, MYC, and chromosome 17 alpha-satellite (D17Z1) DNA probes showed that the additional 19 is an i(22)(q10), the ?add(8)(p11.2) carries MYC, and the ?add(17)(q25) contains the chromosome 17 centromere. The RxFISH multicolor banding study revealed that the add(8)(p11.2) appears to be the result of a pericentric inversion, inv (8)(p11.2q21.2) and the add(17)(q25) is most likely an unbalanced translocation with chromosome 6p, der(17)t(6;17)(p21.1;q25). The latter was confirmed with chromosome painting with the WCP6 probe combined with the chromosome 17 alpha-satellite DNA probe. As a result of the FISH studies, the final karyotype was revised as follows: 46,XX,inv(8)(p11.2q21.2),inv(9)(p11q13),i(22)(q10)[7]/46,idem,der(17)t(6;17)(p21.1;q25)[12]. ish inv(8)(p11.2q21.2)(MYCx1), der(17)t(6;17)(p21.1;q25)(wcp6+;D17Z1+), i(22)(q10)(BCRx2). Thus, combining classical chromosome analysis with molecular cytogenetics, including the new multicolor banding method, RxFISH, significantly clarified our understanding of the unusual acquired chromosome abnormalities in this child with AML.

Program Nr: 1814 from the 1999 ASHG Annual Meeting

Investigating the role of the RET proto-oncogene in small cell lung carcinoma (SCLC). *Y. Shi, B. Campling, S. Myers, L. Mulligan.* Pathology, Queen's University, Kingston, Ontario, Canada.

SCLC clinically often presents many neuroendocrine features. The RET proto-oncogene encodes a receptor tyrosine kinase, which is expressed in cells derived from the neural crest. Mutations of RET have been implicated in neuroendocrine cancers including medullary thyroid carcinoma, and in the cancer syndrome multiple endocrine neoplasia type 2. However, we have shown that no mutations occur in SCLC. RET is normally activated by binding to both a ligand of the glial cell line-derived neurotrophic factor family (GDNF, NTN), and a GPI-linked coreceptor the GFR family (GFRa-1, 2, 3). Our previous studies have shown that RET, GDNF, and GFRa-1 transcripts are expressed in some SCLC cell lines. Thus, we predicted that paracrine or autocrine activation of RET could occur in these lines, and might play an important role in SCLC growth or differentiation. Using 3 cell lines selected for the expression of RET, GDNF, and GFRa-1 transcripts, we have detected RET protein expression in 2 cell lines (MOA, YRA) by immunoprecipitation and western-blotting of RET protein. We have also found cell surface GFRa-1 protein expression in these cell lines by flow cytometry. Thus, these lines have the potiential to respond to GDNF. To address the possibility that other RET ligands (NTN) or coreceptors (GFRa-2 or 3) might be involved in RET activation, we screened for NTN, GFRa-2, and GFRa-3 transcripts by RT-PCR in 22 SCLC cell lines. We have shown that 50% (11/22) of cell lines express NTN. Further, 72% (16/22) of lines express GFRa-3 transcripts, but the expression of GFRa-2 occurs in only a subset of these lines. Our data suggest that SCLC cell lines could potentially be responsive to RET activation through one or more of the possible ligand-receptor complexes. We are currently investigating the response of SCLC to RET ligands using assays for RET phosphorylation and for morphological changes in these cell lines. Our study will elucidate the role of RET in the growth regulation of SCLC.

Program Nr: 1815 from the 1999 ASHG Annual Meeting

Cloning and characterization of genes at reciprocal translocation t(1;9)(p32.3;p21.2) breakpoint in a patient with neuroblastoma. *H.O. Shiwaku[1], M. Hoshi[1], H. Tsuchiya[2], I. Kamino[3], Y. Kaneko[4], A. Horii[1]*. 1) Department of Molecular Pathology, Tohoku University School of Medicine, Sendai, Miyagi, Japan; 2) Department of Pediatrics, Kumamoto University School of Medicine, Kumamoto, Japan; 3) Special Reference Laboratory, Hachioji, Tokyo, Japan; 4) Department of Cancer Chemotherapy, Saitama Cancer Center, Saitama, Japan.

Neuroblastoma is a well-known malignant disease in infants, but its molecular mechanisms have not yet been elucidated. The most frequently observed chromosomal aberration is loss of chromosome arm 1p in neuroblastomas, and this chromosome arm may harbor two or more tumor suppressor genes in this disease. We have established a cell line that was derived from lymphoblast of a patient with neuroblastoma. This patient has a constitutional reciprocal translocation t(1;9)(p32.3;p21.2). A contig spanning an approximately 800-kb consisting of ten BAC clones of minimal overlap was constructed and three overlapping clones that harbor the breakpoint were cloned. A cosmid library was also constructed with the DNA of the patients cell line and the translocation breakpoint was further characterized in detail. We also performed cDNA screening and detected two transcripts from this region. Results of the characterization of the breakpoint as well as cDNA clones will be described in detail.

Program Nr: 1816 from the 1999 ASHG Annual Meeting

The importance of cytogenetic analysis in the diagnosis and treatment of bone and soft tissue sarcoma. *R. Shomrat[1], Y. Yaron[1], M. Goldstein[1], D. Kunig[1], J. Issakov[3], I. Bar-Am[4], I. Meller[2], A. Orr-Urtreger[1].* 1) Genetic Inst, Tel-Aviv Sourasky Med Ctr, Tel-Aviv, Israel; 2) The national unit of Orthopedic OncologyTel-Aviv Sourasky Med Ctr, Tel-Aviv, Israel; 3) Pathology Inst,Tel-Aviv Sourasky Med Ctr, Tel-Aviv, Israel; 4) Applied Spectra Imeging Ltd., Israel.

Chromosomal analysis is becoming increasingly useful in the diagnosis and management of bone and soft tissue sarcomas. The identification of chromosomal aberrations, such as translocations, deletions and/or additions of a part or whole chromosome, double minutes (dmin), and other markers are associated with specific tumor subtypes. We have analysed 78 samples of tumors. The cytogenetic analysis was carried out on a short-term cultured tissues by G-banding, FISH and SKY procedures, as needed. (*)Histopathological examination excluded malignancy in 19 out of the 78 samples. The remaining 59 tumors were diagnosed as Osteosarcoma (16), Ewing's sarcoma (13), Synovial Sarcoma (4), Rhabdomyosarcomas (1 embryonal and 3 alveolar), 3 Liposarcomas (1 myxoid), 3 Extraabdominal Fibromatosis (Desmoid Tumors), and 16 other different types sarcoma. (*)Among the 16 Osteosarcomas studied 8 have demonstrated complex hyperploid karyotypes compatible with the diagnosis of high grade osteosarcoma. In most of the Ewing's sarcomas (including 3 with the typical t(11;22) translocation) other chromosomal abnormalities were seen like trisomies of chromosomes 5, 6, 8 and 14. Three of the four Synovial sarcomas had the typical t(X;18)(p11.2;q11.2) translocation. One of the synovial sarcomas was intially diagnosed histopathologically as Ewing's sarcoma, but the cytogenetic analysis demonstrated a complex X;18 translocation and led to diagnostic revision and specific treatment. Only one of the Alveolar Rhabdomyosarcomas demonstrated the typical t(2;13)(q35;q14) translocation, while hypertetraploid set with dmins was detected in the other two cases. By using SKY, we determined that chromosome 1 is the origion of one of the dims, suggesting that PAX7 amplification could be involved in the pathogenesis of this tumor. (*)Cytogenetic analyses of bone and soft tissue tumors are of important clinical value for accurate definition of the tumor type.

Program Nr: 1817 from the 1999 ASHG Annual Meeting

Loss of Expression By Deletion And Hypermethylation of a New Member of the DNAJ Protein Family On 13q14.1 in Ovarian Cancer. *V. Shridhar[1], J. Staub[1], H. Huang[1], G. Callahan[1], R.K. Bright[2], A. Yokomizo[1], L. Wang[1], H.I. Pass[2], L. Hartmann[1], D.I. Smith[1]*. 1) Experimental Pathology, The Mayo Clinic, Rochester, MN; 2) Department of Surgery, Karmanos Cancer Institute, Wayne State University, Detroit, MI.

We isolated a differentially expressed transcript and its corresponding gene by differential display PCR between a prostate tumor cell line and a cell line derived from matched normal prostate epithelium [1542NPTX and CPTX]. Sequencing followed by EST-based walking of this fragment yielded a new full length cDNA which could code for a predicted 150 amino acid long protein with a transmembrane domain at its N terminus and a DNAJ domain at its C terminus. The gene which mapped to 13q14.1 was designated as MCJ (methylation controlled J protein)and has partial homology in the DNAJ domain to a number of proteins with a similar domain. The genomic structure of MCJ revealed that it contains four exons. MCJ has the highest similarity to a functionally undefined protein from C.elegans. MCJ is expressed as a 1.2Kb transcript in several tissues with testis showing the highest level of expression. Expression of MCJ was completely absent in a cell line established from benign prostate hyperplastic epithelium (the BPH-1 cell line), three of eight ovarian cancer cell lines, in 5 of 28 primary ovarian tumors and three of eight mesothelioma cell lines. Expression was induced in a dose dependant manner in the BPH-1 cell line by 5-aza-2'-deoxycytidine (5-aza-2'-dC) treatment implicating the involvement of methylation in this induction. Expression analysis using semi-quantitative RT-PCR indicates that more than 66% (12/18) of primary ovarian tumors had either a complete absence and /or lower levels of expression of this gene. While no tumor specific mutations were detected in any of the coding exons in cell lines and primary tumors, LOH analysis with a new microsatellite marker identified 80 bases 3' to the gene and Methylation Specific PCR analysis revealed that in primary tumors and cell lines with loss of MCJ expression showed that one allele was lost by methylation and the other by deletion.

Program Nr: 1818 from the 1999 ASHG Annual Meeting

A Genetic study of Hodgkin's lymphoma: an estimate of heritability and anticipation using the Familial Cancer Database in Sweden. *Y.Y Shugart[1], K. Hemminki[2], P. Vaittinen[5], C. Dong[2], J.R. O'Connell[4], A. Kingman[3].* 1) Pediatrics/CIDR, Johns Hopkins University, Baltimore, MD; 2) Department of Biosciences, Karolinska Institute, Huddinge Sweden; 3) National Dental and Craniofacial Institute, Bethesda, MD; 4) Department of Human Genetics, University of Pittsburgh, Pittsburgh PA; 5) Center for Epidemiology, National Board for Health and Welfare, Stockholm Sweden.

Genetic anticipation in Hodgkin's lymphoma (HL) has been reported by Shugart (1998). However, the previous study uses data from published literature and contains a number of biases. We are interested in testing the hypothesis of anticipation in the Swedish population because it is feasible to search for independently ascertained affected relatives through the Familial Cancer Database in Sweden. By linking two Swedish registries: a second generation registry maintained by Statistics Sweden and the Cancer Registry maintained at the Center for Epidemiolgy, we identified 12 parent-child pairs who were both affected with HL. The usual t-test method was used to test whether there is a difference in cancer age of onset between parents and children who are affected with HL. A randomization test was used to test the validity of the p-values. The mean age of onset is 38.41 years (SD=14.61) for parents and 25.58 years (SD=10.91) for the children. The mean anticipation is 12.8 years (SD=11.2). The corresponding paired t-test statistic is 3.98. Assuming normality it would have 11 degrees of freedom with an associated p=0.0011 (one sided). This finding is unlikely to be explained by sampling bias alone. Using methods proposed by Falconer and Mackay (1997), we also estimated the heritability of HL to be 28.4% in the Swedish population.

Program Nr: 1819 from the 1999 ASHG Annual Meeting

Familial Cancer Database. *R.H. Sijmons[1], G.T.N. Burger[2].* 1) Medical Genetics, Univ Groningen, Groningen, Netherlands; 2) Sazinon Foundation, Bethesda Hospital, Hoogeveen, Netherlands.

Cancer is associated with a wide range of hereditary disorders. Recognizing these disorders in cancer patients may be of great importance for the medical management of patients as well as their relatives. Conversely, recognizing the fact that cancer may develop in patients already diagnosed with a hereditary disorder may be important for the same reason. We have developed a stand-alone interactive computer program, Familial Cancer Database, to assist the clinician and the genetic counselor in making a genetic differential diagnosis in cancer patients as well as in becoming aware of the tumour spectrum associated with a particular hereditary disorder already diagnosed. The program tries to match tumour and non-tumour features observed in patients and their families with any of the more than 300 disorders presently contained in the database and provides a clinical synopsis for each of these disorders. Additional features of the program are to search the more than 1000 references in the database, and to search for disorders associated with particular chromosomal regions and genes. Familial Cancer Database has been tested by an International panel of oncologists and geneticists and will be offered free of charge to all interested physicians and genetic counselors.

Program Nr: 1820 from the 1999 ASHG Annual Meeting

LOW PROPORTION OF BRCA1 AND BRCA2 MUTATIONS IN FRENCH CANADIAN BREAST CANCER FAMILIES. *J.R. Simard[1], F. Durocher[2], H. Vezina[3], C. Samson[1], M. Dumont[1], M. Desrochers[1], N. Bolduc[1], H. Malouin[1], V. Paquet[1], L. Larouche[1], M. Tranchant[1], M. Jomphe[3], J. Chiquette[4], L. Provencher[4], M. Plante[1], R. Laframboise[1], F. Labrie[1], D. Easton[2], P. Bridge[5]*. 1) Laval University Medical Center, Quebec City, Quebec, Canada; 2) CRC Genetic Epidemiology Unit, University of Cambridge,Cambridge, UK; 3) Universite du Quebec Chicoutimi/IREP, Chicoutimi, Quebec,Canada; 4) Hopital St-Sacrement, Quebec City, Quebec, Canada; 5) Alberta Childrens Hospital, University of Calgary, Calgary, Alberta, Canada.

Our study was designed to estimate the frequency and penetrance of mutations in BRCA1 and BRCA2, as well as , their relative contribution and the role of the founder effect and demographic history of the country in the origin and spreading of mutated BRCA1 and BRCA2 alleles. 112 affected women from 61 French Canadian families, which included, at least 4 cases of breast/ovarian cancer, was first tested for the 9 BRCA1 and BRCA2 mutations previously reported in this population. This analysis led to the detection of the R1443X (BRCA1) in 8 families and 8765delAG (BRCA2) in 7 families and 2816insA (BRCA2) in 1 family. Therafter, the complete sequence of all exons and splicing sites of BRCA1 and BRCA2 was done, leading to the detection of 4 novel frameshift mutations and 14 sequence variants. Additional analyses were done to test for large duplication or deletion and regulatory mutation in mutation-negative families. The average age at diagnosis of breast cancer was older in the mutation-negative families (51.8 compared to 45.6 $p<0.001$). Among the 42 mutation-negative families, 35 were site-specific breast cancer families, while only one of these families shows >1 case of ovarian cancer. Genotyping analyses have shown evidence for a founder effect for the two most frequent mutations. Calculation of the mean genetic contribution of the ancestors found to be common to the 8 R1443X families suggest that the two most frequent and specific ancestors married in the Quebec City area. The low frequency of deleterious mutations in the BRCA1 and BRCA2 genes in French Canadian breast cancer families suggests that additional cancer susceptibility genes are likely to be important in this population.

Program Nr: 1821 from the 1999 ASHG Annual Meeting

Silencing of the retinoic acid receptor beta (RAR beta) gene by hypermethylation in human breast cancer. *S. Sirchia[1], A.T. Ferguson[2], S. Sukumar[2], R. Orlandi[3], N. Sacchi[1,2].* 1) School of Medicine,University of Milan, Milan, Italy; 2) Oncology Center, John Hopkins University, Baltimore, MD; 3) Istituto Nazionale Tumori, Milan, Italy.

CpG island hypermethylation is known to be associated with gene silencing in human cancer. It has been proposed that this epigenetic event may be determined either by aberrant DNA methyltransferase (DNA-Mtase) activity or other cellular factors. Recent evidence seems to indicate that, aside from random DNA-Mtase action, additional cellular factors exist that govern aberrant methylation in breast cancer cells. By using methylation specific PCR (MSP) we have shown that methylation of the retinoic acid receptor beta (RAR beta) promoter region containing the retinoic acid responsive element (RARE) is occurring in a great proportion of breast cancer cell lines and primary breast tumors, but not in normal human mammary epithelial cells (HMEC). Methylation of RAR beta in breast cancer cell lines is associated with loss of expression of the RAR beta gene. The expression can be restored by demethylating agents. Interestingly, we have observed that aberrant methylation of RAR beta is occurring also in normal breast tissue surrounding breast cancer cells, but not in normal lymphonodes. These observations suggest that aberrant methylation of RAR beta, leading to silencing of the RAR beta gene may be an early event in breast carcinogenesis.

Program Nr: 1822 from the 1999 ASHG Annual Meeting

Two rare cases of leukemia cutis and a literature review. *R.A. Sokolic[1], E. Sotomayor[2], K. Santoro[2], S. Mark[3], P. Rintels[2], H.F.L. Mark[2,4,5]*. 1) Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Rhode Island Hospital, Providence, RI; 3) Brown University, Providence, RI; 4) KRAM Corporation (Medical Genetics Division), Barrington, RI; 5) Brown University School of Medicine, Providence, RI.

Leukemia cutis is a rare presentation of leukemia. It has been reported with many different forms of leukemia, including acute myelogenous leukemia of various subtypes, acute lymphocytic leukemia, B-cell chronic lymphocytic leukemia, and chronic myelomonocytic leukemia. Although, The incidence of this disease varies by leukemic subtype, the morphologic subtype of leukemia seems to have little bearing on the ability of a hematologic malignancy to express itself as leukemia cutis. With the advent of flow cytometry and cytogenetics, hematologic malignancies are more often described as molecular rather than morphologic entities. However, little is known about the molecular cytogenetics of leukemia cutis. The few papers on the cytogenetics of soft tissue lesions in leukemia do not specifically discuss skin lesions. It is not known whether the cytogenetics of leukemia cutis is separate and distinct from the cytogenetics of leukemia cases in general and also from the non-leukemia cutis cases. We report here on the cytogenetic findings in two rare cases of leukemia cutis as a presenting symptom of leukemia in order to shed additional light on the above problem. Results of cytogenetic analyses revealed the following findings: 46,XY,del(9)(q21)[12]/46,XY[10] in patient 1, and 82~91,XXXX,+6,add(7)p22),-10,-10,del(11)(q22)x2,i(17)(q10),+mar[cp35]/46,XX, add(7)(p22),i(17)(q10),+mar[2]/46,XX[1] in patient 2. The existing literature on leukemia cutis was reviewed to establish whether these are recurrent findings.

.

Program Nr: 1823 from the 1999 ASHG Annual Meeting

Spontaneous mutation in Big Blue transgenic mice: the effects of age, tissue type, genotype, vitamin E, and carcinogenesis. *S.S. Sommer, K.A. Hill, V.L. Buettner, A. Halangoda, M. Kunishige, S.R. Moore.* City of Hope, Beckman Research Institute, Duarte, CA.

The Big Blue system provides a powerful tool to examine spontaneous mutation and aging, cancer, or neurodegenerative disease. Substantial evidence has accumulated that the isolated mutants reflect mouse *in vivo* mutations. Methodological enhancements have increased the efficiency of determining mutation frequence and pattern 8-fold. In the past two years, the lab screened 58 million plaque forming units and sequenced 2,645 mutants (3.1 Mb). An analysis of spontaneous mutations and gender, genetic background, tissue type, and aging was performed. Mutations were examined in whole embryos and seven tissues (forebrain, cerebellum, thymus, heart, liver, adipose tissues, and male germ cells) in post-natal mice (10d, 3, 10, and 25 mo). Two time courses of mutation frequency and one core mutation pattern were identified. The previously observed constancy of mutation frequency at young and mid-adulthood was confirmed. The male germline demonstrated significantly lower mutation frequencies than somatic tissues. Three classes of multiple mutations were described; those occurring in tandem, 2-10 bp and greater than 20 bp apart. Mutations within 5 bp are most likely single mutation events. Tandem-base mutations occurred only in liver and adipose tissues, increased significantly with age in liver, and were largely coordinate GG to TT mutations. Mutation frequency was altered significantly in mice nullizygous for the DNA repair gene ERCC6. Of particular interest, given the relationship between mutation and cancer, is the reduction of mutation frequency under certain circumstances (Vitamin E supplementation, ERCC6 nullizygosity in neurons, and the enhanced expression of SOD1). Six of 11 thymic lymphomas derived from p53-deficient mice showed small increases in mutation frequency and one tumor showed an altered mutation pattern. The results provide a profile of spontaneous mutation from which deviations due to alterations in genotype and mutagen exposure are measured.

Program Nr: 1824 from the 1999 ASHG Annual Meeting

Hypotetraploidy in a patient with small cell carcinoma. *E. Sotomayor[1], B. Hongwei[2,3], S. Mark[4], P. Rintels[2,3], H.F.L. Mark[3,5]*. 1) University of Texas Medical Br, Galveston, TX; 2) Rhode Island Hospital, Providence, RI; 3) Brown University School of Medicine, Providence, RI; 4) Brown University, Providence, RI; 5) KRAM Corporation, Barrington, RI.

While numerical and structural chromosomal abnormalities characterize many hematopoietic and non-hematopoietic malignancies, a review of the literature using MEDLINE, CANCERLIT and the Science Citation Index revealed that the occurrence of polyploidy is by and large rare. We report here an interesting patient with small cell carcinoma (SCC) and polyploidy initially referred to us because of a question of acute nonlymphocytic leukemia (ANLL), M3 subtype, with a question of a 15;17 translocation characteristic of acute promyelocytic leukemia. However, the patient did not have a 15;17 translocation and the final hematopathologic analysis of the bone marrow aspirates and immunohistochemistry studies subsequently revealed the patient to have SCC. Small cell carcinoma is a highly malignant and a very aggressive neoplasm. In leukemia, reports of polyploidy point to a distinct category of patients with a poor risk for which more intensive treatment is needed. Little information is currently available to assess the risk of polyploidy in small cell carcinoma. This case is important because of the relative rarity of polyploidy/tetraploidy. Insights gained from the study of this and other similar patients may also help shed additional light on the mechanism of carcinogenesis, which is not fully known to-date. As polyploidization is a manifestation of genetic instability and as genetic instability has been implicated in the genesis and progression of many cancers, it is perhaps not too surprising that hypotetraploidy in this case was associated with a poor disease outcome, namely the demise of the patient.

Program Nr: 1825 from the 1999 ASHG Annual Meeting

Increased Frequency of Glutathione-S Transferase (GSTT1) Null Genotype in Patients with Aplastic Anemia and Myelodysplastic Syndromes. *M.W. Stacey[1], T. McAninch[1], L. Santi[1], C. Osgood[1], R.L. Byrd[2], J.M. Liu[3], N. Young[3], W.G. Kearns[1,4].* 1) Center for Pediatric Research, Norfolk, VA; 2) Division of Hemotology/Oncology, Children's Hospital of the King's Daughters, Norfolk, VA; 3) Hematology Branch, NHLBI, NIH, Bethesda, MD; 4) Inst. of Genetic Medicine, Johns Hopkins Univ Sch of Med. Baltimore, MD.

Background: Aplastic anemia (AA) is a disorder of hemopoetic bone marrow stem cells and is rapidly fatal if left untreated. Patients receiving immunotherapy are at risk for late complications, including progression to myelodysplastic syndromes (MDS). Toxic environmental factors are postulated to contribute to the etiology of AA and MDS. It is possible that patients with a reduced ability to metabolize carcinogens or toxins are at risk for developing AA with progression to MDS. The glutathione S-transferases, GSTT1 and GSTM1, encode proteins that play a role in metabolizing carcinogens and toxins. **Objective:** To determine the prevalence of GSTT1 and GSTM1 null alleles in bone marrow cells from patients with AA, MDS, and controls. **Methods:** Multiplex PCR was performed on extracted DNA to co-amplify the GSTT1 alleles, the GSTM1 alleles, and -globin or actin as an internal control. **Results:** The GSTT1 null genotype was found in 8/26 (31%) AA patients, 9/15 (60%) MDS patients, and 6/37 (16%) control samples. The GSTM1 null genotype was found in 15/26 (58%) AA and 9/15(60%) MDS patients. Fifty-four percent (20/37) of controls had the GSTM1 null genotype. The incidence of the GSTT1 null genotype was significantly higher ($p<0.05$) for the AA and MDS patients versus controls. No significant difference was found in the frequency of the GSTM1 null genotype between controls and patients. Ethnic variability will be discussed. **Conclusions:** These preliminary results suggest there is a significant increase in the frequency of the GSTT1 null genotype in AA and MDS patients from this studied population pool. Abnormal detoxification of environmental or endogenous toxins might lead to genetic instability with possible disease progression.

Program Nr: 1826 from the 1999 ASHG Annual Meeting

Multiplex RT-PCR screening for the detection of specific fusion-genes in childhood leukemia. *S. Strehl[1], H. Christiansen[2], J. Lovmand[2], O.A. Haas[1]*. 1) CCRI, Children's Cancer Research Institute, Vienna, Austria; 2) DNA Technology, A/S, Science Park Århus, Denmark.

The detection of chromosomal rearrangements in childhood acute lymphoid leukemia (ALL) and acute myeloid leukemia (AML) plays an important role for the identification of clinical relevant subtypes. The cytogenetic definition of karyotype abnormalities led to the molecular genetic characterization of many translocation breakpoints and the identification of the involved genes. The expression of the fusion transcripts associated with these rearrangements provides the basis for the refinement and up-scaling of screening technologies. Recently, a multiplex-PCR strategy has been reported that allows the simultaneous detection of 28 different chromosomal aberrations that generate over 80 different fusion transcripts (Pallisgaard et al., 1998). We have used this multiplex-assay (HemaVision™, DNA Technology) for the analysis of bone marrow and peripheral blood samples of AML patients registered in the Austrian AML-BFM 93 and 98 studies. So far, we have studied 15 cases. In eleven we detected a specific fusion transcript, whereas four samples were negative for all 28 translocation products. Except for one case with a MLL/AF6 fusion transcript indicating a t(6;11), all results concurred with the cytogenetic findings. In this patient, the specific translocation was missed, although an 11q23 abnormality was obvious. In addition, we have successfully analyzed methanol/acetic acid fixed cells that had been used for cytogenetic analysis and stored for up to six years at -20C. The possibility to use such fixed material as an additional RNA source facilitates retrospective studies and analysis of cases with restricted amounts of material. The preliminary results of our analyses show that this multiplex RT-PCR test is advantageous to other screening methods, because it covers a broad spectrum of genetic alterations. It may yield new information on their frequencies and provide the information necessary for minimal residual disease studies. Moreover, it will be useful for refinement of leukemia diagnosis and may become relevant for the development of a more individualized therapeutic approach.

Program Nr: 1827 from the 1999 ASHG Annual Meeting

Molecular genetic basis for attenuated familial adenomatous polyposis. *L.-K. Su[1], C.J. Barnes[2], W. Yao[1], Y. Qi[1], P.M. Lynch[2], G. Steinbach[2]*. 1) Cancer Biology, M. D. Anderson Cancer Center, Houston, TX; 2) Gastrointestinal Oncology and Digestive Diseases, M. D. Anderson Cancer Center, Houston, TX.

Familial adenomatous polyposis (FAP) is an autosomal dominant inherited disease that predisposes patients to colorectal cancer. FAP is caused by germline mutations of the *APC* gene. Most FAP patients develop hundreds to thousands of benign colorectal tumors starting in their second decade of life. Patients with attenuated FAP (AFAP) develop fewer tumors and at older age than those with typical FAP. It is clear that patients carrying germline mutations in three specific regions of *APC* usually develop AFAP; these are the first 4 coding exons, the alternatively spliced region of exon 9 (ASRE9), and the 3' half of the coding region. However, it is not clear why mutations in these regions of *APC* cause AFAP.

We investigated the mechanism for AFAP in patients carrying a germline mutation in the ASRE9 of *APC*. We found that transfection of the *APC* cDNA without ASRE9 downregulated catenin mediated transcription as efficiently as transfection of the wild *APC* cDNA did. We then examined somatic mutations in exon 15 of *APC* in 9 tumors from two patients carrying this germline mutation. Every tumor was found to have somatic mutation and 5 of them had mutations in both alleles. A specific mutation was found in the germline mutant allele in 4 of these tumors; although it had rarely been found before in sporadic or FAP associated colorectal tumors.

Our results show that somatic mutations of both *APC* alleles are required for the formation of most colorectal tumors in these patients, therefore fewer tumors are developed in them. However, these patients are still predisposed to colorectal tumorigenesis because some mutations that occur frequently and do not completely inactivate the wild type *APC* allele can inactivate alleles of *APC* carrying germline mutations in ASER9.

Program Nr: 1828 from the 1999 ASHG Annual Meeting

CDKN2A mutations in Canadian malignant melanoma families. *A.M. Summers[1,2], D. Hogg[3], M. Shennan[2], N. Lassam[2,3].* 1) Genetics Program, North York General Hosp, North York, ON, Canada; 2) Toronto Sunnybrook Regional Cancer Centre, Toronto, Canada; 3) Department of Medicine, University of Toronto, Toronto, Canada.

Cutaneous malignant melanoma (CMM) is a serious but potentially preventable skin cancer with a lifetime risk for Canadians of 1/108. About 10% of CMM is inherited in an autosomal dominant fashion with variable penetrance. We have argued that individuals with a genetic predisposition to melanoma represent a high-risk population that should benefit from surveillance programmes. To test this hypothesis, we established a familial melanoma clinic at the Toronto Sunnybrook Regional Cancer Centre in 1996. From the outset, we have used PCR-sequencing combined with a yeast two-hybrid system to identify functionally significant mutations in CDKN2A. To date we have enrolled 155 families in the clinic and have sequenced CDKN2A in both affected and unaffected members of 105 kindreds. Among all 105 families, we have observed 33 germline mutations in CDKN2A (31.4%) including five mutations in the noncoding region at position -34. Among the 37 families with three or more affected members (AFM), the rate of germline mutations increases to 21/37 (56.8%). Thus, it is likely that many of our families with only two affected members merely represent a chance association. Our preliminary data currently indicate that the factors most predictive of finding a germline CDKN2A mutation in a melanoma-prone family include: 1) three or more AFM; 2) one or more cases of pancreatic cancer, 3) multiple primary melanomas; and 4) age of onset 30 years or under, in order of decreasing importance. Although we are steadily accruing families, it is too early to comment on issues such as penetrance, genotype/phenotype correlation, or interactions between CDKN2A and other genes or environmental factors. In the meantime, we can provide persons at risk for CMM with intensive skin surveillance both through self-examination and regular examination by a dermatologist.

Program Nr: 1829 from the 1999 ASHG Annual Meeting

A ROLE OF MEN1 IN TRANSCRIPTIONAL REGULATION AND TELOMERE FUNCTION. *K. Suphapeetiporn, D. Walpita, T. Ashley, A. Bale.* Genetics, Yale University, New Haven, CT.

MEN1 is an autosomal dominant familial cancer syndrome characterized by pituitary, parathyroid, pancreatic islet and carcinoid tumors. The MEN1 gene encodes a nuclear protein of unknown function. Biochemical studies suggest that the gene may regulate the JUN family, and in particular is a negative regulator of JUND (Agarwal et al., 1999). To investigate the function of MEN1, we constructed stable, tet-repressible carcinoid cell lines. Induction of MEN1 expression inhibited colony formation and thymidine incorporation. The Drosophila homolog of JUN induces expression of dpp, the TGF beta homolog. As predicted by the Drosophila model, TGF beta was induced in the absence of MEN1 and strongly repressed by switching on MEN1 in carcinoid cells. MEN1 is highly expressed in testes, suggesting the possibility of a role in meiosis and in recombination and repair. We determined the localization of MEN1 protein on meiotic chromosomes by immunostaining mouse spermatocytes with an antibody raised against an MEN1 peptide identical in human and mouse. The MEN1 protein localized specifically to telomeres during all stages of prophase. Many cancer predisposition genes (e.g., ATM, BRCA1 and 2) have specific localizations on meiotic chromosomes which relate to their function in mitosis and DNA repair. The localization of MEN1 on meiotic chromosomes suggests the possibility of a role in telomere regulation, which appears to be aberrant in all human tumors.

Program Nr: 1830 from the 1999 ASHG Annual Meeting

Ovarian and breast cancer risks to women in families with 2 or more cases of ovarian cancer. *S. Sutcliffe[1], P. Pharoah[1], D. Easton[2], B. Ponder[1]*. 1) Dept of Oncology, Strangeways Research Labs, Cambridge, U.K; 2) CRC Genetic Epidemiology Unit, Strangeways Research Labs, Cambridge,U.K.

There are few published estimates of the risk of developing breast or ovarian cancer in women with a strong family history of ovarian cancer. These women are typical of those presenting to family cancer clinics for counseling and management, so accurate risk estimates for both breast and ovarian cancer are needed. We have estimated these risks in women from families with two or more confirmed ovarian cancers in first degree relatives using data from the UKCCCR Familial Ovarian Cancer Register. A total of 10757 person years of follow-up data from 309 families were used for the ovarian cancer risk analysis and 11804 person years of follow-up data from 314 families for the breast cancer risk analysis. The number of observed cancers was compared with the number expected based on national, age, sex and period-specific incidence rates for England and Wales. The relative risk of ovarian cancer was found to be 6.70 (95% CI 3.46 - 11.70) and that of breast cancer 2.23 (1.48 - 3.22). When restricting the analysis to families that had tested negative for mutations in the breast/ovarian cancer susceptibility genes, BRCA1 and BRCA2, the ovarian cancer risk was 11.31 (3.64 - 26.39) and that of breast cancer 2.68 (1.22 - 5.09). In addition to its clinical importance, this finding suggests that in these families other breast/ovarian cancer genes are segregating or that BRCA1/2 mutations have been missed. More detailed subgroup analyses will also be presented.

Program Nr: 1831 from the 1999 ASHG Annual Meeting

Inherited Breast/Ovarian Cancer in African-American Families. *R. Sutphen[1, 2], T.M. Ferlita[1]*. 1) H. Lee Moffitt Cancer Center, Lifetime Ca Screening, Tampa, FL; 2) Dept. Clinical Genetics #7815, All Children's Hosp., St. Petersburg, FL.

The majority of studies of BRCA1 and BRCA2 have been performed in Caucasian families with a strong family history of breast cancer and few of the studies have included African-Americans. A few, novel recurrent mutations have been identified in limited studies, indicating that founder mutations are present in the African-American population and additional studies are needed. Related data regarding risk perception and attitudes about genetic testing among African-Americans is also limited. We have identified 43 living patients from the Moffitt Cancer Center Registry with 1)breast cancer diagnosed at age 45 or younger and/or 2)a family history of breast and/or ovarian cancer. Genetic counseling and testing are being offered to these women, including complete sequencing of the coding region of BRCA1 and BRCA2. Psychological measures are employed to explore risk perception, cancer beliefs and attitudes, and distress. Thus far, one African-American woman who was diagnosed with breast cancer at age 29 and who has no known family history of breast or ovarian cancer has had gene testing. A novel BRCA1 mutation, 926ins10, was detected. The preliminary results of our study will be presented, including results of laboratory testing and psychological assessment.

Program Nr: 1832 from the 1999 ASHG Annual Meeting

BRCA1 Mutations: Haplotype and Phenotype Analysis Revisited. *C.I. Szabo[1], E. Fleischmann[2], S. Neuhausen[3], P. Devilee[4], D. Goldgar[1], T. Wagner[2], and the Breast Cancer Linkage Consortium[5]*. 1) Unit of Genetic Epidemiology, International Agency for Research on Cancer, Lyon, France; 2) Department of OB&GYN, Univ. Klinik fur Frauenheilkunde, Vienna, Austria; 3) Genetic Epidemiology, University of Utah, Salt Lake City, UT; 4) Dept. of Human & Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 5) A full listing of contributors to the study will be available in the presentation.

Identification of BRCA1 and BRCA2 and subsequent characterization of mutations in these genes revealed that while the majority of mutations are unique, several are found in multiple families. These frequently described mutations appear to be population-specific (2804delAA in the Netherlands) or, in some instances (5382insC), occur in geographically and ethnically diverse families. Initial international collaborative studies defined the haplotype associated with six frequently reported BRCA1 and nine BRCA2 mutations, and explored mutation-specific phenotypic variation. Two BRCA1 mutations showed evidence for multiple independent mutation origins, with the remainder resulting from ancestral founder events arising between 9 and >100 generations ago. In some instances, mutation-specific differences in phenotype (tumor site) and age of onset were observed. Data for BRCA1, obtained from a larger (5X) series of 185delAG and 5382insC mutation carriers representing greater geographic and ethnic diversity will be presented. Haplotypes associated with previously uncharacterized geographically diverse (300T>G) and population-restricted (1806C>T, 3600del11) BRCA1 mutations will also be described. Additional markers are being incorporated for finer resolution mapping of haplotypes over a longer distances. Age of each mutation will be estimated, and a phylogenetic tree of haplotype alterations will be derived for correlation with ethnic and geographic information. In this manner the place of origin and subsequent spread of these mutations to other regions of Europe, and the relevant populations in the United States, Canada and Australia will be characterized. Preliminary analyses of 185delAG and 5382insC indicate extensive haplotype sharing of an ~900 kb region.

Program Nr: 1833 from the 1999 ASHG Annual Meeting

The effects of glutathione-related genes and cigarette smoking on lung cancer short-term survival. *K. Taniguchi, P. Yang, R. Marks, T. Lesnick, A. Yokomizo, J. Sloan, D. Miller, J. Jett, H. Tazelaar, E. Edell, D. Smith, W. Liu.* Mayo Clinic, Rochester, MN.

Genes encoding glutathione (GSH) synthetase and transferases could be useful in predicting lung cancer prognosis because several GSH-related metabolic enzymes could inactivate anti-cancer drugs. We hypothesize that patients with genotypes corresponding to low activity levels of GSH-related enzymes are associated with better lung cancer survival. In a pilot study, we included 313 patients diagnosed in our institution and followed up for one year. Each patient completed a baseline interview regarding cigarette smoking status and family history of cancer and other pulmonary diseases. Medical records were abstracted to obtain clinical staging, histopathology, and treatment data. One hundred and six patients were genotyped at four GSH-related loci: *GSTP1, GSTM1, GSTT1,* and g-*GCS*. The cutpoint of 40 pack-years was used for defining light/moderate vs heavy smokers in our analysis. There were 194 males (62%) and 45 never-smokers (14%). The crude one-year survival rate was 51%. For cases with early- vs late-stage at diagnosis, the survival rates were 83% and 42%, respectively. The survival rates for patients with *null* genotype at two of the four loci (*NN*) was compared to patients with a *positive* genotype at one or both loci (*other*). We found an overall higher survival rate for patients with *NN* (73-86%) than patients with *other* genotypes (59-60%). In heavy smokers, the one-year survival rate was 71-100% in NN group compared to the 65-70% rate otherwise. This disparity between contrasting genotypes among late-stage patients (who usually underwent chemotherapy) was larger than among early-stage patients (who were mainly treated by surgical resection). The survival rate among late-stage patients with NN was approximately 20% higher than patients with *other* genotype. Among late-stage patients who were heavy smokers, the survival rate was 43-67% for NN and 17-33% for *other* genotype. These preliminary data reflect a clinically significant effect although questions involving confounding influences remain. Further investigation with a larger sample is warranted.

Program Nr: 1834 from the 1999 ASHG Annual Meeting

Novel genes in Acute Myeloid Leukemia with Trisomy 8. *S.M. Tanner[1], K. Virtaneva[1], L. Rush[1], M.A. Caligiuri[2], C.D. Bloomfield[2], K. Mrózek[2], C. Plass[1], R. Krahe[1], A. de la Chapelle[1]*. 1) Human Cancer Genetics, Ohio State University, Columbus OH; 2) Comprehensive Cancer Center, Ohio State University, Columbus OH.

Acute myeloid leukemia (AML) is a histopathologically, cytogenetically, and clinically heterogeneous neoplasia. About 55% of de novo AML cases reveal clonal cytogenetic abnormalities while the remaining ones have normal karyotypes. Trisomy 8 is the most frequently encountered aneuploidy in AML (AML+8), either as a sole abnormality or as part of a more complex pattern of abnormalities. AML+8 is associated with poor prognosis, and the molecular mechanisms related to the role of trisomy 8 in AML are unknown. We entertain two hypotheses. First, in concordance with recent findings in trisomy 11 AML, molecular rearrangements of (a) gene(s) on chromosome 8 might be associated with AML+8. Second, trisomy 8 might cause changes in gene expression patterns that lead to or contribute to AML. In order to address both possibilities, we performed cDNA based Representational Difference Analysis (RDA) to compare a pool of AML+8 cells with a pool of AML cells with normal karyotypes. To exclude cryptic chromosome rearrangements, the cytogenetic findings were confirmed by spectral karyotyping (SKY). Using the AML+8 cells as the RDA-tester, we prepared and sequenced 209 different clones from mRNAs presumably present in trisomic and absent in disomic cells. A subsequent BLAST search of GenBank and TIGR databases identified 27 different known genes, five ESTs, and five unknown sequences. We selected two genes, two ESTs, and one unknown sequence for detailed studies and confirmed by comparative RT-PCR that the two genes and one EST were indeed more highly expressed in trisomic than in disomic AML cells. This EST was shown to be expressed only in brain and AML+8 cells, and its genomic location is currently being defined. The second EST was mapped to chromosome 5p13 and the unknown sequence was located on chromosome 14q32. The cDNA sequences and the genomic structure of these candidate leukemia genes are under investigation. Gene expression studies and mutation analysis will help to elucidate the role of these novel genes in the pathogenesis of AML+8.

Program Nr: 1835 from the 1999 ASHG Annual Meeting

YAC-BAC contig of the Carney complex (CNC) critical region on 2p16 and copy number gain of 2p16 in CNC tumors: evidence for a novel oncogene? *S.E. Taymans[1], L.S. Kirschner[1], S. Pack[2], C. Giatzakis[1], C.A. Stratakis[1]*. 1) Genetics & Endocrinology/DEB/NICHD/NIH, Bethesda, MD; 2) Laboratory of Pathology/NCI/NIH, Bethesda, MD.

Carney complex (CNC)(MIM 160980) is an autosomal dominant multiple endocrine neoplasia and lentiginosis syndrome characterized by spotty skin pigmentation, cardiac, skin, and breast myxomas, and endocrine tumors. Linkage analysis placed the first CNC locus at 2p15-p16, between D2S391-D2S378, but a second locus was recently identified at 17q22-24. We are using both positional cloning techniques and molecular cytogenetic studies of tumors to identify the gene causing CNC. A high resolution physical map of the CNC locus on 2p16 was built, using YAC and BAC clones, by STS and EST content mapping and chromosomal walking. Over 100 ESTs from online databases of 2p15-p16 were screened against our contig. 78 unique ESTs were placed in the contig, and 30 were excluded from the region. Four new genes were identified, fully characterized, and excluded as candidates. Positional cloning of genes for familial tumor syndromes is assisted by use of tumor tissue from affected patients. We used polymorphic STSs and BAC clones from the CNC locus on 2p16 to examine DNA from various CNC tumors or tumor cell lines for alterations. Loss of heterozygosity was not present for STSs from 2p16 in CNC tumors. In normal tissue the BACs hybridized specifically to 2p15-p16 as the expected 2 copies. However, in CNC tumors 2p15-p16 BACs were amplified. The degree of amplification varied, and not all BACs were amplified in every tumor. A particular BAC clone from the core of the CNC critical region, containing 5 unique ESTs, including CNC candidate genes, showed the most consistent and greatest level of amplification. This BAC was amplified several hundred fold in pituitary and thyroid tumors; but was specifically deleted in 2/8 adrenocortical tumors, suggesting that deletion of one allele precedes amplification of the other. 2p16 participates in tumor formation in CNC with apparent gain of its genomic material in the process. Together, our contig and cytogenetic data provide an excellent resource for identifying the CNC gene.

Program Nr: 1836 from the 1999 ASHG Annual Meeting

FISH studies of peripheral blood cells for monitoring therapy in chronic myeloid leukemia (CML). *A. Tchirkov, G. Briançon, M. Giollant, P. Travade, G. Lacroute, F. Ait-Ouaret, F.A. Shah, P. Malet.* University of Auvergne, Faculty of Medicine, Clermont-Ferrand, France.

Conventional cytogenetic studies are useful to monitor therapy in CML patients, but regular follow-up requires frequent invasive bone marrow (BM) aspirates. In this study we evaluated the quantification of CML cells using FISH for BCR-ABL in peripheral blood (PB) samples, which can be easier collected from the patients, as a method of monitoring the response to interferon-alpha therapy. The metaphase and/or interphase FISH investigations were performed on cultured and uncultured PB, and the results were compared with BM cytogenetics. In PB cultures, leukemic cells were efficiently detected in 15 samples obtained from 10 patients when there was no hematologic response. In contrast, the percentage of BCR-ABL-positive cells was non significant in 19 samples obtained from 15 patients during complete hematological remission. However, these patients had substantial numbers of Philadelphia-positive cells in BM. This suggests that normal BCR-ABL-negative PB cells may be selected by culture conditions and the FISH approach with PB cultures is not adequate for evaluating residual disease in CML patients with hematologic response. Importantly, the levels of leukemic cells detected in uncultured PB specimens from these patients processed directly for FISH studies compared favourably with BM data. Thus, interphase FISH analysis of uncultured PB may be useful for follow-up investigations in CML patients.

Program Nr: 1837 from the 1999 ASHG Annual Meeting

Geneological and genetic correlation in Finnish Multiple Endocrine Neoplasia Type 1 (MEN 1) families. *B.T. Teh[1], S. Kytölä[1], F.K. Wong[1], A. Villablanca[1], B. Nord[1], C. Larsson[1], T. Ebeling[2], L. Ukkola[2], O. Vierimaa[2], P. Salmela[2], J. Leisti[2]*. 1) Molecular Medicine, Karolinska Hospital, Stockholm, Sweden; 2) Clinical Genetics and Internal Medicine, Oulu University Hospital, Oulu, Finland.

In Finland more than 30 monogenic disorders are known to be clustered in specific regions. The occurrence of MEN 1 shows geographical concentration, with the majority of hitherto identified Finnish families originating from and residing in the Northern parts of the country. In this study we attempted to characterize the spectrum of MEN1 mutations in the Finnish population and to correlate the mutations with our geneological data. Twenty-six clinically confirmed MEN 1 cases representing twenty two families and four isolated MEN 1 cases were screened for MEN1 mutations by SSCA and DNA sequencing. In addition, the disease-associated haplotypes of each case was determined by genotyping 11q13 markers spanning the MEN1 region. Six different mutations were identified in 17 of the cases, while in the remaining nine cases no mutation has been identified yet. 1466del12 was seen in nine families, 1657insC in three families, R527X in two families, D418N,G42A, and 359del4 were found in one family each. All nine families with the 1466del12 mutation were shown to share the same affected haplotypes, thus indicating that the mutation occurred on a common ancestral chromosome. This was confirmed by subsequent geneological search which traced the roots of eight families to a small village approximately 45 kilometers East of Oulu, where the founder couple was born in 1705 and 1709, respectively. In the ninth family the geneological connection has not yet been established. The pedigree consists of about 6-10 generations, when counted from the present-day patients. Three families with 1657insC-mutation could be traced back to a couple living 200 kilometres Northeast from Oulu born in 1844 and 1846, who were four generations from the youngest living patients. In conclusion, the genetic-genealogical correlation established two founder MEN1 mutations in Northern Finland. It is therefore worthwhile to screen for these two mutation in new Finnish MEN1 patients.

Program Nr: 1838 from the 1999 ASHG Annual Meeting

ATM Mutations in Breast Cancer Patients with Early-onset or Family History. *S.N. Teraoka[1], K.E. Malone[2], E.A. Ostrander[3], J.R. Daling[2], P. Concannon[1].* 1) The Program in Molecular Genetics, Virginia Mason Research Ctr, Seattle, WA; 2) Division of Public Health, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Division of Clinical Research, Fred Hutchinson Cancer Research Center, Seattle, WA.

We are screening for mutations in the ATM gene among individuals drawn from a population-based study of breast cancer in a 3 county area of Western Washington. Breast cancer cases have been selected based on meeting one of 2 criteria, early-onset (diagnosed by age 35), or having a first degree relative with breast cancer. To date, we have screened 142 cases and 80 matched controls. The 62 ATM coding exons were amplified by multiplex PCR and screened by SSCP. No truncation or deletion mutations were detected. However, possible ATM missense mutations were detected in 7.7% (11/142) of total cases, versus 1.25% (1/80) in controls. All 11 of the cases with possible mutations had some family history of breast cancer. Of 64 cases with a first degree relative with breast cancer, 8 (12.5%) had ATM missense mutations. Among the 99 cases diagnosed at age 35 or less, 4 (4%) had ATM missense mutations. An additional 27 individuals with rare variants that resulted in amino acid substitutions were also identified (17 in cases, 10 in controls). Some of these rare variants may also represent mutations, but their effects will require further functional studies. We have recently shifted our screening approach to utilize denaturing HPLC and have obtained increased sensitivity over SSCP for the detection of single nucleotide substitution in the ATM gene.

Program Nr: 1839 from the 1999 ASHG Annual Meeting

Rearrangements of both chromosomes 22 in a rhabdoid tumor. *I. Teshima, G. Nie, P.S. Thorner.* Pediatric Lab Medicine, Hosp Sick Children, Toronto, ON, Canada.

Malignant rhabdoid tumors are aggressive tumors that usually occur in children less than two years of age. The tumor was originally described in kidney but can occur in brain, liver, and soft tissues. Classification has been difficult because histological characteristics are variable depending on location. The cell of origin is not known. Because the prognosis for rhabdoid tumors is poor, aggressive therapy is required. Accurate diagnosis is thus important and now includes genetic criteria. Cytogenetic studies of rhabdoid tumors had suggested a common genetic basis for the brain, renal and extrarenal rhabdoid tumors with monosomy 22 being the most common finding. The region involved was localized to 22q11.2. A tumor suppressor gene was postulated with homozygous alterations required for oncogenesis. The candidate gene, INI1, encoding a member of the chromatin remodeling SWI/SNF multiprotein complex, has now been identified. The SWI/SNF complex is capable of opening up nucleosomes to facilitate transcription. Biegel et al.(Cancer Res 59:74-9; 1999) in a study of rhabdoid tumors found homozyous alterations of INI1 in 15 tumors and mutations in 14 tumors; germline mutations were found in 4 of the children with these tumors. An extrarenal rhabdoid tumor presented as a soft tissue tumor in a 9-year-old boy. WT1 was strongly expressed. G-banding of tumor cells revealed two somatic rearrangements, each involving a different homologue of chromosome 22 with breakpoints 22q11.2~12. A translocation between 15 and 22 and a complex rearrangement involving 1, 6, 13, and 22 were present along with a normal 46,XY cell line. This was demonstrated using FISH probes for TUPLE1 (22q11.2)/ARSA (22q13) and BCR (22q11.2), SKY, and paints for 1, 6, 13 and 22. At least 14 cases of rhabdoid tumors with one translocation involving chromosome 22 have been reported. While the loss of the INI1 gene was not directly shown in this case, the presence of two rearrangements in the vicinity of this gene is consistent with the requirement for inactivation of both alleles in the development of this tumor and served as a diagnostic aid for the identification of the tumor in this case.

Program Nr: 1840 from the 1999 ASHG Annual Meeting

Detection of RB1 deletion by primed in situ labeling (PRINS). *S.A. Tharapel[1], J.S. Kadandale[2].* 1) Dept Pediatrics/Div Genetics, VA Med Ctr and Univ Tennessee, Memphis, TN; 2) Clinical and Molecular Cytogenetics Laboratory, Department of Pediatrics, University of Tennessee, Memphis, TN.

Chromosome band 13q14 which contains the retinoblastoma gene (RB1), has been implicated in an array of human malignancies including retinal tumors and certain leukemias. Approximately 10% of B-cell chronic lymphocytic leukemias (CLL) are known to have structural abnormality involving the 13q14 region. Commercial FISH probes have enhanced our ability to identify small deletions including RB1. To assess the feasibility and to develop a less expensive alternative to FISH, we modified the primed in situ labeling (PRINS) technique to enable detection of RB1 deletion. Our study group consisted of 5 patients with 13q14 deletion (demonstrated by convetional cytogenetics and FISH), and 5 normal controls. The method involved use of locus-specific oligonucleotide primers for the RB1 locus in the presence of dATP, dCTP, dGTP, dTTP and digoxigenen-11-dUTP, Tris-HCl, KCl, MgCl2, BSA and Taq DNA polymerase. Annealing and extension were performed on one-day-old chromosome preparations. For each patient and control, 30 cells were analyzed under a fluorescence microscope. The patients' cells were remarkable for absence of labeling for RB1 on one chromosome 13, consistent with the deletion. A normal pattern was seen in the 5 controls. In view of our experience with PRINS localizing of other genes and regions (SRY, SOX3, GABRB3, SNRPN, D22S1638, D22S1648 and AZF) (our unpublished data) we conclude that PRINS is a sensitive and valuable alternative to FISH for the detection of constitutional and acquired chromosomal deletions and rare translocations.

Program Nr: 1841 from the 1999 ASHG Annual Meeting

Evidence for Genotype-Phenotype Correlations in BRCA2. *D.J Thompson, D.F Easton, on behalf of the Breast Cancer Linkage Consortium.* CRC Genetic Epidemiology Unit, University of Cambridge, Cambridge, ENGLAND.

Mutations in BRCA2 confer susceptibility to breast and ovarian cancer. In 1997 Gayther *et al.* identified a 3.3kb region of exon 11 in which mutations appeared to confer a higher risk of ovarian cancer relative to breast cancer than mutations elsewhere in the gene. This section was named the Ovarian Cancer Cluster Region (OCCR). The OCCR coincides with the coding region for a sequence of internal repeats in the BRCA2 protein which have been shown to interact with the RAD51 DNA repair gene and are thought to play an important role in BRCA2's function.

Here we present the results of a study based on a much larger set of 164 families with BRCA2 mutations (including 69 with at least one case of ovarian cancer) to test and evaluate the OCCR effect. Sixty-seven of these families had mutations in the OCCR.

The odds ratio for ovarian versus breast cancer in families with mutations in the OCCR, relative to non-OCCR mutations, was significantly greater than one (odds ratio=3.86, P<.0001, using a randomisation test), confirming the observation that cancer risks are different in this part of the gene. No other significant differences in risk by mutation position were observed.

This does not differentiate between an increased ovarian risk, a reduced breast cancer risk for OCCR mutations relative to the rest of the gene, or a combination of both. To establish the size and significance of each effect the cancer risks for OCCR mutations relative to non-OCCR mutations were estimated. Population frequencies of each BRCA2 mutation are unknown, so risks were estimated using a likelihood conditional on the set of mutations observed in the study.

The maximum likelihood estimates of the relative risks were 0.65 for breast cancer (95% CI=0.48-0.88) and 1.34 for ovarian cancer (95% CI=0.86-2.09). Thus there is significant evidence that the risk of breast cancer is lower for mutations within the OCCR than for mutations outside it, but the evidence that OCCR mutations confer a higher risk of ovarian cancer is weaker.

Program Nr: 1842 from the 1999 ASHG Annual Meeting

Homozygous deletion of CDKN2A (p16/p14) in neuroblastomas. *P.M. Thompson[1], J.M. Maris[1], M.D. Hogarty[2], R.C. Seeger[2], C.P. Reynolds[2], G.M. Brodeur[1], P.S. White[1].* 1) Division of Oncology, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, University of Southern California School of Medicine, Los Angeles, CA.

Neuroblastoma (NB) is the most common pediatric extra-cranial solid tumor. Loss of heterozygosity of several specific genomic regions is frequently observed in NB tumors and cell lines, but homozygous deletion (HD) has been reported in only two cell lines, once each at the NF1 and CDKN2A tumor suppressor genes (TSG). Furthermore, no TSG mutations have been reproducibly identified in NB. We performed a comprehensive search for homozygous deletions (HD), indicative of a disrupted TSG, in a panel of 46 NB cell lines. Our initial search focused upon a well-characterized consensus region of hemizygous deletion (SRO) at 1p36.3 which occurs in 35% of NB tumors. We used a PCR assay to screen each cell with 163 1p36 markers, yielding resolutions of 20 kb within the 1p36.3 SRO and 250 kb throughout 1p36. No homozygous deletions were detected. This approach was expanded to survey 21 known TSGs, specifically targeting intragenic regions most frequently disrupted in other malignancies. HD was detected only at the CDKN2A gene at 9p21 and was observed in 4 of 46 cell lines. The CDKN2A gene produces two overlapping proteins, p16 and p14, which are involved in cell cycle regulation and are disrupted in many malignancies. The observed region of HD included all exons of both CDKN2A and the neighboring CDKN2B (p15) locus for cell line L-AN-6; exons 1 and 2 of CDKN2A and all of CDKN2B for CHLA-174; exons 1 and 2 of CDKN2A for CHLA-179, and only 104 base pairs of exon 2 for CHLA-101. All four rearrangements are predicted to completely or extensively disrupt the coding region of both p16 and p14. HD was observed in a corresponding primary tumor sample only for CHLA-174, which is the first reported incidence of HD in a NB primary tumor, but was not present in constitutional samples. These results suggest that large HDs do not occur within 1p36 in NB, that most known TSGs are not homozygously deleted, and that biallelic inactivation of CDKN2A may be a significant contributor to tumorigenicity in NB.

Program Nr: 1843 from the 1999 ASHG Annual Meeting

Varied effects of a BRCA2 founder mutation. *S. Thorlacius[1], G.H. Olafsdottir[2], L. Tryggvadottir[2], H. Tulinius[2], J.E. Eyfjord[1]*. 1) Dept Molecular & Cell Biol, Icelandic Cancer Society, Reykjavik, Iceland; 2) Cancer Registry, Icelandic Cancer Society, Reykjavik, Iceland.

Breast carcinoma is the most common malignancy among women in developed countries. The contribution of the BRCA1 and BRCA2 genes has been estimated to be 5-10% of all breast cancer. Based on breast cancer families with multiple and/or early-onset cases, estimates of the lifetime risk of breast cancer in carriers of BRCA1 or BRCA2 mutations is varied but may be as high as 85%. Knowledge on the interaction between environmental agents and BRCA mutations in mutation carriers remains unclear. The Icelandic population has a strong founder BRCA2 mutation. We have detected the BRCA2 999del5 germline mutation in 0.6% of the population, 8% of female breast cancer patients, and in 40% of males with breast cancer. The mutation is strongly associated with younger onset of female breast cancer. In a population based study we estimated the risk of breast cancer for a 999del5 mutation carrier to be 37% at age 70. We have studied various BRCA2 families and find different pattern of disease. In some families male mutation carriers develop prostate cancer while in others they are at increased risk of breast cancer. These two cancer types are rarely found occurring in the same families. There are indications of anticipation in BRCA2 families, mainly seen as a higher penetrance or earlier onset in younger generations. It is clear from our studies that factors other than BRCA2 influence cancer risk in this population. These findings suggest that individual risk assessment will always have to take account of family history.

Program Nr: 1844 from the 1999 ASHG Annual Meeting

HER2/neu analysis of paraffin-embedded thymoma and thymic carcinoma specimens. *V.C. Thurston[1], P. Loehrer[2], J. Henley[3], G.H. Vance[1]*. 1) Dept Medical & Molecular Gen, Indiana Univ, Indianapolis, IN; 2) Dept of Medicine, Indiana Univ, Indianapolis, IN; 3) Dept of Pathology, Indiana Univ, Indianapolis, IN.

Thymomas and thymic carcinomas are malignant neoplasms derived from thymic epithelial cells and together represent the most common primary anterior mediastinal tumor in adults. The majority of thymic neoplasms are cytologically benign, encapsulated tumors known as thymomas. Despite their benign appearance, approximately 30-40% of thymomas exhibit malignant behavior and progress or recur with locally advanced, unresectable disease or distant metastases. There exists a lack of reliable pathological or molecular correlates of tumor aggressiveness. We present preliminary data of FISH analysis (Oncor INFORM "HER2/neu" probes) on nine of twenty-five paraffin-embedded tumors. Pathologic diagnosis of the specimens included two thymic carcinomas and seven thymomas (two encapsulated, three invasive and two metastatic thymomas). Forty nuclei were scored per specimen. An average of 1.83 signals/nuclei was found in all samples with an average of 1.9 signals/nuclei in thymic carcinomas; 1.79 signals/nuclei in invasive thymomas; 1.91 signals/nuclei in metastatic thymomas and 1.86 signals/nuclei in thymomas. These results are considered normal. Thus, in this initial group of tumors there is no evidence of HER2/neu amplification.

Program Nr: 1845 from the 1999 ASHG Annual Meeting

Contribution of founder BRCA1 and BRCA2 mutations in French Canadian HBC and HBOC families. *P.N. Tonin[1], D. Provencher[2,3], A.-M. Mes-Masson[2,3], S. Narod[4], W. Foulkes[1], P. Ghadirian[3,5]*. 1) McGill U & MUHC; 2) CHUM Hopital Notre Dame; 3) U of Montreal; 4) Women's College Hospital; 5) CHUM Hopital Hotel Dieu.

Germ-line BRCA1 and BRCA2 mutations account for a large proportion of hereditary breast cancer (HBC) and breast-ovarian cancer (HBOC) families. Mutation analysis has been facilitated by the identification of founder mutations in well defined ethnic groups. Recently we reported founder BRCA1 and BRCA2 mutations in 40/97 families of French Canadian ancestry containing a minimum of three cases of breast and/or ovarian cancer. Here we examine the contribution of the founder mutations in a large series of French Canadian families (n=123) with a minimum of four cases of breast-(dx less than 66 yrs) and/or ovarian-cancer. Genomic DNA from an affected case from each family was analyzed for the presence of BRCA1 (C4446T, 2953del3+C and 3768insA) and BRCA2 (2816insA, G6085T, 6503delTT and 8765delAG) founder mutations. Founder BRCA1 (n=28) and BRCA2 (n=30) mutations were found in 58 families. The BRCA1 C4446T (n=23) and BRCA2 8765delAG (n=15) mutations were the most common mutations identified. Families which harbour the founder mutations were not restricted to Montreal area of ascertainment. A founder BRCA1 mutation was more often identifed in a HBOC (20/54) than a HBC (8/69) family; whereas, a founder BRCA2 mutation was more often identified in a HBC (23/69) than a HBOC (7/54) family. Mutations were identified in all four families (BRCA1 (n=1); BRCA2 (n=3)) with at least one male breast cancer case. The identification of founder mutations will facilitate carrier detection and genetic counselling in French Canadian HBC and HBOC families. In our continuing examinination of founder mutation-negative families, we have uncovered three mutations not previously described in families of French Canadian descent. To date, the analysis of mutation-negative families has revealed that these new mutations are not common in this population. The sequence analysis of BRCA1 and/or BRCA2 in index cases from of a subset of the mutation-negative families (n=10) support the hypothesis that additional factors may be contributing to HBC and HBOC families in the French Canadian population.

Program Nr: 1846 from the 1999 ASHG Annual Meeting

Gene variation and cancer risk: generation of complex haplotypes at the *BLM, WRN* and *ERCC1* loci. *D. Trikka, Z. Fang, D.L. Nelson.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The aim of the project is to develop biallelic markers for each of 25 genes known to be involved in carcinogenesis. Haplotypes based on these markers should provide sufficient information to determine whether certain gene variants (marked by haplotypes) can be associated with a higher or lower risk of tumor development in the general population. Using the genomic sequence data developed in our laboratory, as well as that already available in the databases, we have begun to identify 8-12 single nucleotide polymorphisms (SNPs) per gene. Steps towards the identification of SNPs include screening of BAC and PAC libraries, creation of contigs and sequence analysis of clones for each of 20 genes that have been shown to play a role in carcinogenesis. In parallel, the sequence data that is already available is used in designing PCR primers, randomly spaced along the gene, amplification of the corresponding regions and direct sequencing. The results of the sequence analysis of three genes (*BLM*, *WRN* and *ERCC1*) that were screened for SNPs in this manner are presented here. The genomic sequence of all genes was already available to us. Identification and characterization of the single base changes was carried out by PCR amplification and direct sequencing of the amplified regions in five unrelated individuals. Coding regions were avoided. Ten, fifteen and eleven SNPs were identified within the *BLM*, *WRN* and *ERCC1* genomic regions, respectively. Our data is in agreement with the expected SNP frequency of 1 every 1kb. Allele specific oligo (ASO) hybridization was subsequently used to determine the haplotypes for *BLM* and *WRN*, in 10 CEPH families and 250 samples of different ethnic background (70 Caucasians, 70 Blacks, 70 Hispanics and 40 Asians). Haplotype frequencies were ascertained by computer-assisted statistical analysis based on maximum-likelihood estimates. The haplotype data created this way will be used to compare the haplotype frequencies of human samples ascertained for specific phenotypes and thus determine the role of gene variation in the phenotypic differences selected.

Program Nr: 1847 from the 1999 ASHG Annual Meeting

Comparison of FISH & IHC Techniques in the Detection of HER-2/neu Amplification in Breast Cancers. *A.J. Tsai, M.R. Quddus, M.M. Steinhoff, U. Tantravahi.* Departments of Pathology & Molecular Cytogenetics, Women & Infants Hospital, Providence, RI.

Her-2/neu status has been found to be an important parameter in the treatment strategy of breast carcinoma. Investigators have shown that assessment of Her-2/neu status varies with technique used. The majority of the current testing for overexpression is based on immunohistochemical (IHC) staining of the gene product (protein). A fluorescent *In-situ* hybridization (FISH) gene amplification test has been introduced recently which determines amplification at the gene level. The current study was designed to compare both tests for efficient detection of the status of the oncogene in breast cancers.

Forty-six archival paraffin embedded breast cancer tissues that had previously been assessed for Her-2/neu protein amplification using IHC technique were obtained from the Department of Pathology, Women & Infants' Hospital. FISH was performed on 4m tissue sections. A DNA probe for Her-2/neu gene (Oncor) was used which directly assessed gene amplification rather than gene product. Hybridization signals were detected using Digoxigenin Rhodamine Detection Kit. A total of 50 cells were scored from each slide in a blinded fashion using a fluorescent microscope with triple band filter. Cells with >4 signals were considered to have Her-2/neu gene amplification. Signals of the adjacent normal tissue areas were counted as an internal control.

In 21.8% cases both FISH & IHC were positive for Her-2/neu amplification. In 34.4% cases FISH was positve while IHC being negative. Both were negative in 34.8% cases. Only in 8.6% cases IHC was positive and FISH being negative.

Our study revealed FISH & IHC were in agreement about Her-2/neu amplification status in 56.6% of time. The two techniques were in disagreement in approximately 43.4% of the cases, in 34.8% of cases Her-2/neu was detected by FISH & not by IHC clearly indicating that FISH is a more sensitive technique in detecting Her-2/neu gene amplification.

Program Nr: 1848 from the 1999 ASHG Annual Meeting

Identification of breast-ovarian cancer families without BRCA1 or BRCA2 mutations.. *M. Unger[1], K.L. Nathanson[1], D. Antin-Ozerkis[1], A.M. Martin[1], H.A. Shih[1], K.A. Calzone[1], T. Ward[1], S. Mazoyer[3], T. Rebbeck[2], B.L. Weber[1]*. 1) Depts of Medicine & Genetics and; 2) Dept of Biostatistics & Epidemiology, U of Penn, Phila, PA; 3) IARC, Lyon, France.

Data from the Breast Cancer Linkage Consortium suggest that 83% of families with ³4 cases of breast cancer before the age of 60 and 1 case of ovarian cancer can be linked to mutations in BRCA1 or BRCA2; or 98% if there is ³2 cases of ovarian cancer. These data have led to the hypothesis that BRCA1 and BRCA2 may fully account for all hereditary breast and ovarian cancer. Since families seen in high-risk evaluation clinics tend to have less extensive cancer histories than those studied by the BCLC, the 83% and 98% of mutations may be higher than those typically found in the population. Our objectives are: a) to determine the probability of identifying a BRCA1 and/or BRCA2 mutation in br/ov families identified through a high-risk clinic and b) to identify br/ov families without BRCA1 or BRCA2 mutations.

We selected 116 families with at least one case of female breast and ovarian cancer in the same lineage. One affected member of each family was screened for BRCA1 and BRCA2 coding region and splice junction mutations using CSGE or sequencing. To date, 67 (58%) of the 116 families carry alterations in BRCA1 and/or BRCA2. This percentage increases to 82% if the family has at least one case of breast and ovarian cancer in a single person. Six families(5%) have uncertain variants in BRCA1 or BRCA2. Testing is still pending on 10 families. Lastly, 33 families (28%) have tested negative for BRCA1 and BRCA2. In order to ensure non-coding mutations in BRCA1 are not missed by this screen, BRCA1 and BRCA2 negative families are being analyzed for large genomic deletions.

Our preliminary results suggest that incidence of BRCA1 and BRCA2 mutations in families with multiple cases of breast and ovarian cancer or a case of breast and ovarian cancer in a single individual may approach that found in the BCLC data set. However, smaller families, typically seen in a high-risk clinic may have a lower frequency of mutations.

Program Nr: 1849 from the 1999 ASHG Annual Meeting

SAGE as a tool to identify MYCN downstream pathways in Neuroblastoma. *R. Versteeg, H. Caron, P. Van Sluis, I. Roobeek, K. Boon.* Dept. of Human Genetics, Academic Medical Center, Amsterdam, Netherlands.

SAGE (Serial Analysis of Gene Expression) enables the identification and quantification of all transcripts expressed in a tissue or cell line. We have applied SAGE to identify pathways deregulated in neuroblastoma. Neuroblastoma is a childhood tumor with a heterogeneous clinical outcome. Genetic defects predictive for aggressive neuroblastoma are MYCN amplification, chromosome 1p deletions and extra copies of chromosome 17q. MYCN was identified as a transcription factor, but its downstream pathway is unknown. Analysis of chromosome 1p deletions and chromosome 17q gains revealed that the regions involved are surprisingly large and probably harbor a series of tumor suppressor genes and oncogenes with a role in neuroblastoma pathogenesis. The length of deletions and their complexity has precluded molecular identification of the involved genes so far. We have set out to apply high-througput technologies emerging from the Human Genome project to study these issues. We have established five SAGE libraries, both from MYCN amplified and from MYCN single copy neuroblastoma. We have presently sequenced 65.000 SAGE tags, each corresponding to and identifying a single transcript. By comparing four relatively small SAGE databases, we identified a series of genes potentially under control of MYCN. Northern blot analysis confirmed that 10 of them indeed are strongly induced by MYCN, thus enabling us to identify components of the MYCN downstream pathway activated in neuroblastoma. In addition, we use the database to establish gene expression profiles in neuroblastoma of the 1p35-36 and 17q regions implicated in pathogenesis. The relevant regions were defined by analysis of a panel of 200 neuroblastomas. The genes in these regions were identified on the radiation hybrid map (HGM99). Analysis of our SAGE database showed expression for about 40% of the genes in these regions. Together these data give ample new opportunities to study neuroblastoma pathogenesis and find new targets for therapeutic intervention.

Program Nr: 1850 from the 1999 ASHG Annual Meeting

Functional properties of PAX7 and PAX7-FKHR: A comparative analysis of cell response to ectopic expression of these genes. *E.V. Vorobyov[1], U. Siebers[1], K. Wilke[1], H.-G. Pauels[2], A. Julich[1], B. Dworniczak[1], J. Horst[1]*. 1) Inst. fuer Humangenetik; 2) Inst. fuer Immunologie, Westfaelische Wilhelms Univ, Muenster, Germany.

The PAX3-FKHR and PAX7-FKHR hybrid genes, resulting from similar chromosomal translocations in alveolar rhabdomyosarcoma, are assumed to play an important role in the development of this tumor. In the respective chimeric proteins C-termini of PAX3 and PAX7 are replaced by the FKHR protein moiety, that leads to functional changes of these transcriptional factors. To examine the functional properties of the intact PAX7 and chimeric PAX7-FKHR gene we carried out a systematic comparative analysis of changes in general cell features caused by ectopic activities of these genes. Stable cell lines expressing the corresponding proteins were derived from NIH3T3 cells and characterized in relation to the progenitor cells. These experiments revealed a dual nature of the PAX7 function. PAX7 can simultaneously be characterized as a potential tumor suppressor and a potential proto-oncogene, while its tumor suppressor-like features predominate. As a tumor suppressor-like gene PAX7 negatively controls cell proliferation, enhances contact inhibition and suppresses anchorage-independent growth. As an oncogene PAX7 prevents cells from apoptosis, inhibits cell differentiation and activates an autocrine growth stimulation. In contrast, expression of PAX7-FKHR results in neoplastic transformation: the cells loose contact inhibition, acquire anchorage-independence and gain the ability to form tumors in vivo. However, some changes in cell characteristics which are caused by PAX7 gene expression, such as autocrine growth stimulation, prevention of apoptosis and differentiation, are retained and even enhanced by expression of PAX7-FKHR. Thus, alterations of the PAX7 function in its chimeric version cannot simply be characterized as a general loss or gain of the PAX7 function. They could rather be considered as a loss of one set of functions, combined with a gain of another set of functions: the PAX7 role in negative growth control is abolished and its oncogenic features are enhanced.

Program Nr: 1851 from the 1999 ASHG Annual Meeting

***BRCA1* Analysis by DHPLC in 272 Austrian Breast Cancer only and Breast and Ovarian Cancer Families.** *T. Wagner[1], R. Moeslinger[1], E. Fleischmann[1], D. Muhr[1], M. Hareter[1], P. Kofler[1], Austrian HBOC Group[1], T. Helbich[2], C. Zielinski[3], P. Oefner[4].* 1) Dept OB/GYN, Div Senology, Univ Vienna, Vienna, Austria; 2) Dept Radiology, Univ Vienna, Vienna Austria; 3) Dept of Medicine I, Div Oncology, Univ Vienna, Vienna, Austria; 4) Dept of Biochemistry, Stanford Univ, Stanford.

In this study 272 Austrian families with hereditary breast cancer only (HBC) or breast and ovarian cancer (HBOC) were analyzed by DHPLC for sequence variants in the breast cancer gene 1 (BRCA1): In 54 (20%) HBC/HBOC families 27 different disease associated mutations were identified. Furthermore in 10 families 8 unique sequence variants of unknown functional relevance could be detected. In the total set of 275 families 32 different polymorphisms with heterozygosities of 1 of 43% were present. In 61 families (22%) with HBOC cases 25 (41%) BRCA1 mutation were identified. Ranging from 30% in families with only 1 BC to 67% in families with 3 BC cases in addition to at least 1 OC case. The overall percentage of BRCA1 mutations was 13% in the 194 (71%) HBC families. The highest percentage (26%) was observed in families with BC that occurred before the age of 30. Nine founder mutations were detected in 36 families. The most frequently detected mutation was 1806CtoT (7 families) that occurred only in Carinthia and the South of Styria. This mutation is also frequent in the south of Sweden and all families from Austria and Sweden share a common ancestor. The missense mutation 300TtoG occurred in 6 families that also share a common ancestor. This mutation is found throughout of Europe. We conclude that 40% of Austrian HBOC families and 13% of HBC families can be explained by BRCA1 mutations. More that 60% of all mutation families are identified with 1 of the 9 founder mutations in Austria. However the BRCA1 mutations detected in the remaining 18 families are scattered throughout the whole gene. A fact that makes whole gene screening mandatory in Austrian HBC/HBOC families.

Program Nr: 1852 from the 1999 ASHG Annual Meeting

Loss of heterozygosity of 5q in sporadic hemangiomas suggests that somatic mutations are involved with hemangioma development. *J.W. Walter[1], J.N. Berg[2], M. Evans[3], D. Reinhardt[2], U. Thisanayagam[2], F. Blei[4], A. Diamond[2], M. Waner[5], D.A. Marchuk[1], M.E.M. Porteous[2]*. 1) Department of Genetics, Duke University Medical Center, Durham, NC; 2) Human Genetics Unit, University of Edinburgh, UK; 3) Department of Pediatric Pathology, University of Edinburgh, UK; 4) Department of Pediatrics, New York University Medical Center, New York, NY; 5) University of Arkansas Medical Center, Little Rock, AR.

Hemangiomas are common, benign tumors of infancy which consist of rapidly proliferating endothelial cells, followed by a characteristic phase of self-involution. A locus for autosomal dominantly inherited predisposition to hemangiomas has previously been identified on chromosome 5q. We have performed microdissection of 8 sporadic hemangiomas, followed by PCR amplification and analysis of microsatellite markers on chromosomes 5 and 9. This has revealed a significant loss of heterozygosity for markers on chromosome 5q when compared to either markers from chromosome 5p ($p<0.05$) or markers from chromosome 9 ($p<0.05$). This provides evidence that a locus on 5q is also involved with sporadic hemangiomas, and suggests that formation of sporadic hemangiomas is associated with somatic mutational events.

Program Nr: 1853 from the 1999 ASHG Annual Meeting

Screening of Xq27-q28 Candidate Genes in Familial Prostate Cancer. *L. Wang[1], R.S. Berry[1], E.R. Christensen[1], A.J. French[1], D.J. Schaid[2], S.N. Thibodeau[1].* 1) Lab Medicine & Pathology, Mayo Clinic, Rochester, MN; 2) Health Sciences Research, Mayo Clinic, Rochester, MN.

Prostate cancer (PC) is the second leading cause of cancer death in the United States. Segregation analysis of familial PC suggests the presence of at least one dominant susceptibility locus, that may account for up to 10% of all PC cases. Recently, four presumed PC susceptibility loci (HPC1, PCAP, CAPB, HPCX) have been identified through linkage studies. For the HPCX region, previous linkage data, based on 123 of our PC families, indicated a locus at Xq27 that accounted for an estimated 16% of hereditary PC cases. Among the 21 polymorphic markers from Xq26-q28, we found that the peak lod scores clustered between DXS1200 and DXS1113, covering about a 2Mb region across Xq27.3 and Xq28. In an effort to clone PC susceptibility genes in this region, we constructed a physical and transcript map. Five known genes (FMR1, FMR2, IDS, U66042, MAGE9) and several unknown transcripts were identified. We also isolated a testes-specific gene (LW-1), which was localized to the distal part of our contig. This gene has a 2.2 kb transcript that encodes a protein consisting of 423 amino acids. It also has an HSF DNA-binding domain. No homologous sequences were detected in a search of public databases, suggesting that this may represent a new tumor/testes-specific protein. A total of 42 patients from 21 families were screened for variants of FMR2, U66088, MAGE-9 and LW-1 using conformation-sensitive gel electrophoresis (CSGE) and denaturing high performance liquid chromatography (DHPLC). No truncation type mutation (nonsense, frameshift, splice) was identified. However, in addition to common polymorphisms, we also detected a rare variant in the gene U66042. Mutational analysis showed a base substitution at codon 97 (GAA to AAA, Glu to Lys) in one of our 21 families. The allele frequency was 0.75% (1 of 133 normal individuals). Currently, we are analyzing additional PC families to determine whether this genetic alteration contributes to familial prostate cancer. Additionally, we are continuing to screen other candidate genes in this region.

Program Nr: 1854 from the 1999 ASHG Annual Meeting

The Establishment of a Thy-1 Inducible Expression System in Human Ovarian Cancer Cells. *N. Wang, H.R. Abeysinghe, J.E. Reeder, N.L. Guckert.* Dept Pathology, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

We have recently identified Thy-1 as a putative tumor suppressor gene for human ovarian cancer. To understand the carcinogenic role of Thy-1 and its downstream effects, a Thy-1 inducible system was established for human ovarian cancer cell line SKOV-3 based on the tetracycline (tet) regulating system originally developed by Gossen and Bujard. To establish an inducible system for the Thy-1 expression, two plasmids pTEP4m and pUHD172-1neo, which are hygromycin resistant and neomycin resistant, respectively, were co-transfected into the ovarian carcinoma cell line, SKOV-3, using the selective medium. Prior to transfection, the entire cDNA of Thy-1 was inserted into the plasmid of pTEP4m which contains the tetO-CMV operator sequence. In the plasmid pUHD172-1neo, a mutated tetracycline (tet) repressor gene, rtetR, is combined with the C-terminal domain of the Vp16 from herpes simplex virus which will lead to the production of a defected chimeric protein of rtTA. In the presence of doxycycline (dox), the rtTA will bind to the tetO and turn on the Thy-1 expression which can be reversed by the removal of doxycycline. Therefore, we can manipulate the expression of Thy-1 by doxycycline. The inducibility of Thy-1 expression in SKOV-3 cell line by dox was first confirmed at 24 hours post to dox exposure by Northern blot analysis, immunocytochemistry and flowcytometry. A time course study then revealed that the Thy-1 expression is induced 3 hours post the dox exposure and can be turned off 12 hours post removal of dox. Furthermore, both Fibronectin (Fb) and Thrombospondin were found upregulated immediately after the induced expression of Thy-1 by Northern blot analysis. In contrast, the gene SPARC was found to be independent of Thy-1 expression. In addition to the genes aforementioned, a gene discovery array screening system has been applied to the Thy-1 inducible system to identify other downstream effects of Thy-1.

Program Nr: 1855 from the 1999 ASHG Annual Meeting

HER-2/neu gene amplification in breast DCIS detected by FISH. *Z. Wang[1], L.D. Johnson[2], T. Loging[1], N. Kataoka[1], S.R. Young[1]*. 1) OB/GYN, Univ South Carolina, Columbia, SC; 2) Pathology, Univ South Carolina, Columbia, SC.

It was first reported in 1989 that amplification of the oncogene HER-2/neu is a predictor of early relapse and poor survival in breast cancer. Since that time the observation has been verified many times and extended to include a similar relationship between poor prognosis and overexpression of the HER-2/neu protein. In addition, the association between amplification/overexpression of HER-2/neu and poor prognosis has been suggested for ovarian, colon, endometrial, prostate, lung and stomach cancers. In late 1998, Herceptin, a humanized antibody against HER-2/neu, was approved by the FDA for the treatment of patients with metastatic breast cancer. Ductal carcinoma in situ (DCIS) of the breast is considered by many persons to be a precursor to invasive breast cancer. About 25% of women with untreated DCIS will go on to get invasive cancer within 10 years. The medical/surgical treatment of DCIS is dependent upon the histologic type, nuclear grade, and size of the lesion. Treatment modalities include: mastectomy, lumpectomy, and lumpectomy plus radiation, largely dependent upon the size of the DCIS area. Recurrence rates of lumpectomy with or without radiation are 10-20% within 4-5 years. We studied 30 cases of DCIS with HER-2/neu FISH to see if gene amplification was present and in what frequency. If present in sufficient numbers we could study the relationship of amplification to relapse and perhaps justify the use of Herceptin in this early stage disease. We found that 12 of 30 (40%) DCIS samples had amplification of HER-2/neu present to some degree. This high number of DCIS patients showing amplification of HER-2/neu will certainly allow study of the relationship of HER-2/neu and progression of disease and possible treatment with Herceptin.

Program Nr: 1856 from the 1999 ASHG Annual Meeting

Allele loss from chromosome 1p and from the von Hippel-Lindau locus in a patient with a sporadic carotid body tumour. *N. Weerasekera[1], P.H. Dixon[1], J. Lumley[2], C. Williamson[1].* 1) Dept. of Medicine, Imperial College, Hammersmith Hospital, London, UK; 2) Surgical Unit, St. Bartholomew's Hospital, London, UK.

Carotid body tumours can be sporadic or familial, and are inherited as either hereditary paragangliomas or as a distinct syndrome of familial carotid body tumours and multiple extraadrenal phaeochromocytomas. Hereditary paraganglioma is a genetically heterogeneous condition, with linkage reported to two loci, PGL1 (chromosome 11q23) and PGL2 (chromosome 11q13), both of which are maternally imprinted. Allelic loss of polymorphic markers from chromosome 11q has been reported in familial and sporadic paragangliomas. Allele loss in phaeochromocytomas has been reported from chromosome 1p in patients with multiple endocrine neoplasia type 2 (MEN2), and from chromosome 3p in patients with von Hippel-Lindau syndrome. Loss of tumour heterozygosity has not been reported from these loci in paragangliomas. We have performed loss of heterozygosity studies on five carotid body tumours and one glomus middle ear tumour from four patients, two of whom are from pedigrees with familial paragangliomas, one with a family history of phaeochromocytoma. We used polymorphic microsatellite markers from chromosome 11q23 (cSRL17e5(CA), cSRL17e5(CTTT), D11S1885), chromosome 11q13 (D11S480, D11S956), chromosome 3p2 (D3S1110, D3S1038) and chromosome 1p (D1S476, D1S206). In one sporadic carotid body tumour we have demonstrated allele loss from chromosome 11q23 (cSRL17e5CTTT), from chromosome 3p2 (D3S1110) and from chromosome 1p (D1S206). No loss of heterozygosity was seen in the familial tumours. This is the first report of allele loss from chromosome 3p2 and chromosome 1p in patients with paragangliomas, and suggests that genes on chromosome 1p and 3p may play a role in the multistep aetiology of these tumours.

Program Nr: 1857 from the 1999 ASHG Annual Meeting

Utility of the microsatellite instability (MSI) assay in the setting of sebaceous neoplasia and limited family history. *J.N. Weitzel[1], R. Fishel[2], K.R. Blazer[1], D.J. MacDonald[1], F.K. Fujimura[1]*. 1) Clinical Cancer Genetics, City of Hope Cancer Center, Duarte, CA; 2) Thomas Jefferson University, Philadelphia, PA.

Sebaceous neoplasms are rare. One or more sebaceous adenoma, epithelioma with sebaceous differentiation, or sebaceous carcinoma in association with visceral malignancy define Muir-Torre syndrome (MTS). MTS is an autosomal dominant genodermatosis with variable expression, including cancers of the colon, and less frequently of the stomach, uterus, ovaries, renal pelvis, or larynx. MTS is allelic to hereditary nonpolyposis colon cancer (HNPCC), which is associated with germline mutations in DNA mismatch repair (MMR) genes (primarily *MSH2* or *MLH1*). Approximately 95% of colon tumors in classic HNPCC families manifest MSI in tumor tissue. MSI is used clinically as a marker for germline MMR mutations, and MSI has been reported in sebaceous tumors from MTS families. Because sebaceous neoplasms can occur prior to or concurrently with visceral malignancy, MTS is considered in patients presenting with a sebaceous neoplasm and a positive family history of visceral cancer. The question arises as to how to assess risk for MTS in patients with cutaneous lesions and truncated or otherwise limited family histories. In this study, MSI analysis was performed on tumor specimens from five patients: two presenting with the classic MTS phenotype; one female with a personal history of breast carcinoma and sebaceous adenoma and a modest family history of GI cancers; and two males with isolated sebaceous neoplasm and negative but truncated family histories. Sebaceous tumors in two of the three isolated cases demonstrated high (>40%) MSI. One of the MSI-positive sebaceous tumors was from the female with breast cancer; her breast tumor did not demonstrate high MSI. We interpreted MSI instability as supportive of a probable MMR gene mutation and an indication for increased surveillance for visceral malignancies, and counseled patients accordingly. Germline analysis of MMR genes in the patients with MSI-positive tumors is pending. Preliminary findings suggest the possible utility of MSI testing for the refinement of cancer risk in patients with isolated sebaceous neoplasm and a limited family history.

Program Nr: 1858 from the 1999 ASHG Annual Meeting

Chromosome 8p alterations in solid tumors by array-based comparative genomic hybridization analysis. *M. Wilhelm[1], S. DeVries[1], J. Etzell[1], C. Eng[1], J. Bennington[2], A. Thor[3], J. Presti[1], F. Waldman[1]*. 1) Cancer Center, UCSF, San Francisco, CA; 2) California Pacific Medical Center, San Francisco, CA; 3) Northwestern University, Evanston, IL.

