As part of the Human Genome Education Model Project (HuGEM) II, (a project of Georgetown University Medical Center and the Alliance of Genetic Support Groups), 18 three-hour continuing education workshops were held in 9 states in 1998-1999 for over 600 health professional practitioners. Attendees were primarily dietitians, occupational and physical therapists, psychologists, speech-language pathologists and audiologists, and social workers. At the beginning of each workshop, participants were asked to complete four questions about their prior knowledge of genetics and how important they considered genetic issues to be to society and to their professions. Responses from 423 attendees showed that 40% knew a lot about genetics prior to the workshop and 60% said they knew almost nothing. Those who knew a lot were most likely to be in their 50s (49%) and least likely to be in their 20s (32%). More women (87%) than men attended the workshops and more women (41%) than men (36%) knew a lot. Those who knew a lot considered genetic issues to be more important to society (81% versus 61%) and to their profession (69% versus. 55%). However, by the end of the workshop the gap was narrowed so that 86% of those who knew a lot and 83% of those who knew almost nothing considered genetic issues to be very important to society. And 79% and 71% respectively considered genetics to be very important to their professions. A serendipitous finding was related to individuals who were least satisfied. While 90% were very satisfied with the speakers, topics and information, the 10% who were least satisfied (1-3 on a 5-point scale) went from 44% who considered genetics very important to society before the workshop to 71% after. The change was 35% to 48% who considered genetics very important to their professions. These findings counter the prevailing wisdom that satisfaction equals learning. Additional studies and measures are needed to consider this paradox.

Program Nr: 2177 from the 1999 ASHG Annual Meeting

Contacting at risk relatives for a genetic counseling and testing study: experience with hemophilia A patients.
C.M. Lakon, N. Callanan, T. Jennings-Grant, I. Lubin, J.R. Sorenson, G. White. University of North Carolina at Chapel Hill, Chapel Hill, NC.

One means of recruiting high-risk populations into genetic testing research is to ask patients to inform at-risk relatives about the research. As part of an ongoing hemophilia A study in which genetic counseling and carrier testing is offered at no charge to at risk female relatives, we have contacted 127 hemophilia A patients (or their parents if a minor). Of the 98 patients who met eligibility requirements, 66 (67%) agreed to participate. Mutation analysis has been completed for 59/66 participants and a disease causing or associated mutation has been identified in 50(84.7%). We have been unable to contact 2 patients (11 at risk relatives) with their results. The remaining 48 patients have 341 (average 7.1 /patient) at risk relatives. Patients were asked to inform relatives about the study and obtain their consent to be contacted by the study team. To facilitate this process, patients were provided with a list of at risk relatives, a fact sheet about the study to share with relatives and were reimbursed for the cost of contacting relatives. Thus far 63% (32/48) have supplied us with consent and information to contact 163 (47.8% of total) at risk relatives. There were 77 (22.6%) relatives who were informed about the study but did not wish to participate. Patients or their designees were not willing or not able to contact 37(10.8%) relatives. 19 (5.6%) relatives were contacted by the patient but did not respond within the time limit to be included in the study. There were 45(13.2%) relatives for whom the patient did not provide contact information within the time limit for inclusion in the study. 16/48 patients (33%) have not supplied contact information for any relatives. Of these, 8 report that none of their relatives wish to participate, 1 has refused to contact relatives, and 7 have missed deadlines for providing contact information to the study team. The implications of these data for recruiting at risk relatives into gene testing studies will be discussed.

Program Nr: 2178 from the 1999 ASHG Annual Meeting

Do laws restricting health insurers' use of genetic information reduce the fear of discrimination and increase genetic testing? *J.S. Lawlor, S.S. Rich, M.A. Hall.* Public Health Sciences, WFU School of Medicine, Winston-Salem, NC.

Methods: Qualitative, comparative, case-study analysis in seven states, with varying laws restricting health insurers' use of genetic information. Expert, semi-structured interviews were conducted in 1998 with 29 genetic counselors or medical geneticists and five patient advocates. Informed consent forms and patient information brochures used by medical geneticists were content analyzed. Also, a review was conducted of published articles and unpublished studies based on surveys done at genetic clinics, concerning factors that influence testing decisions and perceptions of the threat of genetic discrimination. **Findings**: (1) Patients' fear of genetic discrimination greatly exceed the reality, at least for health insurance. (2) Whether these fears deter genetic testing depends on the costs and benefits of testing. The greatest difference is to those who do not want to submit the costs of testing for reimbursement and who cannot afford to pay for testing out of pocket. There appears to be little deterrence for tests that are more easily affordable or when the need for the information is much greater. (3) Fear of discrimination plays virtually no role in testing decisions in pediatric or prenatal situations. Fear of discrimination is significant only for adult-onset conditions, and for adults there is less concern when there are existing symptoms or when indications of the condition are already documented in the medical record. (4) There is widespread awareness of these laws among genetic counselors, but counselors' knowledge of the basic provisions is not accurate, and they frequently underestimate how protective these laws are, as written. **Conclusion**: These laws have not greatly reduced the fear of discrimination in part because people in the medical genetics community are not confident these laws will actually prevent discrimination until there are test cases of actual enforcement. Ironically, there may be so little actual discrimination that it is not possible to initiate good test cases. If the fear of discrimination were lessened, this would likely have a strong impact on patients' decisions to undergo testing only in a limited range of conditions.

Program Nr: 2179 from the 1999 ASHG Annual Meeting

Establishment of a dedicated cancer genetics program in a tertiary pediatric centre. *D. Malkin[1], K. Smyth[1], C. Shuman[2], N. Quercia[2], K. Australie[3], R. Weksberg[2].* 1) Hematology/Oncology and; 2) Clinical Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Clinical Genetics, Montreal General Hospital, Montreal, Quebec, Canada.

The Hospital for Sick Children is a tertiary care medical center that serves a population of 8 million. The Division of Oncology admits and treats ~325 newly diagnosed cancer patients annually. Although the cause of childhood cancer is for the most part not known, previous reports have suggested that 5-10% may have a genetic etiology. In a recently completed study of the impact of predictive genetic testing on parents of children with cancer,we observed that parents' perceptions of genetic risk for cancer were innacurate. Furthermore, pediatric oncologists' understanding of a child's right to know the results of genetic screening, of the potential value of genetic information, and of the accuracy of the family cancer history were all incomplete. Based in part on this data, we developed a unique Cancer Genetics Program and Clinic within the Division of Oncology. The primary objective of the Program is to establish an infrastructure to facilitate accurate genetic counseling of families and development of improved education of pediatric oncology health care professionals. A secondary objective is to foster fundamental and clinical genetic interdisciplinary research studies based on a comprehensive database. All newly diagnosed patients and their parents are referred to the clinic for complete pedigree analysis and counseling. A genetic component to the occurrence of cancer is suggested by the family histories taken to date of at least 25% of probands. Furthermore, previously unrecognized clinical characteristics suggestive of a genetic syndrome have also been observed. The clinic has enhanced the presence of clinical genetics in the pediatric cancer setting. We conclude that development of a cancer genetics program aligned with both Oncology and Clinical Genetics in a large tertiary care pediatric centre is feasible. It fascilitates the education of parents and families to the issues of genetic risk and testing, and enhances opportunities for research into the genetic basis of childhood cancer.

Program Nr: 2180 from the 1999 ASHG Annual Meeting

Feeling to blame: do genetic doctors and nurses discuss it during genetic counselling and should they? *C. Metcalf[1], J. Hewison[1], R.F. Mueller[2], A. Walker[3], H. Cuckle[4].* 1) Sch of Psychology, Univ of Leeds, Leeds, England; 2) Dept of Clinical Genetics, St James's Hospital, Leeds, England; 3) Health Services Research Unit, Univ of Aberdeen, Aberdeen, Scotland; 4) Dept of Reproductive Epidemiology, Univ of Leeds, Leeds, England.

Statement of Purpose Unresolved and inappropriate blame for health conditions can have long term psychological consequences. In the case of inherited disorders, the potential for parents and other family members to blame themselves, or one another, is high. A potentially important function of genetic counselling in these circumstances is to address and allay this propensity for blame.

Methods Used This paper reports findings from a UK national study involving ten regional genetics units and 107 cases of genetic counselling: 38 for X-linked disorders (Duchenne muscular dystrophy and Fragile X syndrome), 38 for cystic fibrosis and 31 for chromosomal rearrangements. Post-session questionnaires were obtained from 131 individuals and 100 genetic counselling sessions were recorded on audiotape, transcribed and analysed. Psychological status was measured using the Hospital Anxiety and Depression (HAD) scale.

Summary of Results There was evidence of self-blame in almost one third of cases (31/107). Self-blame was reported in 26 questionnaires but from the corresponding session transcript, half (13) these individuals neither mentioned self-blame, nor were invited to discuss it. Psychological well-being, assessed by HAD anxiety scores, was significantly worse in self-blamers (self-blame mean = 9.2, no self-blame mean = 4.5, $t = 5.35$, $p<0.001$).

Conclusions Self-blame is a common experience among consultands for genetic counselling and is associated with high levels of anxiety. In a number of cases, there is no mention of self-blame by the individual nor encouragement from the doctor or nurse leading the session. This might indicate that the professionals taking the session are not identifying such a psychologically important issue. Left undetected, self-blame and its adverse psychological impact could have lasting implications for mental health.

Program Nr: 2181 from the 1999 ASHG Annual Meeting

Using Multimedia to Enhance Teaching of Contemporary Medical Genetics. *S.A. Metcalfe[1], R. Williamson[1], A. Bonollo[2]*. 1) Murdoch Institute,Victoria, Australia and Dept Paediatrics, Faculty of Medicine, University of Melbourne, Australia; 2) Biomedical Multimedia Unit, Faculty of Medicine, University of Melbourne, Australia.

Rapid advances in human genetics and medical applications of genetic technologies provide new challenges for medical and allied health educators. Lecture-based teaching may not provide sufficient time or depth for students to grasp complex concepts and students are often reluctant to engage in interactive dialogue on social/ethical issues of genetics. We are developing a self-directed learning multimedia package that integrates basic concepts of genetics within a clinical framework. Specific single-gene and chromosomal disorders are used to highlight molecular basis, principles of genetic testing, and counselling issues, which are incorporated into 3 modules: i) Clinical Diagnosis, ii) Laboratory Diagnostics, iii) Counselling and Ethical Issues. The CD-ROM features interactivity, animations and text delivered in a number of ways, including 'rollovers', feedback, and glossary. Various media enhance visual diversity: photos of affected persons, images of molecules, DNA test results, and videos of counselling methods/sessions. Interactive problem-solving exercises are offered, often using the 'drag-and-drop' approach, such as building pedigrees from family histories, karyotyping chromosomes, analysing/understanding molecular basis of DNA tests and multiple choice questions for self-testing. Incorrect solutions are possible at the interactive steps with on-screen feedback. In the counselling module, students can view video clips of scripted genetic counselling sessions with 'time-outs' highlighting key issues. The program is still in its development stage but has been used in a computer lab setting for 1st year medical students. Evaluation is by content and evaluation experts, and students who have been educated in an 'older style' curriculum. This multimedia program allows students to perform problem-solving exercises, explore counselling/ethical issues, and study medical genetics at their own pace, thereby providing a flexible learning environment to enhance self-study and lifelong learning skills.

Program Nr: 2182 from the 1999 ASHG Annual Meeting

ATTITUDE TOWARDS PROPHYLACTIC SURGERY AND EFFECTS OF GENETIC COUNSELLING IN FAMILIES WITH BRCA MUTATIONS. *R. Moeslinger[1], T. Wagner[1], G. Langbauer[1], Austrian HBOC Group[1], A. Auterith[3], A. Friedmann[2], C. Zielinski[4], M. Seifert[1], P. Oefner[5]*. 1) Dept Gyn OB, Div Senology, Univ Vienna, Vienna, Austria/Europe; 2) Dept Psychiatry, Univ Vienna, Vienna, Austria; 3) Dept of Medical Statistics, Univ Vienna,; 4) Dept Medicine I, Div Oncology, Univ Vienna; 5) Dept Biochemistry, Univ Stanford, Stanford.

The intent of this study was to evaluate the effect that awareness of being a BRCA1 or BRCA2 mutation carrier has on the attitude towards prophylactic surgery, as well as on developing depression symptoms, body image, and the ability to cope with carrier status. Thirty-five families were selected on the basis of previously detected BRCA1 or 2 mutations and 90 family members were given the appropriate questionnaires. Prophylactic mastectomy (PM) was considered by 21% of the Austrian mutation carriers (29% affected and 8% non-affected carriers). The majority of affected and non-affected carriers expected PM to impair the quality of their life. Fifty percent would undergo prophylactic oophorectomy (53% affected and 46% non-affected carriers). The self-rating depression scale indicated that following mutation result disclosure the depression scores of carriers decreased (40 baseline vs. 38 after result disclosure, p=0.3), whereas, for non-carriers, scores increased (36 baseline vs. 40 after result disclosure, p=0.05). We conclude, that information about carrier status is not associated with increased depression symptoms in mutation carriers. In non-carriers depression scores increased slightly, probably reflecting survivor guilt. The option of having PM was associated with a negative impact on the quality of life and was declined by the majority of Austrian mutation carriers.

Program Nr: 2183 from the 1999 ASHG Annual Meeting

Genetics in the Nursing Literature: A Source of New Knowledge for Practice, Education, and Research. *R.L. Monsen[1], G. Anderson[2]*. 1) University of Arkansas for Medical Sciences, College of Nursing Little Rock, AR 72205; 2) Stanford Center for Biomedical Ethics Palo Alto, CA 94304.

Nurses are regarded as an important resource in meeting the disease-specific requests for information and assistance as gene-based diagnosis and therapies become routine health care practice. Nurses are more numerous in community health settings than are genetic specialists and have the capacity to acquire the basic concepts needed for recognizing the need for referrals and accessing appropriate sources of genetic information for use by consumers. Moreover, as the need for individual counseling and follow-up accompanying genetic testing for frequently occurring conditions, nurses can be called upon to provide these time-consuming services in collaboration with certified genetic specialists. The nursing literature is one of the most important sources of new knowledge for nursing practice, education, and research. Therefore, the purpose of this ELSI funded study was to conduct the first integrative review of genetics in the nursing literature from its inception in 1962 to the end of the 20th century. Over 500 citations published were ascertained from multiple online bibliographic databases. In this paper, the authors provide statistics about the genetic topics of most concern to these nurse and non-nurse authors, a description of the type and diversity of authorship, a description and a conceptual map of the types of clinical practice models now used by nurses who use genetic information in their practice, and interventions recommended by these authors for the entire discipline of nursing for people who have health care concerns related to genetics. The areas of strength in this nursing literature include cancer genetics, prenatal diagnosis and reproductive technologies, and single gene disorders frequently encountered in children and adolescents. Recommendations for preparing the nation's nurses to assume roles in case-finding, support counseling, and follow-up of genetic services are among the most important next steps in the era of geneticized health care.

.

Program Nr: 2184 from the 1999 ASHG Annual Meeting

Psychosocial effects of type 1 diabetes genetic risk information: a pilot study. *L. Nicol-Smith[1], O. Søvik[2], G. Joner[1], K. Tambs[1], K.S. Rønningen[1]*. 1) Dept. of Population Health Sciences, National Institute of Public Health, Oslo, Norway; 2) Dept. of Pediatrics, Haukeland University Hospital, Bergen, Norway.

In a nationwide project in Norway, approx. 2,200 first-degree relatives of children with type 1 diabetes were HLA-DQ typed between 1994 and 1997. 20 pediatric departments were involved in collecting blood samples and relaying results. Risk information has been relayed, in part, back to the participants. The long-term impact of this project on both participants and physicians is being examined. A questionnaire for the parents who have undergone testing has been developed which evaluates perceived risk, affective response to test result and subjective health. Structured interviews will be undertaken with the pediatricians. Thus far data from one county in Norway has been collected. Of 127 pilot questionnaires that have been sent out 52 (41%) have been returned. Preliminary analysis reveals that 13 (25%) parents report thinking about their test result at least once a month, and 6 (11%) are slightly troubled by these thoughts. None regret being tested, but 2 would not recommend testing to a friend. Understanding of test results appears to be good. No systematic differences between those with perceived increased risk (n=19) and those with normal risk is indicated using standardized measures of anxiety, depression and subjective health. The pilot study has so far shown: 1) a few of the participating parents receiving information about their disposition to type 1 diabetes are "troubled" about their result two years afterwards; 2) methods which have been developed to evaluate psychosocial effects of genetic risk information in a specialist clinical genetic setting may be inadequate for monitoring the population effects of widespread genetic dispositional testing for common disorders; 3) the participating pediatricians have shown varying degrees of unpreparedness to give information regarding genetic susceptibility.

Program Nr: 2185 from the 1999 ASHG Annual Meeting

Clinical Genetics in a Family Practice Residency. *E.J. Palmer.* Family Med, Allegheny Fam Phys, Altoona Hosp, Altoona, PA.

Although referral to a genetics center may be indicated for complex cases, genetic health care, including counseling, for most common problems, should be provided by primary care physicians. Family Practice physicians, faculty, and residents may, however, lack a basic knowledge of clinical genetics and genetic testing, which could result in inappropriate responses to clinical situations in which a significant genetic component is evident. The following study was undertaken to assess the problem. First, a 10 question survey about the Marfan Syndrome was distributed to 72 community family physician attendees at an annual State Medical Society meeting. The survey acknowledged a general lack of formal clinical genetics training in medical school and residency, and only 55% of the questions about Marfan's Syndrome were answered correctly. Second, a poll of 74 Family Practice residency programs demonstrated no specific clinical genetics components in the curriculum. Third, the 50 question quiz from the AAFP Clinical Genetics monograph was administered to 6 faculty and 20 residents at a Family Practice residency program and yielded an average score of 53% correct for faculty and 42% correct for residents. Finally, a retrospective review of 176 obstetrical patient's charts was performed at a Family Practice residency. Of the 36 charts with recorded genetically inherited disorders listed in the family history, an appropriate clinical response was documented for only 33% of the cases. A structured, 3 year, curriculum in clinical genetics has been designed for a residency program. Assessment of the effectiveness of the program includes tests of knowledge base, demonstration of counseling skills, use of resources, audits of charts, and surveys of graduates. Since the primary care physician is usually the first person a patient seeks with medical questions, it is necessary for Family Physicians to assimilate and integrate the information and technology arising from the Human Genome Initiative.

Program Nr: 2186 from the 1999 ASHG Annual Meeting

Genetic education needs for primary care providers: A pre-intervention survey. *B.A. Pletcher, C.L. Koval, G. Gilbert, G. Rodriguez.* Center for Human & Molecular Genetics, University of Medicine and Dentistry- New Jersey Medical School, Newark, NJ.

As part of a federally funded genetic education project for primary care practitioners,78 participants completed a pre-intervention survey to assess their genetic education and service needs. Providers included 27(35%) pediatricians, 18(23%) OB nurse practitioners or midwives, 14(18%) family practitioners, 8(10%) internists, 5(6%) obstetricians, 5(6%) pediatric nurses and 1(1%) internal medicine nurse. Practice trends suggested that obstetricians by far had the greatest numbers of patients requiring testing or genetic referral. In contrast, obstetric nurses had many fewer patients requiring testing or genetic referral. Pediatric providers had intermediate levels of genetic testing and consultation needs whereas family practitioners were more likely to do genetic testing themselves and infrequently referred for genetic consultation. Internal medicine providers tested and referred the fewest patients. Twelve(15%) of respondents did not know where to refer patients for genetic services and 40(51%) did not know what genetic tests are available to patients. In the preceding year 15(19%) had procedural difficulties getting genetic testing done for their patients and 19(24%) had financial problems in this regard. Although 48(61%) stated they had a genetic course as part of their professional school curriculum, only 3(4%) received any CME credits in the past year related to genetic topics. Thirty-two(41%) of respondents have no internet access in their practice settings, 44(56%) do not use the worldwide web regularly and 51(65%) do not even use email regularly to communicate with other clinicians. In summary, in the course of developing a primary care provider educational program it became clear that providers in our region need a) to learn about genetic testing availablity b) to have more genetic offerings as part of CME programs and c) to have information communicated in ways other than through the internet or via email. Genetic testing and referral patterns varied significantly between specialties and these services are used the least by adult medicine specialists.

Program Nr: 2187 from the 1999 ASHG Annual Meeting

Sibling knowledge and attitudes toward carrier testing for X-linked severe combined immunodeficiency. *J.M. Puck[1], J.H. Fanos[2], J. Davis[1]*. 1) NHGRI/NIH, Bethesda, MD; 2) California Pacific Medical Center Research Institute, San Francisco, CA.

X-linked severe combined immunodeficiency (XSCID) is the most common genetic form of SCID, a rare (1/50,000 births) disease with profoundly impaired cellular and humoral immunity. Popularized as the disease of David the Bubble Boy, isolated from birth in a germ-free environment, SCID was previously fatal, but now is usually successfully treated by bone marrow transplantation. Mapping of XSCID in 1985, and identification of the disease gene, IL2RG, in 1993, have made possible patient and carrier diagnosis. We assessed understanding of the genetics of XSCID and attitudes toward carrier testing in siblings recruited from families in which a proband had previously enrolled in our linkage or mutation detection protocols and been proven to have XSCID. 37 female and 3 male adult siblings completed a questionnaire and semi-structured interview. Overall knowledge of the genetics of XSCID was excellent, with 14 of 16 questions answered correctly by >75% of subjects. Questions frequently missed: only 49% knew all daughters of an affected boy would be carriers, and 53% were unaware that spontaneous mutation for XSCID was possible. Of interest, siblings from kindreds with a documented spontaneous mutation were less likely to answer this question correctly than those in multi-generational XSCID kindreds (p=0.01). 93% of our sibling group believed daughters should be tested for XSCID carrier status. 89% would prefer to have their own daughter tested prior to reaching 18 years (M=9, Median=12); 34% would test at birth. 89% would disclose carrier results to their daughter before her 18th birthday (preferred disclosure age M=12 years, Median=12); 51% would disclose prior to adolescence. Preference for carrier testing before adulthood reflected the subjects' desire to have parents impart knowledge at what they felt was an optimal time to minimize childrens misconceptions. We recommend that genetic counseling for XSCID include children in age-appropriate discussions and help parents weigh the benefits of early testing and disclosure vs. the potential harm of loss of child autonomy.

Program Nr: 2188 from the 1999 ASHG Annual Meeting

A Critical Analysis of the Research Performed on Psychosocial Aspects of DNA Testing for BRCA1/2. *D. Punales-Morejon, G. Havens.* Division of Medical Genetics, Beth Israel Medical Center, New York, NY.

Mutations in the BRCA1/2 genes increase the risk of developing certain cancers. Several factors that predict whether a woman will elect genetic testing for BRCA1/2 have been studied. Investigators have identified the following variables as impacting a woman's decision-making process: level of education, having health insurance, number of first degree relatives affected by breast and/or ovarian cancer, perceived versus objective risk of being a mutation carrier, perceived susceptibility of ovarian cancer and/or recurrent breast cancer, level of cancer genetics knowledge, perceived benefits versus limitations of genetic testing, and psychological distress.

However, these studies suffer from limitations which impact on their generalizability. For example, most studies have asked subjects only to consider hypothetically whether they would pursue testing. Yet the literature clearly demonstrates a significant difference between hypothetical consent and actual test use. Other limitations in the prior studies include subjects that were overly diverse regarding cancer risk and knowledge, and various predictive factors were not tested simultaneously.

While it is evident that there is limited information available about the variables that predict utilization of DNA testing, even less is understood about the mechanisms involved in the decisional process. Understanding decisional variables has important clinical implications. Some predictor variables may have greater relative strength than others and as such have different impact potential in decision making. From this analysis of the current research on psychosocial issues in genetic testing for breast and ovarian cancer, a set of recommendations is derived for the purpose of advancing the understanding of the psychological and social factors involved in the pursuit of DNA testing. This understanding may allow genetic counselors and geneticists to better help women and their families make critical decisions in the growing arena of cancer genetics and susceptibility testing.