Chromosome 8p alterations have been identified in a wide range of breast cancer cell lines and primary tumors by chromosomal comparative genomic hybridization (CGH). Deletions of distal 8p combined with gains or amplifications of proximal 8p were seen in 20-50% of breast tumor samples. By chromosomal CGH, the transition point between distal loss and proximal gain can be mapped to band 8p12. However, resolution of this approach is limited in the metaphase chromosome to approximately 10 Mb, making further delineation of this candidate region difficult. An array-based CGH approach increases resolution by hybridizing the tumor and reference DNAs onto a collection of selected target clones. Resolution is thus limited only by the proximity of the clones to each other. In this study, CGH-array analysis was performed with using 20 clones (BAC and P1) spanning chromosome 8. Array-based analyses generally agreed with CGH profiles for chromosome 8 in our samples. One bladder cell line (TCC) showed loss encompassing the whole 8p arm, one kidney cell line (769-P) showed gain of the entire 8q arm, while two cell lines, one renal and one breast (786-0, BT474), showed an associated loss of 8p and gain of 8q. An additional three breast tumor cell lines and 4 primary tumors showed partial loss of chromosome 8p, with a distal deletion starting at band 8p12. Array-based CGH showed these alterations at high resolution, and was able to map a breakpoint within band 8p12. Two DNA clones (RMC08P047, RMC08B2141) were identified adjacent to this transition, with the proximal one showing an amplification. Interestingly, three of the primary breast cancers were well differentiated tubular carcinomas. For these samples, the array analyses were done using DOP-PCR amplified DNA extracted from paraffin sections after microdissection. In conclusion, array-based CGH yields high resolution analysis of cytogenetic aberrations in primary tumor samples, aiding positional cloning of candidate genes.

Program Nr: 1859 from the 1999 ASHG Annual Meeting

A Functional Genomic Approach for the Identification of *PAC-1*, a Novel Chromosome 10 Tumor Suppressor Gene. *P.E. Wong, M.M. Lovell, A. Goodacre, A.M. Killary.* Pathology and Laboratory Medicine, UT M.D. Anderson Cancer Center, Houston, TX.

A major goal of our laboratory's research is to use a functional genomic approach to define and isolate tumor suppressor genes involved in prostatic adenocarcinoma. Previously, we have defined a novel tumor suppressor locus *PAC-1* within chromosome 10p. Introduction of the short arm of chromosome 10 into a prostatic adenocarcinoma cell line PC-3H resulted in dramatic tumor suppression and restoration of a programmed cell death pathway. To functionally dissect the region within 10p containing *PAC-1*, we developed the novel strategy of serial microcell fusion, a technology that would allow the transfer of defined fragments of chromosome 10p into PC-3H and the rapid *in vivo* assay for functional tumor suppressor activity. Serial microcell fusion was used to transfer defined 10p fragments into a mouse A9 fibrosarcoma cell line. Once characterized by FISH and microsatellite analyses, the 10p fragments were subsequently transferred into PC-3H to generate a panel of microcell hybrid clones containing overlapping deletions of chromosome 10p. Additionally, comparative genomic hybridization was used to identify regions of loss in PC-3H. Extensive characterization of 10p deletion hybrids by microsatellite analysis and FISH allowed the exclusion of two separate candidate tumor suppressor regions within chromosome 10p implicated by LOH in gliomas and prostate tumors. Furthermore, these data limited the region for *PAC-1* from approximately 65 Mb to less than 10 Mb. These studies demonstrate the utility of this approach as a powerful tool to limit regions of functional tumor suppressor activity. In addition, the 10p deletion hybrid panel will be a critical resource for the physical mapping of 10p, as well as for the isolation of the important tumor suppressor gene *PAC-1*.

Program Nr: 1860 from the 1999 ASHG Annual Meeting

Tumour Formation in Neurofibromatosis 2 (NF2): a test of fit for a "two-hit" hypothesis. *R. Woods[1,5], D.G.R. Evans[2], H. Joe[1,5], M.E. Baser[3], J.M. Friedman[1,4].* 1) University of British Columbia,Vancouver, British Columbia, Canada; 2) St. Mary's Hospital, Manchester, U.K; 3) Los Angeles, U.S.A; 4) Department of Medical Genetics; 5) Department of Statistics.

Hethcote and Knudson (Proc Natl Acad Sci 1978;75:2453-7) developed a "two-hit" model to describe the incidence of tumours in hereditary and sporadic retinoblastoma. Subsequent molecular genetic analysis has established the validity of this model in retinoblastoma and other inherited forms of cancer. Molecular evidence suggests that a two-hit model is also appropriate for the development of vestibular schwannomas (VS) in patients with neurofibromatosis 2 (NF2). We fit a model analogous to Hethcote and Knudson's to incidence data for sporadic and inherited VS, the latter in NF2 patients, to examine the correlation of epidemiological and molecular evidence in this condition. The data included 72 NF2 patients, all non-probands with bilateral VS, and 50 published sporadic cases of unilateral VS (Clin. Otolaryngol 1999;24:13-18). The age at onset of VS in sporadic cases is later than that in patients with NF2 (mean/median age of onset in years, 52.1/56.5 for sporadic cases, 30.1/26.0 for NF2 cases). The predicted incidence curves for the age at onset of VS from the two-hit model fit the empirical incidence curves very closely. (chi-square(8 df) = 4.59 for goodness of fit, p = 0.80)(See http://mendel.medgen.ubc.ca/friedmanlab/2hitplot.html for the plot). We are extending this model to include provision for the allele-phenotype correlation that has been described in NF2 (e.g., J Med Genet 1998;35:450-455) and to analyze the occurrence of other tumours in this disease. The authors gratefully acknowledge support from the Acoustic Neuroma Association of Canada, the BC Medical Services Foundation, and NSERC.

Program Nr: 1861 from the 1999 ASHG Annual Meeting

Risk of breast cancer from benign breast disease: Incidence Rates for breast cancer and intra observer reliability in classifying benign breast disease lesions. *M.J. Worsham[1], C.C. Johnson[2], U. Raju[1], J. Abrams[2], A. Blount[2], S.R. Wolman[3]*. 1) Cancer Genetics Research, Dept Pathology, Henry Ford Hosp, Detroit, MI; 2) Josephine Ford Cancer Center, enry Ford Hosp, Detroit, MI; 3) Uniformed Services University of the Health Sciences, Bethesda, MD 20814-4799.

Women with benign breast lesions, particularly those classified as proliferative, are at increased risk for subsequent development of breast cancer. We have identified a cohort of women with benign breast disease (BBD) diagnosed by breast biopsy during the years 1981-1994. Classification was based on risk categories for developing invasive carcinoma defined by Page and Dupont. At the current time, 2263 members of the cohort have been followed for occurrence of breast cancer through 1997. One hundred thirty one cases were identified over 21,317 person-years of follow-up. The average incidence rate per year was 615 per 100,000 (95%) confidence interval of 518-729). The incidence of breast cancer in this BBD cohort appears to be higher than the SEER rate of 350.2 per 100,000 for women 50 years from 1990-1994 in the same metropolitan areas. To evaluate intra observer reliability, a 10% random sample of slides, N=74, from years 1981 through 1983 were independently reviewed a second time by the same pathologist who was blinded at both readings to the identity of the patient. Concordance ranged from 85% for simple apocrine metaplasia to 99% for squamous metaplasia. Average agreement was 91%. Kappa statistics indicated significantly greater than chance agreement ($p<.001$) for all lesions but fibrosis. Concordance ranged from 93% for simple adenoid and hyperplasia to 99%for apocrine hyperplasia with a mean of 96%. All kappa statistics indicated significantly more than chance agreement, $p<.001$. Lesions with moderately increased risk are atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH). One case of ADH and no cases of ALH were found and the pathologist agreed at both readings. No high-risk lesions i.e. ductal or lobular carcinoma in situ were found. In summary, a trained breast pathologist can reliably classify lesions of different risk categories.

Program Nr: 1862 from the 1999 ASHG Annual Meeting

HER2/neu and PS6K (17q23) amplification in breast lesions from women with and without a family history of breast cancer. *G. Wu, K. Anderl, C.A. Soderberg, L.C. Hartmann, R.B. Jenkins, F.J. Couch.* Mayo Clinic, Rochester, MN.

Germline mutations in BRCA1, BRCA2, and other susceptibility loci are involved in the initiation of hereditary breast cancer. However, the somatic events that lead to progression of hereditary cancers are not known. In addition, it is not known whether somatic progression pathways differ in hereditary versus sporadic disease. To address this question we have evaluated the frequency of amplification of HER2/neu and a region of chromosome 17q23 containing the PS6K (p70 S6 kinase) gene in a series of 22 cases of breast cancer from families with strong histories of breast and/or ovarian cancer and 29 matched sporadic cases. Paraffin blocks for 46 in situ carcinomas and 51 invasive carcinomas were identified for these cases, along with 32 regions of apparently benign epithelium (for control purposes). These blocks were subjected to fluorescent in situ hybridization (FISH) analysis using HER2/neu/CEN17 and PS6K/CEN17 dual-BAC probe mixtures.

The incidences of gene amplification in hereditary and sporadic cases, respectively, were 28% (6 of 21) and 0% (0 of 13) for HER2/neu, and 44% (7 of 16) and 25% (3 of 12) for PS6K. The incidences of chromosomal gain in hereditary and sporadic cases, respectively, were 65% (13 of 20) and 38% (5 of 13) for +CEN17. In hereditary cancers 1 of 16 had co-amplification of HER2 and PS6K, 3 of 16 had amplification of HER2 only, and 6 of 16 had amplification of PS6K only. In sporadic cancers, 0 of 12 showed co-amplification, 0 of 12 had amplification of HER2 only, and 3 of 12 had amplification of PS6K only. Our data show that chromosomal alterations, as measured by CEN17 gain and HER2/neu and PS6K gene amplification, are more frequent within breast cancers of women with a strong family history of cancer, consistent with an increased underlying chromosomal instability. Further studies will determine if separate pathways of carcinogenesis exist for hereditary and sporadic breast cancer.

Program Nr: 1863 from the 1999 ASHG Annual Meeting

Localization of Transfected B7-1 (CD80) DNA on Human Melanoma Cells after Particle Mediated Gene Transfer. *S. Wu[1], D.O. McCarthy[2], N.J. Glowacki[2], C.A. Emler[3], X. Chen[1], M.R. Albertini[2].* 1) Pediatrics, Children's Hospital, Los Angeles, School of Medicine, University of Southern California, Los Angeles, CA; 2) University of Wisconsin Comprehensive Cancer Center, Madison, WI; 3) Agracetus, Inc., Middleton, WI.

Particle mediated gene transfer (PMGT) is an efficient means to directly deliver transgenes into human melanoma cells for transient or stable gene expression. The aim of this study was to determine the localization of transfected B7-1 cDNA in M-21 melanoma cells following PMGT. Microscopic gold particles coated with a plasmid vector containing B7-1 cDNA and delivered by PMGT were detected in the cytoplasm and nucleus of recipient M-21 cells. Using fluorescence in situ hybridization (FISH), biotin labeled B7-1 DNA was clearly detected in most melanoma cells 24 hours following PMGT. The B7-1 transgene particles were randomly distributed within melanoma cells, and transfected melanoma cells contained between 1 and 14 biotin labeled particles. Stable B7-1 transfectants (M-21-B7) were obtained following PMGT with a plasmid vector containing cDNA for both B7-1 and neomycin phosphotransferase and subsequent selection in media containing G418. While 50-60% of M-21-B7 evaluated by flow cytometry had surface expression of B7-1, analysis by FISH did not detect the B7-1 transgene in these cells. The M-21-B7 were then sorted on the FACStar Plus by brightness of B7 expression to obtain M-21-B7 (bright) cells with 85-90%of cells with B7-1 expression. Analysis by FISH and subsequent chromosome G-banding analysis demonstrated 70% of M-21-B7 (bright) to have two predominant integration sites with extensive amplification of the B7-1 transgene. These integration sites were located on chromosome 15 and 17. These findings demonstrate that B7-1 cDNA can integrate into the chromosomes of recipient M-21 cells following PMGT, and this integration can occur in preferential sites in some cells. The relationship between transgene integration site and expression of the transgene, or other cellular genes, requires further investigation.

Program Nr: 1864 from the 1999 ASHG Annual Meeting

Genomic organization and mutation analysis of Mortalin, a candidate for the chromosome 5q31 tumor suppressor gene in AML/MDS. *H. Xie[1], S.K. Horrigan[2], B. Chyna[1], Z.B. Hu[1], C.A. Westbrook[1]*. 1) Section of Hematology/Oncology, Univ. of Illinois at Chicago, Chicago, IL; 2) Department of Pediatrics, Lombardi Cancer center, Georgetown University Medical Center, Washington,DC.

In malignant myeloid disorders, including myelodysplasia (MDS) and acute myeloid leukemia (AML), interstitial deletion or loss of chromosome 5 frequently occurs, suggesting the presence of a tumor suppressor gene. By heterozygosity analysis of a small deletion, we have defined a minimal localization for this gene to a 700 kb interval on 5q31, to which we have mapped several candidate genes. Among these candidates, mortalin, HSPA9,is a plausible tumor suppressor. Mortalin is a member of the hsp70 family. The protein exhibits differential cellular localization in mortal and immortal cells of human and mouse by virtue of its cytosolic and perinuclear distribution, respectively. The murine cytosolic form (mot-1) induces senescence in NIH3T3 cells whereas the perinuclear form (mot-2) does not. It has been postulated that loss of cytosolic mortalin may lead to cell immortalization and tumorigenesis. As first step in mutation analysis of mortalin in clinical AML and MDS, we determined the genomic structure and intron-exon boundaries of human mortalin by direct sequencing of BAC DNA. We show that the gene spans 19.5 kb. It contains 17 exons and 16 introns, with similar boundaries to its murine counterpart, and all boundary sequences contained consensus GT/AG sequences at the donor and acceptor site of RNA splicing. Mutation analysis of AML was begun by sequencing DNA from three AML cell lines, including 2 with chromosome 5 loss (KG-1 and HL-60) and one without (AML-193). Using intron-based primers, genomic sequence was completed for all 17 exons, and compared to normal (BAC) DNA. No mutation was detected in any of the cell lines, although two conservative nucleotide sequence variants were identified in exon 16. We have shown by RT-PCR that mortalin is expressed in these AML cell lines and normal CD34+ bone marrow precursor. Mutation and expression analysis of clinical MDS and AML samples is ongoing.

Program Nr: 1865 from the 1999 ASHG Annual Meeting

Identification of differetially expressed genes by reciprocal subtraction cDNA array screening. *J. Xu, H.R. Abeysinghe, N. Guckert, N. Wang.* Dept Pathology, Univ Rochester Medical Ctr, Rochester, NY.

A reciprocal subtraction cDNA array screening approach has been applied to identify the differentially expressed genes associated with suppression of tumorigenicity in the human ovarian carcinoma cell line SKOV3. The non-tumorigenic subclones 11(H)7-2 and 11(H)9-8 and slow growing tumorigenic subclone 11(H)8-3 were derived from SKOV3 with the introduction of human chromosome 11. Reciprocal subtraction of cDNAs between tumorigenic and non-tumorigenic subclones followed by gene discovery array screening revealed that 15 known genes and 6 ESTs were either absent or downregulated in the two non-tumorigenic subclones , but were expressed in the slow growing tumorigenic subclone . In contrast, 81 known genes plus 59 ESTs were either absent or downregulated in the slow growing tumorigenic subclone , but were expressed in the two non-tumorigenic subclones . Four of these 81 knonw genes, CRYAB, IGSF4, THY-1, and APLP2, are located at the band 11q23. Structural alterations at this chromosomal region are frequently identified in human ovarian cancer. Therefore, 11q23 may be a critical region for human ovarian cancer.

Program Nr: 1866 from the 1999 ASHG Annual Meeting

Myeloperoxidase Genetic Polymorphism and Colorectal Adenoma Risk. *W.M Xue[1], R.W Haile[1], H.D Frankl[2], E.R Lee[3], S.A. Ingles[1]*. 1) Preventive Medicine, University of Southern California, Los Angeles,CA; 2) Division of Gastrienterology, Sunset Kaiser Permanente Medical Center, Los Angeles, CA; 3) Division of Gastroenterology, Bellflower Kaiser Permanente Medical Center, Los Angeles, CA.

Myeloperoxidase (MPO) is a neutrophillic enzyme which catalyses the reaction of chloride and hydrogen peroxide to yield hypochlorous acid, a strong oxidant. A G/A polymorphism in an Alu repeat in the MPO gene promoter has been shown to be functionally significant in vitro, with the presence of a G rather than an A at this site increasing gene expression. We used an RFLP/PCR method to genotype subjects from a sigmoidoscopy screening program in two Southern California Kaiser Permanente medical centers.This study includes a control group of 474 subjects without adenomas, a case group of 302 subjects with left colon adenomas and 131 with rectal adenomas. The ethnic breakdown was 52% White, 17% African-American, 18% Hispanic and 12% Asian. Among Hispanics and non-Hispanic Whites, 3% of subjects carried 2 copies of the A allele. Whereas 15% of African-Americans and 1% of Asians had the AA genotype. Among African-Americans, the AA genotype was associated with a more than two-fold increase in risk of colorectal adenomas (OR = 2.83, 95% confidence interval, 1.02-7.82; P = 0.04). Risk was similarly elevated for rectal and left colon adenomas. However, the AA genotype was associated only with rectal adenomas in other ethnic groups (OR = 3.05, 95% confidence interval, 1.11-9.07; P = 0.03). Possible explanations for this finding will be discussed.

Program Nr: 1867 from the 1999 ASHG Annual Meeting

A unique clone involving multiple structural chromosome rearrangements in a myelodysplastic syndrome case. *J. Yan[1], R. Whittom[2,3], R. Drouin[1]*. 1) Pathology, Dept Medical Biology; 2) Hematology, Dept Medical Biology; 3) Hematology, Dept Medicine, Laval University, Pav St-Francois d'Assise, CHUQ, Quebec, Quebec, CANADA.

Cytogenetic abnormalities are present in more than 50% of myelodysplastic syndrome (MDS) patients. Cytogenetic studies using bone marrow samples add important diagnostic and prognostic information to this hematological disorder. The clinical prognosis of MDS is greatly affected by karyotype complexity. The patients having a normal karyotype or only one chromosomal abnormality usually predict a better prognosis. On the other hand, patients having complex chromosomal aberrations (more than two abnormalities) are often associated with the worst prognosis (a higher risk of acute leukemia transformation and a shorter survival). We identified a unique clone involving multi-chromosome rearrangements in a 40-year old female patient suffering from refractory anemia with ringed sideroblasts. Fifty G-banded metaphases were initially analyzed. All of the 50 metaphases showed six abnormal chromosomes including two ring chromosomes and other aberrations that are not usually found in MDS. The initial karyotype was defined as: 46,XX,-5,-11,add(11)(p15),del(13) (q14),add(20)(p13),idic(22)(p11),+r1,+r2. To further identify these chromosome abnormalities, we used molecular cytogenetic methods, such as FISH (fluorescence in situ hybridization) and PRINS (PRimed IN Situ labeling). Finally, the karyotype was defined as: 46,XX,r(5)(p13q13), t(5;20)(p13;p13),r(11)(p15q25),dup(11)(p11.2p15), del(13)(q14),idic(22)(p11). The patient quickly progressed to an acute non-lymphocytic leukemia (ANLL) three months following cytogenetic diagnosis and died of a hemorrhage in the brain parenchyma two months later. The very poor prognosis was predicted by the multiple (six) structural chromosome rearrangements and by the types of rearrangements. We concluded that, for this case, the most important chromosome abnormalities were the 5q- and 13q14- (Rb gene deletion). Such rearrangements can be closely correlated to very poor prognosis of the rapid leukemic transformation, the lack of response to treatment and the short survival.

Program Nr: 1868 from the 1999 ASHG Annual Meeting

Absence of SH2D1A point mutation in 62 Burkitts lymphoma cell lines. *L. Yin, T. Tocco, S. Pauly, G.M. Lenoir, G. Romeo.* International Agency for Research on Cancer, Lyon, France.

X-linked lymphoproliferative disease (XLP) is a rare inherited immunodeficiency characterized by selective susceptibility to Epstein-Barr Virus (EBV). The recent identification of the XLP gene, SH2D1A, revealed a EBV-related signal transduction pathway (Coffey et al., Nature Genet. 20:129-135, 1998; Sayos et al., Nature 395:462-469, 1998), which is not only essential in understanding the mechanism of XLP, but also will give some insights into other EBV-associated diseases, including Burkitts lymphoma (BL). BL is characterized as a small, non-cleaved cell lymphoma (SNCL), invariably of B cell origin. Monoclonal EBV DNA is found in virtually all cases of endemic BL in Africa and in a significant part of sporadic BL from other regions. The common feature of XLP and BL is the uncontrolled proliferation of the EBV infected cells. In addition, one of the typical phenotypes of XLP is that the patients often develop malignant lymphomas of the Burkitts type. We hypothesize that a defect of SH2D1A gene, which regulates the signal transduction cascade(s) relevant to the immune response to EBV infection, might be responsible for a certain proportion of BL cases. DNA from 62 BL cell lines were screened for mutations by PCR amplification and sequencing, using primers reported by Coffey et al. 1998. In the coding region of all the four exons of SH2D1A, in the 5 non-translated region, part of the 3 non-translated region, as well as in approximately 50 bp of intronic sequences flanking each exon, no point mutation was present in these 62 BL patients. This result suggests that missense, nonsense, splicing mutations of the SH2D1A gene are not the major cause for this disease. However, it can not be excluded that an altered expression level of the SH2D1A gene may relate to BL.

Program Nr: 1869 from the 1999 ASHG Annual Meeting

Molecular cytogenetic characterization of ovarian carcinoma, III: 20q. *S.R. Young[1], Z. Wang[1], S.T. Smith[1], R.S. Parrish[2]*. 1) Dept OB/GYN, Univ South Carolina Sch Med, Columbia, SC; 2) S.C. Cancer Ctr, Univ South Carolina Sch Med, Columbia, SC.

Ovarian cancer is the leading cause of gynecologic cancer death in the U.S. This high mortality is largely because the ovaries are located deep in the pelvis and the malignancy is not diagnosed until there is an advanced stage of disease. It is important to better understand the biology dictating the etiology and progression of ovarian cancer to facilitate earlier diagnosis and better treatment. In 1989, using Southern blot methodology, it was shown that amplification of the oncogene HER-2/neu was a poor prognostic indicator in ovarian cancer. Overexpression of p53 is found in some ovarian carcinomas but not in benign tissue. More recently serum lysophosphatidic acid was reported to be a biomarker of disease. Pelvic ultrasound and serum CA125 studies have proven inefficient in early diagnosis of ovarian cancer. From Jan 1993 through May 1995 we collected 40 ovarian cancer surgical samples. We have previously described the results of our FISH studies of HER-2/neu and centromere #17, c-myc and centromere #8 and p53 on these samples. Briefly, 10/40 (25%) had amplified HER-2/neu, 16/40 (40%) had amplified c-myc, and 9/40 (22.5%) had deletion of p53. Only those patients whose tumors were amplified for both oncogenes had a statistically significant shorter survival. We now report the addition of FISH studies of 20q13 conducted on these very same samples. Of the 40 samples studied, 4 (10%) showed medium/high amplification of 20q13. There was no significant correlation between these results and the patient's clinical findings. It is of interest that in every sample with amplified 20q13 there was also amplification of c-myc (Fisher's exact p-value= 0.020). This data suggests that there should be further study of the relationship between amplification of 20q13 and c-myc in ovarian cancer samples.

Program Nr: 1870 from the 1999 ASHG Annual Meeting

Detection of homozygous deletions in tumors by hybridization of representational difference analysis (RDA) products to chromosome specific YAC clone arrays. *M. Zeschnigk, B. Horsthemke, D.R. Lohmann.* Institut für Humangenetik, Universitätsklinikum Essen, Hufelandstrasse 55, 45122 Essen, Germany.

Biallelic inactivation of tumor suppressor genes is frequently accompanied by loss of genetic material. Therefore, identification of deleted regions in tumor genomes is an important step towards the isolation of these genes. Subtractive hybridization techniques facilitate to enrich differences between complex genomes and can help to identify homozygously deleted regions. The enrichment efficiency was improved when Lisitsyn et al. introduced the RDA. As this PCR based technique also enriches polymorphic fragments that are lost in driver representation due to chromosomal rearrangements that result in loss of heterozygosity (LOH) laborious clone by clone analysis is required because typically only a few percent of the cloned RDA products are derived from the homozygous deletion. To overcome this limitation, we deviced a novel strategy in which difference products generated by RDA are labeled and hybridized in toto against an ordered array of YAC clones covering a region of interest. The YAC clones identified by the RDA products provide positional information on homozygous deletions and LOH regions. To demonstrate the usefulness of the approach, we have tested this strategy by analyzing a retinoblastoma with a known homozygous deletion affecting the RB1 gene and LOH at neighbouring polymorphic loci on chromosome 13. RDA was performed using representations generated with restriction enzymes BglII, NcoI and XbaI, and the products of each RDA experiment were hybridized to chromosome 13 YAC filters. The map positions of YACs identified by RDA products of a single restriction enzyme were scattered over the whole chromosome with a slight accumulation in the LOH and RB1 region. However, when collating the information from three different RDA experiments only one region which comprised the homozygously deleted region on chromosome 13 showed a cluster of hits. In summary, the combination of the RDA with direct hybridization of the RDA products to chromosome specific YAC clone filters may facilitate to scan multiple tumors for homozygously deleted regions in the presence of LOH regions.

Program Nr: 1871 from the 1999 ASHG Annual Meeting

Role Of The p53 and PTCH Genes in Early Onset Basal Cell Carcinoma. *H. Zhang, X.L. Ping, P.K. Lee, X.L. Wu, Y.J. Yao, M.J. Zhang, F.F. Chen, D.N. Silvers, D. Ratner, M. Peacocke, H.C. Tsou.* Dermatology, Columbia University, New York, NY.

Basal cell carcinoma (BCC) is the most common skin cancer in the Western world. UVB irradiation from sunlight is the major risk factor for the development of BCC. The incidence of sporadic BCC increases in individuals over age 55, with the greatest incidence reported in individuals who are over 70. The incidence of BCC is rare in individuals who are younger than 30. Two tumor suppressor genes, p53 and PTCH, have been implicated in the development of BCC. Mutations in the p53 have been found in 30 to 50% of BCC studied. Somatic mutations in the PTCH gene were identified in 20 to 30% of the sporadic BCC studied. Most of mutations detected in these two genes were UV-specific C->T or CC->TT changes. In this study, we analyzed 23 BCC samples from individuals who have BCC diagnosed by age of 30. They are all Caucasians, and age ranged from 16 to 29 years old. Genomic DNA from each BCC was screened for mutations in the PTCH gene by PCR-SSCP. Seventeen SSCP variants in the PTCH gene were identified from 14 BCC samples. Sequence analysis of these SSCP variants revealed 15 single nucleotide changes, one AT insertion after nucleotide 2709 in exon 7 and one 15 bp deletion after nucleotide 2385 in eoxn 15. Most of these nucleotide changes (9/17) were predicted to result in truncated PTCH proteins. The same 23 BCC samples were then screened for mutations in the p53 gene by complete sequence analysis. Fifteen p53 mutations were found in 11 BCC samples. They consisted of 11 missense mutations, one nosense mutation and three deletions. Over 60% of these nucleotide changes were UV specific. Interestingly, p53 mutations were only found in BCC samples containing PTCH mutations. Our data demonstrated that both p53 and PTCH are implicated in the development of early onset BCC. The identification of the UV specific nucleotide changes in both tumor suppressor genes suggests that UV exposure is an important factor in the early onset BCC.

Program Nr: 1872 from the 1999 ASHG Annual Meeting

DEVELOPMENT OF NEW MOLECULAR GENETIC MARKERS OF OUTCOME IN PEDIATRIC EWING GROUP TUMOUR. *Z.M. Zhang[1], Y.K. Ng[2], J. Bayani[1], P. Marrano[1], M. Zielenska[3], J. Squire[1]*. 1) Cellular & Molecular Biology, Ontario Cancer Institute,University Health Network, Toronto, Ontario, Canada; 2) Cytogenetics Program, Banting Institute, University Health Network, Toronto, Ontario, Canada; 3) Department of Pediatric and Laboratory Medicine, Hospital for Sick Children, Toronto, Ontario, Canada.

Ewing sarcoma (ES) is a bone tumour of childhood in which there is variable response to treatment. ES can be aggressive with a high propensity for local recurrences and distant metastases. In contrast, other children have a very favorable response to therapy and have no subsequent disease complications. This study is focusing on developing prospective panel of cytogenetic markers that will prognosticate for those ES tumours in which advanced disease and tumour recurrence is more likely to occur. Our approach is to use a combination of molecular cytogenetic techniques such as Fluorescence in situ Hybridization (FISH) on paraffin section, Comparative Genomic Hybridization (CGH) and Spectral Karyotyping (SKY) to augment classical cytogenetics, and define a pattern of chromosomal change that will predict which tumours are more aggressive. We present a study of ES tumors in which a more complex pattern of chromosomal change is present and is associated with those tumors that fail to respond to treatment. These include 30 ES tumors derived from paraffin sections by interphase FISH and correlated presence or absence of trisomies 8 and 12 with disease response. In prospective non-responders intervention may be considered earlier, so that intensified treatment regimens can be carried out at an earlier phase in the disease process.

Program Nr: 1873 from the 1999 ASHG Annual Meeting

Variant *NPM-ALK* chimeric product in the anaplastic large cell lyphoma (ALCL). *M. Zielenska[1], W.L. Sirkin[1], N. Fabricius[1], J. Zielenski[2]*. 1) DPLM, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada.

Chromosomal translocations found in neoplasms often result in the creation of hybrid genes encoding chimeric proteins. Anaplastic large cell lymphoma (ALCL) is a distinct clinico-pathologic variant best classified as a high grade non-Hodgkins lymphoma (NHL) composed of large pleomorphic cells that usually express the CD30 antigen and interleukin (IL)-2 receptor. With variable frequency ALCL bears the t(2;5)(p23;q35) chromosomal translocation that fuses the nucleoplasmin (*NPM*) gene on chromosome 5q35 to a novel protein kinase gene, anaplastic lymphoma kinase (*ALK*) on chromosome 2p23. We routinely use RT-PCR method for detection of *NPM-ALK* PCR chimeric mRNA transcripts. In all but one case the *NPM-ALK* RT-PCR products were of identical size, suggesting that the genomic chromosome breaks are clustered in a single intron in both *NPM* and *ALK* genes. The single exception was found in an eight-year old patient with a T-lineage, CD30+ ALCL that expresses a larger (+84 basepair) *NPM-ALK* chimeric product. The consequence of this new variant for *NPM-ALK* is at present unclear. Additional cases will need to be characterized to determine whether this variant translocation carries any significance with respect to clinical features, or prognosis.

Program Nr: 1874 from the 1999 ASHG Annual Meeting

Mosaic tetrasomy 3q25®ter. *M.L. Levin[1], T.R. Dennis[2], P. Spallone[2], A.D. Stock[2].* 1) Pediatrics, Genetics Division, U. Nevada School of Medicine, Las Vegas, NV; 2) Pathology, Molecular Cytogenetics Laboratory, U. Nevada School of Medicine, Reno, NV.

We report the first case of mosaic tetrasomy 3q25®ter and discuss the findings in relation to the 3q duplication syndrome, Cornelia de Lange syndrome, and the Opitz-C syndrome which have been reported to have a superficial resemblance to 3q duplication syndrome. The patient has a de novo 47,XX,+der(3)iso(3)(q25)/46,XX, with the level of mosaicism only 5% in peripheral blood and more than 90% in skin. The derived chromosome's origin was confirmed by microdissection and reverse in situ hybridization. The patient has post-natal growth retardation and is functioning at the 8-9 month level when last seen at 16 months of age. Hypopigmented "striping" of the nose and glabella noted at birth has progressed to a whorled pattern covering most of the body. Dysmorphic facial features include sparse hair, dolichocephaly, narrow nose with pointed tip and anteverted nares, brushfield spots, epicanthal folds and upslanting palpebral fissures, retrognathia, high arch palate, inverted cupid's bow mouth and low set rotated ears. Bilateral styes have developed. Skeletal findings include hip dislocation, sacral vertebral abnormalities, clinodactyly with overlapping index and 5th fingers, single palmar and aberrant flexion creases, and short toes. The patient has labial hypoplsia and severe hydronephrosis which resulted in intestinal obstruction in the neonatal period. Evaluation revealed bilateral ureteropelvic junction obstruction, worse on the right with an ectopic ureteral insertion into the urethra. Percutaneous right nephrostomy with cutaneous pyelostomy were performed. Comparison with other patients with duplication 3q is not straightforward because of mosaicism and tetrasomy; there is one report of mosaic trisomy 3q and all other reports describe trisomy for various segments of 3q, many having other partial aneusomies as a result of unbalanced translocations. Our patient has developmental delay, growth retardation, facial features and genitourinary anomalies common to some patients with 3q duplication , but does not resemble the Cornelia de Lange syndrome or C syndrome phenotypes.

Program Nr: 1875 from the 1999 ASHG Annual Meeting

The product of the Hira gene, a potential chromatin factor, is required for early mammalian differentiation and proliferation. *F.P. Lohman[1], V. Lui[1], S. Snoeren[1], P. Scambler[2], F. Grosveld[1], C. Meijers[1].* 1) Cell Biology & Genetics, Erasmus University, Rotterdam, The Netherlands; 2) Institute of Child health, London.

The Hira gene is a candidate gene for the DiGeorge syndrome, which is characterized by defective development of pharyngeal arches and haplo-insufficiency for chromosome 22q11. The Hira protein shares significant homology with the p60 subunit of the human chromatin assembly factor I (CAF-I) and two co-repressors of gene transcription in yeast, Hir1p and Hir2p. It has been shown that members of the chromatin remodeling Swi/SNF complex in yeast binds strongly to Hir1p and Hir2p. Hira homologues have been identified in mouse, chicken, frog, worm and fly suggesting a fundamental role of the Hira protein in both vertebrates and invertebrates. High levels of Hira mRNA are present in embryonic structures that are affected in 22q11 deletion syndrome patients. Knockout of Hira in mice is lethal at E9.5 and embryonic development in most embryos is arrested at the gastrulation stage. Heterozygous and homozygous mutant embryonic stem cells are viable, indicating that the Hira gene is not essential for cell viability. The cell cycle in these Hira mutants is shortened, while their differentiation is impaired. Introduction of a tagged full size Hira cDNA to -/- ES ells rescues the proliferation phenotype.GFP-tagged Hira locates to the nucleus, cytoplasm or both. This indicates a cell cycle dependent localization. Truncated versions of GFP-Hira constructs indicate that the domain responsible for cytoplasmic localization resides in the NH2 domain. Immunohistochemistry of mouse and human bone marrow and peripheral blood shows that the endogenous Hira protein is excluded from the nucleus in terminally differentiated cells. These results suggest that the Hira protein is required for cellular differentiation and proliferation during early mammalian development and implicate a role of Hira during the cell cycle. A quantitative defect in HIRA production could translate in defects in chromatin remodeling activities, a possible basis for some of the phenotypic features in 22q11 deletion syndrome patients.

Program Nr: 1876 from the 1999 ASHG Annual Meeting

Thymic hypoplasia and multiple malformations in the child of a liver transplant recipient. *M.A. Lovell, L.B. Karns, J.E. Ferguson, M.L. Buck, W.G. Wilson.* Depts. of Pathology, Obstetrics and Gynecology, and Pediatrics, Univ of Virginia Health System, Charlottesville, VA.

We report on a 3 month old girl, born to a 22 year old woman with Alagille syndrome 12 years status post orthotopic liver transplantation, who died from sepsis and complications related to multiple congenital malformations. The 1550 gm infant was born at 33 weeks gestation following a pregnancy complicated by polyhydramnios and maternal medication exposures (tacrolimus, prednisone, and lamotrigine). She died following a 3 month NICU course. Autopsy findings included a type II tracheoesophageal fistula, duodenal atresia, thymic hypoplasia with absence of thymocytes, systemic lymphoid depletion, agenesis of the upper and middle lobes of the right lung, absent upper right pulmonary vein, and segmental bronchomalacia. The liver did not show evidence of Alagille syndrome. A lymphocyte karyotype was normal (46,XX). The malformations present in this child suggest a developmental field defect, and are not typical of those seen in Alagille syndrome. To our knowledge, this pattern of malformations has not been previously reported in association with maternal exposure to these medications. Tacrolimus is a relatively new macrolide antibiotic with potent immunosuppressant properties, and has not been associated with an increased incidence of malformations, although prematurity, transient anomalous renal function, and dilated cardiomyopathy have been reported. Lamotrigine, a phenyltriazine anticonvulsant, is also relatively new and has not been associated with this pattern of malformations. Whether the findings in this infant are coincidental, related to Alagille syndrome, or are related to the medications taken by the mother cannot be determined at this time.

Program Nr: 1877 from the 1999 ASHG Annual Meeting

A clinical study of patients with isolated multiple neurofibromas. *M. MacCollin[1], P. Blakley[2], D. Louis[3], H. Mankin[4], M.P. Short[5]*. 1) Dept Neurology; 2) Genetics and Teratology Unit; 3) Dept Pathology; 4) Dept Orthopaedics, Massachusetts General Hospital, Boston, MA; 5) Dept Neurology, University of Chicago, Chicago, IL.

Neurofibromatosis Type 1 (NF1) is an autosomal dominant disorder characterized by the development of nerve sheath tumors, particularly neurofibromas. Specific criteria have been established to facilitate the diagnosis of NF1.

Participants in this study were chosen from patients assessed in the NF Clinic at MGH. The criteria for inclusion in the study were multiple pathologically proven neurofibromas and the lack of other stigmata of NF1. Eight patients were selected for inclusion in this study and were administered a standardized questionnaire. They underwent a clinical examination, including Wood's lamp inspection and neurologic and ophthalmologic evaluation with slit lamp examination. Archived pathologic material from 18 tumors previously resected from 7 of 8 patients and 2 tumors from affected family members were reviewed.

Mean age of onset of symptoms in these patients was 20.3 years. Presentation was varied and included pain, neurologic change and painless masses of the trunk and extremities. Tumor load was extensive in 5 patients and involved the paraspinal regions, brachial plexis, extremities and pelvis. Three patients had more localized tumor distribution. Family history was positive and consistant with autosomal dominant transmission in only 1 of 8 patients. Major morbidity was pain and deformity due to increased tumor number and size. Examination revealed readily palpable, firm, nodular, subcutaneous tumors. Tumor pathology was consistent with neurofibroma or plexiform neurofibroma.

NF1 is often diagnosed in childhood due to the presence of cutaneous/intracranial tumors, CAL spots and Lisch nodules. We report a series of adult patients with isolated multiple neurofibromas who do not meet the clinical criteria for NF1. Our findings suggest that these individuals may comprise a distinct form of NF. Studies are underway to further define the clinical spectrum and molecular basis for this rare disorder.

Program Nr: 1878 from the 1999 ASHG Annual Meeting

Frequency of celiac disease in Down syndrome in the United States. *J. Mackey, G. Worley, W. Treem, A. Boney, P. Hart, L. Stanford, P. Kishnani.* Pediatrics, Duke University, Durham, NC.

The increased prevalence of immune-related disorders in children with Down syndrome (DS) is well recognized. Results of epidemiologic studies in Europe suggest an association between celiac disease (CD) and DS. The frequency of CD in DS is reported to be 1% -17% in Europe, as compared to an incidence of 1:3,000-10,000 live births in the pediatric population in the United States (US). The frequency of CD in DS in the US has not been reported. Because we expected underdiagnosis of CD in children with DS, we developed a clinical algorithm for screening in our DS clinic population. All patients > one year of age, with gluten in their diet and with a confirmed karyotypic diagnosis of DS were evaluated for CD through clinical and laboratory evaluations [IgG anti-gliadin antibody (IgGAGA), anti-endomysial antibody (EMA), IgA anti-gliadin antibody (IgAAGA)]. Children with symptoms, an AGIgG > 2 times reported normal, a positive EMA, or positive IgAAGA were referred for a small bowel biopsy. In cases where IgGAGA was elevated with a normal IgAAGA, an immune profile was performed to exclude possible selective IgA deficiency. 92 children [57M: 35F age range 1-22 years (mean 5.8 years)] have thus far been screened according to the algorithm. Of the 25 children who met criteria, 16 underwent small bowel biopsy (9 lost to follow up or refused). Villous atrophy, reversed crypt to villous ratio and intraepithelial lymphocytes consistent with CD, was found in 3 patients ages 3, 6 and 10 (2M, 1F) giving a frequency of CD in DS in our population of 3.2%. All three with biopsy proven CD also had a positive EMA; in contrast, only 1 /13 children with a normal biopsy had a positive EMA (sensitivity 100%, specificity 90%). None has thyroid disease or diabetes mellitus. Currently all 3 are on a gluten-restricted diet; serologic tests have not been repeated in any thus far. This prospective study supports the view that there is increased prevalence of CD in children with DS also in the US. We thus recommend screening for CD in children with DS older than one year of age who have been exposed to gluten in their diet. A larger study of this issue is warranted.

Program Nr: 1879 from the 1999 ASHG Annual Meeting

Factor V Rsa I polymorphism as a possible prognosticator of certain complications in Sickle Cell Disease. *R.B. Markowitz[1,2], A. Kutlar[1]*. 1) Dept. of Medicine, Sickle Cell Center; 2) Inst Molecular Medicine & Gen, Medical Col Georgia, Augusta, GA.

The underlying cause of Sickle Cell Disease (SCD) is a single nucleotide mutation in the 6th codon of the human b-globin gene, resulting in a Glu to Val substitution. Its primary effect is the polymerization of deoxy Hb S, which leads to chronic hemolytic anemia, microvascular obstruction, and organ damage. Sickle Cell Disease is clinically heterogeneous; the frequency and severity of vaso-occlusive crises vary among individuals. Other serious complications, e.g., cerebrovascular accidents, acute chest syndrome, avascular necrosis and venous thrombosis, occur only in certain patients. Multiple genetic influences are thought to play a role in determining the occurrence of these complications in affected individuals. Our laboratory is interested in identifying genetic factors that might be associated with certain complications in SCD. We tested for the presence of mutations known to be associated with thrombophilia in a cohort of patients with a history of stroke, avascular necrosis, or severe venous thrombosis. The Factor V Leiden and Prothrombin 20210 mutations were virtually absent in patients with and without these complications. However, the Rsa I polymorphism in the Factor V gene is present. Nearly 20% of all SCD patients tested were heterozygous. The allele frequency for R3 was 0.087 in patients with the complications, and 0.1125 in those without. The allele frequency for R2 was 0.032 in the thrombotic group, but R2 was absent from the non-thrombotic group. Less than 5% of African-Americans without SCD showed these polymorphisms. These preliminary data suggest that the Rsa I polymorphisms are not rare among African-Americans and SCD patients. In addition, R2 may serve as a prognosticator for these complications in SCD. The R2 allele is known to be associated with resistance to activated protein C (APC), which is commonly associated with venous thrombosis. We are using a functional assay to determine if SCD patients with R2 and R3 display APC resistance. Larger numbers of SCD patients with and without these complications are being studied for the Rsa I polymorphisms.

Program Nr: 1880 from the 1999 ASHG Annual Meeting

Aplasia cutis congenita and sagittal sinus anomaly. *D. Massocco[1], C. Bellini[1], P. Mezzano[1], M. Lituania[2], P. Fondelli[3], E. Zullino[1], F. Campone[1], W. Bonacci[1], G. Serra[1].* 1) Servizio di Patologia Neonatale, Universita Genova, Istituto Gaslini, Genova, Italia; 2) Divisione di Ostetricia e Ginecologia, Istituto Gaslini, Genova, Italia; 3) Servizio di Neuroradiologia, Istituto Gaslini, Genova, Italia.

Aplasia cutis congenita (ACC; MIM107600) is a congenital absence of the skin.The scalp is the principal site of the involvement and the defect often involves the calvaria and the dura madre. The defect may be part of malfomative syndromes. The aetiology remains obscure. Case report: a female infant was born at 38 week gestation to healthy non-consanguineous parents. No maternal abuse of alchool, smoke or drugs neither intrauterine infection were reported. Amniotic fluid alphafetoprotein was normal. APGAR was 8/9. Birth weight was 2580 g, lenght 45 cm, head circumference 32 cm (all at 25-50 centile). At birth a cutaneous necrotic area near the bregmatic fontanelle was observed. Horizontalization of ocular edge, hypertelorism, low set ears, short nasal filtrum, short neck with pterigium, broad and short hand fingers, bilateral proximal implantation of thumb were present. Karyotype was 46, XX. Skull radiographs evidenced poor and irregular ossification of frontal edges and of parietal bones near to the sagittal suture. Ultrasonic study was normal. CT-scan showed irregular frontal profiles, aspecific calcification of the frontal white matter, normal ventricles and subaracnoideal spaces. Angiographic-MR study evidenced bifid sagittal sinus. Fundus oculi was normal. Hand radiographs excluded morphological and structural anomalies, renal and cardiac ultrasound were normal, karyotipe was normal so far excluding the principal abnormalities (1). Multiple theories have been advanced to explain the aetiology of ACC. A case of ACC with communication of the patent sagittal sinus and the superficial dilated scalp veins have been reported (2). More recently ACC was described in association with high-flow sinus pericranii (3). Our case, associated with the bifid sagittal anomaly, adds further value to the vascular aetiologic hypotesis. 1)Neuroradiology 36:480,1994. 2) Pediatr Neurosurg 17:203,1992. 3) Pediatr Neurosurg 28:79,1998.

Program Nr: 1881 from the 1999 ASHG Annual Meeting

Trisomy 9: A comparison of mosaic Trisomy 9, duplications of chromosome 9 and Trisomy 9 derived from unbalanced translocations. *G.L. Matika[1], C.A. Bay[1,2], M.A. Del Vecchio[1], S. Wright[1]*. 1) Division of Medical Genetics, Children's Hosp of Pittsburgh, Pittsburgh, PA; 2) University of Pittsburgh School of Medicine, Pittsburgh, PA.

In cooperation with the support organization for Trisomy 9, we designed a survey to further elucidate the phenotype associated with Trisomy 9. One goal of the study was to compare the outcome of individuals with mosaic Trisomy 9 (Group A; n=7), duplications of chromosome 9 (Group B; n=8) and individuals with unbalanced translocations involving chromosome 9 (Group C; n=14). Variations existed within each of the groups based on the extent of trisomy present for chromosome 9 and whether there was imbalance for an additional chromosome. Based on the results of the survey, we found that pregnancy complications such as spotting and certain perinatal complications including RDS and jaundice were more common in Group C. Decreased fetal movement, prenatal ultrasound abnormalities, decreased growth parameters at birth and poor Apgar scores were more common in Group A and equally as common in Groups B and C. Although all individuals had pediatric difficulties, microcephaly, failure to thrive, seizures, feeding difficulties, ophthalmologic, and orthopedic problems were more common amongst individuals in Group C. Cardiac abnormalities were more common in Group A and hypotonia was more common in Group B. GI, GU and behavior problems were equally common among the three groups. Overall, developmental delays were more severe in Group A, however the one individual with the most age appropriate development was in Group A. Gross motor skills including rolling, sitting, and walking were attained at the earliest age in Group B. Although information regarding language skills was limited, the average age of the onset of babbling and first word was closer to age appropriate in Group C. In conclusion, there are differences in phenotypic expression between the three Groups, based on their karyotypic abnormality. In addition, our data is also consistent with the findings of Wilson et al, 1985 which documented that the larger the extent of the trisomy for chromosome 9, the more severe and variable the phenotype.

Program Nr: 1882 from the 1999 ASHG Annual Meeting

Multiple etiologies for hemifacial microsomia. *A.M. Mc Inerney[1], D. Donnai[2], M. Calvert[3], M. Bitner-Glindzicz[4]*. 1) NHGRI, NIH, Bethesda, MD; 2) MGB, St. Mary's Hospital, Manchester, UK; 3) Dental Dept, Great Ormond Street Hospital, London, UK; 4) MGB, Institute of Child Health, London, UK.

Hemifacial microsomia (HFM) results from underdevelopment of one or more branchial arches. This typically causes facial asymmetry and conductive hearing loss, usually due to narrowing of the external auditory canal. Most patients have preauricular skin tags and many also have malformed ears (microtia or anotia).

Due to the asymmetric nature of HFM, it is widely regarded as a non-genetic condition. However, familial cases with autosomal dominant inheritance have been observed[1]. An empiric recurrence risk of 2-3% is usually given to parents of an affected child in the absence of a positive family history. One study showed a 10% recurrence risk in first and second-degree relatives of affected individuals[2]. No other studies have confirmed or contradicted these results.

We reviewed the family and antenatal histories of 32 probands for the spectrum of abnormalities associated with HFM. 3 of 32 individuals (9.4%) had a positive family history, suggesting autosomal dominant inheritance with reduced penetrance.

There was a 3-fold increased incidence of twinning (3 sets in 32 cases) with two MZ and one DZ pairs. All three sets were discordant for HFM and negative for family history. This supports previous findings of a vascular origin for some cases of HFM[3]. The DZ pair may suggest a compressive etiology as well.

The HFM phenotype may result from two different mechanisms. The recurrence risk in the presence of a positive family history approaches 50%. Many others may have an environmental etiology, with a recurrence risk much less than than the empiric 2-3%.

Program Nr: 1883 from the 1999 ASHG Annual Meeting

PHACE syndrome: an association of facial hemangiomas and congenital malformations. *C. McKenna[1], L. Krystal[2], R. Shenoy[3], S. Levine[4], D. Kholwadwala[3], L. Mehta[1].* 1) Medical Genetics; 2) Pediatric Dermatology; 3) Cardiology; 4) Ophthalmology. North Shore Univ. Hospital-N.Y.U School of Medicine, Manhasset, N.Y.

There are at least 43 reviewed cases of a constellation of anomalies represented by the acronym PHACE: Posterior fossa malformations, Hemangiomas, Arterial anomalies, Coarctation of aorta and Cardiac defects, and Eye abnormalities (Frieden, 1996). Ventral wall anomalies such as sternal clefts are also reported. While Dandy-Walker malformation and hemangiomas have been reported to co-exist, the extended spectrum of anomalies listed above is rarely recognized. We report a female infant with features of this association. She was the full term product of an uncomplicated pregnancy. Birth weight was 4010 gm. and no facial dysmorphic features were present. A double outlet right ventricle with V.S.D was diagnosed; head sonogram showed Dandy Walker malformation with no hydrocephalus. A quadrantic lens opacity with adherent leukoma was present in the right eye. High resolution blood chromosomes and FISH testing for a 22q11.2 microdeletion were normal. At 4 weeks age, progressively increasing bluish, tense swellings appeared on the left side of the face, identified as dermal to subcutaneous hemangiomas that eventually involved the entire left cheek, temporal and periorbital regions. About 4-5 small cafe-au-lait spots were present over limbs and trunk. The hemangiomas regressed dramatically with high-dose prednisone but recurred and still present a significant concern at age 1 year. The infant is stable from cardiac and neurological aspects. As reviewed by Frieden, most reported cases of this association are female (88%) and all were identified through large, plaque-like facial hemangiomas, unlike those in our patient. The hemangiomas may be aggressive and can involve airways; posterior fossa malformations are present in 74%, arterial anomalies in 41%, cardiac or aortic anomalies in 26% and eye anomalies in 23%. This combination of birth defects suggests an early prenatal developmental field defect. Awareness of these defects is important in the evaluation and management of these infants.

Program Nr: 1884 from the 1999 ASHG Annual Meeting

Multiple schwannomas in identical twins. *W.C. McKinnon[1], A.E. Guttmacher[2], L.B. Jacoby[3], M. MacCollin[4]*. 1) Dept Pediatrics, Univ Vermont Col Medicine, Burlington, VT; 2) National Human Gemone Research Institute, National Institutes of Health, Bethesda, MD; 3) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown, MA; 4) Neuroscience Center, Massachusetts General Hospital, Charlestown, MA.

Schwannomatosis is a rare condition characterized by multiple nonvestibular schwannomas in the absence of other clinical signs of neurofibromatosis type 2 (NF2). Tumors from patients with schwannomatosis frequently harbor NF2 gene mutations and loss of heterozygosity, however, germline NF2 mutations are not found. Some individuals with multiple schwannomas are somatic mosaics for an NF2 mutation, while others, particularly those with a family history, appear to have an inherited predisposition to form tumors that carry somatic alterations of the NF2 gene. We present a case of identical twins with multiple schwannomas and the molecular analysis on a tumor from one of the twins. The proband has multiple skin tumors, which first appeared on the legs between the ages of 10 and 12, and later on the arms, abdomen, and back. At age 26, the proband had a thoracic nerve root tumor removed and pathological analysis revealed a schwannoma. Detailed dermatologic, ophthalmologic, and radiologic examinations showed no evidence of NF1 or NF2. The probands identical twin had an eosinophilic granuloma removed from his skull as a child. Skin tumors appeared in the second decade in a pattern similar to his twin. MRI of his spine showed no lesions. The family history is of note for a sister who had a pilomatricima removed from her arm. No other family member has a pathological verified tumor and the sister, mother, and maternal grandmother have been examined in detail with no evidence of NF1 or NF2. The family is of French Canadian ancestry. Tumor analysis from the proband's spinal schwannoma revealed a truncating mutation in the NF2 gene in exon 14 (1549 ins 29 base pairs). Schwannomatosis is a rare, third major form of NF. To our knowledge, this is the first report of identical twins concordant for the disorder. Further studies are underway to define the extent of the disease and the underlying molecular basis in this family.

Program Nr: 1885 from the 1999 ASHG Annual Meeting

Haas (Type IV) Polysyndactyly Presenting Prenatally with Bilateral Tibial Aplasia. *E.W. McPherson[1,2], W.A. Hogge[1,3]*. 1) Dept Genetics, Magee Womens Hosp, Pittsburgh, PA; 2) Dept Human Genetics, Univ of Pittsburgh, GSPH, Pittsburgh, PA; 3) Dept of ObGyn, Univ of Pittsburgh, School of Medicine.

A 34 yo primigravida presented at 20 weeks because of fetal limb anomalies discovered on routine ultrasound. The fetus was appropriate for gestational age and the anomalies, which were confined to the limbs, included polydactylous severely clubbed feet, bilateral tibial aplasia, bilateral mild radial hypoplasia and cupped hands. The father had a history of bilateral cutaneous syndactyly of the third, fourth and fifth fingers with polyphalangism and polydactyly of the left thumb. Following surgery his hand function was excellent. His feet were unaffected. The fetal karyotype was normal. Due to the severity of the limb defects, the couple decided to terminate the pregnancy.

The 350 gr fetus had severe limb anomalies but no facial dysmorphism and no internal malformations. The wrists were in mild radial deviation. The hands were cupped with complete cutaneous syndactyly of all digits and fusion of the nails. There were six digits including a duplicated hypoplastic thumb on the right and five digits but no recognizable thumb on the left. There were bilateral severe equinovarus feet due to tibial aplasia. Both feet showed polysyndactyly with fusion of the nails.

The fetal hands and feet were typical for Haas (type IV) polysyndactyly which is an autosomal dominant with marked intrafamilial variability. Several typically affected patients have had a parent with partial syndactyly similar to the father of our patient. One previously reported patient had unilateral tibial aplasia. Because the frequency of Haas polysyndactyly is estimated at 1/300,000 and that for tibial aplasia is 1/1,000,000 coincidental occurrence of these anomalies in a second patient is extremely unlikely. Despite thumb involvement, radial hypoplasia has not been previously reported in Haas polysyndactyly. Our case extends the phenotypic spectrum of Haas polysyndactyly to include bilateral tibial aplasia and radial hypoplasia.

Program Nr: 1886 from the 1999 ASHG Annual Meeting

Pallister Hall syndrome:early diagnosis and natural history. *N.J. Mendelsohn[1,2], C. Ludowese[1,2], R. Kriel[1,2], O.A. Schirripa[3], D.K. Manchester[3], L.G. Biesecker[4].* 1) Dept Pediatrics/Med Genetics, Hennepin County Medical Center, Minneapolis, MN; 2) University of Minnesota, Minneapolis, MN; 3) University of Colorado Health Sciences Center; 4) GDRB, NIH/NHGRI, Bethesda, MD.

Pallister Hall Syndrome(PHS) is a condition with hypothalmic hamartoma(HH), polydactyly, bifid epiglottis and visceral anomalies. Hall et al first delineated the syndrome in 1980. Multiple case reports have broadened the diagnostic features from a lethal presentation to one where multiple generations are affected in an autosomal dominant manner. We report two infants diagnosed at an early age with a large HH and polysyndactyly. These infants demonstrate the imporance of early recognition and diagnosis as well as the natural history of PHS.

A 1st patient presented at ten weeks of age with polydactyly and feeding difficulties. ENT consultation revealed bifid epiglottis. A cerebral MRI disclosed a large suprasellar mass. Neurosurgical resection was planned but afer extensive discussion and evidence of no change in size of the mass, He was diagnosed with a benign HH as part of the PHS. A 2nd child presented at 16 days of age with polysyndactyly and a UTI. Further evaluation revealed an anterior rectal fistula. MRI of her head disclosed a HH. We present photographs of the children, subsequent MRIs, growth charts and results of endocrinologic evaluations.

These cases demonstrate important clinical aspects of Pallister Hall Syndrome. Polysyndactyly of PHS is typically central or postaxial and careful attention should be paid to families with four limb polydactyly. This in combination with midline defects should prompt a cerebral MRI. The correlation with these children's other congential malformations provided the correct diagnoses and avoided surgical removal of a major portion of their hypothalamic regions. Characteristically of PHS, the tumors have now been followed with no enlargement of the hamartoma and no evidence of malignant transformation. PHS has been mapped to 7p13. Biesecker et al reported two PHS families with frameshift mutations in GLI3. Evaluation of the GLI3 region is in progress for these children.

Program Nr: 1887 from the 1999 ASHG Annual Meeting

Autosomal dominant dilated cardiomyopathy with subclinical skeletal muscle involvement. *L. Mestroni[1], S. Miocic[3], G. Sinagra[4], G.L. Brodsky[1], M.R. Di Barletta[5], A. Mateddu[2], D. Toniolo[5], F. Muntoni[2].* 1) Dept Molec Genetics, CV-CVI, Univ Colorado, Aurora, CO; 2) Dept. of Paediatrics, Imperial College, London U.K; 3) ICGEB, Trieste, Italy; 4) Dept. of Cardiology, Ospedale Maggiore, Trieste, Italy; 5) IGBE-CNR, Pavia, Italy.

Background: Dilated cardiomyopathy (DC) is a heart muscle disease, characterised by impaired myocardial contractility and dilatation of the left or both ventricles, which is the leading indication for heart transplantation. DC is frequently inherited (familial DC or FDC) and genetically heterogeneous. The aim of this work was the study of a subgroup of FDC families characterized by autosomal dominant transmission and subclinical skeletal muscle disease. **Methods**: Relatives of 40 index patients with FDC underwent a detailed pedigree reconstruction and a non-invasive clinical screening with electrocardiography and echocardiography. Affected relatives completed the investigations with cardiac catheterization and endomyocardial biopsy. An accurate neurological examination including a skeletal muscle biopsy (SMB) was performed whenever possible. **Results**: Out of 5 families with FDC showing subclinical signs of skeletal muscle involvement, three families presented an autosomal pattern of inheritance, therefore excluding X-linked DC. In family MDDC2 and MDDC3 the cardiac disease was characterised by arrhythmia, severe left ventricular dilatation and dysfunction, segmental wall motion abnormality, and significant improvement with medical treatment. The neurological examination was unremarkable. Family MDDC1 was characterized by the presence of histological myocarditis and highly variabile skeletal muscle involvement in the affected individuals, from none to mild signs of limb-girdle muscle distrophy, or mild rigidity of the elbows, spine and Achilles tendon. Serum CK levels were variable from normal to slightly increased even in the same individual. SMB and EMG were invariably pathological. **Conclusions**: Skeletal muscle disease can underlie FDC and must be carefully investigated. Genes expressed in both skeletal and cardiac muscle may be candidates for causing this disorder.

Program Nr: 1888 from the 1999 ASHG Annual Meeting

Congenital intracranial lipoma. *P. Mezzano, C. Bellini, D. Massocco, E. Zullino, F. Campone, M. Mazzella, W. Bonacci, G. Serra.* Servizio di Patologia Neonatale, Universita Genova, Istituto Gaslini, Genova, Italia.

Case report: a male infant was born by vaginal delivery at 34 weeks of gestational age of uneventful pregnancy (weight 2025 g, lenght 45 cm, head circumference 32 cm; all parameters at 25-50 percentile). Physical evaluation showed multiple ecchymoses (face and left arm) and back dermal sinus on the midline. Shortly after birth he developed respiratory distress syndrome that needed ventilatory support. Neurological examination revealed clonus of the extremities. A routinary cerebral echographic evaluation revealed an hyperechoic image (0.5x0.3 cm, median sagital scan) situated down to the splenium of the corpus callosum, first referred to a possible hemorrage. CT images revealed hypodense lesion that did not enhance after contrast injection. T1-weight images demonstrated marked hyperintense lesion of the velum interpositum region. These radiological findings strongly supported the diagnosis of intracranial lipoma (ICL). ICLs are uncommon, benign and congenital malformations of the central nervous system, most often found in the midline, whose development remains poorly understood. Incidence is estimated at less than 0.1% of all intracranial tumors. The most common sites of occurrence are corpus callosum, quadrigeminal/superior cerebellar cistern, suprasellar/interpeduncolar cistern, cerebello-pontine angle cistern, and sylvian cistern. At least half of these lipomas are associated with other brain anomalies. Generally they are asymptomatic, becoming symptomatic because of both the site of lesion and of the involvment of the surroindings structures in regressive change within the lipoma tissue. ICLs formation might result from abnormal persistence and maldifferentiation of the meninx primitiva into lipomatous elements, so considering ICL as a choristoma.

Program Nr: 1889 from the 1999 ASHG Annual Meeting

Autism: family histories concordant for alcoholism. *J.H. Miles, N. Takahashi, C. Jones, R.E. Hillman.* Univ. Missouri Hospital and Clinics, Columbia, MO.

Genetic overlap between autism and other neuropsychiatric disorders is suggested by 1) reports that alcoholism, affective disorders and schizophrenia aggregate in families ascertained through an autistic child, 2) overlap of candidate genes/areas identified for neuropsychiatric disorders (AJMG.79.1998), & 3) biological/pharmacological evidence that dysregulation of the neurotransmitter systems (serotonin, dopamine, etc) are involved in all these disorders. To begin to define the neuropsychiatric disorders which segregate together, families ascertained through an autism proband were studied to determine prevalence and pedigree configuration of associated neuropsychiatric disorders. We suspect subsets of autism families with similar family histories will be more homogeneous. A consecutive sample of 119 autism probands with complete pedigrees were analyzed. Family history was ascertained using direct semi-structured interviews (family history method). A significant family history of alcoholism (i.e. an affected 1^0 relative; 2^0 relative plus 3 others in a mendelian pattern; or at least 4 affected relatives in the same family branch) was observed in 34% (41/119) of the families. **Results:** In hi-alcohol families, 20% mothers, 61% fathers, 15% MGM, 44% MGF, 25% PGM, 42% PGF were alcoholics. The hi-alcohol autism families had more relatives with an autistic disorder (34% vs. 15%, $p<0.02$), and affective disorders (49% vs. 18%, $p<0.001$), and a higher sibling recurrence (17% vs. 10%, $p<0.2$). These findings were the same for unilineal and bilineal (for alcohol) families and not influenced by the sex of the transmitting parent. In hi-alcohol families, probands had significantly higher IQs/DQs ($p<0.05$), were less likely to be macrocephalic, and more likely to have regressed at onset; families were of lower SES. Hi and low alcohol families reported no difference in cognitive or language disorders, dyslexia, ADHD or seizures. The high incidence of alcoholism in autism families and different features in hi vs. low alcohol families indicates there are genes which predispose to both autism and alcoholism. The lack of association between alcoholism and autism in the alcohol literature suggests that only a subset of alcoholism is caused by these genes.

Program Nr: 1890 from the 1999 ASHG Annual Meeting

Dysmorphic facial features, CNS abnormalities, hand malformations, and myocardial cytomegaly in three female fetuses: A familial fetal neurodegenerative disorder? *P.T. Mohide[1,2], M.J. Huggins[1], J.A. Ramsay[1,2,3], J. Woulfe[1,2,3], J. Provias[1,3], K. Chorneyko[1,2,3], M.J.M. Nowaczyk[1,2,3].* 1) Faculty of Health Sciences, McMaster Univeristy, Hamilton, Canada; 2) Hamilton Health Sciences Corporation, Hamilton, Canada; 3) Hamilton Regional Laboratory Medicine Program, Hamilton, Canada.

A 36 year old G4TA2E1 woman with bilateral fifth finger clinodactyly, minimal cutaneous toe syndactyly, and didelphic uterus had three female fetuses with a unique association of malformations. Her mother and brother had polycystic kidney disease, her renal ultrasound (US) was normal. She was referred at 22 weeks gestation in her first pregnancy for evaluation of abnormal brain contour identified by US. The pregnancy was terminated and postmortem examination showed a dysmorphic fetus with bitemporal narrowing, fifth finger clinodactyly, low set ears, retromicrognathia, 11 pairs of ribs, bilateral club feet, and a thickened frenulum bisecting the upper alveolar ridge. Neuropathologic abnormalites included agenesis of the olfactory bulb and of corpus callosum, minimal frontal lobe hemispheric fusion,and marked midline fusion of the deep gray matter nuclei. In the third and fourth pregnancies, US examinations were normal until 19 and 13 weeks gestation, but repeat US three and two weeks later respectively showed similar cranial abnormalities with overlapping skull bones. External dysmorphic features were similar in the three fetuses. Myocardial cytomegaly was demonstrated microscopically in the absence of congenital heart disease, infection, or cytomegaly in other organs. Ultrastructural studies showed accumulated mitochondria in the enlarged myocardiocytes. The following were normal: electron transport chain assays and lactate/pyruvate ratio in culured fetal skin cells, and amniotic fluid organic acid and 7-DHC levels. The fetal karyotypes were 46,XX. To our knowledge this pattern of malformations has not been reported previously. It is possible that the CNS anomalies are a result of a fetal neurodegenerative disorder progressing during the second trimester, however, at the present time the cause of these abnormalites remains unknown.

Program Nr: 1891 from the 1999 ASHG Annual Meeting

NF1 and overgrowth syndrome resembling Weaver syndrome in 3 sporadic patients. *A. Moncla[1], C. Missirian[2], O. Pincemaille[3], J. Mancini[2], M.O. Livet[2], P. Malzac[1], N. Philip[1].* 1) Department of Medical Genetics, Hopital d'Enfants de la Timone, Marseille, France; 2) Department of Neuropediatrics, Hopital d'Enfants de la Timone, Marseille, France; 3) Department of Pediatrics, Bastia, France.

We report three unrelated patients presenting the combination of an overgrowth syndrome resembling Weaver syndrome and NF1. This association has been described by Hennekam et al (J Med Genet, 1998)in two related patients. The three patients were referred for unexplained mental retardation with behavioral problems. All of them exhibited a remarkable coarse face with hypertelorism, epicanthic folds, large ears, fetal finger pads and hyperextensible fingers. Height and head circumference were above the 97th centile and osseous maturation was advanced in all. All presented more than 5 cafe-au-lait spots. One of them developed precocious puberty related to intracranial glioma. Moderate psychomotor and language delay were present with a particular behavioral phenotype. All three patients had a hoarse and low-pitched voice. RHG-banded karyotypes were normal. Molecular analyses of the 17q11.2 region are in progress to test the hypothesis of a deletion encompassing the NF1 gene.

Program Nr: 1892 from the 1999 ASHG Annual Meeting

Recurrence of Kabuki Make Up Syndrome in siblings. *A. Monier[1], C. Helsemans[2], L. Van Maldergem[1]*. 1) Centre de Genetique Humaine, Inst. Pathologie et Genetique, Loverval, Belgium; 2) Department of Paediatrics, Centre de Sante des Fagnes, Chimay, Belgium.

The Kabuki make-up syndrome is characterized by mild to moderate mental retardation, short stature, prominent fingerpads and characteristic facial features that include long and thick eyelashes, eversion of lateral lower lid, arched eyebrow with sparse lateral third, broad nasal tip, prominent ear lobes and cleft or high arched palate. More than 70 cases have been reported since its first description in 1981 by Niikawa and Kuroki. It usually occurs sporadically, however, in five instances, a possible dominant transmission has been reported. We describe here a boy born to non consanguineous Belgian parents evaluated at 11 years of age for mild mental retardation (IQ 73) , bilateral cleft lip and palate and facial dysmorphia highly suggestive of Kabuki syndrome. His stature was at 50th centile. He underwent surgery for bilateral cryptorchidism. Interestingly, his younger brother also had mild mental retardation (IQ 63) , ventricular septal defect and a facial dysmorphia compatible with Kabuki syndrome. Bilateral renal cortical cysts and left cryptorchidism were also observed. A photograph of the deceased father was normal. He had a digitalized left thumb without any other clinical abnormality. The mother and her three subsequent children are also normal. This is the first report of Kabuki syndrome recurrence in siblings born to normal parents. It may point to gonadal mosaicism in one parent or, alternatively, to genetic heterogeneity of the condition with autosomal recessive or X-linked recessive patterns of inheritance coexisting with an autosomal dominant form.

Program Nr: 1893 from the 1999 ASHG Annual Meeting

The wrinkly skin syndrome: Report of a new case and expansion of the phenotype. *A. Moon, A. Shanske.* Dept. of Pediatrics, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY.

In 1973, Gazit described a disorder in sibs, wrinkly skin syndrome (WSS), characterized at birth by wrinkly skin of the hands and feet who developed hypotonia and winging of the scapulas. Only 9 additional cases have been since reported and most have had prominent neurologic involvement including mental retardation, microcephaly and seizures. We have identified a new case with previously unreported genitourinary and gastroenterologic abnormalities.

PW was the 3.13 kg product od a term pregnancy complicated by polyhydramnios and hydronephrosis diagnosed prenatally. The family history was unremarkable and the parents were unrelated. The newborn exam revealed generalized hypotonia and wrinkled skin over the trunk, abdomen and extremities with sparing of the face and anemia. Ultrasound studies revealed bilateral hydroureters/nephrosis with no refux. Because of poor suck and GER, he required a gastrostomy at 3 months and was hospitalized several times thereafter with pseudoobstruction. Radiologic studies have repeatedly shown multiple dilated loops of small bowel. A skin biopsy showed normal morphology and a normal elastin fiber stain. At 13 months of age he appeared a stigmatized small hypotonic child. His height wsa 68.5 cm(<<3%), his weight was 6.4 kg (<<3%), and his HC was 46.5 cm (25%). He had a preauricular fistula, a tongue-thrust habit, hypertelorism, alternating esotropia and conjunctival melanosis. The skin wrinkling was restricted to the abdomen and the dorsum of the hands and feet and he had a large ventral hernia.

The WSS is a rare connective tissue disorder with prominent neurologic features with no known biochemical defect of collagen. It has been postulated that the pathogenesis of the wrinkled skin is fetal lymphedema and an overabundance of skin. We suggest that perhaps some of the wrinkling is due to urinary tract and gastrointestinal obstruction as observed in our patient. We feel that hydroureter/nephrosis and pseudoobstruction are manifestations of WSS and part of a generalized connective tissue disorder.

Program Nr: 1894 from the 1999 ASHG Annual Meeting

Charcot-Marie-Tooth neuropathy and Duchenne muscular dystrophy segregating in the same family: clinical and genetic studies. *L. Mota-Vieira[1], F. Martins[1], E. Vieira[2], S. Tardieu[3], A. Guimaraes[4], M. Melo Pires[4], E. Medeiros[5], J. Lopes[1], M.R. Santos[2], E. LeGuern[3], J. Santos[1]*. 1) Hosp Ponta Delgada, Ponta Delgada, Portugal; 2) Inst Genetica Medica, Porto, Portugal; 3) INSERM U-289, Paris, France; 4) Hosp St Antonio, Porto, Portugal; 5) Hosp Egas Moniz, Lisboa, Portugal.

In the Portuguese Azorean Islands we identified a family showing segregation of two neuromuscular diseases: Charcot-Marie-Tooth (CMT) neuropathy and Duchenne muscular dystrophy (DMD). In this family the mother, 1 son and 1 nephew are affected with CMT, whereas 2 other sons had a compound phenotype of both diseases. We performed a clinical study, including neurological examination, serum CPK determination, electrophysiological study and nerve and muscle biopsies, and the molecular genetic analyses for both diseases. The two CMT-DMD brothers have generalized weakness, muscle wasting and areflexia, pes cavus and scoliosis, predominantly. The clinical data and the inheritance mode of the hereditary neuropathy were compatible with a CMT1 or a CMTX1. Molecular study showed that the CMT phenotype cosegregates with 17p11.2 duplication. In the CMT-DMD brothers immunohistochemistry analysis showed an abnormal location of dystrophin on the majority of muscle fibers. No deletion or duplication was found on analysis of the DMD gene. Genotyping revelead that the DMD haplotype was of grandpaternal origin, and elevated CPK levels in the mother corroborated her carrier status at the somatic level. One maternal aunt was found to be a non-carrier, based on the haplotype of her son affected with CMT, whereas the other maternal aunts were attributed the a priori risk of 14% of being carriers due to paternal gonadal mosaicism. Our results indicate that the gene dosage of PMP22 associated with the absence of properly localized dystrophin can explain the compound phenotype of both CMT-DMD brothers. To the best of our knowledge these patients are the first cases described. Moreover, the identification of the different mutated genes segregating in this complex family is essential to propose genetic counselling and prenatal diagnosis for all members of the family.

Program Nr: 1895 from the 1999 ASHG Annual Meeting

High rates of schizophrenia in velo-cardio-facial syndrome. *K.C. Murphy[1,2], L.A. Jones[1], M.J. Owen[1]*. 1) Department of Psychological Medicine, University of Wales College of Medicine, Cardiff, UK; 2) Department of Psychological Medicine, Institute of Psychiatry, King's College, London, UK.

Velo-cardio-facial syndrome (VCFS), a syndrome characterised by distinctive dysmorphology, congenital heart disease and learning disabilities, is associated with small interstitial deletions of chromosome 22q11. In view of previous reports of a high prevalence of psychosis in VCFS, we undertook the present study to characterise the psychiatric phenotype in the largest interviewed series to date of adults with VCFS. We evaluated 50 adults with VCFS using a structured clinical interview (Schedules for Clinical Assessment in Neuropsychiatry or Psychiatric Assessment Schedule for Adults with Developmental Disability if IQ < 50) to establish a DSM-IV diagnosis. The schizophrenia phenotype in individuals with VCFS and schizophrenia was compared to a matched series of individuals with schizophrenia without VCFS (n = 12). The Kings Schizotypy Questionnaire was administered to VCFS individuals (n = 41), their first-degree relatives (n = 68) and a series of unrelated normal controls (n = 316). All VCFS individuals were genotyped for a novel promoter polymorphism in the COMT gene and also for a genetic polymorphism in the COMT gene which results in variations in enzymatic activity. Thirty per cent (n = 15) of individuals had psychotic disorder with 24% (n = 12) fulfilling DSM-IV criteria for schizophrenia. In addition, a further 12% (n = 6) had major depression without psychotic features. The individuals with schizophrenia had fewer negative symptoms and a relatively later age of onset compared to individuals with schizophrenia without VCFS. We found no evidence that either a promoter polymorphism or presence of the low activity allele of the COMT gene was associated with psychosis in our sample of individuals with VCFS. The high prevalence of schizophrenia in this group suggests that chromosome 22q11 might harbour a gene or genes of relevance to the aetiology of schizophrenia in the wider population.

Program Nr: 1896 from the 1999 ASHG Annual Meeting

congenital lymphedema,unilateral choanal atresia,pericardial effusion, high arched palate and preauricular pits: A possible new autosomal recessive syndrome. *a.m nadroo, e. lieber, m. zak, i. bialik, d. menos.* pediatrics, new york methodist hospital, brooklyn, NY.

Congenital lymphedema was described by Milroy as an autosomal dominant condition in 1928. Other congenial abnormalities have been described in association with congenital lymphedema, leading to proposals of autosomal dominant, autosomal recessive and X-linked dominant modes of inheritance. We describe a patient with a familial congenital lymphedema, choanal atresia, pericardial effusion and preauricular pits-a possibly undescribed constellation of features. The proband is a 19-year-old female. She was admitted for cellulitis of her left hand. Physical examination revealed lymphedema of lower extremities, both hands and forearms. The patient had preauricular pits and a high arched palate. No other dysmorphic features were noted. She had normal vision and hearing. A review of her records showed that she was a product of a consanguineous marriage and a normal pregnancy, born at 37 weeks of gestation. Her birth weight was 3200g. At the age of one month she had corrective surgery for a left-sided choanal atresia, diagnosed shortly after birth. At the age of 19 months,she developed progressive swelling of both lower extremities, diagnosed as lymphedema. She was admitted for pericardial effusion on three occasions, at the ages of 12, 13 and 14 years. Echocardiograms and renal sonograms failed to reveal any underlying structural cardiac or renal abnormalities. However, the third episode of pericardial effusion was treated with pericardiotomy. The patient has had a normal developmental course and is an average student. Chromosomal studies showed a normal karyotype of 46, XX. There are eight other family members with a variety of phenotypic expressions similar to those present in the patient, all resulting from consanguineous marriages. All the parents are phentypically normal. Three individuals have all five of the phenotypic features present in the patient, including two brothers of the proband.The association of familial lyphedema with unilateral choanal atresia, pericardial effusion, high arched palate and preauricular pits, discloses a possible new autosomal recessive syndrome.

Program Nr: 1897 from the 1999 ASHG Annual Meeting

Deletion 2q37.1 in a child with familial paroxysmal kinesiogenic choreoathetosis. *R. Naeem, A.H. Jackson, G. Cohn, J. Sullivan, H.E. Gilmore.* Departments of Pathology, Pediatrics, Obstetric/Gynecology and Neurology, Bay State Medical Center and Tuft University School of Medicine, Springfield and Boston, MA.

Genes for paroxysmal choreoathetosis have been recently mapped using linkage analysis by two independent groups to chromosome 2q. We present a 7 year old child with familial paroxysmal kinesiogenic choreoathetosis with a deletion in the long arm of chromosome 2 (q37.1). This child presented with mildly delayed motor development but fairly normal language development. At about 17 months of age he developed episodes in which he would have dystonic extensor posturing of the arms which were later noted to be precipitated by activity such as playing with a puzzle. Except for mild cognitive impairment, his neurologic exam was normal. Genetic evaluation revealed evidence of a high arched palate, mild hypotonia and umbilical hernia, but no other significant dysmorphic features. Family history revealed that one of the authors had evaluated the maternal uncle in the past with the same diagnosis. Peripheral karyotypes of mother, affected uncle, maternal aunt and maternal grand parents were normal. Paternal side of history and karyotypes are unavailable. Lymphoblast cell lines from all these family members have been established and further studies will be performed with collaborations. As most of these disorders are probably due to the defects in ion channel genes and there is a cluster of ion channel genes on distal 2q, this case may represent the precise cytogenetic region involved with this disorder and may be helpful for identifying and cloning candidate genes.

Program Nr: 1898 from the 1999 ASHG Annual Meeting

A new X-linked mental retardation syndrome with distal limb defects, hearing impairment, verrucosis and immunodeficiency. *J.C. Oosterwijk[1], A. Wischmeijer[1], M. Losekoot[2], A. Haraldson[3], G. Theunissen[4], I. van Gelderen[5].* 1) Dept Medical Genetics, Groningen Univ, Groningen, Netherlands; 2) Dept Medical Genetics, Leiden Univ Medical Centre, Netherlands; 3) Dept Pediatrics, Univ Hospital, Reykjavik, Iceland; 4) Hooge Burch, Zwammerdam, Netherlands; 5) Eemeroord, Baarn, Netherlands.

We descibe 3 related male patients who are affected with a condition characterized by mild mental retardation, a varying degree of a/symphalangism of hands and/or feet, hearing loss, extensive verrucosis and mild impairment of both cellular and humoral immunity. Additional features are dysplastic ears, scoliosis, hypermetropia, congenital heart defects, body hypertrichosis and facial dysmorphic features. We assume X-linked inheritance in this familial non-progressive retardation syndrome. Two female obligate carriers and one female at 50% risk showed now features other than from mild symphalangism of several toes on extensive investigation. The differential diagnosis of this unusual and previously undescribed combination of symptoms is discussed. DNA analysis using polymorphic markers spanning the entire X-chromosome revealed that the patients share a region from Xp11.4 to Xq24, approximately 90 Mb.

Program Nr: 1899 from the 1999 ASHG Annual Meeting

Growth manifestations and development in the cri-du-chat syndrome. *J. Overhauser[1], M. Kouahou[1], R.C. Marinescu[1], P. Cerruti Mainardi[2].* 1) Dept. of Biochem/Molec Pharm, Thomas Jefferson Univ, Philadelphia, PA; 2) S.Andrea Hospital, Vercelli, Italy.

Cri-du-chat syndrome is a partial aneusomy syndrome that is associated with a deletion of the short arm of chromosome 5. At birth, a cat-like monochromatic cry is heard and is considered diagnostic for the syndrome. In addition, a microcephalic round face with hypertelorism and low birth weight are typically observed. As the infant ages, both growth and developmental delays are common. In order to determine the normal growth pattern for children with cri-du-chat syndrome, growth parameters were obtained for children with cri-du-chat syndrome from ages 0-18. Through the cooperation of members of the US, Australian, and Italian cri-du-chat syndrome parent support groups, pediatric records as well as parent reporting of growth information from over 250 females and 150 males were obtained. Height, weight, and head circumference growth curves have been developed for both males and females and are compared with the growth curves from the normal population. The development of these growth curves will be useful for physicians when determining when nutrient intervention is needed. In addition, information on the age of accomplishment of various developmental milestones was obtained. This information will be useful to parents and physicians in anticipating what and when certain developmental milestones will be achieved by children diagnosed with cri-du-chat syndrome.

Program Nr: 1900 from the 1999 ASHG Annual Meeting

Miller-Dieker syndrome due to ring chromosome 17. *A.P. Pai[1], N. Al-Sanah[2], S. Blaser[3], D. Chitayat[1,2].* 1) The Prenatal Diagnosis Program, The University Health Network, University of Toronto, Toronto, Ontario, Canada; 2) Department of Pediatrics, Division of Clinical Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 3) Department of Pediatrics, Division of Radiology, Hospital for Sick Childen, University of Toronto, Toronto, Ontario, Canada.

Miller-Dieker syndrome consists of lissencephaly, microcephaly, characteristic facies with. vertical furrowing , pre- and postnatal growth retardation, and various other birth defects. About 50-70% of the cases with Miller-Dieker syndrome can be shown to have a deletion of 17p13.3 by light microscopy and almost all the remainder will have a submicroscopic deletion, most easily demonstrated by fluorescent in situ hybridization (FISH). We present a case with ring chromosome 17 and clinical findings consistent with Miller-Dieker syndrome. Prenatally, first trimester ultrasound scanning revealed an increased nuchal translucency measurement of 3 mm. An ultrasound performed at 17 weeks demonstrated mild IUGR with mild polyhydramnios. No other abnormalities were detected. Further ultrasound scans at 30 and 37 weeks showed polyhydramnios, IUGR, query agenesis of the corpus ccallosum and absent cisterna magna. Prenatal chromosome analysis revealed 46,XX,r(17)(p13q q25). Parental karyotypes were normal. MRI showed lissencephaly with an hourglass configuration consistent with Type 1 lissencephaly. A review of the literature has revealed only 3 previous cases where clinical features of Miller-Dieker syndrome were associated with ring chromosome 17. Further studies are being done to delineate the role of dominant genes deleted in this case in the pathogenesis of the clinical findings. This case further emphasize the importance of increased NT in the diagnosis of fetal chromosome abnormalities in general and those associated with fetal akinesia in particular.

Program Nr: 1901 from the 1999 ASHG Annual Meeting

Possible mother-daughter transmission of Wildervanck syndrome. *J.G. Pappas, E. Rimar, V.B. Penchaszadeh.* Div Medical Genetics, Beth Israel Medical Ctr, New York, NY.

The Wildervanck (cervico-oculo-acoustic) syndrome includes congenital perceptive deafness (sensorineural, conductive, or mixed), Klippel-Feil anomaly (fused cervical vertebrae), abducens palsy with retractio bulbi (Duane syndrome), hemifacial microsomia, epibulbar dermoids, facial assymetry, preauricular skin tags and pits, cranial dysostosis and torticollis. Occasional abnormalities include mental retardation, occipital meningocele, pseudopapilledema, hydrocephalus, growth deficiency, cleft palate, ear abnormalities, cardiac defects, cervical ribs, absent kidney and cholelithiases. All reported cases have been sporadic and the disorder is limited to females, raising the question of sex-linked dominance with lethality in the hemizygous male (Wettke-Schafer, R.; Kantner, G.; Hum. Genet. 64: 1-23, 1983). Wildervanck reviewed the subject and concluded that polygenic inheritance with limitation to females is most likely [Handbook of Clinical Neurology. Amsterdam: North Holland (pub.) 32 1978. Pp. 123-130]. Wildervanck syndrome and hemifacial microsomia may be in the same spectrum of developmental disorders (Cohen MM Jr et al, Cleft Palate Journal. 26(4):276-86, 1989). We present a 10 year old girl with Wildervanck syndrome and her mother with hemifacial microsomia. The proband had growth deficiency, asymmetry of face and limbs (right < left), right sensorineural hearing loss, Klippel-Feil sequence, marked scoliosis of the thoracic spine convex to the right, and right sided Duane anomaly, torticollis and Sprengel deformity. The right hand was osteopenic, smaller and delayed in bone maturation. These anomalies are consistent with the diagnosis of Wildervanck syndrome. The chromosome analysis was normal 46,XX. The mother had right microtia, right hearing loss, craniofacial and limb asymmetry (right < left) and history of two first trimester spontaneous abortions. These features are consistent with hemifacial microsomia. The mother of the proband may represent an incomplete presentation of Wildervanck syndrome, lending support to the hypothesis that the inheritance of this syndrome is X-linked dominant with lethality in the hemizygous male.

Program Nr: 1902 from the 1999 ASHG Annual Meeting

A Korean case of partial trisomy 9 by 3:1 segregation of balanced maternal translocation (6q+;9q-). *S.H. Park[1], M.K. Kim[1], Y.T. Kim[2], Y.H. Lee[2], S.H. Park[3], S.H. Lee[4]*. 1) Department of Pediatrics, Korea University, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Korea University, Seoul, Korea; 3) Department of Anatomical Pathology & Institute of Human Genetics, Korea University, Seoul, Korea; 4) Department of Orthopedics, Korea University, Seoul, Korea.

Trisomy 9p syndrome is a disease that the short arm of chromosome 9 is trisomy and was first described by Rethore, et al., in 1970. Almost 100 cases have been reported after that. Clinical manifestations of this syndrome are craniofacial malformation, facial deformity, skeletal and dermatoglyphic abnormalities with variable degrees of mental retardation.

We experienced a case of partial trisomy 9 syndrome in a 15-month-old female who had multiple congenital anomalies of frontal bossing, oblique antimongoloid palpebral fissures, enophthalmos, hypertelorism, globular prominent nose, down-turned mouth, prominent low-set ears, simian creases of both hands, clinodactyly and single crease of 5th fingers, congenital dislocation of both knees and mental retardation. From cytogenetic studies using G banding technique and flourescent in situ hybridization (FISH), she is presented with an extra derivative chromosome 9. The karyotype of the patient was confirmed as 47,XX,+der(9)t(6:9)(q27;q21.2)mat. This will be presented with review of literatures.

Program Nr: 1903 from the 1999 ASHG Annual Meeting

A mild form of autosomal recessive Craniotubular Dyplasia in a large inbred Brazilian family. *M.R. Passos-Bueno[1], W.R. Wilcox[2], N. Alonso[3], L.G. Alonso[4].* 1) Dept Biologia,IBUSP,So Paulo, SP,Brazil; 2) Div.Med.Genet., Cedars-Sinai Med.Cntr., Los Angeles,CA,USA; 3) Dept. Cirurgia Plastica,FMUSP,SP,BR; 4) Dept. Morfologia,UFSP-EPM,SP,BR.