Program Nr: 2189 from the 1999 ASHG Annual Meeting

Implementation of an inherited breast/ovarian cancer susceptibility clinical practice guideline: Who receives counseling, and who is interested in genetic testing? *J. Reiss[1], J. Bergoffen[1], D. Broome[1], E. Harris[1], A. Mims[1], U. Ochs[2], S. Rowell[1]*. 1) Kaiser Permanente (KP) Health Plans—California, Georgia, and Northwest; 2) Group Health Cooperative (GHC), Seattle WA.

KP and GHC provide comprehensive health care for over 9 million persons. A registry of individuals counseled for genetic susceptibility was developed as part of implementing KP's and GHC's clinical practice guidelines for counseling for inherited breast/ovarian cancer susceptibility. Its purpose is to provide a resource for guideline evaluation and research studies. Clinicians (primarily genetic counselors and clinical geneticists) complete a standard form for each person counseled, and submit it to a central database. Regular contributions started between December 1997 and January 1999, depending on the area. As of June 1999, the registry contained forms for 208 persons who received individual counseling.

Referrals most often came from obstetrics/gynecology (35%), internal medicine (25%), and oncology (15%); 6% self-referred. Nearly all counselees were women (99%); median age was 48 years. Most were white (89%); 20% were Ashkenazi Jewish. 31% had breast or ovarian cancer, and 83% had at least one first-degree relative with breast or ovarian cancer. 41% of those counseled met the guidelines; in addition, 20% were judged to be high-risk for carrying a deleterious BRCA1 or BRCA2 mutation or another inherited cancer susceptibility gene. 49% were "definitely interested" in genetic testing, including 17% judged not to be high-risk. 70% of those with breast/ovarian cancer, and 38% of those with only a family history of breast/ovarian cancer, were definitely interested in testing. Our findings suggest that most individuals are being referred appropriately, but a substantial proportion of those counseled (39%) may not be. Future work needs to assess reasons for these referrals, and methods to minimize low-risk referrals without adversely affecting quality of care (e.g., more effective methods of clinician and/or patient education).

Supported by Permanente medical group, Garfield Memorial Fund, and KP Center for Health Research.

Program Nr: 2190 from the 1999 ASHG Annual Meeting

Parental Attitudes Towards a Diagnosis in Children with Unidentified Multiple Congenital Anomaly Syndromes.

E. Rosenthal[1], B. Biesecker[1], L.G. Biesecker[2]. 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Laboratory of Genetic Disease Research, NHGRI/NIH, Bethesda, MD.

Approximately 1% of newborns are affected with multiple birth defects. In over half of these cases it is impossible to identify a specific syndrome to explain the pattern of anomalies. Genetics clinics provide care for many children with unexplained multiple congenital anomaly syndromes, but little is known about the ways in which the lack of a diagnosis affects parental coping and adjustment. We interviewed the parents of 16 children born with an unidentified multiple congenital syndrome in order to learn more about their attitudes towards diagnositic information. The parents in our sample had all been aware of their child's birth defects for between 2 and 23 years, and they had all sought multiple evaluations in an attempt to find a diagnosis that could explain their child's condition. Since our sample was selected from a pool of parents who had already demonstrated an interest in diagnositic information it was not surprising that most of them told us that they are still interested in identifying their child's syndrome. Typically, they told us that they had been especially anxious to obtain a diagnosis when the child was younger, but their interest has diminished to varying degrees with the passage of time.

Using qualitative methodology, we identified six general areas where the parents feel that a diagnosis would have significant impact: Labeling, Causes, Prognosis, Treatment, Acceptance, and Social Support. Some of the most significant issues revolved around obtaining special education services, knowing what to expect in their child's future, watching out for new problems, fears about the child's life-expectancy, concern about recurrence risks, a desire to make sure that the child was receiving appropriate treatment, and feelings of isolation. Parents did not always feel that a diagnosis would help them deal with these issues, and in some cases they felt that a diagnosis could be harmful.

Program Nr: 2191 from the 1999 ASHG Annual Meeting

Experience of Support Persons Participating in Presymptomatic Genetic Testing Protocols for Huntington Disease. *D.L. Schutte[1], J.K. Williams[1], P.A. Holkup[1], C. Evers[2,3], A. Muilenburg[3]*. 1) College of Nursing, The University of Iowa, Iowa City, IA; 2) Iowa Regional Genetics Consultation Service, Iowa City, IA; 3) Department of Pediatrics, The University of Iowa, Iowa City, IA.

The identification of genes associated with adult-onset conditions, such as Huntington disease (HD), enables presymptomatic genetic testing for at-risk healthy individuals. Genetic testing protocols for HD, including pre- and post-testing genetic counseling visits, were developed to integrate this new technology into clinical practice. Most presymptomatic genetic testing protocols for HD recommend that a support person accompany the individual seeking testing throughout the genetic counseling and testing process. While the experiences of persons undergoing presymptomatic genetic testing are described in the literature, little is known about the experiences of the support person. The purpose of this cross-sectional descriptive pilot study is to describe the experiences of support persons participating in presymptomatic HD genetic testing protocols. Semi-structured interviews and quantitative measures of emotional distress were analyzed for 18 subjects. Content analysis of transcribed interviews revealed that support persons cited the importance of being there for the person undergoing testing and reported a variety of strategies to provide support. Despite recognizing the importance of the role, most support persons had not formally prepared for the experience and suggested the need for peer counseling and anticipatory guidance as a means of doing so. Several services were endorsed as potentially helpful either during or following the testing process, including spiritual support, additional counseling, support groups, and financial counseling. Psychological measures indicate worry and distress related to the genetic testing event similar to at-risk persons undergoing presymptomatic genetic testing. Results from this pilot study suggest potential strategies for refinement of existing presymptomatic genetic testing protocols in order to enhance the experience for the persons seeking genetic testing as well as their support persons.

Program Nr: 2192 from the 1999 ASHG Annual Meeting

Family history of breast cancer as a risk factor for breast cancer in Arab women in Israel. *T. Shohat[1], M. Aghassi-Ippen[1], M.S. Green[1], M. Shohat[2]*. 1) ICDC, Israel Center for Disease , Tel-Hashomer, Israel; 2) Genetic Institute,Rabin medical center, Petach tikva , Israel.

While the incidence rate of breast cancer in Jewish women in Israel was 82.3 per 100,000 in 1993, the incidence in Arab women living in Israel was 22.4. One of the possible explanations for this difference is that previously described risk factors for breast cancer do not play a major role in the Arab population. Family history of breast cancer is one of the major risk factors known for this disease. 10-15% of women with breast cancer have a mother and/or a sister with breast cancer. The aim of the study was to investigate the association between family history and breast cancer in Arab women in Israel. 72 women diagnosed with breast cancer aged 30-70 and 140 controls without breast cancer or any other cancer in the same age group were studied. The cases were identified through oncology wards and the controls were recruited from Kupat-Holim and hospital clinics. All study participants were interviewed by a questionnaire which included questions regarding family history of cancers and details on other known risk factors. Eight women with breast cancer and 5 women without breast cancer had a first degree relative with breast cancer. The odds ratio for breast cancer for a woman with a first degree relative with breast cancer was 3.4, (P = 0.04). No association was found between other variables studied (age of menarche, number of births etc.) and breast cancer. The risk for breast cancer for first degree family members of Arab patients with breast cancer is in the same magnitude of the risk that was found for family members in the Jewish population around the world.

Program Nr: 2193 from the 1999 ASHG Annual Meeting

Knowledge and attitudes of Hispanic women and their health care providers about breast cancer risk factors and screening. *M.N. Strecker[1], A.J. Tucker[1], M.L. Bondy[2], D.A. Johnston[3], H. Northrup[1]*. 1) Department of Pediatrics, The University of Texas Houston Medical School, Houston, TX; 2) Department of Epidemiology, The University of Texas M.D. Anderson Cancer Center, Houston, TX; 3) Department of Biomathematics, The University of Texas M.D. Anderson Cancer Center, Houston, TX.

Medically underserved women, specifically those individuals who lack medical insurance, are of lower socioeconomic status, and have less education, frequently face significant barriers to obtaining appropriate breast cancer screening. In order to address the needs of an underserved population, we designed and implemented educational programs for the lay public and for health care providers about breast cancer risk factors, screening guidelines, and implications of hereditary predisposition to breast cancer.

Our specific aims were to assess the knowledge and attitudes of medically underserved Hispanic women in the greater Houston area and their health care providers about breast cancer, and to compare patients' and health care providers' perceptions of barriers to breast cancer screening. To quantify these measures, we administered a brief questionnaire both prior to and following the educational seminars.

Prior to the seminar, health care providers were moderately knowledgeable about breast cancer risk factors and screening recommendations, but were confused about the implications of hereditary predisposition. Patients, on the other hand, had little knowledge of breast cancer risk factors, screening guidelines or hereditary predisposition to breast cancer. Following the educational seminar, both health care providers and patients showed significant improvement in knowledge, however, the concept of risk remained difficult for both groups.

Given the enthusiasm with which the seminar was received, as well as the formidable improvements in knowledge made by the participants, we propose suggestions for modification of the program for the purpose of continued implementation.

Program Nr: 2194 from the 1999 ASHG Annual Meeting

Breakpoints are clustered on chromsome 2 [p11q13] resulting in pericentric inversion. *R.S. Verma[1,2,3], S.M. Kleyman[1], D.A. Rosa[4], S.K. Barrett[2,4], G.S. Kupchik[2,4].* 1) Institute of Biology and Genetics at InterScience, Brooklyn, N.Y; 2) SUNY Health Science Center at Brooklyn, N.Y; 3) Wyckoff Heights Medical Center, Brooklyn/New York Hospital-Weill Medical College of Cornell University, New York, N.Y; 4) Maimonides Medical Center, Brooklyn, N.Y.

Except increased frequencies of reproductive wastage among carriers of a pericentric inversion of chromosome 2, no apparent risk to liveborns have been reported. In most cases the breakpoints on chromosome 2 have been clustered within bands 2p11 and 2q13. However, in a few cases the breakpoints have been noted on p12, p13, p14, p15, p21, p23, p24, p25 and q11, q12, q14, q21, q23 and q36. With a few exceptions, if the breakpoint is in the short arm in band 2p11, the band on the long arm involved was 2q13. A couple was referred for cytogenetic evaluation because they have had 2 ELAB, 1 SPAB plus one prior ELAB with a different partner, while the fourth pregnancy was terminated because of abnormal cytogenetic findings [48,XXX,+18] in amniocytes. The fifth pregnancy again, resulted in fetal loss. Cytogenetic findings with G-banding revealed an abnormal karyotype, 46,XY,inv(2)(p11q13) in the husband's peripheral blood while the wife has a very low level of mosaicism for the X-chromosome i.e. 46,XX[49]/47,XXX[1]. This fortuitous finding of low level mosaicism can not be correlated with double trisomy but increased risk of aneuploidy needs to be mentioned. There is a 10% risk of multiple congential anomalies/mental retardation to the infant if the origin of such inversions are *de novo* but no apparent risk has been cited for inherited cases. Earlier cases with pericentric inversion of chromosome 2 are being reviewed and the counseling aspects discussed.

Program Nr: 2195 from the 1999 ASHG Annual Meeting

Segregation analysis of inattention and hyperactivity-impulsivity. *B.S. Maher[1,2], M.M. Vanyukov[1,3,5], M.L. Marazita[1,2,3,4].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Cleft-Palate Craniofacial Center, School of Dental Medicine, Univ. of Pittsburgh, Pittsburgh, PA; 3) Center for Education and Drug Abuse Research, Univ. of Pittsburgh, Pittsburgh, PA; 4) Department of Oral and Maxillofacial Surgery, School of Dental Medicine, Univ. of Pittsburgh, Pittsburgh, PA; 5) Department of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA.

Segregation analysis was performed on 602 nuclear families in an attempt to estimate the role of genetic and other influences in determining the variability of inattention and hyperactivity-impulsivity(H-I), the behavioral dimensions underlying Attention Deficit Hyperactivity Disorder (ADHD). Families for our study were ascertained as part of a larger study of substance abuse (SA) risk. Factor analysis of the 14 DSM-III-R ADHD symptoms revealed two distinct factors. Items loading on the first factor consisted of the six inattention symptoms. The second factor contained the eight hyperactivity and impulsivity symptoms. Two phenotypes for each individual were determined by summing the items loading on each factor. Segregation analysis was performed separately for inattention and H-I dimensions in the complete data set and the high (309 nuclear families) and average (293 nuclear families) SA risk subgroups. Class D regressive models with covariate effects (SES) and sex dependent means were tested. Segregation analysis of the inattention factor supported a sex-dependent Mendelian codominant model in the complete data set ($p=0.7473$) and in each of the subgroups(high risk: $p=0.2557$; average risk: $p=0.6865$), while other models could be rejected. Segregation analysis of the H-I factor supported a transmissible but non-Mendelian major effect in the complete data set and in each of the SA risk subgroups. Thus, this study demonstrates Mendelian transmission of DSM-III-R defined inattention symptom count and non-Mendelian transmission of hyperactivity-impulsivity in a general population. Overall,our results support the presence of a two distinct endophenotypes (inattention and hyperactivity/impulsivity) underlying the liability to Attention Deficit Hyperactivity Disorder.

Program Nr: 2196 from the 1999 ASHG Annual Meeting

Latitudinal Trends Among Native North American Groups: Examination of Mitochondrial DNA Diversity. *R.S. Malhi[1], B.A. Schultz[1], J.A. Eshleman[1], J. Peterson[1], J.G. Lorenz[2], D.G. Smith[1]*. 1) Dept Anthropology, Univ California, Davis, Davis, CA; 2) National Institues of Health, NIAAA/DICBR/LNG.

Native North American groups display a non-random distribution of haplogroup frequencies across regional and linguistic boundaries. We analyzed the mitochondrial DNA (mtDNA) haplogroup frequency distribution and the mtDNA Control Region (CR) diversity among and within Siouan, Iroquoian, and Algonquian language groups that span from the Rocky Mountains to the Eastern Seaboard. The homogeneity of haplogroup frequency distributions among linguistically related Native American groups located in different geographic regions suggests that ancestral groups are similar in haplogroup frequency distribution to descendant groups. This is consistent with increasing evidence, from studies of ancient mtDNA, that genetic drift has not led to significant stochastic changes in frequencies that would obscure ancestor/descendant relationships. Analysis of mtDNA CR sequences also reveals trans-continental trends among these Native American groups. These trends, along with linguistic and archaeological data, suggests significant movement and tribalization of Native American groups in North American prehistory.

Program Nr: 2197 from the 1999 ASHG Annual Meeting

The unstable mutations on the mitochondrial haplogroup T background. *B. Malyarchuk, M. Derenko.* Genetics Lab, Biological Probl of the North, Magadan, Russia.

The utility of mtDNA markers for study of prehistoric female migrations from one geographic region to another requires the plausible classification for mitochondrial variations. The classification system based on cladistic notation for mtDNA hypervariable segments sequences and RFLPs is developed for West Eurasian mtDNAs and provides motifs, or signature mutations, which are diagnostic for mtDNA haplogroups (Richards et al., 1998). However, the problem of homoplasy at nucleotide sites in mtDNA, especially in the hypervariable segment-1 (HVS-1), remains actual. Haplogroup T with motif 16126C-16294T is one of the most frequent among Europeans. It has been shown that this haplogroup includes the only well-resolved subgroup T1, but other HVS-1 sequences cannot be classified in subgroups due to the possible homoplasy at sites in positions 16292, 16296, and 16304, leading to the reticulations in the topology of phylogenetic networks. To study the problem of molecular instability at these nucleotide positions, we have performed an analysis of published data sets and our unpublished data on mtDNA HVS-1 sequences in Eastern Slavonic sample. After haplogroup T HVS-1 sequences were combined, 172 individual mtDNA sequences were obtained. As a principal analytical approach, a search for a rear mutations, associated with different combinations of nucleotides 16292T, 16296T and 16304C within the haplogroup T sequences and specific to certain ethnic group or the group of closely related by descent populations, was performed. The analysis revealed ten marker mutations, each of them is characteristic for certain group of linguistically or geographically close individuals - for the Adygei, Germans, Kazakhs, and linguistic isolates of the eastern Italian Alps. The occurrence of these marker mutations in association with various combinations of mutations at positions 16292, 16296 and 16304 gives the evidence of molecular instability at positions 16292 and 16296 on the haplogroup T background, at least. The data received allow us to conclude that the identical haplogroup T sequence types might have arisen independently in different ethnic groups.

Program Nr: 2198 from the 1999 ASHG Annual Meeting

Comparison of the Type I error rate of model-dependent linkage analysis for quantitative traits under random ascertainment. *D.M. Mandal[1], A.F. Wilson[2], A.J.M. Sorant[2], B.J.B. Keats[1], J.E. Bailey-Wilson[2].* 1) LSU Medical Center, New Orleans, LA; 2) National Human Genome Research Institute, NIH, Baltimore, MD.

The Type I error rate for model-dependent lod-score linkage analysis may be increased when marker allele frequencies are misspecified and ascertainment is through the trait. When ascertainment is random, as is often the case in linkage studies of quantitative traits, lod-score methods are expected to be robust. However, when parental marker data are missing, lod-score linkage analysis of a trait with a single-locus heritability of 90% is not robust to misspecified marker allele frequencies, even in large random samples of sib-pairs. In the present study, the Type I error rate of the lod-score linkage method was determined for additional traits in the absence of parental data and with misspecification of marker allele frequencies.

G.A.S.P. was used to generate a highly polymorphic marker locus with varying marker allele frequencies and two quantitative traits unlinked to the marker: one 50% due to an additive major locus with two equifrequent alleles and the other one due completely to environmental effect. LODLINK was used to test for linkage in each of 10,000 replicates of 300 families with sibship size two. When the trait was completely environmentally determined, the Type I error rate of the lod-score linkage analysis was found to be robust to misspecification of marker allele frequencies, even if the allele frequencies were severely misspecified (±0.8 of true frequencies). However, for the trait with heritability of 50%, the Type I error rate was sometimes as much as 21 times the nominal significance level of 0.001 when the allele frequency of a common allele in a five-allele polymorphic marker was misspecified in the analysis as rare. In general, the Type I error rates for the trait with a heritability of 90% were the highest among the three traits studied. Thus, when the parental genotype data are missing, the model-based lod-score test of linkage is robust with respect to Type I error for environmentally determined traits but not for the traits which are largely genetically determined.

Program Nr: 2199 from the 1999 ASHG Annual Meeting

The human twinning gene is not syntenic with the sheep twinning gene (FecB) on human chromosome 4. *N.G. Martin[1], D.L. Duffy[1], J. Hall[2], C. Mayne[1], S. Healey[1], J. Brown[3], G.W. Montgomery[1,3], D.I. Boomsma[4].* 1) Queensland Inst Medical Res, Brisbane, QLD, Australia; 2) AxyS Pharmaceuticals Inc, La Jolla, CA; 3) Univeristy of Otago, Dunedin, New Zealand; 4) Vrije Universiteit, Amsterdam, Netherlands.

The tendency to dizygotic twinning is inherited in both humans and sheep. The fecundity gene in Booroola Merino sheep, FecB, has been mapped to sheep chromosome 6 syntenic with human 4q21-25. Our aim was to see whether a gene predisposing to human DZ twinning can be mapped syntenic with FecB. DNA was collected from 169 pairs and 17 sets of 3 sisters (trios) from Australia and NZ who had each had spontaneous DZ twins, mostly before the age of 35, and from a replication sample of 111 families (92 affected sister pairs) from the Netherlands. Exclusion mapping was carried out after typing 26 markers on chromosome 4, of which 9 spanned the 4q21-25 region. We used nonparametric affected sib pair methods for linkage analysis (ASPEX 2.2). Complete exclusion of linkage (lod < -2) of a gene conferring relative risk as low as 1.5 (lambda(S) >1.5) was obtained for all but the p terminus region on chromosome 4. Exclusion in the syntenic region was stronger, down to lambda(S)=1.3. We conclude that if there is a gene influencing DZ twinning on chromosome 4, its effect must be minor. We are currently completing a genome scan and have several regions showing linkage with lods of 2.3, 1.3 and 1.2 which we are pursuing.

Program Nr: 2200 from the 1999 ASHG Annual Meeting

Nucleotide diversity levels at the human alpha-fetoprotein gene AFP1. *J.J. Martinson[1], R.E. Ferrell[2].* 1) Dept Biologicial Anthropology, Oxford University, Oxford, England; 2) Dept Human Genetics, University of Pittsburgh, Pittsburgh PA 15261.

The development of automated sequencing technologies has greatly facilitated the generation of large amounts of sequence data in human populations. Here we report initial data from a survey of sequence variation at the AFP1 gene complex, located on chromosome 4. This gene was chosen for analysis as it is known to be highly variable between primate species, but little is known about its intraspecific variation within humans. The gene product has many functions, but these are poorly understood.

The AFP gene occupies 27kb of DNA and contains several repeat elements in addition to the 2kb of coding sequence that encodes the mature protein. These include Alu, L1, STR and some novel repeat elements. In a sample of 96 unrelated individuals, none of these, with the exception of the STR loci, were found to be polymorphic for repeat number polymorphism. We have begun a study on sequence variation at this gene, and have generated data from 34 unrelated individuals for a region encompassing exon 4 and its flanking introns, which contain a Kpn element and an Alu repeat. To date, over 67kb of sequence data have been generated. Each individual was sequenced in both directions to confirm the polymorphisms seen.

The levels of sequence diversity seen here are comparable with results obtained from studies on other loci. In the 2kb region studied, 15 segregating sites were seen, of which 8 were singletons. No insertion/deletion polymorphisms were observed. Nucleotide diversity levels p were 0.047% for the Kpn repeat region, 0.058% for exon 04, and 0.091% for the Alu repeat region. This preliminary survey would suggest that the Kpn element is not associated with elevated levels of flanking sequence variation, but that diversity is higher in the region around the Alu repeat.

Program Nr: 2201 from the 1999 ASHG Annual Meeting

DYNAMICS OF MOLECULAR GENETIC DIVERSITY IN THE EAST MIDLANDS, ENGLAND. *S.S. Mastana, D.R. Lee.* Dept Human Sci, Human Gen Lab, Loughborough Univ, Loughborough, England.

The main objectives of this investigation were 1) to establish the database of minisatellites (VNTRs), AMP-FLPs, microsatellites (STRs), and ALU Insertion allele frequencies for the regionally sub-divided populations of the East Midlands, which is suitable for population genetic and forensic investigation, 2) to determine if Caucasian sub-population heterogeneity exits within the United Kingdom, within Europe and World Caucasian and racial populations at these loci and 3), whether settlement patterns of various continental European populations have left any detectable genetic imprints in the East Midlands populations. Blood samples (500) were collected at random from the Caucasian East Midlands populations (5 sub-populations, Northwest Derbyshire, Northeast Derbyshire, South Derbyshire, Leicestershire and Nottinghamshire). Using standard molecular genetic techniques, we analysed MS1, MS31, YNH24, MS43a VNTRs and HUMTHO1, F13A, F13B, FES, LPL, VWA31 and CSF1PO STRs. Alu insertion polymorphisms studied included, ACE, TPA, PV92, APO and FXIIIB and three AMP-FLPs were D1S80, APO-B, and YNZ22. Overall significant differences were observed at many different loci. While overall pattern of allelic distribution was within the ranges observed for Caucasian populations, there were significant inter-population/regional differences for a number of loci. As expected the heterozygosity levels for DNA loci were much higher than conventional blood groups. The F_{ST}/G_{ST} values were also higher for DNA loci (average 0.018) compared to blood groups and serum proteins (0.005). The implications of observed genetic diversity in urban contemporary populations are evaluated in the light of settlement patterns of continental European populations. The Caucasian population heterogenetity and its implications for disease mapping, forensic and paternity investigations are presented to evaluate the effectiveness of these markers.

Program Nr: 2202 from the 1999 ASHG Annual Meeting

A net avoidance of close consanguinity on Tangier Island, Virginia. *R.A. Mathias[1], C.A. Bickel[1], A. Shahani[2], T.H. Beaty[1], K.C. Barnes[1].* 1) Johns Hopkins University, Baltimore, MD; 2) George Washington University, Washington, DC.

In small isolated populations mates tend to be less related than two individuals picked at random due to social proscriptions against close consanguinity; thus, a heterozygote excess resulting from avoidance of incestuous mating can be expected. We assessed the presence and magnitude of this heterozygote excess on Tangier Island, Virginia using genealogic data dating back to 1722. With a present population of ~650 permanent residents, we have observed low levels of average inbreeding (F=0.006) in the present generation, which peaked at F=0.01 in 1850 and 1900. To test for heterozygote excess, observed inbreeding was compared to expected inbreeding over 25-year intervals from 1800-1998. At each time point the population was divided into a parent generation and an offspring generation. Observed inbreeding was computed by averaging the inbreeding coefficients for all offspring. Expected inbreeding was computed by averaging kinship coeffieients for (a) all male-female pairs; (b) non-sib male-female pairs; and (c) first-cousin and closer male-female pairs exlcuded in the parent generation. All expected levels of inbreeding exceeded observed levels in the offspring generation between 1.19-11.89 fold. The greatest differences were in the earlier birth cohorts where the parental generation tended to be small and the avoidance of close consanguinity most prominent. We also examined a coefficient d to measure the deviation from random mating. This d, which represents a correlation between uniting gametes relative to the population's genotypic structure, tends to be negative when there is an avoidance of mating of close relatives. Values of d were computed for all three types of parental pairs, and were found to be negative at all time points (-0.001 to -0.027), with earlier cohorts having the lowest values. While recognizing that several factors influence the genotypic structure of a population, we speculate that the decreasing trends in heterozygote excess observed in this extended kindred is a reflection of an increase in mate choices accompanied by a breakdown in isolation and a shift towards exogamy.

Program Nr: 2203 from the 1999 ASHG Annual Meeting

Age-related differences in heterozygote frequencies of mutations commonly found in the Ashkenazi Jewish population. *L.D. McCurdy[1], B. Breuer[2], L. Lebow[2], J. Bernstein[1], R.J. Desnick[1], C.M. Eng[1].* 1) Mount Sinai School of Medicine, New York, NY; 2) The Jewish Home and Hospital, New York, NY.

The Ashkenazi Jewish population is at increased risk for several autosomal recessive conditions. In addition, common mutations in the BRCA1, BRCA2, and APC genes have been identified. Carrier frequencies for these mutations have been determined mainly from Ashkenazi Jewish individuals of reproductive age. In an effort to discern if age-related differences in carrier frequencies exist for any of these mutations, an elderly cohort of 714 Ashkenazi Jewish individuals (avg age 80 yrs;572 females/142 males) was assayed for the following: N370S(GD), delATCTGA/insTAGATTC (BLM), I1307K(APC), 185delAG, 5382insC, and 6174delT (BRCA1&2).

mutation	observed	expected
N370S	31 (4.3%)	37 (5.2%)
delATCTGA/insTAGATTC	4 (0.6%)	6.4 (0.9%)
I1307K	41 (5.7%)	43 (6%)
185delAG,5382insC,6174delT	3 (0.4%)	15 (2%)

Observed rates for the Gaucher disease (GD), Bloom syndrome (BLM), and APC mutations was not significantly different from expected. However, among 142 males no N370S heterozygotes were observed while seven were expected (p=0.014). No difference in I1307K carriers was observed, suggesting that heterozygotes for this variant are not at increased risk. In contrast, female heterozygotes for the BRCA1 and BRCA2 mutations was significantly less than expected (p=0.012). These results indicate that female BRCA1 and BRCA2 carriers are underrepresented in our elderly Ashkenazi Jewish population, suggesting that these mutations may have a relatively higher age-related risk.

Program Nr: 2204 from the 1999 ASHG Annual Meeting

Comparison of several methods to calculate sample size for TDT genome scans. *R.E. McGinnis.* Dept. of Human Genetics, SmithKline Beecham, Harlow, England.

Recently, Tu and Whittemore (AJHG 64:641, 1999) and Knapp (AJHG 64:1777, 1999) presented equations for calculating number (N) of affected sib pair families required for genome scans with the TDT. Both methods avoid simplifying assumptions such as independence of allele transmissions from mother and father to affected offspring in order to calculate precise sample sizes; but the required algebraic formulations are very complex. Like these authors, I also calculated N needed for 80% power to detect linkage with a 500,000 marker TDT scan, but used the following equation for two methods that retain simplifying assumptions: $N=(Z_{a/2}-YZ_{1-b})/[(H/F)(4P_t-2)^2]$. Here Y equals $[1-(H/F)(2P_t-1)^2]^{1/2}$ for method 1 (a generalization of the approach of Risch and Merikangas [Science 273:1516, 1996]) while Y equals $2[P_t(1-P_t)]^{1/2}$ for method 2 (described by McGinnis in Ann Hum Genet 62:159, 1998). For both methods, expressions for P_t and H/F are given in McGinnis (1998) where P_t is the probability of marker allele transmission from a heterozygous parent to an affected child and H/F is the probability that an ascertained parent is heterozygous. Results for methods 1 and 2 were compared with the methods of Knapp and of Tu and Whittmore for the 48 disease models listed in Table 4 of Knapp (1999). For each pairwise comparison between two methods, the table below shows the mean percent difference in N for the 48 models ±StdDev, and the largest percent difference observed (in parenthesis). These comparisons indicate that sample sizes calculated by the four methods do not differ substantially.

	Tu & Whittemore	Method 1	Method 2
Knapp	4.1%±4.0% (16%)	0.7%±0.7% (3%)	1.0%±0.9% (3%)
Tu & Whittemore	---	3.7%±3.8% (16%)	4.8%±4.7% (17%)
Method 1	---	---	1.2%±1.4% (5%)

.

Program Nr: 2205 from the 1999 ASHG Annual Meeting

Towards strategies to assess genetic risk of complex disorders in a multi-ethnic community: ACE polymorphism and diastolic blood pressure in pregnancy. *I.Y. Millwood, E.C. Winchester, M.A. Penny, L. Rand, O.J. Fletcher, A.M. Kessling.* Medical and Community Genetics, Imperial College School of Medicine, London, UK.

Morbidity and mortality from complex genetic disorders may be reduced if genetic screening programs can identify susceptible individuals before disease development. Genetic risk factors are likely to vary between population groups and screening programs would need to cater for the different genetic backgrounds present within communities. In working towards screening tests for polygenic disease risk, we investigated the effects of three genetic variants on diastolic blood pressure variability in a local sample of healthy pregnant women (n=1311) from different genetic backgrounds. The sample included two main population groups, women of UK and Irish origin (n=537), and those with ancestors from the Indian subcontinent (India, Sri Lanka, Pakistan, Bangladesh) (n=391). Individuals were genotyped for known polymorphic variants of the ACE, AGT and AGTR1 genes, which have been previously associated with hypertension. Allele frequencies in UK+Irish and Indian subcontinent groups respectively were ACE I/D 0.45/0.55 and 0.57/0.43, AGT T174M 0.90/0.10 and 0.88/0.12, and AGTR1 A1166C 0.71/0.29 and 0.93/0.07. There were significant differences in genotype distribution between the UK+Irish and Indian subcontinent groups for the ACE I/D and AGTR1 A1166C variants ($p<0.001$), but not for AGT T174M. ACE genotype had a small but consistent influence on basal diastolic blood pressure in all population groups of our sample, the ACE D allele coinciding consistently with increased blood pressure. AGT and AGTR1 genotype did not influence blood pressure consistently across population groups. Our data show that combining samples from different populations may mask population specific effects. Future tests for polygenic disease risk must combine information from multiple genes and take into account population diversity.

Program Nr: 2206 from the 1999 ASHG Annual Meeting

Differences in nutritional pattern between mothers of children with cleft lip and palate and mothers on non-affected children. *J. Mir[1], T. Mosby[1], S. Tolarova[2], L. Pastor[3], A. Goldberg[4], M. Pastor[3], A. Capozzi[5], M. Tolarova[1].*
1) Program for Prevention of Cleft Lip and Palate/Craniofacial Anomalies, UCSF, San Francisco, CA; 2) Veteran's Hospital, University of Minneapolis,MN; 3) University of Cuyo, Mendoza, Argentina; 4) Marin General Hospital, San Rafael, CA; 5) Shreiners Hospital, Sacramento, CA.

Orofacial clefts(OFC)are common and serious birth defects with a prevalence of 1.8/1,000 births.The majority of OFC are caused by interaction of genetic and environmental factors. However,the specific nature of this interaction remains poorly understood.Mother's diet and life style during the embryonic period seems to contribute significantly to environmental factors.There is no doubt that folic acid(FA)plays a key role in etiology of NTD,and very probably in OFC and other dysraphic anomalies.However,still many questions remain.In OFC specifically,the question of the dose of folic acid that is necessary to reduce recurrence and the dose needed for prevention of occurrences still needs to be answered.Our present case-control study is based on an analysis of a sample of 111 mothers of children with OFC and 73 mothers of nonaffected children from Cumana,Venezuela.A personal interview including detailed demographic data,information about living conditions,size and socio-economic status,pregnancy and labor history,mother's and father's medical history, etc.,was conducted with each mother.Cases and controls came from rural areas and belong to a low socio-economic category.Most interesting results were seen when evaluation of consumption of vegetables and fruit was carried out.OFC mothers did consumed practically no fresh vegetables.Only 1.9% of case mothers reported consumption of fresh vegetables one or more times per day. The majority consumed cooked vegetables (74.29% of case mothers vs.32.95%control mothers).Also consumption of fresh fruit in the group of case mothers was minimal.We can conclude that OFC mothers very likely did not have enough FA from the diet during their pregnancies and this could contribute to development OFC. This study was initiated by the Program for Cleft Prevention UCSF and supported by Rotaplast Intl., Inc.

Program Nr: 2207 from the 1999 ASHG Annual Meeting

Genetic association using affected siblings: application to inflammatory bowel disease (IBD) and the HLA-DRB1*0103 gene. *L. Mirea[1], S.B. Bull[1], M.S. Silverberg[2], A.H. Steinhart[2], R.S. McLeod[2], A. Griffiths[4], G.R. Greenberg[2], Z. Cohen[2], J.A. Wade[3], K.A. Siminovitch[1,2]*. 1) Samuel Lunenfeld Research Institute, University of Toronto, Toronto, ON, Canada; 2) Mount Sinai Hospital, Toronto, ON, Canada; 3) The Toronto Hospital Regional Histocompatibility Laboratory, Toronto, ON, Canada; 4) The Hospital for Sick Children, Toronto, ON, Canada.

Standard methods for genetic association analysis, including population case-control and parental control transmission disequilibrium tests (TDT) may be sensitive to lack of independence amongst cases. Association studies are often conducted using affected sibpair (ASP) family data collected for genome scans with independence achieved by randomly selecting one sibling. This process, however, discards at least half of the available cases. The methodology applied in this study permits the use of affected sibpairs in both case-control and TDT analyses. Association between IBD and HLA DRB1*0103, was tested in 216 healthy controls and 120 IBD ASP families using a logistic regression model and the TDTEX procedures of SAGE. Analyses were first conducted with independent randomly selected cases and then using affected siblings assumed to be independent. A generalized estimating equations (GEE) approach, that provides robust variance estimates, was applied to the logistic regression model to adjust for the correlation among siblings. The SIBS TDTEX option of SAGE was employed to assess preferential allelic transmission to the sibpair as a unit. Both case-control (assumed independent: p=0.0005, adjusted: p=0.0011) and TDT (assumed independent: p=0.00003, adjusted: p=0.0039) analyses of this data set confirm that the risk of DRB1*0103 is estimated more conservatively when a correction for sibling correlation is applied than when naïve analysis assumes siblings are independent. More importantly, the risk estimated using proper correlation adjustments with GEE (independent cases: p=0.0026) and SIBS TDT (independent cases: p=0.01946) provides stronger evidence for association than results obtained from analysis of only independent cases.

Program Nr: 2208 from the 1999 ASHG Annual Meeting

ATM Haplotypes in Hispanic Ataxia-Telangiectasia (A-T) families. *E.M. Mitui[1], S. Castellvi-Bel[2], R. Gatti[1].* 1) Department of Pathology, School of Medicine, UCLA, Los Angeles, California; 2) Servei de Genetica, Hospital Clinic i Provincial, Barcelona, Spain - As well as collaborators from each of the countries cited.

This study investigates the possibility of Hispanic A-T patients from different geographic areas sharing a common haplotype and mutation. Initially, we are characterizing A-T patients from Spain (18), Brazil (10) and Argentina (10), using four polymorphic microsatellite markers (D11S1819, NS22, D11S2179 and D11S1818) in an interval spanning approximately 1.4 centiMorgans, within and flanking the ATM gene. All alleles are compared to a standardized sample (CEPH 1347-2). We present the haplotype results of 38 A-T affected patients from 31 families, 16 families from Spain, 7 families from Brazil and 8 families from Argentina. These haplotypes are being compared to 54 Costa Rican families carrying seven mutations and 17 Hispanic American families. The haplotype analysis described here will be extended by identifying the mutations present on each unique haplotype within each ethnic group. To date, no founder effect haplotype has been convincingly documented between these five Hispanic groups.

Program Nr: 2209 from the 1999 ASHG Annual Meeting

Languages, geography and HLA haplotypes in Native American and Asian populations. *M.V. Monsalve[1,2], A. Helgason[3], D.V. Devine[2]*. 1) Dept of Anthropology and Sociology, Univ of British Columbia, Vancouver, BC, Canada; 2) Dept of Pathology, University of British Columbia, Vanciuver, BC, Canada; 3) Department of Biological Anthropology, University of Oxford, UK.

A number of studies based on linguistic, dental and genetic data have proposed that the Amerindians, Na-Dene and Eskimo-Aluet are the descendants of three waves of migration from Northeast Asia to the New World. Recently other studies have suggested that only one major migration occurred. It is our aim in this study to test these opposing migration hypotheses using molecular typed HLA class II alleles to compare the relationships between linguistic and genetic data in contemporary Native American populations. The second exons of the DRB1, DQB1 and DQA1 were amplified in Salishans belonging to the Amerindian linguistic group from the Soawahlie band in British Columbia, Canada. The detection of the alleles were typed using non-radioactive sequence specific oligonucleotides. Haplotype frequencies were estimated using the maximum likelihood method. DRB1/DQB1/DQA1 haplotype frequencies were obtained from 20 Native American groups and 11 Asian populations. Our results suggest that gene-flow and genetic drift have been important factors in shaping the landscape of the Native American populations. Our results also indicate significant correlations between genetic and geographic distances in Native American and East Asian populations. In contrast, a less clear-cut relationship seems to exist between genetic distances and linguistic affiliation. In particular, the close genetic relationship of the neighboring Na-Dene Athabaskans and Amerindian Salishans suggests that geography may be the more important factor. Overall, our results are most congruent with the single migration model.

Program Nr: 2210 from the 1999 ASHG Annual Meeting

Environmental and nutritional factors in etiology of cleft lip and palate anomalies in Guanajuato, Mexico. *T. Mosby[1], A. Goldberg[2], J. Mir[1], J.A. de la Peña[3], M. Covarrubias[3], M. Chavez[4], J.M. Ventura[4], M. Tolarova[1]*. 1) Program for Prevention of Cleft Lip and Palate/Craniofacial Anomalies, UCSF,San Francisco, CA; 2) Marin General Hospital,San Rafael, CA; 3) Programa Nuevo Amacener, Guanajuato,Mexico; 4) Fundacion Mexicana para la Prevencion de Malformaciones Craneofaciales,Leon, Mexico.

Cleft lip and palate affect 1 in 580 Hispanic newborns.Non-syndromic clefts(NSC)are caused by a combination of genetic and environmental factors; the nutrition represents an important part of the environmental ones.As a part of a large case-control study on gene-environmental interactions in NSC,a pilot baseline nutritional study was carried out in Guanajuato,Mexico.Data were obtained from interviews of 118 mothers of NSC child.The interview instruments consisted of 152 questions from General and Food Frequency Questionnaire.75%of our families came from a low or very low socio-economic class.70% of mothers were housewives;5% had occupational exposure to toxic chemicals.A base of the Food Pyramid consisted in all familes of tortillas and beans.Raw vegetables were eaten sporadically (51%)or not at all (23%),but 65% of mothers consumed meat 1-3 times per week.Among our mothers,alcohol,drugs and tobacco use were rare;diabetes and obesity were high.A low level of red cell folate(21 mothers,199.14±15.5 nM/L)was found.Normal range of plasma folate and vitamin B12(32 mothers,24 patients,21 controls)were found(a meal was provided in the hospital!).This pilot study showed that the mothers"nutrition was very inadequate, especially consumption of raw vegetables and fresh fruit was very low.Thus,nutritional factors could contribute to the causes of NSC in the Guanajuato state.Public measures such as fortification of staple food with essential nutrients, recommendation of life style and cooking changes and a broad educational campaign based on present knowledge could also help to decrease the risk for clefting,if implemented. This study was initiated by the Prg.for Prev.of Cleft Lip and Palate/Craniofac.Anom.,UCSF,USA; funded by the Government of Guanajuato,Mexico, supported by Programa Nuevo Amanecero,and Fundac.Mex.para la Prev.de Malf.Craneofac.A.C.

Program Nr: 2211 from the 1999 ASHG Annual Meeting

Sample size requirements for detecting a genotype associated with an adverse drug reaction. *M. Mosteller.* Clinical Genetics Division, Glaxo Wellcome Research & Development, Research Triangle Park, NC.

Each year, hundreds of thousands of patients suffer adverse drug reactions (ADRs). These ADRs can exact a personal toll ranging from simple discomfort to significant injury or even death. The economic impact of treatments, hospitalizations, and lost productivity only add to the importance of finding ways to reduce the occurrence of ADRs. One strategy toward this end is to identify drug-specific patient genotypes that are correlated with the occurrence of ADRs. Such genotypes could be used to ensure that a given drug is prescribed only for individuals with a low risk of experiencing an ADR. A first step in this pharmacogenetic strategy is to determine the number of clinical trial subjects that would be required to demonstrate a statistical association between a genotype and an ADR. Computer simulation was used to investigate this issue under a variety of hypothetical conditions. Given an ADR whose expression is influenced by a single genetic locus, the impact of the following parameters on sample size was explored: prevalence of the ADR, allele frequencies at the causative locus, genotypic penetrance, mode of inheritance, phenocopy rate, degree of linkage disequilibrium with a marker locus, statistical significance level, and desired statistical power. Under conditions that can be considered plausible, the number of subjects required was estimated to be in the hundreds rather than in the thousands. In practice, the number of subjects needed could be arbitrarily large due to low penetrance, high phenocopy rate, or low level of linkage disequilibrium between the causative and marker loci. This work indicates that the search for a patient genotype that is predictive of an ADR may require less than 100 subjects or well over 500. Progress in this area will likely require combining information gathered across several clinical trials and, until tools and technologies emerge that will support genome-wide association studies based on high density maps, will be highly dependent on the selection of appropriate candidate genes and markers.

Program Nr: 2212 from the 1999 ASHG Annual Meeting

Methylenetetrahydrofolate reductase C677T gene mutation, embryo-maternal genotypes interaction, maternal periconceptional folic acid intake and neural tube defects in the Mexican population. *O.M. Mutchinick, M.A. Lopez, L. Luna, J. Waxman, V. Babinsky, RYVEMCE Collaborative Group.* Dept of Genetics, Inst Nac de Nutricion Salvador Zubiran, Mexico,D.F., E-mail: osvaldo@servidor.unam.mx.

Neural tube defects (NTD) and the C677T MTHFR gene mutation have a very high prevalence in the Mexican population, nearly 3 to 4 times higher than in other ethnically related groups. According to our own data (RYVEMCE), 4/1000 births have a NTD, 34.8% of normal individuals are homozygous for the mutation, and Mexican embryos have a higher a priori risk (OR 5.8%) of being carriers of the thermolabile variant (48th ASHG Meeting, A302). This genetic condition is considered a risk factor for anencephaly and spina bifida.The above prompted us to develop a multicentric study to investigate the prevalence of the expected CC, CT and TT genotypes in a sample of 171 cases of NTD, 171 matched controls and their respective mothers. Periconceptional maternal folic acid (FA) and other vitamins intake was estimated using a food frequency questionnaire validated for our population. DNA studies of the 682 blood samples obtained were performed as previously described (48th ASHG Meeting, A302). Our results showed a significantly higher prevalence of the TT genotype in NTD cases (35.7%) than in controls (23.4%), OR:1.81 (1.1-3.0), p: 0.018, with an attributable fraction (AF) for the homozygote TT of 16.03 %. No statistical differences were observed between mothers. The analysis of embryo-maternal genotypes (TT/TT) interaction between cases (25.9%) and controls (15.3%), also showed significant statistical differences, OR: 1.93 (1.1-3.5), p: 0.02, with an AF of 12.5% for that genotypic array. FA daily intake by the mothers of cases was lower than that of control mothers. This difference was even higher when mothers of TT cases (median 168.8ug), were compared with mothers of TT controls (median 235.5ug). These results strongly suggest that a considerable proportion of the very high prevalence of NTD in our population can be explained by the high prevalence of the homozygote for the MTHFR C677T mutation and the associated low maternal folic acid intake during the periconceptional period.(CONACYT, grant # MP0936-96).

Program Nr: 2213 from the 1999 ASHG Annual Meeting

Estimation of the Frequency of Genetic Deafness in Mongolia with a Genotype Index. *W.E. Nance[1], R. Erdenetungalag[2], J. Radnaabazar[2], B. Dangaasuren[3], J. Batsuuri[4], S.H. Blanton[1], W.H. Carter[1], A. Pandya[1].* 1) Dept Human Genetics, Medical Col Virginia, Richmond, VA; 2) MCH Research Center; 3) School of the Deaf; 4) Center for Anthropology, Ulaanbaatar, Mongolia.

Estimates of the genetic component of deafness are based on the recognition of syndromic forms and the assumption that multiplex non-syndromic families are also genetic. Extrapolating from the distribution of affected individuals in multiplex non-syndromic families, the proportion of simplex families that are chance isolated genetic cases can be estimated by segregation analysis. However, it is difficult to appropriately allow for heterogeneity in the penetrance and mode of inheritance for the multiple genes for deafness that are now known to exist. The recognition that mutations at some loci including Connexin 26 and mitochondrial forms of deafness have a high prevalence in many populations suggests that a comparison of frequency of these entities in multiplex and simplex families could be used as an index to estimate the overall frequency of genetic deafness using the formula:

where M and (N-M) are the overall numbers of multiplex and simplex probands and I_s & I_m the number positive for the index trait (s) among n tested mulitplex and simplex probands respectively. To test this approach, we studied 533 school aged deaf Mongolian probands including 12 with recognized forms of syndromic deafness. This sample, along with the deaf relatives of affected probands is estimated to include approximately 70% of the school aged deaf population of Mongolia. The non-syndromic probands included 112 multiplex and 409 simplex families. Twenty of the multiplex and 15 of the simplex probands carried mutations at the mt 1555 site or the mt 7445 restriction site respectively. The overall incidence of mitochondrial deafness in the 533 probands was 6.5%. The estimated proportion of genetic cases among the non- syndromic probands was 37.6 ± 5.8% with an overall estimated frequency of genetic deafness of 39.0%.