We report a four generation inbred pedigree with 10 patients affected by a mild form of craniotubular dysplasia. The proband is a 3 year old boy born to healthy consanguineous parents. He has normal stature and intelligence, but bony expansion of the nasal root, hypertelorism, and difficulty breathing. Radiographs and 3-D reconstructed computed tomography of the skull showed sclerosis of the skull and hyperostosis of the nasal root, mandible, and maxilla. In the long tubular bones of the limbs there is increased radiodensity of the cortex of the diaphyses with relative lucency of the metaphyses. Epiphyses are normal. Genu valgum was also present His serum calcium was normal. The 9 other affected relatives have similar facial alterations and also no cranial nerve involvement. All affected patients were born to consanguineous and apparently healthy parents. They had a total of 31 healthy descendants. One of the affected individuals, a 46 year old woman, is of short stature secondary to a short neck and scoliosis due to vertebral and rib fusions. Similar vertebral and rib fusions were noted in a 5 year old boy in the family. He is short but does not have any facial dysmorphism. The clinical and radiological abnormalities in the proband are compatible with a mild form of craniometaphyseal dyplasia (CMD). The pedigree in this family indicates an autosomal recessive (AR) inheritance. While most CMD is inherited as an autosomal dominant trait, a rare AR form has been suggested with a more severe phenotype and cranial nerve involvement. Except for one reported case of CMD with a balanced translocation [46, XX, t(12;18)(q13;q12); Surg.Neurol. 27:284-290, 1987], there has been no association of vertebral abnormalities and CMD. The vertebral anomalies in this family may be a rare manifestation of the disorder or may be due to a second, unrelated, disorder. This family confirms the existence of an AR form of CMD and will assist in the mapping and identification of the CMD gene. FAPESP, HHMI, CNPq, PRONEX.

Program Nr: 1904 from the 1999 ASHG Annual Meeting

Familial Beckwith-Wiedemann syndrome (BWS) with t(11;14)(p15.5;q24.2) in three generations. *L.M. Pasztor[1], J. McGrath[2], J. Reese[3]*. 1) Section of Genetics & Molecular Medicine, Children's Mercy Hospitals&Clinics and the U of MO School of Medicine, Kansas City; 2) Department of Comparative Medicine,Yale Univ. Medical Center, New Haven, CT; 3) Department of Pediatrics,Kansas University Medical Center, Kansas City, KS.

Although most BWS cases are sporadic, several genetic etiologies have been identified. Of these, maternally derived balanced translocations and inversions have been among the rarest. We report an inherited balanced translocation in three generations, two of which showed an individual with the BWS phenotype. CLINICAL: The proband, LM, a 3.5 year female, was 4675 grams at birth. Although her mother, LA, a 19 yr. primagravida, carried the clinical diagnosis of BWS from infancy, antenatal testing had not been pursued. LM was LGA in length, weight and head circumference. Her physical exam showed features of BWS, including an enlarged, protuberant tongue and vertical creases on both ears with a small pit in the posterior helix of each pinna. There were no palpable masses and her liver was normal in size. Postnatally, her initial blood glucose level was 42, then fell to 35 and she required IV dextrose infusion. To date, her growth has been normal with no organomegaly or hemihyperplasia. CYTOGENETICS: Because of the clinical diagnosis of BWS in two generations, chromosome studies were performed which revealed a balanced t(11;14)(p15.5;q24.2) in the proband, her mother and unaffected grandmother, LL. LL's siblings had normal karyotypes. FISH studies with whole chromosome paints on metaphase preparations showed chromosome 14 genetic material translocated distally to the short arm of one chromosome 11. However,the reciprocal der(14) could be detected only when an 11p subtelomeric probe was used. SIGNIFICANCE: Although IGF2, a maternally imprinted gene in 11p15.5, is overexpressed in many individuals with BWS, the molecular breakpoints have been centromeric to IGF2 in blanced translocations. It is possible that these breakpoints disrupt a specific gene or remove a cis-acting element. Future molecular dissection of this and other chromosomal rearrangements may reveal the 11p15 loci critical to the pathogenesis of BWS.

Program Nr: 1905 from the 1999 ASHG Annual Meeting

Thyroid agenesis in Peters' anomaly - A new syndrome? *J.E. Pellegrino[1], J.M. Engel[2], S. Shen-Schwarz[3], C. Benito[1], M. Hiatt[4], D. Chavez[1], D. Day-Salvatore[1]*. 1) Department of Obstetrics, Gynecology and Reproductive Sciences, UMDNJ-Robert Wood Johnson Medical School and Saint Peter's University Hospital, New Brunswick, NJ; 2) Department of Surgery, SPUH; 3) Department of Pathology, SPUH; 4) Department of Pediatrics, UMDNJ-RWJMS and SPUH.

Peters' Plus syndrome is an autosomal recessive disorder characterized by Peters' anomaly of the eye, short limb dwarfism, cleft lip or palate, and characteristic facial features. Heart defect, renal anomalies and SUA have been reported. Jung et al. reported two patients with anterior cleavage disorders, short stature, and typical facial features of Peters' Plus with additional features of congenital hypothyroidism, cerebellar hypoplasia, vertebral anomalies, and tracheostenosis. We report a patient with congenital hypothyroidism, cerebellar hypoplasia, hemivertebrae and features of Peters' Plus syndrome. Prenatal ultrasound revealed a single umbilical artery, hemivertebrae, and complex cardiac defect (ASD, VSD, and Truncus Arteriosus). Amnio demonstrated a 46, XY karyotype and normal 22q11 deletion studies. The infant was delivered at 30-weeks-gestation; physical exam was notable for a two-vessel cord, hypertelorism, cloudy corneas, small posteriorly-rotated ears with overfolded helices, flattened nasal bridge, wide-spaced nipples, and fifth finger clinodactyly. Neonatal course was complicated by RDS requiring ventilation, congestive heart failure, meconium plugs, congenital hypothyroidism, and spontaneous corneal perforation with Peter's anomaly; the infant expired on day 13. Autopsy revealed truncus, right-sided aortic arch, bilateral absence of interlobular fissures, thyroid agenesis, large horseshoe kidney with duplicated right ureter, focal glomerulosclerosis, hemivertebrae T8-T12, small cerebellum with hypoplasia of the vermis, and facial dysmorphisms.

It is unclear whether our patient and those of Jung et al. fall into the spectrum of Peters' Plus syndrome, or whether they represent a separate disorder distinguished by the presence of thyroid hypo/agenesis.

Program Nr: 1906 from the 1999 ASHG Annual Meeting

Bilateral anophthalmia with a congenital cystic eye on the left in a child with de novo balanced translocation t(10;22)(q24;q13). *M.M. Penttinen[1], K. Lahdes[2], V. Juvonen[3]*. 1) Clinical Genetics Unit, Turku Univ Central Hosp, Turku, Finland; 2) Dept. of Ophthalmology, Turku Univ Central Hosp; 3) Dept. of Medical Genetics, Univ of Turku.

Congenital cystic eye is a rare isolated or syndromic eye malformation with heterogeneous etiology. We describe a 3-month-old infant with bilateral anophthalmia, left sided cystic eye, and de novo balanced translocation t(10;22)(q24;q13). She was born to unrelated, young and healthy parents with unremarkable family history after an uneventful pregnancy at 39 week's gestation. The birthweight was 3660 g and the length 50 cm. The Apgar scores were 9/9/10. At birth bilateral eye malformations were noticed. She did not have either palpable globes or ocular movements. Her left orbit was filled with a large bluish transilluminating mass distending the upper eyelid and on the right she had only a small area of pigmented tissue at the bottom of the socket. She also had supernumerary nipples but no other physical abnormalities. Except of absent vision her growth and development have been within normal limits. MRI of brain as well as abdominal ultrasound examination were normal. Cytogenetic studies with GTG banding showed a balanced translocation t(10;22)(q24;q13) in her peripheral blood. The parents were cytogenetically normal. A search for putative candidate genes around the chromosomal breakpoints revealed that the paired box homeotic gene 2 (PAX2) previously associated with renal-coloboma syndrome has been localized at 10q24.3-q25.1. Molecular studies on the patients and her parents DNA samples however revealed no major rearrangements using the full-length PAX2 cDNA probe.

Program Nr: 1907 from the 1999 ASHG Annual Meeting

Clinical features of Coffin-Siris syndrome. *B.J. Peters[1], A. Pandya[1], L. Vanner[1], K. Kerkering[2], J.N. Bodurtha[1].* 1) Department of Human Genetics, Medical College of Virginia, Richmond, VA; 2) Department of Pediatrics, Medical College of Virginia, Richmond, VA.

We have characterized the phenotypic variability of Coffin-Siris syndrome in 18 new cases and 62 additional cases from the literature. We catalogued the features noted in previously reported cases and conducted a questionnaire study of patients ascertained through an international support group. The most frequent findings in both groups include some degree of mental retardation or developmental delay (99%), coarse facial features (88%), feeding difficulties (90%), frequent infections (87%), hirsutism (91%), abnormal or delayed dentition (96%), hypoplastic to absent fifth fingernails (95%), and hypoplastic to absent fifth distal phalanges (97%). Several other features have been noted in the neurologic, ectodermal, skeletal, gastrointestinal, and cardiovascular systems including hypotonia, sparse scalp hair, short stature, spinal anomalies, intestinal anomalies, and cardiac defects. Developmental delays are global, with the most significant delay in expressive language skills.

The etiology of this condition is unknown, though autosomal recessive inheritance has been inferred from reports of affected siblings and/or parental consanguinity in some cases. There have also been two reports of children with chromosome translocations involving chromosomes 12 and 14 and 1 and 7 respectively. Possible explanations for Coffin-Siris syndrome include etiologic heterogeneity with recessive and sporadic cases, oligogenic inheritance with a correspondingly low recurrence risk, multifactorial transmission or possibly a microdeletion involving a specific region of the genome.

Program Nr: 1908 from the 1999 ASHG Annual Meeting

Costello syndrome: report of eight patients including one with a rhabdomyosarcoma. *N.M. Philip[1], S. Sigaudy[1], D. Lacombe[2], G. Vittu[3], A. David[4], J. Vigneron[5], A. Moncla[1].* 1) Dept de Genetique Medicale, Hosp d'Enfants de la Timone, Marseille, Cedex 5, France; 2) Service de Genetique, Groupe Hospitalier Pellegrin, Bordeaux cedex, France; 3) Service de Neonatologie, centre Hosp Feron-Vrau, Lille cedex, France; 4) Service de Genetique Medicale, Hotel-Dieu, Nantes cedex 1, France; 5) Maternite Regionale A Pinard, Nancy cedex, France.

Costello syndrome is now a well delineated congenital disorder, characterized by post-natal growth retardation, dysmorphism and mental retardation. Most cases are sporadic and a significant increase of mean paternal age has been reported, suggesting de novo dominant mutations. Besides papillomata, which were part of the initial description, patients tend to develop benign tumors of ectodermal origin. We report eight new patients with typical clinical findings and emphasize the importance of cardiac manifestations and the tendency to develop tumors. Seven out of the eigth children exhibited hypertrophic cardiomyopathy. One patient developed an embryonal rhabdomyosarcoma. Occurence of that type of tumor has already been reported twice in the literature. We suggest there might be a causal link between the development of such a rare tumor and this genetic disorder. A point mutation or a microdeletion in a tumor-suppressor gene could be involved in Costello syndrome.

Program Nr: 1909 from the 1999 ASHG Annual Meeting

Poland-Moebius syndrome and symptomatic cardiac arrhythmia. *M.E. Pierpont[1], P. Hesslein[1], D. Martin[1,2], N.J. Mendelsohn[1,2].* 1) Dept Pediatrics, Univ Minnesota, Minneapolis, MN; 2) Medical Genetics Program, Hennepin County Medical Center, Minneapolis, MN.

Poland-Moebius syndrome is a well-documented association of both Poland and Moebius syndromes. It is felt to represent a formal genesis malformation syndrome of unknown etiology. Typically, Moebius syndrome is characterized by congenital facial nerve palsies in association with other cranial nerve palsies. Poland syndrome consists of unilateral symbrachydactyly and ipsilateral aplasia of the sternal head of the pectoralis major muscle. While the etiology of each of these syndromes is unknown, several families with multiple affected individuals have been described in recent years. Cardiovascular arrhythmias have not previously been reported with these conditions.

We describe a 3 year 6 month girl who was diagnosed with Moebius syndrome at birth. She initially presented with bilateral facial palsy, bilateral esotropia, chest asymmetry and poor feeding in the newborn period. There were no other limb malformations noted. The child did well until 3 1/2 years when her mother observed a two-month period with intermittent fatigue and poor appetite as well as several episodes of heart palpitations. During a febrile illness a rapid heart rate was confirmed. Evaluation revealed left axis deviation and a right bundle branch morphology which was compatible with a macro bundle re-entry ventricular tachycardia. The tachycardia spontaneously resolved.

The association of Poland-Moebius syndrome and ventricular tachycardia poses potential clues to the pathology of this rare condition. Several etiologies have been postulated for this syndrome, which include prenatal vascular disruption, primary hypoplasia or absence of the central brainstem nuclei, secondary brainstem nuclear degeneration, or peripheral nerve involvement. A vascular disruption pattern is most consistent with the creation of a focus for tachycardia within the ventricular tissue, as well as the other malformmations of ths child.

Program Nr: 1910 from the 1999 ASHG Annual Meeting

A novel SOX9 mutation in a case of Campomelic Dysplasia. *H.M. Prior[1], J. Giordano[1,2], S. Bamforth[2], M.A. Walter[1,2]*. 1) Dept. Ophthalmology, Univ. Alberta, Edmonton, AB, Canada; 2) Dept. Medical Genetics, Univ. Alberta, Edmonton, AB, Canada.

Campomelic dysplasia (CD) is a sporadic autosomal dominant syndrome that results in skeletal malformation and developmental abnormalities. Death usually occurs within the neonatal period as a result of respiratory insufficiencies, but life expectancy varies depending on the severity of the phenotype. XY sex reversal is frequently associated with CD, and a range of genital defects is observed in both males and females. CD has been linked to mutations in SOX 9, a member of the SOX (SRY-related HMG box) gene family. SOX 9 is postulated to be a transcription factor involved in chondrogenesis and sex determination based on its expression pattern and structure. We present the case of a CD patient with a normal 46,XX karyotype and female phenotype. We have carried out single-stranded conformation polymorphism (SSCP) analysis of DNA from this CD patient to determine if there is a mutation in SOX 9. An SSCP shift was observed for the proband in the C-terminal region of SOX9. DNA sequencing revealed a heterozygous frameshift mutation resulting from the insertion of a single guanine in nucleotide region 1450-1455. This insertion creates a mutant SOX9 open reading frame that is 201 nucleotides longer than the normal gene. It has been shown that the C-terminal region of the SOX9 protein is responsible for the transactivating ability of the protein. The frameshift identified here affects approximately half of the region required for full transactivating function. Functional analysis of this mutant protein may suggest why this particular CD patient has survived beyond infancy.

Program Nr: 1911 from the 1999 ASHG Annual Meeting

Mosaic isotetrasomy 20p in a liveborn. *T. Prosen[1], E. McPherson[1], U. Surti[1], G.R. Diggans[2], C.L. Jackson[3], S.M. Boehmer[3], M.E. Caine[3], J.H. Cummins[1].* 1) Department of Genetics, Magee-Womens Hospital, Pittsburgh, PA; 2) Division of Medical Genetics, The Western Pennsylvania Hospital, Pittsburgh, PA; 3) Reproductive Genetics, Western Pennsylvania Obstetrical and Gynecological Multispecialists, Pittsburgh, PA.

We report the first case of mosaic isotetrasomy 20p resulting in a liveborn infant. A 29 year old G 3 P 2, was referred for genetic counseling for an abnormal multiple marker screen (MMS) (risk for trisomy 18 at 1:35). A detailed ultrasound at 19 0/7 menstrual weeks that showed a 3 3/7 week discrepancy with a composite gestational age of 15 4/7 weeks, making her MMS too early to interpret. This ultrasound showed a deviated cardiac axis with a normal four-chamber view, and a dilated loop of bowel in the pelvis. A repeat MMS drawn at an appropriate gestational age was normal. Follow-up ultrasounds were notable for Dandy-Walker malformation, bowed long bones, and thickened nuchal fold. Fetal echocardiogram revealed dextrocardia with a significant conotruncal abnormality. Amniocentesis was initially declined but was performed at 24 weeks gestation. Results returned as 54% (23 cells) 46,XY and 46% (27 cells) 47,XY,+i(20)(p10). Parental bloods were normal. A normally grown fetus (2320 g, 45 cm length) was delivered by c-section at 35 weeks gestation (by 15 4/7 week ultrasound not consistent with LMP-39 2/7) for breech presentation in labor. Newborn exam was notable for multiple anomalies including dysmorphic features, cleft palate, excess nuchal skin, bilateral equinovarus deformities, rectus diastasis, as well as an abnormal neurologic examination. Echocardiogram revealed a double outlet right ventricle with VSD and abnormal pulmonary venous return. Complications in the newborn period included difficulty with ventilation and nonoliguric renal failure. Support was withdrawn on day two. Autopsy was declined. Chromosome studies included cord blood, 26% (13 cells) 46,XY, 74% (37 cells) 47,XY,+i(20)(p10); placenta, two sections, (100 cells) 46,XY; umbilical cord, one section, (52 cells) 47,XY,+i(20)(p10); and blood from the infant, 30% (15 cells) 46,XY, 68% (34 cells) 47,XY,+i(20)(p10) and 2% (1 cell) 48,XY,+i(20)(p10),+mar.

Program Nr: 1912 from the 1999 ASHG Annual Meeting

A new family with Trismus-Pseudocamptodactyly prompts the search for a gene in this unique form of distal arthrogryposis. *V.K. Proud, S.E. Joyner, W.S. Surka.* Div. of Medical Genetics, Dept. of Pediatrics, Children's Hosp. of The King's Daughters and Eastern Virginia Medical School, Norfolk, VA.

Trismus-pseudocamptodactyly (TPS, Dutch-Kentucky or Hecht syndrome) is an autosomal dominant condition characterized by finger curvature at the interphalangeal joints on wrist dorsiflexion due to short forearm flexor muscle-tendon units and short leg muscles producing foot deformitites. Facial anomalies include short jaw muscles, coronoid hyperplasia, reduced interincisor distance, and occasionally fibrous-like bands between the maxilla and mandible. Literature review revealed at least eleven families and approximately 314 affected individuals reported since the article by Hecht and Beals (1969). No putative genes have yet been identified and analysis using blood group markers in one family failed to show linkage to any chromosome (Robertson et el., 1982). To our knowledge, no further molecular mapping studies have been reported. Case Report: A three-generation family with seven individuals affected with TPS was evaluated when a seven year old male was referred for hand posturing, contractures, chorea, and dystonia. The unusual hand posturing was first noted at eight months of age. Development was otherwise normal. On physical exam, he had jaw muscle tightness, decreased interincisor distance, and flexion contractures of interphalangeal joints during wrist dorsiflexion. However, full extension of the digits during wrist volarflexion confirmed pseudocamptodactyly. Other family members demonstrated variable expressivity of these features, including an uncle with trismus-related anaesthetic complications. Review of Online Mendelian Inheritance in Man, OMIM™ and The Genome Database, GDB™ identified a number of distal arthrogryposis conditions. One disorder, Freeman-Sheldon syndrome (FSS), has key features that are similar to TPS, including microstomia with a puckered mouth and camptodactyly with ulnar deviation. The locus for FSS is at 11p15.5. This family will be valuable in order to complete the molecular studies that will determine if these two disorders are allelic.

Program Nr: 1913 from the 1999 ASHG Annual Meeting

Clinical genetic study and treatment of Traditional Chinese Medicines for HEREDITARY SPASTIC PARAPLEGIA. *y. qi, h.q. lu, y.d. chen.* clinical genetics, qingdao second people's hospit, qingdao, shandong, china.

Our clinical studies are based on families referred to our genetic clinic for counselling. Regulating a balance of Yin and Yang within the human body is our principle of treatment. Hereditary Spastic Paraplegia (HSP) is a degenerative disorder of the motor system, defined by progressive weakness and spasticity of the lower limbs. HSP is inherited as an autosomal dominant (AD), autosomal recessive (AR), or an X-linked trait. We have investigated four families including 18 affected individuals. The symptomatic patients were clinically diagnosed mainly by physical examination. For diagnosis, we have used Magnetic Resonance Imaging (MRI), Computerized Tomography (CT), X-ray, Ultrasound scan, Electrocardiogram (ECG), Electromyogram (EMG), and etc. We have also performed some biochemical detection and cytogenetic analysis. Pedigree and phenotypic analysis were performed. The histories of three families suggest that their inheritance is an autosomal dominant, namely, AD-HSP, and one family is autosomal recessive. The clinical features of probands have shown late-onset HSP. The chromosome of the patients are all normal and the affected individuals' intelligence are normal. We adopted traditional Chinese medicine(TCM)in addition to routine western medicines for treatment of patients in two families. We have used Chinese medicinal herbs such as corktree, saline cistanche, Chinese atractylodes, to treat the patients. We also gave the patients acupuncture and moxibustion therapy. The major acupuncture points we applied include hegu, sanyinjiao, taichong, and baihui. Treatment is effective, the clinical symptoms of some patients have improved, their mental state and the spasticity of the lower limbs are all better than before treatment. TCM has the advantage over routine western medicines and has fewer side effects. We'll coutinue to use this approach for future treatments in a hope to improve patients' quality of life. Our plan for next study is to identify the molecular changes during the treatment of HSP with TCM.

Program Nr: 1914 from the 1999 ASHG Annual Meeting

Anophthalmos-microphthalmos spectrum: characterization of ophthalmic, systemic and genetic features in a large series. *N.K. Ragge, A.J. Vivian, R.B. Jones, J.R. Collin.* Moorfields Eye Hospital, London, England.

Anophthalmos (absence of eye) is an extremely rare congenital anomaly occurring in 0.3-0.6/10,000 births. We reviewed 83 cases of anophthalmos (or extreme microphthalmic remnant), characterising the ocular, systemic and genetic features.

There was a slight predominance of females in the series (44:39). Anophthalmos was unilateral in 28 and bilateral in 55 cases, often asymmetric. A larger proportion of males (29/39) than females (18/44) had bilateral anophthalmos. Systemic abnormalities were present in around 65% of unilateral and bilateral cases, and about the same proportion of males and females. Four patients had lid colobomas: one with a lid coloboma with microphthalmos on one side and cryptophthalmos on the other side, suggesting that these lid anomalies may form part of a spectrum.

Systemic findings included: cleft lip and palate, preauricular skin tags, facial clefting, dysplastic kidneys, corpus callosal dysgenesis, Delleman's syndrome, CHARGE, skin loss over chest wall, and branchio-oculo-facial syndrome. Possible etiologies included gestational exposure to varicella, carbamazepine and i.v. drug abuse. Autosomal recessive inheritance was implied in five cases which were the product of consanguinous marriages. One case had a strong family history of Waardenburg's syndrome. Seven cases had a family history of developmental eye anomalies or early onset blindness and 13 cases had a family history of relevant systemic features, such as deafness or cleft palate. The case with brachio-oculo-facial syndrome had an affected sibling and a cousin with 'cat-eye' phenotype. Only one case was known to have a chromosome anomaly - a Turner's mosaic. Seven families had a history of miscarriage.

This series adds significantly to the world literature on anophthalmos and further clinical and genetic analysis may provide clues to the developmental ocular genetic process.

Program Nr: 1915 from the 1999 ASHG Annual Meeting

A New Holoprosencephaly Syndrome with Major Cerebro-Oro-Facial Malformations. *A. Rajab[1], S.M. Al-Khusaibi[1], A. Riaz[1], D. Da Costa[1], A. Nair[1], M.G. Pai[1], G. Paul[1], H.A. Ghazal[1], M. Khaburi[1], A. Wasti[1], A.I. Darwish[1], T.I. Farag[2]*. 1) Clinical Genetics, Muscat, Sultanate of Oman (email: drarajab@gto.net.om); 2) Dalhousie University, Halifax, NS, Canada (email: tfarag@is.dal.ca).

Holoprosencephaly (HPE), the commonest developmental defect in the forebrain and midface, is anatomically, clinically, and etiologically a heterogeneous disorder. It has been reported in more than 70 syndromes in association with different tratogenic agents and genetic factors (chromosomal and monogenic).

We report a five-month-old girl, born at term to non-consanguineous Arab parents, with multiple major cranio-facial anomalies suggestive of a new holoprosencephalic syndrome. She was noted to have microcephaly, plagiocephaly, trigonocephaly, marked facial asymmetry, triopthalmia, hypotolerism, proboscis, macrostomia, midline V-shaped upper gum clefting, duplicated tongue with interconnecting synychia, and 46 XX, karyotype. MRI examination showed holoprosencephaly, porencephaly, lissencephaly and corpus callosum agenesis. The baby has developmental delay with intermittent febrile convulsions. Molecular analysis is currently in progress for better understanding this new Cerebro-Oro-Facial Syndrome.

Detailed clinical findings and literature review will be presented.

Program Nr: 1916 from the 1999 ASHG Annual Meeting

Congenital melanocytic hairy nevi in the genetic clinic. *J.D. Ranells[1], B.G. Kousseff[2]*. 1) Pediatrics/Genetics, University of South Florida; 2) same.

Congenital melanocytic hairy nevi (CMHN) have an estimated prevalence of 1:20,000. Thus, as rare dermal hamartomas they require adherence to strict diagnostic criteria, (J Am Acad Dermatol 24:747). Without that and reliable molecular diagnostic markers, confusion ensues; the several names used interchangeably underline that: giant hairy nevus, garment hairy pigmented nevus, nevus pigmentosus et pillosus, nevomelanocytic nevus, melanotic nevus, CMHN, Becker hairy nevus, neurocutaneous melanosis and heredofamilial melanosis (Van Bogaert syndrome). The majority of CMHN are sporadic yet familial cases have implied autosomal dominant and recessive modes of inheritance. The latter is disputed by reports of monozygous twins discordant for CMHN. To reflect on these issues we reviewed retrospectively the 18 patients with CMHN at the USF Genetic Clinic. The patients were seen between 1-2-82 and 12-31-98; they were part of the evaluated 35,095 were part of propositi/families. By location and size 12/18 were giant CMHN, 11/12 had satellite lesions and partial excision. One of them had a father with a Becker hairy nevus. Another had NF1 and CMHN with Becker hairy nevus within. One succumbed to cervical cord malignant astrocytoma at age 18 months. Among the 6/18 with moderate size CMHN, 1 had satellite lesions and another had hyperpigmented moles; the latter developed malignant melanoma within the CMHN and did well with excision. 2/6 had solitary CMHN in addition to osteogenesis imperfecta type I and neurofibromatosis type 2 respectively. The latter's father had NF2 and scalp Jadassohn sebaceous nevus, an "epidermal" nevus. The remaining 2 had solitary CMHN. In this study, based on phenotype and histologic findings, CMHN showed a spectrum of hamartomas with frequent involvement of the subcutis. The 2 patients with NF indicated that CMHN are more common in NF patients. As to pathogenesis, through the paracrine growth mechanism, aberrant molecular signaling pathway (s) should be involved in the dermal dysplasia leading to the hamartomas. Peripherin,an intermediate filament, is a candidate molecule (J Cutan Pathol 24:145); this mechanism (s) is still to be deciphered. The same applies to the differentiation between compound epidermal nevi and CMHN.

Program Nr: 1917 from the 1999 ASHG Annual Meeting

Molecular definition of del (2) (q14.1q21) in a patient with a Marfanoid body habitus, early features reminiscent of Sotos syndrome and an attention deficit disorder. *D. Ravine[1], K.L. Baker[1], M.I. Rees[1,2], P.W. Thompson[1], R.T. Howell[3], T.R. Cole[4], H.E. Hughes[1], M. Upadhyaya[1]*. 1) Inst Medical Genetics, Univ Hosp Wales, Cardiff, Wales; 2) Department of Psychological Medicine and Medical Genetics, University of Wales College of Medicine, Cardiff, UK; 3) Regional Cytogenetics Centre, Southmead Hospital, Bristol, UK; 4) West Midlands Regional Clinical Genetics Service,Birmingham, UK.

We report findings in a young male with an attention deficit disorder and learning difficulties combined with a large birth weight, Marfanoid body habitus and early physical features suggestive of Sotos syndrome. Cytogenetic analysis showed an interstitial deletion of chromosome 2 (46,XY,del(2)(q14.1q21). Microsatellite and FISH analysis revealed that the deletion spanned approximately 13cM (D2S2271 to D2S2282). As the chromosome abnormality in our patient may play a role in the occurrence of the physical features found in Sotos syndrome, samples from 18 other individuals with unequivocal Sotos syndrome were assessed for evidence of microdeletions and uniparental disomy involving 2q14.1 to 2q21. Negative results were obtained. This case reveals that haploinsufficiency of this chromosomal region is responsible for intellectual impairment, a Marfanoid body habitus together with some physical features reminiscent of Sotos syndrome.

Program Nr: 1918 from the 1999 ASHG Annual Meeting

Stress urinary incontinence and menarche in women with osteogenesis imperfecta. *S.D. Reed[1,2], M.G. Pepin[3], K. Peters[3], G.M. Lentz[1], E.D. Lease[1], P.H. Byers[3].* 1) Department OB/GYN, University of Washington, Seattle, WA; 2) Gynecology Division, Harborview Medical Center, Seattle, WA; 3) Department of Medical Genetics, University of Washington, Seattle, WA.

Connective tissue alterations are thought to be important in the genesis of female stress urinary incontinence (SUI) and pelvic relaxation. Osteogenesis imperfecta (OI) is one of several heritable disorders of connective tissue with known molecular pathogenesis. To determine if mutations in defined genes might contribute to SUI and pelvic relaxation, we surveyed ~50 adult women > age 25 with OI who are members of the OI Foundation. The survey requested demographic, genetic, obstetric and gynecologic information. 35 responded (70% response rate); 2 were excluded because the diagnosis of OI was not clear or the survey was not completed adequately. Of the 33 subjects, 30 were Caucasian and 3 were Asian. Twelve had OI type I (33%), 9 - OI type III (27%), and 12 - OI type IV (33%). Four (12%) reported symptomatic SUI with loss of urine >1x/wk (OI type I- 1; OI type III-1; OI type IV- 2). Five (15%) reported pelvic relaxation (OI type I- 3; OI type III- 1; OI type IV- 1). Five (15%) had symptomatic SUI and/or pelvic relaxation and 3 of the 5 (9%) had onset at age <30. Pelvic relaxation was related to a prior term delivery, SUI was not. Early onset of SUI/pelvic relaxation was more common in women with OI and may be related to the underlying molecular defect in type I collagen genes.

We analyzed age of menarche to determine if there was a correlation of SUI and pelvic relaxation with overall decreased estrogen exposure. Age of menarche and SUI/pelvic relaxation did not correlate; however, delayed menarche (onset of menses >1 SD after the mean of 12.9 years for US girls) was seen in 42% and was increased in OI type III (55%). Age of menarche ranged from 14-23 years. Delayed menarche has been reported in women of short stature and may be due to decreased body fat or body mass index (BMI), but this was not a consistent finding in our study. Further analysis of the age of menarche in OI is warranted, especially as this affects osteoporosis risks.

Program Nr: 1919 from the 1999 ASHG Annual Meeting

Isolated palatal anomaly is not an indication to screen for 22q11 deletion. *O. Reish[1,2], R. Masterman[2], Y. Finkelstein[3], A. Nachmani[3], B. Wolach[2], M. Fejgin[1], A. Amiel[1]*. 1) Genetic Institute; 2) Department of Pediatrics; 3) Department of Otolaryngology- Head and neck Surgery, Meir Hospital, Kefar Saba, Sackler School of Medicine, Tel Aviv University, Israel.

Velocardiofacial syndrome (VCFS) is the most common syndrome associated with clefting of the secondary palate and is associated with hemizygous deletion of 22q11 region. However, patients with VCFS may present a special diagnostic challenge because the phenotype of patients with VCFS is extremely variable and these patients may present only part of the classically described anomalies. Since the frequency of the deletions in patients presenting with isolated palatal anomalies has not been fully evaluated yet, it has been hypothesised that every patient with palatal anomaly has to be screened for 22q11 deletion. This hypothesis has been verified in our study. Forty-two consecutive patients, referred to our palatal clinic of the ENT department because of velopharyngeal insufficiency and found as having isolated palatal anomalies and negative familial history were included in the study. There were 20 males and 15 women, and their age varied from 2 weeks to 31 years (mean = 12.27.4). 10 patients had overt cleft palate, 10 patients had occult submucous cleft palate and 10 patients nasopharyngeal disproportion. A cytogenetic analysis utilising FISH kit for 22q11 region (Oncor) was performed in all the patients. The analyses were all negative and thus deletion of 22q11 region was excluded in all our patients. Our conclusion is that there is no indication to screen patients presenting with isolated velopharyngeal insufficiency for deletion of 22q11 region. However, patients with palatal anomalies should be followed and re-evaluated. When additional other signs or symptoms relevant to VCFS are found including behavioural or psychiatric disorders, which may evolve at an older age deletion of 22q11 region, should be analysed.

Program Nr: 1920 from the 1999 ASHG Annual Meeting

Fryns Syndrome: association with unbalanced translocations trisomic for 20q13.1-qter in two unrelated families.

R.E. Reiss[1], L. Wilkins-Haug[2,5], E. Quackenbush[3,5], B. Korf[3,5], M. Sandstrom[4], S. Weremowicz[4,5], D. Genest[4,5]. 1) Obstetrics and Gynecology, Ohio State University, Columbus, OH; 2) Obstetrics,Gynecology and Reproductive Medicine, Brigham and Women's Hospital, Boston, MA; 3) Genetics, Children's Hospital, Boston, MA; 4) Pathology,Brigham and Women's Hospital, Boston, MA; 5) Harvard Medical School, Boston MA.

Fryns syndrome is an autosomal recessive disorder for which the genetic defect has not been identified. Cardinal features include diaphragmatic hernia, facial dysmorphism, and digital hypoplasia, often associated with cardiac, skeletal, CNS, and GI tract malformations. We report on 2 families in whom paternally-derived unbalanced translocations involving 20q13.1-qter were associated with features of Fryns syndrome. The first infant, with prenatally-detected hypoplastic left heart, proved to have natal teeth, facial dysmorphism, hypoplastic digits, camptodactyly, and 13 ribs. Karyotype was 46,XX,der(15)t(15;20)(q26.3;q13.1). Cytogenetic studies were not performed on a male sibling who had died with diaphragmatic hernia, and rib and vertebral anomalies. The phenotypically normal father's karyotype is 46,XY,t(15;20)(q26.3;q13.1). In the second family a balanced translocation, 46,XY,t(4;20)(q34.2;q13.1), was found in the phenotypically normal father of 2 anomalous fetuses, each with the unbalanced karyotype 46,XY,der(4)t(4;20)(q34.2;q13.1). The first pregnancy was terminated at 18 weeks. Diaphragmatic hernia, omphalocele, and enlarged fourth ventricle were confirmed on autopsy. They continued the next pregnancy, despite ultrasound findings of hypoplastic left heart and enlarged fourth ventricle. Fetal demise occurred at 27 weeks. Autopsy was declined. External inspection of the macerated fetus found facial dysmorphism (broad flat nose with bifid tip;flat simple pinnae). Unbalanced translocations with breakpoints at 20q13.1 produced similar constellations of malformations in two unrelated families. While these cases may represent phenocopies of Fryns syndrome, it is also possible that a gene localized to the breakpoint is responsible for the syndrome. Molecular analysis of the breakpoint region may help delineate the genetic defect in Fryns.

Program Nr: 1921 from the 1999 ASHG Annual Meeting

A new neurological syndrome with mental retardation, choreoathetosis, and abnormal behavior maps to chromosome Xp11. *E. Reyniers[1], N. Peeters[1], P. Van Bogaert[2], N. Van Regenmorter[2], R.F. Kooy[1]*. 1) Dept Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) 1Erasmus Hospital, Free Brussels University, Brussels, Belgium.

We describe a new X-linked neurological syndrome, characterized by mild mental retardation, choreoathetosis, and abnormal behavior. Choreoathetosis, the most distinguishing feature of those patients, is a dyskinesia characterized by attacks of involuntary rhythmic and arrhythmic movements referred to as chorea and athetosis, respectively. It occurs in a variety of clinically and genetically diverse disorders, albeit rarely in familial forms. Clinically, the disease bears some resemblance to Lesch-Nyhan syndrome (mapped to Xq28). However, we mapped the disease in our family to chromosome Xp11 by genetic linkage analysis, we defined a novel X-linked syndrome. The region contains several interesting candidate genes that play a role in neuronal signaling, including GPR34, a neuronal G-protein-coupled receptor. G-protein-coupled receptor target molecules include small GTPases, three of which have been shown to be mutated in familial cases of non-syndromic mental retardation. Moreover, this receptor class has been suggested to play a role in behavioral and psychiatric disturbances. Mutation analysis of this gene is underway and may in the future elucidate the molecular defect in this family.

Program Nr: 1922 from the 1999 ASHG Annual Meeting

Abnormal vascular proliferation in Poland-Moebius anomaly. *M. Rittler, R. Rosetto, L. Campora, E. Altamirano, R. Fuksman.* Hospital Materno Infantil Ramon Sarda, Buenos Aires, Argentina.

Poland anomaly consists of congenital absence of the pectoralis major muscle with a variable degree of upper limb hypoplasia. Moebius anomaly comprises facial nerve palsy with or without other cranial nerve involvement. When present, the most frequently reported CNS anomalies were hypoplasia or focal lesions of the brainstem or the cranial nerve nuclei. Both conditions frequently overlap and are considered, among others, as part of the subclavian artery supply disruption sequence. Classically, it is considered of vascular pathogenesis, though the underlying cause is unclear and possibly heterogeneous. Many reports suggest an association between Poland-Moebius anomalies and exogenous teratogenic maternal exposures, but familial recurrence has also been reported and syndromes of recognized genetic etiology as Adams-Oliver, Marden-Walker and Carey-Fineman-Ziter also overlap with this spectrum. We report on a newborn with clinical features of Poland and Moebius anomalies. The autopsy revealed replacement of the left pectoralis major muscle and bilateral diaphragms by a thin, fibrous membrane, and pulmonary hypoplasia. CNS findings included enlargement of the lateral ventricles and small third and fourth, with partial aqueductal stenosis; convolutional underdevelopment, absence of the corpus callosum, hypoplasia of the cerebellum, and macroscopically visible focal anomalies of the brainstem. Microscopically, there was proliferation of abnormally shaped vessels, predominantly in leptomeninges, brain, cerebellum and brainstem, and periependymal foci of hemorrhage and calcification. Though the mentioned anomalies could all be due to an unnoticed teratogen, the vascular abnormality in our patient could also be considered as a primary structural defect, leading to secondary hemorrhage, calcification and brain involution.

Program Nr: 1923 from the 1999 ASHG Annual Meeting

Cognitive functioning in Prader-Willi syndrome: Comparison of genetic subtypes. *E. Roof[1], W. Stone[1], W. MacLean[2], I. Feurer[1], T. Thompson[1], M.G. Butler[3].* 1) John F. Kennedy Center, Vanderbilt University, Nashville, TN; 2) University of Wyoming, Laramie; 3) The Children's Mercy Hospitals and Clinics, Kansas City, MO.

Prader-Willi syndrome (PWS) is a classical genetic condition with two distinct genetic subtypes [paternal deletion of 15q11-q13 region in about 70% of subjects and maternal uniparental disomy (UPD) of chromosome 15 in about 30% of subjects] and unusual behavioral characteristics. PWS is characterized by infantile hypotonia, hypogonadism, feeding difficulties, early childhood obesity, short stature, small hands and feet, mental deficiency and a particular facial appearance. Hypopigmentation is a recognized feature in deletion PWS subjects compared with those with UPD; however, recent advances in genetics have led to an increased understanding of the role of the genotype on behavioral functioning. The purpose of the present study was to examine differences in intellectual functioning in individuals with PWS with the 15q11-q13 deletion versus those with UPD. Measures of intelligence and academic achievement were administered to 38 individuals with PWS [24 deletion (9 males, 15 females) and 14 UPD (7 males, 7 females) between 10 and 50 years of age with a mean age of 21 years]. Data demonstrated that persons with UPD had significantly higher verbal IQ scores than those with a deletion. The magnitude of the difference in verbal IQ was 9.1 points (69.9 vs 60.8 for UPD and deletion PWS subjects, respectively). Only 17% of persons with the 15q11-q13 deletion had a verbal IQ > 70 while 50% of those with UPD had a verbal IQ of > 70. This is the first report to document the difference between verbal and performance IQ score patterns among persons with PWS of the deletion versus UPD subtype.

Program Nr: 1924 from the 1999 ASHG Annual Meeting

Symetric or asymetric limb deficiencies in multiply malformed children. *A. Rosano[1], C. Stoll[2]*. 1) ICBDMS, Via Sabotino, Roma, Italia; 2) Service de Genetique Mdicale, Hopital de Hautepierre, Strasbourg, France.

In human beings, the unpaired organs are placed in a highly ordered pattern along the left-right axis.Rarely people are born with complete or incomplete mirror-image reversal of this intricate asymmetry of the visceral organs.How are the organs normally patterned with such precise left-right asymmetry, and what goes awry when they are mispatterned? A cascade of signalling molecules regulating the establishment of embryonic left-right asymmetry is indicated by recent studies of chick and mouse embryonic development.This cascade includes Sonic hedgehog (Shh), nodal (a memeber of the TGF family), the snail-related (cSnR-1) zinc-finger transcription factor, lefty, activin-receptor, cubitus interruptus (Ci), decapentaplegic (dpp) and ZIC proteins, encoding a zinc-finger transcription factor.It has been identified that some of these genes are involved in limb patterning.Therefore a way trying to answer to the abovementionned question is to verify in multiply malformed children, if there is symmetry or asymmetry regarding to the limb defects. The material for this study are the cases with multiple congenital anomalies (the multiple) with limb defect (LD) collected by the International Clearinghouse for Birth Defects Monitoring Systems (ICBDMS);analysis of laterality was performed on 666 non syndromic cases of LD associated with other major malformations. In this material anomalies of the left arm and leg were compared to anomalies of the right arm and leg regarding to the extra limb anomalies present in these multiple i.e congenital heart disease, gut, liver and spleen anomalies.Severe genitalia defects were more often associated to left LD than to right LD (OR=2.6, CI 1.1-6.4).Gastroschisis and axial skeletal defects were more often associated to unilateral than to bilateral LD (OR=9.2, CI 1.2-70.3 and 1.9, CI 1.1-3.0, respectively).Comparisons left versus right by type of LD were not significant in this material.However cleft lip/palate was more often associated with bilateral preaxial LD, gastroschisis with bilateral transverse LD and with amelia and urinary tract defect with amelia.The distribution of LD laterality was also studied in syndromic cases.

Program Nr: 1925 from the 1999 ASHG Annual Meeting

Familial Beare-Stevenson syndrome attributable to a P250R missense mutation in the Fibroblast Growth Factor 3 Receptor (FGFR3). *T. Roscioli[1], S. Flanagan[2], P. Kumar[2], J. Masel[3], R. Lewandowski[4], V. Hyland[2], I.A. Glass[1]*. 1) Queensland Clinical Genetics, Royal Children's Hospital, Brisbane, QLD Australia; 2) Royal Brisbane Hospital Molecular Genetics Laboratory; 3) Radiology Department, Royal Children's Hospital, Brisbane; 4) Craniofacial Unit, Mater Children's Hospital, Brisbane.

Beare-Stevenson Syndrome (BSS), is an autosomal dominant condition comprising craniosynostosis, cutis gyrata, acanthosis nigricans and other anomalies. At least five patients, to date all sporadic, have been described since the initial report in 1969. A proportion of these BSS cases have been found to have mutations in the linker region between the third immunoglobulin-like domain and the transmembrane domain of FGFR2 or the transmembrane domain of FGFR2. Our female proband was born with a severe and progressive turricephaly, a birthweight of 3.4kg. (90th percentile) and a head circumference of 31cm. (3rd percentile). Reflection of the abdominal skin onto the umbilical cord, typical of BSS, was present. Cutis gyrata developed on the palm of the left hand, which became more prominent over the following months. Deep furrowing on both soles and a linear patch of acanthosis nigricans on the left forearm were also noted. The probands father had broad thumbs and brachydactyly and there was cutis gyrata present on his forehead as well as radiological evidence of hypertelorism. Molecular analysis of the FGFR3 gene was carried out by PCR and Nci1 digest. This demonstrated an FGFR3, P250R missense mutation was present in one allele in both the proband and her father. This is yet another example of an activating mutation in a FGFR gene which causes a common phenotype between FGFR syndromes, in this case BSS. The lack of familial examples of BSS with FGFR2 mutations suggests this mutation has a significant impact on reproductive fitness.

Program Nr: 1926 from the 1999 ASHG Annual Meeting

Clinical spectrum of (ponto)cerebellar hypoplasia with anterior horn cell involvement. *S. Rudnik[1], T. Voit[2], L. Sztriha[3], B. Wirth[4], K. Zerres[1]*. 1) Institute for Human Genetics, Technical University of Aachen, Germany; 2) Department of Pediatrics, University of Essen, Germany; 3) Department of Pediatrics, UAE University Al Ain, United Arabic Emirates; 4) Institute for Human Genetics, University of Bonn, Germany.

(Ponto)cerebellar hypoplasia (PCH) is rarely associated with spinal muscular atrophy (SMA) and designated as PCH-1. This phenotype is characterized by severe muscle weakness and hypotonia starting prenatally or at birth with life span not exceeding a few months in most cases. We herewith describe the clinical and pathological findings in 9 families with evidence of cerebellar defects and SMA, representing a hitherto unknown spectrum of clinical variability. In all patients, the diagnosis of SMA was made on the basis of electrophysiological data and muscle biopsy, however, genetic testing failed to confirm the diagnosis of infantile SMA I-III with a gene defect on chromosome 5q and resulted in clinical reevaluation. Four isolated patients had a picture resembling SMA II or III and developed cerebellar atrophy/hypoplasia later. Age at onset was around the first birthday in 3 patients and at 6 years in 1 patient. Last information was obtained at 3-7 years, 1 patient died at 16 years. Five families had an early onset prenatally or shortly after birth with a severe phenotype which might be mistaken for SMA type I (Werdnig-Hoffmann disease). Life span did not exceed a few months in 4 families, whereas 2 sisters died at 16 and 26 months, and 1 sibship survived 4 years. The genetic basis of cerebellar hypoplasia plus SMA remains to be determined, parental consanguinity and affected sibs make autosomal recessive inheritance most likely. Molecular genetic studies allowed to exclude the gene locus for infantile SMA in some families tested.

Program Nr: 1927 from the 1999 ASHG Annual Meeting

Neonatal Incontinentia Pigmenti in an affected male within a normal family. *S. Rugolotto[1], F. Soli[2], M. Benedetti[1], C. Ghizzi[1], P. Biban[1], A. Turco[2], P.F. Pignatti[2]*. 1) Pediatric Intensive Care Unit, Mayor Civil Hospital, Verona, Italy; 2) Section of Biology and Genetics, Mother and Child Department, University of Verona, Verona, Italy.

Incontinentia Pigmenti (IP) is a rare X-linked dominant genodermatosis. Prevalence and incidence in the population are unknown. About 97% of the patients are females. We describe an affected newborn whose family was normal. He was a term baby born to a para 0000, by cesarean section due to fetal distress. APGAR score 8(1') - 9(5') was given. Birth weight was 2670 g, length 47.5 cm, head circumference 33.2 cm. Maternal serum tests for HBsAg, CMV, HSV, HIV, HCV, VDRL, toxoplasmosis were negative and for rubella IgG positive. Family history was negative for skin, neurologic disorders and abortions. At birth erythematous blisters were scattered over the body surface, particularly on the upper and lower extremities, according to a linear distribution and on the back and the armpit in a swirly pattern. Mucosae were normal and dysmorphic traits were absent. C-Reactive Protein, blood culture, skin swab, WBC were normal. At 10 days of life a skin biopsy was consistent with IP. Thus we performed cardiac, head, and abdominal ultrasound, EEG, chest X-Ray, and eye exam which were all normal. The Karyotype was 46, XY. The subsequent neonatal growth pattern was normal. At 30 days of life several skin lesions resolved without scars and some warty, hyperkeratotic lesions were evident on the hands. At 3 months of age the infant was growing and feeding well and the warty lesions were not evident any longer. At present we have observed the first two stages of the disease. Follow-up is needed to evaluate stage 3 (macular hyperpigmentation), stage 4 (hypopigmentation with slightly atrophic skin), which both occur later and to treat possible dental, eye, and neurologic abnormalities which might affect IP natural history. One IP gene has been mapped in Xq28 but it has not been identified yet. The basic defect of IP remains unknown. Karyotypically normal male patients within normal families are very rare, and they might be helpful for a better understanding of this disorder, should we be able to identify the IP gene.

Program Nr: 1928 from the 1999 ASHG Annual Meeting

Neonatal respiratory death in the 22q11.2 deletion. *K.L. Russell[1], D.M. McDonald-McGinn[1], W. Mahle[1], L. Howell[1], S. Kasperski[1], B.M. Wilkes[2], J. Meyer-Cohen[2], S. Adzick[1], E.H. Zackai[1].* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Medical University of South Carolina, Charleston, SC.

The 22q11.2 deletion has been identified in most patients with DiGeorge, VCFS, & CTAF and in some cases of Opitz G/BBB and Cayler cardiofacial syndromes. We found a 5% mortality rate in 305 patients with the 22q11.2 deletion, 90% due to heart disease. Here we report two additional patients with the deletion who succumbed to respiratory complications shortly after birth. Patient 1 presented at 25 weeks gestation with Apgars of 4 and 5. Endotracheal intubation was unsuccessful and the patient expired. Post mortem exam revealed tracheal agenesis with fused main bronchi, bronchoesophageal fistula, and heterotaxia. Minor dysmorphia was noted including small ears with overfolded helices and a bulbous nasal tip. Chromosome analysis was suggested. In addition, 22q11.2 deletion studies were performed based on the association of laryngotracheoesophageal abnormalities (McDonald-McGinn et al. 1995). Subsequent autopsy findings included complete AV canal, posterior malaligned VSD, bicuspid aortic valve, IAA type B, and absent thymus. Karyotype was normal but the patient had a 22q11.2 deletion detected by FISH. Parental studies revealed a deletion in the father as well. Patient 2 presented prenatally with a left-sided diaphragmatic hernia on ultrasound. No other anomalies were noted at that time. Amniocentesis was normal. A subsequent consultation at our fetal therapy center included an echo, which revealed TOF. Deletion studies were suggested based on the association in patients with TOF (15% Goldmuntz et al. 1999). The pregnancy continued without further studies and the patient was born at 39 weeks gestation. The child died at 24 hours from respiratory failure. Post mortem FISH analysis revealed a 22q11.2 deletion. Review of the literature did not reveal any other cases of either tracheal agenesis or CDH in patients with the 22q11.2 deletion. However, we have one additional case of a small CDH in a child who survived surgery. Thus, we suggest that deletion studies be considered when either of these anomalies are present in the face of associated manifestations of the 22q11.2 deletion.

Program Nr: 1929 from the 1999 ASHG Annual Meeting

A new syndrome with large hands, foot deformities, and scoliosis maps to Xq24-26. *D. Salazar[1], A. Vaglio[2], R. Quadrelli[2], S. Reyno[2], A. Lemes[2], R.S. Lachman[1], W.R. Wilcox[1]*. 1) Medical Genetics, Cedars-Sinai Med. Cntr., Los Angeles, CA, USA; 2) Instituto de Genetica Medica, Hosp. Italiano, Montevideo, URUGUAY.

We report a 3 generation family with an apparently previously unreported X-linked recessive skeletal dysplasia. There are 7 affected males. Among the females, there are 3 obligate carriers who have mild manifestations of the disorder or are clinically normal. Although there is no male-to-male transmission, there have been few offspring of affected males. Affected males have a large neck, large palms, scoliosis, prominent muscular development, and progressive joint dislocations and pes cavus deformities in the feet. Radiographs show carpal and tarsal fusions, joint dislocations and secondary osteolysis in the feet. Variable features in males include camptodactyly in the hands, congenital hip dislocation, and degenerative osteoarthritis of the hips. This condition has some similarities with, but is clearly distinct from, two other X-linked disorders, frontometaphyseal dysplasia and otopalatodigital syndrome type I.

Genetic analysis using 18 polymorphic markers along the X-chromosome was performed. Recombinational events were used to narrow the most likely disease gene containing region to a 25 cM interval bounded by the markers DXS424 and DXS8072, corresponding to cytogenetic bands Xq24-26.

Program Nr: 1930 from the 1999 ASHG Annual Meeting

A New Association of Kabuki Make-up syndrome and Malignant Hypertermia. *A.A. Santa Rosa[1], J.C. Llerena[1], R.T. Sudo[2], J.C. Cabral de Almeida[1]*. 1) Centro de Genetica Medica, Instituto Fernandes Figueira/FIOCRUZ, Rio De Janeiro, RJ, Brazil; 2) Centro de Hipertermia Maligna, Dept. Farmacologia, ICB/UFRJ, Rio de Janeiro, RJ, Brazil.

Kabuki Make-up syndrome (KS) is characterized by unusual facies, (oriental gestalt) mild to moderate mental retardation, skeletal abnormalities, dermatoglyphic alterations and postnatal growth retardation. We present a nine year-old boy, referred due to facial dysmorphisms. His parents were third-degree cousins. The diagnosis of KS was made at the first admission, for he had low palpebral eversion, high-arched palate, myopia, ptosis, brachymesophalangy, fetal pads and bilateral cryptorchidism. Cytogenetic analysis was normal and no other anomalies were found. However, when he was submited to orchipexy, during the anesthesia he developed a malignant hyperthermia crisis (41,9°C), immediately reverted with dantrolene sodium IV. A muscular biopsy was performed and the sample was submited to the Kalow test (in vitro caffeine/halothane contraction test for suscetible muscle), the only widely accepted test for malignant hyperthermia (MH) The result was positive. Mutations in the RYR1 gene (19q13.1) are responsible for half of the MH cases. A microdeletion syndrome could explain the findings. To our knowledge, it is the first reported association of KS and MH. Our patient can help mapping the KS if the RYR1 gene is involved in his phenotype, for these two entities may be linked.

Program Nr: 1931 from the 1999 ASHG Annual Meeting

Reevaluation of frequencies of selected features in patients with the 18p- syndrome. *R.L Schaub[1], R.J. Leach[1,2], J.D. Cody[1]*. 1) Pediatrics, University of Texas Health Science Center, San Antonio, TX; 2) Cellular and Structural Biology, University of Texas Health Science Center, San Antonio, TX.

The 18p- syndrome results from loss of genetic material from the short arm of chromosome 18. Mental retardation, short stature, midline defects, and ptosis have been reported previously in the literature as the most common features of this syndrome. In an attempt to better understand this syndrome, we collected medical records and blood samples from 21 individuals with de novo deletions of 18p. After completion of the chart review, we noted that our study population differed significantly from prior case reports in several respects. The incidence of hypotonia and ptosis in our group were 95% and 48%, respectively, higher than the previously reported frequencies of 23% each. Microcephaly (FOC < 3 S.D. below the mean for age) was documented in only one of our participants, in contrast to 23% in the literature. Speech delay was found in 100% of our participants; however, receptive language abilities were considered age appropriate. Although mental retardation is listed as the most common feature of this syndrome in the literature, only three of our participants met DSM-IV criteria for mental retardation (IQ<70) and none were severely mentally retarded. Molecular analysis was performed on the DNA isolated from these samples. A total of 22 chromosome 18 short arm and centromere specific markers were used for estimating the extent of the deletion of 18p and determining the parental origin of the deletion. Some individuals who were determined to have a deletion of the entire short arm had IQ scores in the 70-80 range. Our data suggest that the literature currently available on the 18p- syndrome may not describe accurately this condition and that the primary abnormality associated with 18p- syndrome may be an expressive language/speech delay rather than mental retardation. Further research ultimately may enable physicians to give families a more accurate prognosis concerning the development of their child with 18p- syndrome.

Program Nr: 1932 from the 1999 ASHG Annual Meeting

A *de novo* deletion of more than 2 Mb including the *SOX9* locus in a case of campomelic dysplasia (CD) proofs that CD is a haploinsufficiency syndrome. *G. Scherer[1], K. Lindenberg[1], J. Zimmer[1], B. Schmalenberger[2], D. Pfeifer[1].*
1) Institute of Human Genetics,University of Freiburg, Freiburg, Germany; 2) Medizinische Genetik, Passau, Germany.

Campomelic dysplasia (CD; MIM 114290) is an autosomal dominant skeletal malformation syndrome with XY sex reversal that results from heterozygous missense, nonsense or frameshift mutations in the chondrogenic regulatory gene *SOX9* on 17q. Although all *SOX9* mutations described so far are most likely loss-of-function mutations, arguing for haploinsufficiency for SOX9 product as the cause for CD, definite proof for this hypothesis has been lacking. We studied a male patient with features characteristic for CD: delayed ossification, short and bowed femora, tibiae and fibulae, narrow iliac wings, hypoplastic ischiac and pubic bones, bell-shaped thorax, 11 pairs of ribs, clubbed feet, and Robin sequence. The patient died at the age of 10 months. Chromosomes were unremarkable cytogenetically. FISH analysis with YAC 946E12 that extends from about 2 Mb upstream to 200 kb downstream of *SOX9* resulted in signals on only one of the two chromosomes 17. This deletion of more than 2 Mb was confirmed by analyzing a somatic cell hybrid clone that carried the deleted chromosome 17 in the absence of the normal chromosome 17. By PCR, this hybrid was found negative for all markers mapping on YAC 946E12 as well as for markers located proximal and distal to this YAC. The most proximal and most distal deleted markers are *D17S949* and *D17S1829*, respectively, that are 6 cM apart. Haplotype analysis revealed that the deletion was of paternal origin. A mutation in the remaining *SOX9* allele of the patient was ruled out by DNA sequencing. Together with a recent report on a similar *SOX9* deletion CD patient (Am. J. Med. Genet. 84:20-24, 1999), this case provides strong evidence for CD being caused by *SOX9* haploinsufficiency.

Program Nr: 1933 from the 1999 ASHG Annual Meeting

Anophthalmia/Microphthalmia Registry: Review of 90 cases further demonstrates heterogeneity of anophthalmia/microphthalmia. *A.S. Schneider[1], T.M. Bardakjian[1], C.M. Sellers[2], J.E. Barbagallo[1]*. 1) Dept Genetics, Albert Einstein Medical Ctr, Philadelphia, PA; 2) *Beaver College, Glenside, PA.

The Anophthalmia/Microphthalmia (A/M) registry was established in 1993 to assemble a national database of individuals with A/M, to determine the local and national incidence of A/M and to undertake a descriptive analysis of the registry population. In April 1999, an international conference on A/M was held in Philadelphia in conjunction with the support group, ican (International Children's Anophthalmia Network). This provided the opportunity for clinical evaluation of affected individuals and initiation of DNA collection for a screening initiative looking at 10 eye development genes in 3 laboratories. Our previous observation that there are more males than females with bilateral anophthalmia is again demonstrated with our larger numbers. Of the 90 cases reviewed, 48 were males (53%). Of the males, 71% had bilateral anophthalmia. There were 42 females in the group and 50% had bilateral anophthalmia. In both males and females, developmental delay was more common in those with bilateral anophthalmia, although 23% were too young to assess. A significant number of males with bilateral anophthalmia had other structural anomalies (67%) although not all males with structural anomalies were delayed. 43% of females with bilateral anophthalmia had structural anomalies. The heterogeneity of A/M noted in our registry underscores the importance of identifying the genes involved in this complex and rare malformation.

Program Nr: 1934 from the 1999 ASHG Annual Meeting

A newly recognized trigonocephaly syndrome: Fronto-Ocular Syndrome. *E.N. Schneider[1], A. Bogdanow[1], J.T. Goodrich[2], R.W. Marion[1], M.M. Cohen, Jr[3].* 1) Department of Pediatrics, Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY; 2) Department of Neurosurgery, Montefiore Medical Center/Albert Einstein College of Medicine, Bronx, NY; 3) Department of Oral and Maxillofacial Surgeries, Dalhousie University, Nova Scotia, Canada.

Trigonocephaly can have a variety of different presentations. The common clinical features include orbital hypotelorism, ethmoidal hypoplasia and a keel-shaped, symmetric frontal bone deformity. The skull typically has a triangular shape due to forehead prominence, increased parietal diameter and temporal depression. Trigonocephaly can be isolated, syndromic or associated with other congenital anomalies. We report a mother and her daughters who share a particular constellation of clinical findings including trigonocephaly and facial dysmorphism which encompasses ocular hypotelorism, ocular proptosis and ptosis, epicanthal folds, elevated nasal bridge, thin philtrum, arched palate and a narrow bifrontal region. In addition, both daughters have glabellar capillary hemangiomas, a congenital heart defect and mild developmental delays. Review of the literature failed to disclose any similar syndrome. We believe that this is an autosomal dominantly inherited condition that arose as a new mutation in the mother.

.

Program Nr: 1935 from the 1999 ASHG Annual Meeting

Congenital myotonic dystrophy: Novel phenotypic features. *R.E. Schnur, R.A. Kurnik, L.A. Reed, K.A. Mockridge, S.O. Imaizumi, B.J. Evans, S.E. Courtney, N.M. Razi, P.B. Pandit, J.G. Saslow, G.E. Stahl.* Cooper Hosp/UMDNJ at Camden.

Congenital DM is associated with phenotypic effects of hypotonia. We report novel features in 4 infants with congenital DM. Patient 1, a 2300g/38 week female (~1133 CTG repeats of myotonin protein kinase), had hypotonia, laryngomalacia, vocal cord granuloma, PFO,PPS, frontal bossing, prominent occiput, tall cranial vault, deep set eyes, epicanthi, low-set ears, bulbous nose with underdeveloped tip, small mouth, tented lip, high palate, micrognathia, delayed dentition, joint laxity, & narrow pelvis. MRI: dilated ventricles, decreased WM, & small CC. Patient 2, a 2200g/34 week male (~1633 repeats), had hypotonia, respiratory insufficiency, diaphragmatic paralysis, sepsis, macrocephaly, trigonocephaly, ridged sutures, synophrys, deep set eyes, bitemporal narrowing, asymmetric shield chest, small eyes, hypotelorism, epicanthi, bulbous nose/anteverted nares/underdeveloped tip, small mouth/thin/tented lip, high palate, micrognathia, anomalous ears, 11 ribs, undescended testis, hypospadias, sacral cleft, clubfeet, clinodactyly, single palmar crease, PDA, & ASD. MRI: dilated lateral ventricles, choroid plexus hemorrhage, metopic & coronal craniosynostosis. Patients 3 & 4 were monozygotic AGA twins, born @ 29 weeks (~1067 repeats each). Both had fused eyelids that did not open until ~10 days, hypotonia, sepsis, respiratory distress, small palpebral fissures, prominent nose, anteverted nares/underdeveloped tip, small mouth, micrognathia, bell-shaped thorax, long fingers, prominent heels, high arches, & cryptorchidism. Only twin B survived; at 4 months, length/weight were <5th%ile; head circumference was relatively large at ~50th%ile. Summary: All had typical congenital DM + distinctive facies: bulbous nose, deep-set eyes/fused eyelids, small mouth, & macrocephaly. They also had other anomalies: congenital heart disease, missing rib, laryngomalacia, CNS anomalies, & craniosynostosis. Besides neonatal hypotonia & family history of DM, multiple anomalies, facial dysmorphia, & fused eyelids at a late gestational age are indications for DM testing. **Patient 1Patient 2Patients 3 and 4Summary**.

Program Nr: 1936 from the 1999 ASHG Annual Meeting

Deletion of chromosome band 7q33 results in a syndrome of mild to moderate mental retardation and mild dysmorphic features: a new contiguous gene deletion syndrome? *S.A. Schonberg, C.J. Tifft.* Children's Nat'l Medical Center, George Washington University School of Medicine Department of Pediatrics, Washington, DC.

We report two children with a 7q deletion limited to band 7q33 [del(7)(q32q34)]. This deletion has been reported only very rarely, possibly due to the subtlety of both the cytogenetic findings and the clinical features. We compare our cases to the four other cases in the literature (3 from a single family) and propose that this deletion may define a new contiguous gene deletion syndrome.

Case 1, a 4-year old female, was referred due to developmental delay and Case 2, also female, age 3, was referred neonatally after the de novo deletion had been detected at anmiocentesis performed for an abnormal maternal serum screen. She represents the first unbiased ascertainment for this deletion. She is mildly retarded. Shared physical features, inclusive of previously reported cases, are hypertelorism, bulbous nasal tip, thin upper lip and large mouth. Gross and fine motor delay and mild to moderatre mental retardation are common.

In contrast, terminal 7q deletion, inclusive of or distal to band 7q33, results in a severe syndrome of physical anomalies and mental retardation including growth retardation, microcephaly, and ocular abnormalities. Mild holoprosencephaly may be present.

The clinical features of our two cases, together with the few reported cases of 7q33 deletion, begin to define a new chromosomal deletion syndrome of mild to moderate mental retardation and a few, but highly characteristic physical abnormalities. This is in contrast to the severe anomalies associated with more distal long arm deletions. The scarcity of reports of this deletion may be due to the combination of relatively mild clinical features and a subtle interstitial deletion. Awareness of this chromosomal lesion will likely result in the ascertainment of additional cases and a more complete description of the 7q33 deletion syndrome.

Program Nr: 1937 from the 1999 ASHG Annual Meeting

Further delineation of the Van Den Ende-Gupta syndrome of blepharophimosis, joint contractures, arachnodactyly and normal development. *D.N. Schweitzer[1], R.S. Lachman[1], B.D. Pressman[2], J.M. Graham, Jr.[1]*. 1) Medical Genetics Birth Defects, UCLA School of Medicine, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Department of Radiology, Cedars-Sinai Medical Center, Los Angeles, CA.

We describe two Hispanic brothers born to unrelated parents with a unique combination of characteristic dysmorphic features, skeletal abnormalities, normal development and unique cerebellar hyperplasia. This syndrome was previously delineated by Van Den Ende and Gupta in 1992 and 1995. This is the fourth report confirming this autosomal recessive syndrome characterized by blepharophimosis, beaked nose, hypoplastic maxilla, everted lower lip, slender and long hands and feet, arachnodactyly, self-limiting congenital joint contractures, distinctive skeletal findings and normal development. Recurrence risk in our family confirms suspected autosomal recessive inheritance and brings to six the total number of reported cases from five families, two of which are consanguineous. Our brothers have identical clinical features and both have cerebellar hyperplasia, a unique finding not previously reported. Though the mode of inheritance and some of these clinical features, including blepharophimosis, arachnodactyly and congenital joint contractures, resemble those observed in Marden Walker syndrome, the presence of mental retardation, serious brain malformations, microcephaly, failure to thrive and severe joint limitation in Marden Walker syndrome and not in Van Den Ende-Gupta syndrome, supports a clinical distinction between these two autosomal recessive disorders.

Program Nr: 1938 from the 1999 ASHG Annual Meeting

Greig cephalopolysyndactly is associated with a novel GLI3 point mutation. *L.H. Seaver, M.J. Friez, J.W. Longshore, R.E. Stevenson.* Greenwood Genetic Ctr, Greenwood, SC.

Greig cephalopolysyndactly is a rare autosomal dominant developmental disorder characterized by multiple physical deformities of the hands and feet. The most prominent features include pre-axial and post-axial polydactly as well as syndactly. Additional findings may also include macrocephaly, a high prominent forehead, a broad nose, hypertelorism and mild mental retardation. Disruption and haploinsufficiency of the GL13 gene located on chromosome 7p13 have been associated with Greigs' syndrome. GL13 encodes a putative zinc finger transcription factor expressed in a number of tissues including the limbs in early mammalian embryos. In addition to disruption of the GL13 gene, several point mutations have also been found to be responsible for Greig's syndrome. In this report, we present a male patient with Greigs' syndrome with chromosomes that are apparently normal. Direct sequencing of the first 12 exons revealed a novel C1447G (Gly465SArg) point mutation adjacent to a zinc finger domain. Interestingly, the mother of this patient also carries the point mutation without signs of Greigs' syndrome. Futhermore, the mother has a daughter with a unilateral bifid thumb in which the point mutation is stongly suspected. If confirmed in the daughter, this GL13 mutation would demonstrate a highly variable phenotype.

Program Nr: 1939 from the 1999 ASHG Annual Meeting

Mental retardation and phenotypic features resembling distal arthrogryposis type II-E in a patient with 47,XXX,del(2)(q37.3)qs. *G.S. Sekhon[1], M.S. Williams[2], P.J. Levonian[2], M. Sharifi[1], K.J. Thompson[1]*. 1) Div Clinical Gen, Waisman Ctr, Univ Wisconsin, Madison, WI; 2) Dept of Pediatrics, Gundersen Lutheran Medical Ctr, La Crosse, WI.

We report a 39 year old female with congenital contractures of the fingers and toes, distal digital hypoplasia and pseudoclubbing of the fingers and thumbs, limitation of motion of the temporomandibular joint, scoliosis, microcephaly and moderate mental retardation. A clinical diagnosis of Distal Arthrogryposis Type II-E was assigned.

Initial unbanded chromosomes (1961) showed a karyotype of 47,XXX. High resolution chromosomes were performed in 1998. 47,XXX was confirmed. In addition, one copy of chromosome 2 had a satellite attached to the distal end of the long arm. Multiple banding techniques were applied together with fluorescence in-situ hybridization (FISH) studies to determine the nature and origin of the additional material. NOR-staining detected a positive region on the long arm of chromosome 2. FISH studies with 2q37 and 2q37.3 probes were performed to rule out a deletion of the long arm of chromosome 2. Two signals were obtained with the 2q37 probe, however, only the non-satellited chromosome 2 homologue had a signal with the 2q37.3 probe.

The patient's clinical features have never been reported in any female with triple X. Mental retardation has been reported in patients with 2q37 deletions. There is a single case report of a patient with 2q35 deletion with finger flexion contractures, but neither this patient nor any reported patients with 2q37 deletion have had distal digital hypoplasia. Our patient does not have clinical features of Albright's hereditary osteodystrophy, which has been reported in some patients with 2q37 deletion. Whether our patient's features are due to the 2q37 deletion, are due to an interaction between the chromosomal deletion and gene overdosage from the triple X, or has 3 distinct genetic conditions is indeterminate at this time.

Program Nr: 1940 from the 1999 ASHG Annual Meeting

Incidence of autism and attention deficit hyperactivity disorder (ADHD) in individuals with deletions of chromosome 18q. *M. Semrud-Clikeman[1], J.D. Cody[2], C.I. Kaye[2], R.J. Leach[2,3].* 1) Department of Educational Psychology, University of Texas, Austin, TX; 2) Department of Pediatrics, UT Health Science Center, San Antonio, TX; 3) Department of Cellular and Structural Biology, UT Health Science Center, San Antonio, TX.

We assessed 46 children (>3yrs old) with deletions of 18q. Six were found to qualify for a diagnosis of autism using the Children's Autism Rating Scale. Autism is a rare disorder occuring in approximately 1-2% of the population. The behavior of these children is characterized by lack of interest in relating to others, stereotypy, and language skill delays, frequently beginning between ages 2 and 3. We found an incidence of autism of 13%, higher than would be expected by chance. There was no difference between the autistic and nonautistic groups on performance IQ (mean 58 and 67.4 respecively). We also identified several children (5 of the remaining 40) with autistic-like behaviors who do not qualify for a diagnosis of autism. There is emerging data from other investigators who are studying autism that there may a predisposition gene for autism on chromosome 18q. Case studies of children with deletions of 18q have found evidence for behavioral difficulties including ADHD and emotional dyscontrol. ADHD is reported to be found in approximately 3-5% of the general population. We found an incidence of ADHD of 24% which is significantly above expectations. There was no difference between performance IQ of the ADHD and non ADHD samples (mean 59.5 and 67.4 respectively). We have begun assessing psychopathology in these individuals. Out of the 14 children assessed, 9 have shown significant difficulties with emotional dyscontrol, 3 of them with such magnitude that neuroleptic medications were required. These results suggest a vulnerability for emotional and behavior dyscontrol associated with deletions of chromosome 18q. Such vulnerability appears to increase with age and may be associated with puberty. The co-occurrence of autism, ADHD, and emotional dyscontrol syndromes associated with individuals with deletions of 18q speaks to the need to seek interventions beyond traditional medical and educational methods.

Program Nr: 1941 from the 1999 ASHG Annual Meeting

Discordant MZ twins in familial amyloid neuropathy (FAP)-TTRMet30. *J. Sequeiros[1], J.L. Pedrosa[2], T. Coelho[3], L. Gusmão[4], R. Seruca[4], A. Amorim[4], M. Munar-Qués[5]*. 1) UnIGENe-IBMC and ICBAS, Univ Porto; 2) Hosp Oliveira Azeméis; 3) Centro Estudos Paramiloidose, Porto; 4) IPATIMUP, Univ Porto, Portugal; 5) Grupo Estudio PAF, Palma Mallorca, Spain.

FAP-I is an autosomal dominant systemic amyloidosis presenting mainly as a peripheral neuropathy. The most common defect is a Met30 substitution in transthyretin (TTR); there is a large variability in age-at-onset (mean: 56.7 yrs in Sweden; 46.7 in Majorca; and 33.5 in Portugal, 35.6 in Japan and 32.4 in Brazil.

In a set of Majorcan twins, J begun FAP-I at age 38 and G at age 50 (2 yrs after J died); G was confined to a wheelchair 7 yrs after, while J was still walking with 2 canes when he died (12 years after onset); only G had severe amyloid deposits of the vitreum (bilateral vitrectomy); J died at age 48 and G at 63; we used old paraffin blocks to extract DNA; L(MZ) was 0.9903. In a set of Portuguese MZ twins, there was the simultaneous occurrence of sacrococcygeal cysts, contrasting with relative discordance for FAP: A had onset at age 30 and J at 34; initial symptoms were a severe sensorimotor syndrome with early involvement of the arms, in A, while J had severe weight loss; A also had cardiac rhythm disturbances, orthostatic hypotension, diarrhea and ulcers in both feet, but J had only a light sensorimotor syndrome and gastrectasia; A died upon many complications after liver transplant, at age 34; J had a successful transplant at 35; DNA was extracted from necropsy material in A; L(MZ) was 0.9999.

Two other sets of twins are known. Significant discordance is present in all four pairs (3 male), both in clinical severity and age-at-onset (up to 12 yrs). The TTR mutation and its genetic modifiers are not the only determinants of age-dependant penetrance and variable expressivity in FAP: other, non-genetic, factors (undetected environmental factors or stochastic events at the molecular and/or cellular level, before or during the twinning process) must be operating. Different patterns of somatic mosaicism for (nuclear) modifying genes or different distributions of mithochondrial modifiers could explain these different expressions.

Program Nr: 1942 from the 1999 ASHG Annual Meeting

Proteus syndrome with infantile myofibromatosis and severely disturbed adipose growth and differentiation. *A.L. Shanske[1], H. Kang[1], R.J. Shprintzen[2], J. Goodrich[1], R. Marion[1]*. 1) Ctr Congenital Disorders, Montefiore Medical Ctr, Bronx, NY; 2) Communications Disorders Unit, State University of New York Health Sciences Center, Syracuse, NY.

Proteus syndrome was first described in 1979 as a complex hamartomatous disorder including partial gigantism and asymmetry of the limbs and various neoplasms. The most commonly observed tumors have been subcutaneous hemangiomas, lymphangiomas and lipomas. The overgrowth and neoplastic changes observed in these patients are thought to result from mosaicism for a dominant lethal gene. We have had the opportunity to evaluate a 7 year old girl with this disorder with an unusual course including a previously unreported neoplasm.

JM was the 8 pound product of a term pregnancy. Two large masses were excised at 2 weeks of age from her chest and abdomen. The histology was consistent with infantile myofibromatosis. Facial asymmetry was apparent by 2 months of age and she developed a partial complex seizure disorder at 4 months. Imaging studies showed a right posterior abnormality consistent with cerebral dysplasia or a prenatal infarct with an associated volume loss. The facial asymmetry progressed to hemiatrophy of the right calvarium down to the right lower jaw. She underwent craniofacial reconstruction at one year with multiple osteotomies and recontouring of the orbital rim and correction of orbital dystopia. She has also had strabismus repair and repair of a left cavovarus foot deformity. Her physical examination at the present time reveals a number of additional significant findings including obesity, overgrowth of the right foot, port-wine stain of the right cheek and chest, acanthosis nigricans, and lipodystrophy of the back.

Our patient fulfills the recently published consensus diagnostic criteria for the Proteus syndrome (Am J Med Genet 84:389-95, 1999). In addition, she has had a rare pediatric tumor which has not been previously reported in association with Proteus syndrome and more extensive signs of disturbed adipose growth and differentiation including decreased subcutaneous tissue, obesity and acanthosis nigricans.

Program Nr: 1943 from the 1999 ASHG Annual Meeting

PCR-SSCP analysis of FMR1 gene in autistic and mentally retarded children in Japan. *K. Shinahara, T. Saijo, K. Mori, Y. Kuroda.* Department of Pediatrics, School of Medicine, University of Tokushima, Tokushima, Japan.

Fragile X syndrome is characterized by long face, prominent chin, large floppy ears, macro-orchidism, retarded language development, hyperactivity and seizure, and is one of the most common cause of mental retardation. However, the craniofacial features are difficult to identify in some patients. It is also reported that some patients with fragile X syndrome show autistic features although the relationship between fragile X syndrome and autism is controversial. The majority of the patients with fragile X syndrome has an expansion of trinucleotide (CGG) repeat in the 5 sequence of FMR1 gene, but a partial or total deletion of the gene has been found in a couple of patients and one nucleotide substitution in the coding region in a patient. In order to study the frequency of the FMR1 mutation among mentally retarded and/or autistic patients, we performed polymerase chain reaction (PCR)-single strand conformation polymorphism (SSCP) analysis of the gene. Among 50 patients analyzed (45 males and 5 females, including two pairs of siblings), abnormal SSCP pattern was observed in two samples derived from two unrelated female patients; exon 8 from patient A and exon 9 from patient B. When exon 8 from patient A was cloned and sequenced, a G to A substitution at nucleotide 662, which alters Glu at 221 to Gly, was observed in four clones out of six, whereas the remaining two clones had the normal sequence. When 17 clones carrying exon 9 from patient B were sequenced, 11 clones had an A to C substitution at nucleotide 879. It caused splicing error, presumably resulting in reduced amount of normal FMR1 protein. No mutation was found among boys. Although uncommon, point mutation in FMR1 gene may be the cause of mental retardation in Japanese population.

Program Nr: 1944 from the 1999 ASHG Annual Meeting

Clinical and molecular exploration of two families with demyelinating neuropathies and non neuropathic features. *S. Sigaudy[1], P. Nègre[1], B. Michel[2], J.F Mattéi[1], N. Philip[1,3], N. Lévy[1,3].* 1) Département de Génétique Médicale, Hôpital d'enfants de la Timone, Marseille, France; 2) Service de Neurologie, Hôpital Sainte-Marguerite, Marseille, France; 3) InsermU491 "Génétique Médicale, et Développement", Faculté de Médecine, Marseille, France.

We report two families with affected individuals presenting a demyelinating peripheral neuropathy with low Nerve Conduction Velocities (NCVs). In one, originating North-Africa, 2 brothers and 2 sisters were affected were initially diagnosed as Charcot-Marie-Tooth type 1. One male and 1 female presented a severe phenotype with foot deformity and distal muscular atrophy for both upper and lower limbs. Two other affected individuals, had milder neurological findings. All affected members presented profund deafness and mild mental retardation. A possible asymptomatism in parents, coupled to the absence of consanguinity in this family, made uncertain the mode of inheritance. We present a loci exclusion for PMP22, Cx32 and Po in this family. Connexin 26 mutations were also not found. In another family, two brothers were affected with demyelinating neuropathy, deafness, and chronic nephritis. This nephropathy was classified as Alport syndrome. Neurological features started in childhood, and at 13 and 15 years old respectively, they presented a severe neuropathy with walking difficulties, pes cavus and distal muscle atrophy predominating to the hands. Electrophysiology revealed a denervation process with low NCVs at all limbs. Audiograms determined the sensorineural hearing loss and showed the high tone frequencies beeing predominantly affected. Terminal renal failure leaded to transplantation. The other siblings and the parents as well, were healthy without biological or clinical mild disorders making it impossible to suggest a possible recessive autosomal or X-linked inheritance mode although the parents were native from the same village in Morocco. In this family, we'll present the molecular explorations performed to date which leaded to exclude main loci usually involved in CMT1. Further explorations are now in process for the already known loci beeing linked to recessive forms of hereditary demyelinating neuropathies.

Program Nr: 1945 from the 1999 ASHG Annual Meeting

A severe case of Trichothiodystrophy due to a DNA repair defect. *J. Sigmundsson[1], L. Woolf[1], E. Magenis[1], R.D. Steiner[1], J. Roberts[2], D. Pillers[1], R. Nixon[1], A.N. D'Agostion[1], D. Wilson[3], P. Stenzel[1], A. Lehmann[4].* 1) Oregon Health Sciences University, Portland; 2) Portland; 3) Casey Eye Institute, Portland; 4) MRC Cell Mutation Unit, Sussex University, Falmer, Brighton, U.K.

The patient was a male, born at 35 weeks gestation. Birth weight was 2.1 kg. Pregnancy was complicated by severe pregnancy induced hypertension. Amniocentesis had revealed normal chromosomes. Family history was negative. Sparse, dry, brittle scalp hair was noted and the patient had mild edema at birth that resolved in a few days, but left peeling skin, shiny in parts and taut in the hands. The skin texture normalized in the first few weeks. Most of the hair fell off in the first few weeks of life. The patient had feeding difficulties and failure to thrive. Hair studies revealed low sulfur content and TTD-type hair. At three months of age the patient was noted to have subtle facial asymmetry and low muscle tone. The patient expired suddenly at three months. He had never been exposed to sunlight. Complete autopsy revealed congenital cataract, focal perimedullary fibrosis of the caudal spinal cord and pulmonary parenchyme hemorrhage.

DNA repair studies on skin fibroblasts that had been obtained earlier showed abnormal response to UV irradiation similar to those reported for other TTD patients. Nucleotide excision repair, as measured by unscheduled DNA synthesis was 15-20% of that in normal cells, and RNA synthesis failed to recover after UV irradiation, as previously reported in cells from patients with TTD and other repair-deficient disorders.

This report emphasizes the importance of early awareness of this disorder and prompt work up and demonstrates that not all patients with TTD that have a DNA repair defect have a history of sun sensitivity. More than 50% of patients with TTD, most of whom have had sun sensitivity, have been found to have a DNA repair defect, most of them having mutations in the xeroderma pigmentosum, complementation group D (*XPD*) gene and, in one affected family, in the *XPB* gene. Complementation studies on our patient are currently in hand.

Program Nr: 1946 from the 1999 ASHG Annual Meeting

Clinical and cytogenetic findings in three new cases of deletion 10q26. *S. Sigurdardottir[1], M.T. Geraghty[2], V. Praphanphoj[2], G.H. Thomas[1,2], B.K. Goodman[2].* 1) Kennedy Krieger Institute, Baltimore, MD; 2) Inst of Genetic Medicine, Johns Hopkins Univ School of Medicine, Baltimore, MD.

Deletions of the distal long arm of chromosome 10 [10q26-qter] are rare, with only 16 reported patients. Consistent clinical findings are psychomotor retardation and typical craniofacial features, including prominent nasal bridge, strabismus and hypertelorism. Significant growth retardation and major anomalies, most often involving the heart and urogenital system, have been reported in some patients. We report on 3 patients with de novo 10q26 deletions. All three were born at term with normal birth weights. The first patient, a male, had severe developmental delay, VSD, hydronephrosis, patent urachus and bilateral sensorineural hearing loss caused by a Mondini malformation. At age 3 years he was growth retarded, microcephalic with low set abnormal ears, and hypotonia with decreased muscle strength. Facial features included esotropia, pointed chin, and prominent nasal bridge. Peripheral blood karyotype was 46, XY, del (10) (q26.12). In contrast, the second and third patients had a more distal deletion [del (10) (q26.2)] associated with less severe developmental delay and without major malformations. The second patient, a 3 year old girl, had growth delay, microcephaly with frontal bossing, widow's peak, prominent nasal bridge and bilateral fifth finger clinodactyly. She had a previous normal karyotype. The deletion in this case was confirmed using a 10q-specific subtelomeric probe. The third patient, a 14-month-old girl, was the most mildly affected. Her head circumference and weight were normal but her height was below the 5th centile. She had esotropia, prominent nasal bridge, tapering fingers and axial hypotonia. These 3 cases support the suggestion that patients with distal 10q deletions are not a uniform group. Contrary to some previous reports, we found a relationship between the size of the deletion and severity of clinical findings. The finding of a Mondini malformation in the first patient is interesting, as sensorineural hearing loss has previously been reported in three patients with deletions in this area. Further molecular cytogenetic studies are in progress.

Program Nr: 1947 from the 1999 ASHG Annual Meeting

Prolonged survival in a case of atelosteogenesis type 2. *V.M. Siu[1,2], B.A. Gordon[1], Y. Ouellette[2], A. Superti-Furga[3].* 1) Medical Genetics Program of Southwestern Ontario and CPRI; 2) Children's Hospital of Western Ontario, London, Ontario, Canada; 3) University Children's Hospital, Zurich, Switzerland.

Diastrophic dysplasia (DTD), atelosteogenesis type 2 (AO2), and achondrogenesis 1B (ACG1B) form a spectrum of autosomal recessive chondrodysplasias caused by mutations in the diastrophic dysplasia sulfate transporter (DTDST) gene. Though similar in histologic and ultrastructural features, clinical severity varies widely. A male infant was born at 38 weeks to a nonconsanguineous couple. Ultrasound at 30 weeks had documented hitchhiker thumbs suggestive of DTD. At birth there was severe limb shortening with nubbin-like digits, in addition to edema, macrocephaly, cystic ears, hypertelorism, short neck, cleft palate, small chest, and wide gap between halluces and second toes. Radiographic investigation documented cervical kyphosis, thoracic scoliosis, lumbar lordosis with horizontal sacrum, V-shaped distal humeri, dislocated elbows, bowed radii and tibiae, and dumbbell-shaped femora. The phenotype was compatible with AO2; limb shortening was almost as severe as in ACG1B. MRI scan has revealed cerebral atrophy and BAERA has shown bilateral hearing loss. Molecular analysis confirms compound heterozygosity for the common Finnish mutation and a Q2021C substitution in the cytoplasmic tail of the DTDST gene, each mutation being present in one parent. Urinary glycosaminoglycans were grossly undersulfated. The baby was highly unstable and ventilator dependent in the first year of life due to pulmonary hypoplasia and severe tracheobronchomalacia. At 13 months of age, he breathes independently, is visually alert but makes no sounds, requires gastrostomy feeds, is unable to sit, and has no movement of his digits. Among patients with DTDST skeletal dysplasia surviving beyond the neonatal period, this baby is the most severely affected reported thus far, in terms of limb findings. Despite poor prognosis, parents advocated strongly for life-supporting measures. Mechanical ventilation and repeated resuscitations can allow survival even in the presence of severe skeletal dysplasia. We are concerned about long-term outcome and and anticipate complications related to the cervical kyphosis.

Program Nr: 1948 from the 1999 ASHG Annual Meeting

Pena-Shokeir phenotype secondary to neonatal neuroaxonal dystrophy. *R. Smith[1], J.A. Golden[2], S. Saitta[1], A.D. Kline[3], J.E. Ming[1], D.M. McDonald-McGinn[1], D.F. Carpentieri[2], B.W. Little[4], L.B. Rorke[2], E.H. Zackai[1].* 1) Division of Human Genetics and Molecular Biology and; 2) Department of Pathology, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Clinical Genetics, Department of Pediatrics, Sinai Hospital of Baltimore, Baltimore, MD; 4) Department of Pathology and Laboratory Medicine, Allegheny University of the Health Sciences, Philadelphia, PA.

Infantile neuroaxonal dystrophy, also known as Seitelburger's disease, is a rare autosomal recessive neurodegenerative disease. The onset of clinical disease classically begins during the second year of life with a progressive loss of developmental milestones. Although presentation by 6-9 months is not uncommon, neonatal onset is not generally recognized. Pathologically infantile neuroaxonal dystrophy is characterized by spheroids in central and peripheral nerve axons. We present two unrelated male sibling pairs, who presented with the fetal hypokinesia/akinesia sequence, other minor and major anomalies, and neonatal demise. Neuropathological examination demonstrated axonal spheroid pathology in all four males consistent with a form of neuroaxonal dystrophy. The distribution of spheroids in the first sibling pair was primarily in the dentate nucleus, globus pallidus and thalamus. These brothers also demonstrated cerebellar dysplasia, inferior frontal polymicrogyria and ventriculomegaly. In the second sibling pair axonal spheroids were predominantly found in the cerebral white matter and in the basis pontes. These two sibling pairs, along with a few other reported cases, expand the clinical spectrum of neuroaxonal dystrophy to include a neonatal onset form. These cases provide additional support for autosomal or X-linked recessive inheritance in neonatal neuroaxonal dystrophy, and demonstrate that neonatal neuroaxonal dystrophy must be considered as a neuropathological etiology of the fetal hypokinesia sequence.