Program Nr: 2214 from the 1999 ASHG Annual Meeting

Prevalence of Factor V R506Q in the newborn population of Northwest Louisiana. *D. Napper, K. Yanamandra, D.W. Jalanivich III, T.F. Thurmon, H. Chen, M. Susla, M. Jeroudi.* Dept Pediatrics, Louisiana State Univ Med Ctr, Shreveport, LA.

The Clinical Molecular Genetics Laboratory at LSU Medical School in Shreveport, Louisiana, has been studying the genetics of Activated Protein C resistance (APCR) by assaying mutant Factor V arg506gln.

The mechanism of thrombophilia especially APCR causing venous thrombosis was not known until recently. In 1993, Dahlback *et. al.,* for the first time uncovered that the APCR to be almost exclusively inherited and possibly by autosomal dominant trait. In 1994, Bertina *et. al.,* discovered the cause of APCR to be a mutation in the Factor V gene, a purine transistion G to A at nucleotide position 1691, resulting in mutant Factor V arg506gln called Factor V Leiden (FVL). This R506Q change in the Factor V protein confers resistance to the proteolytic action of APC resulting in unregulated clotting process and makes carriers and homozygotes of FVL lifelong susceptible to risk of 10-fold in heterozygotes and 80-fold in homozygotes to venous thrombosis. Over 90% of familial and over 20% of sporadic thrombophilia are caused by FVL.

Earlier population studies revealed a wide range in the carrier frequency of FVL, from 15% in Greeks to 5-10% in other Europeans, and 0% in Africans and Asians. However, recent American literature revealed about 5% incidence of FVL in white-Americans and 1-3% in African-Americans. The disparity in the frequencies was probably due to the smaller sample size selected or due to the geographic differences. The frequency of FVL in Louisiana is unknown. Thus, the goal of the present investigation was to establish the prevalence of FVL in Louisiana using a larger population study so that meaningful frequency data were obtained in the two races. Data and statistics, methodology used and the break down of gene frequency in different races of Louisiana will be presented.

Program Nr: 2215 from the 1999 ASHG Annual Meeting

Comparing Linkage Disequilibrium Strength Within and Between Population and Genomic Regions. *S.K. Nath[1], M. Blumenfeld[2], I. Chumakov[2], L. Bougeleret[2], A. Cohen[2], L. Essioux[2], D. Cohen[2], N.J. Schork[1,2,3,4].* 1) Epidemiology and Biostatistics, CWRU, Cleveland, OH; 2) Genset, Paris, France; 3) Porgram for Population Gentics, Harvard University, Boston, MA; 4) The Jackson Laboratory, Bar Harbor, ME.

With the emergence of high-density genetic maps of the human genome (as well as other species genomes) has come the need to assess the behavior of alleles at the polymorphic sites constituting the maps. Linkage disequilibrium (LD) is one important population genetic phenomenon that needs to be assessed empirically if the utility of genetic maps for population-based studies is to be put into perspective. We have developed a number of methodologies and study designs for testing and comparing the strength of LD among a set of linked markers within and across different populations and different genomic regions. We showcase the use of these methods by applying them to single nucleotide polymorphism data collected on a large number of individuals at a number of chromosomal regions. We discuss the implications of our results as well as items that need to be considered in any study attempting to qualify LD behavior.

Program Nr: 2216 from the 1999 ASHG Annual Meeting

Association Study of the B3-adrenergic receptor polymorphism with risk factors for colon cancer. *D.H. Nguyen[1], R.C. Bada[1], C.L. Bird[1], R.W. Haile[1], H.D. Frankl[2], E.R. Lee[3], S.A. Ingles[1]*. 1) Preventive Medicine, USC/Norris Cancer Center, Los Angeles, CA; 2) Division of Gastroenterology, Sunset Kaiser Permanente Medical Center, Los Angeles, CA; 3) Division of Gastroenterology, Bellflower Kaiser Permanente Medical Center, Los Angeles, CA.

The B3-adrenergic receptor (B3-ADR) is expressed in visceral adipose tissue in humans, which functions as a lipid oxidizer, regulator of thermogenesis, and regulator of resting metabolic rate. Studies have identified the B3-ADR polymorphism as a factor in obesity in different ethnic cohorts. Our hypothesis is that carriers of the B3-Andrenergic Receptor polymorphism may have an increased BMI (body-mass index), insulin levels, triglyceride levels, and an increased likelihood for polyp development (a precursor to colon cancer). The subjects include a case group of 562 subjects with polyps, and a control of 529 subjects without polyps. All subjects were 50+ years of age and underwent sigmoidoscopies. 52% were Caucasians, 17% African American, 18% Hispanic, and 12% Asian. Current results, from BstNI enzyme genotyping of 353 subjects indicate that 18% of the subjects carry at least one variant allele. Carriers had significantly higher levels of triglycerides (median = 169) compared to non-carriers (median = 140, P = 0.01). C-peptide levels were also higher among males who carry a variant allele (median = 2.9) compared to male non-carriers (median = 2.4, P = 0.02). C-peptide levels did not differ by genotype among females. Possible explanations for these results will be discussed.

Program Nr: 2217 from the 1999 ASHG Annual Meeting

The power and robustness of microsatellite-based tests of population expansion. *G.D.C. Nicholson.* Department of Statistics, University of Oxford, Oxford, U.K.

A number of recent investigations have used hypothesis tests based on variation at microsatellite loci to infer human demographic histories. In any such investigation, robustness of the relevant tests to deviations from the genetic assumptions must be ascertained. Furthermore, knowledge of the power of the tests is extremely useful, not only at the planning stage, but also when interpretating the results. The tests described in this study are based on the following statistics: the *F*-statistic, introduced by Di Rienzo *et al.* (Genetics, 148, 1998), the imbalance index, introduced by Kimmel *et al.* (Genetics, 148, 1998), and the *k*- and *g*-statistics, introduced by Reich and Goldstein (PNAS, 95, 1998). Under the stepwise mutation model, *g* is the reciprocal of *F*; hence the tests based on these two statistics have identical properties. With the intention of providing insights into the power and robustness of each of the three distinct tests, coalescent simulations are conducted for a wide range of demographic, genetic and sampling parameter values. The results of the analysis may be grouped into four sections: (i) A broad comparison of the power of each of the tests under the stepwise mutation model and under the assumption of a constant mutation rate across loci (stepwise growth is also assumed). (ii) An assessment of the robustness of the tests to the introduction of non-stepwise mutation models. (iii) An assessment of the effects of introducing mutation rate variability across loci. (iv) A description of two methods for estimating the power of the *F*-test (i.e. without resorting to simulation). The first method is based on the observation that, in a certain limiting region of parameter space, the power may be be expressed as a function of two parameters: the number of loci sampled and the time since expansion (in units of the initial population size). The second method is based on *G* (defined as the ratio of the expected values of the numerator and denominator of *F* under the stepwise growth scenario). Large values of *G* correspond to large values of the power of the *F*-test. Critical values of *G* are calculated such that if $G > G_{crit}$, then the power > 0.90.

Program Nr: 2218 from the 1999 ASHG Annual Meeting

The probability of identity by descent for unrelated similar haplotypes. *I.M. Nolte, G.J. te Meerman.* Medical Genetics, University of Groningen, the Netherlands.

In our department a new method is developed for mapping genes contributing to complex diseases. This method is based on the length of a genomic region that pairs of haplotypes share. The idea behind it is that patients do not only share more often a disease allele but moreover that they share longer segments surrounding the disease allele. This latter hypothesis arises from the fact that it is likely that patients have a more recent common ancestor for the alleles on the disease locus than controls. Therefore less recombination events have shortened the region shared on either side of the disease locus. We believe that this method is suitable for fine-mapping genes to a region of less than 50 kb. By comparing haplotypes that are with appreciable probability identical by descent we try to detect a small haplotype that is present in most of the patients and that is absent in most of the controls. In order to show that this kind of mapping is possible we demonstrate that on the basis of evolutionary principles statistical support for an interval of 10 kb or less is possible if sufficient marker data are available. We derived a formula for the probability of identity by descent of unrelated similar haplotypes extending over multiple markers. Random mating is assumed and the population is subject to selection, mutation and recombination. We also assume that the population has grown from generation to generation using a discrete generation model. With the formula derived the effects of the population size at the last generation, the number of similar haplotypes in the sample, the sample fraction, the recombination fraction, the mutation rate, the selection coefficient, the growth rate of the population of haplotypes and the allele frequencies per locus on the IBD-probability are studied.

Program Nr: 2219 from the 1999 ASHG Annual Meeting

The spectrum of pathogenic mutations and mtDNA haplogroups among Danish lineages manifesting Leber hereditary optic neuropathy. *S. Nørby[1], J. Saillard[1], P. Magalhães[2], M. Schwartz[2], T. Rosenberg[3]*. 1) Institute of Forensic Medicine, University of Copenhagen, Denmark Copenhagen, Denmark; 2) Laboratory of Molecular Genetics, Rigshospitalet, Copenhagen, Denmark; 3) National Eye Clinic for the Visually Impaired, Hellerup, Denmark.

Twenty-nine Danish lineages manifesting Leber hereditary optic neuropathy (LHON) have been analyzed for their pathogenic mitochondrial DNA (mtDNA) mutation as well as sequenced in both hypervariable segments, HVS I and II, of the mtDNA control region. Twenty-five lineages (86%) were found to have the ND4/11778 transition, two (7%) the ND1/3460 transition, and one (3.5%) the ND6/14484 transition. In one lineage the pathogenic mutation has not been identified. Based on HVS I sequences, and information about position 73 in HVS II, twenty different haplotypes were identified which could be allocated to haplogroups H, U, K, T, and J in a phylogenetic network. In contrast to most other studies on LHON in Caucasians we found the same low frequency (12%) of haplogroup J among Danish 11778 LHON lineages as in our controls. In twenty-three of the twenty-five11778 lineages we obtained information about the polymorphism at position 11719: twelve lineages, belonging tohaplogroups U, K, T and J, had the variant 11719A, whereas the remaining eleven, all haplogroup H, had the 11719G of the reference sequence indicating that A is the ancestral nucleotide.

Program Nr: 2220 from the 1999 ASHG Annual Meeting

Use of disease heterogeneity to search for genes of a multifactorial disease, rheumatoid arthritis. *M. Pascanu*[1, 2]. 1) for ECRAF, the European Consortium on Rheumatoid Arthritis Families; 2) Pole Genetique / LREPA, Universite Paris 7, Paris, France.

Rheumatoid arthritis (RA), the most frequent autoimmune disease with a prevalence of 1% in adults, is clinically and genetically heterogeneous. About 4/5 of patients develop an agressive disease with joint erosions on X-ray examination. HLA-DRB1 alleles associated with the disease are present in 3/4 patients. A genome scan in 90 caucasian RA sib-pair (ASP) families revealed 26 candidate susceptibility loci (linkage $p<0.05$) outside of the HLA locus. The aim of this paper was to take into account the disease heterogeneity in the analysis.

Affected sib-pair analysis was performed on the publicly available genome scan data (www.genethon.fr) with the ANALYZE package in sub-groups of families defined by 1) disease with joint erosions (n=61) and 2) concordance at the HLA locus : HLA-concordant (n=32)(RA sibs with identical genotypes) or -discordant ASP (other families). New candidate loci were defined by markers with linkage evidence $p<0.05$.

Erosive RA genome scan analysis showed 18 candidate loci (4 new). We observed 22 loci (7 new) in HLA-concordant ASP and 10 loci (2 new) in HLA-discordant ASP. Interestingly, they were significantly more loci observed in HLA conc. than disc. ASP ($p<0.05$), suggesting that HLA factors interact with other susceptibility genes. Out of the 12 new candidate loci, one was common to the erosive and HLA conc. groups, suggesting a gene interacting with HLA factors in predisposing to agressive disease. Out of the 26 known candidate loci, 5 more such loci showed similar suggestion and 6 loci were found both for erosive and HLA-disc. groups, suggesting genes involved in agressive disease independently from HLA factors.

In conclusion, taking into account clinical and genetic heterogeneity results in the identification of new candidate loci and provides clues for the search of the underlying susceptibility genes.

.

Program Nr: 2221 from the 1999 ASHG Annual Meeting

Extraction of DNA from Buccal Swabs Using Various Protocols. *H.M. Patterson, S. Knapp, C.B. Sutcliffe, J.L. Haines.* Program in Human Genetics, Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN.

Buccal swabs are useful as a less invasive alternative to blood collection for obtaining cells for DNA extraction. Therefore, it is of critical importance to both diagnostic and research laboratories that a technique for DNA extraction from buccal swabs be developed that is robust and reliable in the hands of multiple users. The goals of this project were to determine the optimal buccal swab extraction kit protocol based on the stability of the DNA over the course of one year and our ability to extract DNA from buccal swabs stored for over one year.

DNA extraction kits from various manufacturers were tested along with the laboratory standard boiling procedure. Twenty-five individuals submitted two buccal swabs each, one for immediate extraction with one of the five protocols and the other stored at 4°C for processing one year from the date of the original extraction. Five buccal swabs were extracted with each of the kits using the manufacturers recommended protocol, as well as the standard boiling procedure. Following extraction, the DNA was quantitated using PicoGreen™ (Molecular Probes) and stored at 4°C. The DNA from each individual's buccal swab was amplified and run out on an acrylamide gel once every month with the exception of the samples from the Purgene™ (Gentra) kit and the standard procedure, which did not yield the expected bands at the onset of the experiment and were therefore excluded from further analysis. The first PCR was done less than one month from the date of the original extraction using D4S2377 primers. Subsequent PCRs were carried out using Cy-3 labeled Amelogenin primers. The samples from the Qiagen™, Promega™ and Epicentre™ kits continued to present the expected bands with all consecutive PCRs. By evaluating each gel, it was determined that the Qiagen™ kit produced the most desirable results of the five protocols tested. The PCR on the year-old buccal swabs was performed successfully using this kit in conjunction with the Amelogenin primers.

Program Nr: 2222 from the 1999 ASHG Annual Meeting

Consanguinity rate in Sultanate of Oman. *M.A. Patton[1], A. Rajab[2].* 1) Medical Genetics, St Georges Hospital, London, UK; 2) Genetics Department, Royal Hospital, Muscat, Oman.

The Sultanate of Oman is located in the north east corner of the Arabian peninsula. It has a population of 1.5 million and has now a comprehensive healthcare system. Like many countries in the Middle East there has been a cultural tradition of consanguineous marriages, but the degree of consanguinity had not been delineated. A questionnaire based study was therefore carried out on 60,635 couples attending antenatal clinics. This represented 20% of the population of child bearing age. It was found that 24.1% of marriages were between first cousins and 11.8% between second cousins. A further 20.4% of marriages were between members of the same tribe and because of the strictly endogamous nature of tribal marriages these were also consanguineous to some degree. The coefficient of inbreeding was calculated as 0.0198.

Program Nr: 2223 from the 1999 ASHG Annual Meeting

HSP70-1 promoter polymorphisms in AD sibships-NIMH Genetics Initiative AD Study Group. *R.T. Perry, J.S. Collins, L.E. Harrell, R.C.P. Go.* Epidemiology, Univ Alabama-Birmingham, Birmingham, AL.

As part of the NIMH Genetics Initiative AD Study Group, we recently reported evidence of linkage to 6p21.3 in 266 AD families with two or more affected siblings. One candidate gene that is located in this area is the heat shock protein, HSP70-1. Heat shock proteins are a family of evolutionarily-conserved proteins that help stabilize proteins and their structure, preventing aggregation, especially during periods of cell stress. Aberrrant proteolytic processing of the APP is implicated in AD pathology and the APP promoter contains a stress response element which responds to stress. Hsp70 proteins are also associated with NFTs in AD and the microtubule-associated protein tau co-immunoprecipitates with hsp70. In addition, a novel HSP70 mRNA has been reported to be expressed in patients with major depression, but not in normal subjects. We have genotyped a polymorphism located at +190 (G®C) of the 5 UT region of HSP70-1 in a set of 406 affected and unaffected siblings from 125 families. Non-parametric analyses was performed by the S.A.G.E. SIBPAL program. The allele frequencies were b1=0.64 and b2=0.36 and the genotype frequencies were found to be in Hardy-Weinberg equilibrium. Using SIBPAL, no significant increase in allele sharing was found in the affected siblings (p=0.19). A sibling association test using unaffected siblings as controls, SIBASSOC (Curtis D., 1997), found no significant association with any allele at this locus (single-allele association test, p=0.59). However, we are genotyping an additional 179 siblings and will analyze these data using a sibship disequilibrium test. We are also typing a second polymorphism located in the promoter region and the two polymorphisms will be analyzed as a haplotype to increase their informativeness.

Program Nr: 2224 from the 1999 ASHG Annual Meeting

Segregation analysis of phenotypic subtypes of dyslexia. *D. Peterson[1], E. Wijsman[1], K. Goddard[2], L. Hsu[3], V. Berninger[1], W. Raskind[1]*. 1) Dept. Biostatistics, University of Washington, Seattle, WA; 2) Case Western Reserve University, Cleveland, OH; 3) Fred Hutchinson Cancer Research Center, Seattle, WA.

There is evidence for a genetic contribution to reading disability (RD), or dyslexia. Many phenotypic measures are used to diagnose RD. Most are continuous, and can be grouped into phonological, orthographic, and rapid automatized naming measures. Within each of these there are multiple measures that are used by different researchers. Etiologic and phenotypic heterogeneity are complications in genetic analysis, and it would therefore be useful to determine whether component phenotypes provide evidence for major gene inheritance.

We are studying the genetic basis of 24 widely used phenotypic components of RD in 102 nuclear families ascertained through a proband with RD. Based on earlier family aggregation studies, we identified 5 phenotypes that warranted more extensive modeling of the mode of inheritance: word attack (WA), digit span (DS), WRAT-3 spelling (WS), nonword memory (NM), and pseudoword reading efficiency (PR). For each, we have carried out complex segregation analyses using two approaches. The first is a Monte Carlo Markov chain (MCMC) analysis, which estimates both the number of underlying trait loci (QTL) and their effects. The second is the regressive model approach to segregation analysis. NM and DS provided the strongest evidence for major gene effects; WA provided no evidence for major gene effects; PR and WS provided modest evidence for major gene effects. For NM, the MCMC analysis estimated a posterior probability of >98% as >1 QTL, with an estimate of 1-3 such QTL. For digit span, the posterior probability of >1 QTL was >88%, with an estimate of 1-3 QTL. For NM, complex segregation analysis suggested a Mendelian model with homozygous means separated by 3.2 sds, and a heterozygote .8 sd from the higher mean. Age, sex and verbal IQ were all significant covariates. For DS, the best model was a dominant mode of inheritance with homozygous means separated by 1 sd. Age and verbal IQ were significant covariates. These results pave the way for gene mapping with these phenotypes.

Program Nr: 2225 from the 1999 ASHG Annual Meeting

A new statistical approach to identify non-pathogenic mutations. Analysis of CFTR gene mutations in a random population. *P.F. Pignatti[1], C. Bombieri[1], S. Giorgi[2], S. Carles[3], R. De Cid[4], F. Belpinati[1], C. Tandoi[2], N. Pallares-Ruiz[3], C. Lazaro[4], B.M. Ciminelli[2], M.C. Romey[3], T. Casals[4], F. Pompei[2], G. Gandini[5], M. Claustres[3], X. Estivill[4], G. Modiano[2]*. 1) Section of Biology and Genetics, DMIBG, Univ. Verona, Italy; 2) E.Calef - Dpt. of Biol., Univ. Roma - Tor Vergata, Italy; 3) Inst. Biology, Univ. Montpellier, France; 4) Medical and Mol. Genet. Center, Hospital Duran i Reynals, Barcelona, Spain; 5) Blood Center, Verona Hospital, Italy.

It may be difficult to determine the role of a not obviously pathogenic mutation in causing disease. We here propose a conceptually straightforward method to identify non-pathogenic mutations. Given q as the global frequency of all the alleles causing a disease, any allele with a frequency certainly higher than q minus the cumulative frequency of the already known disease causing mutations cannot be the cause of that disease. This principle was applied to the analysis of CF mutations: in the CFTR gene more than 800 different mutations have been described. The analysis does not exclude the possibility that, in some individuals, particular combinations of alleles not causing CF may cause attenuated or atypical phenotypes. A total of 191 DNA samples (sufficient to pick up essentially all mutations with a frequency of at least 0.01) from random individuals from Italy, France, and Spain, were investigated by DGGE analysis of all the coding and proximal non coding regions of the gene. A total of 43 mutations was detected. Three mutations (DF508, N1303K, G85E) were known to be CF-causing. Four were new mutations: 1341+28C/T, 2082C/T, L1096R, and I1131V. Ten mutations (125G/C, 875+40A/G, TTGAn, IVS8-6polyT,1525-61A/G, M470V, 2694T/G, 3061-65C/A, 4002A/G, 4521G/A) were classified as non CF-causing alleles on the basis of their frequency. The remaining ones have a cumulative frequency far exceeding q, therefore most of them cannot be CF-causing mutations, but the actual frequency data do not allow their classification. An analysis on a larger sample will clarify their role.

Program Nr: 2226 from the 1999 ASHG Annual Meeting

The San Antonio Family Study of Diabetic Nephropathy in Mexican Americans. . *R. Plaetke[1], P. Pergola[1], S. Eaton[1], R. Duggirala[2], N. Arar[1], C. Diaz[1], M. Stern[2], H. Abboud[1].* 1) Division of Nephrology; 2) Division of Epidemiology; University of Texas Health Science Center at San Antonio, San Antonio, TX.

Diabetic nephropathy (DN) is the most common cause of end-stage renal disease (ESRD). The prevalence of DN is 5-10% in Caucasians with type 2 diabetes (T2DM), but 30-40% in Mexican Americans. In addition, Mexican Americans have a prevalence of T2DM 3 times higher than Caucasians. Studies show that DN can cluster in families and has a genetic component. Little is known about the genetics of DN in Mexican Americans. Therefore, we established a family ascertainment center at the UTHSCSA to enroll families with a clustering of DN in a gene search study using variance components analysis (VCA). To date, we have ascertained 17 pedigrees consisting of ~465 individuals (total of 128 T2DM cases and 39 DN cases) through probands with ESRD secondary to T2DM; 4 additional pedigrees are being identified. On average, each pedigree has 7.5 individuals with T2DM (range: 2-19) and 2.3 cases with DN (range: 1-7). The average age of T2DM onset is 41.2 years (range: 17-61), and of DN onset is 53.8 years (range: 39-64). Phenotyping of family members for T2DM and DN will be established by interviews and urine and blood analyses (fasting serum glucose, serum creatinine, daily protein/albumin urinary excretion). Data from all 21 ascertained families will be presented for (1) ages at onset of T2DM/DN and years elapsed between diagnoses of both diseases, (2) ethnic backgrounds (besides Mexican American), (3) clustering of the two diseases in the pedigrees, and (4) results of the ongoing phenotyping for T2DM and DN. Preliminary power estimates for VCA, using data from 50 extended families with similar pedigree structures to the original 17 families, show that we will have sufficient power to detect DN genes. Research is funded by the San Antonio Area Foundation.

.

Program Nr: 2227 from the 1999 ASHG Annual Meeting

Inference on relationships by IBS allele sharing: the mean number of loci per individual needed to discriminate full sibs from non-relatives in a sequential test. *S. Presciuttini[1,2], L. Casarino[3], S. Verdiani[3], A. Mannucci[3], L. Peirano[3], F. De Stefano[3], J.E. Bailey-Wilson[2].* 1) Dept. Uomo e Ambiente, Univ. Pisa (I); 2) NIH/NHGRI, Baltimore, MD; 3) Ist. Medicina Legale, Univ. Genoa (I).

We studied the discrimination between pairs of full sibs and pairs of unrelated individuals based on the total number of alleles identical by state at a number of loci (Y). The analysis was based on a sample of assumed sib pairs, the donors and their sibling recipients of bone marrow transplantation, typed at 13 markers. We obtained the distributions of Y in: 1) these pairs of siblings; 2) a simulation of 10,000 sib pairs using the allele frequencies estimated from the sample; 3) a sample of unrelated individuals generated by selecting one sib per pair. We also chose a marker with heterozygosity intermediate between those used in the real analyses, and computed the exact probabilities of observing a given Y for both sib pairs and non-relative pairs, for each number of markers (M) from 2 to 50. The accordance between the observed distribution of Y among sib pairs and that expected on the basis of the simulation was satisfactory. The accordance between the distribution among both non-relatives and simulated sib pairs and the exact distributions was also excellent. We then explored the discrimination power of a sequential test based on a first set of ten markers and the addition of five further markers at each step, after removing the pairs that were already discriminated. Two null hypotheses were considered: i) that a given pair was assumed to be non-relatives (and we wanted to obtain the probability that these two subjects were full sibs), and ii) that a given pair was assumed to be full sibs (and we wanted to obtain the probability that these individuals were unrelated). The discrimination of full sibs from unrelated individuals with $P<0.001$ was reached with an average number of 16.4 markers typed per individuals, at a power of 0.997. Similarly, the discrimination of unrelated individuals from full sibs was reached with an average of 15.8 markers per individual. The same power would have been reached by a non-sequential test with 40 markers per individual in both cases.

Program Nr: 2228 from the 1999 ASHG Annual Meeting

Y-CHROMOSOMAL DNA VARIATION IN PAKISTAN. *R. Qamar[1,2], Q. Ayub[1,2], A. Mohyuddin[1,2], T. Zerjal[2], S.Q. Mehdi[1], C. Tyler-Smith[2]*. 1) Biomedical & Gen. Engg. Labs, Islamabad, Pakistan; 2) Dept. Biochemistry, University of Oxford, Oxford, UK.

Pakistan lies on the path of the postulated early migration route out of Africa, but little is known about the origins of its current populations. Of particular interest are the Burusho who speak Burushaski, one of the world's remaining language isolates. The Kalash Kafirs are allegedly descendants of soldiers who accompanied Alexander the Great. The Baltis are considered to be of Tibetan origin, while the Hazara are Mongoloid and probably of Tatar descent. Populations in southern Pakistan of interest are the Balochi (Aleppo origin), the Makrani (Negroid) and the Parsis who are recent immigrants from Uzbekistan/Iran.

We are using Y-chromosomal DNA variation to investigate the genetic history and relationships of these populations. More than 750 males from 13 populations have been analysed with 16 biallelic markers: YAP, SRY -8299, sY81, Apt, 12f2, RPS4Y 711, M9, M20, LINE-1, SRY +465, LLY22g/HindIII, Tat, 92R7, SRY -2627, SRY -1532 and M17. These markers identify 16 haplogroups in worldwide populations, 10 of which were found in Pakistan. North-east to south-west geographical gradients of haplogroup distribution are seen, but there is no obvious correlation with language; despite speaking an isolated language, the Burusho Y-chromosomal haplogroup distribution resembles those of surrounding populations. Ten existing and several novel Y microsatellites are also being scored to investigate variation within the haplogroups.

Program Nr: 2229 from the 1999 ASHG Annual Meeting

Polymorphism of fibrinogen genotypes of three ethnic groups in multiracial Singapore. *S.C. Quek[1], C.K Heng[1], S. Hong[1], N. Saha[2], P.S Low[1]*. 1) Department of Pediatrics, National Univ Singapore, Singapore, Singapore; 2) Department of Human genetics, Graduate School of Public Health, University of Pittsburgh.

Plasma fibrinogen is reportedly associated with a higher risk of coronary artery disease (CAD) in epidemiological studies. Racial variation and difference between sexes have also been described. We investigated newborn cord blood levels of fibrinogen in term babies of three ethnic groups (namely, Chinese, Malays and Indians) in Singapore, as well as five polymorphisms (*Hind*III, *Ava*II, *Bcl*I, *Taq*I, *Rsa*I sites) on the fibrinogen gene. No significant difference was detected among fibrinogen levels between the two sexes nor was there any interracial difference. The rare allele frequencies of the various polymorphisms are presented below. The genotype frequencies examined were in accordance with a population at Hardy-Weinberg equilibrium. Using the *Z*-test, significant differences ($P<0.05$) were noted between the allelic frequencies between all three groups for all the sites. Unlike in the adults, there was no statistical difference in cord fibrinogen levels between all the genotypes.

	*Ava*II	TaqI	*Rsa*I	*Hind*III	*BclI*
	G^{+1689} (*n*)	*T2* (*n*)	*R2* (*n*)	T^{-148} (*n*)	*B2* (*n*)
Chinese	0.243 (382)	0.436 (399)	0.421 (341)	0.229 (166)	0.244 (293)
Malays	0.298 (282)	0.333 (290)	0.300 (255)	0.313 (131)	0.307 (210)
Indians	0.116 (202)	0.264 (191)	0.262 (183)	0.128 (133)	0.113 (181)

Program Nr: 2230 from the 1999 ASHG Annual Meeting

A general approach to family based association tests. *D. Rabinowitz.* FaDepartment of Statistics, Columbia University, New York, NY.

A general approach to family based association tests is presented. The approach involves comparing test statistics to their conditional distribution given the minimal sufficient statistics under the null hypothesis for admixture, ascertainment and the genetic model. The approach results in valid type I error rates, therefore, regardless of admixture, ascertainment and the genetic model. There is no restriction on the test statistics, so the approach may be applied with quantitative traits, traits with variable age-at-onset, and dichotomous traits; it may be applied with multiple tightly linked loci and with multiple unlinked loci, and with bi-allelic or multi-allelic loci; environmental and genetic covariates and a substantive knowledge may be incorporated into analyses; and information from multi-generational pedigrees may be combined. When examining association in order to detect linkage, the minimal sufficient statistics are the observed traits in pedigree members and the genotypes of the pedigree founders; when testing for association in the presence of linkage, the minimal sufficient statistics also encompass identity-by-descent relationships; when examining multiple closely linked markers, the minimal sufficient statistics also encompass phase. If pedigree founder genotypes, identity-by-descent relationships or phase are not available, the minimal sufficient statistic is obtained by treating the missing data as the parameter and computing the corresponding minimal sufficient statistic. The approach may therefore be applied with incomplete marker genotypes and arbitrary pedigree structures. Score statistics from regression models for the influence of genotypes and covariates on traits are natural choices of test statistics. Normalization by the conditional expectations and variances given the minimal sufficient statistics results in likelihood based statistics from the conditional likelihood. P-values may therefore be computed by comparing the normalized statistics to central chi-square distributions. Normalization is efficiently implemented by table-lookup of conditional means and covariances of genotype indicators. Joint work with Qiong Yang, Nan Laird, Steve Horvath and Xin Xu.

Program Nr: 2231 from the 1999 ASHG Annual Meeting

Is there an insulin resistance locus on chromosome 1: Evidence from Mexican American hypertension families with direct assessment of insulin sensitivity. *L.J. Raffel[1], R.C. Davis[2], J.I. Rotter[1], W.A. Hsueh[2], A. Xiang[3], S.P. Azen[3], H.N. Hodis[3], J.-Y. Lu[1], J. Diaz[3], E. Toscano[3], L. Castellani[2], K. Krass[2], P.-Z. Wen[2], B. Juarez[2], M. Quinones[2], S. Tan[3], T.A. Buchanan[3]*. 1) Cedars- Sinai Medical Ctr; 2) Univ of California; 3) Univ of Southern California, Los Angeles, CA.

In an ongoing genetic study of Mexican American families ascertained via a proband with hypertension, a 10 cM genome scan is underway testing for chromosomal regions which demonstrate linkage to quantitative traits associated with hypertension, atherosclerosis and insulin resistance. To date, 168 markers have been genotyped (44% of the genome scan) and analyzed using SIBPAL in 390 individuals from 77 families. An important feature of this study is direct measurement of insulin sensitivity by steady state glucose infusion rate (GINF) during a hyperinsulinemic euglycemic clamp. Linkage analysis suggests that there may be a locus important in insulin resistance on chromosome 1. As shown in the Table, there is evidence for linkage of D1S2141 and D1S549 to fasting and 2-hour OGTT insulin and GINF. Of interest, GINF gives the best evidence for linkage, suggesting that direct trait assessment provides more analytic power. It also appears that insulin resistance at this locus contributes to the broader metabolic syndrome, as indicated by the fasting triglycerides data.

Marker	cM	Fast. Insulin	2-Hr. Insulin	GINF	Triglycerides
D1S2141	233		.01	.01	
D1S549	240	.03	.03	.0003	.02

Although a genome scan in the Pima found evidence linking fasting insulin and glucose to chromosome 1q, our region is separate and more distal. Further investigation of this region, including multipoint analysis, is underway to better localize the region of maximal linkage.

Program Nr: 2232 from the 1999 ASHG Annual Meeting

High incidence of Propionyl-CoA-Carboxylase in Greenland due to a founder mutation, 1540insCCC, in PCCB.

K. Ravn[1], M. Chloupkova[2], E. Christensen[1], N.J. Brandt[1], H. Simonsen[3], I.M. Nielsen[1], F. Skovby[1], J. Kraus[2], M. Schwartz[1]. 1) Clinical Genetics, Rigshospitalet, Copenhagen, Denmark; 2) 2Department of Pediatrics, University of Colorado School of Medicine, Denver, USA; 3) Department of Clinical Biochemistry, Statens Serum Institute, Copenhagen, Denmark.

Propionyl-CoA carboxylase (PCC) is a mitochondrial, biotin-dependent enzyme involved in the catabolism of branched chain amino acids, odd chain fatty acids, and other metabolites. PCC consists of two subunits, alpha and beta, encoded by the PCCA and PCCB genes, respectively. Inherited deficiency of PCC due to mutations in either gene results in propionic acidemia (PA), a severe autosomal recessive disease. The disease is clinically heterogenous, often presenting as a lethal neonatal form. Milder forms with a later onset have also been identified. The disease is considered to be very rare with an incidence < 100.000. Due to an observed apparently high frequency of this disorder in the Greenlandic population, we have analyzed RT-PCR products of the beta-subunit mRNA obtained from cultured fibroblasts from Greenlandic patients, in order to characterized the mutation(s) responsible for PA. SSCP analysis followed by sequencing identified a novel mutation,1540insCCC. This mutation was found in homozygous form in three patients and in heterozygous form in one patient. Due to the observed high frequency of PA in Greenland, we have screened 310 anonymous individual for 1540insCCC. We found a carrier frequency of 6per cent, which is much higher than in any other population studied so far. Haplotype analysis using a closely linked marker suggested a common founder of 1540insCCC. Thes observation will have implications for genetic couselling of the involved families.

Program Nr: 2233 from the 1999 ASHG Annual Meeting

Cladistic Diplotype: A novel method for organizing genotype data for statistical analysis. *H. Razzaghi, C.E. Aston, M.I. Kamboh.* Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Haplotype-based cladistic analysis is a powerful tool to assess genotype-phenotype association. However, several factors limit the wide use of haplotype cladistic analysis in population-based samples. Primary among these is the difficulty in determining multi-locus haplotypes. Subjects with genotypes of indeterminate phase provide no haplotype information and are consequently excluded from the analysis. This limitation becomes increasingly significant as more loci are incorporated in the cladogram. Another limitation is ambiguity in the construction of the cladogram. The structure of a cladogram can vary depending on the perceived evolutionary history among the constructed haplotypes, which can be connected to each other in many ways. We have developed a similar, yet novel algorithm to overcome these limitations. We denote an individual's genotype at multiple variable sites regardless of haplotype assignment as a "diplotype". Genotype data are unambiguously organized into diplotypes by simple cross-classification. Two simple criteria are used to construct a cladogram from diplotypes: gradient distribution and sequential relationship among the diplotypes. Attaching diplotypic phenotype means to the resultant cladogram provides a flow diagram which shows the effect on phenotypic variation of simple mutational changes against a known genetic background. In comparison, univariate (single variable site) multiple regression analysis shows the effect of a simple mutational change against an averaged background which may confound the effects of the mutation amidst, for example, gene interactions. We used this cladistic diplotype approach to examine the effects of six variable sites in the lipoprotein lipase gene on variation in plasma quantitative traits related to homeostasis of lipids, glucose, and insulin. We found several significant associations using cladistic diplotypes which otherwise were nonsignificant in the univariate multiple regression analyses.

Program Nr: 2234 from the 1999 ASHG Annual Meeting

Panorama of Alu insertion polymorphisms in Indian populations. *P.H Reddy[1], M.K. Das[2], K. Das[2], P.A. Reddy[1], N. Malik[3], M.P. Sachdeva[4], S.S. Mastana[5].* 1) NHGRI, NIH, Bethesda, MD; 2) Anthropometry and Human Genetics Unit, ISI, Calcutta, India; 3) Anthropology Department, Ravi Shankar University, Raipur, India; 4) Anthropology Department, Delhi University, Delhi, India; 5) Human Sciences Department, Loughborough University, Loughborough, UK.

Highly dimorphic Alu family members in well-defined populations provide a useful tool to population geneticists for understanding the population dynamics that have occurred over time. We report here a study of Six Alu insertion loci from 15 populations (1200 samples) representing North, Central and East Indian caste and tribal groups. Overall spectrum of variation in these populations is very interesting at different geographical and cultural levels. Average levels of heterozygosities were found to be relatively high in these populations. The genetic diversity coefficient G_{ST} among this group of populations was observed to be high (0.088). Phylogenetic trees and principal components analysis (PCA) computed from Alu frequencies provide support for socio-cultural and geographical assignment of these populations in Indian population structure. Results are discussed with reference to population origins and human evolution in India.

Program Nr: 2235 from the 1999 ASHG Annual Meeting

Familial aggregation of nephropathy-associated phenotypes in pedigrees ascertained for type 2 diabetes. *S.S. Rich[1], J.H. Warram[2], A.S. Krolewski[2].* 1) Dept Public Health Sci, Wake Forest Univ Sch Medicine, Winston-Salem, NC; 2) Dept Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA.

Familial aggregation of nephropathy has been demonstrated in both type 1 and type 2 diabetes. Levels of urinary albumin excretion (UAE) define both the diagnosis of diabetic nephropathy and its progression. Obesity and high blood pressure are also risk factors of nephropathy. In 96 pedigrees (2032 subjects), 1269 individuals had urinary albumin creatinine ratio (ACR), a surrogate of urinary albumin excretion. Analysis using the variance components (SOLAR) was used to estimate heritabilities and familial correlations for log(ACR), systolic blood pressure (SBP), diastolic blood pressure (DBP) and maximum ideal body weight (maxIBW).

Analyses revealed that log(ACR) was heritable (h^2=0.26), as was SBP (h^2=0.41), DBP (h^2=0.29) and maxIBW (h^2=0.63). We had previously shown that log(ACR) was genetically correlated with both SBP (rG=0.27); DBP (rG=0.29), with an increase in diabetics (SBP, rG=36; DBP, rG=0.53). In these pedigrees, using a bivariate analysis, strong genetic (rG) and weak environmental (rE) correlations were observed between maxIBW and SBP (rG=0.41, rE=0.02) and between maxIBW and DBP (rG=0.59, rE=0.06). Using only diabetics, heritability estimates remained similar, but genetic correlations were increased for maxIBW and SBP (rG=0.51) and for maxIBW and DBP (rG-0.66).

These results suggest that the primary determinants for nephropathy-associated traits are strongtly influenced by genetic factors. The high genetic correlations suggest that similar genetic factors may be controlling variation for BP and maxIBW, with small contributions to environmental risk factors. The increase in genetic correlation in diabetes suggest that identification of genes contributing to obesity and hypertension may result in the identification of genes for diabetic nephropathy.

Program Nr: 2236 from the 1999 ASHG Annual Meeting

Family structure and parental affectation status influence the mode of inheritance of HLA-linked rheumatoid arthritis (RA). *A.S. Rigby[1], A.J. MacGregor[2].* 1) Sheffield Children's Hosp, Univ Sheffield, Sheffield, England; 2) Twin Research Unit, St Thomas' Hospital, London, England.

Genetic linkage between RA and the HLA region has been shown using parental haplotype sharing in affected sibpairs. Previous studies have not examined whether the inheritance of RA is influenced by the specific structure of the families ascertained. Recent theoretical developments (Thomson, Am J Hum Genet 1995;57:474-486) take into account sampling schemes based on multiplex sib (MS) and multiplex parent sib (MPS) families. Here, we have used published data from multicase RA families to investigate whether the mode of inheritance of HLA-linked RA is influenced by pedigree type or parental affectation status. A literature search identified 191 nonoverlapping RA sibships (166 MS and 25 MPS pedigrees) consisting of 166 sibpairs, 19 sibtrios, 4 sibquads, 1 set of quintuplets and 1 set of sextuplets. Parental HLA haplotypes (A,B,C and DR loci) had been assigned to the RA sibships. In the group as a whole, the RA sibpairs shared 2,1,0 haplotypes in ratio of 0.39:0.43:0.18 which was significantly different from random expectations (0.25:0.5:0.25) ($p<0.01$). This distribution was closer to a recessive ($Chi^2=2.95$, $p=0.09$) than an additive model ($Chi^2=5.65$, $p=0.02$). Subgroup analysis by family type showed differences in terms of mode of inheritance. In MS families there was still an excess of haplotype sharing with an observed distribution of 0.42:0.41:0.17. There was no such difference in MPS families. The MPS families were analyzed further by considering whether the 'share 1' haplotype came from either the affected or unaffected parent. The distribution of share 2, 1 (affected), 1 (unaffected) and 0 haplotypes was 9,10,8,8. Both recessive (expected 8.8,8.8,8.8,8.8) and additive (expected 13.2,11.5,6.0,4.3) models were not rejected. Since most MPS pedigrees consisted of an affected female rather than an affected male parent, the presence of maternal-fetal interactions cannot be ruled out. The results point to heterogeneity in the genetic contribution to RA and indicate that family structure needs to be taken into account in linkage and family-based association studies of disease.

Program Nr: 2237 from the 1999 ASHG Annual Meeting

A Bayesian Hierarchical Model for Allele Frequencies. *K.M Roeder[1], J.R. Lockwood[1], B. Devlin[2].* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Estimates of allele frequencies are required for most linkage studies. For example, founder genotypes must be inferred for analysis of extended pedigrees; likewise, for affected relative pair methods, ibd-sharing must be inferred from allele distributions. When families are drawn from heterogeneous subpopulations, estimating allele and genotype distributions from the total sample could lead to improper inference of linkage. Building on the work of Lange(1995; Genetica 96:107-117) and Roeder et al. (1998; Biometrika 85:269-287), we propose a Bayesian method to estimate the allele distributions for known subpopulations and multiple loci. Given allele counts for a collection of loci and subpopulations, this Bayesian hierarchical model extends existing approaches by allowing for explicit inclusion of prior information about both allele frequencies and inter-population divergence. We describe a methodology for obtaining informative prior distributions for model parameters based on previous research. Using simulated data, we present an application of the model to highlight its features.

Program Nr: 2238 from the 1999 ASHG Annual Meeting

Host genetic determinants of HIV-1 infection in Italy: an epidemiological survey. *V. Romano-Spica[1], A. Ianni[1], D. Arzani[1], M. Orsini[1], L. Cattarini[1], S. Majore[2].* 1) Institute of Hygiene (Dir. Prof. G.C. Vanini) Catholic Univ. Rome Italy; 2) Institute of Medical Genetics, Univ. of Rome "La Sapienza" Rome Italy.

Inherited factors are involved in determining host response to infectious agents. The interaction between host genetic differences and variant viral strains influences HIV-1 infection and disease progression. The protective effect of mutant alleles at chemokine receptor (CCR) loci has important implications for the outcome of HIV-1 infection among exposed individuals, since these receptors are required cellular ports for viral cell entry and spread. Allelic variants of CCR genes have been described. Hypotheses have also been made for dating haplotype origin after recent strong selective events. A 32-bp deletion (CCR5D32) has been shown to confer partial resistance against HIV-1 infection; a point mutation in the CCR2b receptor gene (CCR264I) confers a prolonged AIDS-free survival to carriers. In the present study we evaluated the frequency of CCR5 and CCR2 wild-type and mutant alleles among a representative sample of the Italian population. Genotype frequency was determined after electrophoresis or RFLP analysis of the amplified products. Observed frequencies for CCR5D32 and CCR264I alleles were 0.0454 and 0.0655, respectively. Genotype distribution was in equilibrium as predicted by the Hardy-Weinberg equation. About 21% of the studied population sample was found to be heterozygous either for CCR2 or CCR5 mutated alleles. The observed allelic frequencies were in accordance with estimates reported for Caucasian populations. These results confirmed that CCR5D32 and CCR264I represent two distinct mutations occurred at different times. The dynamic interaction between host genetic determinants, viral heterogeneity and exposure risk factors has been evaluated, analyzing epidemiological data from different countries. The distribution of allelic variants within a population can be considered a measure of genetic susceptibility to HIV infection and disease progression, and a parameter for risk assessment. Studies on hereditary determinants allow a more comprehensive approach to understand the complex interaction between host and infectious agents within a multifactorial perspective.

Program Nr: 2239 from the 1999 ASHG Annual Meeting

Evaluation of a population-based method to identify affected relative pairs with cancer. *P.A. Romitti, R.M. Squire, M.P. Jones, C.F. Lynch.* Dept PMEH, Univ Iowa, Iowa City, IA.

Lung cancer (LCa) and prostate cancer (PCa) are commonly diagnosed neoplasms in the U.S. Previous studies suggest that both LCa and PCa may have genetic and environmental determinants. One approach to evaluate these determinants is to study families with affected relative pairs. Such studies may be most powerful when families are selected from a population where the underlying incidence of cancer is known. To identify population-based families where cancer affects relative pairs, a two-phase approach was used. First, patients with LCa or PCa were ascertained through the Iowa SEER Cancer Registry, and affected first- or second-degree relatives with the same site cancer were identified through review of the patients medical records. Each patient was classified as family history positive (FHP)entry of a relative with the same site cancer, negative (FHN)entry of no relatives with the same site cancer or unknown (FHU)no entry of family history status. Second, all FHP patients were contacted by mail and asked to complete a comprehensive self-administered questionnaire. A random sample of FHN and FHU patients was also contacted to determine the proportion with an affected relative potentially missed by using medical records. Beginning in 1997, abstraction of family history data has been conducted for Iowans diagnosed with cancer. To date, 1006 living LCa (FHP=87; FHN/U=919) and 1482 living PCa (FHP=136; FHN/U=1346) patients have been ascertained. Of these, 150 LCa (FHP=87; FHN/U=63) and 220 PCa (FHP=136; FHN/U=84) were contacted, and presently, 64 LCa (FHP=36; FHN/U=28) and 123 PCa (FHP=86; FHN/U=37) have returned questionnaires. Percentage of concordance for family history status between medical record data and patient self-report tended to be high for both LCa (FHP=92%; FHN/U=79%) and PCa (FHP=85%; FHN/U=87%). These results provide preliminary evidence that collection of family history data during routine cancer surveillance may provide a cost-efficient method to identify affected relative pairs. Future analyses will include evaluation of additional cases and cancer sites and examination of concordance by age and gender of patients and type of practitioner.

Program Nr: 2240 from the 1999 ASHG Annual Meeting

Statistical power and error of different pedigree structures for the detection of genetic linkage in quantitative traits. *M. Ronderos, LD. Atwood.* Division of Epidemiology, University of Minnesota, Minneapolis, MN.