Program Nr: 1949 from the 1999 ASHG Annual Meeting

Radiographic diagnosis of Shwachman-Diamond Syndrome in a neonate. *W. Smith, A. Amalfitano, C. Miller, A. Patterson.* Divisions of Medical Genetics and Pediatric Radiology, Duke University Medical Center, Durham, NC.

Shwachman-Diamond syndrome (SDS) is a rare, autosomal recessive disorder characterized by pancreatic insufficiency, bone marrow dysfunction and skeletal dysplasia. Diagnosis is usually made in childhood secondary to pancreatic or blood disorders. Restrictive thoracic dystrophy (RTD) in the neonatal period has been retrospectively reported in several patients with SDS. We report a neonate with RTD who was subsequently diagnosed with SDS. This African American male was the 2.6kg (25th%) product of a normal 38 week pregnancy to a G10P5 mother; birth length 45cm (10th%), OFC 33.5cm (50-75th%). He had symmetric rhizomelic limb shortening and a very narrow, bell shaped chest: inter-nipple distance 6.3cm (<3rd %), chest circumference 28cm (3-50th %). Radiographs obtained at age 6 days demonstrated markedly shortened AP and transverse chest diameters with small, short, anteriorly cupped ribs. The thoracic and lumbar vertebrae were ovoid with end-plate sclerosis. There was significant metaphyseal dysplasia of the long bones with deep cupping but no irregularity. A tentative diagnosis of SDS was made based solely on the skeletal findings. Subsequent investigations revealed low serum trypsin and increased stool fat consistent with pancreatic insufficiency. By five weeks of age he developed recurrent vomiting and diarrhea, failure to thrive and a significant anemia: hgb 4.8 mg/dl, hct 15%. Physical examination demonstrated hepatosplenomegaly. A midgut nonrotation was diagnosed and he underwent surgical repair. Simultaneous liver biopsy showed extensive macrovesicular steatosis with canalicular cholestasis and abundant iron. Postoperatively he remained ventilator and blood product dependent. Due to neutropenia he developed concurrent fungal, coagulase negative staphylococcal, and enterococcal sepsis and died at age 10 weeks. Post-mortem histology of the pancreas was characteristic of SDS with highly vacuolated lobules, atrophic acinar spaces and preserved islets. This patient, in whom a prospective radiologic diagnosis of SDS was made as a neonate, suggests that disease severity may be positively correlated with the radiographic features and the degree of RTD.

Program Nr: 1950 from the 1999 ASHG Annual Meeting

Distichiasis, lymphedema, and cleft palate (DLC) : a discrete Mendelian entity with autosomal dominant inheritance. *V. Soupre[1], C. Houdayer[2], M.-P. Vazquez[1], M. Bahuau[1,2]*. 1) Chirurgie Maxillo-Faciale et Plastique et Stomatologie, Hôpital d'Enfants Armand-Trouseau, Paris, France; 2) Biochimie et Biologie Moléculaire, Hôpital d'Enfants Armand-Trouseau, Paris, France (biochimie.trousseau@trs.ap-hop-paris.fr).

In view of identifying monogenic pedigrees with syndromic cleft palate, we have investigated a family showing autosomal dominant segregation of upper- and lower-eyelid distichiasis (double row of eyelashes) in seven affected relatives over three generations, in addition to below-knee lymphedema of pubertal onset (lymphoedema praecox) in three of them, and cleft palate/velum in two, without the previously reported association to the Pierre Robin anomalad. Other ophthalmologic anomalies included divergent strabismus and early-onset myopia. Pterygium colli, congenital heart disease or facial dysmorphism were not features here. This observation confirms previous singular or familial reports with this rare cluster of malformations. We believe this familial condition is a discrete Mendelian trait distinct from previously delineated entities such as distichiasis (MIM 126300), distichiasis-lymphedema (MIM 153400), type-1 (Nonne-Milroy's; MIM 153100), or type-2 (Meige's; MIM 153200) hereditary lymphedema. Linkage analysis in this and other like kindreds is warranted to map the underlying genetic defect, test for allelism to germane but phenotypically distinct entities, and eventually provide new insights into the developmental/signaling pathways involved in palatal closure.

Program Nr: 1951 from the 1999 ASHG Annual Meeting

Clinical study and use of FISH analysis to diagnostic approach of Brazilian patients with Williams-Beurens syndrome. *S. Sugayama[1], M. Chauffaille[2], K. Abe[2], D. Bertola[1], L. Albano[1], C. Utagawa[1], A. Catelani[2], M. Obelar[2], N. Kusagari[2], P. Perroud[2], C. Kim[1]*. 1) Pediatrics, Instituto da Crianca, Sao Paulo, Brazil; 2) Fleury Laboratory, Sao Paulo, Brazil.

Williams-Beurens syndrome (WBS) is a rare (1/20,000-1,50,000 livebirths) neurodevelopmental disorder affecting multiple systems.The main features are typical elfin facies, heart defects, mental deficiency, friendly personality and hypercalcemia in infancy.The syndrome is caused by a submicroscopic deletion in the chromosome region 7q11.23 which is detectable by FISH analysis in 90-95% of the patients. We report on clinical evaluation and FISH analysis(VYSIS/LSI-Williams Syndrome Region DNA FISH probe)from 21 patients (12M/9F);all cases were sporadic. The mean age at diagnosis was 5,2 years (2mo-12y) and the mean current age is 9,7 years (23mo-17,5y).All patients presented typical elfin facies, developmental delay/mental retardation, friendly personality,skeletal and dental anomalies;fourteen (67%) had ocular anomalies, specially strabismus; thirteen (62%)had congenital cardiac defect:eight of them had supravalvar aortic stenosis (SVAS); thirteen (62%) had short stature; ten (48%) presented transitory hypercalcemia; seven (33%) had inguinal hernia; five (24%) had renal anomalies and 3 boys had genital anomalies.One girl presented precocious puberty at 5 years of age.She is likely the second case of WBS patient with this disorder in the literature. Deletion was found in seventeen (81%)patients. FISH analysis of the elastin locus is a useful test as an initial diagnostic approach for WBS. However, the presence of two copies of the elastin locus in a patient does not rule out WBS syndrome.Our four patients without deletion presented typical facies and behavioral but no cardiac defects.Therefore, these results support the importance of molecular studies in further delineation of the WBS phenotype.

Program Nr: 1952 from the 1999 ASHG Annual Meeting

De novo chromosome 2 pericentric inversion in a stillborn infant with Cerebro-Costo-Mandibular syndrome.

W.S. Surka[1], R. Laux[2], J. Arrington[2], S. Warsof[2], J. Zackowski[1], V. Proud[1]. 1) Childrens Hosp Kings Daughters, Eastern Virginia Medical School, Norfolk, VA; 2) Tidewater Perinatal Center, Virginia Beach, VA.

Cerebro-Costo-Mandibular syndrome (CCMS) is a rare condition that consists of severe micrognathia, rib anomalies, cleft palate, and in some cases cerebral anomalies. There are at least 50 patients with CCMS in the literature. Infants with CCMS have a greater than 50% mortality in the first year of life because of lung hypoplasia and upper airway obstruction due to micrognathia and glossoptosis. Although mostly sporadic, pedigrees consistent with autosomal recessive and autosomal dominant inheritance have been documented. Mechanisms that would account for most reported cases include autosomal dominant inheritance with reduced penetrance, germline mosaicism, and genetic heterogeneity. All reported karyotypes are normal and no single putative gene has been implicated.

A 23 year old, $G_3P_1A_1$, African American female presented at 18 weeks gestation for evaluation of a fetal thickened nuchal fold. Ultrasound revealed scalp edema, severe micrognathia, small chest with no identifiable ribs, and possible bifid left thumb. Amniocentesis revealed a fetal karyotype of 46,XX,inv(2)(p24.2q33) and parental karyotypes were normal. Intrauterine fetal demise occurred at 26 weeks and a diagnosis of CCMS was made at post mortem examination. Physical findings in addition to those seen prenatally included broad alveolar ridges, lowset ears with bilateral imperforate auditory meatus, short sternum with bell shaped chest, labia majora hypoplasia, elbow pterygium, proximally placed thumbs, ulnar deviation of the hands, left preaxial polydactyly, and rocker bottom feet.

This case is significant because it is the first case of CCMS with a documented cytogenetic abnormality. This suggests that: (1) a gene or contiguous genes exist at 2p24.2 or 2q33 that may be important in fetal development of ribs and mandible; and (2) it suggests that an autosomal dominant gene or contiguous gene deletion may explain the etiology of CCMS.

Program Nr: 1953 from the 1999 ASHG Annual Meeting

Transverse Limb Defects Associated with Vascular Abnormalities: Atypical Presentation of Adams-Oliver Syndrome? *A.S. Teebi[1], N. Al-Sannaa[1], I. Adatia[2].* 1) Pediatrics & Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Cardiology & Critical Care Medicine, Hospital for Sick Children, Toronto, ON, Canada.

Adams-Oliver syndrome (AOS) is a well-recognized entity that associates cutis aplasia congenita with terminal transverse limb defects and other anomalies. Poland sequence has been considered part of a spectrum having the same pathogenesis. Wide intrafamilial and interfamilial variability was noted. Over the last decade, there has been a surge of publications documenting the association of vascular and cardiac anomalies in AOS. It was estimated that congenital cardiac malformations are present in about 20% of all AOS patients. If the association of the other vascular anomalies were considered, it would appear that this group of anomalies represents an important component of the syndrome. We report a 4 years old boy with terminal transverse limb defects associated with primitive persistence of primitive aorto-pulmonary vascular connections leading to supra-systemic pulmonary artery pressure. This patient did not display the other manifestation of AOS like cutis aplasia congenita or Poland sequence and the family history is negative for that type of anomalies. Based on the association of vascular anomalies as an emerging component of Adams-Oliver Syndrome, we suggest that this patient is an example of AOS with atypical presentation.

Program Nr: 1954 from the 1999 ASHG Annual Meeting

A rare 12p distal interstitial deletion with radial ray anomaly of the hands and ectrodactyly of the feet: Cytogenetic and molecular delineation. *L.L. Thomson[1], C.K. Stein[1,2], A.E. Shrimpton[2], A.M. Willey[3], J.J. Hoo[1]*. 1) Pediatrics, State Univ. NY Health Sci Ctr, Syracuse, NY; 2) Dept. Pathology, State Univ. NY Health Sci Ctr, Syracuse, NY; 3) NY State Dept. Health, Albany, NY.

12p deletions are rare, and of the reported cases, most are proximal interstitial deletions. Only one previous case (Romain et al., 1987) showed a distal interstitial deletion of 12p. While the cases with proximal deletion show severe mental retardation, the distal deletion case of Romain et al. was associated with mild mental retardation.

Our patient was born with normal birth weight, length, and head circumference. The following dysmorphic features were noted at birth: left iridal coloboma, bilateral posteriorly rotated ears, grade 2 hypospadias, bilateral hypoplastic thumbs, and bilateral ectrodactyly of the feet. At almost 2 months of age, he was alert and starting to smile. Muscle tone was normal. No internal organ abnormality was noted. The high resolution karyotype revealed a distal interstitial deletion of the short arm of chromosome 12 [46,XY,del(12)(p13.1p13.2) de novo]. FISH utilizing a whole chromosome paint probe for 12 showed signal along the entire length of both 12s, but no evidence of signal elsewhere in the cells. Molecular studies showed the deleted 12 to be of paternal origin. DNA probes in distal p12.3 were deleted as well as the most distal probe in 13.2, refining the breakpoints to12p12.3p13.2.

Like the patient of Romain et al., our case may only have mild mental retardation. However the radial ray anomaly of the hands and the ectrodactyly of the feet have not been reported in any previous 12p deletion cases. The molecular delineation of the breakpoints may be useful for future mapping of a gene causing the anomaly in the distal extremities.

Program Nr: 1955 from the 1999 ASHG Annual Meeting

Premature osteoporosis in neurofibromatosis type 1. *C.J. Tifft, L.L. Tosi, P.H. White, K.N. Rosenbaum.* Children's National Medical Center, Washington, DC.

Neurofibromatosis type 1 (NF1) has been associated with skeletal manifestations including scoliosis, pseudoarthrosis and sphenoid wing dysplasia. A small number of patients have also been reported with osteomalacia. We report an adolescent and young adult with generalized osteoporosis, a finding not previously associated with NF1. Case 1 is a 12-year-old female first seen at 9 years of age for evaluation of possible NF1. The diagnosis was confirmed by NIH consensus criteria by the presence of Lisch nodules, axillary and inguinal freckling, multiple cafe-au-lait spots, and cutaneous neurofibromas. Fluorescence in situ hybridization demonstrated a deletion of 17q11.2. Additional problems included hydrocephalus secondary to aqueductal stenosis requiring shunt placement and bilateral pes planus requiring surgical intervention. At 11 years of age, during a period of limited activity, this child experienced back pain and radiographs showed vertebral compression fractures. Bone density was evaluated by DEXA scan revealing severe osteoporosis (T-score of -4.79 at L1 to L4, -4.68 at the femoral neck, and -4.51 at the left hip). The patient has been maintained on calcitonin, calcium and vitamin D daily. Case 2 is a 27 year old female diagnosed with NF1 at 12 years of age based on multiple cafe-au-lait spots, cutaneous and plexiform neurofibromas, Lisch nodules and scoliosis. At 25 years of age a follow-up spine radiograph showed compression fractures of T6 and T7. A DEXA scan showed moderately severe osteoporosis (T-score -2.49 for the lumbar spine and -2.17 at the femoral neck). A bone biopsy revealed decreased bone turnover and excluded osteomalacia. A CBC and serum chemistries including calcium and phosphorus were normal as were 24-hour urinary excretion of calcium, phosphorus and creatinine. The patient was placed on bisphosphonates and began a regular program of weight-bearing exercise. A one-year follow-up study showed an increase in bone density. Osteoporosis may be a more common finding in children and young adults with NF1 than previously recognized, particularly those with skeletal involvement or inactivity. DEXA scanning in a subgroup of potentially at-risk patients may therefore be appropriate.

Program Nr: 1956 from the 1999 ASHG Annual Meeting

Study of genetic factors contributing to both isolated and MCA cases of omphalocele. *C.P. Torfs[1], E.V. Semina[2], M. Knipp[2], F. Lorey[4], J.C. Murray[2,3].* 1) CA Birth Defects Monitoring, Emeryville, CA; 2) Department of Pediatrics, Univ Iowa, Iowa City, IA; 3) Department of Biol Sciences, Univ Iowa, Iowa City, IA; 4) Genetic Disease Branch, DHS, Berkeley, CA.

We have studied all cases of omphalocele born in the area of catchment of the California Birth Defects Monitoring Program between 1983 and 1994, excluding trisomies, conjoined twins, and cases with a known genetic or chromosomal defect such as Beckwith-Wiedemann syndrome. For 216 cases, newborn screening blood spots were available from the Genetic Disease Branch of California. The group consisted of 92 (43%) infants with an isolated defect and 124 with multiple congenital anomalies (MCA) including 6 with a recognized syndrome and one mosaic XXX. 59% of the isolated cases and 48% of the MCA cases were male. There was no significant difference in maternal age between the two groups. Maternal ethnicity was 29 % Hispanic, 50 % non-Hispanic Caucasian ;10% African American , and 6 % Asian and 4% Other. To evaluate genetic contributions to both isolated and MCA cases, we screened for mutations in genes known to predispose to omphalocele in specific syndromes (PITX2 in Rieger syndrome, GPC3 in Simpson-Golabi-Behemel syndrome) or to be strongly expressed in the abdominal region, including PITX1. The entire coding regions and all the exon-intron junctions of PITX2 and PITX1 were screened in 208 cases by SSCP analysis and no mutations were identified. Screening for the GPC3 is ongoing. This study provides an opportunity to evaluate an unbiased collection of omphalocele cases and to determine the effect of specific gene mutations on etiology.

Program Nr: 1957 from the 1999 ASHG Annual Meeting

Multisystem involvement in congenital insensitivity to pain with anhidrosis (CIPA), a nerve growth factor receptor (TrkA) related disorder. *E. Toscano[1], R. Della Casa[1], S. Mardy[2], G. Marzano[1], N. Varricchione[1], F. Sadile[1], C. Pignata[1], Y. Indo[2], G. Andria[1]*. 1) Pediatrics, "Federico II" University, Naples, Italy; 2) Pediatrics, Kumamoto University,Honjo, Kumamoto, Japan.

Congenital insensitivity to pain with anhidrosis (CIPA) is an autosomal recessive sensory and autonomic neuropathy. CIPA is caused by a defect of the high affinity tyrosine kinase (TrkA) receptor for nerve growth factor (NGF). PC,female, age 12 years and MC, female, age 5 years, are two unrelated CIPA patients, diagnosed on the basis of insensitivity to pain, self mutilating behavior, recurrent episodes of fever, absence of sweating and mental retardation, with presence of fungiform papillae and corneal reflexes and normal structure of sweat gland at skin biopsy. Both patients presented bone involvement (joint deformities, pelvic dysplasia, frequent fractures) and immune system alterations (decreasing of proliferative response of peripheral blood mononuclear cells to PHA, Con-A and CD3X-L stimuli). PC died from renal insufficiency, secondary to a rapidly progressive systemic amyloidosis. Molecular analysis of the TrkA gene revealed in PC a homozygous G to A transition, causing a Gly to Ser substitution at amino acid 708, and in M.C. a C to T transition, causing a Gln to a termination codon at amino acid 9, respectively (Mardy et al AJHG 64:1570-79,1999). NGF increases the synthesis of acetylcholine in cholinergic neurons, playing a role in the survival of selected populations of neurons. NGF can also modulate synaptic plasticity and transmission and maintain a balanced interplay between nervous, immune and endocrine systems. Bone involvement in CIPA patients suggests that NGF exerts also a role in skeletal cell metabolism. CIPA is the first human genetic disorder caused by a defect in the neurotrophin signal transduction system and this is the first clinical report about CIPA patients characterized on the molecular ground. The clinical phenotypes of our patients reveal that a multisystem involvement may be observed in CIPA patients. Molecular characterization might improve our understanding of the physiological roles of NGF/TrkA system in human and eventually suggest new therapeutic approaches.

Program Nr: 1958 from the 1999 ASHG Annual Meeting

Neurological phenotype in Waardenburg type 4 patients with SOX10 mutations. *R. Touraine, T. Attié-Bitach, J. Amiel, A. Pelet, J. Auget, A. Munnich, M. Vekemans, S. Lyonnet.* Department of Genetics, INSERM U-393, Hopital Necker-Enfants-Malades, Paris, France.

Waardenburg syndrome type 4 (WS4) or Shah-Waardenburg syndrome is a rare neurocristopathy resulting from the absence of melanocytes and intrinsic ganglion cells of the terminal hindgut. WS4 is inherited as either an autosomal recessive trait due to EDN3 or EDNRB mutations, or an autosomal dominant condition when SOX10 mutations are involved. Here we report on three unrelated WS4 patients with growth retardation and an as yet unreported neurological phenotype with impairment of both the central and autonomous nervous systems and occasionally neonatal hypotonia and arthrogryposis. Each of the three patients was heterozygous for a SOX10 truncating mutation (Y313X in two patients, S351X in one patient). A likely hypothesis for the extended clinical spectrum would be that the S251X and Y313X mutations resulted in a dominant negative effect. The extended spectrum of the WS4 phenotype is relevant to the brain expression of SOX10 during human embryonic and fetal development. Indeed, the expression of SOX10 in human embryo was not restricted to neural crest derived cells but also involved fetal brain cells most likely of glial origin. These data emphasize the important role of SOX10 in early development of both neural crest derived tissues, namely melanocytes, autonomic and enteric nervous systems, as well as in glial cells of the central nervous system.

Program Nr: 1959 from the 1999 ASHG Annual Meeting

Cat-like cry associated with a familial 5p terminal deletion distal to the cri-du-chat syndrome critical region. *L.C. Tuttle, X. Li, J.B. Ravnan, L. Bros, S. Owen, J. Kobori.* Genetics Department, Kaiser Permanente Northern California, San Jose, CA.

The existence of a cat-like cry critical region distal to the cri-du-chat critical region on chromosome 5p has previously been proposed. We report a family with an inherited 5p terminal deletion associated with a cat-like cry and variable degrees of intellectual impairment. N.C. was first seen as an inpatient at 3 days of age. She was noted to be SGA and hypotonic, with brachycephaly, full cheeks, microretrognathia, poor neurologic responsiveness and a high pitched cry. Cytogenetic studies revealed a small terminal deletion of 5p, 46,XX,del (5) (p15.2). Fluorescence in situ hybridization (FISH) using a DNA probe containing the cri-du-chat critical region at band 5p15.2 (D5S23, Oncor, Inc.) revealed a normal pattern, indicating that the deletion is distal to the probe locus. FISH analysis using a 5p telomeric probe (T5p5q, Cytocell Ltd.) confirmed a terminal deletion. Parental cytogenetic studies revealed the same deletion in the mother, M.O., a 34 year-old with a history of learning disability but no birth defects or medical problems. She has two other children, J.B. and S.C. J.B., an 8-year-old maternal half-brother to the proband, had been diagnosed with cerebral palsy. He has dysmorphic features including medial flare of eyebrows and broad nose, and significant developmental delay. S.C., a full sibling to the proband, is a non-dysmorphic 5-year-old girl with normal development but recently noted to have difficulty concentrating in school. Cytogenetic analysis revealed the presence of the same 5p deletion in both J.B. and S.C. The mother recalls that J.B. and S.C. also exhibited similar, high-pitched cries as infants. In conclusion, additional FISH studies are warranted on patients with cat-like cry and features not typical of classical cri-du-chat syndrome who have negative FISH studies for the cri-du-chat critical region. This report also illustrates the milder phenotypes in individuals with a more distal 5p terminal deletion than that which causes the classical cri-du-chat syndrome.

Program Nr: 1960 from the 1999 ASHG Annual Meeting

Dysostosis spondylocostal: a clinical study of 14 patients. *C.Y. Utagawa[1], C.A. Kim[1], S.M.M. Sugayama[1], D. Bertola[1], L.A.N. Oliveira[2], C.H. Gonzalez[1].* 1) Dept. of Pediatrics, Instituto da Crianca, University of Sao Paulo, Sao Paulo, Brazil; 2) Dept. of Radiology, Instituto da Crianca, University of Sao Paulo, Sao Paulo, Brazil.

Spondylocostal dysostosis is a skeletal disorder characterized by short trunk and short stature due to multiple vertebral and rib segmentation defects. There is an evident genetic heterogeneity with two patterns of inheritance: autosomal recessive and autosomal dominant. We report on clinical data from 14 patients (7 females and 7 males) belonging to 13 families. The age of the diagnosis ranged between 11 days and 6 years. Only 4/14 (28%) cases were diagnosed during the neonatal period. Half of the patients presented short stature at birth, while scoliosis and ribcage deformity were present in all cases. Recurrent pneumonias occurred in 6/14 (43%) and respiratory failure in 4/14 (28%). This latter event was the cause of death in one of these children during the neonatal period. Hernias (64%), neural tube defects (36%), congenital heart disease (14%) and urinary tract anomalies (14%) were the most frequent associated anomalies. Cerebral poligiria and delayed psychomotor development were found in only one child. The main skeletal malformations were hemivertebrae, fusion and hypoplasia of the vertebral bodies, agenesis, hypoplasia and fusion of the ribs. Dorsal column was affected in 92% of the patients, followed by lumbar (78%) and cervical region (43%). Progression of the scoliosis was present in 23% of the cases. Patients with extensive involvement of the column showed a less severe degree of scoliosis compared to the ones with mild vertebral anomalies. The children's parents were evaluated and none of them presented vertebral anomalies. Consanguinity was observed in two occasions and there was a recurrence (two sibs affected) in another one, suggesting a pattern of autosomal recessive inheritance in these families. Therefore, the majority of the cases (72%) were sporadic, in concordance to the literature.

Program Nr: 1961 from the 1999 ASHG Annual Meeting

A syndrome of multiple exostoses, hirsutism, mental retardation and seizures in a patient with a 8q24 submicroscopic interstitial deletion. *L. Van Maldergem[1], W. Wuyts[2], M. Foulon[3], C. Wetzburger[3], D. Roland[1], Y. Gillerot[1], W. Van Hul[2]*. 1) Medical Genetics, Inst Pathology & Genetics, Gerpinnes, Belgium; 2) Centrum Medische Genetica, Universitaire Instelling, Antwerpen, Belgium; 3) Department of Pediatrics, Centre Hospitalier Universitaire, Charleroi, Belgium.

Multiple exostoses is a genetically heterogeneous condition with currently two genes being identified : EXT1 in 8q24 and EXT2 in 11p11-12. The exostoses can occur isolated or as part of a syndrome. Multiple exostoses and mental retardation are part of the trichorhinophalangeal syndrome type II (TRP II) which is caused by a deletion of the region encompassing the EXT1 gene. We describe a single patient born to unrelated Tunesian parents with multiple exostoses, mild mental retardation, hirsutism, a porencephalic cyst and seizures. Interestingly, this patient doesn't have the classical symptoms of TRP II since no cone shaped epiphyses are present on hand radiograph and no pear shaped nose or sparse hair are observed. By contrast, he has a striking hypertrichosis of the face with bushy eyebrows. FISH was performed with probes for the EXT1 gene (8q24) and EXT2 gene (11p11-p12). This analysis revealed the presence of a deletion of the EXT1 probe on chromosome 8q24. Further PCR analysis with polymorphic markers surrounding the EXT1 gene showed a deletion in the paternal chromosome flanked by the markers D8S547 (122,6cM) and D8S1728 (127,6cM), including the entire EXT1 gene. This case only resembles a single case report described by Wiedemann et al. (Am J Med Genet 46:403-409; 1993) with hirsutism and exostoses in a 19 year-old male. However, the topography of hypertrichosis from this patient (the trunk but not the face) and also the facial dysmorphia appear different. We suggest that the unique association in our patient of facial hirsutism, dysmorphia, mental retardation, seizures and multiple exostoses represent a new contiguous gene syndrome that partially overlaps with TRP II.

Program Nr: 1962 from the 1999 ASHG Annual Meeting

A clinical, cytogenetic and molecular study of three Brazilian patients with supernumerary inv dup(15) marker chromosomes. *M.C. Varela[1], C. Fridman[1], T.E. Matsumoto[1], C.A. Kim[2], F. Kok[3], A. Diament[3], C.P. Koiffmann[1]*. 1) Dept Biology, University of Sao Paulo; 2) Child Unit, Child Institute, Faculty of Medicine; 3) Child Neurology Service, University of Sao Paulo, School of Medicine, Sao Paulo, Brazil.

The presence of supernumerary marker chromosomes (SMC) is not rare and the inv dup(15) is the most common (~0,02% of liveborn). Patients with inv dup(15) containing the Prader-Willi (PWS)/Angelman syndrome (AS) critical region usually have hypotonia, mental retardation, seizures, growth retardation and autism. Here we present two girls (9 and $8^{5/12}$y) and one boy (2y) with inv dup(15). Banding GTG studies disclosed the presence of a bissatellited SMC that had the size of a G-group chromosome. Parental karyotypes were normal. FISH using the probes D15Z1 (a-satellite probe) and single-copy sequences that map to 15q11-q13 (GABRB3 and SNRPN) disclosed two signs on the SMC, and normal chromosome 15 homologues. The analysis of SNRPN methylation was normal, excluding the AS or PWS diagnosis. The girls showed an increased intensity of the maternal band indicating the maternal origin of the extra chromosome that was confirmed through the microssatellite analysis (D15S542, D15S11, D15S113, GABRB3); these markers were not informative in the boy and additional loci will be tested. All three probands showed delayed motor development, mental retardation, seizures, lack of speech and ataxic gait. The girls presented growth retardation (height £3rd; weight £10th) and outsburts of laughter. Hypotonia, microcephaly, brachycephaly, macrostomia and hyperactivity was presented in 1 girl. The boy showed normal growth patterns (height and weight - 75thcentile), no hyperativity and no outsburts of laughter. All of the probands have 4 copies of the PWS/ASCR; the girls also have a physical excess of maternal versus paternal alleles of these region as well as an increased maternal dosage of this imprinted region. The phenotypic variability observed among patients with inv dup(15) is influenced by the origin of the marker, the extend of the euchromatic segment and by its isodysomic or heterodysomic nature. Supported by FAPESP.

Program Nr: 1963 from the 1999 ASHG Annual Meeting

OSTEOPATHIA STRIATA WITH CRANIAL STENOSIS : PHENOTYPIC SPECTRUM AND SUGGESTION OF X-LINKED INHERITANCE. *G. VIOT[1], D. LACOMBE[2], A. DAVID[3], D. SANLAVILLE[1], M. MATHIEU[4], A. de BROCA[4], A. MUNNICH[1], S. LYONNET[1], M. LE MERRER[1], V. CORMIER-DAIRE[1]*. 1) Department of Genetics, Hopital Necker AP-HP, PARIS, FRANCE; 2) Department of genetics, Hopital Pellegrin, BORDEAUX, FRANCE; 3) Department of genetics, Hopital Mere-enfant, NANTES, FRANCE; 4) Department of genetics, Hopital NORD, AMIENS, FRANCE.

Osteopathia striata with cranial sclerosis (OS-CS) is a rare autosomal dominant multiple congenital anomaly syndrome including dysmorphic features with frontal bossing, hypertelorism, cleft palate, macrocephaly, hearing loss and mild mental retardation. The diagnosis is based on radiological findings namely longitudinal striations of long bones metaphyses and cranial sclerosis. Here we report on 10 OS-CS patients, including 2 sporadic and 4 familial cases. In each of the patients macrocephaly and typical craniofacial appearance were present at birth, and radiographic survey confirmed the diagnosis. In addition to the classical findings, marked phenotypic variability was observed. In particular, 3 cases presented a cardiac anomaly (VSD, PDA or cardiomyopathy). Cerebral ventricular dilatation with normal pressure was noted in 3 cases, and hydrocephaly with coronal craniosynostosis required surgical treatment in one patient. Corpus callosum hypoplasia, Pierre Robin sequence, hearing deficiency, irregular teeth and scoliosis were noted in 2/10 patients. One patient presented with Hirschsprung disease, which has never reported in the syndrome thus far. Psychomotor development was retarded in 7/10 cases. Finally, chromosome analysis could be performed in 6/10 cases and was normal. Our series suggests both inter- and intra-familial variable expression of OS-CS. Although severe motor retardation could be observed during the first years of life, long term follow-up showed a significant improvement. Interestingly, we found a marked skewed sex ratio with high excess of affected females (9F/1H), suggesting that OS-CS might behave as a dominant X-linked trait with male lethality, especially as the only male patient was severely affected with cardiomyopathy, corpus callosum hypoplasia, Hirschsprung disease and mental retardation.

Program Nr: 1964 from the 1999 ASHG Annual Meeting

Kaposiform hemangioendothelioma and cerebral cortical dysplasia in a newborn with Prader-Willi syndrome caused by maternal UPD 15. *J. Wagstaff, H. Kozakewich, J.B. Mulliken, B.-L. Wu, V. Lip, A. Duplessis.* Children's Hospital, Boston, MA.

Maternal UPD 15 causes approximately 30% of cases of Prader-Willi syndrome, as a result of lack of an active paternal copy of one or more imprinted genes from 15q11-q13. A female infant was born to a 41-year-old mother after a pregnancy complicated by decreased fetal movements. At birth, the infant had a massively enlarged left thigh, marked hypotonia, and profound thrombocytopenia. Biopsy of the thigh mass showed kaposiform hemangioendothelioma; the tumor was treated with interferon alpha-2b for 10 months, with resolution of the tumor and thrombocytopenia. Karyotype was 46,XX on amniotic fluid, peripheral blood, and the hemangioendothelioma. Brain MRI showed focal areas of thickened cortex within the left precentral gyrus, right frontal lobe, and posterior right parietal lobe. Methylation analysis with PW71B showed a maternal-only pattern, and polymorphism analysis showed maternal UPD 15. The findings of a rare vascular tumor and cerebral cortical dysplasia in a child with Prader-Willi due to maternal UPD 15 have not been reported previously. Possible explanations for these associated findings include homozygosity for recessive alleles on chromosome 15, trisomy 15 mosaicism, or a cryptic chromosomal anomaly (e.g., translocation) associated with loss of the paternal chromosome 15 during early development.

Program Nr: 1965 from the 1999 ASHG Annual Meeting

The evolving clinical phenotype of Rothmund-Thomson Syndrome. *L.L. Wang[1], M.L. Levy[1], R.A. Lewis[1], M.M. Chintagumpala[1], L.R. Carlson[2], C.M. Cunniff[3], S.C. Elliott[2], M. Frydman[4], S.E. Iden[3], D.M. Koeller[5], S.E. Plon[1], D. Lev[6], M. Rogers[7], S.P. Yang[8]*. 1) Baylor College of Medicine, Houston, TX; 2) Blank Children's Hospital, Des Moines, IA; 3) U. of Arizona HSC, Tucson, AZ; 4) Chaim Sheba Medical Center, Tel Hashomer, Israel; 5) U. of Colorado HSC, Denver, CO; 6) Wolfson Medical Center, Holon, Israel; 7) New Children's Hospital, Sydney, Australia; 8) UC Davis Medical Center, Davis, CA.

Rothmund-Thomson Syndrome (RTS) is a rare autosomal recessive genodermatosis characterized by a persistent rash that starts in infancy, small stature, skeletal abnormalities, sparse hair, bilateral juvenile cataracts, and predisposition to developing skin and bone cancers. RTS was first described by Rothmund (1868) in a large consanguinous Austrian kindred. His patients had rapidly progressive bilateral juvenile cataracts and a peculiar rash. Since then approximately 250 cases of RTS have been described in the English literature, 17 with osteosarcoma (OS) (~7%). As part of a study to determine the molecular basis of RTS we have identified a contemporary cohort of 23 patients with RTS (ages 2-35 years), ascertained by referral from dermatology, ophthalmology, genetics, and oncology. 8 patients have had OS, 3 have radial dysplasias, but none by family and/or physician report has developed cataracts or skin cancer. Concordance of OS in siblings from 2 families was observed. 2 cases of OS were multifocal. Of the 15 patients without OS, 12 are less than 15 years-old and thus remain at risk for developing this tumor. Ascertainment bias may influence the high rate of OS. However, 3 of 5 patients originally diagnosed with RTS as young children at Baylor have subsequently developed OS. The clinical profile of our patients, with a high rate of OS and low rate of cataracts, suggests a different phenotype from Rothmund's patients, and may reflect either allelic heterogeneity at the RECQL4 locus or genetic heterogeneity. These findings also suggest that consideration be given to screening for OS during adolescence as part of the clinical management of RTS.

Program Nr: 1966 from the 1999 ASHG Annual Meeting

Microcephalic osteodysplastic primordial dwarfism type I in the Amish. *J.A. Westman[1], E.H. Stover[1], C. Singley[2].*
1) Human Cancer Genetics Program, 519 James Cancer Hosp, Columbus, OH; 2) Children's Hospital, Columbus, OH.

Microcephalic osteodysplastic primordial dwarfism type I (OMIM #210710) is a rare syndrome characterized mainly by low birth-weight dwarfism, extreme microcephaly, a prominent nose and eyes, sparse scalp hair, a short neck, short limbs with dislocation of the elbows and hips, relatively broad hands and feet and dry hyperkeratotic skin. Less than 15 cases have been previously described in the world literature. We report four affected infants in two Ohio Amish families, providing further evidence for the autosomal recessive nature of the syndrome. The genetic and/or biochemical cause of the syndrome has not been established. Electron microscopy of skin fibroblasts from the most recently born child did not show any cytoplasmic inclusions which might indicate the presence of a storage disorder. All four parents of the two Amish families are related through multiple family lines. An eight to twelve generation pedigree analysis extending back to the initial Amish-American immigration limits the likely founder mutation to one or more of 8 families and assists in interpretation of future linkage analysis. Additional Amish families with affected children are being identified.

Program Nr: 1967 from the 1999 ASHG Annual Meeting

Genetic assessment of mentally retarded dysmorphic adults with primary psychiatric diagnoses. *M.S. Williams[1], C.L. Wood[2], A.C. Wendorff[3]*. 1) Dept Pediatrics, Gundersen Lutheran Medical Ctr, La Crosse, WI; 2) Dept Psychiatry, Gundersen Lutheran Medcical Ctr, La Crosse, WI; 3) Gundersen Lutheran Medical Foundation, La Crosse, WI.

We report the results of evaluations of 23 mentally retarded adults referred for suspected genetic disease. Patients ranged in age from 19 to 48 years. There were 12 males and 11 females. All had at least one primary psychiatric diagnosis. Impulse control disorder, NOS was the most common psychiatric diagnosis. Other common diagnoses included bipolar disorder, schizophrenia and dysthymia. Only seven patients had had a previous evaluation by a geneticist. Four had a specific genetic diagnosis, of which two were confirmed, one ruled out and one in which an additional (causative) diagnosis was added. Specific genetic diagnoses were made in five additional patients and suspected diagnoses in three others. Private or familial syndromes were suspected in five patients, although evaluation of other putatively affected individuals was not accomplished.

We will present clinical vignettes including pictures and diagnostic modalities employed to arrive at specific diagnoses. The potential value of genetics evaluation in this patient population will be discussed.

Program Nr: 1968 from the 1999 ASHG Annual Meeting

Three patients with Autistic Disorder and isodicentric chromosome 15: Implications for genetic counseling. *C.M. Wolpert[1], M.M. Menold[1], M.P. Bass[1], M.C. Qumsiyeh[2], S.L. Donnelly[1], S.A. Ravan[3], R.K. Abramson[3], H.H. Wright[3], L.O. Maddox[1], J.M. Vance[1], J.R. Gilbert[1], M.L. Cuccaro[3], M.A. Pericak-Vance[1]*. 1) Dept Medicine, Duke Univ Medical Ctr, Durham, NC; 2) Dept Pathology, Duke Univ Medical Ctr, Durham, NC; 3) W.S. Hall Psychiatric Institute, Univ of South Carolina, Columbia, SC.

Isodicentric chromosome 15 anomalies encountered in clinical practice can be problematic when providing phenotypic information due to wide variation in clinical presentations of these patients. This includes recent research findings implicating the proximal 15q region in the genetics of Autistic Disorder (AD). This evidence includes 1) proximal 15q anomalies are the most frequently reported cytogenetic anomalies in AD patients; 2) several genetic-mediated, developmental disorders that can include autistic-like behaviors map to this region, including Prader Willi Syndrome and Angelman Syndrome; 3) Genomic-wide linkage screens identified 15q11-13 as a candidate region housing potential AD susceptibility genes; 4) linkage disequilibrium with AD has been reported in this region. We hypothesize those individuals with AD and an isodicentric chromosome 15, encompassing the 15q11.2 region, will share physical and developmental findings. Three unrelated patients were identified through family ascertainment efforts for a gene identification study for AD. All three patients met DSM-IV/ICD-10 diagnostic criteria for AD, confirmed by the Autism Diagnostic Interview, and had neurological examinations. Cytogenetic analysis revealed the following karyotypes: 47XX, idic (15q11.2), 47XX, idic (15q11.2), and 47XY, idic (15q11.2). Comparison of these 3 patients with published case reports (N=17) reveals a clustering of physical and developmental features. Specifically, all patients exhibited hypotonia, seizures, and delayed gross motor skills. All three of our patients and a majority of patients in the literature exhibited speech delay, lack of social reciprocity, abnormal eye contact, and stereotyped behaviors. This data may provide more detailed information for families of individuals with both AD and isodicentric 15q anomalies.

Program Nr: 1969 from the 1999 ASHG Annual Meeting

Hirschsprung-like aganglionosis of the colon in patients with nail patella syndrome: Extension of the NPS phenotype to a fourth organ system. *M.J. Wright, I. McIntosh.* Greenberg Center for Skeletal Dysplasias & Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Nail patella syndrome (NPS) is a pleiotropic condition characterized by dysplasia of the nails, hypoplasia of the patellae, elbow dysplasia and progressive kidney disease. In addition, open-angle glaucoma has recently been shown to be part of the phenotype. The syndrome is inherited in an autosomal dominant manner and has been shown to result from mutations in the LIM-homeodomain encoding LMX1B gene. A number of individuals affected with NPS describe symptoms of severe constipation, often from birth, and often requiring medication. A proportion of these had been diagnosed with megacolon. Together these findings are suggestive of short-segment Hirschsprung disease. One 16 year old male with a history of constipation from birth, with failure to pass meconium until 2 weeks of age, presented with recurring fecal impaction. Barium enema demonstrated enlargement of the rectum and left colon consistent with the diagnosis of secondary megacolon. Transmural rectal biopsy performed at analrectal strip myomectomy showed aganglionosis and fibrosis of the muscularis propria confirming the diagnosis of aganglionic megacolon. Anecdotal evidence would suggest that aganglionic megacolon may be as common and as clinically significant among patients with NPS as kidney disease or glaucoma. Of interest, it has recently been shown that the *C. elegans* ortholog of LMX1B, *lim-6*, regulates the outgrowth and differentiation of neurons controlling rhythmic enteric muscle contractions. *lim-6* mutant animals exhibit a bloated gut and defective defecation behavior. In conclusion, we suggest that assessment of individuals with NPS should include direct questioning regarding symptoms of constipation to allow definitive diagnosis of this treatable complication.

Program Nr: 1970 from the 1999 ASHG Annual Meeting

Benign familial infantile spasms syndrome (BFISS) with autosomal dominant inheritance. *K. Yasuda[1], K. Fujii[1], J-i. Takanashi[1], T. Fukuda[2], K. Obata[2], H. Yamagata[2], Y. Kohno[1], I. Kondo[2].* 1) Dept. of Pediatrics, Shcool of Med., Chiba Univ., Chiba 260-8670, Japan; 2) Dept. Hygiene, Ehime Univ. School of Med., Ehime 791-0295, Japan.

West syndrome (WS) is an age-related epileptic syndrome of infancy and the classical triad of the WS are 1) infantile spasms (IS), 2) electroencephalogram (EEG) pattern of hypsarrythmia, and 3) mental retardation. Prognosis is generally considered to be poor and seizures often persist. Some patients with the WS, however, recover completely and have a normal intellectual outcome. The WS is etiologically heterogeneous. Although most patients with WS are sporadic, a possible hereditary predisposition has been considered. Recently, the disease locus of an X-linked IS (WS) has been mapped to Xp21.3-p22.1. We report a family of 5 affected individuals (two males and three females) with IS in two generations. All affected members first had epileptic attacks between the ages of 3 and 4 months. Hypsarrhysmia was detected in EEG findings, but affected members recovered completely after adrenocorticotropichormone (ACTH) therapy and have a normal neurodevelopmental status. Male twins in the family had the same clinical characteristics. All patients had no cutaneous and focal neurological abnormality. Laboratory findings were normal and the magnetic resonance imaging (MRI) scan showed no underlying neurologic disorder. Clinical prognosis and mode of inheritance in our family differ from those of the X-linked IS. Our family suggests a new infantile spasms syndrome with an autosomal dominant inheritance, a benign familial infantile spasms syndrome (BFISS).

Program Nr: 1971 from the 1999 ASHG Annual Meeting

***De novo* t(3;4)(q21;q31) translocation in an infant with spinal muscular atrophy type I (Werdnig-Hoffmann disease) and no deletion of SMN1.** *A. Zankl, M.-Cl. Addor, D.F. Schorderet.* Division of Medical Genetics, CHUV, Lausanne, Switzerland.

Spinal muscular atrophy (SMA) is the second most common lethal, autosomal recessive disease in Caucasians after cystic fibrosis. The disorder is characterized by degeneration of the anterior horn cells of the spinal cord, leading to symmetrical weakness and wasting of muscles. Three types can be distinguished: type I (Werdnig-Hoffmann disease) is a severe form with onset of symptoms in the first 6 months of life and death due to respiratory failure usually occuring within 2 years; type II is an intermediate form; type III (Kugelberg-Welander disease) takes a more benign course with onset of symptoms in late childhood and slow progression. All three types have been mapped to 5q11.2-13.3 and seem to be caused by alterations in the SMN1 gene. Up to 98.6% of patients with SMA show homozygous deletion of exon 7 (Lefebvre et al., 1995). In most of the remaining cases other mutations of SMN1 have been identified. However, Wirth and coworkers (1999) found no deletion or mutation of SMN1 in 14 of 525 SMA patients, suggesting the existence of SMN-unlinked SMA.

We report on an infant who was investigated for hypotonia and muscle weakness and died at 10 months of age from respiratory failure. He was diagnosed clinically as having Werdnig-Hoffmann disease fulfilling the inclusion and none of the exclusion criterias for SMA set forth by the International SMA Consortium in 1992. No deletion of exons 7 or 8 of SMN1 could be detected in this patient. However, his karyotype revealed an apparently balanced t(3;4)(q21;q31) translocation. Karyotypes of the parents were normal, indicating a *de novo* event. To our knowledge, this is the first report of a patient with SMN-undeleted Werdnig-Hoffmann disease and a chromosomal aberration. We conclude that genes in 3q21 or 4q31 might play a role in the development of spinal muscular atrophy. Molecular characterization of the chromsome breakpoints observed in our patient will allow a better understanding of the gene(s) involved in SMA.

Program Nr: 1972 from the 1999 ASHG Annual Meeting

A syndrome with autosomal recessive polycystic kidneys with skeletal and facial anomalies is not linked to the ARPKD gene locus on chromosome 6p. *K. Zerres[1], N. Kohlschmidt[2], G. Muecher[1], C. Hallermann[2], P. Shahidi[2], B. Welleck[3], U. Theile[3], R. Schumacher[4], F. Bahlmann[5], S. Rudnik[1], H. Muentefering[2]*. 1) Institute for Human Genetics, Technical University of Aachen, Germany; 2) Department of Pediatric Pathology, University of Mainz, Germany; 3) Genetic Counseling Unit, Mainz, Germany; 4) Department of Pediatric Radiology,University of Mainz, Germany; 5) Department of Gynecology, University of Mainz, Germany.

We report on two siblings, one male born at 37 weeks and one male fetus of 24 weeks of gestation, both with a syndrome similar to that seen in three sets of siblings by Gillessen-Kaesbach et al. (Am J Med Genet 45:511-518, 1993). Both proposity had polycystic kidneys and hepatic fibrosis indistinguishable from autosomal recessive polycystic kidney disease (ARPKD), plus skeletal malformations and facial anomalies. Skeletal abnormalities included butterfly vertebrae, square shape of the pelvis and brachymelia. The facial anomalies included hypertelorism, epicanthic folds, and anteverted nares. Additional external findings were low set ears and short neck. Histopathological examination of the kidneys of the neonate showed radial orientation and cystic dilatation of the cortical and medullar tubules. The liver showed "congenital hepatic fibrosis". The hepatic findings in the fetus were less severe. Renal abnormalities were limited to focal tubular cystic changes. Linkage analysis with polymorphic markers of the region 6p21.1-p12, flanking the gene locus of ARPKD, showed different haplotypes in both siblings, thus excluding the ARPKD gene locus in this family and indicating genetic heterogeneity.

Program Nr: 1973 from the 1999 ASHG Annual Meeting

Telomeric Translocations with Abnormal Phenotypes. *C.B. Lozzio, E. Bamberger, T. Ryan, E. Holland, C. Worthington, I. Anderson.* Develop & Genetic Ctr, Med Ctr, Univ Tennessee, Knoxville, TN.

Translocations involving the telomeric regions 7q and 11p were observed in cases with apparently balanced karyotypes and abnormal phenotypes. Two cases had de novo rearrangements including the tel 7q and one was an inherited translocation with normal phenotype in the mother and abnormal phenotype in two fetuses who had inherited the same apparently balanced translocation involving the telomeric region 11p15.5. The two cases with the de novo rearrangements of the tel 7q included , one with a complex rearrangement and one with a reciprocal translocation. The complex rearrangement had four breaks, at bands 7q32, 7q35, 2p12 and 2q31. Cytogenetic studies at band level 800 and FISH studies with wcp 2 and wcp 7 showed the translocation of the region 2p12®2ptr to band 7q32 in the derivative chromosome 7 and an insertion of the region 7q32-q35 to 2q31 in the derivative chromosome 2. Only the FISH studies with the telomeric probe 7q showed the translocation of tel 7q to band 2p12 in the derivative chromosome 2. This rearrangement was observed in a 15 month old girl with infantile spasm, severe developmental delay, marked hypotonia, microbrachycephaly and mild dysmorphic features. Another de novo translocation t(7;8)(q36.3;q22.3) was found in a child with cleft lip and palate, hypodontia, microcephaly, malrotation of the intestines and complex partial seizures. The translocation of tel7q to the derivative chromosome 8 was only found with the tel 7q probe and not with wcp 7 and wcp 8. An inherited translocation t(4;11)(q23;p15.3) was found in an amniocentesis of a fetus with omphalocele. The normal mother was a balanced carrier of the translocation and she had a previous fetus who died at 25 weeks with omphalocele. FISH studies with the tel 11p probe showed that the 11p15.5 region containing the genes for Beckwith Wiedemann Syndrome (BWS) was translocated to the derivative chromosome 4. The possibility that maternal imprinting of the BWS could explain the two fetuses with omphalocele will be considered. The implications of position effect and/or molecular deletions and/or duplications causing abnormal phenotypes will be discussed.

Program Nr: 1974 from the 1999 ASHG Annual Meeting

An abnormal fetus with trisomy 20 and trisomy 9 mosaicism. *J.K. Lundberg, M.G. Bialer, A. Yenamandra, L. Trinchitella, E.. Schneider, R. Perrone, X. Zhou, E. Kahn, P. Koduru.* Dept. of Pediatrics, Laboratory and OB/GYN, North Shore Univ. Hospital/NYU School of Medicine, Manhasset, NY.

A 39 year old Saudi Arabian/Asian Indian woman was seen for genetic counseling for advanced maternal age and consanguinity (1st and 2nd cousins). Family history was significant for a son with pulmonic stenosis. Screening revealed that she is an a-thalassemia carrier. At 15 3/7 wk a comprehensive ultrasound revealed bilateral cerebral ventriculomegaly, dilated cisterna magna, bilateral cystic lesions in the anterolateral neck, and pleural effusion. On amniocentesis, AF-AFP was normal, but chromosome analysis of 20 metaphases from in-situ cultures of the amniotic fluid showed 47,XY,+20. Because this is usually a mosaic finding, we counted additional cells. Of 56 total cells counted, 50 were 47,XY,+20 and 6 were 47,XY,+9. No normal cells or double trisomy cells were seen. Pregnancy was terminated by Prostin induction at 18 wk. Post-mortem examination revealed cystic hygroma, low-set ears, micrognathia, truncus arteriosus, VSD, left diaphragmatic hernia, and hypoplastic left lung. Microscopic examination of the skin revealed lymphangiectasia. Chromosome analysis of 20 metaphases each of cells cultured from placenta, umbilical cord, heart, blood, skin, lung, liver, right and left kidney (total of 160 metaphases) all showed a combination of trisomy 9 and trisomy 20 cells with no normal or double trisomy cells, except lung had only trisomy 20 cells. The clinical findings are consistent with trisomy 9. Trisomy 20 mosaicism is usually benign and not confirmed in blood. Trisomy 20 cells in blood may have phenotypic consequences, but this has not been proven. It is not clear how these chromosome anomalies arose. If there had been 2 separate non-disjunction events, there should be a normal cell line. If the pregnancy had started with a single trisomy and a second non-disjunction occurred, with subsequent loss of one of the original trisomic chromosomes, then a cell line with double trisomy should exist. If both trisomies were the result of an autosomal recessive condition predisposing to karyotypic instability, then additional abnormal cell lines would be expected.

Program Nr: 1975 from the 1999 ASHG Annual Meeting

Varations of the heterochromatic segment of non-fluorescent Y-chromosome [Yq^{nf}] as revealed by FISH-technique. *M.J. Macera[1], R.S. Verma[1], N. Merhi[2], H. Wehbeh[2].* 1) Wyckoff Heights Medical Center, Brooklyn, NY. Institute of Molecular Biology and Genetics at InterScience, SUNY Health Science Center at Brooklyn, NY; 2) Luthern Medical Center, Brooklyn, NY.

The major variation of the long arm of human chromosome Y is accounted for by the heterochromatic segment that fluoresces brightly by quinacrine. This variation was established immediately after the advent of the QFQ-banding technique. Later, the variation of the non-fluorescent segment was also noted [Verma et al. J Med Genet 15:277-281, 1978]. Earlier, we reported a prenatal case that has a non-fluorescent Y by QFQ-staining, however, using the FISH technique with the Y-cocktail probe [DYZ1/DYZ3](Oncor), which is specific for satelite III and alpha satellite heterochromatin, a small amount of satellite III DNA was detected in both fetal Y and the father showing that the Yq^{nf} chromosome had heterochromatin [Silverman et al Genet Med 1:70; 1999]. Recently, we were referred another case for genetic amniocentesis that had a Yq^{nf}, by QFQ, in amniocytes. The biological father also posseses the Yq^{nf} chromosome by QFQ staining. However, when FISH was employed with the Y-cocktail probe, no signals were observed at the DZ1 location, suggesting another variation identified by the FISH technique. The second Yq^{nf} is obviously different from the first one. The satellite III sequences are completely absent, or more likely, the number of satellite III sequences present is below the detection level of the probe. The mothers in both cases experienced one fetal loss. These two Yq^{nf}'s were discovered from approximately 1000 cases evaluated prenatally. Their clinical significance is unknown but may serve as phylogenetic markers for those who are in search of family lineage using the Y-chromosome for haplotyping.

Program Nr: 1976 from the 1999 ASHG Annual Meeting

Characteristics of two cases of DUP(15)(Q11.2-Q12). *R. Mao[1], S.M. Jalal[1], K. Snow[1], V.V. Michels[1], S.M. Szabo[2], D. Babovic-Vuksanovic[1]*. 1) Mayo Clinic, Rochester, MN; 2) LaSalle Clinic, Oshkosh, WI.

We describe the clinical, cytogenetic, and molecular findings of interstitial duplication of 15q11.2-q12 in two unrelated patients. By high resolution chromosome analysis patient one was normal and duplication was suspected in patient two. The duplication was established in both patients by metaphase FISH using two critical region (SNRP-N and D15S10) probes and their control probes. The parents of patient one were normal by FISH analysis but the parents of patient two were unavailable. Southern blot analysis based on parent of origin specific DNA methylation at D15S63 (PW71) locus detected a difference of intensity of methylated and unmethylated fragments. The molecular pattern suggested a maternal origin of the duplication in patient one and a paternal origin in patient two. Patient one (2 years old) had developmental and speech delay with pervasive developmental disorder or mild autism, strabismus, and normal growth parameters with seizures. Patient two (16 years old) had global developmental delay, verbal I.Q. of 94, depression, obesity, food-seeking behavior, and significant behavioral problems that included self-injurious tendencies. Neither patient had significant dysmorphic features or abnormalities of internal organs. It has been suggested that patients with duplication in the PWS/AS critical region of maternal origin tend to have milder features of Angelman syndrome and those of paternal origin may have milder features of Prader-Willi syndrome, although this has not always been true. Our two cases suggest that some patients with 15q11.2q12 duplication may have significant anomalies, and there appears to be phenotypic differences between maternal and paternal transmission of the anomaly. Role of imprinted loci and gene dosage in these duplications remains speculative.

Program Nr: 1977 from the 1999 ASHG Annual Meeting

Two unrelated cases of (2q;12q) balanced translocation sharing abnormal features and learning disability. *K. Marks[1], L. Telvi[2], A.M. Ion[2], J.C. Carel[3], J.L. Chaussain[3], M.A. Patton[1].* 1) Medical Genetics, St George's Hospital, London, United Kingdom; 2) Genetics Department, St Vincent de Paul Hospital, Paris, France; 3) Paediatric Endocrinology, St Vincent de Paul Hospital, Paris, France.

We report two unrelared cases presenting with a balanced translocation involving the chromosomal band 12q15: 46,XY,t(2;12)(q22;q15) and 46,XX,t(2;12)(q32;q15),inv(6)(p21.1;p23) respectively. Common features in both patients included feeding problems in early childhood, short stature, moderate learning difficulties, cubitus valgus, squint, short and prominent filtrum, full lips, high arched palate and micrognatia. Chromosomal rearrangements occured de novo (normal parents' karyotype), and detailed cytogenetic analysis, including high resolution chromosomes and FISH techniques showed that no other chromosome was involved in either of the balanced translocations. Since a common break-point was found on the chromosome 12 but not on the chromosome 2, common features in the two patients may be due to an abnormal gene functioning at 12q15. Both patients had been referred for Noonan syndrome, but this could not be clinically confirmed due to the lack of full diagnostic criteria, such as heart abnormalities. However, suggestive features for this disorder were present in both cases. This condition has been previously mapped at 12q24.1, but a number of familial cases do not appear to be linked to this locus, suggesting a degree of heterogeneity or a more complex aetiology. The cytogenetic and molecular DNA analysis of the present reported cases, suggest the possibility of a second locus involved in Noonan syndrome.

Program Nr: 1978 from the 1999 ASHG Annual Meeting

Partial trisomy 9 due to 3:1 segregation of a maternal 9;14 translocation. *S.L. Marles[1,3], T. Sudha[3], J. De Nanassy[4], D.E. Wickstrom[2], D. Konkin[2], A.J. Dawson[1,2,3].* 1) Section of Genetics and Metabolism, HSC, Winnipeg, MB, Canada; 2) Cytogenetics Laboratory, HSC, Winnipeg, Manitoba, Canada; 3) Dept. Human Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 4) Dept. Pathology, HSC, Winnipeg, Manitoba, Canada.

Tertiary trisomy is uncommon and generally occurs when the derivative chromosome is of small genetic content. Partial trisomy 9 has been reported previoulsy with the most common clinical abnormalities including microcephaly, skeletal anomalies, hand abnormalities, malformed ears, a "bulbous" nose, and nail hypoplasia. We report a 29 yr old G3P1SA1 woman who was referred for amniocentesis because of a positive triple screen test in which the risk for trisomy 18 was 1/30. Cytogenetic analysis showed an unbalanced female karyotype in the fetus with an apparent terminal deletion of the long arm of chromosome 9: 47,XX,+del(9)(q22). The pregnancy was terminated at 22+ weeks gestation. Autopsy revealed facial, skeletal, and brain anomalies consistent with previous reports of partial trisomy 9. These anomalies included low set ears, micrognathia, a broad and bulbous nose with a prominent nasal bridge, aplasia of the distal phalynx of the right second toe, absence of the twelfth rib and under mineralization of the cervical vertebrae. Brain anomalies included large anterior and posterior fontanelles and wide sutures. There was no significant family history. Cytogenetic analysis of the mother showed a female karyotype with a balanced translocation between the long arms of chromosomes 9 and 14: 46,XX,t(9;14)(q22;q32). The chromosome anomaly in the fetus was the result of a 3:1 segregation of the maternal 9;14 translocation. The fetal karyotype was amended to: 47,XX,+der(9)t(9;14)(q22;q32)mat. The fetus did not show any clinical features which might be associated with duplication of the distal segment of 14q, suggesting that distal 14q does not contribute significantly to the phenotype. The charateristics associated with the meiotic configuration of the 9;14 translocation suggest that more than one type of malsegregation may be possible. This implies an atypically higher recurrence risk for a liveborn aneuploid child.

Program Nr: 1979 from the 1999 ASHG Annual Meeting

Molecular cytogenetic characterization of an unbalanced t(4p;21q) in a patient misdiagnosed as Full Monosomy 21. *L. Martelli[1,2], E.S. Ramos[2], C.G.C Lemos[1], V.M. Motta[1], S.A. Santos[2], T.A. Bernardes[1], A.C.C. Nassr[1], J.R. Coelho[1], J.E. Chufalo[1], S. Almeida[1], J.G. Franco Jr.[1].* 1) Division of Genetics,Sinha Junqueira Maternity Foundation,Ribeirao Preto,SP,Brazil; 2) Dept.Genetics, School of Medicine of Ribeirao Preto - University of Sao Paulo, Brazil.

Monosomy 21 is a rare aneuploid condition, generally considered to be incompatible with life. According to the literature, most of the reported cases may represent structural rearrangements resulting in only partial monosomy 21. The proband is the first child of non-consanguineous parents and was delivered at 31 weeks of gestation with a birth weight of 495g. Physical examination showed a peculiar facies, hypertelorism, high forehead with furrowing in central forehead, posterior midline scalp defects, cleft lip and palate, micrognathia, cardiac anomaly, simian crease, clubfeet and dorsiflexed hallus. He survived for 36 hours. Conventional cytogenetic analysis of peripheral blood lymphocytes revealed a 45,XY,-21 karyotype in 150 metaphases. Re-evaluation combining high resolution GTG banding and FISH analysis showed an unbalanced translocation characterized by 45,XY,-21,der(4)t(4;21)(p15.2;q21.1). The derivative chromosome presented the Down syndrome critical region (21q22.13-q22.2) and deletion of the region 4p16.3, justifying the clinical manifestations of the Wolf-Hirschhorn syndrome.We concluded that the patient presented a partial monosomy on both 4p and 21. The parental karyotypes including FISH studies were normal. Our findings confirm the need for complementary molecular cytogenetic investigations in cases of apparent monosomy 21.

Program Nr: 1980 from the 1999 ASHG Annual Meeting

Limitations of FISH analysis for prenatal diagnosis of chromosomal aneuploidies. *M.M. McCorquodale[1], J.K.B. Matheson[2], F.E. Tahmaz[3], T. Nguyen[2], M. Freidine[3].* 1) Michael Reese Hosp & Med Ctr, Chicago, IL; 2) Dept Ob/Gyn, Univ of Illinois, Chicago, IL; 3) Dept Peds, Univ of Illinois, Chicago, IL.

Following the FDA approval of the use of FISH probes, our laboratory has received a number of requests for prenatal diagnosis using the FISH technique without concurrent cytogenetic analysis. We recently experienced a case of a 29 year-old female referred at 26 weeks of gestation due to the detection of multiple congenital abnormalities by ultrasound. FISH analysis revealed no chromosomal aneuploidy for the sex chromosomes or for chromosomes 13, 18, and 21. Cytogenetic analysis, however, revealed the presence of an isochromosome 18q. The pregnancy was terminated and a detailed autopsy was performed. This case demonstrates that isochromosomes, cannot be detected by FISH using alpha satellite probes. FISH analysis should always be accompanied by concurrent karyotype analysis.

Program Nr: 1981 from the 1999 ASHG Annual Meeting

A candidate region for Coffin Siris - Syndrome at 7q32-34. *E.M. McGhee[1,2], C. Klump[2], S. Bitts[2], P.D. Cotter[1,2], E.J. Lammer[1]*. 1) Pediatrics - Medical Genetics, Univ California, San Francisco, San Francisco, CA; 2) Medical Genetics - Children Hospital, Oakland, CA.

Coffin - Siris syndrome is an autosomal dominant disorder characterized by mild to severe mental retardation and clinodactyly (5th digit). Other symptoms include intrauterine growth retardation and post-natal short stature, developmental delays and difficulties with feeding. We report a case of Coffin Siris syndrome in an 11-year-old Caucasian female with a de novo apparently balanced translocation of chromosome 7 and 22 [t (7;22)(q32;q11.2)] identified by GTG-banding. In addition to our case, there is one other reported case of Coffin - Siris syndrome with a de novo apparently balanced translocation involving chromosome 7q34. Since the breakpoints for both cases are similar this suggests a region location and possibly a candidate region for the Coffin- Siris gene. In the breakpoint region (7q32-34) seen in the two patients, there are several candidate genes: calumenin, podocalyxin-like, prolactin-inducible protein, and eph tyrosine kinase 1, for which no syndrome has yet been associated. Identification of a breakpoint location (7q32) strongly suggest a gene region for the Coffin Siris syndrome.

Program Nr: 1982 from the 1999 ASHG Annual Meeting

Proximal deletion of chromosome 14q. *L. Mehta[1], C. Cervantes[2], K. Small[1], A. Yenamandra[3], P. Koduru[3].* 1) Div. Medical Genetics; 2) Div. Pediatric Endocrinology, Dept. of Pediatrics; 3) Dept. of Laboratories, North Shore Univ. Hospital-N.Y.U School of Medicine, Manhasset, N.Y.

Interstitial deletions of chromosome 14q are rare and are of interest because of the possibility of imprinted genes in this region. We report a patient with deletion 14q13.2-q21.2. The patient was a full term, male infant with birth weight 8.5 lb. He developed severe respiratory distress after birth, eventually resulting in bronchopulmonary dysplasia. He was diagnosed to have congenital hypothyroidism and required progressively increasing thyroid hormone replacement for persistent TSH elevation, despite normalization of thyroxine levels. At 19 months, weight was 10%, height 25% and head size 10%. Motor development was mildly delayed with generalized hypotonia. He had a long face, frontal bossing, downslanting palpebral fissures, high palate and oral hypotonia. Hands and feet were relatively large. No heart defects were present and brain MRI was normal. Karyotype was 46,XY,del(14)(q13.2q21.2).The chromosome analysis was prompted by a case report of chromosome 14q deletion in a child with respiratory and thyroid abnormalities with mild developmental delays (Devrjendt,1998). Proximal 14q deletions are reported to have non-specific dysmorphic features, hypotonia and motor delays. Thyrotrophin abnormalities are described in 2 patients and neonatal respiratory distress in one patient. The latter patient was found to be deleted for PAX9 and TTF-1 (thyroid transcription factor-1) on the paternal chromosome by FISH (Devrjendt,1998). TTF-1 is expressed in embryonic forebrain, lung and thyroid epithelium and regulates production of surfactant B in the lung (Ikeda,1995). Deficiency of TTF-1 could therefore explain both thyroid and respiratory disease. Of note are 3 patients also with similar deletions of 14q13-q21 who had major brain malformations (cebocephaly/holoprosencephaly). These differing phenotypes may be a result of varying extent of deletions or variable expression of deleted genes; however, it would be important to consider parent of origin effects if imprinted genes are present in this deleted segment.

Program Nr: 1983 from the 1999 ASHG Annual Meeting

FISH screening for microdeletions of DMRT1 in 46,XY sex reversed individuals. *A.M. Mengelt[1], C.S. Raymond[2], L.G. Brown[3], D.C. Page[3,4], D. Zarkower[2,5], B. Hirsch[1]*. 1) Department of Laboratory Medicine and Pathology, University of Minnesota Medical School, Minneapolis, MN; 2) Biochemistry, Molecular Biology and Biophysics Graduate Program, University of Minnesota, Minneapolis, MN; 3) HHMI, Whitehead Institute for Biomedical Research, Cambridge, MA; 4) Department of Biology, Massachusetts Institute of Technology, Cambridge, MA; 5) Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN.

Sex reversal is a complex and genetically heterogeneous condition, the etiology of which is unknown in many cases. The role of SRY as a transcription factor and the identification of sex reversed individuals with an apparently intact SRY gene has lead investigators to identify other loci involved in sex reversal. Several X-linked and autosomal loci have been implicated in 46,XY male to female sex reversal, including the distal short arm of chromosome 9, specifically band 9p24.3. Recently, a candidate gene, DMRT1, with homology to the sexual regulatory genes *mab-3* of *C.elegans* and *doublesex* of *Drosophila* was mapped to 9p24.3.

To determine whether microdeletion of DMRT1 is a common mechanism leading to sex reversal, lymphoblastoid cell lines from 27 46,XY individuals with varying degrees of sex reversal were evaluated by FISH with a DMRT1 probe. All cell lines were previously tested for the presence of SRY by PCR, and most were sequenced for mutations in the HMG box domain of SRY.

No deletion of DMRT1 was identified. In a recent study of a larger cohort of such sex reversed individuals, no point mutations of DMRT1 were identified (Raymond et al., 1999). The results of these studies demonstrate that neither deletions encompassing DMRT1 nor point mutations within the coding region of DMRT1 are a common cause of 46,XY sex reversal. Ongoing studies include Southern blot analysis to rule out smaller deletions within DMRT1 that would not have been detected by FISH.

Program Nr: 1984 from the 1999 ASHG Annual Meeting

Cytogenetic internet based external quality assessment pilot study . *J.H. Miyazaki[1], P.R. Wyatt[2], V.M. Lopes[2]*. 1) Laboratory Proficiency Testing Program (LPTP), Toronto, ON, Canada; 2) North York General Hospital, Toronto, ON, Canada.

CytoNet is a Web server for CytoVision users that is within the custody of and administered by Applied Imaging Corporation. This service allows access to cytogenetic digital images for review and interpretation. For twenty-five years, LPTP has provided an annual series of test challenges to evaluate technical and professional proficiency in cytogenetics. Enhancements of the testing model are continually pursued. *Objective: The Laboratory Proficiency Testing Program (LPTP) was to evaluate CytoNet, an Internet enabled case transfer system as to facilitate an external quality assessment program for cytogenetic laboratories. *Study Design: In December 1997, invitations for the pilot study were sent out to the LPTP participants. Four 1998 LPTP surveys were included in the study. Laboratories followed routine procedures to complete each survey. In addition to submitting to LPTP a paper copy of the metaphase(s) and karyotype(s), a digital copy was sent via the Internet using the Applied Imaging CytoNet. Both the paper and digital version of the images were evaluated at LPTP. *Results: Three laboratories submitted their entire case files for the four LPTP surveys. Transmission of all images was successful. The electronic files identified the slides, cells examined and the respective images (metaphase N=120; composite N=16; karyotype N=33 and probe N=13). The paper copy of the images was compared to those submitted by CytoNet. Upon evaluation, minor variation was noted as some of the digital images were deemed to be clearer in resolution than the paper copy. *Conclusion: The use of Internet access to cytogenetic digital images may permit the development of alternate evaluation modalities and a more standardized international external quality assessment system for cytogenetics.

Prenatal diagnosis of GREIG syndrome in a fetus with a de novo translocation t(5;7)(p15;p13). *N. Morichon-Delvallez[1], P. Gosset[1], A.L. Delezoide[1], S. Chemouny[2], S. Loison[1], S. Fert-Ferrer[1], C. Ozilou[1], Y. Dumez[2], M. Vekemans[1], S.P. Romana[1]*. 1) Department of Genetics, Hopital Necker-Enfants Malades, Paris, France; 2) Prenatal Diagnosis Center, Hopital Necker-Enfants Malades, Paris, France.

A 27 years old woman was referred at 27 weeks of pregnancy for amniocentesis because ultrasound examination revealed several anomalies including hydramnios, moderate ventriculomegaly, bilateral syndactyly of the hands and bilateral polydactyly of the feet. Cytogenetic study on amniotic fluid cells in culture showed a de novo apparently balanced translocation t(5;7)(p15;p13). After genetic counselling, the pregnancy was interrupted. Fetopathological examination was carried out and showed the presence of high forehead, postaxial polysyndactyly, moderate ventricular dilatation, abnormal hyppocampus and moderately hypertrophic temporal lobes. The diagnosis of Greig cephalopolysyndactyly syndrome was suggested. A FISH study with a GLI3 probe showed a deletion of the GLI3 locus and confirmed the diagnosis of GREIG syndrome. Firstly this case hightlights the importance of detailed ultrasound examination on cases where an apparently balanced translocation is discovered during prenatal diagnosis. Secondly it shows the importance of FISH studies with locus specific probe to detect breakpoints cryptic deletion associated with de novo chromosome rearrangments.

Program Nr: 1986 from the 1999 ASHG Annual Meeting

Hereditary neuropathy with liability to pressure palsies: two cases with a reciprocal translocation t(16;17)(q12;p11.2) interrupting the *PMP22*gene. *M. Nadal[1], A. Valiente[2], A. Domenech[1], M. Pritchard[1], X. Estivill[1], M.A. Ramos-Arroyo[2]*. 1) Medical and Molecular Genetics, IRO, Barcelona, Spain; 2) Servicio de Genetica, Hospital Virgen del Camino, Pamplona, Spain.

Hereditary neuropathy with liability to pressure palsies (HNPP) or tomaculous neuropathy is an autosomal dominant disease that causes acute or recurrent transient muscle palsies and paresthesias, usually after minor trauma. HNPP is characterized from the pathological point of view by the presence of sausage-shaped swelling of the myelin sheath or tomacula in sensory and motor nerves. A large deletion on the proximal short arm of chromosome 17 was detected in affected members of HNPP. The deleted region is the same as that duplicated in Charcot-Marie-Tooth type 1 (CMT1A). The HNPP phenotype is due to monosomy of the same region in over 85% of cases. The *PMP22*gene spans aproximately 40 kb and contains four coding and two 5-untranslated (1A and 1B) exons. Five mutations in the *PMP22*gene have been described that result in a HNPP phenotype: two frameshift mutations, two nonsense mutations and a splite site mutation. We report here a pedigree with two affected members (mother and son) with HNPP, both of whom carry a reciprocal translocation t(16;17)(q12;p11.2), which we have studied by FISH. The breakpoint on chromosome 17 in both patients lies within exons 1a to 3 of the *PMP22*gene. This is the first case of HNPP being caused by a reciprocal translocation that interrupts the *PMP22*gene. Cytogenetic studies and FISH confirmed the diagnosis of the patient. The two cases presented here not only confirm that the HNPP phenotype was due to the interruption of the *PMP22*gene, but also show the variable penetrance of the phenotype in two related patients carrying the same mutation.

Program Nr: 1987 from the 1999 ASHG Annual Meeting

Unbalanced cryptic t(1q;12p) translocation in an apparently X-linked syndrome with pachygyria, mental retardation and hypogenitalism. *G. Neri[1], E. Rossi[2], C.A. Walsh[3], O. Zuffardi[2], M. Zollino[1]*. 1) Inst Di Genetica Medica, Univ Cattolica, Rome, Italy; 2) Istituto di Patologia Umana ed Ereditaria, Univ di Pavia, Pavia, Italy; 3) Dept of Neurology, Harvard Univ, Boston, MA.

We previously described a new XLMR syndrome with characteristic face, hypogenitalism, congenital hypotonia and pachygyria in 4 members (3 males and one female) of a large family. The trait "pachygyria" was detected in two male patients only, who also presented with a facial appearance typical of the a-talassemia/mental retardation (ATR-X) condition, whose gene, XH2, maps to Xq13.1. Four female carriers were normal, both clinically and neuroradiologically. By linkage analysis with 54 polymorphic X markers, no co-segregation of any allele was observed in all the patients, although a positive lod score (1.701, =0.01) was obtained with marker DXS6673E , mapping to Xq13.1, provided that the male patient without pachygyria was not included. If we consider, indeed, a full penetrance in males of the mutation, this patient should be affected by a different disorder. Mutational analysis of XH2 gene gave normal results. X-inactivation pattern was similarly random in the 4 normal carriers and in the only affected female. From all these clinical and molecular inconsistencies, an umbalanced cryptic translocation was inferred as cause of this condition. FISH analysis with subtelomeric probes, and then with chromosome specific "painting" probes, did show a cryptic t(1;12)(q44;p13.3) translocation:1) a partial 12p trisomy, in association with a partial 1q monosomy, was detected in both patients with pachygyria;2) a partial 1q trisomy, in association with a partial 12p monosomy, was detected in the last two patients without pachygyria. Prometaphase chromosomes were apparently normal, the translocated segments being very similar in size (about 10 Mb) and in banding pattern. These results suddenly make the genetic counseling proper, and the prenatal diagnosis undoubted. In addition, they identify two chromosome regions in which genes involved in cerebral cortical development are likely to reside.

Program Nr: 1988 from the 1999 ASHG Annual Meeting

A simple fluornucleotide coupling method for M-FISH analysis of patients associated with MR and Autism. *M.A. Nimmakayalu, O. Henegariu, P. Bray-Ward, D.C. Ward.* Dept Genetics, Yale Univ, New Haven, CT.

Although 1-2 % of the general population has MR/autism, only few genes responsible for these disorders have been identified to date. Karyotypic changes are detected by Giemsa banding in 10-20% of individuals with mild MR and 40% of those with severe MR and, among individuals with mild to moderate retardation and normal karyotypes, approximately 7.4% have cryptic telomere translocations detectable by LOH analysis. Therefore we began karyotyping a large population of patients with MR, autism and related disorders (currently >100) by two multi-color fluorescence in situ hybridization (M-FISH) techniques: karyotyping using pooled chromosome painting probes that were combinatorially labeled; and telomere analysis using combinatorially-labeled subtelomeric probes. The cost of such screening using commercially available fluor-labeled nucleotides has led us to explore several different methods for coupling fluors to nucleotides or DNA. First, probes were labeled with allylamine-dUTP (AAdUTP) and the DNAs were chemically coupled with N-hydroxysuccinimide esters (NHS) of various fluors or haptenes. However, this two-step labeling procedure was not sufficiently robust for routine work since highly charged fluors gave very weak signals. Next we developed a "non-chemist" approach to rapidly sythesize "semi-pure" dNTPs. AAdUTP is reacted in borate buffer with a NHS of a fluor or haptene. Each reaction was absorbed onto 1 ml of diethylaminoethylyl cellulose (DEAE-52), washed with 0.1 M triethylammonium bicarbonate (TEAB) to remove free fluor or haptene then the fluor or haptene labeled dUTP is eluted with 0.6 M TEAB. The eluates are lyophilzed and resuspended in a Tris buffer. Five to 10 reactions, each at 1-5 umole scale, have been run simultaneously using FITC, CY3, CY5, BIOTIN, DIG, Rhodamine 6G, Texas Red, DEAC, DNP, AMCA. Although these preparations contain unreacted AAdUTP, they work extremely well for probe-labeling. This protocol modification reduces the overall M-FISH probe cost to less than $4/slide.

Program Nr: 1989 from the 1999 ASHG Annual Meeting

Genotype analysis of the Maternal and Paternal Contributions in a 46,XX/46,XY Hermaphrodite. *D. Niu[1], M-y. Chung[2], C-W. Chou[1], B. Hwang[1].* 1) Pediatrics, Veterans General Hospital, Taipei, Taiwan; 2) Medical Research and Education, Veterans General Hospital, Taipei, Taiwan.

True hermaphroditism in human is extremely rare. About 20% of true hermaphrodites show mosaic 46,XX/46,XY karyotype. The mechanisms that cause such conditions are poorly understood. Several mechanisms such as amalgamation of two embryos and parthenogenetic chimeras fertilized by a single or two spermatozoa have been reported previously. All of them have been clearly demonstrated by studies using polymorphic markers. In this report, we describe an infant with true hermaphroditism and a 46,XX/46,XY karyotype in lymphocytes. Nineteen microsatellite markers from eight autosomes and ten from the X chromosome were analyzed in DNAs extracted from the blood of the proband and both parents. At each of the eight fully informative and ten partially informative loci of the autosomes, the proband inherited a single maternal and a single paternal allele. Genotypes at the X chromosome loci also revealed single maternal and single paternal genetic contributions. These results suggest that the mechanism for the 46,XX/46,XY karyotype in this case is different from those reported previously. Hereby, we report this interesting case and possible mechanisms will be discussed.

Program Nr: 1990 from the 1999 ASHG Annual Meeting

Detection of two chromosomal arrangements in the subtelomeric region of 9q in mentally retarded children. *P.T. Nokelainen[1], O. Quarrell[2], B. Kerr[3], R. Regan[1], J. Flint[1]*. 1) Dept. of Molecular Haematology, Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, United Kingdom; 2) Center for Human Genetics, Sheffield UK; 3) Royal Manchester Childrens Hospital, Manchester, UK.

One of the major challenges of child neurology is to reveal new causes of mental retardation (MR). 2.5 % of the population suffer from MR (IQ<70): etiological diagnosis is not possible for almost 30% of the moderately to severely affected cases. Subtle chromosomal rearrangments affecting the ends of chromosomes (telomeres) account for about 8% of these cases. Molecular characterization of these small deletions may be a useful tool for the discovery of dosage sensitive genes that give rise to MR and also for an understanding of the processes that give rise to chromosomal aberrations. During a survey of individuals with undiagnosed MR for the presence of subtelomeric rearrangements, two families where identified with abnormalities involving the same region of terminal 9q. In the first family the mother has a balanced translocation between 9q and 13p whilst her two daughters have the unbalanced derivative of chromosome 9, creating a monosomy of the most distal part of 9q. In the second family the affected son has a de novo deletion of the same region. Clinically both girls show severe global developmental delay, profound hypotonia, ligamentous laxity, hearing loss and dysmorphic features. The boy from family 2 shows developmental delay, microcephaly, hypotonia and dysmorphic features. To further characterise these rearrangements, STSs selected from published maps were used to screen PAC libraries. Selected PACs were then used as FISH-probes in order to map the break point regions. The break-point of the first family has been localized to one PAC and the deletion is estimated to be approximately 1.4 Centirays. In the second case the break point was localised more distally. These two deletions represent the smallest known terminal deletions of 9q.

Program Nr: 1991 from the 1999 ASHG Annual Meeting

Abnormal brain developpement and fuzzy chromosomes: a new syndrome? *M. Nouchy[1], E. Gautier[2], C. Fallet[1], N. Bondeux[1], P. Blot[3], C. Nessmann[1], P. Eydoux[1]*. 1) Lab Biol Development, Hosp Robert Debre, Paris, France; 2) Lab Cytogenetique, American Hospital, Paris, France; 3) Obstetrics/Gynecology, Hosp Robert Debre, Paris, France.

We report a patient with cerebral dysplasia and a peculiar aspect of the chromosomes. A severe fetal microcephaly was detected through ultrasound examination, at 37 weeks of an uneventful pregnancy. The parents were not consanguineous, and there was no contributing family history. No other ultrasound abnormalities were seen, and no infectious cause was identified. Chromosome examination from amniotic fluid cells showed a 46,XX chromosome complement. However, an unusual aspect of the chromosomes was noted, with a wavy aspect of the chromatin. Chromatids looked circumvoluted, and G-banding techniques were unsuccessful. Autopsic examination of the fetus showed severe microcrania and microcephaly (-4DS) with no other structural abnormality. Cerebral histology showed a low density of normally differentiated cortical neurons; all other brain structures did not show any abnormality in size or differenciation. A blood karyotype was done in a second center, anaware of the first results. Culture was poor and showed very small, poorly R-banded chromosomes. Parental karyotypes were normal. The patient was pregnant again soon after delivery; a fetal karyotype was performed because of maternal age and did not reveal any abnormality. A normal baby was delivered. This observation could be related to a cytogenetic artefact. However, two independant centers have found a very unusual aspect of our patient's chromosomes.This finding may be related to an abnormal component of the chromatin, altering gene function, and resulting in a possibly autosomal recessive disorder of neuronal growth and/or migration.

Program Nr: 1992 from the 1999 ASHG Annual Meeting

Chromosomal analysis of sperm from severe oligozoospermic men using fluorescence in situ hybridization. *Y. Ohashi, N. Miharu, H. Honda, N. Honda, K. Ohama.* Dept. of OB/GYN, Hiroshima univ. Sch. Medicine, Hiroshima, Japan.

[Purpose]To determine if men with severe oligozoospermia have an elevated risk of aneuploidy in spermatozoa. [Methods] Semen samples were obtained from nine severe oligozoospermic men, six oligozoospermic men and seven normozoospermic men. Routine semen parameters (concentration, motility rate, volume) were analyzed using a Makler counting chamber. Cytogenetic analysis was performed on GTG-banded chromosomes after culture of lymphocytes obtained from peripheral blood. Three color fluorescence in situ hybridization was performed using three probes (D18Z1; biotin and digoxigenin labeled , DXZ1; digoxigenin labeled, DYZ1; biotin labeled) simultaneously. Hybridization and detection was performed basically according to manufacturer's instructions with only minor modification of the post-hybridization washing step. Hybridization signals in sperm nuclei were examined under a Nikon Axiophot microscope to compare aneuploid frequencies of each groups. Statistical analysis was done with chi-square analysis. [Results] Karyotype of all donors were 46, XY. A minimum of 6,000 sperm nuclei per sample for each chromosome were evaluated, for a total of 181,350 sperm nuclei. Hybridization efficiency was 99.8%. Disomic sperm frequencies for chromosome 18, XX, XY, YY were ranged from 0.09 to 0.52, 0.04 to 0.11, 0.05 to 0.59 and 0.04 to 0.14 in men of severe oligozoospermia; ranged from 0.08 to 0.24, 0.03 to 0.12, 0.08 to 0.16 and 0.02 to 0.15 in men of oligozoospermia; ranged from 0.11 to 0.23, 0.06 to 0.19, 0.14 to 0.24 and 0.05 to 0.18 in men of normozoospermia. Diploid sperm frequencies in men of severe oligozoospermia, oligozoospermia and normozoospermia were ranged from 0.20 to1.44, 0.15 to 0.25 and 0.12 to 0.30 respectively. The severe oligozoospermic men showed significantly increased frequencies of XY disomy and diploid spermatozoa comparing to oligozoospermic men and normospermic men . [Conclusions] These data indicate that there might be higher frequency of X-Y non-disjunction in meiosis of spermatogenesis in men of severe oligozoospermia than that in men of oligozoospermia and normozoospermia.

Program Nr: 1993 from the 1999 ASHG Annual Meeting

Hypohidrotic ectodermal dysplasia and Hypomelanosis of Ito in a girl with a de novo t(X;13)(q13;p11.2). *S.J. Orlow[1], R. Marion[2], C. Duncan[3], H. Gu[3], M. Genovese[3], E. Jenkins[3], A. Shanske[2]*. 1) Dermatology, NYU Medical Center, New York, NY; 2) Pediatrics, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; 3) Institute for Basic Research, Staten Island, NY.

Hypohidrotic ectodermal dysplasia (HED)is caused by mutations of the EDA1 gene at Xq12-13.1 that is critical for the morphogenesis of epidermal derivatives.Heterozygous women may show mild abnormalities of ectodermal derivatives and fully manifesting females look like affected males.Hypomelanosis of Ito(HI)is a heterogeneous disorder characterized by macular hypopigmented whorls, streaks, and patches.Abnormalities of the CNS occur frequently.Mosaicism for different aneuploidies is a common finding and often involves the X chromosome.We evaluated a 5-year-old female with features of both HED and HI.Her physical examination at 4 10/12 years of age revealed an unstigmatized youngster whose height was 104 cm (50%); weight 16 kg (10-25%)and HC 51 cm (50%). She had maxillary hypoplasia,low nasal bridge,conical teeth with increased spacing,periorbital wrinkling,patchy alopecia,and sebaceous hypoplasia over the bridge of her nose consistent with HED and striped hypopigmentation on her trunk following Blaschko's lines consistent with HI.Short term whole blood lymphocyte cultures revealed an apparently balanced de novo X;13 translocation in 40 cells analyzed with a karyotype of 46,X,t(X;13)(q13;p11.2).The same nonmosiac translocation was identified in fibroblast cultures derived from hypopigmented and pigmented areas of skin. Replication X studies using a BrdU terminal pulse showed an inactive normal X chromosome in 100%of blood cells but were unsuccessful in fibroblasts.

We conclude that our patient is a fully manifesting female with HED because the translocation affects the EDA1 gene.Functional disomy has been proposed as a likely mechanism because of the skewed X-inactivation observed in most cases.PCR analysis of DNA extracted from uncultured cells show that a more balanced pattern of inactivation can be observed in these cells.Partial functional disomy in the fibroblast cell lineage may also be responsible for the HI in our patient.

Program Nr: 1994 from the 1999 ASHG Annual Meeting

Chimeric mice containing a human chromosome 21. *M. Oshimura[1], T. Shinohara[1], K. Tomizuka[2], S. Miyabara[3], S. Takehara[1], Y. Kazuki[1], K. Funaki[4], A. Ohguma[2], I. Ishida[2].* 1) Dept Mol Cell Genet, Tottori Univ Sch Life Sciences, Yonago, Tottori, Japan; 2) Pharmaceutical Res Lab, Kirin Brewery Co, Ltd, Takasaki, Gunma, Japan; 3) Dept Pathol, Saga Med School, Saga, Saga, Japan; 4) Dept Biol, Shimane Univ, Fac Education, Matsue, Shimane, Japan.