The statistical efficiency of different pedigree structures for the detection of human genetic linkage is not fully understood. This information is important for the design of genetic epidemiology studies. The purpose of this simulation study was to compare the statistical power and error provided by different pedigree structures when the total number of subjects in the study is kept constant. The pedigree structures tested included CEPH families (CF; 2 sibs, 2 parents, 4 grandparents), CEPH families with two grandparents missing (CFM), nuclear families (NF; 2 sibs, 2 parents), nuclear families missing one parent (NFM), and sibships (no parents) of two (S2), three (S3) or four sibs (S4). For each of these groups, a total of 600 data sets were generated. Each data set contained 480 subjects, and the number of pedigrees per data set was adjusted according to pedigree size. The generating model assumed a quantitative trait on which a single gene accounted for 50% of the population variance. The remaining 50% of the variance was explained by random variation. The results indicate that sibships of three or four sibs provide significantly higher statistical power than CEPH families, nuclear families or sib-pairs (P<0.0001). The mean (95% CI) LOD scores for linked markers were 1.58 (1.51, 1.66), 1.39 (1.32, 1.46), 1.17 (1.11, 1.23) and 0.90 (0.85, 0.94) for the CF, CFM, NF, and NFM groups, respectively. The mean LOD scores for S2 were 0.89 (0.85, 0.94). Data sets composed of sibships of three or four sibs presented mean LOD scores of 2.08 (2.01, 2.16) and 3.30 (3.19, 3.49), respectively. The differences between groups were consistent for linked markers located at recombination fractions of 0.01 or 0.05, and for additive or dominant traits. The results were also consistent when the population gene frequency was 0.1, 0.3 or 0.5. The error was significantly higher for CEPH families as compared to nuclear families or sibships (P<0.0001). This study suggests that, given a limited number of subjects, the recruitment of large sibships should be preferred over recruiting either nuclear or CEPH families.

Program Nr: 2241 from the 1999 ASHG Annual Meeting

Paraoxonase (PON1) as a predictor of plasma lipid and lipoprotein levels. *L.S. Rozek, T.S. Hatsukami, R.J. Richter, V.H. Brophy, N.T. Tsai, C.E. Furlong, G.P. Jarvik.* Dept of Medicine, University of Washington, Seattle.

Studies suggest that two common paraoxonase (PON1) polymorphisms, Gln (Q) to Arg (R) at codon 192 ($PON1_{192}$) and Leu (L) to Met (M) at codon 55 ($PON1_{55}$), are associated with cardiovascular disease (CVD). We evaluated 105 Caucasian CVD patients and 153 controls for paraoxonase and diazoxonase activity (POase, DZOase) and $PON1_{192}$ and $PON1_{55}$ genotypes and tested for their correlation with standard lipid and lipoprotein phenotypes. In the entire sample, POase and DZOase showed a small significant positive correlation with apolipoprotein AI (apoAI) (correlations= 0.16, 0.27), high density lipoproteins (HDL) (0.15, 0.19), HDL subfraction 3 (HDL3) (0.18, 0.26), and total cholesterol (TC) (0.13, 0.23), DZOase only with low density lipoprotein cholesterol (LDL-C) (0.17) and apoB (0.12) but not with HDL2, triglycerides (TG) or very low density lipoprotein cholesterol (VLDL-C). $PON1_{192}$ genotype predicted significant variation in HDL3 level (p=0.024) and marginal variation in HDL level (p=0.067) by ANOVA. In cases, POase and DZOase showed a small but significant positive correlation with TC (0.30, 0.30), VLDL-C (0.26, 0.22) and TG (0.23, 0.22); HDL3 and apoAI were significantly correlated with only DZOase (0.23, 0.26). $PON1_{192}$ genotype predicted significant variation in HDL (p=0.006), HDL2 (p=0.019), HDL3 (p=0.009) and marginal variation in VLDL-C (p=0.062) and TG (p=0.059). In controls, POase and DZOase showed a small significant positive correlation with HDL (0.18, 0.20) and HDL3 (0.20, 0.26), DZOase was significantly correlated with apoAI (0.27) and TC (0.18). $PON1_{192}$ genotype did not predict significant variation in any of the measures in the controls. $PON1_{55}$ genotype predicted marginally significant variation in apoB level (p=0.062) only in cases and controls combined. Variation in these traits predicted by any PON1 measure ranged from only 0.1% to 7.4% and appear to differ in cases and controls. DZOase, often not measured in studies of CVD risk, is a better predictor of these traits than PON1 genotype. The association of PON1 and CVD is not expected to be wholly attributable to its small lipoprotein effects. PON1 may be an independent predictor of CVD.

Program Nr: 2242 from the 1999 ASHG Annual Meeting

Cosegregation of single nucleotide polymorphisms in exon I of keratin 14 determined by allele specific sequencing. *E.L. Rugg[1,2], N.J. Wilson[2], G. Magee[2], E.B. Lane[2].* 1) Centre for Cutaneous Research, St Bartholomew's & the Royal London Hospital, Queen Mary & Westfield College London, UK; 2) CRC Cell Structure Research Group, Department of Anatomy & Physiology, University of Dundee, Dundee, UK.

Single nucleotide polymorphisms (SNPs) are the most common type of genetic variation. They are estimated to occur at a frequency of approximately one per thousand base pairs and as such are potentially powerful tools for mapping human genetic diseases. Recent studies however indicate that SNPs do not necessarily occur in an entirely random fashion and that they may show a high degree of disequilibrium making them potentially useful markers for mapping human migration and evolution.

Exon I of keratin 14 (K14) contains six neutral SNPs within a 525 base pair fragment (Sorensen *et al*, 1999). In the course of establishing a data base of the normal DNA sequence for this region of the K14 gene we identified a novel G/C polymorphism in intron I. Our data suggested the SNPs were linked and that there were only two haplotypes in the population under study. PCR was used to specifically amplify a fragment of DNA from fifty unrelated individuals of British origin which contained all seven SNPs. The products were sequenced using the two PCR primers and a primer specific for the G variant of the intronic SNP. The intronic primer only bound to DNA to which it was an exact match and this enabled us to carry out allele specific sequencing. The data confirmed the SNPs cosegregated into two haplotypes, K14a and K14b. These were present in the samples analysed at a frequency of 0.628 and 0.372 respectively with a genotype frequency of K14a/a, 33.3%; K14a/b, 60.0%; K14b/b, 7.7%. The same two haplotypes were also present in two unrelated individuals of Jewish Askenazi extraction however a third haplotype, which differed from K14b by one base pair, was found in DNA from a Japanese individual. These data suggest that the polymorphisms arose in separate populations and may therefore be useful for studies of population genetics and mapping human migration.

Program Nr: 2243 from the 1999 ASHG Annual Meeting

The contribution of mutations 167delT and 35delG in connexin 26 gene to nonsyndromic deafness in Ashkenazi Jews. *M. Sagi[1], I. Lerer[1], E. Malmud[1], H. Levi.[2], A. Raas-Rothschild[1], D. Abeliovich[1].* 1) Dept Human Genetics, and; 2) Speech and Hearing Center, Hadassah Hebrew University Hospital, Jerusalem, Israel.

Mutations in the connexin 26 gene (Cx26) are associated with nonsyndromic recessive deafness DFNB1. In several Mediterranean populations a single mutation in the Cx26 gene, the 35delG, is the most common mutation for sensoneural deafness. Recently, the 167delT mutation in the Cx26 gene was identified as an Ashkenazi founder mutation with an estimated carrier rate of 4%. In the present study we evaluate the contribution of the 167delT and 35delG mutations to nonsyndromic deafness (NSD) in the Ashkenazi Jews.

Twenty unrelated Ashkenazi or half Ashkenazi Jewish patients with prelingual NSD were tested. In 13 patients biallelic Cx26 mutations were identified and 3 patients were heterozygotes with no other mutation identified on the other allele. Thus, in 79% of a total of 38 Cx26 alleles of Ashkenazi origin, a mutation was detected. The mutations frequencies were: 53% for 167delT, 18% for 35delG, others (50del12, E114G and V27I) were 8%. The haplotypes of both 167delT and 35delG mutations indicate that these are founder mutations. In a control group of 210 unselected Ashkenazi individuals, 13 were carriers of the mutation 167delT, 1 was homozygote for the mutation 167delT and 1 was compound heterozygote 167delT/35delG, giving a carrier frequency of 7.3% for the 167delT mutation and 1.1% for the 35delG.

The expected rate of 167delT homozygous in the Ashkenazi Jews, based on a carrier frequency of 5% (a mean carrier frequency based on our results and Morell et al. 1998), is 1/1600. Based on our results, about 50% of NSD among Ashkenazi is due to the 167delT mutation, therefore the expected rate of all NSD in this population is about 1/800. The observed rate of all NSD in the Israeli Ashkenazi population is around 1/1200. The discrepancy between the expected, as predicted by the carrier frequency, and the observed rate of all NSD in the Ashkenazi may suggest incomplete ascertainment of homozygous 167delT children due to incomplete penetrance or variable expression.

Program Nr: 2244 from the 1999 ASHG Annual Meeting

Genetic polymorphisms in Transforming Growth Factor-b**1 and the risk of coronary heart disease.** *N. Saha, E.K. Luedecking, M.I. Kamboh.* Department of Human Genetics, Univ Pittsburgh, Pittsburgh, PA.

Transforming Growth Factor-b1 (TGF-b1) is a multifunctional cytokine thought to be involved in the pathological development of coronary heart disease (CHD). The aim of this study was to investigate the role of three polymorphisms in TGF-b1 in affecting the risk of CHD. Two of the polymorphisms are located in the promoter region at positions -800 (G®A) and -509 (C®T), and the third in the coding region at codon 263 (Thr®Ile). We screened 201 Chinese patients and 201 controls, and 130 Asian Indian patients and 200 controls using PCR based assays. Although there was no difference in genotype or allele distribution at the -800 polymorphic site between patients and controls in either the Indian or Chinese cohorts, there was significant inter-racial variablity in allele frequency between the two populations ($p<0.0001$). The genotype distribution at the -509 polymorphism was significantly different between patients and controls in both the Chinese ($p=0.016$) and Indian ($p=0.027$) samples. There was significant difference in allelic distribution for the -509 polymorphism between the two populations ($p<0.0001$). There was no statistically significant difference in genotype or allele frequency for the codon 263 polymorphism between patients and controls in either the Chinese or Indian populations. Our data indicates that the -509 polymorphim may affect the risk of CHD in the general population.

Program Nr: 2245 from the 1999 ASHG Annual Meeting

Apolipoprotein E promoter polymorphisms and Alzheimer disease in black populations. *A. Sahota[1], M. Yang[1], S. Gao[2], C. Emsley[2], O. Baiyewu[3], A. Ogunniyi[3], K.S. Hall[2], H.C. Hendrie[2].* 1) Dept. Genetics, Rutgers Univ., Piscataway, NJ; 2) Dept. Psychiatry, Indiana Univ. Sch. Med., Indianapolis, IN; 3) Dept. Medicine, Univ. Ibadan, Ibadan, Nigeria.

We have previously shown that the e4 allele of apolipoprotein E (APOE) is not associated with late-onset probable Alzheimer disease (AD) in Nigerian blacks, but may be a weak risk factor in African-Americans who are e4 homozygotes. The e4 allele frequencies in the two groups were comparable, and were higher than those in Caucasian and Japanese populations, where APOE e4 is strongly associated with AD. However, even in at-risk populations, as many as 50% of e4 homozygotes who survive until age 80 years do not develop AD. Recent studies have suggested that sequence variations in the APOE regulatory regions may increase the risk for AD independently or in combination with the e4 allele. These variations include the 491A/T, -427T/C, -219G/T, and +113G/C polymorphisms (positions are relative to the APOE transcriptional start site) and a T/C mutation at codon 28. In particular, homozygosity for the 491A allele was reported to be associated with increased risk for AD in Caucasian subjects independent of their APOE e4 status. For this study, we examined the relationship between the 491A/T polymorphism and probable AD, with and without the confounding effects of APOE e4, in Nigerian blacks from Ibadan (AD = 25, controls =116) and African-Americans from Indianapolis (AD = 39, controls = 39). These individuals are participating in our on-going community-based study of dementia and AD in elderly black populations (age 65 and over). The A and T allele frequencies for patients and controls within each group, and between the two groups, were not significantly different (mean A = 67.1%, mean T = 32.9%), and the APOE e4 allele frequencies were comparable to those previously reported. Logistic regression models did not detect any consistent relationship between the -491A allele and AD in the two groups, indicating that this polymorphism does not represent an independent risk factor for AD in black populations. Analysis of other regulatory region polymorphisms is in progress. Supported by NIH grant AG09956.

Program Nr: 2246 from the 1999 ASHG Annual Meeting

Polymorphism of noncoding regions of mitochondrial DNA in Evenks. *V.B. Salukov, V.P. Puzyrev, S.A. Eletskaya, T.P. Muravyeva.* Population genetics laboratory, Institute of Medical Genetics, Tomsk, Russia.

Restriction polymorphism of D-loop and V region length polymorphism of mitochondrial DNA were investigated in sample of aboriginal Siberian population, namely Evenks living in Chita region (Russia). The sample consisted in total from 93 non-related individuals. No polymorphism was detected by BamHI, AvaII, Kzo9I endonucleases. The frequencies of other polymorphic sites were: 77.42% for KpnI 16129, 57.00% for AspS9I, 45,16% for HaeIII 16517, and 1.08% for EcoRV 16278. No length polymorphism in V region was detected. There were 7 different haplotypes formed by all the polymorphic sites and two of the haplotypes account for 68.48% of the whole sample. Evenks show less variability of mitochondrial DNA comparing with Russians, Mongols, Tuvinians, and Buryats studied earlier with the same set of markers. However, some features of mtDNA polymorphism characterize Evenks as a typical Mongoloid population.

Program Nr: 2247 from the 1999 ASHG Annual Meeting

A two-stage design for linkage disequilibrium. *J.M Satagopan, C.B Begg, E.S Venkatraman.* Epidemiology and Biostatistics, Mem Sloan-Kettering Canc Ctr, New York, NY.

BACKGROUND: We address the optimization of the design of studies of linkage disequilibrium, where one wishes to search for correlation between markers of disequilibrium and disease for a large number of markers. METHOD: We propose a two-stage design when the principal design constraint is the total cost of marker studies, rather than the total number of subjects. It is cost-effective to perform a two-stage design where in the first stage all the markers are evaluated on an initial group of patients, and in the second stage only the most promising markers are further evaluated on all the patients, thus eliminating wastage of resources on markers unlikely to be associated with disease on the basis of the results of the first stage. RESULTS AND CONCLUSION: Using simulation results we show that, as a general guideline, screening all the markers on approximately 25% of the patients and then evaluating the most promising 10% of the markers on the remaining patients provides close to the optimal power for a broad range of parametric configurations.

Program Nr: 2248 from the 1999 ASHG Annual Meeting

Comparison of the power of the transmission distortion test (TDT) for affected and unaffected trios when disease is highly prevalent. *L.J. Scott[1], A. Krolewski[1], J.J. Rogus[2]*. 1) Genetics & Epidemiology, Joslin Diabetes Ctr, Boston, MA; 2) Program for Population Genetics, Harvard School of Public Health, Boston, MA.

TDT was developed to avoid bias due to population stratification in testing candidate genes and works by sampling affected children and their parents (Aff Trios). The use of unaffected trios (Unaff Trios) as a comparison group has been advocated to rule out segregation distortion, but under certain conditions can also be used to effectively detect transmission distortion. To determine when Unaff Trios might have more power than Aff Trios to detect transmission distortion, we calculated the sample sizes necessary both groups for 80% power and 5% type 1 error for a variety of genetic models. Sample sizes were estimated using a Gaussian approximation. The table shows an example of the sample size (N) of Aff Trios relative to Unaff Trios for a dominant model with a risk ratio of 2 and a disease allele frequency of 0.5. The baseline penetrance was varied from 0.2 to 0.4.

Baseline Penet	Disease Prevel	N Aff Trios	N Unaff Trios	Ratio Aff/Unaff
0.2	0.35	479	1711	0.3
0.3	0.53	479	408	1.2
0.4	0.70	479	91	5.2

The sample size of the Unaff Trios decreased with increasing baseline penetrance, whereas the sample size remained constant in Aff Trios. In general, Unaff Trios power exceeds that of the Aff trios when the disease prevalence is greater than 45-55%. In highly prevalent diseases, selection of Unaff Trios with little risk of developing disease in the future may provide a more powerful test than the use of Aff Trios.

Program Nr: 2249 from the 1999 ASHG Annual Meeting

Increased haemochromatosis gene (HFE) mutation in alpha-1 antitrypsin (PiZ) deficient heterozygotes. *M.J. Sharrard[1], A.S. Rigby[1], S. Povey[2], M.S. Tanner[1].* 1) Dept Paediatrics, Univ Sheffield, Sheffield, UK; 2) University College, Univ London, UK.

Alpha-1 antitryspin deficiency (A1ATD) and genetic haemochromatosis (GH) are highly prevalent disorders in the United Kingdom (U.K.) Adults with GH, and both homozygotes and heterozygotes for A1ATD are at increased risk of chronic liver disease, with hepatic deposition of iron. Low penetrance mutations in the haemochromatosis (HFE) gene may interact with the A1ATD heterozygote state to exacerbate liver disease. This study aimed to determine the frequency of HFE gene mutation in those UK individuals carrying the A1ATD mutation. 113 parents (54 mothers, 59 fathers) of PiZZ A1ATD patients, and 1430 healthy controls were genotyped for the C282Y and H63D mutations of the HFE gene using the polymerase chain reaction and restriction enzyme digestion. Data was analysed by relative risk (RR) and 95% confidence intervals (95%CI). In the study group, the H63D allele frequency was significantly elevated (frequency 0.23 and 0.14 for controls, RR 1.67, 95%CI 1.30-2.15), while the C282Y allele frequency was not significantly elevated (0.09 and 0.07 for controls, RR 1.29, 95%CI 0.84-1.98). The frequency of haplotypes associated with the haemochromatosis phenotype was significantly higher in the study group than in controls (12% versus 4%, RR 2.95, 95%CI 1.66-5.21). In the UK, it is probable that racial admixing of populations in which the HFE and A1ATD mutations arose accounts for the high coprevalence detected in this study. There may be selective pressure to maintain this coprevalence as a result of increased fertility. However, increased awareness of HFE gene mutations should lead to investigation of A1ATD liver disease patients for HFE gene mutation, as GH may be a treatable compounding factor.

Program Nr: 2250 from the 1999 ASHG Annual Meeting

Higher than expected carrier rates for familial Mediterranean fever in various Jewish ethnic groups. *M. Shohat, N. Stoffman, T. Shohat, R. Lotan, S. Koman, A. Oron, Y. Danon, G. Halpern, N. Magal.* Department of Medical Genetics and Immunology, FMRC, Schneider Children's Medical Center of Israel, and Rabin Medical Center.Sackler School of Medicine, Tel Aviv University, Israel.

Familial Mediterranean Fever (FMF) is an autosomal recessive disease characterized by recurrent attacks of inflammation of serosal membranes. Amyloidosis leading to renal failure is the most severe complication in untreated patients. In Israel FMF is most frequent among Jews of North African origin. Recently the causative gene (MEFV) has been found and the common mutations characterized. The aim of this study was to investigate the carrier rates of the common MEFV mutations among 400 healthy members of 4 different ethnic groups (100 in each group) in Israel, and to compare the distribution of the different mutations between FMF carriers and patients. We found a high frequency of carriers among Jews from the various ethnic groups. In North African Jews it was 22%, in Iraqi Jews 39%, in Ashkenazi Jews 21%, and in Iranian Jews 6%. The distribution of the 4 most common MEFV mutations among healthy individuals (M694V 29%, V726A 16%, M680I 2% and E148Q 53%) was significantly different ($p < 0.003$) from that found in patients (M694V 84.4%, V726A 9.0%, M680I 0% and E148Q 6.6%). Six healthy asymptomatic individuals were found to carry mutations in both alleles. Of these, 2 were homozygotes for E148Q and 4 were compound heterozygotes, of which 3 were E148Q/M694V, and one was E148Q/V726A. These results demonstrate a very high carrier rate among all Jewish ethnic groups. They confirm that mutation E148Q is associated with a milder phenotype, which explains the lower prevalence of FMF among the Ashkenazi and Iraqi Jews. This study raises the question of the need for molecular screening for M694V homozygotes in the Israeli North African Jewish community.

Program Nr: 2251 from the 1999 ASHG Annual Meeting

Gene characterization using high-risk families: a sensitivity analysis of the MOD score approach. *K.D. Siegmund, W.J. Gauderman, D.C. Thomas.* University of Southern California, Los Angeles.

To estimate penetrance using high-risk families, the MOD score approach maximizes the conditional likelihood of linked marker data given the disease status of all subjects. Several authors have shown that this approach is valid when ascertainment is through the trait only. Easton et al. (1995) apply the method to data from the Breast Cancer Linkage Consortium to estimate the penetrance of BRCA1. In their analysis, the allele frequency, recombination fraction, and baseline rates of disease were fixed and only the estimates of penetrance in carriers were obtained. Because breast cancer is a heterogeneous disease with two known susceptibility genes, they restricted their analysis to families having a LOD score above a given threshold at markers near BRCA1. As they note, such ascertainment is related to the distribution of markers and trait values in a pedigree and can lead to biased penetrance estimates. In a simulation study, we investigate the sensitivity of the MOD score approach to mis-specified (fixed) parameters, unmodeled GxE interaction, and ascertainment based on a LOD score criterion.

We simulate one marker locus linked to a disease locus (q = 0.05). The marker locus has eight alleles and the disease locus two, the frequency of the (dominant) susceptibility allele is 0.01. The penetrance in carriers (p_1) is 0.51 and in non-carriers is 0.05. Results show that carrier penetrance was underestimated when the baseline rate of disease was under-stated (p_1 = 0.36, -29% bias) and overestimated in a sub-sample of families having a LOD ³ 1.0 (p_1 = 0.74, 45% bias). Ignoring a positive GxE interaction resulted in bias only if E was correlated within families (p_1 = 0.66, 29% bias). Maximizing the likelihood over all parameters can eliminate bias of the first and third kind. Bias from the ascertainment on LOD score can be problematic. Easton et al. argue that such ascertainment is not a concern in their data since the majority of information on penetrance comes from families that would have been selected on any threshold. Although this may be true, we caution against the general use of LOD scores for ascertainment.

Program Nr: 2252 from the 1999 ASHG Annual Meeting

Quantitative genetics of blood pressure and adiposity in adults from hypertensive and normotensive families.
R.M. Siervogel, E.W. Demerath, W.A. Wisemandle, C.M. Zeller, C. Greenberg, B. Towne. Division of Human Biology, Department of Community Health, Wright State University School of Medicine, Dayton, OH.

The extent to which blood pressure and body composition share a common genetic basis in individuals with a family history of hypertension vs. individuals from randomly selected families has yet to be fully elucidated. We explored this issue using variance components methods and data from adults in two family studies of body composition and CVD risk - Genetics of Hypertension Study (GHS) families were reqruited through a proband with essential hypertension, whereas Fels Longitudinal Study (FLS) families were randomly ascertained. Using age- and sex-matched data from 450 individuals in 4 large extended GHS families, and 779 individuals in 147 nuclear and extended FLS families, we estimated the heritabilities of systolic and diastolic blood pressure (SBP and DBP), two adiposity measures (body mass index: BMI; and triceps+subscapular+suprailiac skinfolds: SUM3) and two fat pattern indices (subscapular/triceps: STI; and subscapular/subscapular+suprailiac: RFPI), and the additive genetic correlations between SBP and DBP and these adiposity and fat pattern measures. Heritabilities (±SE) from the GHS vs. FLS data were all significant: SBP = 0.38±0.09 vs. 0.27±0.07, DBP = 0.33±0.09 vs. 0.30±0.07, BMI = 0.46±0.10 vs. 0.45±0.07, SUM3 = 0.21±0.11 vs. 0.32±0.09, STI = 0.21±0.07 vs. 0.36±0.11, and RFPI = 0.33±0.10 vs. 0.32±0.08. Genetic correlations (±SE) from best models of the GHS vs. FLS data were: SBP&BMI = 0.77±0.15 vs. 0.71±0.13, SBP&SUM3 = 0.53±0.26 vs. 0.62±0.18, SBP&STI = 0.64±0.24 vs. (0), SBP&RFPI = 0.47±0.26 vs. (0), DBP&BMI = 0.65±0.14 vs. 0.68±0.13, DBP&SUM3 = 0.47±0.26 vs. 0.78±0.15, DBP&STI = 0.62±0.25 vs. (0), and DBP&RFPI = (0) vs. (0). Although blood pressure and body composition phenotypes differ between the two studies, the heritabilities of the traits are similar in both. The genetic correlations between blood pressure and adiposity measures also are similar in the two studies, but there appear to be stronger genetic associations between blood pressure and fat patterning in the GHS families than in the FLS families. Supported by NIH grants HL19931 and HD12252.

Program Nr: 2253 from the 1999 ASHG Annual Meeting

Significant admixture linkage disequilibrium in African Americans across 30 cM around the *FY* locus. *M.W. Smith[1], J.A. Lautenberger[2], J.C. Stephens[3], S.J. O'Brien[2].* 1) IRSP, SAIC, Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD 21702-1201; 2) Laboratory of Genomic Diversity, National Cancer Institute, Frederick, MD 21702-1201; 3) Population Genomics Department, Genaissance Pharmaceuticals, Inc., New Haven CT 06511.

Understanding the importance of allelic polymorphisms on quantitative and environmentally interacting phenotypes is now turning to population association screens, especially in cases where pedigree analysis is difficult. Because association screens require linkage disequilibrium between markers and disease loci, maximizing the degree of linkage disequilibrium increases the chance of discovering functional gene-marker associations. One suggested approach, mapping by admixture linkage disequilibrium (MALD) using recently admixed African Americans, is evaluated here by measuring marker associations with 15 short tandem repeats (STRs) and an indel polymorphism of the AT3 locus in a 70 cM segment at 1q22-23 around the *FY* (Duffy) locus. The FY polymorphism (46T-C) disrupts the GATA promoter motif specifically blocking FY expression in erythroid cells and has a nearly fixed allele frequency difference between Caucasians and Africans which is likely a consequence of a selective advantage of *FY* -/- in malaria infections. The product of the *FY* gene is a chemokine receptor which functions as a scavenger of chemokines and no obvious deleterious phenotype of *FY* -/- individuals is currently known. Analysis of linkage disequilibrium around the FY gene revealed that four flanking loci (*D1S303, SPTA1, D1S2635* and *D1S484*) spanning 8 cM showed strong and consistent linkage disequilibrium with FY. Significant linkage disequilibrium signals were observed over a 30 cM region from 4.4 cM (*D1S2777*) to 16.3 cM (*D1S196*) for STRs and at *AT3* (25.3 cM), affirming the theory of MALD for genome scans and association analysis in population studies. This project has been funded in whole or in part with Federal funds from the National Cancer Institute, National Institutes of Health, under Contract No. NOI-CO-56000.

Program Nr: 2254 from the 1999 ASHG Annual Meeting

In spite of being caused by a single point mutation, familial amyloid polyneuropathy (Val30Met) is not a simple Mendelian disorder. *A. Sousa[1,3,4], T. Coelho[2,3,4], L. Lobato[2,3,4], J. Sequeiros[1,4].* 1) Dept Population Studies, ICBAS; 2) HGSA; 3) CEP; 4) UnIGENe, IBMC, Porto, Portugal.

Although first described in Portugal by Andrade (1952), FAP is now known to be present in clusters in Japan, Northern Sweden, Majorca and Brazil, as well as in families of various origins. FAP is a motor, sensory and autonomic neuropathy, expressing in adulthood, and is inherited in an autosomal dominant mode. In all populations, a single point mutation (G for A) is responsible for the production of abnormal transthyretin, the precursor of amyloid.

Age-at-onset varies from an average of 33.5 yr. in Portugal to 56.7 yr. in Sweden (Majorcan patients show intermediate onset). However, within each of these clusters, some common patterns of variation can be observed: 1) late-onset and aged proven carriers cluster in some families, which seem to be more protected from the effects of the gene; 2) mean age-at-onset is higher in patients who had no affected parent than in patients with one affected parent; 3) anticipation of age-at-onset is significant. Although in the case of Swedish and Majorcan patients the sample size is small, in the case of Portuguese patients the anticipation study was performed in 770 parent-offspring pairs: it was significant (average 5.0 yrs) under different sampling schemes (exclusion of probands, exclusion of pairs with simultaneous onset, correction for cohort bias, all three together and a random sample).

We had previously postulated the possibility of a modifying gene of a dynamic-mutation type. So far, search for TNR were not conclusive. The number of studied twins (MZ vs. DZ) is not conclusive about the relative importance of genetic and environmental factors in age-at-onset. However, high correlations of age-at-onset in pairs of relatives (0.66 for sibs, 0.38 for parent-child in Portuguese population; 0.8 for sibs and parent-child in Majorcan population) point out to the importance of a genetic factor in regulating age-at-onset. Complex segregation analysis may yield some answers to the intriguing variability of an apparently simple genetic disorder.

Program Nr: 2255 from the 1999 ASHG Annual Meeting

Y-chromosome microsatellite haplotypes demonstrate presence of several components in male gene pool of Tuva population. *V.A. Stepanov*[1, 2], *V.P. Puzyrev*[1]. 1) Institute of Medical Genetics, Tomsk, Russia; 2) Tomsk State University, Tomsk, Russia.

Tuva is a native Siberian ethnic group living in Southern Siberia and speaking a language of Turkic branch of Altaic language family. Y-chromosome microsatellite haplotype analysis in three populations of Tuva reveals substantial intrapopulation variability in male Tuva population. In the sample of 111 chromosomes 49 different haplotypes were found, and frequency of only 4 of them was higher than 5%. The level of genetic diversity (H=0.935) demonstrate high discrimination power of Y-chromosome haplotypes. Analysis of molecular variance (AMOVA) and some other data testify for the absence of population subdivision in Tuva. Most of Tuva haplotypes fall in two lineages. Lineage A comprises ~64% of chromosomes and lineage B includes 24%. Presumable ancestral haplotype for lineage A is close to most common haplotype in modern Caucasians (Md=3), whereas ancestral haplotype for lineage B is distant from both "Caucasian" and "Mongolian" haplotypes. Age estimate for Y-chromsomes lineages in Tuva shows that male gene pool of modern Tuva population have its roots in upper Paleolithic or Neolithic periods. The computation of the age of Y chromosome lineages gives an estimate of 3500 years for lineage A (95%CI 1500 - 9180 years), and 5500 years for lineage B (95%CI 2360 - 14400 years). We suppose that lineage B corresponds to the ancient Indo-European contribution to the male gene pool of modern Tuva. More vast and less ancient lineage B may reflect the migration of ancient Turkic tribes to the territory of modern Tuva in Hun-Sarmatian period.

Program Nr: 2256 from the 1999 ASHG Annual Meeting

Vitamin D receptor polymorphisms and total hip bone mineral density in Baltimore women. *O.C. Stine, J.C. Scott, S. Zheng, D. Wiesch, K.M. Fox, E.R. Bleeker, M. Hochberg, D.A. Meyers.* Ctr Gen Asthma Complex Disease, Univ Maryland, Baltimore, MD.

Osteoporosis, a major cause of morbidity in the elderly, is a multifactoral disorder that has a substantial genetic component. In order to find genes associated with bone density, we have begun genetic studies of the women in the Baltimore cohort of the Study for Osteoporotic Fractures and their daughters. Total hip bone mineral density (BMD), a measure with significant heritability, was determined by DXA technology on 425 women (m = 75.3 years) and 55 of their daughters (m = 47.8 years). We obtained DNA samples and determined vitamin D receptor genotypes at the Fok I and Bsm I polymorphisms. Mothers and daughters were analyzed separately in order to avoid age as a confounding factor. When the average total hip BMD was compared between groups defined by their genotypes {Fok I, genotype = 1(uncut)1, n=135, $m_{BMD} = 0.75 \pm 0.13$; 12(cut), n = 158, $m_{BMD} = 0.75 \pm 0.13$; 22, n = 42, $m_{BMD} = 0.75 \pm 0.13$. Bsm I, genotype = 11, n = 97, $m_{BMD} = 0.74 \pm 0.13$; 12, n = 125, $m_{BMD} = 0.76 \pm 0.12$; 22, n = 120; $m_{BMD} = 0.74 \pm 0.13$}, no differences were found between the groups at either polymorphism. Of note, we observed, post hoc, that the Bsm I polymorphism was not in Hardy-Weinberg equilibrium in the mothers ($p < 0.0000005$). In contrast, the polymorphism is in Hardy-Weinberg equilibrium in the daughters. Inspection of the data for the mothers reveals that the cause of the disequilibrium is a deficit of heterozygotes. This may be because our sample is composed of several subpopulations, a Wahlund effect, or may be the result of selection against heterozygotes in older women. Additional information on the ethnicity of the mothers will be examined and a sample of elderly men will be genotyped to test these possible explanations. We conclude that there is no association between either VDR polymorphism and hip BMD in Caucasian women. We are continuing to study the relationship of other genetic polymorphisms to osteoporosis.

Program Nr: 2257 from the 1999 ASHG Annual Meeting

Estimation of admixture proportions in African-American and Hispanic populations of the continental US using highly polymorphic STR loci. *D.N. Stivers[1], R. Deka[2], B. Budowle[3], R. Chakraborty[1]*. 1) Human Gen Ctr, Sch Public Hlth, Univ Texas Health Sci Ctr, Houston, TX; 2) Dept. Environmental Health, Univ Cincinnati, Cincinnati, OH; 3) FBI Laboratory, FBI Academy, Quantico, VA.

It is well known that allele frequencies in admixed populations are weighted linear combinations of allele frequencies in the contributing parental populations, with the weights representing the admixture components from each parental population. Consequently, all allele frequency-based admixture proportions estimators are ratio-estimators whose depends upon the history of admixture and sampling uncertainties of the allele frequency estimates in the parental populations. A recently developed coalescence-based method of admixture estimation which exploits the natural of alleles at repeat loci by their repeat sizes apparently avoids such biases. The purpose of this research is to provide empirical support for this assertion.

We show that the logic of the coalescence-based method is mathematically equivalent to the least-square method based on decomposition of the variance of allele sizes in an admixed population. For illustration, we use allele size distributions in regional continental US populations of African-Americans and Hispanics in at nine short tandem repeat (STR) loci, for which allele frequency estimates are also available for Europeans, Africans and Native Americans. Estimates of admixture components (proportions of European, African and Native American genes) were obtained by least-squares, gene diversity and coalescence-based methods, along with the goodness-of-fit scores of the admixture models. The results support the earlier conclusions from protein polymorphism data suggesting bi-parental origin of African-Americans with regional differences in the proportion of Europen genes (increasing from South-East to Northwest). In contrast, the Hispanic populations of South-east and North-east appear to have a significant African contribution, which is not substantial in Western regions of the country.

(Research supported by US Public health Service research grants GM 41399, GM 53545 and GM 45861).

Program Nr: 2258 from the 1999 ASHG Annual Meeting

Polymorphisms in the IL-1 gene cluster and risk of osteoporotic fractures in elderly women. *K.L. Stone[1], S. van Dijk[2], H. Tabor[1], J. Cauley[1], K. Ensrud[1], E. Harris[1], J. Zmuda[1], M. Hochberg[1], J. Sorrell[3], G. Duff[3], S. Cummings[1].* 1) Study of Osteoporotic Fractures, San Francisco, Pittsburgh, Minneapolis, Portland, Baltimore; 2) Medical Science Systems, San Antonio; 3) Univ Sheffield, UK.

Polymorphisms in the interleukin-1 (IL-1) gene cluster have been associated with decreased bone mineral density in postmenopausal women. To test the hypothesis that these polymorphisms influence risk of osteoporotic fractures (FXs), we conducted a case-cohort study in a prospective study of 9,704 Caucasian women aged 65 yrs and older. FXs occurring since baseline over an average of 9.4 yrs were validated by X-ray. Incident spine FXs were determined by morphometry using X-rays collected at baseline and an average of 3.5 yrs later. Polymorphisms in the IL-1 gene cluster on chromosome 2 (IL-1A +4845, IL-1B +3954, IL-1B -511, IL-1RN +2018) were determined by PCR analysis of previously collected whole blood samples stored on filter paper. Genotypes were compared among women who suffered incident hip (n=216), spine (n=183) or wrist (n=216) FXs and controls drawn from a random cohort sample (n=626). Non-spine FX (n=185) risk was analyzed within the cohort sample. Results are reported as relative risks (RR). After excluding current or previous estrogen (ERT) users and adjusting for age, BMI, medical conditions, health status and other FX risk factors, the IL-1A 2,2 genotype was associated with an increased wrist FX risk (RR=1.8; 95% CI 1.0-3.5) relative to those with type 1,1, with similar patterns for non-spine (RR=1.6; 0.9-2.8) and spine (RR=1.4; 0.7-2.6) but not hip (RR=1.0; 0.5-2.2) FX. Non-spine FX risk was increased among those with IL-1B (+3954) genotype 2,2 (RR=2.0; 1.1-3.8), and decreased among those with IL-1RN genotype 2,2 (RR=0.4; 0.2-0.9). Different risk patterns were observed when ERT users were included, suggesting a possible gene-environment interaction. For example, in models including ERT users, women with IL-1RN genotype 2,2 experienced nearly double the risk of wrist fracture (RR=1.9; 1.1-3.3). Polymorphisms in the IL-1 gene cluster may influence risk of osteoporotic fracture in elderly women. Further study is needed to explain differences in patterns of association by fracture type.

Program Nr: 2259 from the 1999 ASHG Annual Meeting

Molecular Screening for Smith-Magenis Syndrome Among a Large Population of Patients with MR. *J.L. Struthers, S. Taylor, K. Harrison, M.M. Khalifa.* Department of Pathology and Pediatrics, Queen's University, Kingston, Ontario, Canada.

Smith-Magenis syndrome (SMS) is a MCA/MR syndrome caused by a microdeletion of chromosome 17p11.2. Clinical findings in SMS patients include facial anomalies, speech delay, behavioral problems and peripheral neuropathy. The incidence of SMS is estimated to be 1 in 25 000, however, it may be significantly underdiagnosed due its recent description and phenotypic variability.

In order to investigate the frequency of SMS among patients with undiagnosed MR, we have established a protocol to screen for this deletion in a large number of patients referred over a ten year period. DNA samples from these patients are digested with EcoRI and hybridized with the D17S258 probe--previously identified as the most commonly deleted region in SMS. This probe is non-polymorphic with EcoRI. Another EcoRI non-polymorphic probe on the X chromosome is included for a dosage control; males display a single dose with this probe, while females display a double dose. Detection of suspected SMS cases is by dosage comparison with the control probe using densitometry; individuals with the SMS deletion display only a single dose of the D17S258 band. Patients that are suspected as having the SMS deletion are selected and tested again. Samples that display a persistence of dosage difference are analyzed further. Highly polymorphic markers in the SMS region are then used to detect hemizygozity in these patients. Comparative Genomic Hybridization is also performed to identify the SMS deletion through comparisons with normal controls and known patients. Suspected patients are then requested to submit a new blood sample for conformation of the diagnosis by FISH.

To date, over 600 samples have been screened. Repeat testing has been performed in 14 cases; 9 exhibit persistence of the dosage difference. In 2 cases the dosage difference has been explained by a diagnosis of Klinfelter's syndrome. Conformation of SMS in the remaining cases is underway. This will be the largest study to identify SMS in patients with MR. The results will provide important insight into the phenotypic variability and frequency of this disease among individuals with undiagnosed MR.

Program Nr: 2260 from the 1999 ASHG Annual Meeting

The origin and genetic affinity of Sino-Tibetan speaking populations. *B. Su[1], R. Deka[2], C. Xiao[1,3], J. Xiao[4], P. Underhill[5], L. Cavalli-Sforza[5], R. Chakraborty[1], L. Jin[1,4].* 1) Human Genetics Center, Univ Texas Sch Pub Hlth, Houston, TX; 2) Department of Environmental Health, University of Cincinnati, Cincinnati, OH; 3) Department of Biology, Yunnan University, Kunming, China; 4) Institute of Genetics, Fudan University, Shanghai, China; 5) Department of Genetics, Stanford University, Palo Alto, CA.

Among over 6,000 languages currently spoken in the world. The Sino-Tibetan language family is the largest of all in view of population size (more than 1 billion speakers), including 360 languages spoken in nine Asian countries, China, India, Bhutan, Myanmar, Bangladesh, Laos, Thailand and Vietnam. By using 19 Y chromosome biallelic markers and 3 Y chromosome microsatellite markers, we analyzed the genetic structures of 20 indigenous Sino-Tibetan speaking populations from East, Southeast, and South Asia. Our results showed that H6 (defined by a T to C mutation at M122 locus) and H8 (defined by a G deletion at M134 locus) are the predominant haplotypes in almost all Sino-Tibetan populations, implying the genetic affinity of populations in the same language family. Furthermore, the clinal distribution of H8 suggest that an ancient westward and then southward migration that resulted in the peopling of the Himalayan areas, including Tibet, Northeast India and North Myanmar. We therefore postulate that the ancient Qiang people living in Upper Yellow River basin in 7000 years ago, who developed the earliest Sino-Tibetan civilization, might be the ancestor of modern Sino-Tibetan populations.

Program Nr: 2261 from the 1999 ASHG Annual Meeting

Population genetics of the SCA6 locus in British families with ADCA. *M.G. Sweeney, P. Giunti, V.J. Stinton, P.F. Worth, M.G. Hanna, N.W. Wood, M.B. Davis.* Clinical Neurology, Institute of Neurology, London, UK.

An expanded CAG repeat in the voltage-gated calcium channel subunit (CACNA1A) has been shown to cause an autosomal dominant, predominantly late onset, 'pure' cerebellar ataxia (SCA6). We have studied this mutation in 70 families with autosomal dominant cerebellar ataxia (negative for SCAs 1, 2, 3 and 7), of these 35 have been shown to be have an expansion at this locus. All affected individuals in this population had 22 or 23 repeats. Other reports have found expansions ranging from 21 to 30 repeat units. In 9 phase known families (of which 6 had 22 repeats) haplotype analysis using markers which closely flank the repeat unit and an intragenic marker (D19S1150) were studied. All individuals with 22 repeats shared a common allele for the intragenic marker and one or more flanking markers. One individual with 23 repeats also shared this common haplotype. These data suggest that all chromosomes with the repeat expansion appear to have derived from a small number of ancestral chromosomes and provide evidence of a founder effect. Of the 3 remaining families with 23 repeats, 2 shared a haplotype that differed from those with 22 repeats at all markers studied so far. The remaining family showed clear evidence for a new mutation at the SCA6 locus, in which the expansion occurred on a maternal chromosome with 13 repeats.

Program Nr: 2262 from the 1999 ASHG Annual Meeting

Epidemiological, genetic and etiologic study of the congenital and infantile cataract in Colombia. *M.L. Tamayo[1], A. Ordoñez[1], C.M. Leyva[1], J.C. Prieto[3], M. Lozano[2], J.C. Serrano[4], C. Peñaranda[4], P. Garavito[4], S. Scaff[4], F. Escallon[4], F. Vejarano[4], A. Cortez[4], F. Betancourt[4], P. Echeverry[4], O. Alvis[4], E. Gutierrez[4], A.M. Alvarez[4].* 1) Unidad de Genetica Clinica, Univ Javeriana, Instituto de Genetica Humana. Bogota, Colombia; 2) Fundacion Oftalmologica Nacional. Bogota, Colombia; 3) Laboratorio de Genetica, Hospital La Victoria. Bogota, Colombia; 4) Several eye institutions in Colombia.

Cataracts are one of the most common causes of subnormal vision and blindness. We evaluated a series of individuals with congenital and infantile cataract from 9 Colombian cities in order to determine its etiology (genetic or acquired) and to analyze the diverse epidemiological factors in our country. We selected 264 individuals with confirmed diagnosis of congenital and infantile cataract. A complete physical, ophthalmologic and genetic evaluation was performed to each individual and available family members. The clinical history included a detailed analysis of family and personal background and data regarding important epidemiological aspects. Samples were taken to perform the following laboratory examinations: general metabolic - biochemical studies in blood and urine (qualitative tests in biochemical genetics, aminoacid and carbohydrate chromatography), galactose-1-Uridyl transferase enzyme activity, antibodies against toxoplasm and rubella, and karyotype. The karyotype analysis showed a cytogenetic abnormality in 8.46% of the individuals. A high frequency of microphthalmus and other ocular associations with cataract was observed. The genetic cases correspond to the highest frequency (58%), followed by not defined (30%) and acquired (12%). It was established that the autosomal dominant congenital cataract was the most frequently encountered and in those families an inter and intrafamilial clinical variability was observed.

Program Nr: 2263 from the 1999 ASHG Annual Meeting

Extent of confounding odds ratio in case control association studies due to population stratification. *M.D. Teare[1], A.M. Dunning[2], C.S. Healey[2], F. Durocher[1], D.F. Easton[1], B.A.J. Ponder[2], N.E. Day[3].* 1) CRC Genetic Epidemiology Unit, University of Cambridge, Cambridge, England, United Kingdom; 2) CRC Department of Oncology, University of Cambridge, UK; 3) Department of Community Medicine, University of Cambridge, UK.

Population stratification is often cited as a problem when conducting case-control genetic association studies. If stratification exists, then cases may be drawn from different sub-populations to the controls. If these populations experience different rates of disease, marker genotypes may appear associated whenever sub-population marker allele frequencies are sufficiently different. This could result in confounding odds ratios which are greater than 1.

We have attempted to evaluate the extent of such confounding association in a series of 700 control from East Anglia, UK. In a pair-wise association analysis of six unlinked loci, only one pair (out of 15 possible) showed significant association. At this stage, therefore, we have no evidence of stratification in this population. We have formulated a random effects model that provides a powerful framework within which to test for stratification utilising an unlimited number of unlinked marker loci. Using this approach, for any association detected between marker and disease it is possible to estimate what fraction of this could be due to stratification alone. We have also investigated under what circumstances such stratification can be detected. For example, a sample size of 1000 should be sufficient to detect any stratification causing a confounding odds ratio of 1.3 or more, assuming that the disease is no more than twice as common in one stratum than the other. Failure to detect associations between unlinked markers should therefore protect against spurious associations unless there is extremely strong heterogeneity of risk.

Program Nr: 2264 from the 1999 ASHG Annual Meeting

Evaluation of DNA isolated from mouthwash for genetic studies. *L.H. Toji, E.A. Morgan, P.K. Bender, J.C. Beck.*
Coriell Cell Repositories, Coriell Institute for Medical Research, Camden, NJ.

In order to evaluate the suitability of the simple mouthwash procedure described by Lum and LeMarchand [*Cancer Epidemiol. Biomarkers Prev.* **7:** 719-724 (1998)] for collection of DNA for genetic/epidemiological studies, samples were collected with informed consent from dental patients at the time of dental examination and from several inhouse laboratory staff.

The DNA was isolated with the Qiagen Blood Kit, quantitated by SYBR green fluorescence and characterized by routine and pulsed-field agarose gel electrophoresis. Yields of DNA ranged from 0.6 to 8 micrograms and the size varied from 20 to 40 kb. The DNA was suitable for PCR-based assays such as: (a) the allelic discrimination assay for gender using the amelogenin locus, (b) genotyping with a set of six microsatellite markers and with the chromosome 3 and 22 portions of the ABI mapping panel II recommended for genome scanning, (c) the detection of trinucleotide repeats in the normal range of the Huntington disease locus and (d) long PCR (Calm-1, 5.6 kb).