Since three copies of genes on human chromosome 21 (hChr.21) contribute to Down syndrome (DS), mice containing an additional copy of hChr.21 genes could be a useful model to investigate the contribution of genes or combination of genes responsible for the DS phenotypes. Thus, we attempted to make trans-chromosomic mice with hChr.21 via microcell-mediated chromosome transfer (MMCT). The advantage of using this method is that foreign genetic material could be transferred to mice by using the human chromosome itself as a vector, which enabled us to analyze the expression and function of genes on hChr.21 in the same chromosomal structure as in human. We made chimeric mice using the following steps. (1) We constructed human-mouse A9 monochromosomal hybrids with hChr.21 derived from normal human fibroblasts by whole cell fusion and MMCT. The hChr.21 was tagged with a dominant selectable marker, pSTneo, that can confer G418-resistance to ES cells. (2) The hChr.21 was transferred to mouse TT2F ES cells using MMCT, and the ES cells were injected into 8-cell embryos. We isolated 14 ES clones, and examined the transferred hChr.21 by fluorescence in situ hybridization (FISH) and PCR. 3 of the 15 clones contained an intact hChr.21, whereas other clones contained hChr.21 fragments. 12 chimeric mice exhibiting more than 95% chimerism were produced from 2 of the ES clones with an intact hChr.21. The presence of the transferred hChr.21 was confirmed by PCR and FISH analysis using tail fibroblasts derived from 8 chimeric mice. In 3 of the 8 chimeric mice, the hChr.21 was retained in more than 90% of fibroblasts, although small deletions were present. We are currently investigating (1) the retention and gene expression of hChr.21 in various adult chimeric tissues, (2) germline transmission of hChr.21, (3) phenotypic effects of hChr.21 in chimeric mice.

Program Nr: 1995 from the 1999 ASHG Annual Meeting

Aneuploidy in sperm from fifty-four oligoasthenoteratozoospermic patients undergoing intracytoplasmic sperm injection. *M.G. Pang[1], S.F. Hoegerman[3], J. Pfeffer[2], M. Stacey[3], L. Lunsford[3], C. Osgood[3], G. Donsel[4], S. Oehninger[4], A.A. Acosta[4], W.G. Kearns[3,4,5]*. 1) Biomed. Res. Cent. Korea Advanced Inst. of Sci. and Tech. Taejon, Korea; 2) DHUYS IVF Center, Zerah-Taar-Pfeffer Lab, Bagnolet, France; 3) Cent. for Pediatric Research, EVMS, Norfolk, VA; 4) Jones Inst. for Reproductive Med. EVMS. Norfolk, VA; 5) Inst. Med. Genetics Johns Hopkins Univ. School of Med. Baltimore, MD.

Objective: We summarize data on aneuploidy in sperm from 54 OAT patients undergoing ICSI. **Study Design:** This study determined aneuploidy in sperm from OAT patients and tabulated fertilization and pregnancy rates following ICSI. **Methods:** Aneuploidy frequencies were determined in sperm from 54 OAT patients and 18 proven fertile donors using fluorescence in situ hybridization. Direct labelled DNA specific for chromosomes 1,4,6,8,9,10,11,12,13,17,18,21,X and Y were used and over 200,000 sperm were scored. Chi-square analysis or Fisher's Exact Test were performed. **Results:** Per chromosome disomy frequencies for the gonosomes and autosomes ranged between 0 and 5.7% for patients and 0 to 0.3% for controls. The frequency of diploid sperm ranged from 0 to 9.6% in patients and 0 to 1.2% for controls. The OAT patient group was heterogeneous for the type and frequency of numerical chromosome abnormalities observed. Total aneuploidy in sperm from the 54 OAT patients was estimated to range between 33 and 74%. Total aneuploidy in sperm from the 18 proven fertile donors was between 3.9 and 7.7%. Thirty-six ICSI cycles were performed. Sixty-nine percent (175/252) of oocytes fertilized. Following fresh embryo transfer, 2 preclinical abortion's, 1 first trimester loss and 2 healthy term deliveries (2/26 = 7.7%) resulted. **Conclusions:** There were significant increases in the frequencies of diploidy, autosomal disomy, sex chromosome aneuploidy and total cytogenetic abnormalities in sperm from 54 OAT patients versus controls. The data suggest that meiotic errors occur at highly elevated frequencies in the germ cells of severely affected OAT patients. Males with severe OAT donating sperm for ICSI are at risk of transmitting genetic abnormalities to their offspring.

Program Nr: 1996 from the 1999 ASHG Annual Meeting

UPD risk assessment: Three cytogenetic subgroups. *P.R. Papenhausen[1], J.H. Tepperberg[1], P.N. Mowrey[1], I.K. Gadi[1], H.O. Shah[2], J. Sherman[2], V. Pulijaal[3], H. Nitowsky[3], G. Sachs[3], J.H. Lin[2].* 1) Dept Cytogenetics, Labcorp of America, Res Triangle Pk, NC; 2) Nassau County Med. Center East Meadow, NY; 3) Albert Einstein Col. Medicine Bronx, NY.

Since the recognition of genomic imprinting in man, detection of UPD and determination of its incidence has been crucial for genetic counseling. It is especially important to define predisposing conditions or linked results in prenatal analysis so that appropriate molecular testing can be offered. Starting in early 1996, we have been offering UPD follow up testing for what we felt were risk associated prenatal cytogenetic results; 1) Placental confined mosaicism or single colony amniocyte trisomy, 2)Balanced Robertsonian translocations (RT) involving chromosomes 14 or 15, and 3)Extra marker chromosomes(EAC)derived from chromosome 14 or 15. UPD was detected in all groups, but not in 11 cases with single colony trisomy. One of 12 cases of placental confined trisomy revealed UPD(chr.17). Two cases of UPD were found in the study of 58 Robertsonian translocations. A de novo 13;14 and a de novo 14;14 demonstrated maternal heterodisomy 14 and maternal isodisomy, respectively. The EMC cases generated one additional case of 13 studied (4 de novo). The positive case involved a pedigree with two RT(14;15)mat sib carriers who had balanced carrier fetal analyses with normal biparental molecular results. Their deceased brother had a Prader-Willi clinical diagnosis, the balanced translocation, no deletion, and a chromosome 15 positive bisatellited marker. It was felt this strongly supported UPD 15mat, although molecular confirmation was not possible. Familial RT's may be thought more likely to be associated with UPD than de novo alterations(providing more unbalanced gametes), however, other than the EAC case no UPD was noted in 46 familial RT's studied. One of 12 de novo non-homologous and all three homologous 14;14 RT's had UPD(two archival cases included). It seems likely from a breakaway rescue hypothesis that only denovo EAC's will be associated with UPD. The reported UPD cases appear to confirm the existence of at risk cytogenetic subgroups, although more positive cases are necessary to establish risk.

Program Nr: 1997 from the 1999 ASHG Annual Meeting

The parental origin and chromosomal mechanism for duplication 17p11.2 - the reciprocal recombination product of deletion 17p11.2 associated with Smith-Magenis syndrome. *S.S. Park[1], K.S. Chen[1], L. Potocki[1,2], J.R. Lupski[1,2]*. 1) Dept. of Molecular and Human Genetics; 2) Dept. of Pediatrics and Texas Children's Hospital, Baylor College of Medicine, Houston, TX.

Interstitial duplications of 17p11.2, representing the recombination reciprocal of the common deletion of Smith-Magenis syndrome (SMS), have been found in patients with mild clinical findings such as short statue, behavioral abnormalities and mild mental retardation. We determined the parental origin and chromosomal mechanism of the duplication 17p11.2 in seven dup(17)(p11.2p11.2) patients by fluorescent microsatellite analysis. We used four loci within the common deletion region of SMS, and eleven loci around the region. For quantitative analysis, we compared the height ratios of upper and lower alleles of each genotype with those of the normal control with the same genotype. We found the duplications of the markers within the SMS deletion region in all seven cases, and could elucidate the parental origin and chromosomal mechanism in six cases. Haplotype reconstruction showed that 5 of 6 informative cases are paternal in origin and 1 of 6 is maternal. These data also indicate that this duplication can be derived from either interchromosomal (4/6) or intrachromosomal sister chromatid exchange (2/6). Examining the haplotype of an unaffected sibling to determine the phase of marker genotypes demonstrated unequal crossing over in a patient whose rearrangement occurred by an interchromosomal exchange. These data suggests that duplication 17p11.2 is caused by the homologous recombination reciprocal of the deletion of SMS, and occurs primarily during paternal gametogenesis by either interchromosomal recombination or intrachromosomal sister chromatid exchange.

Program Nr: 1998 from the 1999 ASHG Annual Meeting

Marker gene detection using FISH and CGH in chromosomal abnormality. *Y.J. Park[1], E.K. Park[1], Y.J. Choi[1], D.S. Ko[1], M.H. Park[2], J.S. Park[2], D.W. Kim[2], S.H. Shim[3], Y.H. Cho[3], H.J. Lee[1,2].* 1) Laboratory of Human Genetics, Eulji Med. Science Institute, Eulji Medical College, Seoul, Korea; 2) Department of Physiology, Eulji Medical College; 3) Department of Genetics, University of Hanyang, Seoul, Korea.

We report that two cases of chromosomal abnormality, which one is 47,XY,+mar/46,XY from amniotic fluid of 20 weeks in 35-yr-old woman, the other one is 45,XO,+der(21)/45,XO, from lymphocyte in 23-yr-old woman, detected by using FISH and CGH. In the first case, in order to identify the origin of marker gene which was detected by karyotype, we tried CGH. As a result of CGH, we defined that marker gene is originated from No. of 15 chromosome. And to confirm this finding, we performed the FISH using locus specific gene probe. A result of FISH was demonstrated that this gene is a part of No. of 15 chromosome. Second case was demonstrated as Turner syndrome (45,XO) from karyotype. But, as a result of FISH and CGH, we defined that Y chromosome is translocated in short arm of No. of 21 chromosome. In this case, to determine the gonadectomy, we have to detect expression of Sry gene, which is related with sex determination, from lymphocyte and gonad. In conclusion, it is suggested that FISH and CGH is a more effective technique to define the clinical diagnosis of patients with chromosomal abnormality.

Program Nr: 1999 from the 1999 ASHG Annual Meeting

A mother and two sons with a small terminal rearrangement of Xp leading to a deletion of Xpter-p22.32; A lesson learned. *M.I. Parslow[1], I.P. Miller[1], P.M. MacLeod[2], K.M. Boycott[3], N.T. Bech-Hansen[3].* 1) Cytogenetics Lab, Capital Health Region, Victoria, BC, Canada; 2) Medical Genetics, Capital Health Region, Victoria, BC, Canada; 3) Dept. of Medical Genetics, University of Calgary, AB, Canada.

We present a 45 yr old G7 P3 A4 mother with short stature who has a terminal rearrangement of the short arm of one X chromosome at Xp22.32, and her two sons, who inherited the rearranged X chromosome and who are affected by short stature, mild mental retardation and joint contractures.

Molecular and cytogenetic analysis of one son had demonstrated him to be fragile X negative and with a "normal karyotype". Subsequent to a 22 yr old female sib presenting for reproductive counseling, cytogenetic studies of the mother demonstrated a small terminal rearrangement without any apparent translocation of material to another chromosome. Re-evaluation of the affected son's karyotype, and analysis of the other affected son, demonstrated they both carried the rea(X), but the female sib did not. She was consequently counseled that her pregnancy was not at risk for the familial rearrangement and a healthy normal female baby was born.

FISH to the mother's chromosomes using an X chromosome paint demonstrated hybridization to the complete X chromosome short arm with no hybridization elsewhere in the karyotype. FISH with probes for Kallman syndrome (KAL) and the STS locus demonstrated both these loci to be present on the rearranged chromosome.

This family demonstrates the benefit of maternal studies in shedding light on the presence of subtle X chromosome rearrangements where the family history is suggestive of an X linked condition. It has also permitted further study of the relationship between terminal Xp deletions, proportional short stature, and mental retardation.

Program Nr: 2000 from the 1999 ASHG Annual Meeting

Mosaic chromosomal 22q11.22 deletion. *S.R. Patil, Q. Qian, D. Jordan, K. Horton, W. Rhead.* Division of Medical Genetics, Department of Pediatrics, University of Iowa Hospitals & Clinics, Iowa City, IA.

Mosaicism for obvious autosomal structural abnormalities is rare. Establishing mosaicism with conventional cytogenetics can be problematic, particularly in microdeletion syndromes. We describe here a mosaic case for this deletion. A six-month old female was recently seen in our regional genetics clinic because of minor dysmorphic features and a history of laryngotracheomalacia, peripheral pulmonic stenosis, and declining growth. She was a 3380gm product of a 39 weeks gestation born to a 20 year-old mother. Prenatal and perinatal history was complicated by polyhydramnios, shoulder dystocia and tight nuchal cord and apgars of 2 and 8. She had apnea and choking with feeding, which resolved within a week. At five months, she was below the 5th percentile for height, weight and head circumference. She has small, low-set, over-folded ears, a tented upper lip, a small narrow nose and a small mouth. Neurological examination was normal. Chromosome studies with GTG banding showed a subtle interstitial deletion of the band 22q11.22. FISH studies with TUPLE-1 were done to confirm the deletion. Five out of 55 metaphase cells (9.1%) showed two target signals, and the remaining 50 cells had only one target signal. The existence of mosaicism was confirmed in the repeat blood sample, both in metaphase cells and in interphase nuclei, using the TUPLE-1 and N-25 probes. How common this is at this region of chromosome 22 is not known. It could reflect mitotic instability of this critical region.

Program Nr: 2001 from the 1999 ASHG Annual Meeting

No occurrence of interchromosomal effect in sperm of chromosomal rearrangement carriers evidenced by FISH and PRINS labeling. *F. Pellestor, I. Imbert, P.O. Harmand, B. Andreo.* Inst Genetique Humaine, CNRS, UPR 1142, Montpellier , France.

The possibility that a chromosomal rearrangement might disturb the meiotic behavior of chromosomes not involved in the rearrangement and favour nondisjunction is a contreversial issue in human cytogenetics. An efficient approach to investigate this point is to directly analyse the chromosomal constitution of gametes obtained from carriers of rearrangements. Presently, molecular cytogenetic techniques allow chromosomal analysis on large samples of cell nuclei. The present work was designed to study the occurrence of interchromosomal effect in gametes from rearrangement carriers using FISH and PRINS in parallel. Sperm samples from 4 reciprocal translocation carriers, 1 robertsonian translocation carrier, 1 inversion carrier and 3 control donors were investigated. In each case, dual-color FISH and PRINS procedures were utilized to estimate the incidence of disomy for chromosomes 1, 4, 9, 13, 15, 16, 20 and 21. Among the rearrangement carriers, the frequencies of disomy ranged from 0.08% to 0.34%, comparable to estimates of disomy in control samples. Thus, our results provide no evidence for the occurrence of a meiotic interchromosomal effect in male carriers of single balanced rearrangements.

Program Nr: 2002 from the 1999 ASHG Annual Meeting

Narrowing the 4q- syndrome critical region to the band 4(q32-33). *C. Perandones[1], M. Segovia[1], A. Corominas[1], E. Pastene[1], M. Yannibelli[2], R. Bennun[2], O. Pivetta[1].* 1) Clinical Genetics Dept., Natl Ctr of Medgenetics, Buenos Aires, Argentina; 2) Asociacion Piel, Buenos Aires. Argentina.

Interstitial deletion of the long arm of chromosome 4 is a relatively rare anomaly and is classfied into 2 o3 clinically distinct entities: the distal interstitial and terminal (4q33-qter) deletions and the more proximal (4q21-q22) ones. The most commonly reported rearrangement of 4q is deletion 4q31 which is associated with a characteristic phenotype of mental and growth retardation , absent glabella, upward slanting palpebral fissures, hypertelorism, cleft lip and palate, micrognathia, abnormal ears and unique pointed 5th finger which is found in more than two thirds of patients. One patient with an intersititial deletion from band 4q31.22 :: 4q34.2(Sarda et al,1992) with the full phenotype suggested the critical region for the 4q- syndrome phenotype was delimited by these breakpoints. We report on a child with a small interstitial deletion within band 4q32 who exhibits most of the features of the established 4q phenotype. The proband is a 3 year-old boy with microcephaly (-2DS), mental and growth retardation, upward-slanting palpebral fissures, hypertelorism, short nose with flat nasal bridge, cleft lip and palate, micrognathia, abnormal ears, epicanthus, long eyelashes, altered palmar flexion creases and severe bilateral hydronephrosis with hydroureter and vesicoureteral reflux. Chromosomal analysis by G banding to the level of 550 bands per haploid genome demonstrated 46,XY,del(4)(q32-33). Our patients phenotype would imply that most of the components of the 4q- syndrome including the characteristic dysmorphism mainly results from loss of the segment q32.q33. This case together with those previously quoted suggests that the 4q- phenotype is not restricted to terminal deletions and that the severity of the phenotype is not necessarily proportional to the extent of the missing segment.

Program Nr: 2003 from the 1999 ASHG Annual Meeting

Comparative Mapping of Cercopithecus aethiops by karyotyping, chromosome painting and M-FISH. *M.J. Pettenati, C. von Kap-Herr, M. Saner.* Dept Pediatrics/Div Med Gen, Wake Forest Univ Sch Medicine, Winston-Salem, NC.

The Old World monkey family Cercopithecidae includes macaques and the African green monkey (Cercopithecus aethiops). Both species play important roles in biomedical research. Macaques and C. aethiops are not closely related, however, physically they are very similar. Cytogenetically, macaques are 2n=21 while C. aethiops are 2n=30. Karyotypic comparisons have suggested that the C. aethiops karyotype could be reconstructed after fusion to match the macaques. The banding pattern homology between C. aethiops and humans is believed to be nearly 95% although chromosome banding for chromosome homology is considered subjective.

To determine C. aethiops synteny, we used karyotyping, chromosome painting and M-FISH. Blood from 16 C. aethiops were cultured using standard cytogenetic techniques. Chromosomes were GTG. A total of 15 human chromosome paints were used initially per manufacturer's protocols with the exception of a 68-hour hybridization. M-FISH was performed using the VYSIS SpectraVysion Assay. Protocol modifications included a reduced stringency wash of 50% formamide/1XSSC at 40^{o}C.

Chromosome analysis of C. aethiops revealed a modal number of 60. Karyotypic comparison of C. aethiops to macaques and humans suggested that nearly all C. aethiops chromosomes have a similar banding pattern when considering fission as an evolutionary event. Karyotypic analysis suggests that C. aethiops arose from macaques as a result of 7 fission events. Human chromosome paints and M-FISH identified 6 fission and 1 fusion event. M-FISH was most useful in delineating the complete C. aethiops/macaque/human chromosome synteny.

This data showed agreement with 7 of the reported chromosome homologies and identified 16 new chromosomal homology assignments. Only those chromosomes homologous to human chromosome 2 are still present as separate chromosomes in both macaques and C. aethiops supporting the concept that formation of a single human chromosome was a major step in human evolution. This study delineates the complete chromosomal homology between C. aethiops, macaques and humans.

Program Nr: 2004 from the 1999 ASHG Annual Meeting

Isolation of the motile fraction does not separate aneuploid from haploid sperm prior to intracytoplasmic sperm injection (ICSI). *J. Pfeffer[1,2], M.W. Stacey[1], M.G. Pang[3], S.F. Hoegerman[1], L. Lunsford[1], G. Doncel[4], A.A. Acosta[4], W.G. Kearns[1,4,5]*. 1) Center for Pediatric Research, EVMS, Norfolk, VA; 2) DHUYS IVF Center, Bagnolet, France; 3) Biomed Res Cent, Korea Adv Inst of Sci and Tech, Taejon, Korea; 4) Jones Inst EVMS, Norfolk, VA; 5) Inst of Genet Med, Johns Hopkins Univ Sch of Med, Baltimore, MD.

Objective: We summarize data on aneuploidy in sperm from 23 infertile males with oligoasthenoteratozoospermia (OAT) undergoing ICSI. **Design:** Prospective study to determine whether isolation of the motile fraction separates aneuploid from haploid sperm. **Materials and Methods:** FISH to determine aneuploidy frequencies for chromosomes 1, 13, 18, 21, X and Y in sperm from swim-up and pellet fractions. **Results:** Chromosome aneuploidy in patients was significantly ($p < 0.05$) greater versus controls. Per chromosome disomy for patients ranged between 0.0 and 3.8% in swim up and 0.0 to 2.1% in pellets; for controls, the frequencies were 0.0 to 0.3% in swim up versus 0.0 to 0.7% in pellets. The frequencies of diploid sperm in patients were 0.0 to 1.7% in swim up versus 0.0 to 1.4% in pellets; for controls the rates were 0.0 to 0.3% in swim up versus 0.3 to 1.1% in pellets. Per chromosome aneuploidy for patients ranged from 0.0 to 10.0% in swim up versus 0.3 to 3.9% in pellets; in controls the rates were 0.0 to 0.6% in swim up versus 0.0 to 0.8% in pellets. Total aneuploidy in sperm from whole semen ranged between 32 and 69%. Patient-to-patient heterogeneity was shown. **Conclusions:** The data show significantly higher rates of diploidy, autosomal disomy and nullisomy, sex chromosome disomy and nullisomy and total aneuploidy in sperm from all separated fractions from all OAT patients versus controls. The type and percent of aneuploid sperm for all OAT patients studied found in both swim-up and pellet fractions was not different, with the exception of diploid sperm, which remained in the pellet fraction. Isolation of the more motile sperm fraction does not separate aneuploid from haploid sperm in these patients. These infertile males may be at an increased risk of transmitting genetic abnormalities to their offspring.

Program Nr: 2005 from the 1999 ASHG Annual Meeting

Is pediatric T-cell ALCL always associated with an ALK rearrangement? *D. Pickering[1], P. Aoun[2], D. Weisenburger[2], M. Wiggins[1], W.G. Sanger[1].* 1) Human Genetics, Univ Nebraska Med Ctr, Omaha, NE; 2) Pathology/Microbiology, Univ Nebraska Med Ctr, Omaha, NE.

Anaplastic large cell lymphoma (ALCL) is a distinct subtype of NHL morphologically characterized by large pleomorphic tumor cells which express CD30 antigen. It is predominantly seen in children and young adults and has a better overall survival than other large cell lymphomas. These tumors are typically T or null immunophenotype and have variable histological features. A specific genetic subtype of this heterogeneous group is characterized by a 2p23/ALK rearrangement which is most often seen as the t(2;5)(p23;q35)-associated NPM/ALK fusion. This abnormality has been reported in up to 50% of all ALCL; however, recent studies have shown a molecular variant of this rearrangement which can be cytogenetically indiscernible. The focus of this study was to examine all pediatric T-cell ALCL's studied at our institution and to compare the cytogenetics, FISH and immunohistochemistry of these tumors. There were 17 ALCL cases and 11 of them had cytogenetics and/or FISH data available for this study. All 11 cases were CD30+ and positive for the ALK protein by immunostaining. Seven of the 11 cases were positive for the t(2;5)(p23;q35) and FISH studies were concordant with these results. Three cases did not have cytogenetics but were positive for the ALK rearrangement by interphase FISH studies on paraffin block tissue. One case was t(2;5) negative but exhibited NPM/ALK co-localization in two different complex derivative chromosomes which were ascertained by FISH and M-FISH procedures. These findings suggest that all ALCL of T-cell origin cases in this series exhibited aberrant ALK activity and that correlation of the cytogenetics, FISH and immunohistochemistry very specifically identifies this unique genetic subtype of NHL. This study demonstrates that even though classical cytogenetics may not reveal a t(2;5) in all cases, ALK FISH and extended FISH procedures (i.e., M-FISH) can resolve the variant ALK rearrangement which occur with this disease. Supported in part by the National Childhood Cancer Foundation.

Program Nr: 2006 from the 1999 ASHG Annual Meeting

A complex chromosome rearrangement in a patient with multiple anomalies. *L. Plumley, J. Yu, A. Szekely, B. Pober, T. Yang-Feng.* Genetics, Yale University Med. School, New Haven, CT.

The proband was a 37 week female product to a 22 yr old primigravida. Family history was unremarkable. Prenatal ultrasound revealed IUGR. Birth weight was at the 3rd centile, length and head circumference were at 15-25th centiles. Dysmorphic facial features including a round face with upslanting palpebral fissures, large nose with a flattened bulbous tip, U-shaped cleft palate and mild micrognathia. She also had a sacral dimple, joint laxity, transverse palmar creases, proximally set, finger-like thumbs, arachnodactyly of fingers II-V, irregular toes, and bifid 5th toes. She was irritable but otherwise had normal tone and newborn reflexes. Further evaluations revealed retinal detachment with normal brain and spinal cord imaging.

Cytogenetic study revealed a complex chromosome rearrangement including a translocation between chromosomes 5 and 8, a der(16) resulting from a translocation between chromosomes 11 and 16 and a rearranged chromosome 11 which cannot be fully delineated. Both parents are chromosomally normal. FISH study using whole chromosome painting probes confirmed these abnormalities and demonstrated that both ends of the abnormal chromosome 11 showed positive hybridization signals for the chromosome 16 probe. This rearranged chromosome 11, thus, appears to have arisen from a translocation between the long arms of chromosomes 11 and 16, followed by a duplication of 16q material which was then moved to distal 11p after an inversion. During this process, an interstitial deletion of 11q and possibly 11p occurred. The patient thus has partial deletion of 11q (and ?11p) and partial duplication of 16q. Her phenotypic abnormalities have some overlap with the del(11q) syndrome. The patient's karyotype can best be designated as: 46,XX,t(5;8)(p15.3;p23), der(11)(16qter®16q22::11p15®11q?14::16q22®16qter),der(16)(16pter®16q22::11q23®11qter). Further characterization of this unique rearrangement with chromosome region-specific probes is in progress.

.

Program Nr: 2007 from the 1999 ASHG Annual Meeting

Molecular cytogenetic evaluation of a de novo balanced translocation associated with Blepharophimosis, Ptosis and Epicanthus inversus Syndrome. *V. Praphanphoj[1,2], G.H. Thomas[1,2], B.K. Goodman[2,3], M.J. Dixon[4], C. Toomes[4], K. Nield[4], M.T. Geraghty[1]*. 1) Dept. Pediatrics, Johns Hopkins Hospital, Baltimore, MD; 2) Kennedy-Krieger Institute, Baltimore, MD; 3) Dept. Gynecology and Obstetrics, Johns Hopkins Hospital, Baltimore, MD; 4) School of Biological Sciences, University of Manchester, Manchester, UK.

Blepharophimosis, ptosis, epicanthus inversus syndrome type I (BPES; OMIM 110100) is an autosomal dominant disorder affecting craniofacial development and ovarian function. Recent studies in a patient with a balanced translocation [46,XY,t(3;4)(q23;q15.2)] assigned the critical region to a 45 kb interval on chromosome 3q23. We have identified a patient with BPES who presented in the newborn period with characteristic facial features. Chromosome analysis showed a de novo reciprocal translocation involving chromosome 3q23 [46,XX,t(3;21)(q23;q22.1)]. FISH studies were performed using PACs 108L15 and 106C10 (RPCI1) and a BAC 175G20 (Research Genetics) as probes. These clones were previously shown to map to 3q23 and to cross the breakpoint in the first patient described above. In FISH studies on our patient, each of the above clones simultaneously hybridized to both derivative chromosomes. This confirms that the breakpoint in our patient also resides within the overlapping region of the three clones. Using BAC 106C10 as a probe, we observed an unequal signal intensity on the derivative chromosomes, with the weaker signal being present on the der(3). Combining these results with the previous case we estimate that the breakpoint in our patient lies within 60 kb of the centromeric end of BAC 106C10. To our knowledge, this is the second patient with BPES and a balanced translocation that has been evaluated by molecular cytogenetics. Further studies in this region will help to elucidate the gene defective in this disorder.

Program Nr: 2008 from the 1999 ASHG Annual Meeting

Reciprocal 1;17 translocation in a patient with apparent Aicardi syndrome plus complex congenital heart disease and limb malformation. *M.C. Prieto[1], S. Khan[1], C. Tuck-Muller[1,3], S. Li[1,3], R. Gordon[2], M. Marble[1]*. 1) Human Genetics Program, SL31, Tulane Univ Medical Ctr, New Orleans, LA; 2) Department of Ophthalmology, Tulane University Medical Ctr, New Orleans, LA; 3) Department of Medical Genetics, University of South Alabama, Mobile, AL.

We present a 3-month-old girl with microphthalmia, chorioretinal lacunae, vertebral malformations, total agenesis of the corpus callosum, Dandy Walker anomaly, EEG abnormalities, limb defect and congenital heart disease (single left ventricle with AV canal). Most of these findings are indicative of Aicardi syndrome, an X-linked disorder mapping to Xp22. However, congenital cardiac anomalies and limb abnormalities are not part of Aicardi spectrum. Chromosome analysis revealed an apparently balanced *de novo* reciprocal 1;17 translocation. C-banding confirmed the breakpoint in chromosome 1, and the heterochromatic band of chromosome 1 was split between the derivative 1 and the derivative 17. Fluorescence *In Situ* Hybridization (FISH) using DNA probes (from Oncor, Inc.) specific for Smith-Magenis (D17S258) and Miller-Dieker (D17S379) regions confirmed the breakpoints in chromosome 17. The STS probe (Oncor, Inc.), specific for the steroid sulfatase region (Xp22.3) which maps close to but distal to the Aicardi locus, hybridized to both X chromosomes. The karyotype was determined to be 46,XX,t(1;17)(q12;p12).ish t(1;17)(q12;p12) (D17S379+;D17S258+,D17S379-),Xp22.3(STSx2). In conclusion, our patient has the typical features of Aicardi syndrome but also has a complex congenital heart disease and a limb abnormality. We speculate that the apparently balanced 1;17 translocation may have a submicroscopic imbalance causing Aicardi-like features with additional anomalies. Alternatively, our patient may have Aicardi syndrome due to an X-linked mutation and the heart and limb anomalies due to the translocation.

Program Nr: 2009 from the 1999 ASHG Annual Meeting

Predominance of Down syndrome phenotype in mos 45,X,+mar(X)[18]/46,XX,+21,der(21;21)(q10;q10)[2] in cardiac tissues. *H.H. Punnett[1], A.S. Schneider[2], D.W. Sabol[3], T.M. Bardakjian[2], K.A. Martin[2], P.N. Howard-Peebles[4], P.K. Rogan[5]*. 1) St Christopher's Hosp Children, Philadelphia, PA; 2) Albert Einstein Medical Center, Philadelphia PA; 3) Phylogenetix Laboratories, Pittsburgh PA; 4) Genetics & IVF Institute, Fairfax VA; 5) The Childrens Mercy Hospital and Clinics, Kansas City MO.

We report an infant with de novo mos 45,X,+mar(X)/46, XX, +21, der (21;21)(q10;q10). Although clinical features of both Down and Turner syndromes are usually evident in patients with this karyotype, only findings of Down syndrome have been noted. Endocardial cushion defect and short femurs were seen on ultrasound. Duodenal atresia and Down syndrome stigmata were documented postnatally. In amniocytes, 46, XX, +21, der (21;21)(q10;q10) was twice as prevalent as 45,X, +mar(X). Similar proportions of each cell line were evident in cord and peripheral blood. Surprisingly, chromosomal studies of cardiac tissues (atrium, ventricle, and connective) obtained during surgery revealed ~10% with 46,XX,+21,der(21;21) and ~20% in pericardium, whereas both cell lines were equally represented in thymus. This suggests that cardiac findings in Down syndrome are the result of a specific subset of cells harboring trisomy 21, rather than being based on the proportion of cells with this karyotype. The intact sex chromosome in the 45,X,+mar(X) line was maternally derived, based on a comparison of thymus and cardiac tissue genotypes. The parental origins of the derivative 21 and the marker could not be determined due to the small size of the marker chromosome and presence of only two chromosome 21 alleles at each locus analyzed. Two alleles were present by microsatellite analyses of markers on each of 6 euploid chromosomes (excluding X and 21), suggesting that mixed aneuploidy resulted from simultaneous loss of both chromosomes rather than chimerism. These distinct abnormal cell lines presumably arose prior to the morula stage of development because both karyotypes were observed in the embryoblastic and extraembryonic mesodermal lineages.

Program Nr: 2010 from the 1999 ASHG Annual Meeting

Complex Chromosome Rearrangement (CCR) involving chromosomes 2, 5, 11, and 16 and a reciprocal translocation between chromosomes 6 and 8 verified by spectral karyotyping (SKY) in a girl with mild dysmorphic features and mental retardation. *E.S. Ramos[1], S.R. Rogatto[2], L. Martelli[1,3], A. Piram[1], S.A. Santos[1], J.A. Squire[4]*. 1) Dept.of Genetics, School of Medicine of Ribeirao Preto, University of Sao Paulo, Rib. Preto, SP, Brazil; 2) Dept. of Genetics, Instituto de Biociencias, UNESP, Botucatu, SP, Brazil; 3) Div. of Genetics, Sinha Junqueira Maternity Foundation, Rib. Preto, SP, Brazil; 4) Ontario Cancer Institute, Princess Margaret Hospital, University of Toronto, University of Toronto, ON, Canada.

Congenital Complex Chromosome Rearrangements (CCRs) compatible with life are rare in humans. We report an apparently de novo CCR involving chromosomes 2, 5, 11, and 16 and a reciprocal translocation between chromosomes 6 and 8, in a 4 1/2-year-old girl. Clinical features associated were mild dysmorphic features and psychomotor retardation. The proband was born to a 29-year-old father and a 19-year-old (G4P4A0) mother at 37 weeks of gestation. No consanguinity was related. Birth weight was 3110g and length was 48cm. She was reffered to us at the age of 4 1/2 years and her weight was 18000g (p50-75), length was 97.5cm (p3-10) and head circunference was 51.5cm (p50). The clinical examination showed apparent telecanthus [but the inner canthal distance was 3.2 cm (p75-90)], infiltrated upper eyelids, broad nasal root, depressed nasal bridge, long philtrum, large mouth, thin upper lip, spaced teeth with maxillary midline diastema, dysplastic ears, short neck, umbilical hernia and Sydney line on the left hand. There was neither visceral (cardiac, abdominal or pelvic) malformation nor anomaly in standard laboratory investigations. Conventional cytogenetic analysis on peripheral blood lymphocytes revealed a CCR in 100 metaphases. Spectral karyotyping (SKY) was performed as an adjunct to high-resolution GTG-banding for characterization of the abnormal chromosomes. The final karyotype was 46,XX,t(6q;8p),t(2q;5q;11q;16q). We point out the usefulness of SKY in elucidating CCRs and other cryptic constitutional chromosomal changes.

Supported by FAEPA, FAPESP, NCIC and CCS.

Program Nr: 2011 from the 1999 ASHG Annual Meeting

Cardio-facio-cutaneous syndrome phenotype in an individual with an interstitial deletion of 12q. *K. Rauen[1], S. Bitts[2], P. Cotter[1,2], V. Cox[1], M. Golabi[1]*. 1) Department of Pediatrics-Division of Medical Genetics, University of California San Francisco, San Francisco, CA; 2) Division of Medical Genetics, Children's Hospital Oakland, Oakland, CA.

Cardio-facio-cutaneous syndrome (CFC) and Noonan syndrome (NS) are thought to be allelic or part of a contiguous gene syndrome. The molecular basis of both disorders is unknown. Only one patient with a cytogenetic abnormality and a Noonan-like phenotype has been reported in which an interstitial deletion of proximal 12q was identified: del(12)(q12q13.12). However, more recently, families have been reported with individuals having phenotypes characteristic of both NS and CFC suggesting variable expression of the same genetic locus. In one such family, linkage analysis has mapped the NS/CFC region to 12q24. We describe a 19 month female with features of CFC including developmental delay, growth retardation, macrocephaly, abnormal cranial contour, ptosis, telecanthus, blepharophimosis, short nose, depressed nasal bridge, bulbous tip, small nares and a small chin. Skeletal findings include pectus excavatum and a broad chest with wide-spaced hypoplastic nipples. Ectodermal abnormalities include fine, sparse hair, scant eyebrows and generalized hyperkeratotic papules. Brain MRI revealed significant delay in myelination with an overall reduction in white matter volume and hydrocephalus. Karyotyping of peripheral blood lymphocytes showed an interstitial deletion of one chromosome 12 in all metaphases examined: 46,XX,del(12)(q21.2q22). FISH analysis was performed with microdissected chromosome band specific probes for 12q21 and 12q22-23. The del(12) chromosome showed a significant reduction in the size of the hybridizing region for the 12q21 probe, confirming that the chromosome band 12q21.3 was deleted. CFC may represent a heterogeneous disorder. Individuals with a severe phenotype, as in our patient, may have a 12q21.3 deletion, whereas a milder phenotype may be due to a microdeletion. This is suggestive of a contiguous gene syndrome.

Program Nr: 2012 from the 1999 ASHG Annual Meeting

A stable acentric marker chromosome formed by interstitial deletion of 17q and subsequent inverted duplication of the deleted segment resulting in partial trisomy for 17q22 to 17q23 diagnosed in a dysmorphic newborn. *J.B. Ravnan[1], K. Ouellette[1], A. Fabre[1], D.C. Crenshaw[1], S. Guillory[2], R. Siewert[2], S. McCoy[2], J. Kothari[2].* 1) Genzyme Genetics, Santa Fe, NM; 2) Provena Saint Joseph Hospital, Elgin, IL.

A 34 year old G4P2/0/1/2 Hispanic female gave birth to a baby boy at 38 weeks gestation. Her history was significant for an IUFD at 32 weeks gestation. Prenatal ultrasound and maternal serum alpha fetoprotein were reported as normal. At birth, a small placenta and a bifurcation at the base of the umbilical cord of 1 cm in length were noted. Initially the baby was hypotonic and had Apgars of 3, 6, and 10. Dysmorphic features noted at birth include a sacral dimple with a hair tuft over the base of the spine, low set ears, high arched palate, bilateral undescended testes, slight hypotonia, high pitched cry, large open anterior fontanel, wide split between the big and second toe, and syndactyly bilaterally between the 2nd and 3rd toes. A newborn metabolic panel, echocardiogram, and renal ultrasound were normal. The baby was discharged home at 6 days.

Chromosome analysis revealed a male karyotype with an interstitial deletion of the long arm of chromosome 17 and an additional marker chromosome in every cell examined. Fluorescence in situ hybridization (FISH) studies demonstrated that the marker chromosome was derived from inverted duplication of the deleted segment of chromosome 17 and did not contain detectable centromeric alpha-satellite sequences. The resulting karyotype was interpreted as 47,XY,del(17)(q22q23),+der(17)(q22->q23::q23->q22). This results in partial trisomy for 17q22 to 17q23. This report provides another example of a newly-defined class of mitotically stable marker chromosomes which lack alpha-satellite sequences.

Program Nr: 2013 from the 1999 ASHG Annual Meeting

Subcortical white matter abnormalities and rib anomaly in a child with Trisomy 12p syndrome. *P.J. Reitnauer[1,2], W.O. Young[1], C.M. Powell[2], M.J. Pettenati[3].* 1) Pediatric Teaching Program, Moses Cone Health System, Greensboro, NC; 2) Pediatrics and Medical Genetics, UNC, Chapel Hill, NC; 3) Medical Genetics, WFUMC, Winston-Salem, NC.

Trisomy 12p syndrome is characterized by typical craniofacial features and mental retardation. We are following a child diagnosed as a neonate with trisomy 12p as a result of a paternal reciprocal translocation involving chromosomes 12 and 14 [46,XX,-14,+der(12)t(12;14)(q11;q11.2)pat]. Our patient has dysmorphic facies, post-axial polydactyly and global delays. Nystagmus was apparent in infancy and adduction of each eye is limited. There is no gross visual impairment. The optic nerves and retinas are clinically normal. There have been no seizures. Motor development is progressing with a 6 month delay. The head circumference is at the 10th percentile at age 14 months (weight and length just below the 5th percentile). Clinical features in our patient that have not been previously described include persistent direct hyperbilirubinemia of unknown cause which resolved, absence of the left 12th rib and dextroposition of the heart with normal anatomy. Magnetic resonance imaging of the brain showed extensive patchy abnormal signal throughout the deep and subcortical white matter of both hemispheres. Other areas of myelination appeared normal for age. The corpus callosum was normally formed. There was a small choroid fissure cyst. It has been suggested that a dosage effect of genes on chromosome 12p may play a role in brain development given the findings in other conditions associated with chromosome 12p duplications such as Pallister-Killian syndrome (tetrasomy 12p) and acrocallosal syndrome (12p13.2-p11.2 inverted tandem duplications, agenesis of the corpus callosum, seizures and post-axial polydactyly). A recent report by Elia et al.(1998) postulated that the high signal abnormalities seen on the brain MRI of their patient with trisomy 12p could have been caused by a perinatal event. The presence of similar findings in our patient supports the possibility that dysmyelination could be a significant feature of trisomy 12p syndrome and associated with neurodevelopmental gene(s) on chromosome 12p.

Program Nr: 2014 from the 1999 ASHG Annual Meeting

Multiple applications of FISH analysis with locus-specific probes generated by means of a novel procedure. *P. Riva, L. Corrado, A. Bentivegna, P. Colapietro, L. Larizza.* Dept Biol & Genetics, Univ Milan, Milan, Italy.

The availability of suitable locus-specific (LS) probes for FISH analysis improves both diagnosis and basic science making the characterization of chromosomal breakpoints rapid and precise. The current way of generating LS probes involves the stepwise subcloning of clones with large inserts and/or screening of genomic libraries. As alternative to this approach we set up a novel procedure which, by selection of LS sequences from YAC clones, allows to produce LS probes. It involves single strand DNA polymerization by a specific primer on YAC DNA and subsequent combined locus-specific-Alu PCR. Gel electrophoresis of labeled single strand DNA allowed to assess that the most represented DNA fragments ranged from 0.6 to 5 Kb. The use of two LS primers extending the polymerization toward opposite directions allows to obtain a product, even at a low yield, covering about 10 Kb around the selected locus. The subsequent locus-specific-Alu PCR on single strand DNA greatly enrich the selected genomic region making it suitable to be labeled for FISH analysis. We apply this novel procedure to remove the non desirable signal of chimeric YACs and to obtain a refined characterization of gross deletions of NF1 patients. The resolution of this procedure was assessed by using an NF1 intron-27-specific probe which allowed a small intragenic deletion to be detected. Sixteen LS probes developed from 17q11.2 contig YACs also allowed SUPT6H, BLMH and ACCN1 genes to be precisely mapped within gross deletions of NF1 patients and deletion boundaries to be identified in each case. The procedure also allows the generation of FISH probes from ESTs or cDNA sequences without undertaking time-consuming experiments. We successfully used LS probes for fiber FISH experiments showing that this kind of probes is suitable for high resolution mapping of closely linked loci. Some of the inconveniences that hamper LOH testing in tumors, such as the need of polymorphic markers, may be overcome by this method. FISH test of LOH can provide information on heterogeneity of tumor cells facilitating identification of critical homozygous LOH regions. Patent number MI98A 002060. Supported by Telethon.

Program Nr: 2015 from the 1999 ASHG Annual Meeting

Partial hexasomy of 15q11-q13 in a child with two supernumerary inv dup(15) chromosomes. *C. Sarri[1], J. Gyftodimou[1], H. Laskari[2], M. Grigoriadou[1], E. Pandelia[1], M.B. Petersen[1].* 1) Dept Genetics, Inst of Child Health, Athens, Greece; 2) 1st Pediatric Clinic, "Aghia Sophia" Children's Hosp, Athens, Greece.

Inv dup(15) is the most common supernumerary marker chromosome in humans. An eight month old female infant was referred to our Dept. because of severe psychomotor retardation, cleft lip/palate and hypotonia. Cytogenetic investigation showed that she carried two extra bisatellited chromosomes in all cells. Fluorescent in situ hybridisation (FISH) with a chromosome library 15 probe identified the supernumerary chromosomes as inv dup(15). FISH using the SNRPN probe mapping to the Prader-Willi/Angelman syndrome (PW/AS) region implied that each extra chromosome contained two copies of the PW/AS critical region. Molecular analysis revealed biparental inheritance for the two normal chromosome 15 homologues (i.e. no UPD). To our knowledge, our case is the second in the literature having the PW/AS region six times in each cell examined. Since most individuals carrying a small inv dup(15) are asymptomatic, it seems that the symptomatic ones are associated with an increased dosage of the PW/AS region.

Program Nr: 2016 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of a stable *de novo* dic(13;18)(p12;p11.3) with deletion of 18p subtelomeric sequences using chromosome and FISH analysis with postnatal follow-up. *M.A. Scanlan-Stahl[1], H.D. Dietrich-Cook[1], J. Wailand[1], J.E. Takacs[1], S.E. Mundt[2], J.B. Ravnan[1]*. 1) Cytogenetics Laboratory, Genzyme Genetics, Santa Fe, NM; 2) Perinatal Center, Saint Luke's Hospital of Kansas City, Kansas City, MO.

An amniocentesis was done for a 36 year old G3P2 woman after a maternal serum screen gave an increased risk for Down syndrome (1/109). Chromosomal analysis revealed a stable dicentric translocation, 45,XY,dic(13;18)(p12;p11.3), that appeared balanced at the 400 band level. Fluorescence *in situ* hybridization (FISH) studies showed the presence of the chromosome 13 centromere and rRNA genes and deletion of the 18p subtelomeric region. Dicentric chromosomes may be stable or unstable during cell division; chromosomes studied from cord blood confirmed the dicentric rearrangement to be stable. Parental blood chromosome studies indicated normal chromosomes. Prenatal ultrasound at 34 weeks showed a two vessel cord, although a second trimester ultrasound had documented a three vessel cord. The pregnancy was delivered by induction at 38 weeks. The two vessel cord, a left club foot (also seen in a paternal cousin) and a suspected subtle urogenital anomaly were noted. The baby resembled his siblings at birth, and at three months of age he shows normal development.

Program Nr: 2017 from the 1999 ASHG Annual Meeting

Cytogenetic and molecular characterization of evolutionary chromosome breakpoints in great apes. *Z.H. Shan, E. Zend-Ajusch, F. Gruetzner, T. Haaf.* Max-Planck-Institute for Molecular Genetics, Berlin, Germany.

While differences between man and great apes are obvious, they need not have involved a large number of adaptive changes in gene loci. Most of the genome remained relatively undisturbed. Most current models postulate a secondary role for chromosome rearrangements in speciation by their acting as a postmeiotic barrier between closely related species. However, it is also possible that evolutionary chromosome rearrangements are functionally important. They may interfere with genome function either directly, by disrupting a gene(s), or indirectly, by (in)activating closely juxtaposed genes by position effect. To address this question, we performed a systematic search for genes in evolutionary breakpoint regions. FISH with genetically and cytogenetically anchored YACs was used to visualize homologous regions on great ape chromosomes and to characterize evolutionary chromosome rearrangements in fine detail. In particular, we have studied a translocation in the gorilla lineage involving the GGO homologs of HSA 5 and 17. We identified breakpoint-spanning YACs for the two breakpoint regions in HSA 5q13 and 17p12. Alu-PCR products of these YACs were used to isolate smaller genomic clones, such as PACs and cosmids, which were then used to build contigs of the breakpoint regions. cDNA library screening, exon trapping, and Alu-splice PCR strategies are being used to isolate genes from the breakpoint regions. Thus far, we have mapped and characterized the human homolog of a mouse gene which may be involved in intracellular signaling. It is well known that pericentric inversions in PPY 2 (homolog of HSA 3) separate the Borneo and Sumatra orangutan subspecies. YAC-FISH mapping demonstrated that the evolutionary rearrangements are more complex than those suggested by classical chromosome banding, involving breakpoints on HSA 3p24, 3p14, 3q13, and 3q21. Two pericentric inversions are required to derive the Borneo PPY 2 from the ancestral HSA 3. One pericentric inversion and one transposition are needed for the Sumatra PPY 2. In addition, several megabases of DNA from the pericentromeric region of HSA 3 are found at the short-arm telomere of both Borneo and Sumatra PPY 2.

Program Nr: 2018 from the 1999 ASHG Annual Meeting

Identification of balanced translocation t(5;9)(q15;p22.3) in amniocytes. *J.C. Shin, E.J. Baik, D.Y. Jung, Y. Lee, K.O. Kim, S.C. Kim, S.P. Kim.* Dept OB/GYN, Catholic Univ. of Korea, Medical Col, Seoul, Korea.

Standard cytogenetic analysis of amniocytes obtained at 19 weeks in gestation from a 36-year old pregnant woman revealed the balanced reciprocal translocation of chromosome 5 and 9. The G-banded karyotype was interpreted as 46,XY,t(5;9)(q15;p22.3). We performed chromosome analysis using GTG-banding from the parental peripheral blood. The parental chromosome analysis showed that the father carried the balanced translocation 46,XY,t(5;9)(q15;p22.3). Parental clinical features were normal. To clarify these results, FISH study were performed using whole chromosome painting probes 5 and 9. These study conformed the cytogenetic results. To our knowlege, this is the first report of 5q;9p balanced translocation in the prenatal diagnosis.

Program Nr: 2019 from the 1999 ASHG Annual Meeting

Spectral Karyotyping for marker chromosomes. *K. Siriwardena[1], R. Babul[1], D. Chitayat[1], C. Cytrynbaum[1], L. Dupuis[1], B.S. Emanuel[2], S. Kennedy[1], H. Kurahashi[2], G. Nie[1], A. Teebi[1], R. Weksberg[1], E. Winsor[3], I. Teshima[1]*. 1) Clin Genetics and Pediatric Lab Medicine, Hosp for Sick Children, Toronto,Canada; 2) Children's Hosp of Philadelphia, PA,USA; 3) Toronto Hosp,Canada.

Spectral karyotyping (SKY) can identify marker chromosomes not identifiable by G-banding. In a series of 17 cases, only eight were identified by G-banding and known clinical correlations. These were i(9p) and inv dup(15) [1 case each]; i(12p), i(18p) and bisatellited (22)[2 cases each]. However, nine cases (mostly mosaic) required SKY identification with followup FISH (locus specific /paints). These were two each of mar(1), mar(8) and mar(22), and one each of acentric mar (from 12pter), mar(15) and mar(16). Phenotypes of these markers identified by SKY compared to known reported abnormalities allows for genotype /phenotype correlations. Cases 1 and 2, both with markers originating from chromosome 1, presented with poor growth. Neither had striking facial dysmorphic features unlike the mosaic trisomy 1 case reported. Case 3 and 4 both with mar(8) have distinct phenotypes that share features and malformations seen in full mosaic trisomy 8. These include developmental delay, abnormal eye findings, structural abnormalities of the brain, scaphocephaly, cleft plate and external genitourinary abnormalities. Case 5 with mar(12) has global developmental delay as well as coarse facies and other dysmorphic features seen in Pallister-Killian syndrome (PKS). Craniofacial features included bifrontal sparseness of hair, abnormally placed prominent ears and mild hypertelorism. In addition, there were upslanting palpebral fissures with epicanthic folds, a flattened nasal bridge, a long philtrum with a prominent lower lip and a high-arched palate also seen in PKS. Case 6 with a nonsatellited marker derived from 15 was referred for poor growth and developmental delay. Case 7 was investigated for possible velocardiofacial syndrome but was shown to have a mar(16). Case 8 included a parent and infant with different markers derived from 22. Case 9 had a mar(22) that included the 22q11.2 region (D22S427, D22S36, TUPLE1, cHKAD26, HCF2, D22S801). Phenotypes and analyses of these cases will be discussed further.

Program Nr: 2020 from the 1999 ASHG Annual Meeting

Correlation between numerical and structural chromosome damage in sperm from 13 healthy men using multicolor FISH. *E. Sloter[1,2], J. Nath[2], A.J. Wyrobek[1].* 1) Biology and Biotechnology Research Program, Lawrence Livermore National Laboratory, Livermore, CA; 2) Genetics and Developmental Biology Program, West Virginia University, Morgantown, WV.

Numerical and structural chromosomal damage transmitted via sperm have been associated with birth defects and genetic diseases. Our lab has developed and validated a multicolor FISH strategy for human sperm to simultaneously detect premeiotic and meiotic chromosomal abnormalities (numerical and structural) as well as postmeiotic structural chromosomal abnormalities using DNA probes for three target regions on chromosome 1. This includes the ability to detect (a) disomy 1 and diploidy, (b) partial duplications or deletions of 1p which are the consequence of premeiotic or meiotic rearrangements and (c) chromosome breaks within the 1cen-1q12 region which are presumably postmeiotic breakage events. We have analyzed ~100,000 total sperm from 13 healthy non-smoking men with no known exposure to genotoxic agents. A positive correlation ($P<0.01$) was found between the number of sperm with numerical abnormalities and the number of sperm with premeiotic or meiotic structural abnormalities. No association was found between the frequency of postmeiotic structural chromosomal defects and the frequency of premeiotic or meiotic abnormalities (numerical or structural). This finding suggests independent causal mechanism(s) for pre- and postmeiotic chromosomal damage in sperm. In addition, chromosomal breakage within the 1cen-1q12 region appeared to be non-randomly distributed. Multicolor FISH analysis of the centromere and adjacent heterochromatin of chromosome 1 revealed that >50% of the breaks within the 1cen-1q12 region occurred at or near the border between these two regions in 8 of the 13 men. There also appeared to be a non-random distribution of breaks within the large heterochromatic region. This sperm FISH methodology has promising clinical and toxicological applications for evaluating the etiology and risk factors associated with chromosomal aberrations in human sperm. [Work performed under the auspices of the US DOE by LLNL, contract W-7405-ENG-48 and funding from NIEHS Superfund P4ZES04705 and WVU].

Program Nr: 2021 from the 1999 ASHG Annual Meeting

Cytogenetic damage in human hematopoietic CD34+ progenitor cells. *M.T. Smith, M. Jeng, L. Zhang, Y. Wang, W. Guo, P. Duramad, G. Hofstadler, N.T. Holland.* Division of Environmental Health Sciences, School of Public Health, University of California, Berkeley CA 94720, USA.

Progenitor or stem cells are the likely target in the development of leukemias and other bone marrow (BM) disorders. Cytogenetic damage in these cells was assessed by two methods, micronucleus(MN) assay and fluorescent in situ hybridization(FISH). Micronuclei are easily measured under fluorescent microscopy. They consist of small amounts of DNA that arise in the cytoplasm when chromatid/chromosomal fragments or whole chromosomes are not incorporated into daughter nuclei during mitosis. We have used the MN assay to assess the baseline level of cytogenetic damage in progenitor cells enriched for CD34 antigen from human BM and umbilical cord blood(CB). To our knowledge no previous studies have used the MN assay in progenitor cells. Using a two-step immunomagnetic bead separation system (Miltenyi Biotech, Inc, CA), BM and CB progenitor cells were enriched for CD34 antigen. The purity of CD34+ in the enriched population was verified by FACScan analysis. The BM and CB progenitor cells were cultured for 72 hours in a media with an optimized combination of cytokines. MN frequency in CD34-enriched CB and BM was higher than that in CD34-negative cells. A lower MN frequency was noted in CB samples when compared to BM progenitor cells and peripheral lymphocytes, which is consistent with previous data showing that MN frequency is age-related. FISH analysis was performed in CD34-enriched cells, CD34-negative cells and granulocytes, using simultaneous hybridization with chromosome-specific probes for chromosomes 7 and 8. Monosomy 7 and trisomy 8 are commonly observed in leukemia. These changes have also been detected in the peripheral blood of workers exposed to benzene, established leukemogen. Like MN, significantly higher background levels of trisomy 7 and 8 were observed in CD34-enriched cells. Background levels of monosomy 7 and 8, however, were higher in CD34-negative cells for unclear reasons. Further studies with chemical exposures are underway to evaluate differential sensitivity of progenitor cells to in vitro cytogenetic damage.

Program Nr: 2022 from the 1999 ASHG Annual Meeting

Prenatal diagnosis and FISH characterization of an inherited ring (19) showing telomeric fusion and ring opening. *M.D. Speevak, G. Chow, C. Smart, J. Cardoso, S.A. Farrell.* Division of Genetics, Department of Laboratory Medicine, The Credit Valley Hospital, Mississauga, ON, Canada.

An amniotic fluid specimen from a 37-year-old phenotypically normal woman showed the presence of a single normal chromosome 19 and a ring (19) chromosome in cells of all colonies examined. Parental studies demonstrated that the father's chromosomes were normal. However, the mother was found to be a mosaic carrier of the ring (19) (4/100 cells examined). Following genetic counselling, the pregnancy was terminated. External examination of the male fetus revealed no obvious phenotypic abnormalities.

Fetal chromosome studies confirmed ring (19) in 19/20 cells examined. Dual colour FISH, using probes specific for the short and long arm subtelomeric regions of chromosome 19, was performed on cultured fetal cells. Hybridization signals were observed for each probe, indicating fusion of the chromosome 19 arms was distal to the probe loci. Our findings suggest that ring formation in this family arose from telomeric fusion rather than terminal deletion and joining of the chromosome arms. In the case of the fetus, mosaicism was likely due to *in vitro* opening of the ring (19), since a single normal male cell was detected in an otherwise abnormal colony of amniotic fluid cells. Perusal of the literature revealed no consistent correlation between cytogenetic data and the phenotype of individuals with ring (19). The counselling issues will be discussed.

Program Nr: 2023 from the 1999 ASHG Annual Meeting

Molecular cytogenetic characterization of the chromosomal region 2q37 in patients suffering from brachydactyly E including probes for the putative candidate gene LOBO1. *H. Starke[1], A. Rump[2], J. Seidel[3], V. Beensen[1], M. Stumm[4], J. Wirth[5], A. Heller[1], U. Claussen[1], T. Liehr[1]*. 1) Institute of Human Genetics and Anthropology, Jena, Germany; 2) Institute of Molecular Biotechnology e.V., Jena, Germany; 3) Childrens Hospital, Jena, Germany; 4) Institute of Human Genetics, Magdeburg, Germany; 5) Max-Planck-Institute for Molecular Genetics, Berlin-Dahlem, Germany.

We have identified the 3' portion of a large gene located on 2q37 (around STS marker WI8964), which leads to abnormal bone development in transgenetic mice. Given this murine phenotype, the human gene, which we call LOBO1, might be a candidate for brachydactyly E (Rump et al, 1999, Med. Genetik 11, 116). Brachydactyly E, the shortening of the metacarpals and phalanges of hands and/or feet, combined with mental retardation is suspected to be caused in some cases by small deletions in the subtelomeric region in 2q37, detectable only by molecular cytogenetics (Mc Kusick No. 600430). Here we report on 5 clinically confirmed cases suffering from brachydactyly-mental retardation syndrome. The following YAC clones have been used as probes to look for microdeletions: y780a10, y695g12, y770f05, y210e14, y854c09, y627d09, y963g7 and y764g8; additionally, a 3' derived LOBO1 cosmid probe has been used. In case 1 a micro-deletion in 2q37 could be detected, using the YAC y210e14 as probe. The deletion appeared in connection with a structural chromosome aberration described as 46,XY,add(2)(q37). After microdissection and reverse painting this translocation could be described as .rev ish der(2)t(2;acro)(q37;p11.2). As no deletion could be found with the 3' derived LOBO1 cosmid probe, further efforts will be done to clone the lacking parts of the human LOBO1 gene and complementary FISH studies with this new probes will be done. Moreover, to clarify if the LOBO1 gene is a candidate gene for brachydactyly E, mutation screening within the LOBO1 gene will be performed in case1. Acknowledgments: This work was supported by the Madeleine Buehler-Kinderkrebs-Stiftung and a fellowship to A. Heller and H. Starke by the Herbert Quandt Stiftung der VARTA AG.

Program Nr: 2024 from the 1999 ASHG Annual Meeting

Molecular Cytogenetic Analysis of a rec(7)dup(7q)inv(7)(p22q31.3)pat. *G. Stetten, K.M. Stone, J.M. Coddett, E.D. Gurewitsch, C.B. Cargile, K.J. Blakemore, B.K. Goodman.* Johns Hopkins University School of Medicine, Baltimore, MD.

Duplication and associated deletion within a single chromosome provides a unique opportunity to observe the consequences of gain and loss of specific genetic material. Current technology allows us to define the boundaries of these duplications and deletions with far greater resolution than previously possible. This is critical in order to facilitate direct karyotype-phenotype correlations. We have used a series of locus-specific and subtelomeric FISH probes to define a recombinant chromosome 7, involving a large duplication (7q31.3-qter) and a very small terminal deletion (7p22). The chromosome was detected at amniocentesis following an ultrasound study that revealed hemivertebrae and a two-vessel umbilical cord. The abnormality arose during meiotic recombination of a paternal pericentric inversion chromosome, inv(7)(p22q31.3).

Following G-band analysis, six DNA probes were mapped by standard FISH techniques to refine the short and long arm breakpoints. A probe mapping to 7p22 (containing D7S589) (Oncor) hybridized to the abnormal short arm in the rec(7), but a 7p telomere-specific probe (Vysis) was deleted from this chromosome. The long arm breakpoint was narrowed to an interval between markers D7S490 and D7S686, less than 0.1Mb, using the father's inv(7) (probes kindly provided by S. Scherer).

Prenatal and postnatal findings included skeletal abnormalities, dilated cerebral ventricles, microretrognathia and a short neck. The clinical phenotype appeared to result primarily from duplication of the long arm segment. Comparison of these findings to previously reported cases of terminal duplication 7q indicated good agreement with a consensus phenotype.

Program Nr: 2025 from the 1999 ASHG Annual Meeting

Subtle overlapping deletions in the terminal region of chromosome 6q24.2-q26: Three cases studied using FISH.

S. Sukumar[1], S. Wang[1], C.M. Vanchiere[2], K. England[3], R. Fick[4], B. Pagon[5], K.S. Reddy[1]. 1) Cytogenetics, Quest Diagnostics Inc., San Juan Capist, CA; 2) Childrens Clinic of Southwest Louisiana, LA; 3) Casa Blanca Clinic, Mesa, AZ; 4) Mary Bridge Childrens Health Center, Tacoma, WA; 5) Childrens Hospital and Regional Medical Center, Seattle, WA.

Interstitial deletions in the terminal region of chromosome 6 are rare. Three new cases with subtle interstitial deletions in the q24-q26 region of the long arm of chromosome 6 are described in this study. The karyotypes were analyzed at 550 band level. Patient-1 is a nine-month old boy with an interstitial deletion, del(6)(q24.2q25.1), developmental delay, low birth weight, hypotonia, heart murmur, respiratory distress, craniofacial and genital anomalies. This is the first report of a case with deletion, del(6)(q24.2q25.1). Patient-2 is a 17-year old male with an interstitial deletion, del(6)(q25.1q25.3), developmental delay, short stature, mental retardation, autism, head, face, chest, hand and feet anomalies and a history of seizures. For the first time autism has been described as a clinical feature in 6q deletions. Patient-3 is newborn baby boy with a de novo interstitial deletion, del(6)(q25.1q26), developmental delay, anomalies of the brain, genital organs, limbs and feet. This is the first report of a case with deletion, del(6)(q25.1q26). In all the patients, fluorescence in situ hybridization (FISH) using chromosome 6 painting probe ruled out a possible insertion. The ESR (6q25.1) and TBP (6q27) probes are used to confirm the breakpoints. Since TBP signal is present in all cases, it confirmed an interstitial deletion proximal to this probe. Patient-1 has a deletion of the ESR locus; Patient-2 and 3 have a signal for the ESR locus. Therefore the deletion in both these patients are distal to Patient-1 between ESR and TBP loci. FISH validated the deletion breakpoints assessed by conventional cytogenetics.

Program Nr: 2026 from the 1999 ASHG Annual Meeting

An analphoid marker chromosome shown to be an inverted duplication 8q23qter with a neocentromere. *V. Sulcova[1], K.S. Reddy[1], S. Schwartz[2], J. Noble[3], H. Lin[3]*. 1) Cytogenetic, Quest Diagnostics Inc, San Juan Capist, CA; 2) Department of Genetics and Center for Human Genetics, Case Western Reserve University School of Medicine and University Hospitals of Cleveland, Cleveland, OH; 3) Department of Medical Genetics, Harbor UCLA, Torrance, CA.

We report a new marker chromosome that was acentric but stable through cell division in a 15-year-old with a history of developmental delay, mental retardation and behavioral problems. The patient was hirsuit with polycystic ovaries and spasticity of the lower extremities. She was recently diagnosed with myasthenia gravis, presumed to be an ocular variant. G-banded chromosome analysis revealed a marker chromosome in 75% of metaphases studied. The marker was C-band negative. By FISH alpha-satellite sequences were not detected on the marker. Subtelomeric probe for 8q hybridized to the two ends of the marker and the c-myc probe that maps to 8q24 also gave two signals. The marker was shown to be entirely chromosome 8 material by using coatasome 8 probe, which painted the marker uniformly end to end. The G-bands gave the appearance of mirror image duplication. This was confirmed by the pattern of the two telomeric, subtelomeric and c-myc probe signals. The marker was concluded to be an inverted duplication 8q23qter, and the karyotype was 46,XX,der(8)(qter®q23::q23®[neocen]®qter). Both parents had normal karyotypes. The marker was found in 84%lymphoblastoid culture cells. Centomeric proteins CENPC, CENPE and not CENPB were present at a position defining a neo-centromere. This 8q marker that appears analphoid by FISH was remarkably stable in mitosis and was shown to have the known critical centromeric proteins at its neocentromere.

Program Nr: 2027 from the 1999 ASHG Annual Meeting

Should patients with a triploid pregnancy be offered prenatal diagnosis in subsequent pregnancies? *J.C. Sullivan, G. Cohn, T. Marini, R. Naeem.* Baystate Medical Ctr, Springfield, MA. Departments of Pathology and Obstetrics and Gynecology.

Triploidy is estimated to occur in approximately 2% of all conceptuses. Recurrence risk for triploidy or aneuploidy in subsequent pregnancies has been discussed in a handful of papers and abstracts (Inati et al., Uchida and Freeman, and Warburton et al.). It has been suggested that recurrence of triploidy may simply be due to chance given the small number of cases. Yet, controversy remains as to whether the occurrence of a triploid pregnancy confers an increased risk for another triploid and/or aneuploid. This question is of practical importance in the clinical setting where couples seek options and recommendations for prenatal diagnosis in pregnancies following a triploid conception. During a five and a half year period our cytogenetics laboratory identified 121 consecutive cases of triploidy in products of conception, stillbirths, and intrauterine fetal demises from 118 women. Three women (2.5%) had consecutive triploid pregnancies. Five of 118 (4.2%) women had a previous or subsequent pregnancy with aneuploidy (3 trisomies and 2 tetraploids). Three of the aneuploidies were trisomies, only one of which occurred in a patient with advanced maternal age. Although these numbers are small and may indeed be due to chance, recurrence risk for triploidy remains an ongoing clinical dilemma. Larger studies or pooled data from several surveys are necessary to lay the controversy to rest and provide clinical guidelines for counseling patients following a triploid conceptus.

Program Nr: 2028 from the 1999 ASHG Annual Meeting

Identification of a cryptic reciprocal translocation t(5;10) by FISH resulting in 5p microdeletion in two subsequent pregnancies. *F.E. Tahmaz[1], M. Freidine[2], M.M McCorquodale[2], B.K. Burton[3]*. 1) Dept Pediatrics, Div Genetics, Univ Illinois at Chicago, Chicago, IL; 2) Cytogenetics Laboratory, Michael Reese Hospital Medical Center, Chicago, IL; 3) Division of Genetics, Children's Memorial Hospital, Northwestern University, Chicago, IL.

Deletion 5p or Cri du Chat syndrome is characterized by partial deletion of short arm of chromosome 5. It has been reported that approximately 85% of the cases result from sporadic de novo deletions, whereas 15% are secondary to unequal segregation of a parental translocation. We report here a case of a 38 year-old female with two miscarriages and a child with Cri du Chat Syndrome. Her first pregnancy ended in a miscarriage at the 12^{th} week of gestation. Subsequently she had a child with the phenotypic features of Cri du Chat syndrome including postnatal growth retardation, microcephaly, hypertelorism, facial asymmetry, low-set dysplastic ears, VSD, unilateral simian crease, developmental delays, seizures and the typical high pitched cry. FISH analysis using the probe D5S23, specific for the 5p15.2 Cri du Chat critical region, revealed the presence of 5p microdeletion. In her third pregnancy, which resulted in a miscarriage at the 14^{th} week, prenatal FISH analysis of CVS again showed absence of one of the 5p critical regions. High resolution chromosome analysis revealed normal karyotypes in both parents. In addition, FISH analysis for the 5p critical region showed two signals in both parents. However, subsequent FISH studies in the mother using whole chromosome paints for chromosomes 5 and 10 revealed a cryptic translocation between distal portions of 5p and 10p involving the bands p14.2 and p12.2 [46, XX, t (5;10) (p14.2;p12.2)]. While most cases of Cri Du Chat Syndrome are caused by de novo deletions, this case demonstrates the importance of performing FISH studies in the parents of 5p microdeletion cases in order to rule out the presence of small cryptic translocations.

Program Nr: 2029 from the 1999 ASHG Annual Meeting

Stability of transferred human chromosomes in human and mouse cells. *S. Takehara[1], T. shinohara[1], K. Yamauchi[1], K. Tomizuka[2], A. Ohguma[2], I. Ishida[2], M. Oshimura[1].* 1) Dept Mol Cell Genet, Tottori Univ Sch Life Sciences, Yonago, Tottori, Japan; 2) Pharmaceutical Research Laboratory, KIRIN Brewery Co., Ltd., Japan.

Introduction of human chromosomes or fragments into variable cells via microcell- mediated chromosome transfer (MMCT) is an useful technique for mapping, cloning particular genes and functional studies. The MMCT made it possible to (1) transfer intact or megabase regions of chromosomal fragments, (2) study epigenetic modifications such as genomic imprinting. Thus, it is important for the transferred chromosome to be maintained in host cells. To examine the stability of transferred human chromosome, chromosomes 2, 11, 14, 21 and/or these fragments were transferred into the mouse fibrosarcoma cell line (A9), the mouse embryonic stem cell line (ES), the chicken pre-B lymphoid cell line (DT40), the human cervical tumor cell line (Hela), the human fibrosarcoma cell line (HT1080), and then cultured with or without selection. The intact or fragments of human chromosome 2, 11, 21 were lost at ~100 PDL, but chromosome 14 or the fragment were stably maintained at least at 100 PDL in all the cell lines examined. We also examined the retention of the human chromosome 14 fragment (~10Mb) in trans-chromosomal mice (F1 and F2), which were produced from ES cell line containing a human chromosome 14 fragment. Fluorescence in situ hybridization (FISH) analyses revealed that the single human chromosome 14 fragment was stably maintained at least in brain and liver tissues. FISH analyses using a human chromosome 14 centromere specific probe, mouse major and minor satellite specific probes confirmed that the human chromosome 14 fragment consisted of human centromere. Thus, some human chromosomes are stable in variable cell types, including tumor cells and mouse ES cells, and that some chromosome fragments can be also stably transmitted through germline. In future, the human chromosome 14 fragment may be useful for developing as a vector for gene delivery into mouse and human.

Program Nr: 2030 from the 1999 ASHG Annual Meeting

Numerical Chromosome Aberrations in Normal and Patient Cells Using PNA Probes by FISH. *K.L. Taneja[1], C. Whitney[2], E.A. Chavez[3], J. Coull[1], P. Newburger[2], P.L. Lansdorp[3].* 1) Boston Probes, Inc, Bedford, MA; 2) Department of Pediatrics, U. Mass. Med. School, Worcester, MA; 3) Terry Fox Laboratory, BC Cancer Research Center, Vancouver, Canada.

We have developed multicolor fluorescence in situ hybridization to detect and localize DNA repeat sequences within single cells. Telomeric and centromeric repeat sequences were detected in chromosomes of human metaphase spreads using PNA probes labeled with different fluorochromes. Using specific PNA probes for chromosome X, Y and 1, we could easily distinguish chromosomal aneuploidy and polyploidy by four color analysis in patient cells with known autosomal and sex chromosomal abnormalities. With specific PNA probes for chromosomes X, Y, 1, 2, 6, 10, 17 and 18, we performed a FISH analysis on different HL60 cell lines. Trisomy or tetrasomy of chromosome 18 was present in all cell lines, whereas tetrasomy of chromosomes 2, 6, 10 and 17 with two copies of X chromosome, as well as an extra copy of dicentric chromosome 1 was observed with two cell lines. Three cell lines showed one copy of X chromosome and two out of three cell lines showed trisomy of chromosome 6. The Y chromosome was not detected in any of the cell lines. These results demonstrated the usefulness of chromosome specific PNA probes in the analysis of numerical chromosomal abnormalities and highlight the difficulty in comparing results of all biological experiments with HL60 cells between laboratories.

Program Nr: 2031 from the 1999 ASHG Annual Meeting

Mosaicism for Angelman syndrome. *M. Tekin[1], C. Jackson-Cook[1], A. Buller[2], A. Ferreira-Gonzalez[2], A. Pandya[1], J. Bodurtha[1]*. 1) Dept of Human Genetics, Virginia Commonwealth Univ, Richmond, VA; 2) Dept of Pathology, Virginia Commonwealth Univ, Richmond, VA.

We present a 28-month-old Caucasian female with developmental delay, severe speech impairment,inappropriate happy demeanor, a wide-based gait, frequent ear infections with mild hearing loss, and distinctive facial features including deep-set eyes, a wide mouth and widely-spaced teeth. A FISH chromosome analysis, using probes D15Z1, D15S10, and SNRPN, revealed mosaicism for the presence of a structurally abnormal chromosome 15 that was characterized by a duplication of the centromeric region and loss of the proximal long arm [dic(15)(pter ® q11.1::p11.2 ®q11.1::q13® qter)]. The aberrant chromosome was present in 40% of peripheral blood lymphocytes and was inferred from interphase FISH studies to be present in 30% of buccal mucosa cells. Parental chromosome studies were within normal limits, indicating that the aberrant chromosome formed as a de novo event (as expected from the mosaicism). Methylation studies using PCR with sodium bisulfite treated DNA revealed a normal biparental methylation pattern. Although the patient's facial, behavioral, and neurological findings were suggestive of Angelman syndrome (AS), developmental delay seemed to be milder than that observed classically in this syndrome. She also currently does not have microcephaly and seizures, which have been noted in most patients with AS. Although rare, mosaicism has been reported for Prader-Willi syndrome (PWS). The clinical presentation of these cases ranged from classical PWS phenotype to atypical, but PWS-like features. To the best of our knowledge, this is the first case of Angelman syndrome with a FISH-detectable deletion in a mosaic pattern. We recommend FISH studies for the detection of mosaicism in patients with Angelman syndrome clinical findings, even if methylation analyses show a normal pattern.

Program Nr: 2032 from the 1999 ASHG Annual Meeting

A GIRL WITH CORNELIA DE LANGE SYNDROME PRESENTING A DE NOVO 1q41->qter TRISOMY REVEALED BY SPECTRAL KARYOTYPING (SKY). *L. Telvi*[1], *R. ION*[1], *G. PONSOT*[2]. 1) LABORATOIRE DE CYTOGENETIQUE, HOPITAL ST VINCENT DE PAUL, PARIS, FRANCE; 2) SERVICE DE NEUROPEDIATRIE, HOPITAL ST VINCENT DE PAUL, PARIS, FRANCE.

We describe a girl presenting Cornelia de Lange syndrome with characteristic face, short stature (-2SD), large thorax, hypoplastic thenar and feeding difficulties. The blood karyotype after RHG and high resolution banding showed the 46,XX,5q+; pattern, with an unknown trisomic material at the end of the long arm of the chromosome 5. The whole paint of chromosomes 5 and 3 labelled to digoxigenin (ONCOR) showed that the extra piece do not belong to these chromosomes. Spectral karyotyping (SKY) revealed that the extra piece on chromosome 5 originated from chromosome 1. This was confirmed by chromosome painting. The karyotype of the child is thus 46,XX,der(5)t(1;5)(q41;q35). The patient has partial trisomy of chromosome 1. These findings emphasize the importance of using advanced techniques as the Multicolor karyotype to characterize extra material in chromosomes. Recent attention has focused on 3q as the localisation of the Cornelia de Lange gene. Ireland et al. suggested that the critical region for the Cornelia de Lange syndrome is between 3q25.1 and 3q26.3. The reported case raises the question of the involvement of the 1q41->qter trisomy and the implicated breakpoints in the pathogenesis of this syndrome.

Program Nr: 2033 from the 1999 ASHG Annual Meeting

Low Grade Mosaicism for a Derivative Y with Partial 5q Trisomy in a Small Male. *J.H. Tepperberg[1], R.E. Schnur[2], P.R. Papenhasuen[2], I. Gadi[1], P.N. Mowrey[1], L. Howard[2]*. 1) Dept Cytogenetics, Laboratory Corp of America, Res Triangle Pk, NC; 2) Div Genetics, Cooper Hosp/UMC Benson St, 3rd Fl Camden, NJ.

Duplications of chromosome 5 distal long arm (q33->35) are associated with severe psychomotor retardation, intrauterine growth retardation, brachydactyly, microcephaly, and facial abnormalities. The patient had mild facial abnormalites. External genetalia appeared normal although the scrotum and testicals were small. LH and FSH levels were normal. Kidneys were normal. When last seen at 2 and 1/2 years he demonstrated normal cognitive and motor development.Cytogenetic analysis of a 1 year old male referred for developmental delay showed a 5,X[48]/46,X,der(Y) t(Y;5)(p11.3;q33)[2]. The identification of the abnormal Y chromosome was confirmed by FISH, using a Y pericentromeric DNA probe. A multiprobe FISH device was used to show that the additional chromosome material was derive from chromosome 5. The 5q33->5qter origin was based on the G-banding and absence of a chromosome 5 unique sequence short arm FISH probe. PCR for the testis determining region (SRY) showed the presence of SRY. Additional FISH on a buccal smear is being evaluated to determine the percentage of mosaicism of the derivative Y in another tissue. Paternal chromosome analysis showed a normal 46,XY karyotype. Thus, this patient is partially trisomic for 5q and nullosomic for distal chromosome Y, in those containing the derivative Y chromosome.

Program Nr: 2034 from the 1999 ASHG Annual Meeting

Clinical application of PRINS as an alternative to FISH in the diagnosis of Prader Willi/Angelman and DiGeorge syndromes. *A.T. Tharapel, J.S. Kadandale.* Clinical and Molecular Cytogenetics Laboratory, Department of Pediatrics, University of Tennessee, Memphis, TN.

Diagnoses of Prader Willi/Angelman (PW/AS) and DiGeorge syndromes (DGCR) are facilitated by FISH with DNA probes spanning the critical region of the deletion. But a newly-developed methodology, primed in situ labeling (PRINS), can be adapted to the diagnosis of microdeletions. To demonstrate the utility of PRINS in the detection of microdeletions, we studied 3 patients each with PW and DGCR syndromes. Deletions in these patients were previously confirmed by FISH. Two normal individuals served as controls for each experiment. Oligonucleotide primers for SNRPN and GABRB3 for PW syndrome, and D22S1638 and D22S1648 for DGCR syndrome were synthesized locally. The reactions were performed separately with primers for the respective loci. Annealing and extension were done on chromosome preparations in the presence of labeled nucleotides and Taq DNA polymerase. For each patient, 50 metaphase spreads were analyzed under the fluorescence microscope. The 3 patients with PW syndrome showed absence of labeling (for SNRPN and GABRB3) on one chromosome 15 representing the deletion. Similarly, 3 patients with DGCR syndrome showed deletion for the D22S1638 and D22S1648 loci on one of the chromosomes 22. A normal pattern for all loci was obtained in controls. In view of its sensitivity, specificity and cost effectiveness, PRINS can thus serve as an alternative to FISH in the diagnosis of microdeletion syndromes.

Program Nr: 2035 from the 1999 ASHG Annual Meeting

Trisomy 10 mosaicism detected prenatally and confirmed in fetal tissues by interphase FISH. *D. Thibodeau, J. Bergoffen, B. Saxon, D. Sipos, K. Nguyen, S. Owen, L. Bros, X. Li.* Genetics Dept, Kaiser Permanente Medical Group, San Jose, CA.

Trisomy 10 mosaicism is a rare chromosome anomaly. Significant features in five liveborn cases include failure to thrive, dysmorphic facies, cardiopathy, and early death. We present a case of trisomy 10 mosaicism detected prenatally by amniocentesis and confirmed in various fetal tissues using interphase fluorescence in situ hybridization (FISH).

Genetic amniocentesis for maternal age 35 was performed at 13.7 weeks gestation by ultrasound dating. Two colonies from one in situ culture showed trisomy 10. The remaining 19 colonies in five cultures revealed a normal karyotype (46,XX). From a repeat amniocentesis, standard cytogenetic analysis of 25 colonies revealed a normal female karyotype. Analysis of a direct preparation of the amniotic fluid by interphase FISH using an alpha satellite DNA probe specific for chromosome 10 (Vysis, Inc.) showed trisomy 10 in 12% of cells. Fetal anatomy and interval growth were normal by serial ultrasound.

The pregnancy was terminated by D&E at 19.8 weeks gestation. No trisomy 10 cells were found in 75 metaphases analyzed from cultures (50 from kidney, 25 from heart). Interphase FISH analysis of these cultured cells revealed 12% and 0% trisomy 10 cells, respectively. Interphase FISH analysis of the direct preparations (touch prep) of 14 different fetal tissues showed the following proportions of trisomy 10 cells: kidney (23%), heart (27%), lung (12%), ovary (10%), fascia lata (9%), amnion (9%), umbilical cord (7%), muscle (6%), skin (1%), villi (1%), liver (0%), intestine (0%), rib (0%), and head soft tissues (0%). Pathology evaluation of highly fragmented products of conception failed to reveal any gross or microscopic abnormality.

Our findings indicate that the trisomy 10 cells might have been selectively lost due to a growth disadvantage in vitro. We highly recommend prenatal and postnatal interphase FISH on direct tissues for confirmation of fetal trisomy 10 or other mosaicism.

Program Nr: 2036 from the 1999 ASHG Annual Meeting

Trisomy 21 mosaicism in monozygotic twins discordant for Down syndrome. *H. Thiele[1], P. Wiegand[2], C. Baldermann[1], H. Schmidt[3], W. Knopp[4], I. Hansmann[1], U. Hehr[1].* 1) Humangenetik, Martin-Luther-Universität, Halle, Germany; 2) Rechtsmedizin, Martin-Luther-Universität, Halle, Germany; 3) Pathologie, Martin-Luther-Universität, Halle, Germany; 4) Kinderklinik, Weissenfels, Germany.

Monozygotic twins typically are equipped with identical sets of chromosomes and hence expected to present with similar phenotypic features. The few reported instances of discordance for monogenic conditions or chromosomal aberrations were attributed to incomplete penetrance, a wide phenotypic spectrum of the observed syndrome or to mosaicism. Here we present the clinical, cytogenetic and molecular data of monozygotic twins discordant for Down syndrome. At the age of 4 months the first twin presented with short stature, hypotonia and typical craniofacial features of Down syndrome, while here twin sister did not show any abnormalities. Repeated chromosome analysis from lymphocytes revealed for both twins an identical diagnosis: trisomy 21 was found in appr. 4-5% of all analyzed cells. This observation confirmed trisomy 21 mosaicism in both girls and suggested them to be monozygotic. By chromosome analysis from skin fibroblasts the phenotypically normal twin was found to have a normal karyotype in all analyzed cells while trisomy 21 was found in 14 of 21 cells of her affected twin sister. Reexamination of both girls at the age of 17 years confirmed the previously established clinical diagnosis. The impaired physical performance of the twin with Down syndrome was further restricted because of a complex cardiac malformation, she was unable to communicate by intelligible speech. In contrast, her twin sister presented both physically and mentally as a normal teenager. In addition, a psychological test at the age of 3.5 years had confirmed her mental abilities to be within normal range. Monozygosity was established using 16 informative marker from 12 chromosomes (>99.9% probability). Reevaluation of the chromosomes from lymphocytes again documented trisomy 21 mosaicism in the affected twin (1/100 cells) and her normal sister (2/100 cells). These twin sisters once more impressively demonstrate the wide phenotypic spectrum observed in probands with weak trisomy 21 mosaicism in blood cells.

Program Nr: 2037 from the 1999 ASHG Annual Meeting

A cytogenetic and clinical evaluation of a de novo duplication 7(q36.1®qter). *K.J. Thompson, G.S. Sekhon, D. Wargowski, H. Singh.* Dept Genetics, Univ Wisconsin, Madison, WI.

We report a 4-year-old with multiple anomalies caused by a de novo duplication of the long arm of chromosome 7. The patient exhibited developmental delay, hydrocephalus, cleft lip and palate. High resolution chromosome analysis of 75 lymphocyte metaphases revealed: 67% of cells with 46,XX,dup(7)(pter®q36.3::q36.1®qter) and 33% with a normal female karyotype. Fluorescent in-situ hybridization approaches, including use of regional specific cosmid probes, were used to confirm the chromosome 7q origin of the duplicated material. The possible mechanisms of formation of the duplication will be discussed.

Program Nr: 2038 from the 1999 ASHG Annual Meeting

Ring 4 chromosome in two sibs with abnormal growth pattern and apparently normal parents. *D.J. Tomkins[1], R. Couch[2], J. Chernos[3,4], J. Gerritsen[3], D.R. McLeod[3]*. 1) Dept Medical Genetics, Univ Alberta and Cytogenetics, UA Hospital, Edmonton, AB, Canada; 2) Dept Pediatrics, Univ Alberta and UA Hosp; 3) Dept Medical Genetics, Univ Calgary and Alberta Children's Hosp, Calgary, AB; 4) Cytogenetics, Alberta Children's Hosp.

A large ring chromosome 4 was found in a girl with a profound growth abnormality. She was karyotyped at age 1 year 9 months because of small size since birth and a question of Turner syndrome. All cells but one from a peripheral blood sample had the karyotype: 46,XX,r(4)(p16q35). One open duplicated ring was found out of 30 cells. At two years of age, her growth was well below the 3rd %ile for weight and height, but her endocrine studies and developmental milestones were normal. The same pattern of growth was recognized in a daughter born three years after the proband. Chromosomal analysis revealed the same ring 4 chromosome in 25 out of 31 metaphases with monosomy 4 in 3, monosomy 4 plus a marker in 2 and a duplicated ring in 1 cell. No ring was found in 30 cells from peripheral blood specimens from either parent or in fibroblast cultures from the mother; the father declined a skin biopsy. Gonadal mosaicism in a parent remains the most likely explanation for the recurrence of the ring 4. A general ring syndrome of severe growth retardation without major anomalies has been attributed to loss of cells with imbalances due to instability of rings (Côté *et al*., 1981). Two cases of ring 4 in children with severe growth retardation and mild dysmorphism were shown by FISH to have an intact 4pter (Pezzolo *et al*., 1993; Calabrese *et al*., 1997). This suggested that the growth retardation was due to the general ring syndrome; however, the 4qter region was not studied. The ring 4 in the present study was investigated by FISH with subtelomeric probes for 4p and 4q. The 4p subtelomeric region was intact but there was no 4qter fluorescent signal on the ring chromosome indicating a deletion within 400 kb of the telomere. This suggests that there may be a critical region for normal growth in the 4q subtelomeric region. Further molecular analysis is underway to determine the extent of the deletion in the 4qter region.

Program Nr: 2039 from the 1999 ASHG Annual Meeting

Evaluation of the chromosomal contents of micronuclei (MN) using spectral karyotyping (SKY) and FISH. *N. Tszine, C. Jackson-Cook.* Dept. of Human Genetics, Medical College of Virginia of Virginia Commonwealth University, Richmond VA.

DNA loss by the process of micronucleation is associated with aging, cancer and environmental exposure. The primary aim of this study was to identify the chromosomal content of the DNA being extruded into MN. This was achieved using our novel application of SKY and FISH technologies. To our knowledge, this study is the first to evaluate MN using SKY. Cytochalasin B (CytB) treated lymphocyte cultures from 3 females (ages 28,42 and 72) were analyzed. SKY revealed that the majority of MN (89.8%, 82.9%, 97.3% in the 28,42 and 72 year-old (y.o.), respectively) had a uniform, single color, suggesting that they were comprised of DNA from a single chromosome. Overall, the X chromosome was seen most frequently. However, a significant difference was noted (confirmed using FISH with a whole chromosome paitning probe (wcp) for the X chromosome) in its frequency among individuals (46.1% in the 42 y.o., 12.5% in the 28 y.o., and just 5% in the 72 y.o.). SKY also allowed for the identification of MN that contained autosomes. In fact, all 22 autosomes were observed to be excluded into MN in the 28 y.o. individual. Overall, the confirmation studies (using FISH with wcp) were in agreement with the SKY assignments for 73.5% of the MN. Studies are ongoing to identify refinements in the SKY procedure that will result in a higher accuracy level. The subset of MN with confirmed chromosomal contents showed no correlation between micronucleus size and the size of the chromosome it contained. Sequential staining of the same MN, using a pancentromeric probe, revealed 78.7% to have one signal. The frequency of MN was also compared between CytB treated and untreated cultures from these females. In 2/3 cases a significant difference in MN frequencies was observed ($p<0.001$ for the 28 y.o. and $p=0.019$ for the 72 y.o.). Collectively, these study results support the hypothesis that MN induced by CytB contain DNA from a single, monocentric chromosome (probably due to chromosome loss). The observed variation in response to the CytB treatment raises the possibility of individual-specific susceptibility to exogenous agents that potentially could influence chromosome segregation.

Program Nr: 2040 from the 1999 ASHG Annual Meeting

DNA Demethylation, Heterochromatin Decondensation, and Generation of Pericentromeric Rearrangements in Chromosomes 1 and 16 in B Cell Lines from Patients with the ICF Syndrome.. *C.M. Tuck-Muller[1], A. Narayan[2], F. Tsien[2], D. Smeets[3], E. Fiala[4], O. Soon[4], M. Ehrlich[2].* 1) Dept Medical Genetics, Univ South Alabama, Mobile, AL; 2) Human Genetics Program/Hayward Genetics Center, Tulane Univ Medical School, New Orleans, LA; 3) Human Genetics, Univ Hospital Nijmegen, Nijmegen, The Netherlands; 4) American Health Foundation, Valhalla, NY.

One of the diagnostic features of the rare, recessive ICF syndrome (immunodeficiency, centromeric region instability, facial anomalies) is rearrangements involving the juxtacentromeric heterochromatic regions of chromosomes 1 or 16 (1qh and 16qh) in mitogen-stimulated lymphocytes. ICF leukocytes display abnormal hypomethylation of satellite 2 DNA which is primarily located in 1qh and 16qh. We show that in B cell lines from two ICF patients the 1qh and 16qh regions are frequently rearranged while satellite 2 DNA hypomethylation characteristic of in vivo-derived ICF cells is maintained. These rearrangements include multibranched chromosomes with 3-6 chromosome arms observed in up to 22% of the metaphases, whole-arm deletions, and pericentromeric translocations, as seen in mitogen-stimulated T cells from ICF patients. An even higher percentage of the cultured ICF B cells display decondensation in the normally highly condensed 1qh and 16qh regions. Telomere associations, not previously reported in ICF syndrome, were seen in up to 14% of cells. Fusions between 1qh or 16qh and telomeric regions of other chromosomes were also observed. We propose that ICF-specific DNA hypomethylation predisposes the heterochromatin of chromosomes 1 and 16 to decondensation, which in turn, leads to rearrangements targeted specifically to these hypomethylated regions. We also demonstrate by high performance liquid chromatography of digests of DNA from ICF autopsy tissue, as well as of ICF B cell lines, that the extent of overall hypomethylation of genomic DNA in ICF is much less than that of satellite 2 DNA. Therefore, ICF, the only human genetic disease known to involve Mendelian inheritance of a DNA methylation anomaly, has hypomethylation restricted to only a portion of the genome.

Program Nr: 2041 from the 1999 ASHG Annual Meeting

A hierarchical approach of chromosome analysis employing multiplex-FISH, multicolor bar codes, and locus specific hybridizations in pre- and postnatal diagnostic applications. *S. Uhrig[1], S. Schuffenhauer[2], C. Fauth[1], A. Wirtz[2], J. Kraus[1], C. Daumer-Haas[3], M. Cohen[4], C. Apacik[4], T. Cremer[1], J. Murken[2], M.R. Speicher[1]*. 1) LMU-Munich, Institute of Human Genetics, Munich, Germany; 2) Abteilung Medizinische Genetik der Kinderpoliklinik der Universitt Mnchen, Munich, Germany; 3) Prnatal-Medizin, Lachnerstr. 20, Munich, Germany; 4) Kinderzentrum Mnchen, Heiglhofstr. 63, Munich, Germany.

A hierarchical approach of chromosome analysis is presented. The first step in this approach is the application of multiplex-FISH (M-FISH) which allows to identify the twenty-four different human chromosomes in a metaphase spread based on different colors. This initial M-FISH experiment determines the appropriate subsequent step or steps to take. These steps can include a variety of different techniques, such as CGH, reverse painting, locus specific hybridization or multicolor-chromosome-specific-bar-codes. With this hierarchical approach we have already analyzed more than 150 cases. Our experiences with the first 120 cases will be published shortly (Uhrig et al. Am J Hum Genet, in press). Here we will focus on additional cases. Specifically, the potential of M-FISH to characterize the origin of euchromatin in supernumerary marker chromosomes occurring in only 10% of amniotic fluid cells was shown in two cases where the euchromatin was derived from chromosome 22 or 19. In addition, we show examples, in which M-FISH found abnormalities not visible by GTG-banding alone. One of these cases involved a mosaic deletion of chromosome 11q. However, M-FISH revealed that the "normal" cells had in fact a cryptic translocation t(11;13). In our ongoing study in which M-FISH is used to screen metaphase spreads defined as normal by G-Banding in patients with a phenotype highly suggestive for a chromosomal syndrome we can add two new cases in which M-FISH identified unbalanced translocations. Overall, in this patient group we identified rearrangements in about 10%. M-FISH and chromosome-specific-bar-codes improve cytogenetic analysis and therefore should contribute to a better phenotype-genotype correlation and improve genetic counseling.

Program Nr: 2042 from the 1999 ASHG Annual Meeting

Molecular mechanism and consequence of intrachromosomal triplication of proximal 15q. *P. Ungaro, S.L. Christian, J. Fantes, D.H. Ledbetter.* Dept. of Human Genetics, University of Chicago, Chicago Illinois.

Deficiencies of paternal or maternal contributions of chromosome 15q11-q13 due to deletion or uniparental disomy are known mechanisms for Prader-Willi syndrome (PWS) and Angelman syndrome (AS). In the present study we describe the molecular characterization of the 15q11-13 region in four patients with severe mental retardation and some features similar to PWS or AS. Fluorescence in situ hybridization (FISH) was performed using BACs or PACs identified with STSs for D15S18, *UBE3A*, D15S1019, D15S165 and D15S144. In all four patients three copies of 15q11-q13 were identified on one homolog. In three of them the triplicated region involved the most proximal breakpoint (BP1) and a distal breakpoint that lies between D15S1019 and D15S165. In all patients the triplication appears to have the same normal-inverted-normal orientation. Microsatellite analysis was performed to establish the parental origin of the triplication. Results show that in three cases the triplication is derived from a maternal unequal recombination event and in the fourth from a paternal one. To determine how the triplication affects the methylation status, exon alpha of the SNRPN gene was analyzed by M-PCR. The patient that received the triplicated allele from the father shows a paternal product three times more intense than the maternal one, while the others, who inherited the triplication from the mother, have a maternal product approximately three times more intense than the paternal one. In addition expression of the SNRPN gene was analyzed by northern blot and was found to be concordant with the inheritance of the triplication, i.e. SNRPN expression in the patient that inherited the triplication from the father is three times higher than normal controls and the patients with a maternal triplication. In conclusion, our data indicate that both the methylation pattern and SNRPN expression show a dose-dependent increase that correlates with the parental origin of the triplication. The mechanism involved in the origin of the triplication remains to be clarified, however the orientation (N-I-N) of the triplication in all our patients suggests a common mechanism of rearrangement.

Program Nr: 2043 from the 1999 ASHG Annual Meeting

Interphase FISH analysis of the PLP gene in Pelizaeus-Merzbacher disease. *G.H. Vance[1], O. Henegariu[2], V.C. Thurston[1], L. Sendi[1], S. Dlouhy[1], J.A. Trofatter[3], M.E. Hodes[1].* 1) Dept Med & Molec Genetics, Indiana Univ, Indianapolis, IN; 2) Dept of Genetics, Yale University, New Haven, CT; 3) Dept Psychiatry, Indiana Univ, Indianapolis, IN.

The proteolipid protein gene, PLP, encodes the major protein of myelin of the central nervous system. Duplications of the PLP gene have been observed in patients with Pelizaeus-Merzbacher disease (PMD), an X-linked neurodegenerative disease. Duplication analysis of five affected males and their carrier mothers has been reported using dual-color probes of both the PLP gene and alpha satellite region of the X chromosome[1]. In contrast to this published report, we have established two-color interphase FISH analysis for the PLP gene duplication in our cytogenetic laboratory with a cosmid for Xq rather than an X alpha satellite probe. The PLP probe, cosmid 350.1 was labeled with digoxigenin and a 40 kb cosmid, cos 9, was labeled with biotin. Both probes were hybridized to slides with fixed cells of established lymphoblastoid cell lines from 32 PMD family members (7 females and 25 males). One hundred nuclei for each sample were scored on a grid comparing the number of green (1-2) with the number of red (1-4) signals. Duplication mutations were detected in 44% of these individuals. Four females were duplication carriers and 10 affected males were carriers. It is now clear that PLP gene duplication is a significant mutation in the etiology of Pelizaeus-Merzbacher disease.

[1] Woodward K, Kendall E, Vetrie D, Malcolm S. Pelizaeus-Merzbacher Disease: Identification of Xq22 Proteolipid-Protein Duplications and Characterization of Breakpoints by Interphase FISH. Am J Hum Genet 63:207-217, l998.

Program Nr: 2044 from the 1999 ASHG Annual Meeting

A rare dicentric chromosome 22 variant detected during prenatal diagnosis in three unrelated pregnancies. *V. Velissariou[1], A. Hatzipouliou[1], S. Christopoulou[1], J. Donohue[1], K. Bakou[1], M.B. Petersen[1], P. Grigori[2], E. Lyberatou[2].* 1) Dept of Genetics and Molecular Biology, "Mitera" Maternity Hospital, Athens, Greece; 2) Dept of Genetics, "Alexandra" Hospital, Athens, Greece.

A chromosome 22 with extra chromosomal material in region 22q11 was detected in three different, unrelated pregnancies during prenatal diagnosis. The extra genetic material was shown to be a tandem duplication of the centromeric region and the satellites, using conventional cytogenetic techniques and FISH analysis. The variant chromosome 22 was inherited in all three cases from one of the parents and was not associated with any clinical abnormality.

Program Nr: 2045 from the 1999 ASHG Annual Meeting

Screening for chromosome abnormalities in spermatozoa from infertile men in a clinical setting. *F. Vidal[1], J. Blanco[1], M.C. Rubio[2], B. Aran[3], S. Egozcue[1], R. Alcolea[4], C. Simn[2], A. Veiga[3], Y. Mnguez[2], J. Remoh[2], A. Pellicer[2], P.N. Barri[3], J.M. Vendrell[3], S. Marina[4], J. Egozcue[1]*. 1) Cell Biology, Univ Autonoma de Barcelona, Barcelona, Spain; 2) IVI, Valencia,Spain; 3) Institut Dexeus, Barcelona, Spain; 4) CEFER, Barcelona, Spain.

Since the use of fluorescent in situ hybridization (FISH) techniques in decondensed sperm nuclei, several groups have undertaken the study of aneuploidy and diploidy levels in spermatozoa from infertile men. From june 1996, spermatozoa FISH analysis in infertile men showing moderate to extremely impaired semen parameters, most of them referred as ICSI candidates, have been incorporated as an adjunct to the standard genetic screening suggested in these patients. In this paper we report our results in a series of 57 patients studied during this period. Sperm samples from 5 normal fertile donors served as a control group. In all cases, semen parameters were evaluated and ejaculated spermatozoa were collected and fixed for FISH analysis. Disomy and diploidy frequencies, using triple color FISH with centromeric DNA probes for chromosomes X, Y and 18 and dual color FISH with locus specific probes for chromosomes 13 and 21, have been evaluated. Our results are in concordance with previous reports from series including lower number of patients and significantly higher incidence of sex chromosome disomy and of diploid spermatozoa were observed in the infertile patients. Furthermore, infertile patients have been delineated into specific subgroups according to their semen parameters. Patients with severe oligoasthenoteratozoospermia reflected higher disomy and diploidy frequencies. Detailed results obtained in each subgroup will be presented and discussed. Our results confirm that FISH studies to estimate aneuploidy an diploidy levels in human sperm seem to be indicated in ICSI candidates and that this approach is feasible in a clinical setting.

Program Nr: 2046 from the 1999 ASHG Annual Meeting

Familial case of inversion in chromosome 7 with break-point within alphoid DNA in child with mesodermal displasia, ectrodactyly and growth deficiency: Is it an example of position effect variegation in man? *S.G. Vorsanova[1], Y.B. Yurov[1,2], A.D. Kolotii[1], E.S. Useinova[1], V.V. Monachov[2], M.S. Strachova[1], A.A. Tcheburkin[1]*. 1) Molecular Cytogenetics, Institute of Pediatrics, Moscow, Russia; 2) National Centre of Mental Health,RAMS, Moscow, Russia.

Familial case of chromosomal inversion (inv(7)(p11q21.1) was analyzed by conventional cytogenetic and molecular-cytogenetic methods. Inversion segregated from phenotypically normal father to his daughter and son. Boy has severe phenotypic abnormalities, including mesodermal dysplasia, ectrodactyly, growth and sexual development retardation, chicken breast, osteoporosis, gothic oral ark, short neck, deformations of ears, whereas his sister was healthy. Clinical picture in affected boy is similar to atypical form of EEC syndrome (MIM 129810). The breakpoints was detected by GTG and FISH using centromeric alphoid DNA probe and site-specific PAC probes from the short and long arm of the chromosome 7. One break-point was situated in alphoid DNA from the long arm distal of active centromere, and second at 7q21.1 in region of the locus of EEC syndrome. Therefore, alpha-satellite DNA was presented in two separate blocks-one is situated around the active centromere at the region of primary construction and second - in the short arm. New disposition of heterochromatic DNA leads to unusual junctions of euchromatic DNA from both short and long arm with alphoid satellite DNA. Variable phenotypic appearance in three individuals with inv7 could be, probably, related with variable expression of the genes, which are located near heterochromatic DNA. This familial case of inversion with break-points within heterochromatin and variable phenotypic appearance could be explained by phenomenon of position effect variegation, which is not yet discovered in man. Supported in parts by Russian Human Genome Program.

Program Nr: 2047 from the 1999 ASHG Annual Meeting

Clinical applications of PRINS: evaluation of X-Y interchange and AZF deletion in an azoospermic male. *S.S. Wachtel[1], J.S. Kadandale[2], R.S. Wilroy[3], Y. Tunca[2], P.R. Martens[3], A.T. Tharapel[2]*. 1) Reproductive Genetics Laboratory, Dept Obstetrics & Gynecology, Univ Tennessee, Memphis, TN; 2) Clinical and Molecular Cytogenetics Laboratory, Depts Obstetrics & Gynecology and Pediatrics, Univ Tennessee, Memphis, TN; 3) Dept Pediatrics, Univ Tennessee, Memphis, TN.

Nearly 15% of azoospermic men have microdeletions in Yq. Atypical cases involve 45,X/46,XY mosaics with a nonfluorescent Y chromosome. We used primed in situ labeling (PRINS) to delineate a chromosomal rearrangement in an azoospermic male with a mosaic karyotype and an Xp;Yp translocation. The patient was a 27-year-old man referred for infertility. Examination revealed standard height (172.2 cm) and unremarkable external genitalia; the testes were normal-appearing and soft. The karyotype in blood lymphocytes was 45,X/46,der(X)t(Xp;Yp),+mar (<10% of cells were 45,X). Translocation was ascertained by FISH with dual color X and Y paint probes, and confirmed by PRINS with locus-specific primers. By use of FISH, several individual loci were identified on the X chromosome, including STS, DMD, DXZ1, AR, XIST and subtelomeric Xp and Xq. On the Y chromosome, AMELY, DYZ3, DYZ1 and subtelomeric Yp were identified, but subtelomeric Yq was not. Yq contains AZF (azoospermia factor), a region of 4-5 Mb subsuming the RRM (RNA recognition motif) gene family, implicated in normal spermatogenesis. Using PRINS, we identified SRY on Xp and noted absence of two genes in the AZF region: RRM1 and RRM2. Our results confirm (i) X-Y interchange and (ii) deletion within the Yq-situated AZF region. The karyotype was accordingly redesignated: 45,X/46,t(X;Y)(p22.3;p11.2),del(Y)(q11.2). We infer that PRINS, combining features of FISH and PCR, is a valuable diagnostic tool with potential applications in the study of unusual chromosome rearrangements such as the one described here.

Program Nr: 2048 from the 1999 ASHG Annual Meeting

A familial interstitial deletion of 21q. It is possible for a recessive gene responsible for mental retardation to exist within 21q11-21. *K. Wakui[1], T. Kubota[1], E. Hidaka[2], M. Ishikawa[2], T. Katsuyama[2], Y. Fukushima[1]*. 1) Dept Hygiene & Med Genetics, Shinshu Univ Sch Medicine, Matsumoto, Japan; 2) Dept Lab Med, Shinshu Univ Sch Medicine, Matsumoto, Japan.

We report a family including a mother of normal intelligence and two children with mild mental retardation. All these family members had the same interstitial deletion of 21q11.2-q21.3. A four-year-old first daughter of the couple experienced deafness, strabismus and mild mental retardation. As the mother had suffered from rubella during pregnancy, the daughter had been thought to have congenital rubella syndrome. However, chromosome analysis revealed that she had an interstitial deletion of 21q. Parental karyotyping showed that the mother also had the same deletion of 21q. The mother was phenotypically and mentally normal. Any extra signals were not observed on her other chromosomes by FISH analysis using whole chromosome painting 21 probe. A one-year-old second daughter was healthy, mentally normal and had normal karyotype. The first son had been diagnosed as having 21q monosomy by prenatal diagnosis. But the parents wanted to continue the pregnancy, and the mother was delivered of him at 39 weeks gestation. His birth weight was 2900 g. He had no deafness or malformations, but developmental delay was noticed at 4 months. High resolution chromosome analysis revealed that these three members had the same deletion of 21q, and the breakpoints were 21q11.2 and 21q21.3. The extension of the cytogenetically visible deletion of these three members was defined by analyzing those genomic DNA with highly polymorphic DNA markers located on the proximal region of 21q (cen-D21S215-D21S1433-CHLC.GATA22H11-D21S1435-D21S1442-D21S261-D21S1909-D21S1898-D21S1920-D21S1921-CHLC.GATA45C03-D21S1444-tel). Molecular analysis with these markers demonstrated that these three members had the same deletion of 21q. The proximal breakpoint of the deletion was located between D21S215 and D21S1433 and the distal breakpoint was located between D21S1442 and D21S261. These clinical and molecular findings suggest that it is possible for a recessive gene responsible for mental retardation to exist within 21q11-21.

Program Nr: 2049 from the 1999 ASHG Annual Meeting

Chromosomal abnormalities in autism. *T.H. Wassink[1], J. Piven[1], V.C. Sheffield[2], S.E. Folstein[3], J.L. Haines[4], S.R. Patil[2]*. 1) Department of Psychiatry, University of Iowa Hospitals and Clinics, Iowa City, IA; 2) Department of Pediatrics, University of Iowa Hospitals and Clinics, Iowa; 3) Department of Psychiatry, New England Medical Center, Boston, MA; 4) Program in Human Genetics, Vanderbilt University Medical Center, Nashville, TN.

A wide range of chromosomal abnormalities have been reported in subjects with autism. The estimated frequency of such abnormalities varies from 1 to 15%. We report here our series of cytogenetic examinations of subjects with autism, and a related examination of micro-deletions and duplications on the 15q11.2-q13 region. From 1989 to 1999, there were 898 subjects diagnosed with autism through the University of Iowa Child and Adolescent Psychiatry Clinic. Of these, 264 (29%) were referred for cytogenetic analyses. Referrals were not controlled, but rather were based on clinical judgement. Of subjects who were referred for cytogenetics, 25 (9.6%) had an identifiable cytogenetic abnormality. The most common abnormality was fragile X, found in 6 subjects (2.3%). Five subjects (1.9%) had some other form of sex chromosome abnormality, and the remaining 14 (5.3%) had an autosomal abnormality. Of these, 2 had Trisomy 21 (0.8%), and 5 (1.9%) had an abnormality involving the 15q11.2-q13 region. Because of the prevalence of the chromosome 15 abnormalities, and the broader interest in 15q11.2-q13 in autism, we also examined 12 polymorphic markers spanning this region in 49 autism trios, looking for deletions and duplications of parental alleles in the offspring. Approximately 8% of the trios were found to have such abnormalities, the most common being duplication of maternal alleles. Taken together, these data may help to focus the search for autism disease genes, and provide further support for 15q11.2-q13 as a region of interest in autism.

Program Nr: 2050 from the 1999 ASHG Annual Meeting

Interstitial 1p deletion in an infant arising from a unique paternal karyotype. *L.M. Welter-Dahl, J. Ahmad, S. Herath, J.L. Andeweg, T. Barnhart, M. Engel, C.A. Curtis, R.R. Higgins.* Allina Cytogenetics Laboratory, Abbott Northwestern Hospital, Minneapolis, MN.

Cytogenetic studies were requested on a one day-old infant to rule out Down syndrome. Phenotypic findings of the newborn included: unusual eyes, prominent palmar creases, prominent nasal bridge, long creased ears, and hypospadias. Chromosome analysis revealed a 46,XY karyotype with an interstitial deletion in one chromosome 1 involving G-band region 1p11-1p13.3 [46,XY,del(1)(p11p13.3)]. Both parents are phenotypically normal. Parental cytogenetic studies were subsequently done. The mother's karyotype is 46,XX. The father has a mosaic karyotype with two cell-lines: one male cell-line [4 cells] with the deleted chromosome 1 previously identified in the child and a second male cell-line [16 cells] with the deleted chromosome 1 as well as a small ring-shaped chromosome. FISH analysis using a chromosome 1-specific painting probe established that the ring chromosome originates from chromosome 1. The ring chromosome also stains weakly positive following CBL-staining. We speculate that the r(1) chromosome contains the DNA sequences 1p11-1p13.3 that are absent in the del(1), resulting in a paternal karyotype of mos 47,XY,del(1)(p11p13.3), +r(1)(p11p13.3)[16]/46,XY,del(1)(p11p13.3)[4]. Such chromosome rearrangements are very rare and this appears to be the first such case involving the 1p arm.

Program Nr: 2051 from the 1999 ASHG Annual Meeting

Molecular cytogenetic identification and characterization of marker and derivative chromosomes. *G.D. Wenger, A. Thomas, J. Labanowska.* Laboratory Medicine, Children's Hosp, Columbus, OH.

Identification of the origin of additional genetic material in marker and derivative chromosomes is of importance for clinical management and establishment of karyotype-phenotype correlations. We have used a variety of molecular cytogenetic techniques and reagents to identify and characterize marker and derivative chromosomes identified by high resolution cytogenetic analysis, including a satellite probes, unique sequence probes including subtelomeric probes, whole chromosome paints, Cytocell Multiprobe (Rainbow Scientific) devices, and comparative genomic hybridization (CGH). In each case, the additional material was not readily identified by GTG-banding analysis, but was fully identified by molecular cytogenetic techniques. We have examined 10 cases with derivative chromosomes, including 3 *de novo* cases and one in which the supernumerary derivative chromosome is apparently the result of 3:1 segregation. Three cases were found to have duplication of sequences within the same chromosome; CGH was successful in evaluating the duplicated material in 2 of these. Supernumerary marker chromosomes were identified in 6 cases, each with 1-3 markers and all apparently *de novo*. These include one case with a small marker of cs 15 origin and uniparental disomy for cs 15 resulting in diagnosis of Prader-Willi syndrome, and one case with an asymmetrical bisatellited cs 22 marker for which investigation of the marker was conducted in buccal smears and hair follicles as well as peripheral blood. The ease of identification of the additional material varied with the size and nature of the material; CGH was limited in sensitivity and resolution. These strategies are particularly important in characterization of *de novo* rearrangements, or in cases in which study of both parental karyotypes is not possible. These studies indicate that careful choice of molecular cytogenetic reagents and techniques, applied in a systematic fashion, provides efficient characterization of subtle chromosome aberrations, the results of which can aid in clinical management and contribute to the cytogenetic/clinical genetics literature in terms of karyotype-phenotype correlations.

Program Nr: 2052 from the 1999 ASHG Annual Meeting

Partial trisomy 16q in a full term infant, mosaic for an unbalanced translocation, der(19)t(16;19)(q13;q13). *H.E. Wyandt, X.L. Huang, J.M. Milunsky.* Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA.

A 2.935 kg infant with ambiguous genitalia and multiple congenital abnormalities was delivered, by cesarean section, to a 36-y-o Hispanic female. Family history was non-contributory. The pregnancy was complicated by oligohydramnios and a small-for-gestational-age fetus. Apgars were 3, 7 and 8 at 1, 5 and 10 min, respectively. An echocardiogram showed PDA and mild isthmic hypoplasia. Weight was in the 40th, length in the 10th and head circumference in the 75th percentiles. Anomalies included low-set, posteriorly rotated ears with over-folded helices, broad nasal bridge, epicanthal folds, high-arched palate, short, webbed neck, barrel chest with wide-spaced nipples, bifid scrotum, small phallus and 4th-degree hypospadius. Extremities, especially the feet, showed lymphedema. Fingers were tapered with hyperconvex nails and contractures of PIP joints. Fifth finger clinodactyly was present. The feet were small with increased distance between the first and second toes. The infant had hypotonia and probelms sucking and feeding. BAERS revealed moderate hearing loss. Study of peripheral blood revealed 70% of cells with a translocation between chromosomes 16 and 19, with telomeric loss only from the terminal band of 19q and parital trisomy for most of 16q(q13-qter), confirmed by chromosome painting. Thirty percent of of cells had a normal male karyotype. Maternal chromosomes were normal; father was not available. A comparison is made of the findings in our patient with those reported.

Program Nr: 2053 from the 1999 ASHG Annual Meeting

Evidence of a locus for cardiac development on mouse chromosome 13C3.4-D1.5. *K.L. Wydner[1], J. Zhang[2], T. Williams[2], D. Sciorra[1], L.J. Sciorra[1]*. 1) Dept OB/GYN, Diagnostic Genetics, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 2) Dept. Molecular, Cellular, & Developmental Biology, Yale University, New Haven, CT.

Normal development requires a series of finely orchestrated processes in which intact genetic information plays a critical role in determining cell viability, function, and fate. Transcription factors are important in the regulation of cellular gene expression, operating at specific target sequences or in regions of promotors and enhancers. Interruption of normal transcription factor activity can result in aberrant development or lead to disease. Using a 40 kb portion of the human transcription factor AP-2a gene fused to a 3.8kb lac Z reporter, a transgenic mouse strain was generated by pronucleus injection of fertilized mouse eggs. Random integration of the transgene resulted in an altered cardiac phenotype in the transgenic mice. Expression of the lac Z was observed in early developing heart tissue (E8.0 - E11.0 mouse embryos) in addition to where the endogenous AP-2a is expressed (trigeminal ganglia, limb buds, and facial mesenchyme). To aid in the discovery of gene(s) involved in the generation of this phenotype, we performed FISH on high resolution metaphase chromosomes prepared from transgenic mouse embryo fibroblasts. Utilizing a digoxigenin-labelled 13 kb genomic probe and conventional FISH methods, the site of the AP-2a transgene was localized to the 13C3.4-D1.5 region of DAPI banded mouse chromosomes. Interestingly, dual color FISH experiments with a biotinylated mouse cosmid probe Tcfap2 (Warren et al., Genomics, 1996) confirmed the assignment of the transgene to mouse chromosome 13 clearly below the 13A5-B1 location of the endogenous sequence. The non-endogenous localization of the transgene suggests 13C3.4-D1.5 is a cytogenetic location of mouse sequences which somehow influence cardiac development. Physical mapping of the transgene sequence to this region of mouse chromosome 13 in these mutant animals provides the groundwork for future studies to clone and ultimatley identify the sequence(s) of gene(s) involved in the creation of the aberrant phenotype.

Program Nr: 2054 from the 1999 ASHG Annual Meeting

Direct duplication of 4p14p15.31. *J. Xu[1,2], V. Freeman[1,2], M.J.M. Nowaczyk[1,2,3].* 1) Department of Pathology & Molecular Medicine, McMaster University, Hamilton; 2) Hamilton Regional laboratory Medicine Program, Hamilton; 3) Department of Pediatrics, McMaster University, Hamilton.

Delineation of a cytogenetic duplication and its associated clinical features has potential in physical mapping of phenotype, understanding gene dosage effect, or identifying genes interrupted by the breakpoints. We report a de novo direct tandem duplication of 4p14->p15.31 in a boy with congenital anomalies. The boy was born at full term following an uncomplicated pregnancy to a 34-year old G7P5SA1. At six months of age he was referred for genetic investigation because of poor growth, hypotonia, and developmental delay. On physical examination at 10 months, his weight was at the 3rd centile. He had mild dysmorphic facial features, including deep set eyes, bitemporal narrowing, small, beak-like nose, and thin and sparse scalp hair. There was hypoplasia of terminal phalanges of fingers, fifth finger clinodactyly, ulnar deviation of hands.

Chromosome analysis showed the presence of a duplication in the proximal short arm of chromosome 4:46,XY,dup(4)(p14p15.31). This duplication is confirmed to consist of only chromosome 4 material using whole chromosome painting. Parental chromosomes were apparently normal.

Approximately 40 cases of duplication 4p have been reported. Most of these cases are mixed duplication/deletion derived from translocations and involve the distal half of 4p. Main features of 4p duplication patients include large and low-set ears, microcephaly, a prominent glabella, a bulbous nose, growth deficiency, severe mental retardation, seizures, scoliosis and 5th finger clinodactyly.

To our knowledge, this is the first case of "pure" trisomy of 4p14->p15.31. Clinical follow-up of our patient and a further molecular characterization of the breakpoints involved should shed light on the developmental effect of the duplicated genes in this region.

Program Nr: 2055 from the 1999 ASHG Annual Meeting

A novel 21p+ chromosome with duplication of Down syndrome critical region in the amniotic fluid cells of a second trimester pregnancy. *A.K. Yenamandra[1], L. Trinchitella[1], G. Haberman[1], R. Perrone[1], C. McKenna[2], M. Bialer[2], P. Koduru[1]*. 1) Dept. Path/Lab Cell Genetics; 2) Dept. Pediatrics/ Div. Human Genetics, North Shore Univ. Hospital, 300 Community Drive, Manhasset, NY 11030.

The majority of Down syndrome cases are due to complete trisomy of chromosome 21 or the long arm (q) of 21. Much less frequently it is caused by partial trisomy 21 resulting from a duplication which is associated with certain features of Down syndrome phenotypes, with the region 21q22.13-22.2 having prominent influence. These infants will have the typical manifestations like hypotonia, brachycephaly, flat facial profile, upslanting palpebral fissures, epicanthal folds, protruding tongue, redundant nuchal skin, fifth finger clinodactyly, and abnormal palmar creases. We report on a second trimester female fetus detected at 21.5 weeks gestation with bilateral ventriculomegaly. Cytogenetic analysis of amniotic fluid cells revealed an abnormal karyotype of 46,XX, 21p+. The 21p+ chromosome had a very large p arm and had a different banding pattern than the q arm. This region was negative with C-banding and silver stain. Chromosome analysis of PHA stimulated blood from both parents revealed normal karyotypes. Therefore, the 21p+ chromosome was considered as a de novo event. Chromosome 21 specific painting fluorescence probe WCP 21 (Vysis Inc.) completely painted this chromosome indicating that the additional material on the 'p' arm was derived from a partial duplication of the long arm. This was confirmed by hybridization with a Down syndrome critical region FISH probe LSI 21 (Vysis Inc.) which showed two pairs of distinct signals one on either side of the centromere in the 21p+ chromosome and only one pair of signals in the normal 21 homologue. These results suggest that the fetus is trisomic for Down syndrome region. A fetal echocardiogram revealed two small VSD's. A comprehensive fetal ultrasonographic study was recommended to rule out additional clinical features. Parents were counseled about Down syndrome and were informed that hydrocephalus is not seen at increased incidence in Down syndrome. The couple decided to continue the pregnancy which is currently in progress.

Program Nr: 2056 from the 1999 ASHG Annual Meeting

Molecular and FISH analysis of a chromosome 8p duplication syndrome case study. *J.H. Youngblom, G. Helbig, J.J. Youngblom.* Biology Dept., California State University-Stanislaus, Turlock, CA.

We present a new case involving a 4-year-old girl with an inverted duplication of chromosome 8p. The clinical presentation of this syndrome is variable in patients due to differences in the duplicated and deleted regions. However, consistent features in all reported cases include severe mental retardation and speech disorder. Some patients, as in this case, also have autism. Fluorescence in situ hybridization (FISH) analysis was conducted on this patient to ascertain the specific regions involved in the duplication and deletion. This process is essential for all individuals with the syndrome in order to identify the common critical region associated with the classical symptoms of the disorder. PCR was used to generate a biotin labeled DNA probe representing the tip of chromosome 8p23.1-.3. Results of the FISH analysis using this probe showed that the patient has a partial duplication of this region. The duplicated segments are not situated tandemly, but are separated by a small non-labeled region. The proximal segment is smaller than the distal segment. The distal segment appears to be of normal size, indicating that any deletion at the terminal end must be quite small. Additionally, the probe had a high homology to the centromeric regions on chromosome 1, and to a lesser extent chromosome 7. This observation was also noted in the control sample. To delineate the region of the terminal deletion on the chromosome, we used a polymorphic dinucleotide repeat marker, designated D8S201. This marker is one of the most terminal markers on the 8p chromosome available to date and has been mapped to 8p23.2. DNA isolated from cheek samples donated by the mother, father, and the patient were used to amplify this region by PCR. The PCR products were run on a 6% denaturing polyacrylamide gel. Each of the parents was heterozygous for different alleles. The child unequivocally showed the presence of both alleles, one from each parent, thereby indicating that the deletion is distal to the 8p23.2 region. This finding is in contrast to virtually all other reported cases of this condition, which have shown the deleted segment includes the 8p23.2 region.

Program Nr: 2057 from the 1999 ASHG Annual Meeting

Double chromosome abnormalities-- mosaic monosomy 13 and extra marker iso(22q) in a new born. *C.W. Yu[1], H-G. Bock[1], M. LeBlanc[2], R.E. Shenefelt[3]*. 1) Dept. of Preventive Medicine; 2) Dept. of Pediatrics; 3) Dept. of Pathology, Univ. of Mississippi Medical Ctr., Jackson.

Patient BGM was a 37 week new born to a 40 year old G6P5 black female. The birth weight was 2,325g, birth length 49cm, and head circumference 34.5cm. Mother had PIH, polyhydramnios, and non-reactive NST during pregnancy. Patient was admitted to hospital due to congenital anomalies and failure to thrive. Physical examination showed a soft and flat fontanelle, opacity of the right eye, epicanthal fold, small nose, smooth and flat philtrum, micrognathia, bilateral ear tag, preauricular pits, and widely spaced nipples.

Cytogenetic analysis was performed from 72 hour PHA stimulated peripheral blood cultures. GTG banding demonstrated that all cells had a small, extra bisatellited marker chromosome. Four of the fifty metaphases examined also had monosomy 13. FISH studies using alpha-satellite DNA probes and unique sequence DNA probes confirmed the marker chromosome was a bisatellited, dicentric isochromosome 22 with breakpoint at 22q11.2, containing the DiGeorge syndrome/ velocardiofacial syndrome (DGS/VCFS) region. Patient expired at the age of 22 days. Postmortem tissue from heart, lungs, kidneys, and skin all had the marker chromosome. Parental blood chromosome studies were normal.

The presence of three or four copies of proximal 22q11.2, including at least the locus D22S57, is the most common molecular finding of cat-eye syndrome (CES). Our patient had mild features of CES which may be attributed to the presence of a monosomy 13 cell line. FISH studies indicate this marker has a breakpoint distal to locus TUPLE1, possibly including locus D22S941. A region of overlap on 22q11.2 for genes responsible for CES and DGS/VCFS suggests the presence of dosage sensitive genes in this interval.

.

Program Nr: 2058 from the 1999 ASHG Annual Meeting

Tourette syndrome in two brothers with balanced and unbalanced chromosome 12 rearrangements. *J. Yu[1], X. Guan[2], B. Pober[1], T. Yang-Feng[1]*. 1) Genetics Dept, Yale Univ Sch Medicine, New Haven, CT; 2) Hong Kong University, Hong Kong.

A 9 year old boy was referred for genetics evaluation because of minor dysmorphic features and developmental delay. Medical problems included: recurrent otitis media, strabismus, mild motor and speech delays and Tourette syndrome (TS) diagnosed at age 5 years requiring treatment with Tenex. Pertinent physical findings were: low set ears, narrow palate and mild joint hyperextensibility. Family history was remarkable for a 4 year old brother with tics considered probable TS. Parents, brother and a sister are all developmentally normal; there is no family history of TS. Cytogenetic study on the proband revealed an increased size of band 12q15. Paternal karyotype was normal while maternal karyotype demonstrated a balanced intrachromosomal insertion [ins(12)(q15p12p11.2)] which was also present in the brother and sister. The proband thus appeared to have a duplication of 12p11.2-p12 inserted into band 12q15, possibly resulting from crossing over between the maternal normal and rearranged chromosomes 12. The proband's karyotype is designated as: 46,XX,rec(12)dup(12)(p11.2p12)ins(12)(q15p12 p11.2)mat. These findings were further confirmed by FISH using a chromosome 12 painting probe and the microdissected probe spanning breakage/reunion breakpoints in 12q15 of maternal ins(12). Both the proband and his brother have TS, however, the rearranged 12 is unbalanced in the proband but apparently balanced in his brother. Of further interest is that 2 female family members carry the presumably same balanced ins(12) but have no evidence of TS. TS has been considered a sex-influenced autosomal dominant disorder as 3/4 patients are male; multiple disease loci appear possible. This family suggests a link between TS and chromosome 12 particularly in the regions of insertion breakpoints, although coincidental occurrence of these two findings cannot be excluded. Additional phenotypic abnormalities in the proband are likely associated with the duplication of the 12p11.2-p12 region.

Program Nr: 2059 from the 1999 ASHG Annual Meeting

Direct evidences for skewed X-chromosome inactivation at Rett syndrome by combination of FISH and BrdU+Hoechst staining techniques. *Y.B Yurov[1,2], S.G. Vorsanova[1,2], A.D. Kolotii[2], V.O. Sharonin[1,2], I.V. Soloviev[1].* 1) National Centre of Mental Health, RAMS, Moscow, Russia; 2) Institute of Pediatrics and Children Surgery MH, Moscow, Russia.

Rett syndrome (RS) is a developmental disorder, affecting girls. The aetiology of RS is unknown, but genetic factors are important. RS is commonly thought of as an X linked dominant disorder lethal to hemizygous males. However, at present time its biological and genetic basis remains obscure. There is one remarkable finding in cytogenetic studies of RS, indicating on specific alterations in replication pattern of inactive X chromosome in girls with RS. X inactivation is thought to be a random process with 50%:50% ratio for maternal and paternal chromosomes X. However, for some X-linked disorders, non-random X-inactivation could take place leading to completely skewing of X-inactivation and selection against cells in which the mutant gene is on the active X chromosome. We have performed cytogenetic studies to establish that skewed X inactivation could take place at RS. In preliminary FISH studies using centromeric alphoid DNA probe we have detected three RS girls from 20 studied with heteromorphism of homologous chromosomes X on amount of alphoid DNA. This phenomenon allows us to clearly differentiate maternal and paternal X-chromosomes by FISH in metaphase cells of these girls. Step-wise application of BrdU + Hoechst staining to identify early (active) and late (inactive) replicating chromosomes X and FISH technique to clearly differentiate two homologous chromosomes X allows directly determine the origin of inactive chromosome X. We have detected non-random X-inactivation in RS patients with preferential inactivation of one X chromosome over the other X chromosome in 100% of cells of two RS girls and 70% cells of the third girl. Therefore, RS similarly to X-linked diseases, could be characterized by skewed X inactivation with variable penetrance in peripheral blood cells. Supported in parts by INTAS and IRSA grants.

Program Nr: 2060 from the 1999 ASHG Annual Meeting

Prenatal Diagnosis of Trisomy 4 Mosaicism. *A. Zaslav[1], D. Blumenthal[2], J. Willner[3], G. Pierno[4], J. Fox[2].* 1) Dept. of Pathology, Long Island Jewish Medical Center, The Long Island Campus of The Albert Einstein College of Medicine, New Hyde Park, NY; 2) Dept. of Pediatrics Schneiders Childrens Hospital, The Long Island Campus of The Albert Einstein College of Medicine, New Hyde Park, NY; 3) Dept. of Human Genetics, Mount Sinai School of Medicine, New York, NY; 4) Sonoscan Genetic Sciences, Forest Hills, NY.

Trisomy 4 mosaicism is rare. We present a prenatally diagnosed case of trisomy 4 mosaicism. Amniocentesis was performed for AMA. The karyotype was 47,XY,+4[3]/46,XY[33]. Trisomy 4 was found in three cells from two different vessels, indicating true mosaicism. A high-resolution US and fetal echo were performed at 23 wk and neither revealed abnormalities. The infant was delivered at 37 wk. Apgar scores were 9 and 9 at 1 and 5 min. The infant had a normal examination. Chromosome analysis of 150 cells from cord and peripheral blood, foreskin and umbilical cord revealed 46,XY in all cells. There was no evidence of trisomy 4. Only 2 prenatally diagnosed cases of mosaic trisomy 4 have been reported. One resulted in a live born male who was developmentally and physically normal at one year. Normal cells were found in PUBS and foreskin (Hsu, et al., 1997, Prenat Diag 17:201). The other resulted in an abnormal live born female with multiple congenital anomalies, but no significant developmental delay at one year (Marion, et al., 1990, Am J Med Genet 37:362). PUBS and peripheral blood were normal. Trisomy 4 was found in placental and bilateral forearm biopsies. The absence of trisomy 4 cells postnatally in our patient indicates that the trisomy 4 mosaicism was most likely placental. Prenatally diagnosed chromosome mosaicism presents a diagnostic dilemma for both patient and clinician. This is only the third report of trisomy 4 mosaicism. Additional cases of prenatally diagnosed mosaicism for rare trisomies are necessary to accurately access the significance of these findings.

Program Nr: 2061 from the 1999 ASHG Annual Meeting

High throughput mapping of Cri du Chat deletions on 5p using comparative genomic hybridization to DNA microarrays. *X. Zhang[1], R. Segraves[1], L. Bolund[2], H.M. Yang[2], E. Niebuhr[3], J. Gray[1], D. Albertson[1], D. Pinkel[1]*. 1) Cancer Center, UCSF, San Francisco, CA; 2) Inst. of Human Genetics,Aauhus University, Danmark; 3) Medical Genetics, University of Copenhagen, Copenhagen, Denark.

Cri du Chat is caused by 5p deletions, with the detailed phenotype dependent on the deleted region. High resolution mapping of the deletions will permit localization of genes that may be associated with the phenotype. We have developed a microarray form of comparative genomic hybridization, array CGH, that permits reliable detection of these deletions. The array elements consist of genomic BAC and P1 clones, each containing a mapped STS or EST, spaced at approximately 1 Mb intervals along 5p. A higher density of elements was used for the established critical area at 5p15.2, as well as at 5p13. Hybridization employed 400 ng each of specimen and normal reference genomic DNA labeled with fluorescein and Alexa 568 respectively. Fluorescence data for each fluorochrome was obtained from the entire array in a few seconds using a custom designed CCD imaging system. Illumination was supplied by a mercury arc lamp. Fluorescence ratios for diploid targets were 1.0 +/- 0.07 while ratios on deleted clones were 0.55 +/- 0.05 (mean +/- s.d.). This measurement precision is expected to permit recognition of deletions with false positive and negative rates below one in several thousand. One clone was found to have a ratio of 0.75 when included in some deletions. FISH mapping showed that this clone hybridized to two locations on chromosome 5p, indicating its probable duplication in the normal genome. Thus copy number of this clone decreased from 4 to 3 copies in the deletions. Array CGH analysis of 91 Cri du Chat cases will be presented. The measurement precision obtained in this work indicates that arrays containing clones that map to established loci involved in deletion/duplication syndromes plus clones at regular intervals throughout the genome could be used to provide a rapid high resolutions diagnostic capability for constitutional aberrations. Work supported by NICHD RO1 HD 17665 and Vysis Inc. ±±±±±±±.

Program Nr: 2062 from the 1999 ASHG Annual Meeting

Telomere-telomere fusion of chromosomes 7 and 22 with an interstitial deletion of chromosome 7p11.2-p15.1: phenotypic consequences and possible mechanisms. *S.M. Zneimer, S.D. Stewart.* Cytogenetics Laboratory, SmithKline Beecham Clinical Laboratories, Van Nuys, CA.

We report a rare, if not unique, case of a telomere-telomere fusion of chromosomes 7 and 22 as well as an interstitial deletion of chromosome 7p11.2p15.1 in a newborn with congenital anomalies. This newborn presented for chromosome analysis with bilateral cataracts, distal limb abnormalities and renal dysmorphogenesis. Chromosome analysis showed 45,XY,-7,der(22)psudic(7;22)(p22;p13)del(7)(p11.2p15.1)[20]. This short arm to short arm fusion of chromosomes 7 and 22 results in a psuedodicentric chromosome. C-banding confirms the presence of 2 centromeres with the active centromere derived from chromosome 22. In addition, the chromosome also appears to have a deletion of chromatin from bands p11.2 to p15.1. Parental blood chromosome analysis revealed normal karyotypes. Fluorescence in situ hybridization studies are underway to better characterize this complex rearrangement. Loss of genetic material in this region of chromosome 7p has been implicated in the pathophysiology of craniosynostosis syndromes, cephalosyndactyly syndrome and ocular manifestation syndrome. Given the number of reports in the literature describing syndromes associated with deletions in chromosome 7p, this region of the genome may be predisposed to deletions/duplications due to misalignment of conserved homologous sequences. It is also a region involving at least 3 different syndromes described, suggesting contiguous genes with microdeletion syndromes. The few reports in the literature describing telomere fusions have been associated with a neoplastic process. There is a paucity of information describing telomere fusions which are constitutional in origin, let alone in combination with an interstitial deletion causing clinical consequences. Telomere fusions have been shown to be a part of chromosome replication by the formation of "hairpin" 5' to 3' covalent binding, and since telomeres contain repeated short base pair sequences, it is possible to fuse two telomeres with a lack of fidelity and loose DNA sequences in the process causing deletions near the telomeres.

Program Nr: 2063 from the 1999 ASHG Annual Meeting

Clinical diagnostic criteria for Wolf-Hirschhorn syndrome. *M. Zollino[1], C. Di Stefano[1], G. Zampino[2], L. Bortotto[3], T.J. Wright[4], M.R. Altherr[5], G. Neri[1].* 1) Genetica Medica, Univ Cattolica, Rome, Italy; 2) Istituto di Pediatria, Univ Cattolica, Rome Italy; 3) Ospedale S.M.M., Udine, Italy; 4) Dept.of Neurobiology and Anatomy, Univ of Utah, Salt Lake City, UT; 5) Genomics group,Life Sciences Division, Los Alamos Natl Lab, Los Alamos.

Eighteen Wolf-Hirschhorn syndrome (WHS) patients have been comparatively evaluated for their clinical phenotypes and their respective genotypes. In eleven patients a 4 pter deletion, with proximal breakpoint varying from p15.1 to p16.1, was detected by conventional chromosome analysis. In five patients a microdeletion, whose size varied from 4.4 to 2.8 Mb, was detected by molecular probes only. In two unrelated patients the microdeletion was associated with a large 4p duplication. The last two patients had no deletions in an interval of about 500 kb spanning the WHS critical region (WHSCR). We found that genotype-phenotype correlations in WHS mostly depend on the extent of the deletion. We identified three clinical categories. 1)Patients harboring a large deletion usually presented with a severe phenotype, including markedly delayed psychomotor and physical growth, microcephaly (11/11), congenital heart defects (9/11), midline defects (9/11), renal abnormalities (5/11) and seizures(10/11). 2)Patients harboring a microdeletion of 4.4-3.2 Mb presented with a milder phenotype, usually lacking congenital malformations, with less severe developmental delay, but microcephaly still present. 3) The patient harboring the smallest microdeletion (2.8 Mb) and both nondeleted patients had a very mild expression of the disease: the head circumference was normal, congenital malformations were absent, mental and growth retardation was of a mild degree. If we look at WHS as a contiguous genes syndrome, the clinical manifestations observed in the nondeleted patients are likely to represent the "basic" phenotype of this condition, consisting of typical facial appearance, mild mental retardation, slight congenital hypotonia and mild growth retardation. Nondeleted patients presenting with a "basic" phenotype are extremely important in a general strategy for the identification of the gene(s) responsible for the WHS.

Program Nr: 2064 from the 1999 ASHG Annual Meeting

The efficiency of prenatal diagnosing of congenital malformations (CMs)in Belarus. *G.I. Lazjuk.* Dept Monitoring for Cong Malfo, Inst Hereditary Disease, Minsk, Republic of Belarus.

Under conditions existing in Belarus, congenital and inherited anomalies appeared to be the main cause of infants'diseases, disabilities and deaths. The main emphasis in prevention of the births of abnormal children in Belarus is laid on timely prenatal diagnosing(PD)with subsequent termination of pregnancy with incurable anomalies found in a fetus. Prenatal diagnosing is provided at 4 levels of medical care, at Maternal Counsellings(MC),Regional Medical Genetic Centers (RMGC), Belarus Medical Genetic Center(BMGC)and Belarus Institute for Hereditary Diseases. MC provide counsellings for 10,000 to 30,000 women. There, the blood is taken for prenatal biochemical screening and ultrasound screening of fetal condition is performed. RMGCs are available for the regions with the population of 1.3-1.5 million people. At RMGCs total ultrasound diagnosing of fetal condition and biochemical prenatal screening of the 2 nd trimester of pregnancy are performed. BMGC provides service for the residents of Minsk-city and Minsk region (3.3 million people) and all the patients, sent by RMGCs because they need more specific genetic examination. Various medical genetic examinations, practiced in Belarus, are provided at BMGC. Using all PD examinations in 1997 the anomalies were found in 512 fetuses, in 1998 the anomalies were recorded in 532 fetuses, that is 24.7% and 22.5% of all congenital malformations, registered by National Register, respectively. Of these anomalies, in 73% of cases congenital malformations were recognized before 22 weeks of gestation. Of PD methods, ultrasound diagnosing is found the most efficient at the populational level. Using ultrasonography more than 80% of all prenatally diagnosed CMs were revealed in Belarus. Invasive methods account for 23% of primary or confirming diagnoses. In 80% of prenatally diagnosed CMs, the women have their pregnancies terminated. When the anomaly is recognized after 22 weeks of gestation, only 50% of pregnancies are terminated. Practically all pregnancies with prenatally diagnosed chromosomal diseases are terminated. Each year about 480 pregnancies are terminated in Belarus because of diagnosed congenital anomalies.

Program Nr: 2065 from the 1999 ASHG Annual Meeting

Effects of BPA and OP on protamine-2 and P450 family gene expression of spermatogenesis in mice. *H.J. Lee[1], M.K. Kim[2], D.S. Ko[2], S.W. Han[2], D.H. Kim[2], H.G. Kang[2].* 1) Dept. of Physiology, Eulji Medical Science Instutite, Eulji Medical College, Seoul, Korea; 2) Eulji Medical Science Institute, Eulji Medical College, Seoul, Korea.

Recently, there are reported several factors, such as hormone, cytokines, transcription factors, others, which is affected on spermatogenesis. This study was done to investigate effects of endocrine disruptors (Eds) like as bisphenol-A (BPA) and 4-tert-Octyphenol (OP) on gene expression of spermatogenesis and to clarify the aromatase changes in testicular cells according to stages of testis when testicular cells were cultured with BPA and OP. Spermatogenic cells of mice were cultured for 3 days treated with 0.001-10 uM of BPA, OP and E2 as control group. To detect the gene expression of spermatogenesis in each group, gene expression of LDH-C4, p450 family were demonstrated by amplification of spermatogenic cells RNA by RT-PCR. This results shows that BPA and OP (0.1-10 uM) inhibited expression of protamine-2, CYP17 in spermatogenic cell for 3 day culture and also, expression of protamine-2 was inhibited in control group (E2). That is, BPA and OP were observed similar to functions like estrogenic effects on spermatogenesis. However, LDH-C4 were not inhibited in spermatogenesis and CYP11A1 which catalyses the first step in steroid hormone biosynthesis were expressed in all groups. As a result, normal spermiogenesis was inhibited in groups of E2 and BPA and OP treatment. In conclusion, it is suggested that phenolics Eds like as BPA and OP could have inhibitory effects of sperm maturation, especially spermiogenesis which is premeiotic process, in spermatogenesis.

Program Nr: 2066 from the 1999 ASHG Annual Meeting

Extensive survey of unexpected short limbs detected by fetal ultrasound screening.. *M. Le Merrer[1], M. Roubin[1], J. Amiel[1], P. Sonigo[2], N. Gigarel[1], V. Cormier Daire[1], P. Maroteaux[1], A. Muunich[1]*. 1) Genetique INSERM U 393, Hopital Necker, Paris, France; 2) Infantile radiology, hopital Necker, Paris, France.

The ultrasound measurement of femoral lenth is usually performed in France during the second and third trimesters of pregnancy. The aim of this study is to estimate itssensivity for detection of chondrodysplasias without familial history and its consequences for management of the pregnancy and delivery. From march 1996 to may 1999, a series of 149 pregnant women were refered for isolated short limbs (- 3 rd percentile) detected between 24th and 32rd weeks of pregnancy. In all cases fetal ultrasound measurements, in utero radiographies (performed around 28th weeks of pregnancy), fetal karyotype and FGFR3 mutation screening for achondroplasia were obtained and a tentative diagnosis with information on prognosis was given to parents in all cases. Post natal follow up revealed that : 1- A total of 42% of the newborns were normal with no features of chondrodysplasias regardless of antenatal growth 2- Non lethal chondrodysplasias were present in 45% of the newborns, essentially when prenatal short femora was noted during the second part of the pregnancy. Achondroplasia represented half of these cases (24%). Lethal chondrodysplasia was exceptional in our series as it was detected earlier than the 24 th week of pregnancy and interrupted . 3 - A total of 10% of newborns showed multiple malformations syndromes, not detected by ultrasound examination. 4- Finally, in 40 % of the cases, termination of pregnancy was decided by the informed parents according to the current legislation. The feasability and the reliability of the prenatal detection of chondrodysplasias by ultasound examination will be analysed . The possible factors associated to the decision to continue or terminate a pregnancy in which a chondrodysplasia has been diagnosed are discussed.

Program Nr: 2067 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of X-linked ichthyosis by percutaneous umbilical blood sampling. *X. Li, H. Xiao, L. Li, G. Lu.*
Human Reprod Engineening Lab, Hunan Medical University, Changsha, Hunan, P. R. of China.

X-linked ichthyosis (XLI) is an inherited skin disorder caused by deficiency of steroid sulfatase (STS) activity and occurs in 1/2000-1/6000 males. The STS gene is located at Xp22.32. Over 90% of patients with XLI have large deletions of the STS gene. Prenatal diagnosis is considered to be an effective way to prevent the occurrence of this disease and has clinically been performed in this disease by FISH and metabolite or enzyme. We report a successful prenatal diagnosis of XLI by molecular genetic method. A 30-year old woman came to our clinic at the 27th week gestation for genetic counseling of XLI because she had previously delivered a male affected by XLI who was diagnosed by dermatologists according his typical ichthyotic skin. The boy except with XLI suffered from severe physical and mental dysgenesis and died of physical exhaustion at two years old. The pedigree showed six male relatives with XLI, but no one of six was with physical and mental dysgenesis. By percutaneous umbilical blood sampling (PUBS) we obtained fetal blood cells to prepare chromosome and genomic DNA. Chromosome analysis showed a karyotype 46,XY. PCR with primers for SRY confirmed that the fetus was male. In order to investigate for STS gene deletion we used two sets of primers (Ballabio A, Hum Genet 1990, 84:571) to examine the 5'- and 3'-regions of STS by means of PCR in several members of this family (the fetus, the pregnant woman , one of six relatives with XLI, who is the nephew of the pregnant woman and the patient's mother who is the pregnant woman's sister) and normal controls. The product of amplification of the 3'-region of STS in the pregnant woman's nephew wiht XLI was displayed by agarose gel electrophoresis, but no product of the 5'-region was seen. Two amplified products were seen in the fetus and all of others on agarose gel. Our result demonstrated that this male fetus had not deletion in 5'- or 3'-region of STS gene and chromosomal abnormality. The gestation was suggested to continue and a normal boy was born at the 40th week gestation. To our knowledge our report is the first case of prenatal diagnosis of XLI by PCR in the gene level.

Program Nr: 2068 from the 1999 ASHG Annual Meeting

DGAP: Developmental Genome Anatomy Project. *A.H. Ligon[1,5], G.A.P. Bruns[3,5], J.F. Gusella[2,5], B.R. Korf[3,5], R.L. Maas[4,5], M.E. MacDonald[2,5], A.M. Michelson[4,5], B.J. Quade[1,5], C.C. Morton[1,5].* 1) Depts. of OB/GYN & Pathology, Brigham & Women's Hospital, Boston, MA; 2) Dept. of Neurogenetics, Mass. General Hospital, Charlestown, MA; 3) Dept. of Pediatrics, Children's Hospital, Boston, MA; 4) Dept. of Medicine, Brigham & Women's Hospital, Boston, MA; 5) Harvard Medical School, Boston, MA.

DGAP has been established to identify genes critical in human development that are disrupted or dysregulated by balanced chromosomal rearrangements in patients with multiple congenital anomalies. These anomalies occur in approximately 3-4% of all livebirths, and can include clinically recognizable syndromes or isolated defects such as cleft palate/lip, limb defects, cardiac defects or mental retardation. Chromosomal abnormalities occur in 0.8% of liveborns, with ~50% showing an abnormal phenotype. Numerous structural chromosomal abnormalities have been reported as *de novo* in children with congenital developmental defects; a significant number of the breaks may disrupt or dysregulate genes critical to specific molecular pathways. We are collecting samples from patients with congenital anomalies and apparently balanced chromosomal rearrangements to use the breakpoints as signposts to locate critical genes. The potential of DGAP is enhanced by rapidly evolving genomic resources such as the complete human DNA sequence and an ordered FISH BAC map of the human genome. Collaborations between cytogeneticists and clinical geneticists have been formed to collect patient samples that reflect a variety of developmental defects. FISH analysis of chromosomal breakpoints will identify genomic clones containing candidate sequences. Molecular analysis of candidate genes will be the focus of subsequent studies, followed by expression analyses and isolation of orthologs in mice and *Drosophila*. Ultimately, transgenic and knockout animals will be used to study specific clones and to elucidate their roles in development. DGAP is a multi-laboratory, multi-institutional approach drawing on clinical genetics, cytogenetics, molecular biology and developmental genetics to illuminate genes involved in fundamental pathways of human development.

Program Nr: 2069 from the 1999 ASHG Annual Meeting

Comparison of Prenatal Ultrasound for Fetal Anomalies and Pathological Findings. *C. Llanusa, M. Gutierrez, J. Oliva, R. Sanchez, L. Carrillo, A. Nodarse, L. Rodriguez, I. Fundora.* Genetic, Gonzalez Coro Hospital, Havana City, Cuba.

The National Program for the Diagnosis and Prevention of Genetic Disease began in Cuba in 1984. This program includes the prenatal diagnosis of fetal malformations by maternal serum AFP screening at 15-19 weeks and fetal ultrasound at 22-24 weeks. Abnormal findings are followed by genetic counseling and the option of voluntary termination of the pregnancy. Gonzalez Coro and Clodomira Acosta hospitals are two neighboring maternity hospitals in Havana City where fetal ultrasounds are performed as part of the program. Between 1992-1996 the pathology department examined 220 malformed fetuses, stillbirths and/or neonatal deaths. Of these, 186 were pregnancy terminations because of abnormal ultrasound findings. One case was a stillbirth with anencephaly that had been diagnosed by ultrasound but opted to continue the pregnancy. The remaining 33 were cases in which ultrasound had failed to detect fetal anomalies, and the outcome was spontaneous stillbirth or neonatal death. The most common pathology diagnosis in the group of pregnancy terminations were neural tube defects (47), hydrocephalus and other CNS malformations (24), heart defects (24), ventral wall defects (18), renal anomalies (14), fetal edema (9) and MCA (7). The pathology diagnosis in this group coincided with the gestational ultrasound, although the former diagnosed additional anomalies not previously detected in 5 of the 7 cases of MCA. In the group of 33 malformed stillbirths and /or neonatal deaths in which ultrasound had failed to detect anomalies, the most common malformations found on pathology examination were MCA (7), renal anomalies (4), pulmonary hypoplasia (4) and heart defects (3). Overall, ultrasound detected 85% of anomalies. The proportion of correct prenatal ultrasound diagnosis by category was: neural tube defects 95.9%, ventral wall defects 94.7%, hydrocephalus other CNS malformations 88.8%, heart defects 88.8%, renal anomalies 77.7% and MCA 50%.

Program Nr: 2070 from the 1999 ASHG Annual Meeting

Elevated maternal serum alphafetoprotein in VACTERL-Hydrocephalus. *K.M. MacDonald[1,2], B.N. Chodirker[1,2], J.A. Evans[1,2]*. 1) University of Manitoba, Winnipeg, MB; 2) Children's Hospital, Winnipeg, MB, Canada.

Genetic counseling after a diagnosis of fetal hydrocephalus is problematic given the heterogeneous nature of the defect and the uncertainty of the prognosis. We report a male infant in whom hydrocephalus was identified during investigation of elevated MSAFP and who was found at birth to have VACTERL-H.

The mother of the proband was a 27-year-old G1P0 Canadian Aboriginal woman with well controlled Type II diabetes whose MSAFP at 19 weeks gestation was 2.6 mom. Fetal assessment revealed a disproportionately large head (75th centile) compared to femur length and abdominal circumference (both 5th centile) and lack of intracranial landmarks other than the falx. Amniotic fluid analysis showed elevated AFAFP (2.6 mom) but was gel negative for acetylcholinesterase. Karyotype was 46,XY. Follow up evaluations indicated increasing head size with only a thin rim of cortical mantle. Amniotic fluid volume remained normal. The infant was born at 35 weeks weighing 2840g (75th-90th centile) and with a head circumference of 46.9cm (>>95th centile). Additional anomalies suggesting VACTERL-H were cervical and sacral vertebral anomalies, tracheoesophageal fistula with esophageal atresia, renal dysplasia, thin distally placed thumbs, microphthalmia and micrognathia. MRI showed aqueductal stenosis. No increase in spontaneous or induced chromosome breakage was demonstrated on repeat chromosome analysis.

Although hydrocephalus has been observed with otherwise unexplained elevations of MSAFP (Burton, 1988), levels in pregnancies with VACTERL-H have rarely been reported. However, two infants in our series of cases with esophageal atresia (Chodirker et. al., 1994) had this diagnosis. Both had MSAFP levels at 1.6 mom and neither had polyhydramnios. Thus the mechanism of above normal AFP in this group may relate more to esophageal atresia than hydrocephalus. The diagnosis of VACTERL-H should be considered especially when apparently isolated fetal hydrocephalus is detected in women with high MSAFP, given that the diagnosis of esophageal atresia in the absence of polyhydramnios is difficult.

Program Nr: 2071 from the 1999 ASHG Annual Meeting

Nuchal Translucency Measurement in Twin Pregnancy. *J.N. Macri[1], D.A. Krantz[1], T.W. Hallahan[1], J.W. Larsen, Jr.[2], P.D. Buchanan[3], F. Orlandi[4], C. Rossi[4], L. Dugoff[5]*. 1) NTD Laboratories, Huntington Station, NY; 2) The George Washington Univ. Medical Center,Washington, D.C; 3) GeneCare Medical Genetics Center, Chapel Hill, N.C; 4) Centro Di Diagnosi Prenatale, Palermo Italy; 5) Univ. of Colorado, Denver Co.

Maternal factors have been used to adjust biochemical marker levels when screening for Down syndrome and open neural tube defects. To date, no maternal factors have been identified which effect nuchal translucency (NT) measurements. If the NT measurement of each fetus in a twin pregnancy tended to be similar, this might indicate that there are as yet unidentified maternal factors that effect NT values. A total of 32 first-trimester clinically normal twin pregnancies between gestational ages 10w4d and 13w6d in which NT was measured in both fetuses were analyzed. Using an analysis of variance procedure, data were analyzed to determine whether there was greater variation in NT measurements from woman-to-woman than between the twin fetuses in each pregnancy. Since NT increases with crown rump length data were analyzed using NT MoM results. The variance within the twin pairs was 42% of the variance among the twin pregnancies (.0651 vs. .1533). This was a significant difference (p=.009). To rule out operator variation as a cause of these results, a subset of 13 cases were analyzed in which the same operator performed all of the measurements. In this subset, the variance within the pairs was still less than the variance among the twin pregnancies (.0652 vs. .1065), however, this difference was not statistically significant. In conclusion, the data indicate that the 2 NT values in twin pregnancies tend to be associated although the association is not as strong when the measurement is performed by a single operator. This information suggests the possibility that maternal factors may affect the degree of nuchal translucency in the fetus.

Program Nr: 2072 from the 1999 ASHG Annual Meeting

ES Cell Neural Differentiation Reveals a Substantial Number of Novel Neural ESTs. *F.C. Mansergh, M.A. Wride, J. Hance, G. Bain, D.E. Rancourt.* Dept Biochem + Mol Biol, U. of Calgary, Calgary, Alberta, Canada.

We have developed methods for differentiating murine embryonic stem (ES) cells into functional neurons and glia in culture. ES-neural differentiation recapitulates the expression of neural markers in vivo and can generate large cell populations undergoing synchronous neural differentiation. We have therefore utilized this process to isolate novel genes expressed during early neurogenesis. Using a subtractive hybridization approach, we have isolated approximately 1200 cDNA clones expressed early in neural differentiation. Of 690 clones screened by single-pass sequencing, to date, 198 (27%) had no high level matches when analysed using BLAST and were therefore deemed novel. An additional 30 clones (4%) matched uncharacterized sequences. 131 (19%) matched genes that functioned predominantly in neural tissue, neural development or general developmental processes. 6% were involved in cell migration and proliferation, or cell cycle control. 24% represented housekeeping genes, while the remainder matched genes that were either incompletely characterized, or derived from non neural tissues. Pilot expression studies involving the first 10 clones identified 4 unique sequences that are expressed during neural development. RNase protection assays and whole mount in situ hybridization have revealed that 3 of these genes are preferentially expressed in the embryonic CNS. This system has the potential to identify genes which not only establish the embryonic nervous system, but also correlate with the over 800 chromosomal breakpoints and mapped or linked loci associated with congenital neurological handicaps and disorders in mankind. Given the recent discovery of human ES cells, this system also has great potential in neural drug discovery and cytotherapeutics.

Program Nr: 2073 from the 1999 ASHG Annual Meeting

Prenatally identified 47,XX,+8/47,XX,+14 karyotype. *J. Matheson[1], J. Santolaya[1], T. Nguyen[1], W. Jao[1], M. Freidine[1,2], M. McCorquodale[2]*. 1) Dept Ob/Gyn, Univ of Illinois, Chicago, IL; 2) Michael Reese Hospital, Chicago, IL.

A woman presented at 22 weeks gestation for evaluation of multiple fetal anomalies. Serial ultrasound evaluations revealed hypertelorism, dilated cisterna magna, micrognathia, cleft palate, VSD, ASD, omphalocele, bilateral renal pelvis dilatation, clenched fingers, clubfeet and increased amniotic fluid. Metaphase analysis of amniotic fluid cells revealed 47,XX,+8/47,XX,+14 mosaicism. At 42 weeks gestation, a 2600 g female infant was delivered and expired soon thereafter. In addition to previously identified anomalies, autopsy revealed low-set ears, absent gallbladder and double outlet right ventricle. Parental karyotypes were normal. Confirmatory FISH analyses were performed on different tissues.

Results of FISH studies in 100 cells/tissue for chroms 8 & 14

Tissue	Euploid	Tri 14	Tri 8	Tri8/Mono14
Blood	19	27	64	-
Skin	6	10	84	-
Placenta	20	64	10	6
Lung	9	3	66	20
Heart	31	65	3	-
Kidney	6	12	81	-

We propose the fetus was originally 46,XX and 2 separate cells underwent mitotic nondisjunction early in pregnancy leading to 3 independent cell lines. The differential survival of these cell lines may have improved the likelihood for viability until delivery.

Program Nr: 2074 from the 1999 ASHG Annual Meeting

Empirical validation of risk-based screening for Down Syndrome in Ontario. *C. Meier, AM. Summers, PR. Wyatt.* Genetics, North York General Hospital, Toronto, Ontario, Canada.

Since July 1993, triple marker maternal serum screening for Down syndrome in Ontario, Canada has been coordinated at the provincial level. As part of this coordination, all screening data is kept in a central repository, the Ontario Maternal Serum Screening Database (OMSSD), and is matched with pregnancy outcomes as they become available.

The database consists of the patient demographics, pregnancy details and results of over 400,000 screening tests. Triple marker screening involves combining a number of factors, including maternal age, race, diabetic status and the three biochemical markers (a fetoprotein, unconjugated estriol and chorionic gonadotrophin) to produce a single adjusted risk. Because of the relative complexity involved when computing these risks, the accuracy of the risk figures generated is not immediately obvious. One way in which the accuracy of the screening test can be determined is through **risk validation**, a process by which predicted risk is compared with actual disorder prevalence.

We used the OMSSD to categorize about 130,000 women who had received maternal serum screening in Ontario between October 1st, 1993 and September 30th, 1995 on the basis of their predicted risk for having a pregnancy affected by Down syndrome. We then compared the mean predicted risk in each risk category to the observed prevalence.

We found that the risk estimates generated closely matched the observed prevalence of Down syndrome, suggesting that the methodology used for screening here is accurate. We also evaluated the accuracy of other risk models.

Program Nr: 2075 from the 1999 ASHG Annual Meeting

Diagnostic dilemmas in prenatal identification of XX/XY mosaicism. *M.A. Micale[1], S.A.D. Ebrahim[2]*. 1) Dept Pathology, Medical Col Ohio, Toledo, OH; 2) Dept Pathology, Wayne State Univ, Detroit, MI.

Prenatal identification of a mosaic 46,XX/46,XY karyotype can be a counseling dilemma. Accepted practice for interpretation of such a karyotype, when ultrasound examination reveals a female fetus, would be that the XY cells might represent a sequestered or resorbed male twin. In the event that a male fetus is identified by ultrasound, the most likely explanation is maternal cell contamination (MCC). In addition, the presence of a chimeric fetal karyotype, while rare, cannot be excluded. We report two cases of sex chromosome mosaicism with unexpected outcomes, which demonstrate that the clinical significance of prenatally ascertained XX/XY mosaicism is not always straightforward. Case 1 is a woman referred for genetic counseling and amniocentesis because of multiple fetal anomalies. Cytogenetic examination demonstrated a 46,XX[14]/46,XY[6] karyotype while ultrasound revealed a fetus with female genitalia. Postnatal examination of cord blood and placenta revealed only XY with no evidence of XX cells in either tissue. Postmortem examination of the fetus revealed normal internal and external female genitalia. Thus the XX/XY fetal karyotype, originally believed to reflect a female fetus with a resorbed male twin, actually represented an XY female. Case 2 is a woman of advanced maternal age with a mosaic fetal karyotype 47,XY,+15[18]/46,XX[2]. The initial interpretation was a trisomy 15 male fetus, with the XX cells most likely representing MCC; however, ultrasound demonstrated a female fetus with no structural anomalies. A polymorphism on the short arm of chromosome 13 was shared in the XX and XY cells. Two percutaneous umbilical blood samplings (PUBS) revealed a 46,XX karyotype. Thus, the interpretation of these results in this ongoing pregnancy is a 46,XX fetus with a resorbed or sequestered male twin with trisomy 15. In addition, one of us (SADE) has previously reported a true chimeric XX/XY fetus. Based on these experiences, we suggest: 1) cautious interpretation of prenatally diagnosed XX/XY mosaicism even when ultrasound reveals the expected fetal sex and 2) confirmation of fetal sex by PUBS or postnatally by analysis of cord or peripheral blood.

Program Nr: 2076 from the 1999 ASHG Annual Meeting

b **Thalassemia mutation spectrum and prenatal diagnosis in Iranian population.** *H. Najmabadi[2], R. Karimi-nejad[1], S. Timorian[1], F. Pourfarzad[1], S. Homayounpour[1], A. Karimi-nejad[1], N. Lashkarian[1], N. Nabavi[1], T. Mohajerin[1], MH. Karimi-nejad[1]*. 1) Karimi-nejad Path & Genetic Center, Tehran, Iran; 2) Welfare & Rehabilitation University, Tehran, Iran.

Over 140 mutations have been determined for the b-globin gene. The mutation spectrum of bThalassemia in Iran is very heterogenous, and reflects east-west migration. Over a seven years period, we screened 873 individuals with bthalassemia minor and major for 20 common bglubin gene mutations by PCR ARMs analysis and nine RFLPs different systems were used. Because Iranians are a mixture of people from several Middle Eastern countries which have settled in different regions of Iran,we divided Iran into six regions to demonstrate the prevalence of different mutations in the North (N), Northwest (NW), Northeast (NE), Central (C), Southwest (SW), and Southeast (SE). A total of 313 families were screened,of which 33.4% were consanguineous marriages. Out of these consanguineously married couples,60.6% had the same mutation,31.2% were heterogenous for their mutations, and 8.2% were undetemined. Compared to the general population, homozygous couples were more common. Out of 179 amnion and CVs which were analyzed for prenatal diagnosis, 25.8% were affected, 44.5% had bthalassemia minor, and 23.3 % were normal for b globin gene. For 6.4% of the fetuses, we were only able to determine the condition of one chromosome. In conclusion we could detect only 70 to 85% of Iranian b thalassemia mutations and for the most of the remaining family RFLPs systems were informative. IVS II-I was the most common mutation in N, although it remained a common mutation throughout the country, it lessened in the east and IVS 1-5 became more common. As it is a prevalent mutation of Pakistan and India.

Program Nr: 2077 from the 1999 ASHG Annual Meeting

Mosaicism for trisomy 21 and sex chromosome monosomy (45,X/47,XX,+21) detected prenatally. *S.N. Palaniappan[1], A. Yearell[1], B. Bunke[1], M. Boschen[1], K. Kupke[2], K.M. May[1], D.F. Saxe[1].* 1) Div. Med. Genet., Dept of Peds., Emory Univ. Schl. Med., Atlanta, GA; 2) Neonatology Associates, Atlanta, GA.

Chromosome mosaicism in amniotic fluid can present difficult counseling issues concerning the fetal phenotype. We report a prenatal diagnosis of a double mosaic aneuploidy of 45,X/47,XX,+21, with a majority of the cells representing sex chromosome monosomy, presenting in a fetus with clinical features suggestive of Down syndrome. An amniocentesis was performed at 21.5 weeks gestation on a 32 year old woman referred for an abnormal multiple marker screen with an increased risk for Down syndrome. Initial FISH analysis on uncultured amniotic fluid cells revealed one signal for the X chromosome in 80% of the cells and a normal hybridization pattern for chromosome 13, 18 and 21, consistent with sex chromosome monosomy. Chromosome analysis of cultured amniotic cells revealed 47,XX,+21 (17%) and 45,X cells (83%), and no normal cells. Ultrasound did not reveal any fetal anomalies. The patient declined PUBS and elected termination. Examination of the fetus revealed low set and slightly posteriorly rotated ears, mid-face hypoplasia with slightly flattened nose and wide-set nipples. There was no evidence of webbing of the neck, or defects of the upper and lower extremities. The internal examination was unremarkable. Uterus, tubes and ovaries were present. Chromosome analysis of the skin, lung and kidney were unsuccessful due to cell growth failure. Analysis of the placenta from seven different sites revealed 45,X, 46,XX and 47,XX,+21 cell lines in various percentages. The presence of these cells lines could represent true mosaicism, a deceased co-twin or confined placental mosaicism. Molecular studies are pending.

True mosaicism of double aneuploidy is extremely rare, but has been reported for various aneuploidies. There has been one reported incidence of 45,X/47,XX,+21 prenatally diagnosed, in which the fetus presented with features of both Down and Turner syndrome. The present case emphasizes the need for documentation of clinical and cytogenetic findings for rare mosaic aneuploidies to aid in counseling regarding phenotype.

Program Nr: 2078 from the 1999 ASHG Annual Meeting

Chromosomal localisation and characterisation of *SOX18*, a developmentally expressed transcription factor. *D.J. Pennisi, G.E.O. Muscat, P.A. Koopman.* CMCB, University of Queensland, Brisbane, QLD, Australia.

The *SOX* gene family is an evolutionary conserved family of transcription factors that are developmentally expressed, with *SOX* genes involved in various aspects of development. Mutations in a number of *SOX* genes have been implicated in inherited disorders in humans and as the underlying cause of classical mouse mutations. We have cloned a member of this family, *Sox18*, and identify it as a gene involved in cardiovascular and follicle formation during development. We have mapped the human homologue to 20q13.3 by radiation hybrid mapping and it appears not to be associated with any inherited disorders. This allocation is consistent with the synteny between this region of the human genome and distal mouse chromosome 2 - the region where mouse *Sox18* has been mapped. We have produced mouse mutants null for *Sox18* and are currently conducting preliminary analyses.

Program Nr: 2079 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of isolated femoral bent-bone skeletal dysplasia: Problems in differential diagnosis and genetic counseling. *P.G. Pryde[1], C. Zelop[2], R.M. Pauli[1]*. 1) Obstetrics and Gynecology, and Medical Genetics, U of Wisconsin, Madison, WI; 2) Obstetrics and Gynecology, U of Chicago, Chicago, IL.

Severe localized and symmetric bowing of the femora, in the absence of other nonskeletal abnormalities, is a rare prenatal ultrasound finding.

A 38-year-old woman was referred at 19 weeks gestation after triple marker screen estimated Down syndrome risk of 1 in 10. Family history was unremarkable. Ultrasound showed severe shortening and marked, symmetric bowing of the femora. The remainder of the long bones appeared normal in length, shape, and echodensity. Spine, calvarium, face, hands, feet, and thoracic skeleton appeared normal. Karyotype of amniocytes was 46,XY. A provisional diagnosis of kyphomelic dysplasia (KD) was provided. Despite the possibility of a favorable outcome, the patient elected termination of pregnancy by labor induction. Fetal post-mortem examination and radiographs were consistent with KD, although we feel that definitive distinction from femoral hypoplasia unusual facies syndrome (FH-UFS) may not, in this case, be possible.

KD is an autosomal recessive bent-bone dysplasia that, in contrast to campomelic dysplasia, involves principally the femora with relative sparing of the remainder of the skeleton. The diagnosis can be difficult to distinguish from symmetric cases of FH-UFS, which are thought in most instances to have sporatic inheritance or are seen in association with pregnancies complicated by diabetes mellitus. Although potentially lethal neonatal problems may arise, both KD and FH-UFS are compatible with probable normal life expectancy and normal neurodevelopment. The possibility that definitive distinction may not be possible prenatally, and even post-mortem (in cases choosing to terminate) is an important counseling consideration.

Program Nr: 2080 from the 1999 ASHG Annual Meeting

Cromosome prenatal diagnosis in Havana City, Cuba, 1984-1999. *J. Quintana, O. Quiñones, L.A. Méndez, M. Lavista, M. Gómez, N. Dieppa.* Dept Cytogenetics, Natl Ctr Medical Genetics, Havana, Cuba.

A National Program for the Diagnosis and Prevention of Genetic Diseases was implemented in Cuba in 1984. All components of the program are centrally planned and organized by the National Center of Medical Genetics and are financed by the governmental national health system free of charge. It includes newborn screening for PKU and congenital hypothyroidism, sickle-cell screening of pregnant women, maternal serum AFP screening, fetal ultrasound and prenatal diagnosis of sickle-cell and chromosome anomalies by amniocentesis (CVS was added in 1987). Indications for chromosome prenatal diagnosis are maternal age 38 years and over, positive family history, abnormal maternal serum screening and abnormal fetal ultrasound. Our laboratory provides centralized cytogenetic services for the western region of the country with a population of about 3 million, which includes Havana City and the provinces of Havana, Pinar del Rio and Isla de la Juventud. It also functions as a national reference laboratory for the rest of the country. Increased risk for chromosome anomalies in the offspring is detected early in pregnancy by family physicians at the primary care level following national criteria. Detected at-rik couples are referred to a network of genetic units where genetic counseling is provided and prenatal chromosome diagnosis is offered. Between January 1984 and April 1999, 6923 pregnant women underwent chromosome prenatal diagnosis (5138 by amniocentesis and 1785 by CVS). A total of 218 fetuses with chromosome abnormalities were diagnosed: 136 with aneuploidies (85 with trisomy 21), 41 with structural rearrangements (15 unbalanced) and 41 with mosaicisms. Abnormal results were informed to the couples by clinical geneticists following the principles of full and objective disclosure and non directive genetic counseling. The majority of couples with chromosomically abnormal fetuses requested to interrupt the pregnancy, a service also provided by the program. This included most cases with the milder sex chromosome aneuploidies.

Program Nr: 2081 from the 1999 ASHG Annual Meeting

Sources for misdiagnosis in preimplantation diagnosis of single gene disorders. *S. Rechitsky, O. Verlinsky, C. Strom, V. Ivakhnenko, J. Nefedova,, T. Amet, J. Pameranetz, M. Rechitsky, T. Kouliev, Y. Verlinsky.* Reproductive Genetics Inst, Illinois Masonic Medical Ctr, Chicago, IL.

Because preimplantation genetic diagnosis (PGD) of single gene disorders is based on single cell DNA analysis, its accuracy depends mainly on overcoming the major limitations of single cell PCR, which include allele drop out (ADO) and preferential amplification (PA). Both ADO and PA may be represented by a lack of one of the alleles in single heterozygous cell PCR analysis. With introduction of fluorescence PCR (F-PCR), there is a possibility to distinguish ADO from PA, allowing investigation of the proportion of PA detected as ADO by conventional methods. We tested 148 single fibroblasts heterozygous for cystic fibrosis Delta F-508 mutation by both conventional and F-PCR. ADO and PA rates were also recorded for Intron 6 polymorphism, which is closely linked to the gene. Our data showed that only a small proportion of lacking signals in conventional PCR were due to PA detected by F-PCR (1% for Delta F-508 mutation and 0.9% for Intron 6 polymorphism). This proportion is even lower following simultaneous amplification of both genes (0.6%). Our experiments also showed that the application of two markers picks up as much as 96.5% of all ADO, with almost no risk for misdiagnosis if 3 or more markers are included in multiplex PCR analysis. Our current experience includes PGD of 23 single gene disorders, performed by polar body biopsy and conventional or F-PCR. Overall, 66 clinical cycles has been performed by the present time, showing 97% diagnostic accuracy, based on the follow up analysis of 407 embryos resulting from oocytes predicted to have a mutant gene. The work has presently resulted in pre-selection and transfer of mutation free embryos in all but 3 cycles, with 23 established pregnancies resulting in the birth of 17 healthy children.

Program Nr: 2082 from the 1999 ASHG Annual Meeting

Combined elevation of maternal serum AFP and serum hCG predict adverse perinatal outcome. *S.B. Reddy, E. Ryu, S. Reddy.* AFP, National Medical Diagnostic La, Livonia, MI.

Elevated levels of maternal serum alphafeto-protein (MSAFP) in midtrimester are associated with neural tube defects, intrauterine growth retardation (IUGR) and other adverse pregnancy outcome. It has been demonstrated that elevated levels of serum human chorionic gonadotrophin (MShCG) during midtrimester are indicative of increased risks of IUGR and prematurity. The present report was designed to examine whether combined elevation of both MSAFP and MShCG lead to more pronounced pregnancy complications of adverse outcome than elevated MSAFP alone. Forty six patients with elevated MSAFP (>2.5 MOM) and MShCG (>3.2 MOM) and 64 patients with elevated MSAFP (2.5 MOM) as control group were studied in this report. In the present study, we observed that combined MSAFP and MShCG in midtrimester have significant increase in the rate of adverse preganncy outcome in 34 (73.9%) in contrast to elevated MSAFP alone in (1.6%). Stillbirth, fetal loss and neonatal death occured in 9 (26.5%) of the 34 patients with no losses among 64 control group. Major congenital defects were observed in 12 (35.3%) while none occured among controls. IUDR was noted in 13 (38.2%) compared to 1.6% among control group. These results indicate that a combined elevation of both MSAFP and MShCG in midtrimester is associated with a high risk of pregnancy outcome when compared to elevated MSAFP alone.

Program Nr: 2083 from the 1999 ASHG Annual Meeting

Pregnancy outcome for patients with an elevated first MSAFP sample and normal second sample. *J.R. Roberson, S. Diment.* Dept Medical Genetics, Henry Ford Hosp, Detroit, MI.

The Henry Ford Hospital MSAFP Program screening protocol allows a repeat serum sample for certain patients with an elevated initial sample (>2.2 MOM, <3.0 MOM and less than 19 weeks gestation). Patients who meet these criteria are offered ultrasound and/or amniocentesis if their second sample is screen positive. For those with a negative second sample, no further testing is offered. 155 patients with a negative second sample between 1995-1998 were studied to determine whether this protocol significantly reduced the false positive rate (FPR) and detection rate (DR)for open neural tube defects (NTDs) or had poor fetal outcomes in a higher frequency than expected.

24,549 initial serum samples were assayed between 1995-1998. 784 (3.2%) were elevated (>2.2 MOM). 521 (2.2%) were less than 3.0 MOMs and less than 19 weeks gestation,so were eleigible for a second sample. 182 of those had no second blood sample (first sample was recalculated based on ultrasound dating, declined a second sample, proceeded directly to amniocentesis or had early fetal demise). 339 (1.3%) of all patients had a second sample. 184 of those (54.3%) had a second elevation, while 155 (45.7%) had a negative second sample. 8 of 155 in the study group (5.2%) were lost to follow-up. One infant in this group had an open meningomyelocele and one had hypospadias. 112 were liveborn full term infants (38-42 weeks gestation) while 30 liveborns were born prematurely. Two of three fetal losses occurred before 24 weeks gestation. During this same screening period, 18 of 19 fetuses with neural tube defects were detected.

Conclusion: Although one fetus with NTD was missed because her second sample was < 2.2 MOM, our overal detection rate for NTDs during this period was 94% which is within the expected range. Allowing certain patients with an initial elevation to have a second sample reduced the FPR from 3.2% to 1.8%. Pateints with an initial elevated MSAFP who had a normal second sample still had a higher than expected rate of prematurity although they did not have a higher rate of fetal anomalies.

Program Nr: 2084 from the 1999 ASHG Annual Meeting

Safety of early amniocentesis: time to reevaluate CEMAT data. *R.M. Roberts.* Genetics and Prenatal Diag Ctr, Signal Mountain, TN.

The Canadian Early and Mid-trimester Amniocentesis Trial (CEMAT) found a significant excess of miscarriage, post-procedure leakage, and equinovarus malformation in the early (EA) group. As a result, the use of early amniocentesis has declined. Evaluation of the methodology of CEMAT can explain why their results are different from other studies, and in fact may reveal the cause of equinovarus--and how to avoid it. Here presented are the technical problems associated with EA. One of the most accessible pockets of fluid may be near the feet. At 10 to 14 weeks, the fetus has periodic episodes of a bicycling reflex, alternate repetitive flexion and extension of the legs. Fetuses who developed equinovarus may have been those who repetitively extended the feet onto a sharp needle tip, resulting in vascular disruption and tissue necrosis--hence a disruptive, not malformative etiology. This etiology of EA-associated equinovarus can be confirmed or rejected by reexamination of their videotaped procedures later resulting in equinovarus. Two other procedural factors may have contributed to their increased rate of miscarriage. The Canadian group had no instruction on what to do if the first aspiration resulted in no return of amniotic fluid. They can not know in how many such instances the operator re-aimed the needle tip laterally before attempting to re-aspirate. In many instances of no return, the amnion is tented, and not visualized by ultrasound. Lateral movement of the sharp bevel across the tense amnion could be the main cause of amnion leakage. I recommend never re-aiming the needle laterally without first withdrawing it to the uterine wall. The amnion is most easily punctured where it adheres to the chorion--hence, transplacental procedures should actually have less risk of post-procedure leakage, as their study found. Lastly, their assumption that removal of less amniotic fluid volume than usual would be safer could be wrong. I have found that the pressure in the extracoelomic space is 0, while inraamniotic fluid pressure can be twice that of mid-trimester pressure. Removal of a larger volume would result in lower intraamniotic fluid pressure, with less likelihood of the puncture site leaking prior to healing.

Program Nr: 2085 from the 1999 ASHG Annual Meeting

Prenatal diagnosis of duplication 4p mosaicism. *C. Rodriguez[1], T. Cimaroli[1], L. Sciorra[1], E. Guzman[2], J. Smulian[2], D. Day-Salvatore[1]*. 1) Division of Clinical Genetics, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ; 2) Maternal-Fetal Medicine, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, NJ.

Duplication 4p syndrome is characterized by severe mental retardation, seizures, intrauterine growth restriction, clinodactyly, camptodactyly, and characteristic facial features; neither mosaicism nor prenatal diagnosis of this syndrome have been previously described. We report the prenatal diagnosis of two cases of *de novo* duplication 4p syndrome, one of which was mosaic, prompted by abnormal ultrasound findings. The first case was identified at 19 weeks gestation after amniocentesis was performed in a 32-year-old gravida 2 for a positive maternal serum triple screen for Down syndrome and 5th finger clinodactyly on ultrasound. The fetal karyotype was 46,XX,inv dup (4) (p12p16.3) in all cells analyzed. On autopsy, the fetus was noted to have clinodactyly, camptodactyly, preaxial polydactyly, horseshoe kidney, and characteristic facial features of duplication 4p syndrome. In the second case, a routine level II ultrasound at 19 weeks in a 31-year-old gravida 2 demonstrated bilateral absence of the middle phalanx of the 5th digit, single umbilical artery, echogenic focus in the left ventricle of the fetal heart, small fetal stomach, and one-week lag in fetal growth compared to the LMP. Amniocentesis revealed a karyotype of 46,XX[14]/46,XX,dup4(p16p16)[4] in the primary culture, with a mosaic result also identified in the subculture. This mosaic chromosome complement was confirmed in both a repeat amniocentesis and percutaneous umbilical blood sample. Postmortem examination could not be obtained. Chromosome analysis of both sets of parental bloods were normal. The prenatal diagnosis of structural chromosome abnormalities may be prompted by subtle, non-specific findings on ultrasound. In addition we report the first documented case of duplication 4p mosaicism.

Program Nr: 2086 from the 1999 ASHG Annual Meeting

Genomic cloning and characterization of the human homeobox gene *SIX9* reveals a cluster of *SIX* genes in chromosome 14 and associates *SIX9* hemizygosity with bilateral anophthalmia and pituitary anomalies. *S. Rodriguez de Cordoba[1], M.E. Gallardo[1], I. Fernaud-Espinosa[1], J. Lopez-Ríos[5], R. Sanz[2], C. Ramos[2], C. Ayuso[2], M.J. Seller[3], H.G. Brunner[4], P. Bovolenta[5]*. 1) Departamento Immunología, Centro de Investigaciones Biológicas (CSIC), Madrid, Spain; 2) Servicio de Genética, Fundación Jiménez Díaz, Madrid, Spain; 3) United Medical and Dental Schools, Guys Hospital, London, UK; 4) Department of Human Genetics, University Hospital Nijmegen, The Netherlands; 5) Departamento de Neurobiología del Desarrollo, Instituto Cajal (CSIC), Madrid, Spain.

The Drosophila gene *sine oculis* (*so*), a nuclear homeoprotein that is required for eye development, has several homologues in vertebrates (the *SIX* gene family). Among them, *SIX3* is considered to be the functional orthologue of so because it is strongly expressed in the developing eye. However, embryonic *SIX3* expression is not limited to the eye field and *SIX3* has been found to be mutated in some patients with holoprosencephaly type 2 (HPE2), suggesting that *SIX3* has a wide implication in head development. We report here the cloning and characterization of *SIX9*, a novel human *SIX* gene that is homologue of the chick *Six9*(*Optx2*) gene. *SIX9* is closely related to *SIX3* and is expressed in the developing and adult human retina. Data in chick and mouse suggest that human *SIX9* gene is also expressed in the hypothalamic and the pituitary regions. *SIX9* spans 2628 bp of genomic DNA and is split in two exons that are transcribed into a 1514 nucleotide-long mRNA. Chromosomal mapping of *SIX9* revealed that it is closely linked to *SIX1* and *SIX4* in human chromosome 14q22.3-q23, which provides clues about the origin and evolution of the vertebrate SIX family. Recently three independent reports have associated interstitial deletions at 14q22.3-q23 with bilateral anophthalmia and pituitary anomalies. Genomic analyses in one of these cases demonstrated *SIX9* hemizygosity, strongly suggesting that *SIX9* haploinsufficiency is responsible for these developmental disorders.

Program Nr: 2087 from the 1999 ASHG Annual Meeting

Role of Fetal ultrasound and molecular cytogenetics for karyotype-phenotype correlation of unbalanced structural chromosomal aberrations at prenatal diagnosis. *H.M. Ryu[1], M.Y. Kim[1], E.S. Kim[1], S.Y. Park[2], S.K. Choi[2], Y.H. Lee[3], H.W. Han[1].* 1) Dept OB/GYN, Samsung Cheil Hos, Sung Kyun Kwan Univ, Seoul, Korea; 2) Genetic Laboratory; 3) Dept Radiology.

The detection of unbalanced structural aberrations at prenatal diagnosis raises serious concern the phenotypic consequences on the fetus. The purpose of this study is to evaluate the role of the fetal ultrasound and molecular cytogenetics in predicting the prognosis of the fetuses with structural aberration. During July 1995 -June 1999, we performed about 3,781 fetal karyotyping, by which we detected 24 fetuses(0.63%) with unbalanced structural aberrations. There were 16 de novo cases and 5 familial cases and 3 unknown cases by parental karyotyping. For unbalanced structural chromosomal aberrations, we performed 1) detailed sonography and autopsy when the fetus was terminated or died in utero, 2) comparative genomic hybridization (CGH) and/or fluorescent in situ hybridization. Most common indication for fetal karyotyping was abnormality at fetal screening sonography. At detailed sonography, 18 fetuses showed abnormal findings; growth retardation in 6, oigohydramnios in 4, cardiac anomaly in 5, CNS anomaly in 6, and others. No abnormality was found at detailed sonography in 6 cases; three with structural aberration and three with marker chromosome. The cases with three structural aberration were terminated and showed no abnormality at autopsy. Two with marker chromosome showed normal CGH profiles and normal healthy babies were delivered. One with non-satellite marker chromosome was terminated. Seven cases where the conventional karyotyping was not conclusive, showed greater accuracy with CGH and/or FISH. Fetal sonography and molecular cytogenetics play an important role in predicting the prognosis of fetus with unbalanced structural aberrations at prenatal diagnosis.

Program Nr: 2088 from the 1999 ASHG Annual Meeting

Circumventing Male Infertility by ICSI should not Preclude Basic Evaluation. *S. Saitta, S. Zderic, G. Anadiotis, R. Colliton, L. Celle, R. Kline, N. Spinner, E. Zackai.* Children's Hosp of Phila, Philadelphia, PA.

Intracytoplasmic sperm injection (ICSI) was used for in vitro fertilization in a couple where the male had a decreased sperm count and low motility. Amniocentesis performed at 17 weeks showed a normal 46,XX karyotype in 15 cells studied. The pregnancy resulted in a newborn with abnormal genitalia including a shawl scrotum, single palpable gonad, and microphallus with hypospadias. Vaginal and uterine structures were found on a genitogram. Cytogenetic testing of the infant's peripheral blood lymphocytes revealed a mosaic karyotype of 46,XX[40]/47,XX,+r(Y)[10]. Surgical intervention included removal of both the scrotal gonad as well as the intraabdominal gonad due to increased risk of gonadoblastoma in this patient. Histology confirmed that the scrotal gonad was a testis, while the undescended gonad proved to be an ovotestis, providing evidence of true hermaphroditism. At this point, the father's peripheral blood karyotype was analyzed for the first time and showed a 46,Xr(Y) constitution in 100 cells studied. Highly polymorphic microsatellite DNA markers (heterozygosity greater than 70%) from the X chromosome (DXS990, DXS993, DXS999, DXS1001, DXS1227, PLP-CA, PLP-AhaII, PM2A) were used to analyze genomic DNA from the infant and father to determine the origin of the nondisjunction leading to the infant's 47,XX,+r(Y) lineage. Eight loci were studied and in all cases, the proband and father shared an allele, consistent with a paternal nondisjunction event resulting in this previously unreported mosaic karyotype. These findings illustrate the importance of routine karyotype analysis to help uncover the etiology of a patient's infertility, such as Y aneuploidy. This is underscored especially when newer technology-driven methods are used to circumvent the infertility.

Program Nr: 2089 from the 1999 ASHG Annual Meeting

Comparison of fetal cell recovery from maternal blood using high density gradient for initial separation step: 1.090 vs. 1.119. *O. Samura, A. Sekizawa, D.K. Zhen, V.M. Falco, D.W. Bianchi.* Division of Genetics, Dept. of Pediatrics, Tufts University School of Medicine, Boston, MA.

Objective: To improve the recovery of fetal nucleated erythrocytes (NRBCs) from maternal blood for noninvasive prenatal genetic diagnosis.

Methods: Samples were obtained from 27 women(28 samples)who had just undergone pregnancy termination at 6 to 23 weeks. Samples were split and mononuclear cells were isolated using Histopaque densities 1.090 and 1.119. CD45 depletion using magnetic activated cell sorting followed by flow-sorting with antibody to g globin and FISH analysis were used to evaluate the number of fetal cells recovered.

Results: In samples separated with the 1.119 density gradient, the yield of true anti-g positive cells (median: 14.9, range: 0-717.5)was significantly higher than that in the 1.090 density (median: 4.9, range: 0-532.5). In 13 out of 28 samples, the number of anti-g positive cells recovered from the 1.119 density gradient was two times or greater than that from the 1.090 gradient. After FISH analysis, in the 14 samples in which the fetal karyotype was different from mother, we detected a median range of 22.9 (range: 2-717.5) confirmed fetal NRBCs per 10-ml maternal blood in the 1.119 density gradient, whereas a median of 11.5 confirmed fetal NRBCs were detected in the 1.090 gradient (range: 0-532.5). The number of fetal NRBCs recovered from the 1.119 density gradient was significantly higher than from the 1.090 gradient.

Conclusions: Increased density results in improved fetal cell recovery in fresh post-termination maternal samples. The increased yield of fetal cells using the 1.119 density gradient may permit better noninvasive detection of fetal chromosome as well as DNA abnormalities in maternal blood.

Program Nr: 2090 from the 1999 ASHG Annual Meeting

MRI: An emerging tool in the assessment of fetal anomalies . *R.L. Schonberg, D.I. Bulas, K.D. Newman, K.N. Rosenbaum, C.J. Tifft.* Children's National Medical Center, Washington, DC.

High-resolution ultrasonography has been the traditional mode for the identification of fetal malformations. Magnetic resonance imaging (MRI) has further refined our ability to clarify the anatomy in some cases of suspected malformations. We report 2 cases where fetal MRI provided additional diagnostic information that influenced genetic counseling and pregnancy management.

Case 1 is a 36-year-old G2 P1 female whose fetus at 27 weeks gestation was suspected of having agenesis of the corpus callosum. The ultrasound was inconclusive due to fetal positioning. Images in multiple planes were obtained using a T2 weighted single slice technique with a Signa Horizon LX 1.5 Tesla GE scanner (Milwaukee, WI). Sedation was not used. The MRI established the the presence of the corpus callosum and the family was counseled that the risk of developmental delay was very small. The pregnancy continued to term with the birth of a healthy female infant.

Case 2 is a 29-year-old G1 P0 female who was evaluated by ultrasound at 21 weeks gestation. The fetus was found to have a large cystic adenomatoid malformation in the left lung resulting in severe mediastinal shift. No normal lung was visualized sonographically. MRI using the technique described above was performed at 23 weeks gestation and showed a large multicystic left upper lobe mass. Normal appearing lung was identified in the lower left lobe and right lung. The infant delivered at 39 weeks gestation. No immediate intervention was required.

The use of fetal MRI in our patients resulted in improved diagnostic accuracy and assessment of fetal outcome. This technique will continue to evolve as an important adjunct to ultrasound imaging in selected pregnancies.

Program Nr: 2091 from the 1999 ASHG Annual Meeting

Rescue of a conditional p53 mutation by the *lac*repressor in preimplantation mouse embryos. *H. Scrable, W. Gluba, L. Ligon, A. Leung.* Dept Neuroscience, Univ Virginia, Charlottesville, VA.

The *p44*gene encodes a truncated version of p53 that is missing the amino-terminal overlapping domains for transactivation and mdm2 binding. We have inserted *lac*operator sequences into the promoter region of *p44*downstream of the transcription start site. In assays of reporter function *in vitro*, the modified *p44*promoter was found to be fully regulatable by lactose when introduced into cultured cells along with the *lac*repressor. A line of transgenic mice carrying this conditional *p44*mutation was created on a *p53 (+/+)*background. *p44*expression paralleled that of *p53*in all tissues examined, but at a consistently higher level. Adult male *p44*transgenic mice developed giant cell degenerative syndrome of the testis, which has been associated with reduced levels of p53. *p44*transgenic mice were mated to a line of transgenic mice homozygous for the bacterial gene encoding the *lac*repressor. Adult male *p44, lacI/lacI*mice did not develop testicular giant cell degenerative syndrome. To determine what effect this had on gamete formation, we compared the viability of sperm from *p44*males to *p44, lacI/lacI*males by counting the number of one-cell embryos harvested from hormonally-prepared, non-transgenic females of a similar genetic background to which they had been mated. There was no difference in the fertilization rate of sperm derived from males of either genotype. When the embryos were cultured, however, many more embryos derived from the *p44*male died at the morula to blastocyst transition than did embryos derived from the *p44, lacI/lacI*male. The difference in embryo death rates was statistically very highly significant (*p=0.00088*). Taken together, these data suggest that p53 has both an effect on gamete formation in the testis and a male-derived, epigenetic effect on preimplantation embryogenesis that occurs at the time of blastulation, and that these effects are independent of each other.

Program Nr: 2092 from the 1999 ASHG Annual Meeting

Alpha fetoprotein (MSAFP) screening:Our five years experience. *M. Segovia, L. Lopez Miranda, L. Alba, M. Mollica, A. Rebechi, O. Pivetta.* Centro Nacional de Genetica Medica, Buenos Aires, Argentina.

The purpose of this research work is to present the outcomes of a group of patients with unusually high maternal serum a-fetoprotein levels. 3000 MSAFP determinations were performed in our center during 5 consecutive years, between 15 and 21 weeks of gestation. 75 (2.5%) of the 3000 samples showed high MSAFP levels. In 41 (54.6%) of the samples the results obtained were: 10(24.4%) fetal deaths with X=4.33MOM(dn=1.6;dn-1=1.68); 2(4.87%)presented anencephaly with X=8.55 MOM(dn=3.45;dn-1=4.80); 2(4.87%) gastroschisis with X=7.7MOM(dn=1.75;dn-1=2.47); 2(4.87%) omphalocele with X=3.7MOM(dn=0.1; dn-1=0.14); 2(4.87%)retroplacental haematomas with X=2.85 MOM ((dn=0.25;dn-1=0.35);1(2.4%) craniorachischisis with 23 MOM; 1(2.4%) risk of abortion with 5.9 MOM; 1(2,4%) oligohidramnios with 3.6 MOM; 1(2.4%) spontaneous abortion with 22.7 MOM; 1(2.4%) moderate hydronephrosis with 2.4 MOM; 1(2.4%) ascites plus complex heart defect with 3.0 MOM; 17(41.4%) twin pregnancies with one X=2.4 MOM(dn=1.0;dn-1=1.03). There is no apparent clinical reason for the remaining 34(45.3%),although the most probably cause could be: 1) inaccuracy to determine the gestacional age; 2)blood samples obtained a few days after chorionic villus sampling. In our research the most common findings with high MSAFP levels were fetal death (24.4%) and twin pregnancies (41.4%), and the highest MOM values were found in pregnancies with neural tube defects. In conclusion , the aim of this work is to emphasize that abnormally high alpha fetoprotein values, even with normal ultrasound findings, are a reliable sign to identify high risk pregnancies.

Program Nr: 2093 from the 1999 ASHG Annual Meeting

Outcome of pregnancies after maternal renal transplantation. *M. Sgro[1], T. Barozzino[1], T.M. Mirghani[2], M. Sermer[2], H. Akoury[2], D. Chitayat[3]*. 1) Deparment of Pediatrics, The University Health Network, University of Toronto, Toronto, ON, Canada; 2) Department of Obstet & Gynecology, The University Health Network, University of Toronto, Toronto, ON, Canada; 3) The Prenatal Diagnosis Program, The University of Toronto, Toronto, ON, Canada.

We studied retrospectively the outcome of pregnancies of women recipients of renal transplant, who were on cytotoxic medication prior to conception and for the duration of the pregnancy. There were 44 pregnancies in 30 women and 32 of them resulted in liveborn children. One child was lost for follow-up. Information regarding the growth and development was obtained on 31 children through direct assessment or telephone interviews. The mean maternal age was 28 years (19-38 years). The mean interval between the renal transplantation and conception was 5 years. Cytotoxic medications used included: cyclosporine + azathioprin + prednisone in 24, azathioprin + prednisone in 13 and cyclosporin + prednisone in 5. The average gestational age at delivery was 36 weeks and 44% (14) were delivered prior to 37 weeks. The average birth weight was 2.53 kg and 3 children had birth weight <3rd centile. One child (3%) was born with multiple congenital abnormalities. The range of follow-up was 3 months to 11 years (mean 3.1 years) and no additional congenital abnormalities were detected on follow-up. Diabetes mellitus type 1 developed in one child, moderate to severe sensorineural hearing loss in 1, 2 children had asthma and 1 child had recurrent otitis media. One child had a learning disability and one child had prevasive developmental delay. Conclusion: long term follow-up of children born to renal transplant recipient mothers does not show an increased incidence of congenital and/or developmental abnormalities or late onset conditions compared to the general population. There was an increased incidence of premature delivery and low birth weight.

Program Nr: 2094 from the 1999 ASHG Annual Meeting

Detecting prominent nuchal translucency among first-trimester fetuses with autosomal abnormalities: assessing frequency and operator experience. *L.P. Shulman[1, 2], O.P. Phillips[1], D.S. Emerson[1], Y. Tunca[1], A.T. Tharapel[1]*. 1) Univ of Tenn, Memphis; 2) Dept of Ob/Gyn, Univ of Ill at Chicago.

The detection of a prominent nuchal translucency (PNT) during the ultrasound exam of a first-trimester fetus is associated with marked increased risk for fetal aneuploidy. Indeed, PNT measurement is now an integral part of investigational first-trimester screening protocols. PNT screening is dependent on ultrasound equipment and operator experience; accordingly, current practice calls for special training and certification for those performing aneuploid risk assessment. Much has been written about the ability of PNT to detect fetal aneuploidy with relatively little reported about the frequency of PNT among fetuses with aneuploidy. We sought to assess the frequency of PNT among fetuses with autosomal aneuploidy and the role of ultrasound experience. All women presenting for first-trimester prenatal diagnosis were evaluated by a group of experienced sonographers who subsequently received certification, in early 1998, to provide aneuploidy screening. We prospectively studied all first-trimester fetal autosomal aneuploidy cases from 1994 to 1998. Scans were performed between 9.5 and 12.9 weeks; all were performed on the same ultrasound machines. PNT was defined as a separation of skin from body wall ³ 2.5 mm. Approximately 85% of women presented for prenatal diagnosis for AMA (³ 35 years at EDC). Results: Ninty-five consecutive cases were included in this study. In 1994, 38.5% of fetuses with autosomal aneuploidies were prospectively found to have PNT. This increased to 47.1% in 1995, 65% in 1996 and 76.2% in 1997. In 1998, 70.8% of the 24 affected fetuses had PNT. No other atypical ultrasound findings were reported. Conclusions: Although PNT will detect many fetuses with autosomal aneuploidy, approximately 30% of affected fetuses will have normal first-trimester scans. Operator experience plays a role in detecting PNT and could affect screening outcomes. Such information is thus critical for women with normal first-trimester scans. Uniform training and certification may serve to diminish the impact of operator inexperience and maintain the screening efficacy of PNT measurement.

Program Nr: 2095 from the 1999 ASHG Annual Meeting

Skewed X-inactivation in Incontinentia Pigmenti (IP2). *A. Smahi, S. Heuertz, J.P. Bonnefont, A. Delanay, P. Vabres, A. Munnich.* Genetique INSERM U393, Hopital Necker, Paris, France.

Incontinentia Pigmenti (IP2) or Bloch-Sulzberger syndrome is a rare neurocutaneous syndrome characterized by developmental abnormalities of the tissues and organs derived from the embryonic neuroectoderm. The mode of inheritance is X-linked, dominant, with male lethality. Highly skewed X-inactivation has been observed in peripheral blood leukocytes and fibroblasts of IP2 patients (Migeon B.R., et al., 1989; Harris A., et al., 1992; Parrish et al., 1996). We analyzed the pattern of X-inactivation in blood leukocytes of a cohort of 49 sporadic and 70 familial cases of IP2. A total of 98.5% of affected females showed a non-random X-inactivation. Otherwise, a random X-inactivation was observed at the vesicular stage of the disease in two one-year-old girls. These results suggested that the apparent skewed X-inactivation is the result of selection occurring in the early postnatal development against cells expressing the mutated IP2 gene on the active X-chromosome. The study of X-inactivation allowed us to determine the parental origin of the mutant allele in sporadic cases. In 71% of sporadic cases, the paternal X-chromosome was inactivated, suggesting that the IP2 mutation occurred in the father's germline. The remaining 29% were shown to inactivate their maternal X-chromosome. Gonadal and somatic mosaicism were also occasionally noticed. These data indicate that highly skewed X-inactivation is a hallmark for IP2 and is therefore of considerable help in establishing diagnosis in "mild" IP2 phenotype. Thus, combining the X-inactivation test and linkage analysis is required for accurate genetic counseling in IP2.

Program Nr: 2096 from the 1999 ASHG Annual Meeting

Ectopic expression of Sonic Hedgehog from the human Keratin 1 promoter gives rise to limb abnormalities and skin lesions in transgenic mice. *I. Smyth[1], J. Bowles[1], J. Rothnagel[2], C. Wicking[1], B. Wainwright[1]*. 1) CMCB, University of Queensland, Brisbane, Australia; 2) Dept of Biochemistry, University of Queensland, Brisbane, Australia.

The Patched/Sonic Hedgehog signalling pathway controls the differentiation of a range of tissues and organs including the central nervous system, the limbs and the skin. The involvement of this pathway in human disease has been demonstrated by the finding of mutations of Patched in the naevoid basal cell carcinoma syndrome (NBCCS), which is characterised by predisposition to basal cell carcinoma (BCC) and medulloblastoma, and by a variable range of developmental defects. Tumorigenesis in this syndrome is thought to result from homozygous inactivation of the Patched protein, which in turn leads to the constitutive activation of an associated protein, Smoothened. We have endeavoured to model this inactivation by over-expressing the hedgehog gene in transgenic mice, a process which also leads to constitutive activation of Smoothened. A full length rat sonic hedgehog cDNA was expressed from the human keratin 1 (HK1) promoter which is transcribed in mitotic interfollicular basal cells and in suprabasal layers from around 15 days post coitum. The resulting mice exhibit limb defects similar to the syndactyly occasionally noted in NBCCS patients. They also develop inguinal skin lesions which display sebaceous differentiation and unusual pigmentation. Immunohistochemistry indicates that these lesions express the BCC markers keratin 6 and keratin 14, but do not express proteins characteristic of suprabasal epidermal layers, such a loricrin. Transgenic back skin is phenotypically normal, however tail and foot skin exhibits basal cells hyperproliferation and abnormal dermal pigmentation. These studies demonstrate the ability of ectopic Sonic Hedgehog to alter epidermal development, even when expressed at a late embryonic stage, and also suggest that tumour like lesions can form as a result of expression of the transgene in interfollicular basal cells.

Program Nr: 2097 from the 1999 ASHG Annual Meeting

A structural mutation of *HOXA1* may be associated with autism spectrum disorders (ASDs). *C.J. Stodgell[1], D.A. Figlewicz[2], S.L. Hyman[3], P.M. Rodier[1]*. 1) Obstetrics and Gynecology, Univ. Rochester Sch. Med., Rochester, NY; 2) Neurology; 3) Pediatrics.

ASDs are common congenital diabilities, occurring in 2-6/1000 births. Several lines of evidence suggest that some cases involve very early injury resulting in craniofacial anomalies, maldevelopment of the brain stem, and cranial nerve dysfunctions, along with the behaviors diagnostic of autism. Null mutation of *Hoxa1* in mice leads to a similar set of somatic and neurologic deficits. While examing the sequence of the *HOXA1* gene in humans cases, we found a region of the 2nd exon that could not be amplified by PCR. When the primers were moved distally, the sequence was amplified successfully, and proved to match the published sequence, suggesting that the defect in the 2nd exon is structural, and is generated by a change in sequence outside of this exon. Semi-quantitative ratings of 51 probands and 112 controls indicated that the structural anomaly is strongly associated with ASDs. Its pattern of inheritance is unusual. Some parents homozygous for the wild-type allele have 2 children with the structural variant. This suggests genetic anticipation. These characteristics argue that the variant is important, and prompted a search for the source of the structure. We used a restriction endonuclease (Pvu II) to digest genomic DNA from a proband homozygous for the variant. The large fragment containing the *HOXA1* coding region was retrieved by size-selecting 3-5kb fragments from an agarose gel, cloning them, and testing the excised inserts to find ones that contained the 1st and 2nd exons of *HOXA1*. Surprisingly, the sequence of a clone positive for *HOXA1* revealed the presence of *HOXA2*, a gene that is known to be over 8kb away. Further, 5 Pvu II cut sites should be present between the coding regions of the 2 genes. This suggests that a deletion of about 3,500 bases is present, eliminating the cut sites and brings the genes closer together. Further description of the deletion in probands and controls will tell us whether the deletion is unstable, as the inheritance pattern suggests, and will allow a definitive quantification of the distribution of the variant in probands and controls.

Program Nr: 2098 from the 1999 ASHG Annual Meeting

Evaluation of prenatal diagnosis of congenital anomalies by fetal ultrasonographic examination in Europe. *C. Stoll[1], M. Clementi[2]*. 1) Service de Genetique Medicale, Hopital de Hautepierre,Strasbourg, France; 2) Registry of congenital anomalies for the prenatal U.S.Diagnosis Working Group, Padova, Italy.

Ultrasound scans in the midtrimester of pregnancy are now a routine part of antenatal care in most European countries. Thanks to registries of congenital anomalies a study was undertaken in Europe. The objective of the study was to evaluate prenatal detection of congenital anomalies by routine ultrasonographic examination of the fetus. All congenital malformations suspected prenatally and all congenital malformations, including chromosome anomalies, confirmed at birth were identified from the Congenital Malformation Registers, including 21 registers from the following European countries : Austria, Croatia, Denmark, France, Germany, Italy, Lithuania, Spain, Switzerland, The Netherlands, UK, Ukrainia. These registries are following the same methodology. The study was performed between july 1996 and december 1997, including 407.000 pregnancies per year. 5041 babies were judged abnormal at delivery. The percentage of detection was variable for the diverse categories of congenital anomalies; it was high for neural tube defect (NTD) 94.5 per cent for anencephaly, 73.3 per cent for spina bifida, but low for ventricular septal defect and for atrial septal defect (ASD), 9.2 per cent and 4.9 per cent, respectively. However the detection rate was higher for multiply malformed children (for example 4 times higher for ASD). Detection rate varied between European countries. Termination pregnancy rate was high for central nervous system anomalies (52.9 per cent) and chromosomal anomalies (49.8 per cent) and low for renal anomalies (24.3 per cent) and congenital heart defects (14 per cent). Overall 24.5 per cent of all pregnancies were terminated after prenatal detection of congenital anomalies. This study showed that many fetuses with major malformations can be identified prenatally in routine practice. Because policies, methods and techniques continually change, ongoing surveillance of prenatal diagnostic services is vital.

Program Nr: 2099 from the 1999 ASHG Annual Meeting

Fraser syndrome: Prenatal Diagnosis and autopsy findings. *M. Thomas[1], A. Toi[2], W. Sirkin[3], H.A. Gardner[4], L. Moore[5], D. Chitayat[1]*. 1) The Prenatal Diagnosis Program,The University Health Network, University of Toronto; 2) Department of Diagnostic imaging,The University Health Network, University of Toronto; 3) The Department of Pathology, North York General Hospital, Toronto,ON, Canada; 4) Genetic Services, Lakeridge Health Centre, Oshawa,ON,Canada; 5) Dept. of Radiology, Lakeridge Health Centre, Oshawa,ON,Canada.

Fraser syndrome is an autosomal recessive condition with multiple abnormalities including cryptophthalmos, syndactyly, genital, nose, ear, laryngeal, renal, and skeletal abnormalities, cleft lip and palate, umbilical hernia and mental retardation. Death is usually associated with laryngeal atresia or renal agenesis. We report the prenatal ultrasound and autopsy findings on a case with Fraser syndrome. The mother was a 28-year-old G1P0 and the father was 30 years. The couple was healthy and distantly related. Detailed fetal ultrasound at 21 weeks gestation revealed mild cerebral ventriculomegaly, thick nuchal fold, echogenic and large lungs with inverted diaphragm and cardiac compression, absent lift kidney and malrotated right kidney. There was ascites, abnormal hands, low umbilical cord insertion and abnormal genitalia. The findings were felt to be consistent with Fraser syndrome. The pregnancy was terminated and the autopsy confirmed the ultrasound findings. The facial features were dysmorphic with short palpebral fissures and eyelids coloboma, notched alae nasi, microstomia and micrognathia. The ears were low set and posteriorly rotated, the nuchal fold was thick, the chest was distended and the abdomen was prominent. There was a low insertion of the umbilical cord, the external genitalia was abnormal and there was syndactyly of the fingers and toes. Internal examination revealed bifid uvula, tracheal stenosis with cricoid cartilagenous ring, distended lungs with abnormal lobation, left renal agenesis and malrotated right kidney. The fetal karyotype was normal (46,XY). The prenatal U/S finding of enlarged and echogenic lungs in association with ascites should raise the possibility of laryngeal atresia and Fraser syndrome should be included in the differential diagnosis of such cases.

Program Nr: 2100 from the 1999 ASHG Annual Meeting

Evaluation of Downs Risks obtained from a Triple Screening Program in African-Americans. *T.F. Thurmon, K. Yanamandra, D. Napper, H. Chen, S. Ursin.* Dept Pediatrics-Genetics, Louisiana State Univ, Shreveport, LA.

LSU Medical School began a triple analyte (MSAFP, MSHCG and MSuE3) screening program serving pregnant women from Northwest Louisiana, a few years ago. To evaluate our program and to improve the quality of screening, we started analyzing the MSAFP elevations generating NTD risks and the Down syndrome risks generated for the outcome of chromosomal defects.

Typically we see higher Downs risks in African-Americans (AA) over European-Americans (EA). We make adjustments to the MSAFP MOM for weight, race and diabetes status, however we only make weight adjustment to HCG and uE3. Unconfirmed LMP dating revealed much higher risk differences. Thus we eliminated this variable by comparing risks only through US dating. We also refined the comparisons by excluding twins, diabetes status, and AMA. However, the risks were still higher in AA even after these exclusions.

After excluding several variables, we found that the predominant marker contributing to the higher Downs risks in AA community was the MSHCG. MSAFP and MSuE3, were still contributing to the difference but not as much. Even after excluding AMA cases, age difference could still be a factor. So, we compared the maternal ages between the two races but found minimal difference. The mean and median maternal ages in our program in the non-AMA category in AA and EA were 22.4, 23.1, 21, and 22 years respectively. Although it is easy to conceptualize separate MSAFP, MSHCG and MSuE3 medians for each race, it may not be practical in smaller programs and with cumbersome software development for each race especially if the patient population was small. Also, it cannot be discounted of the importance of using local population medians lest false risks can be generated.Thus in our view making race adjustment to MSHCG MOM and possibly to MSuE3(race adjustment to MSAFP is likely in practice in most prenatal centers)may be a practical alternative in eliminating some of the problems in the risk calculations for individual races. Data and statistics will be presented.

Program Nr: 2101 from the 1999 ASHG Annual Meeting

The First Trimester Multiparametric Screening is to Become the Standard of Prenatal Diagnosis. *G.L. Tsukerman[1, 2], I.A. Kirillova[1], N.B. Gusina[1], S.A. Schreder[1], L.M. Lishtvan[1], S.I. Kovalev[1], G.A. Krapiva[1], L.A. Savenko[1], O.V. Pribushenya[1], L.V. Podleshuk[1], E.Y. Jaroshevitch[1], L.K. Shamgina[1]*. 1) Center for Med Genetics Serv, Inst Hereditary Diseases, Minsk, Republic of Belarus; 2) Reproductive Genetics Institute, Chicago, IL, USA.

Before introduction of the whole population multiparametric first trimester prenatal screening ultrasound examination with special attention to nuchal translucency (NT)of 27,265 first trimester pregnant women with parallel biochemical testing of 15,000 serum samples, including more than 400 samples at various fetal anomalies, for AFP, free b-hCG and partly for PAPP-A was carried out for 3 years (1996-1998). 481 empty sacs and non-viable fetuses, 215 multiple pregnancies, and 67 cases of fetal malformations including 48 neural tube defects were revealed. NT³3 mm. was noted in 633 of the fetuses. Karyotyping of 417 of them gave us the possibility to detect 34 cases of aneuploidies (trisomy 21-12 cases, trisomy 18-7 cases, trisomy 13-3 cases, monosomy X-11 cases, and 1 case of triploidy). 37 cases of Down's syndrome were screened in the first trimester. NT measurement was performed in 29 of them, 12 fetuses had NT³3 mm. and 2 cases more could be detected using the risk calculation program. The Gaussian distribution parameters were estimated for Down's syndrome and unaffected pregnancies and used for risk calculation. At cut-off risk ³ 1:360 at the expected date of delivery detection rates for different markers combinations were: 77% for all three, 73% for PAPP-A and free b-hCG and 65% for AFP and free b-hCG (6; 7 and 8% false-positive rate, respectively). A modelling exercise for the screened population with NT, AFP, PAPP-A and free b-hCG predicts a 92% detection rate for Down's syndrome at 6% false-positive rate. It is still surprising that the first trimester screening has not become the standard of prenatal care yet.

Program Nr: 2102 from the 1999 ASHG Annual Meeting

A New Technique of Depositing Blastomeres onto Polycarbonate Filters for FISH. *W.D. Weber[1], C.H. Lytle[2], L.L. Estabrooks[2], K.T. Rapiejko[1], M.A. Lee[3], E. Johnson[3], G. Miller[1].* 1) Research & Develoment, Genzyme Genetics, Framingham, MA; 2) Genzyme Genetics Santa Fe, NM; 3) Fertility Center of New England Reading, MA.

Preimplantation Genetic Diagnosis(PGD) is a powerful technology capable of generating additional genetic information through the isolation and analysis of individual blastomeres from a developing embryo. Problems in the developmental process of the fetus can be predicted through specific genetic changes such as chromosomal aneuploidy, deletions or mutations. Molecular analysis of single blastomeres can be carried out through PCR amplification techniques, however information regarding individual chromosomes are lost since PCR is not quantitative.

Fluorescence In Situ Hybridization(FISH) can identify chromosomal aneuploidy that can be associated with fetal loss. Detection of chromosomal aneuploidy would potentially increase the success of IVF while reducing fetal loss, stillbirths and live children born with multiple anomalies. Advances in FISH technology have enabled multiple targets to be tested simultaneously in interphase nuclei providing specific information about chromosomal number in less than 4 hours. Currently FISH is performed on a blastomere after the deposition onto a microscope slide, a process that is technique dependent and difficult to control.(J. Harper et al., 1994)

We have identified a deposition methodology where the blastomeres are applied to polycarbonate filters for subsequent FISH analysis. This eliminates many of the problems associated with the current slide based deposition. An overview of this method will be presented.

.

Program Nr: 2103 from the 1999 ASHG Annual Meeting

Prenatal Diagnosis, Cytogenetic analysis and Postnatal FISH study of a structurally abnormal Y chromosome in a patient with Turner syndrome. *J.L Weiss[1], K.P. Magee[1], S.W. Cheung[2]*. 1) OB/GYN, Methodist Hospital, Dallas, TX; 2) Laboratories for Genetic Services, Inc. Houston, TX.

It has been suggested in the literature that all live born females with Turner syndrome carry a cell line containing two sex chromosomes, which may be present at low level of mosaicism. Delhanty JD et al (Ann Hum Genet 1998 62:99-106) reported that 2 of the 50 patients with a 45,X karyotype by conventional cytogenetic analysis were positive for six of the eight Y chromosome loci using PCR. Additional cytogenetic analysis confirmed the presence of a rearranged Y chromosome in 8% and 3% of the cells respectively. We reported a case of a 21-year-old primigravida with an abnormal triple screen suggesting an increased risk for Down syndrome (1 in 92). Amniocentesis was performed at 20 weeks gestation with level II ultrasound examination. Gender appeared to be female. The initial chromosome analysis from amniocytes revealed a 45,X chromosome pattern thereby indicating a fetus affected with Turner syndrome. This analysis excludes 20% mosaicism with 99% confidence when 20 colonies of cells are analyzed from 3 independent cultures. The patient elected to continue the pregnancy. Upon delivery, male genitalia was identified in the 6 lb. 4.4 oz infant and cord blood chromosome analysis revealed a 45,X[14]/46,X,idic(Y)(q11.2)[16] chromosome pattern. We retrospectively analyzed all the metaphase cells available on the amniotic culture slides and found 3.5 % of the colonies to have the idic (Y) (i.e. one colony each from the 3 primary cultures). Physical examination revealed a male infant with stage I hypospadias. A MRI revealed a 1.8 x 2.0-cm mostly fluid filled structure posterior to the bladder possibly representing an uterine remnant. A single testicle was identified on the right side of the scrotum. Neither testicle nor ovary was identified on the left side. Congenital heart disease was suspected and confirmed by an echocardiogram revealing an atrio-septal defect and a patent ductus arteriosus for which no intervention was required. The infant physically did well and was discharged on day three. Detailed cytogenetic studies and clinical observations of the infant will be presented.

Program Nr: 2104 from the 1999 ASHG Annual Meeting

Evaluation of maternal serum triple screen as identifier of trisomic fetuses. *S.L. Wenger, J. Lane, L.R. Brancazio, G.R. Hobbs, Jr.* West Virginia Univ, Morgantown, WV.

Maternal serum triple screen identifies women under 35 years of age who are at risk for carrying a fetus with Down syndrome. In order to detect 60% of trisomy 21 fetuses, the screen is designed to identify 5% of all women tested to be at increased risk. Of these women that undergo follow-up amniocentesis, 2-3% have a trisomy fetus. To determine our rate of detection, we retrospectively looked at amniocentesis performed for reasons of maternal serum triple screen or advanced maternal age since 1993. Medical records for approximately 800 cases in each category were reviewed for woman's age, risk of Down syndrome, karyotype results and number of ultrasound abnormalities. Our results showed that among 1600 women, six trisomy 21 and three trisomy 18 (all advanced maternal age) fetuses were identified. Among the maternal serum screen group 0.38% were trisomic, and among the maternal age group 0.75% were trisomic. While 5% of all ultrasounds had one or more abnormalities, they were present in 67% of trisomic fetuses. Currently less than half of pregnant women who are counseled about their increased risk for a fetus with Down syndrome have an amniocentesis. Our low detection rate may reflect that either not enough amnios are being performed to detect at risk pregnancies, or that our population is different from that of the national norm.

Program Nr: 2105 from the 1999 ASHG Annual Meeting

Challenges in the prenatal diagnosis of Walker-Warburg syndrome. *P.G. Wheeler[1], D. Levine[2], T.L. Stewart[1], D.W. Bianchi[1]*. 1) Division of Genetics, Department of Pediatrics, Tufts University School of Medicine, Boston, MA; 2) Dept. of Radiology,Beth Israel Deaconess Medical Center, Boston, MA.

Walker-Warburg syndrome is an autosomal recessive condition involving anomalies of the brain(lissencephaly and other structural defects), eye(cataracts and anterior chamber defects) and muscular dystrophy. We have recently had a case that highlights the difficulties and importance of making this diagnosis.

Abnormalities in the 1st pregnancy of a 33-year-old woman were first detected at 33 weeks' gestation when a prenatal ultrasound examination was performed for maternal concerns of decreased fetal movement. It showed marked hydrocephalus, cerebellar hypoplasia, and possible club feet. Fetal head MRI showed severe hydrocephalus,porencephaly,a non-dilated 4th ventricle, and cerebellar hypoplasia. The corpus callosum was not visualized. The preliminary diagnosis was cerebro-cerebellar dysplasia with porencephaly. Delivery occurred at 34 weeks. At birth, multiple joint contractures and minimal muscle mass were noted. The neonate died at 1 day of age from respiratory failure. At autopsy, partial lissencephaly, hydrocephalus and absence of the corpus callosum were detected. A muscle biopsy done shortly after death found abnormalities consistent with a congenital muscular dystrophy. Examination of the eyes revealed early sub-capsular cataracts. These findings are consistent with the diagnosis of Walker-Warburg syndrome.

The diagnosis of Walker-Warburg syndrome in the baby highlights several important factors, including that this diagnosis typically can not be made based on fetal ultrasound or fetal head MRI alone, since neither study generally detects the lissencephaly seen in this condition. Also, without a complete autopsy (including muscle pathology and eye dissection) the diagnosis of Walker-Warburg syndrome cannot be made accurately when it is the first presentation in the family. The accurate diagnosis of this condition is essential since as an autosomal recessive condition it has a 25% recurrence risk, which is considerably different than the neglible recurrence risk for porencephaly.

Program Nr: 2106 from the 1999 ASHG Annual Meeting

***SOX14* maps to human chromosome 3q22-23 and is expressed in the central nervous system and apical ectodermal ridge of the developing chick limb.** *H.P. Wilmore, M.J. Smith, S. Wilcox, K.M. Bell, A.H. Sinclair.* Dept of Paediatrics, Centre for Hormone Research, University of Melbourne and Murdoch Institute, Royal Childrens Hospital, Melbourne, Australia.

Members of the *SOX* gene family encode proteins with homology to the HMG box DNA-binding domain of *SRY*, the Y-linked testis-determining gene. A number of *SOX* genes have been shown to be important for normal embryonic development. Mutations in *SRY*, *SOX9* and *SOX10* are responsible for XY sex reversal, campomelic dysplasia and Waardenburg-Hirschsprung disease, respectively. In order to identify novel human *SOX* genes, a genomic library and two foetal brain cDNA libraries were probed with PCR products obtained using degenerate primers for known *SOX* (HMG) box sequences. One of the positive clones represented the human *SOX14* gene and the sequence of the entire coding region was obtained. Homology between the amino acid sequences places *SOX14* within the subgroup of *SOX* genes containing *SOX1*, *SOX2*, *SOX3* and *SOX21*, all of which are expressed in the central nervous system. In order to investigate the embryonic expression pattern of *SOX14*, we used PCR to amplify the chick orthologue and this was used as a probe in whole mount *in situ* hybridisation analysis of day 2 to day 6 embryos. Expression was seen in the ventral intermediate zone of the neural tube and in the apical ectodermal ridge (AER) of the developing limb. This is the only SOX gene known to be expressed in the AER, a structure which directs outgrowth of the embryonic limb bud.

The expression patterns and assignment of genes to human chromosomes has previously been used to correlate *SOX* genes with human disease phenotypes and known chromosomal locations. We therefore carried out FISH analysis, which localised *SOX14* to human chromosome 3q22-23, and further localised the gene to a 3Mb YAC within this region. Two human congenital syndromes which have been mapped to this chromosomal region are BPES (blepharophimosis, epicanthus inversus and ptosis) and Moebius syndrome. *SOX14* is therefore a candidate gene for these syndromes.

Program Nr: 2107 from the 1999 ASHG Annual Meeting

In Utero Fetal Therapy Using Pig Tail Shunts (1990-1998). *R.D. Wilson, M. Bebbington, D. Farquharson, F. Galerneau, N. Kent, D. Money, K. Williams, F. Tessier, A. Gagnon, K. Lim.* Division of Maternal-Fetal Medicine, University of British Columbia, Children's & Women's Health Center, Vancouver, British Columbia, Canada.

OBJECTIVE: In-utero fetal therapy using pig tail shunts has been a therapeutic option for a number of years. The most common anatomical areas for which this therapy is recommended are bladder, thorax and abdomen. This present report will review the in-utero fetal therapy pig tail shunting experience at the University of British Columbia, B.C. Women's Hospital from 1990-1998.

METHOD: This retrospective review evaluated cases identified through the fetal treatment register at B.C. Women's Hospital, Centre for Prenatal Diagnosis and Treatment. All fetuses that underwent evaluation whether or not a shunting procedure was undertaken were included. Complete outcome is available for this population including morbidity and mortality.

RESULTS: For bladder obstruction 19 pregnancies were worked up for obstructive uropathy. 10 had poor renal function while 6 had good renal function with 3 undergoing serial bladder aspirations and 3 undergoing vesicoamniotic shunting. Three did not have any evaluation of renal function. For the thorax, 12 pregnancies underwent work-up for unilateral/bilateral fetal pleural effusions. Three cases underwent thoracoamniotic shunting. Nine had serial aspirations only. Abdominal pathology was present in 7 cases with 1 case undergoing peritoneal-amniotic shunting. Other cases were treated with single or serial aspirations.

CONCLUSIONS: The appropriate selection of cases for in-utero shunting is required. Fetal morbidity and mortality is high within this treatment group and often shunting procedures do not improve fetal outcome in anatomical areas other than bladder neck obstruction.**OBJECTIVE**.

Program Nr: 2108 from the 1999 ASHG Annual Meeting

Congenital apnea in newborn mice lacking the Na^+/myo-Inositol cotransporter (SLC5A3) gene. *S. WU, R. BUCCAFUSCA, J. GOLDEN, J.J. MALLEE, A.D. LUCENTE, K.E. McVEIGH, G.T. BERRY.* Departments of Pediatrics and Pathology, The University of Pennsylvania School of Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA.

The known roles of myo-Inositol (mI) are to serve as precursor of the phosphoinositides, important in signal transduction, and as an intracellular osmolyte. A millimolar cellular concentration gradient for mI is maintained by Na^+-dependent mI transport in certain brain, peripheral nerve, ocular and renal cells. The only gene identified to date whose product is capable of active mI transport is SLC5A3 and its transcription is under osmoregulatory control. As part of a study designed to analyze SLC5A3 function *in vivo*, the murine homologue of SLC5A3 was cloned. Similar to human tissues, its transcription was found to be high in adult murine tissues such as brain and kidney. It is also expressed in murine mid- and late-gestational stage embryos and in placenta. Consistent with the abscence of active mI transport, no expression of SLC5A3 was found in striated muscle tissues, and minimal in liver. To evaluate the developmental and physiological role of SLC5A3-mediated high affinity, Na^+-dependent mI transport, mice lacking SLC5A3 (SLC5A3 -/-) because of targeted gene inactivation were generated. At postnatal 14 days of age, of 170 offspring of (SLC5A3 +/-) X (SLC5A3 +/-) matings, 63 were SLC5A3 +/+, 107 were +/- and 0 were -/-. The SLC5A3 -/- animals die shortly after birth without establishing sustained respiration. Initial anatomical and histological examinations of these mice at birth have not revealed gross abnormalities. These results suggest that the SLC5A3 gene is not critical for embryonic development, *de novo* mI synthesis by the fetal-placental unit probably being sufficient, as well as responsible for the relatively high concentrations of mI reported in fetal blood. The respiratory failure in SLC5A3 (-/-) newborn pups is probably due to restricted, albeit lethal, post-natal deficits in cellular mI availability. This model that simulates the stillborn may provide insight into the molecular mechanisms of control of respiratory/cardiovascular function and pathogenesis of apnea in human infants.

Program Nr: 2109 from the 1999 ASHG Annual Meeting

The Role of M6p/Igf2r in Mouse Heart Development. *A.A. Wylie[1,3], D.J. Pulford[1,3], J.G. Falls[1], P.H. McDonald[2], T.C. Orton[3], R.L. Jirtle[1].* 1) Radiation Oncology, Duke University, Durham, NC; 2) Departments of Medicine (Cardiology) and Biochemistry, Duke University, Durham, NC; 3) Safety of Medicines Department, Astra-Zeneca Pharmaceuticals, Cheshire, UK.

The M6p/Igf2r is a cell membrane associated glycoprotein involved in lysosomal targeting, degradation of the mitogen Igf2, and activation of the mitoinhibitor TGFb. The M6p/Igf2r has been mapped to the mouse Tme locus and is genomically imprinted with exclusive expression from the maternal allele. Several lines of evidence support the involvement of M6p/Igf2r in embryonic growth and organogenesis. M6p/Igf2r knockout studies in mice demonstrated that maternal inheritance of a M6p/Igf2r null allele as well as homozygosity for the inactive allele was lethal at birth. Histological analysis of these mice revealed multisystem defects and in particular abnormalities of the heart and lungs. Hearts were 2-5 times larger than controls and were characterized by a disorganized ventricular myocardium. To further address the role of the M6p/Igf2r in embryogenesis we have generated transgenic mice in which the single functional allele of M6p/Igf2r can be conditionally inactivated using the CRE-loxP recombination system. In particular we investigated the contribution of developmental defects in the heart to the lethal phenotype of M6p/Igf2r knockout mice. A transgenic line expressing CRE-recombinase under the control of the cardiac specific MLC-2v promoter was crossed with a transgenic line in which exon 10 of M6p/Igf2r was flanked by two loxP sites. CRE expression in the hearts of F1 hybrids results in the excision of exon 10, generating a M6p/Igf2r gene that encodes for a truncated protein lacking the entire extracellular domain of the receptor. Our data indicates that loss of M6p/Igf2r in the heart during development by itself is not lethal and the mice appear phenotypically normal. Using the same CRE-loxP system, we are now investigating the contribution of defects in lung development to the lethal phenotype of M6p/Igf2r knockout mice.

Program Nr: 2110 from the 1999 ASHG Annual Meeting

Functional and Structural Dissection of a novel Human BETA3 Gene, a bHLH Transcription Factor. *Z. Xu[1], A. Dutra[2], J. Piatigorsky[1]*. 1) Laboratory of Mol.& Dev. Biol., National Eye Institute, Bethesda, MD; 2) National Human Genome Research Institute Bethesda, MD20852.

The genes encoding basic helix-loop-helix proteins have been implicated in many aspects of neural development, including cell growth, differentiation and migration of precusor cells and postmitotic cells. A neural specific bHLH protein, human BETA3 (hBETA3) was cloned by homologous screening of human BAC library and subsequently mapped to chromosome 8q13. The mouse homologue gene (mBETA3) was mapped to chromosome 3qA3, which is a region of conserved synteny with human chromosome 8q13. Several candidate genes have been mapped to chromosome 8q13 in human, including Duanes syndrome type II. Genomic sequence analysis of the human and mouse BETA3 gene indicate that it contains a single exon, which is about 3.75 kb encoding a 381 amino acids bHLH protein (37 kDa predicted molecular weight). Multiple alignments of amino acid sequences of known BETA3 genes indicates several conserved motifs, and an identical 147 amino acid C-terminal region which contains a 60 amino acid bHLH domain. A 27-bp trinucleotide repeats (CAG)9 encoding poly-serine was found in human BETA3, and only one CAG in the corresponding position of mouse and hamster BETA3.Northern analysis of human BETA3 gene revealed its brain-specific expression pattern, which is most abundant in cerebellum. A putative transcription factor which contains two bHLH domains was identified by searching Caenorhabditis eleganss database, and each of the bHLH domains showed 73% and 63% identity to human BETA3 bHLH domain.

Program Nr: 2111 from the 1999 ASHG Annual Meeting

A MOUSE MODEL FOR RIEGER SYNDROME. *B. Yang[1], E. Semina[2], T. Hjalt[2], X. Cao[1], R.S. Reiter[3], P.A. Kirby[4], R.F. Hrstka[1], J.J. Lin[3], R.A. Williamson[1], J.C. Murray[2,3].* 1) Dept OB/GYN, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics, Univ Iowa, Iowa City, IA; 3) Dept Biologocal Science, Univ Iowa, Iowa City, IA; 4) Dept Pathology, Univ Iowa, Iowa City, IA.

Rieger syndrome is an autosomal dominant human disorder affecting eye, tooth and umbilical development, and whose primary morbidity is the 50% occurrence of glaucoma in affected individuals. The identification of etiologic mutations in the PITX2 gene and its encoded protein, solurshin, inspired the development of a transgenic animal that might serve as a model for this disorder. In addition, the more recent identification that PITX2 also plays a role in left-right axis determination also suggests that both heterozygote and homozygote knockouts might contribute to our understanding of cardiac development, as well. The mouse PITX2 homolog was identified and inactivated through gene targeting by deleting the homeobox region of the gene. Mice heterozygous for the deletion show Rieger-like in the craniofacial features, including smaller teeth and eyes, increased height of the skull, and smaller length of the mandible compared with their wild-type littermates. The heterozygotes are otherwise normal, including body weight, size, and fertility of both sexes. Mice homozygous for the Pitx2 deletion die in utero around embryonic day 9.5, though our analysis thus far does not suggest the cause of death. The heart, placenta, and umbilical core are normal and development is not obviously impaired. Further analysis of the homozygous embryos is ongoing.

Program Nr: 2112 from the 1999 ASHG Annual Meeting

X-inactivation patterns in cytotrophoblast vs tissues of human female fetuses. *S. Zeng[1], J. Yankowitz[1], J.C. Murray[2]*. 1) Dept OB/GYN, Univ Iowa Hosps & Clinics, Iowa City, IA; 2) Dept Ped, Univ Iowa Hosp & Clinics, Iowa City, IA.

One of the two X-chromosomes is inactivated in the early embryogenesis of female mammals to compensate for gene dosage compared to males. In the embryonic tissues the inactivation is random. There is controversy concerning human extra-embryonic tissues. Some have hypothesized and offered limited data to support preferential paternal X-inactivation. Some of the studies have not delineated the nature of the placental tissues studied, and there may be differences based on whether one evaluated the villus core versus the cytotrophoblast. We hypothesized that there would be skewed X-inactivation in human cytotrophoblast.

Placental tissue was collected from 137 first trimester abortuses and a variety of fetal tissues (heart, lung, liver, kidney, muscle, intestine, brain) were obtained when possible. Cytotrophoblasts were isolated by established protocols involving enzymatic digestion, filtration, Percoll density gradient and monoclonal antibody bound to magnetic beads. Sixty-three were females as identified by use of PCR for an X-Y marker. X-inactivation was analyzed using methylation status of the first exon of the androgen receptor gene. Of the 55 heterozygotes 37 displayed random inactivation (skewing 50-65%) and 18 had skewed inactivation (mild skewing >65-75%, n=9, moderate >75-85%, n=8, and severe >85%, n=1). Tissues were obtained from 24 of the 55 female fetuses (heart n=20, lung n=16, liver n=19, kidney n=23, muscle n=24, intestine n=24, and brain n=19: not all tissue types could be obtained from each fetus), only two instances of skewed inactivation were seen. This was in the liver (67.8%) and intestine (75.4%) of different fetuses. Our results indicate a greater degree of skewing in the extraembryonic tissues compared to embryonic tissues. However, it would appear that preferential X-inactivation in the placenta is not absolutely required for normal human embryonic or extra-embryonic development. The etiology of the skewing and the developmental implications are not clear.

Program Nr: 2113 from the 1999 ASHG Annual Meeting

A novel Pax-6 binding site with a high similarity to a region in B1 repetitive elements. *Y.-H Zhou[1], J.B. Zheng[1], X. Gu[2], W.-H Li[3], G.F. Saunders[1].* 1) Department of Biochemistry and Molecular Biology, The University of Texas M. D. Anderson Cancer Center, Houston, TX; 2) Department of Zoology-Genetics, and Iowa Computational Biology Laboratory (ICBL), Iowa State University, Ames, IA; 3) Department of Ecology and Evolution, University of Chicago, Chicago, IL.

Pax-6 encodes a paired domain and homeodomain transcription factor that plays an important role in the development of eye and central nervous systems. Through various combinations of its DNA binding domains, Pax-6 achieves specific and modular transcription regulation from their multiple DNA binding domains. Since the Pax-6 consensus binding sequence is relatively long, it is applicable to screen Pax-6 binding sequences from genomic DNA or search them from sequence database. Using an in vitro approach for the isolation of PAX6 binding sequences from a *Mbo* I digested human single-copy genomic DNA pool, we have identified a novel PAX6-specific binding site hGCa1BLs1 which has a high similarity with the 29-bp duplication region in B1 repetitive element. We examined the corresponding sequences in the consensus B1 elements for PAX6 binding by electrophoretic mobility shift assays (EMSA). As expected, PAX6 does not bind to consensus B1. However, mutation of G to T in position 93 or A to T in position 103 in the consensus B1 sequences examined leads to a gain of PAX6 binding ability. Search of database for B1 elements that contain the putative active PAX6 binding sequences retrieved 34 unique sequences from the rodent genome and one from the primate genome. Some are in functional genes which will be asigned for functional analyses. Sequence alignment analysis reveals that 14 sequences exhibit the modern B1 feature, while most of the other sequences exhibit feature of proto-B1 elements PB1 or PBD7. Phylogenetic analysis showed that these putative Pax-6 binding B1 sequences were mixed with rodent null B1 sequences included in the tree. All these analyses suggests that the Pax-6 binding B1 elements arose before the divergence of the primate and the rodent, and the null B1 could be re-activated by a single-step mutation. Thus B1 repetitive elements have the potential to be involved in the evolution of gene regulation by pax-6.

Program Nr: 2114 from the 1999 ASHG Annual Meeting

Exclusion of Neuropilin-2 as a candidate gene for Familial Primary Pulmonary Hypertension (FPPH). *K.B. Lane[1], R. Gaddipati[1], N. Fretwell[2], W.C. Nichols[3], FPPH Consortium[1,2,3,4].* 1) Department of Medicine, Vanderbilt University, Nashville, TN; 2) Dept. of Genetics, Leicester University, University Road, Leicester; 3) Division of Human Genetics, Children's Hospital Medical Center, Cincinnati, OH; 4) Indiana University School of Medicine Indianapolis, IN.

Primary pulmonary hypertension (PPH) is a vasocclusive disease of the pulmonary circulation. Prior to vasodilation therapy the average survival from diagnosis to death was 3.5 yrs. Six percent of PPH patients have an affected relative. Transmission is autosomal dominant with reduced penetrance. While the ratio of affected females to males is 2:1, the mortality curves for the sexes are similar. Father-to-son transmission is noted in several families. Five generations of transmission have been detected. In subsequent generations the disease is detected at earlier ages, displaying genetic anticipation, which has been linked to tri-nucleotide repeat expansions (TRE). Previous linkage analysis by us has localized the FPPH gene to a 10 Mb region of human genome at 2q32-q33 with a LOD score of >7. Cloning and EST makers have identified »100 transcription units in this region. We have begun screening candidate genes found in the region. A vascular endothelial growth factor (VEGF) receptor gene, neuropilin-2 (Nrp-2), was identified near the telomeric end of the FPPH CI. VEGF is involved in neovascularization, endothelial and SM growth, and recanalization, all associated with the lesions seen in PPH. A receptor for VEGF was considered a high priority candidate gene. EST primers for Nrp-2 were obtained and Nrp-2 expression in the lung was confirmed by RT-PCR. A 3' cDNA was obtained by PCR amplification. This probe was used to screen northern blots from control, FPPH, PPH, and Interstitial Pulmonary Fibrosis (IPF) lung RNA. No apparent differences, in quantity or size of the transcript were noted. Southern hybridization did not detect any alterations in genomic DNA structure associated with Nrp-2. Importantly, recombination at several novel microsatellite markers near and within Nrp-2, including one shown to be centromeric to NRP-2 by physical mapping, was detected which excludes NRP-2 and all genes telomeric as the FPPH gene.

Program Nr: 2115 from the 1999 ASHG Annual Meeting

Disruption of the dystrophin binding site of b-**dystroglycan in the mouse.** *J.C. Lee[1], M.D. Henry[1], R.F. Hrstka[2], R.A. Williamson[2], K.P. Campbell[1]*. 1) Departments of Physiology and Biophysics and Neurology, HHMI, University of Iowa College of Medicine, Iowa City, IA; 2) Department of Obstetrics and Gynecology, University of Iowa College of Medicine, Iowa City, IA.

The dystroglycan complex is composed of two proteins which are transcribed from a single gene and post translationally modified to produce a-dystroglycan, a 156 kD extracellular protein and b-dystroglycan, a 43 kD transmembrane protein. Based on its wide tissue distribution, the dystroglycan complex is believed to play diverse roles in various tissues. In skeletal muscle, the dystroglycan complex is part of the larger dystrophin-glycoprotein complex and contributes to the overall structure and function of the cell by creating a linkage between the extracellular matrix and the intracellular cytoskeleton through interactions of a-dystroglycan with laminin and b-dystroglycan with dystrophin. Dystroglycan also binds with high affinity to Dp116 in peripheral nerve. It is important in basement membrane formation, epithelial morphogenesis and as a receptor for certain viruses. Previous studies have determined that the 15 C-terminal amino acids of b-dystroglycan contain the binding site for both dystrophin and Dp116. In order to further elucidate the role of b-dystroglycan in skeletal muscle and other tissues, we introduced a premature stop codon eliminating the dystrophin binding site in murine embryonic stem (ES) cells through targeted homologous recombination. Biochemical analysis of total cell homogenates from heterozygous ES cells indicated that both the native (43 kD) and truncated (41.5 kD) forms of the protein were produced. *In vitro* analysis of ES cells homozygous for this mutation will allow us to examine the consequence of this mutation on the organization of the intracellular cytoskeleton. In addition, there may be effects of this mutation on a-dystroglycan and its laminin binding properties. Mice heterozygous for the truncated form of b-dystroglycan were viable and appeared healthy. Analysis of mice homozygous for the truncation is currently underway. Given the diverse roles of dystroglycan, it will be interesting to see the effect of this mutation in muscle and other tissues in the mouse.

Program Nr: 2116 from the 1999 ASHG Annual Meeting

Differential Expression of Human Genes in Hippocampus and Cerebellum. *S-J. Lee, L.E. Varnavas, C.B. Naves, R.J. Zahorchak.* R&D Departmant, Research Genetics, Huntsville, AL.

The hippocampus is responsible for learning and memory of intellectual functions and cerebellum for motor movement. The relative expression levels of genes in human hippocampus and cerebellum were determined using Human Gene Filters (Research Genetics Inc.) containing 25,000 genes hybridized with probes prepared from mRNAs from pooled human hippocampi and cerebella. By searching the differential expressed genes, we want to explore the candidate genes responsible for the differential functions between hippocampus and cerebellum. Collected data analyzed by Pathway 2.01 (Research Genetics Inc.) were calculated as relative ratios of gene expression in hippocampus to that in cerebellum. The obtained results indicated that 43 genes were expressed more abundant in hippocampus than in cerebellum by a factor of two or greater and that 16 genes were expressed more abundant in cerebellum than in hippocampus by a factor of two or greater. Myelin basic protein (MBP) was the gene most highly differentially expressed in hippocampus compared to cerebellum. The gene expression of MBP, which was expressed 3-4 fold higher in hippocampus compared to cerebellum, was confirmed by an independent method using Human RNA Master Blot (Clontech, Inc.) probed by MBP cDNA sequence. The later analysis also showed that MBP mRNA was highly and specifically expressed in 14 human brain tissues when compared to 28 other body tissues. Among brain tissues, MBP mRNA was expressed the least in cerebellum and the most in spinal cord. The protein expression level of MBP was also measured by western blot analysis with antibody against human MBP and homogenates from different parts of rat brain. The results showed that each MBP isoform was expressed the most abundant in spinal cord relative to other brain tissues. To date, we also have confirmed relative expression levels of three other genes more abundantly expressed in hippocampus when compared to cerebellum with Human RNA Master. These data suggest that using Gene Filters as an initial screening tool is a good approach to filter out potential candidate genes for further validation.

Program Nr: 2117 from the 1999 ASHG Annual Meeting

Alternative splicing and polyadenylation processes occur in the gene HFE. *J-Y. Le Gall, A. Thenie, I. Gicquel, M. Ohrant, V. David, J. Mosser.* Faculty of Medicine, UPR 41 CNRS, Rennes, France.

The gene HFE responsible for hemochromatosis, which is located 4.5 Mb to HLA-A, has been cloned in 1996; it belongs to the MHC class I gene family. Several direct and indirect studies have demonstrated its involvement in both the metabolism of iron and the pathogeny of hemochromatosis. The HFE gene covers 12 kb and its structural organization, deduced from a 2.7 kb cDNA, includes 7 exons. Even if HFE might take a prominent place in the maintenance of iron homeostasis, poorly is known concerning the regulation of its expression. Hybridization experiments carried out on human multiple-tissue Northern blots revealed at least five differentially expressed mRNA. As previously described, the major transcript, 4 kb in size, is almost ubiquitously expressed, but with different expression levels among the tissues tested. We never observed a 2.7 kb mRNA, indicating that the cDNA, published at present, does not correspond to a full length molecule. Moreover the multi transcript pattern observed on Northern blots strongly suggests that HFE undergoes alternative splicing processes. Using the cDNA selection approach performed on mRNA from HeLa cells, we could clone and sequence two differentially spliced cDNA: one resulting from a proximal terminaison occurring in exon 6 and the other resulting from the splicing of several central exons. In parallel, RT-PCR experiments were carried out on the same mRNA; further hybridizations of these RT-PCR products with the different HFE exons evidenced at least ten other transcripts resulting from the splicing of one or several exons. These molecules are now under studies; the analysis of these alternative HFE mRNA might extend our knowledge of the molecular mechanisms of iron metabolism and the implication of HFE in hemochromatosis.

Program Nr: 2118 from the 1999 ASHG Annual Meeting

Characterization of human CYP17 (P450c17) promoter elements required for basal transcription in human adrenal cells. *C.J. Lin, W.L. Miller.* Pediatrics, UCSF, San Francisco, CA.

Cytochrome P450c17 is a single protein that catalyzes steroid 17a-hydroxylase and 17,20 lyase activities which are required for glucocorticoid and sex steroids synthesis, respectively. P450c17 is expressed in testicular Leydig cells, ovarian theca cells, and in the adrenal zonae fasciculata and reticularis, but not in ovarian granulosa or adrenal glomerulosa cells. Thus, characterization of factors involved in its tissue-specific transcriptional regulation may allow a better understanding of the diversity of steroid production among steroidogenic tissues. We constructed and expressed 13 promoter/reporter constructs containing from 63 to 3700 bp of CYP17 5' flanking DNA in human adrenal NCI-H295A cells, localizing essential basal elements between -184 and -227 bp. DNase I footprinting of -1 to -330 bp detected footprints at -24/-17, -70/-33, -107/-84, -178/-152 and -220/-185 bp. The -24/-17 region contains the TATA box (TTTAAAA) of P450c17 and presumably binds RNA polymerase. The -33/-70 fragment contains a putative recognition site for SF-1 and a potential site for GATA-1. Oligonucleotides containing -107/-84, -178/-152 and -220/-185 bound specifically to NCI-H295A nuclear proteins. Methylation interference assay revealed that the nuclear proteins interacts with both -107/-84 and -178/-152 through the NF-1 recognition sequence ((C/T)TGGC$(N)_6$CC$(N)_3$). Mutation of only 2 relevant bases (GG or CC) in these sequences decreased the DNA-protein binding in both fragments significantly. In the -220/185 fragment, bases -197/-195 were essential for the DNA-protein interaction but there is no factor known to bind to this sequence. Thus a NF-1-like nuclear factor binds to two of three sites in the basal enhancer sequence but the identity of the third, potentially specific factor is not yet known. Identification of this novel transcription factor binding site will permit the cloning and identification of the cognate factor.

Program Nr: 2119 from the 1999 ASHG Annual Meeting

Expression and evolution of the RBMX gene family. *P.A. Lingenfelter[1], M.L. Delbridge[2], S.S Thomas[1], J.M. Graves[2], C.M. Disteche[1]*. 1) Dept. of Pathology, Univ. of Washington, Seattle, WA; 2) Dept. of Biochemistry and Genetics, La Trobe Univ., Melbourne, Australia.

RBMX and RBMY are members of a pair of RNA-binding-motif genes with homologues on the human X and Y chromosomes (Delbridge et al., Nature Genetics, in press). RBMY, originally isolated from the Y, is specifically expressed in testis and has been implicated in male fertility. RBMX, located at Xq26, was previously shown to have a similar intron-exon structure as RBMY and to be subject to X inactivation. However, unlike RBMY, RBMX is ubiquitously expressed. FISH analysis using a probe for RBMX revealed several highly homologous sequences in the human genome. RBMX-like sequences were found at loci on human chromosomes 1, 4, 6, 9 (two loci), 11 and at a second locus on the X, which was confirmed by analysis of somatic cell hybrids retaining single human chromosomes. Sequence analysis of the RBMX-like genes revealed absence of introns, consistent with these sequences representing processed retroposons. Stop codons and deletions were found in some of these RBMX-like genes, suggesting that they are not functional. However, three of the RBMX-like genes are expressed in human tissues with different patterns between the genes, suggesting that they have evolved separate functions. These processed RBMX-like genes are conserved in primates where copies were found by PCR and FISH analyses on the corresponding chromosomes. Thus the dispersion of this family of expressed retroposons has occurred prior to the divergence of primates. The high conservation and expression of these RBMX-like genes suggest that they play important roles.

Program Nr: 2120 from the 1999 ASHG Annual Meeting

An XIST Promoter Mutation Associated with Skewed X Inactivation Alters the Pattern of Transcription Factor Binding. *M.D. Litt[1], M.A Goldman[2], R.M. Plenge[3], B.D. Hendrich[3], H.F. Willard[3], T.P. Yang[1]*. 1) University of Florida College of Medicine, Gainesville, FL; 2) San Francisco State University, San Francisco, CA; 3) Case Western Reserve University, Cleveland, OH.

Female mammals inactivate genes on one of two X chromosomes to compensate for the dosage imbalance of X-linked genes in males and females. The XIST gene, a gene transcribed only from the inactive X chromosome, has been shown to play a crucial role in the process of X chromosome inactivation. To identify cis- and trans-acting elements that regulate transcription of the human XIST gene, we analyzed the minimal promoter of the active and inactive genes by ligation-mediated PCR in vivo footprinting. Analysis of the normal XIST promoter on the inactive X chromosome revealed in vivo footprints over two potential Sp1 binding sites and a sequence of seven consecutive cytosines. No in vivo footprints were detected in the XIST promoter on the active X chromosome. These results are consistent with previous in vitro promoter analysis of the XIST gene which indicated that the Sp1 binding sites and the cytosine string are important for XIST expression. Recently, a C to G promoter mutation within the seven consecutive cytosines was identified in two unrelated families demonstrating preferential inactivation of the X chromosome harboring the mutation. In vivo footprint analysis of the mutant promoter on the inactive X chromosome revealed loss of multiple guanine contacts on the lower strand and the gain of two novel guanine contacts on the upper strand in the vicinity of the mutation. These data provide direct in vivo evidence that the functional consequences of the mutation (i.e., skewed X inactivation) may be mediated by altered transcription factor binding to the mutant XIST promoter. Therefore, we postulate that: 1) cis- and trans-acting regulatory elements in the promoter region play a key role in XIST allele selection during the process of X chromosome inactivation, and 2) the propensity to establish expression of the mutant XIST allele, and thereby inactivate the corresponding X chromosome, may be caused by a disruption or alteration of normal transcription factor binding to the mutated promoter.

Program Nr: 2121 from the 1999 ASHG Annual Meeting

Cloning of two members of the human *erg* potassium channel gene family. *N. Masuda[1, 2], S.-Y. Jeong[1, 2], H. Hashida[1, 2], T. Suzuki[1], Y. Ichikawa[2], N. Hazeki[1, 2], J. Goto[1, 2], I. Kanazawa[1, 2].* 1) CREST, Japan Science and Technology Corporation, Tokyo, Japan; 2) Department of Neurology, Graduate School of Medicine, University of Tokyo.

Potassium channels are ubiquitous membrane proteins that form the largest family of ion channels in terms of both function and structure. More than 40 genes encoding potassium channel subunits are now identified in mammals. The *erg* potassium gene families share the six-membrane-spanning architecture of the Kv class of voltage-gated potassium channels. The *erg* gene recently has become the center of considerable interest because mutations in this gene have been shown to underlie one form of a human genetic disease known as long QT syndrome, which gives rise to arrhythmias and an increased incidence of sudden death. We report here the clonings of two members of the human *erg* potassium channel gene family, *erg2* and *erg3,* which was isolated from human brain cDNA library. Human *erg2* was cloned by PCR using the primers that were designed based on the sequence of EST. Human *erg3* was isolated by PCR using the degenerate oligonucleotides directed against conserved region of the human *erg1*, rat *erg2*, and rat *erg3*. The complete coding region of *erg2* shares 90% protein homology with rat *erg2* . The human *erg3* shares 89% protein homology with rat *erg3*. The expression of human *erg2* and *erg3* in human tissues were examined by Nothern blot analysis. The human *erg2* gene and *erg3* gene were expressed exclusively in the nervous system and the sizes of the messages were approximately 3.2kb and 3.7kb respectively.

Program Nr: 2122 from the 1999 ASHG Annual Meeting

Tuberous sclerosis type 2: RNA based detection of complex splicing aberrations in the *TSC2* gene by the protein truncation test (PTT). *K. Mayer, S. Schirdewahn, W. Ballhausen, HD. Rott.* Institute of Human Genetics, Erlangen, Germany.

Mutation analyses in tuberous sclerosis (TSC) have reported a wide variety of disease causing aberrations in the two known predisposing genes, *TSC1* and *TSC2* on chromosomes 9q34 and 16p13, comprising mainly small truncating mutations distributed over the entire genes. We performed an RNA based screening of the entire coding regions of both TSC genes applying the protein truncation test (PTT) and identified a high proportion of unusual splicing abnormalities affecting the *TSC2* gene. Aberrant splicing products were initially detected as shortened polypeptides after in vitro transcription/translation, were identified through cloning and sequencing, and were confirmed by direct amplification of RT-PCR products. In two representative examples the causative changes on the genomic level turned out to be different splice acceptor mutations in intron 9 (IVS9-15G>A and IVS9-3C>G) both leading to identical exon 10 skipping and simultaneous usage of a cryptic splice acceptor in exon 10. Another splice acceptor mutation (IVS38-18A>G) destroyed a branch point sequence in intron 38 and resulted in simultaneous intron 39 retention and usage of a downstream cryptic splice acceptor in exon 39. All splice acceptor mutations described lead to different types of abnormal truncated transcripts deleting or affecting one of the known interaction domains of tuberin either for hamartin or for rabaptin5. One further patient exhibited a C>T transition in intron 8 (IVS8+281C>T) activating a consensus splice site and resulting in inclusion of a newly recognized exon in the mRNA followed by a premature stop. It is important to note that three of the reported splicing abnormalities are due to sequence changes remote from exon/intron boundaries which are described for the first time in TSC. These findings strengthen the importance of investigating intronic changes and their consequences on the mRNA level as disease causing mutations in TSC.

Program Nr: 2123 from the 1999 ASHG Annual Meeting

Recombinant Hepatitis B Surface Antigen Particles and Anionic Phospholipid Bind to Identical Sites on Apolipoprotein H (b**2-Glycoprotein I) as Revealed by Site-Directed Mutagenesis.** *H. Mehdi, A. Naqvi, M.I. Kamboh.* Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Apolipoprotein H (apoH) is an essential cofactor for the production of antiphospholipid antibodies (APA) and it has also been implicated as a possible soluble receptor for hepatitis B virus (HBV). Two naturally occurring missense mutations, Cys306Gly and Trp316Ser, in the fifth domain of apoH have been shown to disrupt the binding of apoH to anionic phospholipid (PL). We have previously shown that the binding of recombinant hepatitis B surface antigen (rHBsAg) particles with apoH is dependent on the integrity of disulfide bonds and lysine residues of apoH. Since the Gly306 mutation disrupts a disulfide bond which clusters several lysine residues and the Ser316 mutation affects the integrity of an evolutionary conserved hydrophobic sequence at positions 313-316, we hypothesized that anionic PL and rHBsAg particles would have similar binding sites on apoH and therefore these mutations would also disrupt the apoH-rHBsAg binding. We created the two mutations in apoH cDNA by site-directed mutagenesis and expressed them in COS-1 cells. The binding of recombinant apoH with rHBsAg particles and anionic PL was examined by ELISA. As compared to normal binding of the wild type apoH to rHBsAg particles and anionic PL, the mutant types apoH did not bind to either ligand. To further examine if the hydrophobic sequence at positions 313-316 is critical for binding with rHBsAg particles and anionic PL, we mutagenized the remaining three hydrophobic residues to neutral residues (Leu313Gly, Ala314Ser and Phe315Ser) and expressed them in COS-1 cells. While the Ala314Ser mutant type showed normal binding with rHBsAg particles and anionic PL, the Leu313Gly and Phe315Ser mutants showed only 38% and 9% binding with rHBsAg particles, respectivly and 27% and 17% binding with anionic PL, respectively. These data demonstrate that rHBsAg particles and anionic PL share identical binding sites on apoH. The characterization of binding sites for anionic PL and rHBsAg particles on apoH may help to understand the role of apoH in APA production and mediating the entry of HBV to hepatic cells, respectively.

Program Nr: 2124 from the 1999 ASHG Annual Meeting

Structural and functional analysis of a novel mammalian *trans*-effector of nonsense-mediated RNA decay. *J.T. Mendell[1, 2], S.M. Medghalchi[1, 2], R.G. Lake[1], H.C. Dietz[1]*. 1) HHMI and The Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) These authors contributed equally to this work.

The recognition and accelerated decay of transcripts harboring premature termination codons (PTCs) is a ubiquitous feature of eukaryotic cells. This phenomenon, termed nonsense-mediated RNA decay (NMD), has been postulated to serve a protective role by preventing the translation of potentially deleterious truncated peptides. NMD has also been implicated in the regulation of steady-state levels of selected physiologic transcripts. In *S. cerevisiae*, 3 *trans*-acting factors (Upf1p-3p) are required for NMD. Strong structural and functional homologues of Upf1p have been identified in numerous species, including *S. pombe*, *C. elegans* (smg2), mouse (rent1), and human (rent1), showing that the NMD machinery, at least in part, is conserved through evolution. No counterparts for Upf2p or Upf3p have been described in other species. Here we report the initial characterization of a human homologue (RENT2) of UPF2. When compared to *S. cerevisiae* Upf2p, rent2 exhibits 21% identity and 39% similarity. Northern blot analysis demonstrated that RENT2 encodes a 5.5 kb ubiquitously expressed transcript. As an initial attempt to confirm that weak Upf2p homologues function in the NMD pathway, we identified a protein in *S. pombe* (pUpf2p) that shows the same degree of structural divergence from Upf2p as rent2. Stabilization of Ade6 nonsense transcripts in *S. pombe* following targeted disruption of pUPF2 established that the gene product is essential for NMD. These data provide compelling evidence that rent2 is the mammalian orthologue of Upf2p. Ongoing functional analyses include complementation studies in yeast and dominant negative expression studies in mammalian cells. Despite the fact that NMD is not essential in yeast or *C. elegans*, these data document strong selective pressure for conservation of Upf2p function. The study of evolutionarily conserved domains of Upf2p/rent2 may provide new insight regarding the basic mechanism and physiologic role of NMD in eukaryotic cells.

Program Nr: 2125 from the 1999 ASHG Annual Meeting

Isolation and Characterization of a new WD-repeat protein, GNB5, on Human Chromosome 21q22.3. *J. Michaud[1], M.D. Lalioti[1], J. Kudoh[2], S. Minoshima[2], N. Shimizu[2], C. Rossier[1], S.E. Antonarakis[1], H.S. Scott[1]*. 1) Div. of Medical Genetics, Geneva University Medical School and University Hospitals, Switzerland; 2) Dpt of Molecular Biology, Keio, University School of Medicine, Japan.

In order to identify candidates genes for Down syndrome phenotypes or for monogenic disorders that map to HC21, we are using exons trapped from a partial 21q22.3 bacterial contig, with homology to proteins from other species or containing specific protein motifs to pursue full-length transcripts.

We isolated a full-length cDNA mapping between D21S212 and D21S171, encoding a putative peptide of 412 amino acids with 4 guanine nucleotide-binding WD-repeats, GNB5. Northern analysis revealed two RNA species of 1.5 Kb and 2.1 Kb, the 1.5 Kb transcript being produced due to a splicing event after the stop codon. The 2.1 Kb transcript was mainly observed in fetal tissues while the shorter transcript was highly expressed in fetal liver. Both transcripts encode the same protein. Homologies, secondary structure and motif analyses of the putative GNB5 protein show the presence of 4 WD-repeats, likely to forming a propeller structure similar to known WD-repeats containing proteins. Most of these contain between 4 to 8 repeats and have diverse functions such as, among others, signal transduction and regulation of cytoskeletal assembly and cell cycle. Two alternative splicing events have been observed by RT-PCR, mainly in fetal tissues. An alternative splicing of 270 bp resulted from the omission of exons 4 and 5 which encode for two WD-repeats, and maintained the open reading frame. The second alternative splicing of 52 nucleotides removed a part of exon 3, destroying the open reading frame. From its mapping position, GNB5 is a candidate for genetic disorders linked to 21q22.3, such as one form of bipolar affective disorder, and of non-syndromic autosomal recessive deafness (DFNB10). The genomic sequence and structure of the gene have been determined to enable mutation analysis. The GNB5 gene contains eleven coding exons and a twelfth exon in the 3'UTR of the 1.5 Kb mRNA, spanning 36 Kb in total. In addition we are pursuing identification of mouse homologues to aid in functional analyses.

Program Nr: 2126 from the 1999 ASHG Annual Meeting

The regulatory function of CFTR is evolutionarily conserved. *J.E. Mickle, M.I. Milewski, G.R. Cutting.* Institute of Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD.

Cystic fibrosis (CF) is a disorder of epithelial cell ion transport caused by mutations in the CF transmembrane conductance regulator (CFTR). CFTR functions as a chloride channel and a regulator of separate channels in the same cell. The importance of the regulator function in the development of the CF phenotype is unknown. Evolutionary conservation of the regulator function would indicate that it plays an important role in CFTR-mediated ion transport. The most distant cousin of human CFTR cloned to date is from the killifish (*Fundulus heteroclitus*). Killifish (kf) and human (h) CFTR share 60% amino acid identity. In this study, we expressed kfCFTR in human cells to determine whether it regulates separate chloride channels. To assess whether kfCFTR was processed in the same fashion as human CFTR, we transiently expressed kfCFTR in human embryonic kidney 293 cells. Cell lysates were immunoprecipitated with a monoclonal antibody specific for the C-terminus of kfCFTR followed by protein kinase A radiolabeling with ^{32}P, SDS-PAGE and autoradiography. Similar to mature hCFTR, kfCFTR was detected as a single band with an approximate molecular mass of 190 kDa, indicating the kfCFTR is fully processed in human cells. The function of kfCFTR was studied in IB3-1 human CF airway epithelial cells by whole cell patch clamp. To facilitate detection of transfected cells, kfCFTR was co-expressed with GFP at a 10:1 ratio (kfCFTR:GFP). Cells were bathed in CPT-cAMP(200mM) and forskolin(5mM), conditions that maximally activate hCFTR. Whole cell recordings reveal that expression of kfCFTR in IB3-1 cells is associated with two chloride currents: a non-rectifying glybenclamide-sensitive component characteristic of the intrinsic channel of CFTR, and an outwardly-rectifying DIDS-sensitive component indicative of CFTR-mediated regulation of separate chloride channels. These data suggest that CFTR-mediated regulation of other channels is evolutionarily conserved and therefore likely to be essential for normal epithelial ion transport.

Program Nr: 2127 from the 1999 ASHG Annual Meeting

The human EZH2 gene: Genomic organization and revised mapping in 7q35 within the critical region for malignant myeloid disorders. *C. MIGNON[1], C. CARDOSO[1], G. HETET[2], B. GRANCHAMP[2], M. FONTES[1], L. COLLEAUX[1]*. 1) INSERM U491, Faculte de Medecine de la Timone, Marseille, FRANCE; 2) INSERM U409 and Centre de Recherche Claude Bernard, Faculte de Medecine Xavier Bichat, Paris, FRANCE.

The EZH2 gene is a human homolog of the Drosophila Polycomb-group (Pc-G) gene Enhancer of zeste, a crucial regulator of homeotic gene expression. Several lines of evidence suggest a critical role for the EZH2 protein during normal and perturbed development of the hematopoietic and central nervous systems. Indeed, the EZH2 protein has been shown to associate with the Vav proto-oncoprotein and with the XNP protein, the product of a mental retardation gene. The EZH2 gene was previously reported to be located on chromosome 21q22 and was proposed as a candidate gene for some characteristics of the Down syndrome phenotype. We report here the genomic structure and fine mapping of the EZH2 gene. We demonstrate that the functional gene actually maps to chromosome 7q35 and that the sequence previously isolated from a chromosome 21 cosmid corresponds to a pseudogene. Finally, the nature of the EZH2 protein and its mapping to the critical region for malignant myeloid disorders lead us to propose the EZH2 gene to be involved in the pathogenesis of 7q35-q36 aberrations in myeloid leukemia.

Program Nr: 2128 from the 1999 ASHG Annual Meeting

Charaterization of the mouse Ccs gene and mapping the human counterpart. *S.D.P. Moore, M.M. Chen, D.W. Cox.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Copper does not exist in a free state within cells, but is always bound to metalloproteins. Specific metallochaperones escort copper to numerous targets within the cell, providing protection from the toxic effects of intracellular free copper. The known components of the intracellular copper transport pathway are identical in yeast and mammals. Yeast Lys7p (human CCS (copper chaperone for superoxide dismutase)) delivers copper to superoxide dismutase (SOD1), yeast Cox17p (human COX17) delivers copper to cytochrome c oxidase in the mitochondria via Sco1p (human SCO1), and yeast Atx1p (human ATOX1) delivers copper to the P-Type ATPase, Ccc2p (human ATP7A and ATP7B). Many, but not all, of these genes have been characterized in yeast, mouse, and human. To further characterize murine Ccs we have cloned it by screening a murine cDNA library with a human CCS clone, providing both the coding region and the 5' and 3' UTRs. We obtained a 1174 base pair (bp) cDNA with an 825 bp open reading frame. The open reading frame putatively translates a 274 amino acid protein that is 86.9% identical to human CCS. A comparison of the hydrophobicity plots confirms both the conservation between hydrophobicity and the cytosolic nature of the conserved proteins. In addition, we have mapped human CCS to 11q13, utilizing a hamster/human radiation hybrid panel. CCS has been demonstrated to be an integral part of the disorder amylotrophic lateral scerosis (ALS). Further characterization of mouse and human CCS will aid in studying this disorder.

.

Program Nr: 2129 from the 1999 ASHG Annual Meeting

Isolation and characterization of a novel human transcript in the Familial Dysautonomia candidate region on human chromosome 9q31. *J. Mull[1], M. Leyne[1], S.P. Gill[1], C.B. Liebert[1], C.M. Robbins[2], H.W. Pinkett[2], I. Makalowska[2], C. Maayan[3], A. Blumenfeld[3], F.B. Axelrod[4], M. Brownstein[2], B.P. Chadwick[1], S.A. Slaugenhaupt[1]*. 1) Molecular Neurogenetics, Harvard Medical School, Boston, MA; 2) National Institutes of Health, Bethesda, MD; 3) Hadassah University Hospital, Jerusalem, Israel; 4) New York University Medical School,New York, NY.

Familial Dysautonomia (FD; Riley Day syndrome or hereditary sensory neuropathy type III) is an autosomal recessive disorder characterized by pervasive sensory and variable autonomic dysfunction. FD affects the development of sensory, sympathetic and some parasympathetic neurons. The gene defect is found almost exclusively in the Ashkenazi Jewish population where it has a carrier rate of 1 in 30 and an incidence of 1 in 3600 live births. We used a combination of linkage analysis, haplotype analysis and physical mapping to narrow the candidate region of the FD gene to a 0.5 cM region on human chromosome 9q31. Exon trapping, cDNA selection and genomic sequencing of overlapping BACs, YACs, and cosmids were used to isolate a novel transcript, CG-8, from the FD candidate region. Northern analysis revealed a ubiquitous 2kb transcript with highest expression in adult testis. An open reading frame was identified that encodes a 181 amino acid protein with 30% amino acid identity to the glycine cleavage system H protein of Yeast and bacteria. A total of six exons were identified for CG-8 by direct genomic sequencing, covering approximately 6.5kb. The full coding region of CG-8 was sequenced from genomic DNA and reverse transcribed RNA in four affected, and two non carrier individuals. A 4 bp deletion was identified in the 3' UTR of CG-8. Further analysis showed the 4bp deletion in two non-carrier individuals indicating that the sequence change was not responsible for the pathogenesis in FD. Although no coding mutaions were found, a promoter or non-coding mutation remains a possibility and is currently under investigation.

Program Nr: 2130 from the 1999 ASHG Annual Meeting

Analysis of *GFR*a*1* polymorphism and splice variants; effect on GFRa1/GDNF/RET complexes. *S. Myers[1], D. Worley[2], G. Cote[3], L. Mulligan[1].* 1) Dept Pathology, Queen's University, Kingston, ON, K7L 3N6, Canada; 2) BIOGEN, Inc., Cambridge, MA 02142; 3) M.D. Anderson Cancer Center, Houston, TX 77030.

The signaling complex of the RET receptor tyrosine kinase, GFRa1 and GDNF, is recognized as essential for normal sympathetic enervation of the gut. Mutations throughout the *RET* gene have been found to be responsible for Hirschsprung disease (HSCR) and mutations in *GDNF* are also believed to contribute to this disease. No mutations have been identified in the *GFRa1* gene in HSCR patients but five polymorphisms are present in this gene which result in amino acid changes. The variable penetrance and expressivity of HSCR suggest that one or more loci may modify the HSCR phenotype associated with *RET* mutations. One possible modifier could be functional differences associated with these different polymorphic isoforms of GFRa1. In order to test this we have generated *GFRa1* cDNA clones containing each polymorphic allele at two of these sites, 253T/A (Y85N) and 1081A/G (T361A), using *in vitro* mutagenesis. We have transfected these constructs into E293 cells and assayed for the amount of GFRa1 protein produced and translocated to the cell surface by western analysis of PIPLC cleaved GFRa1, and FACS analysis using anti-GFRa1 antibodies. Our data show that GFRa1 proteins containing either of the two amino acids at codons 85 or 361 are expressed and translocated to the cell surface with similar efficiency. FACS analysis of GDNF binding to E293 cells expressing these different forms of GFRa1 further suggests that binding efficiency is similar among the three forms. Binding of RET to GFRa1/GDNF complexes also appears to be equivalent for the GFRa1 forms using a similar FACS analysis. In addition to the polymorphisms, a splice variant of GFRa1, resulting in the addition of five amino acids, has been identified. We have generated a GFRa1 construct containing these extra amino acids. In the context of the GFRa1 polymorphisms described, we are currently comparing the expression and binding of these GFRa1 proteins in E293 as outlined above.

Program Nr: 2131 from the 1999 ASHG Annual Meeting

Splice variants, expression and identification of the murine orthologue of the retina-specific L-type calcium channel *CACNA1F* gene, which is mutated in patients with incomplete CSNB. *M.J. Naylor[1], D.E. Rancourt[2], N.T. Bech-Hansen[1]*. 1) Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Oncology, University of Calgary.

Patients with incomplete X-linked CSNB (iCSNB) have mutations in *CACNA1F*, an L-type calcium channel alpha-1-subunit gene mapping to Xp11.23 (Nature Genet. 19:260-263 and 264-267, 1998). More than 18 different mutations of this gene have been identified by our laboratory in patients with iCSNB and in several patients reported to have Aaland Island eye disease (AIED) or AIED-like disease, suggesting that iCSNB and AIED/AIED-like conditions are allelic forms of the *CACNA1F* gene. In studying the genomic organization of *CACNA1F*, several splice variants were observed across the cDNA of this gene. For example, variants involving two forms of exon 1 and five forms of exon 2 were identified; several combinations of these exons are predicted to yield complete splice-variant proteins. Mutations in three families with incomplete CSNB were located in the unique portion of the larger variant of exon 2, suggesting a significant role for this particular exonic variant. Our findings suggest a prototypical cDNA sequence of *CACNA1F* which produces a protein of 1977 amino acids. In further studies, we have identified the sequence of the full-length murine homologue of *CACNA1F*, *Cacna1f*. Mapping of this homologue to a mouse BAC which also contained the mouse synaptophysin gene established that the identified *Cacna1f* gene is the orthologue of the gene for incomplete CSNB. Furthermore, *in situ* hybridization using mouse probes of *Cacna1f* on mouse retinal sections showed expression of *Cacna1f* in the outer and inner nuclear layers, and the ganglion cell layer of the retina. Having identified the full-length mouse orthologue of *CACNA1F* and the expression pattern of *Cacna1f* in the retina, we are in a position to construct an animal model of iCSNB. This research was supported in part by the RP Research Foundation (Canada) (NTBH, DER), the Odd Fellow Rebekah Visual Research Student Awards (MJN).

Program Nr: 2132 from the 1999 ASHG Annual Meeting

Cloning and sequence analysis of Drosophila, Xenopus and Chicken orthologs of the human Ubiquitin-Fusion-Degradation 1 (UFD1L) gene. *G. Novelli[1], A. Ratti[2], M. Bozzali[2,3], A. Botta[1], F. Sangiuolo[1], A. Pizzuti[2,3], B. Dallapiccola[1,3].* 1) Dpt Biopathology Tor Vergata University and CSS Mendel Institute, Rome,Italy; 2) Institute of Neurology, University of Milan, Milan, Italy; 3) IRCCS CSS San Giovanni Rotondo, Italy.

UFD1L gene encodes the human homolog of the yeast ubiquitin fusion-degradation 1 protein (UFD1p), which in yeast is active in a ubiquitin-dependent proteolytic pathway. Depletion of this protein also affects polyadenylation activity, resulting in defective RNA processing. The UFD1L mRNA is expressed in brain, lungs, branchial arches, cardiac outflow tract, lens, otocyst and limb bud. UFD1L is deleted in DiGeorge syndrome (DGS) and velocardiofacial syndrome (VCFS) patients and, based on expression profile, is considered at present a strong candidate for this disease. In order to elucidate the biochemical role of the gene product during invertebrate and vertebrate development, we characterized the UFD1L orthologs from D.melanogaster, X.laevis and Chick. The nucleotide homology of the Drosophila and Xenopus orthologs compared to the mammalian cDNAs is low. However when the sequence got translated into protein the overall homology raised to more than 84% (60% identity) of the mammalian cDNA. The maximum homologies rest in the central and COOH portions of the protein, while at NH2 end the homology is low. The chicken protein has a 95% identity to the mammalian proteins. The gene structure is conserved in human, mouse and Drosophila. This study demonstrates that the biological function of the UFD1L gene product is evolutionary conserved and provides new insight into understanding the DGS pathogenesis. Work supported by an Italian Telethon grant (E.723) and (364/bi).

Program Nr: 2133 from the 1999 ASHG Annual Meeting

Genomic Organization and Immunofluorescence Studies of Human Sarcospan. *K.F. O'Brien[1], L.M. Kunkel[1,2]*. 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) HHMI/Division of Genetics, Children's Hospital, Boston, MA.

Sarcospan has recently been identified as the 25 kDa component of the dystrophin associated protein complex (DAPC). Within the DAPC, sarcospan has been shown to be most closely associated with the sarcoglycan complex (a-, b-, g-, and d-Sgn). Each of these four sarcoglycans is known to cause limb girdle muscular dystrophy (LGMD2-D, E, C and F, respectively) when mutated. While the sarcoglycans share several structural features, sarcospan is homologous to proteins from the tetraspanin family (TM4SF).

When muscle biopsies taken from Duchenne Muscular Dystrophy (DMD) patients are analyzed by immunofluorescence for the presence of the sarcoglycan complex, staining is often found to be reduced. Similarly, primary mutations in any one of the sarcoglycan genes lead to secondary loss of staining for the other members of the sarcoglycan complex. To elucidate sarcospan's function in the muscle membrane we chose to examine sarcospan's presence in muscle biopsies from a variety of muscular dystrophy patients. To do this, we have developed a human sarcospan specific antibody with which we have analyzed a number of LGMD, DMD and congenital muscular dystrophy (CMD) patient samples. Sarcospan staining is decreased in cases where there is loss of the sarcoglycan complex and/or dystrophin.

There are still patients for whom mutations have not been identified in any of the genes known to cause muscular dystrophy. Since sarcospan is intimately associated with the sarcoglycan complex, it is conceivable that mutation of the sarcospan gene would lead to muscular dystrophy. We have determined the complete genomic organization of the human sarcospan gene, and have designed a primer set to specifically amplify sarcospan exons from human genomic DNA. These are currently being used to screen DNA samples from patients with muscular dystrophies that are not caused by mutations in any of the known genes, as well as patients with diseases linked to chromosome 12p11, sarcospan's genomic location.

Program Nr: 2134 from the 1999 ASHG Annual Meeting

Characterization of the *GFRA3* locus and investigation of the gene in Hirschsprung disease. *C.I. Onochie, L.M. Korngut, D. Michaud, S.M. Myers, L.M. Mulligan.* Department of Pathology, Queen's University, Kingston, ON, K7L 3N6, Canada.

The GFR alpha family of GPI-linked cell membrane proteins act as adapter molecules in binding of the GDNF family of soluble neurotropic factors to the cell surface RET receptor. This system is essential for development of many neural crest derived cell types and the kidney. Mutations in RET and in two of its ligands, GDNF and NTN, play a role in the development of Hirschsprung disease (HSCR), a congenital absence of the enteric ganglia. Mutations have not been found in the *GFRA1* gene in HSCR samples, however, other members of the GFR alpha family remain candidates. One such gene is *GFRA3*, which is highly expressed in the peripheral nervous system, developing nerves, heart, lung, and kidney. We have characterized the *GFRA3* locus and investigated the occurrence of sequence variants of this gene in a control population and in a panel of HSCR patients. We have shown that *GFRA3* spans 8 coding exons on chromosome 5q31. The gene structure and organization is conserved with those of GFRA1 and 2. Using a combination of single strand conformation polymorphism (SSCP) analysis and direct sequencing, we have identified polymorphic variants in exons 4, 5, 7 and 8 of *GFRA3* in both normal controls and HSCR patients. We are currently investigating 3 additional sequence variants in *GFRA3* exons 1, 5 and 7. The expression pattern of GFRA3, its predicted role in differentiation of embryonic cell types, and its involvement in RET mediated signaling, all suggest that GFRA3 could be a candidate for mutations in HSCR. The current study will elucidate the potential role of GFRA3 in this disease.

Program Nr: 2135 from the 1999 ASHG Annual Meeting

Cloning, expression analysis, genomic localization, and functional characterization of a novel Class I cytokine receptor expressed in cells of lymphoid origin. *J. Parrish, S. Presnell, D. Conklin, A. Hammond, C. Sprecher, S. Schrader, W. Xu, K. Madden, C. Brandt, J. Gross, J. Johnston, S. Mudri, A. Nelson, S. Dillon, K. Hambly, H.-P. Ren, F. Raymond, T. Whitmore, M. Maurer, D. Foster.* Stem Cell Biology, ZymoGenetics, Inc., Seattle, WA.

We have identified a novel Class I cytokine receptor, zalpha11, which is expressed in lymphoid tissues. This receptor contains the hallmark motifs of its class, including two pairs of conserved cysteine residues and a conserved "WSxWS" motif in its extracellular domain, and conserved Box I and Box II signaling motifs in its intracellular domain. Northern analysis indicates low-level expression in spleen, thymus, lymph node, bone marrow, and peripheral blood leukocytes; expression appears to be upregulated in a Burkitt lymphoma cell line (Raji). RT/PCR and flow cytometry suggest expression of zalpha11 on resting and activated B cells and on activated T cells. Immunohistochemistry using a polyclonal antibody raised against soluble zalpha11 localizes the receptor to a subset of cells in spleen and thymus, and shows upregulation in PMA-activated HL-60 cells. Using RH panel mapping, zalpha11 was localized to 16p11, a region associated with susceptibility to inflammatory bowel disease. In order to assess the signaling capability of zalpha11, a chimeric receptor was constructed which consisted of the extracellular and transmembrane domains of Mpl, which forms a homodimer in the presence of thrombopoietin (TPO), fused with the cytoplasmic domain of zalpha11. This construct was transfected into the murine IL3-dependent cell line BaF3, and proliferative capacity was measured in the presence of TPO without IL3. Cells transfected with the chimeric receptor were able to proliferate in response to TPO, indicating that homodimeric zalpha11 is capable of delivering a proliferative signal to BaF3 cells. Given the lymphoid expression pattern and signaling capability of zalpha11, its ligand can be expected to be a potent lymphopoietic factor.

Program Nr: 2136 from the 1999 ASHG Annual Meeting

DAX1, SF1 and SOX9: Evolutionary Rates of Sequence Variation May Reflect Relative Positions in the Mammalian Sex Determining Pathway. *M. Patel[1], E. Vilain[2], K. Dorman[3], Y.-H. Zhang[4], B.-L. Huang[4], A.P. Arnold[1], J. Sinsheimer[2,3], E.R.B. McCabe[4].* 1) Depts. of Physiological Science; 2) Human Genetics; 3) Biomathematics; 4) Pediatrics, UCLA, Los Angeles, CA 90095-1752.

Mammalian sex determination is dependent upon the Y chromosome gene, SRY. SRY acts to trigger male sex determination in mammals, presumably by regulating downstream genes in the sex determining cascade. DAX1 is a candidate gene for dosage sensitive sex reversal seen in XY females with tandem duplications of Xp21.3. Investigators speculate that DAX1 and SRY are antagonistic, suggesting that they may be involved at the same level of the sex determining pathway. These genes would act to regulate the activity of downstream genes such as SF1 and SOX9 in a dosage dependent manner. Sequence comparisons of SRY and DAX1 across primate species suggest both genes may be rapidly evolving. Here we compare the rates of evolution of SRY, DAX1, SF1 and SOX9 in primates. A measure of evolutionary divergence is the number of nonsynonymous substitutions. We sequenced the coding regions of SRY, DAX1, SF1 and SOX9 from rhesus genomic DNA and calculated the number of nonsynonymous (Ka) and synonymous (Ks) substitutions. Ka values for SRY, DAX1, SF1 and SOX9 were 0.051+/-0.011, 0.012+/-0.003, 0.013+/- 0.004 and 0.00+/- 0.00 respectively. Ks values were 0.102+/-0.03, 0.025+/-0.009, 0.055+/-0.012 and 0.029+/-0.008 respectively, suggesting pressure for SRY, DAX1 and SF1, but not SOX9, to acquire nonsynonymous changes. Ka/Ks ratios were 0.497 for SRY, 0.491 for DAX1, 0.227 for SF1 and 0.000 for SOX9. We conclude that DAX1 is evolving more rapidly than SOX9 and at a rate similar to SRY, perhaps to maintain a functional relationship with SRY. SF1 seems to evolve at an intermediate rate, perhaps reflecting an intermediate position in the sex determination hierarchy. Our data suggest DAX1 is involved early in the sex determinating pathway and may functionally interact with SRY either directly or indirectly.

Program Nr: 2137 from the 1999 ASHG Annual Meeting

Genomic structure of a retinal expressed candidate gene for dominant optic atrophy (Kjer type). *U.E.A. Pesch, C. Alexander, B. Wissinger.* Molecular Genetics Lab, University Eye Hospital, Tuebingen, Germany.

Dominant optic atrophy, Kjer type, is the most common form of hereditary atrophies of the optic nerve. Patients suffer from a progressive loss of visual acuity and colour vision disturbance from early childhood onwards. Pathological examination of patients eyes demonstrated a loss of retinal ganglion cells. Linkage studies showed the OPA1 gene to be located in a 1-2 cM intervall on chromosome 3q28-q29. 7 ESTs have been fine mapped so far to the disease critical region. EST SHGC37414 was found to belong to a very large THC (tentative human consensus sequences) Hs.32473 consisting of 89 different cDNA-clones and to be expressed in retinal tissue. The full length transcript was cloned by Nagase et al., 1998. BLAST analysis of the coding region revealed homology to dynamin. A GTP-binding site was predicted by various motiv search programs. Our aim was to determine the genomic structure of the KIAA0567 gene by comparing the full length cDNA with the genomic sequence. A genomic PAC clone containing the SHGC37414 sequence was subcloned and sequenced. The sequences were assembled into contigs using the staden software package and screened for exons with the KIAA0567 cDNA sequence. Primers were designed in order to experimentally verify the virtually identified 16 intron/exon boundaries. Exon hopping by expand PCR was applied to identify another 10 intron/exon junctions. The KIAA0567 gene seems to have a very complex structure of at least 25 exons. Mutation screening in affected individuals is currently in progress.

Program Nr: 2138 from the 1999 ASHG Annual Meeting

Identification of a novel *DMD* exon that is alternatively-spliced in retinal isoform (Dp260) of dystrophin. *D.M. Pillers[1,2], J. Pang[1], R.G. Weleber[2,3], S.A. Tokarz[1,2], S.M. Rash[1], N.M. Duncan[1]*. 1) Dept Pediatrics, Oregon Health Sci Univ, Portland, OR; 2) Dept Molecular and Medical Genetics, Oregon Health Sci Univ, Portland, OR; 3) Dept Ophthalmology, Oregon Health Sci Univ, Portland, OR.

Introduction: The *DMD* gene spans more than 2.6 Mbp but the coding sequence comprises only 14 kb and 79 exons. The *DMD* gene does not follow the "one gene - one protein" paradigm, as there are at least five described protein products, or isoforms, of dystrophin: Dp427, Dp260, Dp140, Dp116, and Dp71. A number of new exons have been identified as isoform-specific exons, bringing the total of known exons to 86. These exons occur in the first exon position of the isoforms, and are either isoform or tissue-specific. Other than characterizing patterns of alternative splicing at the 3' end of dystrophin, the remaining sequence of the various dystrophin isoforms has been inferred by homology with Dp427. **Purpose:** The purpose of our study was to sequence the complete Dp260 isoform to determine if all of the known exons were expressed as a guide to identifying features of the isoform that might predict unique functional roles. **Methods:** Dp260 isoform was amplified by long RT-PCR from mouse mRNA using primers specific to the unique Dp260 first exon R1 (forward) and to the junction of exons 78 and 79 (reverse). The product was sequenced in two directions and the sequence was compared to Dp427 in GenBank. **Results:** An amplimer of predicted size was obtained. Sequence analysis confirmed the presence of exon R1 followed by exons 30 through 79 of Dp427, in predicted order. An additional 36 bp exon not previously defined was also identified. The open reading frame was preserved through the new exon. **Conclusions:** The *DMD* gene is both large, and complex, and there may be many aspects of its expression yet to be elucidated. We have identified a new exon that appears to be uniquely expressed in retina. The exon is also unique in that it is in the center of the message, and not at either the 5' or 3' ends as occurs with other alternatively spliced exons of dystrophin. Further characterization of this exon may lead to important insight into potential key roles that dystrophin isoform Dp260 plays in retinal electrophysiology.

Program Nr: 2139 from the 1999 ASHG Annual Meeting

Characterization of *COX17*,a component of the mitochondrial copper transport pathway. *F. Punter, D. Adams, D.M. Glerum.* Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Cytochrome c oxidase (COX), the fourth and final electron-accepting enzyme complex of the mitochondrial respiratory chain, catalyzes the transfer of electrons to molecular oxygen. Dysfunctional COX hinders cellular respiration and ATP synthesis, giving rise to a number of human disorders. One important aspect of COX biogenesis involves the incorporation of copper into the apoenzyme, where the heavy metal acts as an essential electron-accepting prosthetic group. From previous studies in yeast, the mitochondrial copper transport pathway is thought to consist of two proteins, Cox17p and Sco1p. Functioning as a copper shuttle, Cox17p is believed to transport copper from the cytosol to Sco1p, which is embedded in the inner membrane of the mitochondrion.

To elucidate the human mitochondrial copper transport pathway and its role in COX biogenesis and human COX deficiency, we are characterizing the human *COX17* gene. Southern blot analysis of human genomic DNA has shown that *COX17* is present in multiple copies in the human genome. BAC and P1 clones harbouring *COX17* are currently being sequenced in order to characterize the two putative copies of *COX17*. Using radiation hybrid mapping, we have identified one of the *COX17* loci at chromomsome 13q14-21. Hybridization of the *COX17* cDNA to a multiple tissue Nothern blot shows one ubiquitously expressed *COX17* transcript. We are in the process of determining which of the genomic loci expresses a functional *COX17* gene product. This study, which will result in the characterization of the *COX17* gene in humans, is an important first step in the delineation of the human mitochondrial copper transport pathway and and its role in human COX deficiencies.

Program Nr: 2140 from the 1999 ASHG Annual Meeting

Molecular characterization of a Rieger syndrome mutation in PITX2. *I. Saadi[1], K.P. Murphy[2], A.F. Russo[1,3]*. 1) Genetics PhD Program; 2) Department of Biochemistry; 3) Department of Physiology and Biophysics, University of Iowa, Iowa City, IA.

Rieger syndrome is an autosomal-dominant developmental disorder characterized by ocular anterior chamber anomalies, dental hypoplasia, mild craniofacial dysmorphism, and umbilical stump formation in humans. Mutations in the PITX2 bicoid-type homeodomain protein have been found in Rieger syndrome patients. A lysine residue at position 50 of the PITX2 homeodomain (K50) imparts the bicoid-type binding specificity (TAATCC) to its homeodomain. This lysine residue is mutated to an arginine (K88R) in a Rieger patient. Although lysine to arginine would normally be considered a conservative change, our studies show that the K88R mutant protein is severely defective in its binding and transactivation properties. We have computer-modeled the PITX2 homeodomain-DNA complex based on the NMR structure of the antennapedia homeodomain-DNA complex and show that the defective binding is likely due to steric hindrance of the arginine side-chain. We also wanted to know if an arginine at position 50 of the homeodomain would result in a different binding specificity. Selection and amplification binding (SAAB) assay shows that the K88R mutant protein does not have a preferred DNA binding specificity. However, the K88R mutant acts in a dominant-negative fashion when co-transfected with wildtype PITX2, suggesting that it forms nonfunctional dimers with wildtype PITX2. This may explain the autosomal dominant nature of Rieger syndrome wherein a single allele variant confers the phenotype, and this work suggests an approach to understanding the genotype-phenotype correlations found for other transcription factors.

Program Nr: 2141 from the 1999 ASHG Annual Meeting

Transthyretin gene: transcription pattern in livers and heart from transplanted patients with hereditary Amyloidosis. *F. Salvi[1], E. Manzati[2,3], Y. Ando[4], A. Ferlini[2,3]*. 1) Div di Neurologia, Ospedale Bellaria, Bologna, Italy; 2) Istituto di Genetica Medica, Universita' di Ferrara, Italy; 3) Neuromuscular Unit, Imperial College School of Medicine, Hammersmith Campus, London ,UK; 4) Department of Human Genetics, Yamamoto University, Japan.

Transthyretin (TTR) gene missense mutations are associated with hereditary Amyloidosis, an autosomal dominant disease mainly characterised by peripheral neuropathy and cardiomyopathy. The only therapeutic approach for this disease is the liver transplant, eliminating the plasma aliquot of the mutated TTR. We performed transcription analysis on 7 livers and 1 heart from transplanted patients with documented TTR mutations (Met30, Pro36,Ala47,Gln89), searching for additional/alternative transcripts. Transcription studies on patients tissues and normal adult liver have been performed using a 5 RACE-PCR approach, resulted in the amplification of two transcripts: the first corresponding to the canonical transcription starting site (TTRP1, nucleotide 583 in TTR genomic sequence accession number m11844), the second one representing the RAT-like transcription starting site (TTRP2, transcription starting site at nucleotide 499). Northern blot hybridisation using a 80 bp probe containing specific for the TTRP2 transcript, confirmed the presence of the TTRP2 message. The two transcripts coexist in normal and patients livers. Surprisingly, the heart carrying the TTR89 mutation showed the two TTRP1 and TTRP2 transcripts as well as an additional longer transcript. We demonstrated the presence of two alternative TTR messages,due to the presence of two active transcription starting sites. Livers from controls and transplanted patients display an identical transcription pattern, suggesting that TTR mutations do not apparently affect the transcription pathway. Interestingly, the heart carrying the TTRGln89 mutation showed both the TTRP1 and TTRP2 transcripts and an additional longer product. This is unexpected, given the absence of the TTR transcription/expression in normal adult heart. Further investigations are needed for establishing a possible role of these transcripts in the pathogenesis of TTR-related amyloidotic cardiomyopathy.

Program Nr: 2142 from the 1999 ASHG Annual Meeting

Cloning and genomic structure of OTX2, a candidate gene for Congenital Microphthalmia. *M. Sarfarazi, I. Stoilov, E.F. Percin.* Molecular Ophthalmic Genetics Laboratory, Surgical Research Center, University of Connecticut Health Center, Farmington, CT.

OTX2 is the human cognates of Drosophila head gap gene, orthodenticle. This gene is involved in early specification of rostral neuroectoderm and sense organ development. Based on its proposed function as a regulator of early forebrain development, OTX2 is a good candidate for many developmental eye defects including microphthalmia. We have recently screened 9 multiply affected families with congenital microphthalmia for possible linkage to the 14q21-q22 region, of whom 3 showed homozygosity for an area that contains the OTX2 gene. We therefore embarked on cloning of this gene as a candidate for this condition. Using RACE, this gene was cloned from both human retinal and brain cDNA libraries. The genomic region amplified by Long Range (LR) PCR and the intron-exon junctions were determined by comparative sequence analysis of cDNA and genomic DNA. The 5' flanking region recovered by LR-PCR using primers designed from the mouse Otx2 gene. Additional 5' sequences obtained by upstream genome walking experiments. The OTX2 gene spans 4,991 bp, including 1,137 bp of 5' region, 3 exons, 2 introns and 3' UTR. All intron-exon junctions conform to the GT/AG rule. Exon II encodes the bicoid-like homeodomain and resides within a CpG island that is marked by a cluster of six HpaII restriction sites. Comparative analysis revealed that human OTX2 gene is highly conserved and resembles that of the mouse Otx2 gene. The two cis-acting elements controlling expression of the mouse Otx2 gene in mesencephalic neural crest cells are conserved and present at similar positions in the 5' flanking region of the human OTX2 gene. The obtained sequences and genomic structure of OTX2 gene were used to screen the affected members of 3 above-mentioned families and 7 other sporadic cases for possible mutations. Sequence analysis of the entire coding regions found no mutations in any of these subjects. Since families showing homozygosity for the OTX2 region have a nuclear structure, we concluded that this observation is either coincidental or, another regional gene is involved in the etiology of this phenotype.

Program Nr: 2143 from the 1999 ASHG Annual Meeting

HUMAN TYPE XVIII COLLAGEN (COL18A1) GENE: STRUCTURAL ORGANIZATION, IDENTIFICATION OF NEW SNPs, AND ITS EXCLUSION AS THE KNOBLOCH SYNDROME GENE. *A.L. Sertie[1], V. Sossi[2], M.R. Passos Bueno[1], C. Brahe[2].* 1) Dept of Biology, University of Sao Paulo, Sao Paulo, Brazil; 2) Inst of Medical Genetics, Catholic University, Rome, Italy.

The gene responsible for Knobloch syndrome (KS) - an apparently rare autosomal recessive disorder characterized by high myopia, vitreoretinal degeneration with retinal detachment, macular abnormalities and occipital encephalocele - was mapped to 21q22.3, within a candidate region of 1.6Mb. COL18A1, the gene which encodes type XVIII collagen, lies in this interval and was considered a good positional and functional candidate gene for KS. We report here the characterization of most of the genomic structure of COL18A1 gene throughout the amplification and/or sequencing of the gene introns using a set of 45 flanking exonic primer pairs deduced from the human cDNA COL18A1 sequence and taking into account the organization of the mouse Col18a1 gene. The data showed that COL18A1 consists of 43 exons spanning over 102kb of genomic DNA and is very similar to the mouse gene. Although 45% of the donor splice junctions are identical to the consensus sequence G/GT(AG)AGT, 84% of the acceptor splice sites agree with the consensus sequence (TC)nN(CT)AG/G. These results suggest that the conservation of the acceptor sequence is very critical for a correct splice in this gene. We also have identified two new SNPs in this gene which occur in a relatively high frequency in the Caucasian population: a G to A exchange at the +58 nucleotide of intron 6 and an A to G exchange at the +54 nucleotide of intron 17. These markers were analysed in Brazilian patients with KS revealing recombination between it and the disease gene. In addition, exons 4 to 7 of COL18A1 were screened for mutation and no changes were identified. Taken together, our data provide strong evidence that COL18A1 gene is not the gene responsible for KS. Furthermore, the genomic structure of COL18A1 and its polymorphic markers will certainly be important for the study of other genetic diseases mapping to distal 21q. Supported by: FAPESP, HHMI, CNPq, PRONEX.

Program Nr: 2144 from the 1999 ASHG Annual Meeting

Human lysosomal sialidase: analysis of the gene promoter. *V. Seyrantepe[1], C. Richard[1], J. Engert[2], T. Hudson[2], A.V. Pshezhetsky[1]*. 1) Dept of Medical Genetics, Ste-Justine Hospital, Montreal University; 2) Montreal General Hospital, McGill University, Montreal, Quebec, Canada.

The inherited deficiency of sialidase (neuraminidase) causes a lysosomal storage disease, sialidosis characterized by cherry-red macular spots, myclonus, skeletal dysplasia, mental retardation and hepatosplenomegaly. In addition to its well-established role in the intralysosomal catabolism of sialilated glycoconjugates, sialidase is also involved in the cellular signaling. In particular, sialidase of T lymphocytes converts group specific component (Gc) protein into a macrophage activating factor and is also required for the production of cytokine IL-4, the potent regulator of many homeopathic and nonhomeopoetically derived cells and tissues. Activation of T-lymphocytes is associated with the increase of sialidase activity on their surface due to the up-regulation of sialidase gene. In order to understand the mechanism of this activation, we analyzed the promoter region of human sialidase gene for the presence of consensus sequence for upstream regulatory elements. Transcription start sites of sialidase mRNA were identified by 5'RACE PCR experiments using total RNA from fibroblasts and placenta and confirmed by ribonuclease protection assays. To identify essential promoter elements in sialidase gene, we generated several constructs by cloning 5-end fragments of sialidase gene (nucleotides 1 to 2200) into the pBLCAT6 vector in front of a reporter, chloramphenicol acetyl transferase (CAT) gene. Transient transfection of these constructs into COS-7 cells and subsequent analysis of CAT activity demonstrated that the region of sialidase gene ~300 bp upstream the initiation codon has minimal promoter activity and the region ~550 bp upstream the initiation codon has dominant promoter activity containing all essential promoter elements. Larger reporter construct, within 2.2 kb of the upstream sequence had lower promoter activity suggesting the presence of the potential elements for down-regulation of gene expression. These findings elucidate the basic mechanism for the regulation of sialidase gene expression and may explain its induction observed in the immune cells.

Program Nr: 2145 from the 1999 ASHG Annual Meeting

identification of a novel gene and its exclusion as a candidate for the urofacial (ochoa) syndrome (ufs) gene on chromosome 10q23-10q24. *J.D. Shi, C.Y. Wang, Y.Q. Huang, P.E. Cruz, J.X. She.* Dept Pathology/Immunol/Lab Med, Univ Florida, Gainesville, FL.

The Urofaical (Ochoa) syndrome (UFS) is an autosomal recessive disease. The major characteristics of this syndrome are congenital obstructive uropathy and abnormal facial expression. Our previous study narrowed the gene to two overlapping BAC clones, a region of less than 360 kb genomic DNA. In the present study, we have isolated a novel candidate gene (UFSC1) within the UFS critical region from one of the two BAC clones (369I8). The UFSC1 gene consists of 4.8-kb nucleotide sequence containing an ORF of 1759-bp and encodes a putative polypeptide of 586 amino acids. The gene contains 11 exons. We searched for mutations in two UFS patients (4-3 and 6-3) from Columbia and two patients (30-3 and 41-3) from the US as well as one unaffected mother (31-2). The entire coding region, untranslated regions and intron/exon junctions were amplified from genomic DNA using 18 primer pairs and sequenced by an ABI 310 automated sequencer. Comparison of the sequences from patients with normal control failed to detect any pathogenic mutation. Therefore, UFSC1 does not appear to be the gene responsible for the urofacial syndrome.

Program Nr: 2146 from the 1999 ASHG Annual Meeting

The human survival motor neuron (SMN) genes are developmentally regulated. *L.R. Simard, C.F. Rochette, T. Brun, S. Meilleur.* Centre de Recherche, Hopital Sainte-Justine, Montreal, PQ, Canada.

Spinal muscular atrophy (SMA) is an autosomal recessive lower motor neuron disease and the leading monogenic cause of infant mortality. The critical 5q-SMA region contains an inverted repeat element of about 500-kb. Mutations involving the SMN1 gene in the telomeric element are responsible for childhood-onset SMAs. Analyses of SMN interacting proteins has revealed two functions; one involving the assembly and transport of spliceosomal snRNP complexes, the other involving the maintenance of active pre-mRNA splicing complexes. Despite these advances, it remains unclear why mutations in SMN1 alone cause SMA and why loss of SMN1 specifically affects motor neuron cells. To address this issue, we initiated SMN1 and SMN2 gene expression studies. Previous analyses of the 2 kb region upstream of the translation initiation site did not reveal significant differences in SMN1 and SMN2 promoter activity. We now provide evidence that the SMN genes are developmentally regulated. In this study, we have characterized the transcription initiation site(s) of the SMN genes using RNAs prepared from various fetal and adult tissues. Primer extension studies mapped two major initiation sites; one or the other is preferentially used during development. The major SMN transcript in fetal tissues contains a longer 5' UTR than that found in adult tissues, the initiation site mapping 320 nucleotides upstream of the translation start site. This site is used by the single SMN1 gene found in the chimpanzee and transcripts harboring the longer 5' UTR are absent in RNA samples from type I SMA patients suggesting that these transcripts are the primary product of the SMN1 gene. Corroborating 5' RACE and RNase protection studies will be presented. Finally, transient transfection studies in P19 cells indicated that the SMN promoters are 10 fold more active in undifferentiated cells compared to P19 cells treated with either DMSO or retinoic acid. Taken together, these results provide strong evidence that the SMN genes are developmentally regulated and suggest that important differences between SMN1 and SMN2 gene expression may exist. *Funded by MRC and MDAC.*.

Program Nr: 2147 from the 1999 ASHG Annual Meeting

A protein which specifically binds to triplet repeat $(CTG)_n$. *P.A. Slominsky, M.I. Shadrina, S.A. Limborska.* Dept Human Molec Genetics, Inst Molecular Genetics, Moscow, Russia.

In a basis of a dynamic mutation the phenomenon of increase of number of copies (expansion) simple di- and three nucleotide microsatellite repeats lays. Mechanisms and the reasons of expansion are investigated not enough and probably, that the process of expansion is adjusted with participation of specific DNA-protein interactions between repeats and replication complex proteins. For revealing specific $(CTG)_n$ microsatellite binding proteins a method of gel retardation was used. Was shown, that in nuclear and total cell extracts from rat liver and brain are present two $(CTG)_9$ repeat binding proteins. One of these proteins is highly specific - the complex formation did not blocked by 100 fold excess of "cold" unlabelled random oligonucleotide of the same length, but is suppressed significantly already by 10 fold excess unlabelled. cDNA for $(CTG)_n$ microsatellite binding protein was cloned by screening of expressed human fetal brain cDNA with $(CTG)_9$ probe. After cloning and sequencing one of $(CTG)_n$ binding protein appear identical to well known protein, growth/differentiation factor 1 or LAG1. This protein are highly homologous to C.elegans longevity gene. It is possible that $(CTG)_n$ repeat binding protein - such a LAG1 - plays a role in prevention of hairpin formation or hairpin stabilisation and by that suppresses process of triplet repeat expansion. It may be critical for cell surveillance and fate.

Program Nr: 2148 from the 1999 ASHG Annual Meeting

Identification of a Matrix Attachment Region at the X-linked Transferrin Locus. *P. Smith, D. Catalaa, M.A. Wong, W. Zupko, M.A. Goldman.* Dept Biol, San Francisco State Univ, San Francisco, CA.

The transferrin transgene array consists of 11 tandem repeats of a 17 kb construct which includes the 11 kb transferrin gene as well as 6 kb of 5' and 3' flanking sequence. In contrast to most X-linked genes, transferrin is expressed from both the active and inactive X chromosomes. It is suggested that transferrin constitutes its own chromatin domain(s), allowing it to maintain a transcriptionally competent conformation amidst an otherwise transcriptionally silent environment. A nuclear matrix binding assay was employed in an attempt to locate matrix attachment regions (MARs), which are sequence elements that preferentially bind to the nuclear matrix, and which serve as endpoints of chromatin domains. A 1.6 kb fragment consisting of roughly equal parts of the 3' end of transferrin and the 3' flanking region was identified as a MAR. Significantly, this fragment contains a topoisomerase II recognition sequence, which is a consistent feature of MARs. Also, the location of the MAR coincides with the location predicted by the MARfinder algorithm. Further cloning of this region should facilitate more precise mapping of the MAR. Also, we predict the presence of a MAR in the 5' region of transferrin.

Program Nr: 2149 from the 1999 ASHG Annual Meeting

Inhibition of FMR1 gene expression with phosphorothioate antisense oligonucleotides. *O. Sobolev[1], PJ. Hagerman[2], MB. Brennan[1], F. Tassone[2].* 1) Eleanor Roosevelt Institute, Denver, CO; 2) Department of Biochemistry and Molecular Genetics,UCHSC, Denver, CO.

FMRP is an RNA-binding protein containing both nuclear localization and nuclear export signals. FMRP binds to its own message with high affinity and interacts with a number of other human fetal brain messages. It is important to identify the RNA species within the cell to which FMRP binds, because it appears likely that loss of binding to such RNAs might result in the pleiotropic phenotype associated with fragile X syndrome. Furthermore, it is not clear how FMRP binding influences stability, localization and translation efficiency of this class of RNAs. One of the major problems in identifying changes in mRNA levels in the absence of FMRP is the isolation of FMRP-specific effects in RNA backgrounds that may differ between different cell lines. Decreasing FMR1 gene expression may be important for identifying the mRNAs to which FMRP binds. To circumvent this problem, we have tested phosphorothioate antisense oligodeoxynucleotides (PS-ODNs) targeted against the FMR1 gene to specifically disrupt its expression. We have used a number of PS-ODNs on human cultured fibroblasts. Cells were treated in the presence of a lipofecting reagent for 5 days. Total RNA was then isolated, reverse transcribed, and the amount of FMR1 cDNA was quantified by fluorescence RT-PCR. Two of these antisense PS-ODNs resulted in a significant decrease in FMR1 mRNA expression level (up to 90%). Differentially expressed mRNAs are currently being identified using cDNA arrays.Results will be discussed.

Program Nr: 2150 from the 1999 ASHG Annual Meeting

Clonning and mapping of human FTCD, a candidate for the glutamate formiminotransferase deficiency (FIGLU-URIA). *A. Solans, X. Estivill, S. de la Luna.* Medical and Molecular Genetics, IRO, Barcelona, Spain.

Human chromosome 21 (HC21) has been intensively studied, mainly because trisomy 21 causes Down syndrome (DS) and because it is the smallest human chromosome, thus acting as a model for studies on other human chromosomes. HC21 is estimated to contain 300-400 genes (EMBO Workshop Molecular Biology of Chromosome 21 and Down Syndrome, June 1999). International gene cloning efforts have led to the identification of numerous genes and transcriptional units and more recently, large scale sequencing has enabled the prediction of many more. Nowadays 112 genes (GDB, June 13, 1999) have been assigned to HC21. However, the function of most of these genes remains unknown. In order to contribute to the development of the transcriptional map of human chromosome 21, we have used in silico cDNA cloning by searching NCBI databases (UNIGENE, GeneMap'98). In these searches a novel human gene, hFTCD, has been identified by its sequence similarity to porcine FTCD (Formiminotransferase ciclodeaminase, EC_number=2.1.2.5, EC_number=4.3.1.4), an intermediate metabolism enzyme involved in the histidine degradation pathway. hFTCD full length cDNA has been cloned and mapped to 21q22.3. The gene is expressed, as different mRNA species, mainly in adult and foetal liver; expression can also be detected in adult kidney and testis, and in foetal tissues such as kidney and lung. The human FTCD amino acid sequence shows a high degree of identity to a putative protein from Dictyostelium discoideum and predicted ORFs in prokaryotic organisms including Streptococcus pyogenes, Porphiromonas gingivalis, Thermotoga maritima, Chlorobium tepidum and Clostridium acetobutylicum. In some of these, the FTCD amino acid sequence seems to be split into two separate ORFs corresponding to the two different activities of FTCD, and thus suggesting that the eukaryotic gene may have evolved by fusion of two distinct prokaryotic cistrons. FIGLU-URIA (OMIM 229100) has been described as a glutamate formiminotransferase deficiency. Searching of mutations in hFTCD will allow to study the implication of this new described gene in the disease.

Program Nr: 2151 from the 1999 ASHG Annual Meeting

TRPC5, the human homologue of a mouse brain transient receptor potential Ca^{2+} channel. *K. Sossey-Alaoui, J.A. Lyon, L. Jones, F.E. Abidi, A.J. Hartung, B. Hane, C.E. Schwartz, R.E. Stevenson, A.K. Srivastava.* Center for Molecular Studies, J. C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC.

A novel human gene, TRPC5, was cloned from the region of Xq23 that contains loci for non-syndromic mental retardation (MRX47 and MRX35) and two genes, DCX and HPAK3, implicated in two X-linked disorders (LISX and MRX30). Within a single YAC, we have also mapped a placenta-specific gene that encodes a calpin-like protein, CAPN6, and determined the order, cen - HPAK3 (5'-3') - CAPN6 (3'-5') - DCX (3'-5') - DXS7012E - TRPC5 (3'-5')/DXS1059 - ter. Here we report the detailed characterization of the most telomeric gene, which encodes a 974 residue novel human protein, TRPC5 (111.5 kDa predicted mass) and displays 99% homology with mouse trp5, a novel member of a family of receptor-activated Ca^{2+} channels. It contains eight transmembrane domains, including a putative pore region. A transcript larger than 9.5 kb is observed only in fetal and adult human brain, with a relatively higher level in the adult human cerebellum. A 4.0 kb transcript variant is detected in pancreas. The human TRPC5 gene comprises 11 exons spanning about 300 kb of genomic DNA.

We devised an efficient method, Incorporation PCR SSCP (IPS), for detection of gene alterations. Five single nucleotide variations in the TRPC5 gene were identified in males with mental retardation. However, these were found to be polymorphic variants. Exclusive expression of the TRPC5 gene in developing and adult brain suggests a possible role during development and provides a candidate gene for instances of mental retardation and other developmental defects.

Program Nr: 2152 from the 1999 ASHG Annual Meeting

Identification of novel alternatively spliced human biotinidase mRNAs that potentially encode distinct signal peptides and are expressed in a tissue specific manner. *C.M. Stanley, B. Wolf.* Department of Human Genetics, Medical College of Virginia of Virginia Commonwealth University, Richmond, VA.

Biotinidase is an enzyme essential for biotin recycling. Children with an inherited deficiency of biotinidase have been effectively treated with biotin. Biotinidase has been suspected of having multiple functions possibly requiring it to be located in different cellular and extracellular spaces. To better understand more about this process, we have identified and characterized three human biotinidase mRNA splice variants using rapid amplification of cDNA 5' ends-polymerase chain reaction (5'-RACE-PCR). Sequence analysis of the amplified products resulted in additional 5'sequence, extending the former exon 1, now called 1a, and two novel alternative exons, 1b and 1c. These three distinct transcripts appear to have resulted from alternative splicing of exons 1a, 1b and 1c at the 5' end of the biotinidase pre-mRNA. Northern blot analysis was used to determine the tissue-specific expression of each splice variant. The 1a and 1b splice variants were identified in various human tissues including liver, kidney, pancreas, placenta, testes, whole brain and caudate nucleus, but the proportion of expression differed in each tissue type. Exon 1a was the most highly expressed variant in liver, whole brain and caudate nucleus while exon 1b was a minor variant in these tissues. Both 1a and 1b were expressed in equal proportions in pancreas and placenta. Exons 1a and 1b each contained two putative, in-frame, AUG, translation initiation codons, that are predicted to result in distinct signal peptides. The 1c splice variant was found only in testes, and its expression in testes was confirmed by both 5'-RACE-PCR and a published expressed sequence tag. Moreover, exon 1c was the most abundant variant in testes and contained three in-frame AUGs, but also contained an in-frame stop codon (TGA) at its 3' end. Depending on the site of translation, each splice variant could encode a distinct signal peptide, which may result in tissue-specific intracellular localization of biotinidase. Further studies are examining the intracellular localization of biotinidase in these various tissues.

Program Nr: 2153 from the 1999 ASHG Annual Meeting

Genomic structure and localization within Y chromosome interval 6 of the BPY2 gene. *L. Stuppia[1,2], V. Gatta[1], I. Fogh[3], G. Calabrese[1,4], D. Fantasia[1,4], F. Capodiferro[1,4], E. Morizio[1,4], A. Ratti[3], A. Pizzuti[3,5], G. Palka[1,4].* 1) Dept di Science/Biomed, Univ G D Annunzio, Chieti, Italy; 2) Istituto di Citomorfologia Umana CNR, Chieti, Italy; 3) Istituto di Clinica Neurologica, Univ. di Milano, Italy; 4) Servizio di Genetica Umana, Ospedale Civile di Pescara, Italy; 5) C.S.S. - Mendel Institute, Roma, Italy.

In recent years, a number of studies have investigated the relationship between male infertility and Yq microdeletions, which are detected in about 10% of infertile patients. So far, at least 12 genes have been isolated within Yq, in the regions involved by the microdeletions, but only RBM1, DAZ and DFFRY genes have been specifically analyzed as candidate for male infertility. In this study, we investigated BPY2 (Basic Protein 2) gene, which has been mapped within the subinterval 6E of the Y chromosome, where the presence of a locus specific for oligozoospermia have been previously suggested. PCR analysis with specific primers for BPY2 performed on 7 patients with previously detected microdeletions of subinterval 6E showed the presence of a normal amplification product, thus suggesting a different localization of the gene or the presence of multiple copies. In order to characterize BPY2, we performed a screening of a human Y chromosome YAC library, and identified the clone yOX10 as containing BPY2. Cosmid clones were derived, and sequencing of the clone 26 allowed to indentify the genomic structure of BPY2, which consists of 8 exons, with the first ATG codon located within exon 4. Cosmid 26 was used as a probe for two colors fiber FISH analysis, which displayed two copies of BPY2, one localized within the DAZ gene cluster, and the second one mapped within subinterval 6E. These results indicate that deletions of DAZ cluster should cause the loss of at least one copy of BPY2 gene, suggesting that the role of this gene in male infertility should be evaluated. Further studies are in progress in order to investigate the presence of BPY2 deletions or mutations in infertile patients.

Program Nr: 2154 from the 1999 ASHG Annual Meeting

HMG20A and HMG20B map to human chromosomes 15q24 and 19p13.3 and constitute a distinct class of HMG-box genes with ubiquitous expression*HMG20A HMG20B*. *L. Sumoy[1], L. Carim[1], M. Escarceller[1], M. Nadal[1], M. Gratacos[1], M.A. Pujana[1], X. Estivill[1], B. Peral[1,2].* 1) Dept. de Genètica Molecular, Institut de Recerca Oncològica, Hospital Duran i Reynals, L'Hospitalet, Barcelona, Spain; 2) Unidad de Neurología, Fundación Jiménez Díaz, Madrid, Spain.

Working within the EURO-IMAGE Consortium full-length cDNA sequencing initiative, we have discovered HMG20A and HMG20B, two novel human HMG box-containing genes. The HMG box encodes a conserved DNA binding domain found in many proteins with roles in the regulation of transcription and chromatin conformation. The predicted HMG20A and HMG20B proteins encoded by these two genes are 48% identical (74% within the HMG domain). The HMG domain of both HMG20 proteins is most similar to that of yeast NHP6A (38-42%), human BAF57 (33-38% identity; 58-59% similarity to HMG20A-HMG20B respectively) and human SOX14 (32-36% identity; 58-59% similarity to HMG20A-HMG20B respectively). Outside of the HMG domain, HMG20 proteins lack any significant homology to other known proteins. Phylogenetic and protein comparison analysis excludes HMG20A and HMG20B from the TCF/SOX group of HMG proteins, and places them along with HMG1/2 type proteins which bind to DNA in a non-sequence specific fashion. However, HMG20 genes do not branch together with any of the established HMG1/2 subtypes. We determined the genomic structure and expression pattern of HMG20A and HMG20B. Both genes have several alternative transcripts, expressed almost ubiquitously. mRNA sizes are 1.5, 4 and 9 kb for HMG20A, and 1.5 and 2.6 kb for HMG20B. HMG20A maps to human chromosome 15q24 (D15S1227) and HMG20B to 19p13.3 (D19S209-D19S216, between TBXA2R and CTF-1). Five other gene pairs map to these two regions indicating the possible existence of homologous gene clusters in 15q24 and 19p13.3. We isolated mouse Hmg20A and Hmg20B cDNAs and found very strong identity between the human and mouse counterparts. Thus, HMG20 genes define a distinct class of mammalian HMG-box genes. Funded by EU Biomed Project BMH4-CT97-2284.

Program Nr: 2155 from the 1999 ASHG Annual Meeting

Amino acid homologies between human biotinidase and bacterial aliphatic amidases: Putative identification of the active site of biotinidase. *K.L. Swango[1], J. Hymes[1], P. Brown[4], B. Wolf[1,2,3]*. 1) Department of Human Genetics; 2) Department of Pediatrics; 3) Department of Biochemistry and Molecular Biophysics, Medical College of Virginia of Virginia Commonwealth University, Richmond, Virginia 23298; 4) Molecular Biology and Biophysics Section, Division of Biomedical Sciences, King's College London, Strand, London WC2R 2LS, United Kingdom.

Biotinidase is an aminohydrolase that cleaves biocytin, the degradation product of carboxylase turnover, to regenerate the vitamin biotin. Biotinidase deficiency is an inherited disorder characterized by neurological and cutaneous symptoms. The cutaneous symptoms can be effectively treated with the administration of oral biotin. If diagnosis is made at birth and biotin treatment is begun immediately, all symptoms can be prevented. A search of protein databases revealed amino acid homologies for human biotinidase, bacterial aliphatic amidases, and some bacterial and plant nitrilases. Previous studies have shown that amino acid sequences of aliphatic amidases and nitrilases contain four major regions of homology, one of which contains the cysteine involved in the active site of both enzymes. Human biotinidase has considerable homology to these enzymes, particularly in this latter region. This suggests that Cys_{245} is likely the cysteine in the active site of biotinidase and the site of the putative thioester formation that is integral for enzyme function. In addition, because the slightly upstream sequence, $YRK_{210\text{-}212}$, is highly conserved among the three enzyme families and because there are naturally-occurring mutations that cause profound biotinidase deficiency within this region, this region is likely to be essential for enzyme activity. Aliphatic amidase from *Pseudomonas aeruginosa* does not have biotinyl-hydrolase or biotinyl-transferase activities, probably because it lacks a biotin-binding site. In addition, purified human biotinidase does not cleave the substrate used to assay aliphatic amidase activity. Homology between biotinidase and the aliphatic amidases putatively localizes the active site of biotinidase and suggests that the active site of biotinidase is conserved from bacteria.

Program Nr: 2156 from the 1999 ASHG Annual Meeting

Localization of MYOC (GLC1A) transcripts in human eye and optic nerve by in situ hybridization. *R.E. Swiderski[1], J.H. Fingert[2], J.L. Ross[3], W.L.M. Alward[2], G.S. Hageman[2], E.M. Stone[2], V.C. Sheffield[1,4].* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Dept of Ophthalmology; 3) Central Microscopy Research Facility; 4) The Howard Hughes Medical Institute.

The glaucomas are a heterogeneous group of diseases that are unified by characteristic optic nerve head damage with associated loss of peripheral vision. Primary open angle glaucoma (POAG) is the most commmon form of glaucoma, affecting 1-2% of the population over the age of 40. Recently, our laboratory demonstrated that mutations in the human MYOC (GLC1A) gene are associated with juvenile open angle glaucoma (JOAG) as well as typcial late-onset POAG. Examination of dissected human ocular tissues or derived cell lines by Northern blotting as well as in situ hybridization analysis of mouse eyes indicates that MYOC is widely expressed in ocular tissues. In this study, we confirmed these findings using in situ hybridization analysis of human eye tissue and extended the study to include the optic nerve which is the primary site of neuropathy in the disease. In the anterior region of the eye, MYOC transcripts were present in the corneal stroma, beneath the anterior surface of the iris and in the iris stroma, in the ciliary muscle, and in the sclera. Elevated expression was noted in the trabecular meshwork, a region of the anterior segment associated with the elevated intraocular pressure frequently observed in POAG. MYOC expression in the optic nerve was localized to the dura mater, arachnoid, subarachnoid trabeculae, pia mater, perivascular connective tissue surrounding the central retinal vessels, and in the fascicles of optic nerve fibers. The widespread MYOC expression pattern suggests that an important role for the cognate protein, myocilin, in the structure and function of the eye.

Program Nr: 2157 from the 1999 ASHG Annual Meeting

Investigating the influence of sequence diversity in the *CDKN2A* gene on its expression and melanoma susceptibility. *T.-L. Tseng[1], A.M. Goldstein[2], J.P. Struewing[1]*. 1) Laboratory of Population Genetics &; 2) Genetic Epidemiology Branch, NCI, Bethesda, MD.

Single nucleotide polymorphisms (SNPs) are common within and near the coding regions of cancer susceptibility genes, including the *CDKN2A* gene. These SNPs alone, however, are not often highly predictive of cancer susceptibility. This may be due to the diversity of gene expression, such as splicing diversity due to SNPs within exonic splicing regulatory elements. We have systematically examined the expression patterns of p16 in more than 40 melanoma and fibroblast cell lines carrying alterations in *CDKN2A*. Surprisingly, we detected smaller proteins in certain cell lines, ranging between 8 kDa and 15 kDa, by western blotting with p16 antibodies. Because of the cell line specific patterns, we believe that these smaller proteins are either the products of aberrant splicing or sequence dependent proteolysis but not degraded p16 due to the extraction procedures. From a cell line carrying a splice site mutation, we have identified and cloned a splicing variant that has not been described previously. This novel alternative splicing variant skips the entire exon 2 and conceptionally translates 89 amino acids. Interestingly, we have also observed an aberrant protein close to 9.4 kDa, p9, in this cell line. Based upon the close correlation in the expression pattern between RT-PCR and western blotting, we believe that this is not a rare aberrantly splicing variant of p16 amplified by RT-PCR but a physiological splicing variant that can express a novel stable protein *in vivo*. Moreover, a low level of this alternative splicing product can be detected by exon1 and 3 junction specific primers in several cell lines carrying different single nucleotide alterations. We are currently investigating the relationship between the expression of p9 and the development of melanoma, as well as identifying the environmental factors that may affect the expression levels of aberrant splicing in cell lines carrying SNPs in the *CDKN2A* gene. This study will offer an excellent model system for understanding how SNPs in genes may influence disease susceptibility via splicing diversity.

Program Nr: 2158 from the 1999 ASHG Annual Meeting

The role of p80 coilin in murine development and coiled body formation. *K.E. Tucker[1], E.Y. Jacobs[1], E.K. Chan[2], L. Massello[1], D.F. LePage[1], R. Conlon[1], A.G. Matera[1].* 1) Department of Genetics, Case Western Reserve University, Cleveland, OH; 2) W. M. Keck Autoimmune Disease Center, La Jolla, CA.

Coiled bodies (CBs) are conserved nuclear organelles that have been identified in numerous species from plants to *Drosophila*, *Xenopus*, and humans. Although the function(s) of CBs are poorly understood, they have been implicated in many nuclear processes, including snRNP biogenesis, snRNA transcriptional regulation, and histone RNA maturation. CBs contain many nuclear epitopes including fibrillarin, Nopp140, the splicing snRNAs, the survivor motor neuron protein (SMN), and the coiled body marker protein p80 coilin. To gain insight into the role of coilin in CBs, the nucleus, and the organism as a whole, we have generated a knockout mouse deleted for exons 2 through the coilin stop codon at the 5 end of exon 7.

Northern and western analyses demonstrate that we have successfully removed the coilin protein from our knockout animals. Preliminary studies of the animals reveal that mice lacking the coilin protein are both viable and fertile and cannot be distinguished phenotypically from their heterozygote and wildtype littermates. We have also derived mouse embryonic fibroblasts (MEFs) from coilin null embryos. These cells will be used to determine the presence, composition and behavior of CBs in the absence of the coilin protein. MEFs will also be used to examine nuclear and nucleolar architecture in the presence of mutant coilin proteins. In order to better understand the role of coilin in CB formation, transient transfection experiments using various coilin constructs in the null cell lines will also be described.

Program Nr: 2159 from the 1999 ASHG Annual Meeting

Characterisation of the human snail (*SNAI1*) gene and exclusion as a major disease gene in craniosynostosis.
S.R.F. Twigg, A.O.M. Wilkie. Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK.

The snail family in vertebrates comprises two zinc-finger transcription factors, snail and slug, that are thought to be involved in the formation of the mesoderm and neural crest. We have isolated and characterised the human snail (*SNAI1*) gene and a related snail-like pseudogene (*SNAI1P*), both homologues of the mouse snail gene (*Sna*). Initially, using a *Sna* cDNA probe, a genomic clone with DNA sequence showing 79.3% identity to *Sna* was isolated. This gene, which mapped to 2q34, contained a substantial open reading frame but no introns. Moreover, the potential coding sequence was preceded by an *Alu* element, encoded only 2 *bona fide* zinc-fingers, and did not yield any detectable cDNA. Collectively, these observations suggested that this sequence represented a non-functional processed pseudogene. We subsequently isolated a second genomic clone that contains *SNAI1*. This gene spans approximately 6.4 kb, contains three exons and has a CpG island upstream of the coding sequence. A single transcript of 1.9 kb was detected in several human fetal tissues, with highest expression in kidney. The *SNAI1* open reading frame encodes a protein of 264 amino acids containing 4 zinc-finger motifs that shows 87.1% identity to *Sna*. FISH and radiation hybrid analysis indicates probable localisation between markers *D20S109* and *D20S196* in 20q13.

It has been postulated that mutations in the human orthologue of snail may result in congenital anomalies, because mutations in *TWIST*, a gene thought to have a complementary role to that of snail in mesoderm formation, cause Saethre-Chotzen syndrome. To address this issue, we have searched for DNA variants within the *SNAI1* gene, in patients with craniosynostosis, by single-strand conformation polymorphism (SSCP) analysis. This excluded *SNAI1* as a major disease gene in craniosynostosis. Two single nucleotide polymorphisms encoding synonymous amino acids were identified in exon 2; these may be helpful for analyses of allele-specific expression and linkage mapping. Our localisation of *SNAI1* to 20q13. leaves open the possibility that it is involved in other congenital or acquired diseases mapping to this region.

Program Nr: 2160 from the 1999 ASHG Annual Meeting

The protein encoded by *FRG1*, a candidate gene for FSHD, is localized in the nucleolus. *S.M. van der Maarel[1], S. van Koningsbruggen[1], G. Deidda[2], R.J.L.F. Lemmers[1], G.W. Padberg[3], J. Hewitt[4], R.R. Frants[1]*. 1) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Institute of Cell Biology, CNR, Rome, Italy; 3) Department of Neurology, University Hospital Nijmegen, Nijmegen, The Netherlands; 4) Institute of Genetics, University of Nottingham, Nottingham, United Kingdom.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant myopathy mainly characterized by the progressive wasting of the facial, shoulder and upper arm muscles. The major locus, FSHD1, is mapped to the subtelomere of chromosome 4q. This subtelomere is composed of a polymorphic repeat array consisting of 3.3kb units (D4Z4). In the population, the number of units may vary between 10 and >150, while patients, due to the deletion of an integral number of repeat units, carry an array <10 units.

FSHD is likely caused by a position effect in which the deletion in the repeat array causes the dysregulation of genes nearby. The first gene identified, *FRG1*, is localized 120kb proximal to the repeat array. Several features make this gene an interesting candidate gene for FSHD: the close proximity to the rearrangement, the high conservation between vertebrates and invertebrates, and the possible upregulation of gene expression in cultured myoblasts of patients.

FRG1 encodes a protein of 258 amino acids with unknown function. To obtain more insight in its function, we generated fusion constructs of FRG1 with a FLAG epitope. After transfection, the protein was exclusively detected in the nucleolus where it co-localizes with rDNA. Ongoing EM studies should reveal its subcellular localization. Deletion constructs are currently analyzed to define functional subdomains of the FRG1 protein.

These studies will provide a better understanding of the biological function of FRG1 and may explain its high conservation between different species. Hopefully, it may give us more insight in the putative role of FRG1 in the pathophysiology of FSHD.

Program Nr: 2161 from the 1999 ASHG Annual Meeting

Genomic structure of the human DLX4/7 gene: evidence for alternative splicing . *S.J. Walker[1], J.A. Price[2], J.T. Wright[3], T.C. Hart[1]*. 1) Dept Pediatrics/Med Genetics, Wake Forest University Baptist Medeical Center, Winston-Salem, NC; 2) NIH Bethesda, MD; 3) Dept. Pediatric Dentistry, University North Carolina, Chapel Hill, NC.

The Distal-less (Dll) gene of Drosophilia is a single-copy regulatory gene that specifies a homeobox-containing protein required for normal limb development. In vertebrates there is an entire class of Dll-like homeobox transcription factors, identified by the conserved 60 amino acid (homeodomain) they have in common. In humans, six DLX genes have been identified and localized; DLX1 with DLX2 on chromosome 2q near the HOXD locus; DLX5 and DLX6 on chromosome 7 with the HOXA cluster; and DLX3 with DLX4 or DLX7 on chromosome 17q21, 1-2 Mb from the HOXB cluster. Human DLX7 and DLX4 cDNAs have been previously cloned and sequenced from a leukemia cell line and from a placental cDNA library, respectively. We describe here the subcloning and sequencing of a 3.8 kb Xba1 genomic DNA fragment that contains the entire human DLX4/7 coding region, including several kilobases of 5' and 3' untranslated DNA. This report of the genomic sequence identifies two protein coding regions, separated by a 430 base-pair intron. A comparison of this genomic sequence with the published sequences of human cDNA clones from two different sources (DLX7 from leukemis cells and DLX4 from 32-week placenta) revealed the presence of two different mRNAs which have resulted from alternative splicing. The sequence comparison also revealed that DLX4 and DLX7 are isoforms of the same gene. We have confirmed the presence of both of these species in placental RNA and herein present the genomic organization of DLX4/7. The presence of alternatively spliced RNAs for this homeobox-containing gene suggests a regulatory mechanism that may be tissue-specific.

Program Nr: 2162 from the 1999 ASHG Annual Meeting

Characterization of murine subunit 3 of the COP9 signalosome; genomic structure and expression pattern. *K. Walz, C. Boerkoel, J. Yang, J.R. Lupski.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Smith-Magenis syndrome (SMS) is a multiple congenital anomalies mental retardation syndrome associated with a heterozygous deletion of 17 p11.2. Clinical features include neurobehavioral abnormalities and sleep disturbances. One of the genes mapping in the critical deletion interval encodes the subunit 3 of the COP9 signalosome. The COP9 signalosome is a multi-subunit complex conserved between plants and mammals. In *Arabidopsis* this complex functions as a repressor of photomorphogenesis. Considering the function of this complex in plants and its conservation among species, haploinsufficiency of this gene (Cop9S3) may play a role in the disturbed circadian rhythm in SMS patients. In order to generate a knock out mouse for the Cop9S3 gene, we determined its genomic structure. Eight exons have been characterized todate, using cDNA and genomic sequencing. Additionally, a vector has been created which will generate a disruptive integration of 10 kb in the Cop9S3 gene and is being targeted in ES cells. Northen blot analysis using the whole cDNA as a probe detected a 1.8 kb transcript expressed ubiquitously in mouse, with strongest hybridization to heart, brain, liver, kidney and testis tissues. Some larger mRNAs of 4-6 kb are also observed in all tissues examined. The expression pattern in humans is quite similar suggesting that the knock out mouse will be an invaluable tool to undestand the contribution of Cop9S3 to the SMS phenotype.

Program Nr: 2163 from the 1999 ASHG Annual Meeting

Identification, mapping and genomic structure of a novel X-chromosomal human gene (SMPX) encoding a small muscular protein. *M.S. Wehnert[1], D. Patzak1[1], O. Zhuchenko[2], C.C. Lee[2]*. 1) Inst Human Genetics, Ernst-Moritz-Arndt Univ, Greifswald, Germany; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, One Baylor Plaza, Texas 77030, USA.

By reciprocal probing, a cDNA clone (xh8H11) was identified representing a gene preferentially expressed in striated muscle. The gene maps close to DXS7101 31.9 cM from the short arm telomere of the X-chromosome at Xp22.1. Searching expressed and genomic databases, 21 ESTs were found that allowed to assign a human extended consensus sequence of 886 bp suggesting a completely expressed gene symbolized as SMPX. Using the human consensus sequence, the orthologous mouse Smpx and rat SMPX genes could be aligned. An open reading frame was identified encoding a peptide of 88 to 86 and 85 amino acids in human and rodents, respectively. The predicted peptide has no significant homologies to known structural elements. BLASTN searches allowed to define the genomic structure of SMPX which consists of five exons (172, 57, 84, 148, 422 bp) and four introns (3639, 10410, 6052, 31134 bp) comprising together 52.1 kb. The gene is preferentially and abundantly expressed in heart and skeletal muscle. Thus a novel human gene encoding a Small Muscular Protein that maps to Xp22.1 (SMPX) has been identified and structurally characterized.

Program Nr: 2164 from the 1999 ASHG Annual Meeting

Changing concepts of the gene. *J.A. White, E.A. Bruford, H.M. Wain, M.S. Povey.* Galton Laboratory, Univ Col London, London, UK.

There is increasing evidence that even in the mammalian genome a single stretch of DNA can be utilised in several different ways. Fascinating as this is, it does pose some problems for nomenclature. The "gene" remains a useful concept and clearly a working definition is needed. The current definition used by the HUGO gene nomenclature committee is deliberately somewhat vague: *A gene is a DNA segment that contributes to phenotype/function.*

Most genes are easily recognized as such, but a significant proportion challenge our current definition. We present a few examples.

1. Fusion genes: in addition to the products of individual genes, fusion transcripts are produced from segments of a number of different loci along the same DNA strand. eg *HHLA1*, *OC90* and the HERV-H element (Genomics 57:371-9).

2. Alternative reading frames: transcripts from different frames at the same locus. eg. p16(INK4a) and p14(ARF) from the *CDKN2A* locus (EMBO J 17:5001-14).

3. Bicistronic genes: two products from adjacent or overlapping stretches of the same mRNA eg *SNRPN* and *SNURF* (PNAS USA 96:5616-21).

4. Antisense genes: a gene product encoded on the anti-sense strand of another gene eg *ORCTL2* and *ORCTL2S* (Genomics 49:38-51).

5. Imprinted genes: product depends on parental origin of the allele, many unusual mRNA examples (bicistronic, antisense, non-coding) are also imprinted. eg An imprinted antisense transcript - LIT1- within the *KCNQ1* locus (Hum Mol Genet 8:1209-1217).

These situations may be interpreted differently, but decisions are required about which entities are assigned approved gene symbols. It is becoming ever more important to be aware of the different levels of nomenclature for loci, genes, transcripts and proteins (as well as phenotypes, mutations, alleles etc). This requires increased communication and collaboration between different nomenclature groups, as well as appropriate database structures to represent the relationships. A consensus among scientists about the philosophy would however be a start, and we welcome comments.

Program Nr: 2165 from the 1999 ASHG Annual Meeting

Expression of the human 21-hydroxylase (CYP21) gene requires far upstream elements within the C4B gene: the evolutionary drive to maintain two unrelated genes in close linkage. *S.D. Wijesuriya, A. Dardis, G. Zhang, W.L. Miller.* Pediatrics, UCSF, San Francisco, CA.

Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase (P450c21) deficiency is caused by mutations in the CYP21 gene and occurs in 1 in 14000 individuals leading to errors in sexual differentiation and potentially lethal salt loss. P450c21 is expressed only in the adrenal cortex. The 5' ends of the human CYP21 genes lie 2466 bp downstream from the complement component C4 genes. 300 bp of the proximal promoter and two regions between exons 38 and 40 of the mouse slp C4 gene are known to be required for expression of the mouse CYP21A gene and we have identified a cryptic adrenal-specific Z promoter within intron 35 of human C4. To investigate the upstream regulatory elements affecting the human CYP21 gene, the 5' flanking region up to -9 kb from the CYP21 transcription initiation site was examined using promoter/reporter constructs and transient transfection assays in human adrenal NCI-H295A cells. The 300 bp proximal promoter provided substantial transcriptional activity, but addition of DNA to -4.6 kb, including the regions that activiate mouse CYP21, did not increase activity. Constructs retaining the Z promoter DNA at -4.6 to -5.6 kb, with or without the DNA from -0.3 to -4.6 kb, had 2-3 fold increased promoter activity indicating the presence of distal *cis* regulatory elements. DNase-I footprinting identified two protein binding sites (F1 and F2) lying -132 and -179 bp upstream of the Z cap site (-4.8 and -5.0 kb upstream of the CYP21 cap site). Band shift assays confirmed binding specificity and identified specific protein DNA complexes with each element. Mutations in these elements abolished complex formation and decreased reporter expression in NCI-H295A cells. Oligonucleotides corresponding to the wildtype but not mutant regions conferred expression to a heterologous TK32 promoter. Competetive gel mobility assays identified the F2 site as binding SF-1, but the factor binding the F1 site is unknown. These data indicate that the Z promoter or elements therein are far upstream components of the C21 promoter needed to drive its expression.

Program Nr: 2166 from the 1999 ASHG Annual Meeting

Genomic characterization of the SMN interacting protein (SIP1) and molecular genetic analysis of patients with spinal muscular atrophy. *B. Wirth[1], C. Helmken[1], A. Wetter[1], F. Schoenen[1], T. Liehr[2], S. Rudnik-Schöneborn[1,3], K. Zerres[1,3]*. 1) Inst. Human Genetics, Bonn, Germany; 2) Inst. Human Genetics and Anthropology, Jena, Germany; 3) Inst. Human Genetics, Aachen, Germany.

Autosomal recessive spinal muscular atrophy (SMA) is caused by mutations within the telomeric copy of the survival motor neuron gene (SMN1) on 5q13. The molecular genetic analysis of 525 type I-III SMA patients revealed homozygous mutations of SMN1 in 96%, while 4% failed to show any mutation, despite a typical SMA phenotype (Wirth et al. 1999, Am J Hum Genet 64:1340-1356). Additionally, we have shown that sibs with homozygous absence of SMN1 and identical SMN2 copy number, can show variable phenotypes which implies that SMA is modified by others, yet unknown factors. We therefore analysed the SMN interacting protein (SIP1) which belongs to the same large protein complex of 300 kD as SMN. The SMN-SIP1 complex has an essential function in snRNP biogenesis and both proteins are localized in so called gems within the nucleus. First, we identified the genomic location of SIP1 and assigned it to chromosome 14q13-q21 by fluorescence in situ hybridization of a BAC clone that contains the entire gene. No similar disorder has yet been assigned to this chromosomal region. Furthermore, we determined the exon-intron structure of the SIP1 gene which allowed us to analyse those SMA patients from whom no RNA was available. We sequenced either RT-PCR products or genomic DNA covering the complete coding region from 20 SMA patients, who failed to show any SMN1 mutation. Unfortunately, no mutation has been found within SIP1. Additionally, we sequenced RT-PCR products of the entire SIP1 coding region from sibs of SMA families with identical genotype but different phenotype and again no mutation was found. Finally, we identified five SIP1 transcription isoforms caused by alternative splicing. Quantitative analysis of SIP1 transcription products in SMA patients and controls is in progress. Based on the data obtained so far, we were able to show that neither the phenotypic variability nor the 5q-unlinked SMAs are caused by mutations within SIP1.

Program Nr: 2167 from the 1999 ASHG Annual Meeting

***JAK3* genomic sequence in human B-cell precursors.** *C.M. Wood, F.M. Uckun.* Molecular Genetics, Parker Hughes Cancer Ctr/HI, St Paul, MN.

Janus tyrosine kinase 3 (JAK3) is one of a number of key regulatory enzymes in human B-cell precursors. The gene for *JAK3* has been mapped to chromosome 19p12-13.1 and encompasses at least 23 exons. Constitutively high levels of JAK3 activity may contribute to drug resistance and enhanced clonogenicity of leukemic B-cell precursors from children with acute lymphoblastic leukemia (ALL). As part of a systematic effort to determine the genomic sequence of the *JAK3* gene in normal and leukemic B-cell precursors, we sequenced a relatively short region of *JAK3* spanning two introns, previously termed introns 10 and 11. Unexpectedly, a gap was identified in the original *JAK3* genomic sequence within intron 10 across an Alu repetitive element. Furthermore, the sequence we obtained from intron 11 did not match to that previously reported, and the length of the intron was much larger than expected (1.1 kb vs. 414 bp). Four regions with homology to repetitive elements (Alu, 698 bp total, and LINE2, 188 bp total) were seen across the entire sequence covering exons 10-12 (2.1 kb total). Two potential single nucleotide polymorphisms (SNPs) were observed in intron 11. No germline mutation was found across this region in leukemic B-cell precursors from any of the ALL patients examined. Our results significantly extend previous efforts to determine the genomic sequence of *JAK3*.

Program Nr: 2168 from the 1999 ASHG Annual Meeting

A new paramyotonia congenita SCN4A mutation in domain I-S5 of the sodium channel suggests novel regions involved in channel inactivation. *F.F. Wu[1], E. Pegoraro[2], P. Colleselli[3], E.P. Hoffman[1,4].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Neurological & Psychiatric Sciences, University of Padova, Italy; 3) Unita' Locale Socio-Sanitaria Belluno, Italy; 4) Research Center for Genetic Medicine Washington DC.

Paramyotonia congenita (PC)is a non-progressive muscle disorder showing cold-induced myotonia and transient weakness. A series of missense mutations have been identified in the adult skeletal muscle sodium channel gene (SCN4A). Here we describe a new three generation Italian family segregating PC. SSCP was used to screen all 24 exons of the SCN4A gene. A C to G transversion was observed at nucleotide 796, causing a missense mutation (L266V). This change adds only a single methylene group to the 1,800 aa protein, but is likely causative of PC as the L266 residue is completely conserved throughout evolution, was not observed in 130 control chromosomes, and co-segregated with the disease. Previously characterized missense mutations causing PC have been found to be clustered in Domain IV, particularly in the intracellular loops known to be involved in fast inactivation of the channel. Additional mutations in the extracellular loops of Domain IV have also been found to disrupt inactivation, and these human mutations have led to the identification of novel domains involved in channel inactivation. The novel L266V mutation we have identified is only the second to be found in Domain I, and the first to be seen in the transmembrane S5. The previously published domain I (V445M) family showed an unusual phenotype of painful myotonia, particularly in the intercostal muscles (Ann Neurol 42: 811-14, 1997). Our Italian family shows classic paramyotonia congenita. The localization of this mutation is highly unexpected, and identifies a new region of the channel which was not previously thought to be important for inactivation. Electrophysiological tests of this mutation in eukaryotic expression systems are currently underway.

Program Nr: 2169 from the 1999 ASHG Annual Meeting

Refinement of the genomic structure of *STX1A* and mutation analysis in nondeletion Williams syndrome patients. *Y.Q. Wu[1], L.R. Osborne[2], L.C. Tsui[2], L.G. Shaffer[1]*. 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Genetics and Genomic Biology, the Hospital for Sick Children, Toronto, Ontario, Canada.

Williams syndrome (WS) is a neurodevelopmental disorder characterized by mental disability with unique cognitive and personality profiles, distinctive facial features, vascular anomalies, connective tissue abnormalities, and infantile hypercalcemia. Our previous studies have shown that ~ 90% of WS patients have a consistent-sized deletion involving multiple genes on chromosome 7q11.23. In this study, we identified 5 individuals who met the clinical criteria for WS by history and physical findings; however, molecular analyses using 10 polymorphic markers within the common deletion region, and FISH analyses using probes to the *ELN*, *LIMK1* and *STX1A* loci showed no microdeletions. Since *STX1A* is a nervous system-specific protein implicated in the docking of synaptic vesicles with the presynaptic plasma membrane, *STX1A* is a good candidate for cognitive or behavioral abnormalities found in WS. In this study, the complete genomic structure of the human *STX1A* was elucidated. In our analysis, published exons 3 and 4 were each found to be comprised of two exons. Therefore, exons 3 and 4 have now been assigned as exons 3 and 4, and 5 and 6, respectively. Thus, *STX1A* is composed of at least 9 exons. Knowledge of the genomic structure has allowed us to do mutation screening using the genomic DNA of the 5 WS patients who do not demonstrate deletions. By sequencing the PCR products for each exon, no point mutations were found in these 5 WS patients. Therefore, these results do not support a role of *STX1A* in the WS phenotype; although continued mutation analysis, such as in the promoter region or in other nondeletion patients, may help to elucidate the role of *STX1A* in Williams syndrome.

Program Nr: 2170 from the 1999 ASHG Annual Meeting

PHR1, encodes a pleckstrin homology domain protein expressed at high levels in mammalian photorecepters. *S. Xu[1], R. Ladak[2], D.A. Swanson[1], H. Sun[3], L. Ploder[2], R.R. McInnes[2], D. Valle[1]*. 1) Institute of Genetic Medicine and HHMI, Johns Hopkins Univ, Baltimore, MD, 21205; 2) Department of Genetics, Hospital for Sick Children, Toronto, Ontario, CA, M5G1X8; 3) Department of Molecular Biology and Genetics, Johns Hopkins University, Baltimore, MD, 21205.

In a screen to identify genes expressed preferentially in retina, we identified one, designated PHR1, that is of interest because it encodes 4 isoforms of 243, 208, 224 and 189 amino acids, all with pleckstrin homology (PH) domain at their N-terminus and a transmembrane domain at their C-terminus. Using in situ hybridization, immunohistochemistry, and immunoblot studies, we found isoforms 1 and 2 are integral membrane proteins in photoreceptor outer segments while isoforms 3 and 4 are abundant in brain. The PHR1 gene (11q13.5-14.1) utilizes two promoters and alternative splicing to produce 4 transcripts. In mouse, transcript 1 is comprised of 9 exons and originates from a 5' photoreceptor-specific promoter with at least three CRX elements, a cis-acting photoreceptor specific promoter element. Transcript 2 originates from the same promoter but lacks exon 7, which encodes 35 amino acids immediately C-terminal to the PH domain. Transcripts 3 and 4 originate from an internal promoter in intron 2 and either contain or lack exon 7, respectively. Human PHR1 has a similar genomic organization, except at the 5' end, where the sequence corresponding to murine exon 1, intron 1 and exon 2 forms the first exon. In human and mouse, transcripts driven by the internal promoter start in intron 2. To investigate PHR1 function, we performed in vitro binding assays with a series of PHR1 isoform 1 and 2 GST fusion proteins. We found no binding to inositol phosphates but specific binding to transducin bg subunits. Using truncated PHR1 fusion proteins, we located this activity to the PH domain. This binding activity together with abundant expression in the photoreceptor outer segment suggests that PHR1 may function as a modulator of the phototransduction. We have targeted murine PHR1 exon 3 and recently obtained heterozygotes. Study of these animals and their progeny should provide more information on PHR1 function.

Program Nr: 2171 from the 1999 ASHG Annual Meeting

Molecular regulation of human *single-minded* 2 (SIM2) gene. *A. Yamaki[1], J. Kudoh[2], S. Minoshima[2], N. Shimizu[2], Y. Shimizu[1]*. 1) Medical Genetics, Kyorin Univ Sch Health Sci, Tokyo, Japan; 2) Dept. Mol. Biol., Keio Univ. Sch. Med., Tokyo, Japan.

The single-minded 2 (SIM2) gene located on the human chromosome 21q22.2 is a human homolog of Drosophila sim gene which encodes a transcription factor essential for the development of midline cells in the central nervous system. We thus previously proposed the SIM2 is a good candidate gene for the pathogenesis of Down syndrome, particularly the mental retardation. Human SIM2 and mouse Sim 2 consist of 11 exons, spanning 50 kb and 40 kb in size, respectively. Mouse Sim 2 gene was expressed in the diencephalon of 8.5-day embryo and adult kidney, skeletal muscle, and hippocampus. Northern blot analysis revealed that human SIM2 mRNA was detected in fetal kidney, kidney, skeletal muscle, and prostate. As a step toward understanding the molecular mechanisms of SIM2 gene expression, we examined the transcription initiation site in the human SIM2 gene by 5'-RACE method using RNA isolated from the SIM2 gene-expressing glioblastoma cell line. The starting point of the transcription was found to be at 1.2-kb upstream of the initiation codon. To futher characterize the SIM2 promoter region, we made a series of deletion constructs by ligating with luciferase reporter gene. Transfection assay in the glioblastoma cells revealed that significant promoter activity located in the 43-bp sequence between nt -1307and nt -1349 upstream of the translation initiation site. Computer analysis in fact showed three cis-elements for c-myb, E-47 and E2F in the 43-bp sequence. We then made point mutations in each of these three cis-elements and found that a mutation in c-myb element was most affected the luciferase activity. The gel- shift assay using the 18-bp sequence containing c-myb element revealed at least two specific bands of oligonucleotide-protein complex. Thus, the c-myb transcription factor appears to be involved in the regulation of SIM2 gene expression in human glioblastoma cells.

Genomic structure of the human plasma prekallikrein gene, and association and mutation analysis in End-Stage Renal Disease. *H. Yu, B.I. Freedman, S.S. Rich, D.W. Bowden.* Biochem, Wake Forest Univ Sch Medicine, Winston-Salem, NC.

Kallikreins are serine proteases which catalyze the release of kinins and other vasoactive peptides involved in the regulation of blood pressure and renal perfusion. Previously, we have studied one tissue-specific and one plasma-specific human kallikrein gene in the End-Stage Renal Disease (ESRD). We found that polymorphisms for the human plasma prekallikrein gene (KLKB1, previously known as KLK3) on chromosome 4 were associated with ESRD in African Americans (Yu et al., Hypertension 1998;31:906-911). We have extended the study of the role of KLKB1 in ESRD. First, we determined the exon-intron boundaries of KLKB1. Second, based on this information of gene structure, we designed primers to amplify KLKB1 exons. These primers were used to screen for mutations in the ESRD patients. The exon-intron boundaries were determined using the Polymerase Chain Reaction (PCR) with primers designed from KLKB1 cDNA. Sequence of the 5' region of KLKB1 was extended by shotgun-cloning. Mutations were detected using the Single Strand Conformation Polymorphism (SSCP) method. All exon-intron boundaries have been determined. Like the rat gene, the human plasma kallikrein gene contained 15 exons and 14 introns. The longest intron, F, was almost 12 Kb long. The total length of the gene was approximately 30 Kb. Two new "CA/GT" repeat markers were identified within the gene, and designated as KLK3f and KLK3g. They had heterozygosities of 0.65 and 0.84, respectively. We have detected 8 allelic variants in 7 exons, with a major one at position 521 of KLKB1 cDNA. This mutation (A521G) replaced an asparagine with a serine at position 124 in the human plasma prekallikrein peptide. Results using the Relative Predispositional Effect (RPE) technique indicated that the frequencies of alleles 4, 8 of KLK3f and allele 8 of KLK3g were significantly different between controls and ESRD cases. They accounted for 0.226, 0.096 and 0.313, respectively, in the probands of 166 ESRD families as compared to 0.172, 0.066 and 0.244 in 139 race-matched controls (allele P and total $P < 0.05$ for all three alleles). Therefore, KLKB1 might contribute to the risk of developing ESRD in African Americans.

Program Nr: 2173 from the 1999 ASHG Annual Meeting

Patient willingness to contact at risk relatives for genetic testing studies: experience with hemophilia A. *T. Jennings-Grant, N. Callanan, C. Lakon, I. Lubin, J.R. Sorenson, T. Spinney, G. White.* University of North Carolina at Chapel Hill, Chapel Hill, NC.

As part of a NHGRI funded study 127 hemophilia A patients (or parents if a minor) with hemophilia A were asked to participate in a study in which genetic counseling and carrier testing would be offered at no charge to their at risk female relatives. For patients, participation was limited to providing family history and giving consent to have their medical chart reviewed, submitting a blood sample for DNA mutation analysis and completing a single intake questionnaire. Twenty-nine of the 127 did not meet study inclusion criteria. Of the remaining 98 patients 66 (67%) agreed to participate. Preliminary analysis of the data suggests that participation is not influenced by race, education or religion. However, the participation rate was 89% for patients ³ 19 and 58% for those £ 18 years of age. 89% of patients with severe and 63% of those with mild or moderate hemophilia A participated. Overall, 98% reported that someone had previously talked with them about the inheritance of hemophilia, and 84% had been informed that female relatives might be carriers. Among those who had not received prior information about the carrier risks for relatives 93% participated. 30% think their relatives have a high or extremely high risk for having a child with hemophilia, and 60% have previously discussed carrier testing with their relatives. Overall, 84% thought they would be able to contact relatives about the study and 88% did not think that our asking them to do so was an invasion of their or their relatives' privacy. Of the 71% of patients who felt that they had an obligation to inform relatives about the study 78% participated whereas 59% of those who did not feel this obligation participated. The implications of these data for recruiting at risk relatives into gene testing studies will be discussed.

Program Nr: 2174 from the 1999 ASHG Annual Meeting

Dilemma to chronic ventilation in Werdnig-Hoffmann disease: study of 16 patients. *C.E. Kim, P. Lecussan, E. Casella, L. Albano, G. Oselka.* Pediatrics, Instito da Crianca, Sao Paulo, Brazil.

Werdnig-Hoffmann disease, the most common lethal autosomal recessive disorder and its frequency is 1 per 10 000 births. Affected patients usually die before 2 years of age, due to the respiratory involvement. In Brazil, due to cultural,religious and legal problems, almost all patients are submitted to chronic ventilation and have their lives actively prolonged for unlimitated time.Therefore,iniciation of ventilator use in this condition is raising an important ethical issue and high medical costs. We studied 16 patients, all under permanent mechanical ventilation, started from 2 to 19 months (mean age=6,6 mo). Ten patients are maintained in intensive care units of hospitals and 6 patients are at home care. The duration of ventilation varied from 7 months to 13 years. The average time of ventilation was 6 years in patients at home and 2 years and 9 months in patients at hospital.Two among the patients in hospital died after 4 and 21 months of ventilation. The current ages of alive patients range from 1 year and 5 months to 14 years. Tracheostomy and gastrostomy were performed in all patients. interestingly, the parents of all patients prefere their child to be submitted to ventilation, even thoughsuffering emotional stress and poor quality of the life style without any pespectives of improvement.

Program Nr: 2175 from the 1999 ASHG Annual Meeting

The Development of a Web-Based Family Health History Collection Tool. *W. Knaus[1], W. Cohn[1], J. Barrett[1], M. Kinzie[2], S. Pelletier[1], M. Julian[2], J. Einbinder[1].* 1) Health Evaluation Sciences, University of Virginia, Charlottesville, VA; 2) Department of Educational Studies.

The human genome project is providing a wealth of information about the genetic basis of common diseases. This information has implications for clinical practice however; it will only be useful to physicians and patients when coupled with family history information. The effective use of family history information in the primary care setting will depend on to factors. The first is the ability of the patient to collect complete family health history information. The second is the ability of the primary care physician to interpret this information to provide specific recommendations. The Family Health History Collection Tool is designed to improve the collection and interpretation of family health history information. This web tool will provide an easy and efficient way for patients to collect, maintain and update their family health history. Additionally, this tool will apply interpretive algorithms to stratify patients' risk for the most common diseases. Algorithm development involved specialists in oncology, endocrinology, neurology, and cardiology. A geneticist and genetic counselor participated in the development phase of both the algorithms and the system design. Primary issues related to the development of the system included; the necessity of involving professionals from many fields due to the complexity of the project; conducting a thorough needs assessment of stakeholders including all potential users; developing a strategy to balance the needs and professional interests of each stakeholder and designing a process for algorithm development in each specialty area.