Because the yields of DNA are very variable and not always sufficient for detailed analyses, three samples, ranging from the lowest to highest yields, were also examined as template for whole genome amplification (WGA) [Zhang *et al., Proc. Natl. Acad. Sci., USA*, **89:** 5847-5851 (1992)] to determine if the available quantities of these samples could be extended. The whole genome amplified product exhibited the same microsatellite profile with the six tetranucleotide repeat microsatellite markers and the panel of dinucleotide repeat markers as the DNA before WGA while these microsatellite markers were not detectable in comparable dilutions of the mouthwash DNA without WGA. These results attest to the utility of DNA isolated from mouthwash samples for genetic studies.

Program Nr: 2265 from the 1999 ASHG Annual Meeting

Cleft lip and palate anomalies in South America. A case-control study of gene-environment interactions targeted on primary prevention. *M. Tolarova[1], L. Pastor[2], S. Tolarova[3], A. Goldberg[4], M. Guinazu[2], T. Mosby[1], M. Pastor[2], J. Mir[1], A. Capozzi[5]*. 1) Prg for Cleft Prevention, Univ California, San Francisco, CA; 2) University of Cuyo,Mendoza, Argentina; 3) Veteran's Hospital, University of Minneapolis, MN; 4) Marin General Hospital, San Rafael, CA; 5) Shreiners Hospital, Sacramento, CA.

Cleft lip and palate anomalies represent a major problem in oral health worldwide.Every two minutes in this world one child with cleft is born-660 every day and 235,000 each year.With a projected population growth of 1.8 million/year, an additional 3,200 cleft children will be born every year in the future unless we invest our scientific knowledge and finances into prevention. At present, 7,500 children with cleft are born every year in the USA and at least 13,000 in South America (SA).In SA, 25-30% of individuals with cleft will never have surgery. With the projected population growth, the numbers of affected individuals will increase dramatically in future years.Our case-control study is focused on identifying genetic and environmental factors that contribute to the high prevalence of clefting in 5 locations in SA.Altogether, data from interviews of mothers of 1334 cases and 981 controls have been collected and blood specimens for genotyping and for blood levels of folates and other vitamins were obtained from chilld-mother pairs.Preliminary results from one location showed a high prevalence of 677C®T mutation of MTHFR gene in cases (18.3%)compared to controls(5.7%),but low plasma and red blood cell levels of folate and a dietary pattern that is lacking sufficient sources of folate in both cases as well as in controls. Other locations, however, showed significant differences between the nutritional pattern of cases and control mothers.Based on these preliminary results we extrapolate that among environmental factors,nutrition will always play an important role.It will be necessary to develop a different preventive aproach based on local data.

This study was initiated by the Program for Prevention of Cleft Lip and Palate/Craniofacial Anomalies, UCSF and supported by Rotaplast Intl., Inc.

Program Nr: 2266 from the 1999 ASHG Annual Meeting

A population-based survey reveals an extremely high FMF carrier frequency in Armenia, suggesting heterozygote advantage. *Y. Torosyan[1], I. Aksentijevich[1], T. Sarkisian[2], V. Astvatsatryan[3], A. Ayvazyan[4], M. Centola[1], J.J. Chae[1], D.L. Kastner[1]*. 1) Dept Arthritis & Rheumatism, NIAMS/NIH, Bethesda, MD; 2) Department of Genetics, Yerevan State University; 3) Department of pediatrics, Yerevan Medical University; 4) Erebuni Medical Center, Yerevan, Armenia.

Familial Mediterranean fever (FMF) is a hereditary inflammatory disease characterized by self-limited recurrent episodes of fever and aseptic serosal and synovial inflammation, mostly occurring in Armenians, Jews, Turks, and Arabs. Some patients also develop systemic AA amyloidosis. Among 201 independent carrier chromosomes from a cohort of 111 affected individuals, 91% were positive for a panel of 13 mutations, and 80.6% carried 1 of 3 common mutations. In a single family a novel R42W mutation was identified. M694V was the most frequent mutation, but M680I (20.4%) and V726A (23.4%) demonstrated comparable levels. Comparisons between the frequencies of these 3 mutations among affected individuals and in the general population suggest that M680I has the highest penetrance. Among the mutations outside of exon 10, where a majority (90.8%) of the identified mutations clustered, F479L (exon5) appears to have the highest penetrance. Analysis of 10 FMF patients with amyloidosis revealed a spectrum of mutations, with M694V most common (55%) but with substantial contributions from other mutations (M680I 30%, V726A 10%, R761H 5%). Unlike all other mutations, P369S (exon 3) was more frequent in controls (9.95% in 392 chromosomes) than among affected individuals (2.0% of 201 alleles), suggesting a possible protective effect. The total carrier frequency (2pq) in Armenia, derived by screening for 9 common MEFV mutations, is about 1:2. Based on the frequencies the 3 high-penetrance exon 10 mutations (M680I, M694V, V726A), the disease frequency may be as high as 1:25. Comparison with a 1993 population-based estimate of 1.13% suggests incomplete penetrance even for these mutations. Nevertheless, these data indicate the highest frequency of MEFV mutations measured to date, and underscore the possibility that some of these mutations may confer an as yet unidentified heterozygote advantage.

.

Program Nr: 2267 from the 1999 ASHG Annual Meeting

Genetic regulation of skeletal maturation from 3 to 15 years. *B. Towne[1], R.M. Siervogel[1], J.S. Parks[2], M.R. Brown[2], A.F. Roche[1], J. Blangero[3].* 1) Wright State University School of Medicine, Dayton, OH; 2) Emory University School of Medicine, Atlanta, GA; 3) Southwest Foundation for Biomedical Research, San Antonio, TX.

We used a multivariate variance components method incorporating parametric correlation functions to model the heritability of skeletal maturity in healthy children aged 3 to 15 years, and the genetic and environmental correlations between skeletal maturity assessed across this age range. A total of 6,893 annual skeletal age (SA) assessments from hand-wrist radiographs, collected since 1932 as part of the Fels Longitudinal Study, from 807 children in 192 kindreds, were simultaneously analyzed. SA was assessed using the FELS method, a maximum likelihood procedure that estimates a child's SA at their current chronological age. Models positing a stable heritability of SA from chronological ages 3 to 15 years, and models positing constant genetic and/or environmental correlations between SAs across this age range, were rejected. The best fitting model had 65 parameters and allowed for an exponential decay in genetic and environmental correlations as a function of chronological age differences. The heritabilities of SA at each chronological age were: 3=0.71, 4=0.73, 5=0.77, 6=0.93, 7=0.78, 8=0.77, 9=0.73, 10=0.63, 11=0.45, 12=0.39, 13=0.34, 14=0.23, and 15=0.11. The genetic correlation matrix showed a pattern of decreasing correlations between SA at different chronological ages as age differences increased (e.g., the correlation between SA at age 3 and SA at age 4 was 0.96, but was 0.56 between SA at age 3 and SA at age 15). The environmental correlation matrix showed a more pronounced pattern of decreasing correlations between SA at different chronological ages as age differences increased (e.g., the correlation between skeletal age at age 3 and skeletal age at age 4 was 0.77, but was 0.12 between skeletal age at age 3 and skeletal age at age 15). These results show a significant heritability of skeletal age through puberty, and suggest that there are developmental stage-specific genetic and environmental influences on skeletal maturation. Supported by NIH grants HD12252, HD31621, MH59490, and HD36342.

Program Nr: 2268 from the 1999 ASHG Annual Meeting

Apolipoprotein E and morbidity in an elderly population. *C.M. Van Duijn[1], A.J.C. Slooter[1], M. Cruts[2], M.M.B. Breteler[1], P.V.T.M. De Jong[1], H.A.P. Pols[1], J.C.M. Witteman[1], C. Van Broeckhoven[2], A. Hofman[1]*. 1) Epidemiology & Biostatistics, Erasmus Univ Medical Sch, Rotterdam DR, Netherlands; 2) Neurogenetics Laboratory, Flanders Interuniversity Institute for Biotechnology, Born-Bunge Foundation, University of Antwerp (UIA), Belgium.

The apolipoprotein E gene (APOE) plays an important role in lipid metabolism. APOE also is a genetic determinant for Alzheimer's disease (AD), an important cause of mortality in the elderly. APOE has been reported to be a gene determining longevity. We studied the impact of the APOE gene on morbidity and mortality in a population-based study of 5290 subjects aged 55 years or older (the Rotterdam Study). Subjects were followed 4.0 years. Up to age 65 years, subjects of the APOE44 genotype had a significantly higher risk of myocardial infarction than carriers of the APOE33 genotype. No effect of APOE was found on the risk of myocardial infarction at old age. The risk of stroke was not significantly related to APOE. Although carriers of the APOE*4 allele were at increased risk of AD, the contribution of APOE*4 to the development of AD at the population level was modest. Each year, an estimated 185 per 100000 individuals aged 55 years or over were estimated to become demented due to carrying the APOE*4 allele. As an association of APOE to longevity would predict a change in allele frequency, we assessed APOE allele frequencies by age. The APOE*4 allele frequency decreased from 0.17 in 55-years old to 0.12 in subjects 90 years or over. The decrease in APOE*4 was to the benefit of APOE*3 because also the frequency of the APOE*2 allele slightly decreased with age. Our findings suggest that the APOE genotype does not play a major role in mortality in the elderly.

Program Nr: 2269 from the 1999 ASHG Annual Meeting

Analysis of the C677T and A1298C mutations of the MTHFR gene as risk factors for spina bifida. *K.A. Volcik[1], S.H. Blanton[2], G.H. Tyerman[3], S.T. Jong[3,4], E.J. Rott[4], R.J. Mier[3], N.K. Romaine[1], H. Northrup[1]*. 1) Div Medical Genetics, Univ Texas Houston Med School, Houston, TX; 2) Dept of Ped, Univ Virginia, Charlottesville, VA; 3) Shriners Hospitals for Children- Houston, Los Angeles and Lexington; 4) Dept of Ped, Baylor College of Medicine, Houston, TX.

The C677T and A1298C mutations in the 5,10-methylenetetrahydrofolate reductase (MTHFR) gene are each associated with reduced MTHFR activity. The C677T mutation in the heterozygous and homozygous state correlates with increased enzyme thermolability, with homozygous mutant genotypes showing significantly elevated plasma homocysteine levels and decreased plasma folate levels. Changes in neither homocysteine nor folate levels are associated with heterozygous or homozygous A1298C variant genotypes. However, there is an interaction between these two variants such that combined heterozygosity for the C677T and A1298C variants results in even lower MTHFR activity than heterozygosity for either of the MTHFR mutations separately, thus resulting in significantly elevated homocysteine and decreased plasma folate levels. Our study determined the frequencies of the C677T and A1298C MTHFR mutations for spina bifida (SB) cases, their parents and controls in two ethnic populations: Hispanics of Mexican-American descent and North American non-Hispanic whites. Our populations were further categorized as to whether the spina bifida lesion occurred as an upper or lower level defect, according to the Van Allen multi-site closure model. Hispanic SB cases with upper level defects and their mothers were homozygous for the C677T variant allele at a significantly higher rate than the Hispanic control population [OR=2.05,p=0.03; OR=2.62,p=0.01, respectively]. Non-Hispanic white SB cases with lower level defects have a greater frequency of the compound heterozygous C677T/A1298C genotype [OR=2.78,p=0.01]. Due to our current findings, we postulate that the C677T MTHFR homozygous mutant genotype is a risk factor for upper level spina bifida defects in Hispanics, while the combined C677T/A1298C heterozygous genotype is a risk factor for lower level spina bifida defects in non-Hispanic whites.

Program Nr: 2270 from the 1999 ASHG Annual Meeting

Familial aggregation of carotid atherosclerosis in sibling pairs with type 2 diabetes. *L.E. Wagenknecht, B.I. Freedman, W. Riley, D.W. Bowden.* Wake Forest Univ Sch of Med, Winston-Salem, NC.

Type 2 diabetes is a major risk factor for atherosclerotic cardiovascular disease. A subclinical measure of atherosclerosis is the intimal medial thickness (IMT) of the common carotid artery (CCA). The role of genetic factors that contribute to CCA IMT is controversial, with heritability of CCA IMT ranging from 10% - 80%. We hypothesize that type 2 diabetes, commonly characterized by obesity and dyslipidemia, accelerates atherosclerosis at a rate dependent, in part, upon genetic factors.

A total of 53 diabetic relatives in 24 families were studied for extent of atherosclerosis (CCA IMT measured by B-mode ultrasound), as well as lipids, blood pressure and other risk factors using a standardized questionnaire. These data were analyzed by univariate and birariate variance components using the SOLAR (Almasy & Blangero) software package. Two strong risk factors (phenotypes) were chosen for the focus of this analysis -- CCA IMT and HDL. In this group of sibships, the mean ($\pm$ se) CCA IMT was 0.663 $\pm$ 0.015 mm and HDL level was 37.5 $\pm$ 1.8; mean age was 59.6 $\pm$ 1.2 yrs, duration of diabetes 9.8 $\pm$ 1.1 yrs, and BMI 32.5 $\pm$ 1.9.

Univariate analyses suggested that CCA IMT was strongly heritable (0.84 $\pm$ 0.36, $p < 0.008$), as was HDL (0.55 $\pm$ 0.39, $p < 0.07$). Using a bivariate analysis of CCA IMT and HDL, the estimated heritability of CCA IMT was 0.71 ($p < 0.001$), of HDL was 0.35 ($p < 0.05$). The genetic correlation between CCA IMT and HDL was 0.15, and the environmental correlation between CCA IMT and HDL was -0.21. These results suggest that strong (but independent) genetic factors contribute to the variance of CCA IMT and HDL, with relatively small contributions to the variance due to measured covariates. In these data, both CCA IMT and HDL are highly heritable in sibling pairs concordant for type 2 diabetes, and may serve as an important feature in designing studies to map genes contributing to atherosclerosis and diabetic macrovascular disease.

Program Nr: 2271 from the 1999 ASHG Annual Meeting

Cloning of primate P450c17 cDNAs from genomic DNA: the molecular evolution of adrenarche. *J.T. Wang, W. Arlt, J.W.M. Martens, W.L. Miller.* Pediatrics, UC San Francisco, San Francisco, CA.

The CYP17 gene encodes a single form of cytochrome P450c17 that catalyzes two distinct, independently post-translationally regulated reactions: 17a-hydroxylation of pregnenolone (preg) or progesterone (prog) to 17OH-preg or 17OH-prog, and 17,20 lyase activity converting 17OH-preg to dehydroepiandrosterone (DHEA). Children produce very little DHEA, but at adrenarche at age 7-10 years DHEA production increases reaching maximum levels at 25-35 years which then wane slowly to childhood levels at > 70 years. The chimpanzee and gorilla have similar developmental DHEA patterns, but other primates including the rhesus monkey and baboon show a continuous high secretion of DHEA throughout life. To identify sequences important for post-translational regulation of human 17,20-lyase activity, we cloned and sequenced the P450c17 genes and cDNAs from rhesus monkey, baboon, and chimpanzee and compared them to our previously cloned human sequences. The rhesus cDNA was cloned by RT-PCR of adrenal RNA, but baboon and chimp adrenals were not available. Therefore, we used human oligos to amplify the full-length 6.5 kb chimp and baboon genes from leukocyte DNA and subcloned these into CMV-based pcDNA3 vector, and expressed these in COS-1 cells. The chimp and baboon P450c17 cDNAs were then PCR-amplified from the transfected cells; their sequences were correctly spliced and were identical to the sequences of each exon determined by PCR from the original genomic DNA. The human sequence was 99.2% identical to chimp, 96.5% identical to baboon and 96.1% to rhesus. Of 29 non-identical amino acids across the four species, 19 were differences between the higher (human, chimp) and the lower (baboon, rhesus) primates. These 19 amino acids included 3 Thr and 3 Ser residues in the higher primates, but only 2 Thr and one Ser in the lower primates. This may influence the Ser/Thr phosphorylation of P450c17 that is required for human 17,20-lyase activity (PNAS 92: 10619). Thus the sequence identities among these four species of P450c17 correlate well with the presence of adrenarche.

Program Nr: 2272 from the 1999 ASHG Annual Meeting

Lack of association between the a**2-macroglobulin polymorphism and Alzheimer's disease.** *X. Wang*[1], *S.T. DeKosky*[1,2], *M.I. Kamboh*[1,2]. 1) Department of Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Deparment of Psychiatry, Univ Pittsburgh, Pittsburgh, PA.

Alzheimer's disease (AD) is a complex and multifactorial disease involving many genetic and environmental factors. Among the genetic factors, the apolipoprotein E (APOE) gene has been identified as a susceptibility gene for AD. In addition, a2-macroglobulin (A2M) has been implicated in pathogenesis of AD. A2M is upregulated in brain during injury. In AD patients, A2M has been localized immunochemically to senile plaques. *In vitro*, A2M binds to and attenuates the propensity of Ab peptide to form neurotoxic fibrils. Recent association studies indicate the potential involvement of A2M in affecting the risk of AD. However, unlike APOE, this association has not been well established. This study was undertaken to investigate the role of the A2M intronic 5-bp deletion polymorphism in the development of AD and to define the interaction between APOE and A2M. The A2M polymorphism was screened using a PCR based assay in 567 white cases of late-onset AD cases and 319 controls. The distributions of A2M genotype (p=0.35) and allele (p=0.68) frequencies were comparable between cases and controls. Although the frequency of the A2M/DD genotype was higher in cases than controls, the difference was not statistically significant (3.6% vs. 1.9%; p=0.16). When we divided our data by *APOE*4* status, no significant difference was found between cases and controls either. Logistic regression analysis did not reveal any significant interaction between the APOE and A2M genes in affecting the risk of AD (p=0.19). In conclusion, our study indicates that there is no association between the intronic polymorphism of A2M and AD.

Program Nr: 2273 from the 1999 ASHG Annual Meeting

Increased prevalence of chronic rhinosinusitis in CF mutation carriers. *X.J. Wang, G.R. Cutting.* Institute of Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD.

Chronic rhinosinusitis is one of the most prevalent of the chronic diseases, affecting about 15% of the U.S. population. It is an almost invariable feature of Cystic Fibrosis (CF). To evaluate whether CFTR plays a role in isolated rhinosinusitis in the general population, we initiated a CFTR gene mutation analysis in the patients with chronic rhinosinusitis. Screening of 147 Caucasian patients identified 11 patients with a CF mutation. Nine had the common mutation, DF508, one had G542X, and one had N1303K. Two DF508 carriers were identified in the 123 Caucasian controls. DGGE and sequencing of each CFTR coding region revealed that one of the eleven patients carried a second CF mutation (2789+5G®A). Sweat chloride testing and nasal potential difference (NPD) measurement indicated that only the patient with 2 CF mutations had CF. Ten CF mutation carriers among 146 patients (7%) is significantly higher than the rate in the control group (P=0.03 fisher exact). If 7% of chronic rhinosinusitis patients are carriers of a CF mutation, we estimate that about one third of CF carriers in Caucasians should have chronic rhinosinusitis. To evaluate this hypothesis, we surveyed the parents of CF patients who are obligate CF mutation carriers in 2 stages. In the first step, we asked participants whether they ever had rhinosinusitis, and, if so, the frequency and duration. Among 190 responses, 60% reported positively and 19% of the responses met established criteria for the chronic rhinosinusitis. As a control, we asked participants whether they ever had back pain. Chronic back pain has a prevalence of 18% in U.S. adults. Among 190 responses, 69% reported positively but only 13% met criteria for chronic back pain. In the second phase, a detailed questionnaire for historical evidence of chronic rhinosinusitis was sent to every participant. In 122 returns, 46 (38%) met the diagnostic criteria for chronic rhinosinusitis. The 38% chronic rhinosinusitis rate in CF carriers was significantly higher than the 15% prevalence in the U.S. population ($P=1 \times 10^{-4}$, c^2 test). Carrying a single CF mutation is a risk factor for the development of chronic rhinosinusitis.

Program Nr: 2274 from the 1999 ASHG Annual Meeting

Frequency analysis of autosomal dominant cerebellar ataxias at Ibaraki prefecture in Japan. *M. Watanabe[1], M. Kanemoto[4], N. Ohkoshi[1], A. Tamaoka[1], A. Hayashi[1], T. Yoshizawa[1], A. Mochizuki[1], H. Yoshida[1], S. Matsuno[1], K. Ishikawa[2], H. Miura[3], S. Shoji[1]*. 1) Neurology/Inst Clinical Sci, Tsukuba Univ, Tsukuba, Japan; 2) Neurology/Tokyo Medical and Dental Univ, Tokyo, Japan; 3) 5th department of Internal Medicine/Tokyo Medical Univ, Ibaraki, Japan; 4) School of Medicine/Tsukuba Univ, Tsukuba, Japan.

Purpose : To obtain a estimate of the relative frequency of spinocerebellar ataxia (SCA) type 1, 2, 3, 6, 7, 8, and DRPLA among ataxia families at Ibaraki prefecture in Japan. Materials and methods : Thirty two unrelated kindreds with ADCA were available for frequency analysis of ADCAs. Genomic DNA was extracted from peripheral blood samples of these ADCA patients with informed consent. Polymerase chain reaction amplification of the CAG repeat was performed using FITC labelled gene specific primer sets. PCR products were separated by electrophoresis with an autoread sequencer (ALFII, Pharmacia), and their sizes were determined using the associated software (Fragment Manager, Pharmacia). In the case of ADCA type III, ADCA type I, and progressive myoclonus epilepsy, we checked SCA6, SCA3, and DRPLA mutation for the first place respectively. Then we screened sequentially for the SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, and DRPLA CAG (CTG for SCA8) expansion until an expansion at one of these ataxia loci was identified in the proband. Results : Among the 32 dominant kindreds, we found SCA6 expansion at a frequency of 45%, SCA3(MJD) expansion at a frequency of 34%, SCA2 at a frequency of 9%, and DRPLA at a frequency of 6%. No patients in our population tested were positive for SCA1, SCA7, and SCA8. SCA6 presented with predominantly cerebellar syndrome and patients often had onset after 40 years of age. SCA3(MJD) patients frequently developed ophthalmoplegia, spasticity, dystonia, and muscular atrophy, apart from ataxia. In SCA6 and SCA3(MJD), the CAG repeat lengths correlated inversely with age at onset. Conclusion : SCA6 is most prevalent in our population, while SCA3(MJD) is most prevalent in the other area of Japan.

.

Program Nr: 2275 from the 1999 ASHG Annual Meeting

Sequence polymorphism and divergence in the human b-**globin gene cluster.** *M.T. Webster, R.M. Harding, J.B. Clegg.* MRC Molecular Haematology Unit, Institute of Molecular Medicine, John Radcliffe Hospital, Headington, Oxford, OX3 9DS, UK.

In an extension of our analyses of variability in the b-globin gene, we have examined levels of DNA sequence diversity and human/chimp divergence in 3 further loci within the human b-globin gene cluster, using samples from a Kenyan population. These loci lie within a 12.3 kb region 5' to the b-globin gene, separated from it by a hotspot of recombination. In order of increasing distance from the hotspot (3' to 5') they are the d-globin gene, a 3 kb intergenic region (known as the R/T) and the b-globin pseudogene. The d-globin gene is a functional adult globin gene, expressed at relatively low levels, the R/T region has no known function and the pseudogene is thought to have been inactivated early in primate evolution. These 3 loci each show the same levels of divergence between human and chimp, consistent with the b-globin gene, situated on the other side of a recombination hotspot, and also with average divergence for autosomes. Nucleotide polymorphism, measured as the number of segregating sites in our sample of 46 chromosomes, is also evenly apportioned among loci. Contrary to neutral expectations, neither levels of divergence nor diversity are greater in the b-globin pseudogene compared with the b-globin gene. One striking anomaly becomes apparent when we compare the 3 loci for nucleotide diversity measured as heterozygosity (i.e. from average pairwise sequence difference). Compared with the b-globin gene and pseudogene, nucleotide heterozygosity is reduced in d-globin and substantially higher in the R/T region. These patterns in the heterozygosity indicate differences in haplotype structure among loci and are consistent with the presence of two highly divergent alleles at the R/T locus in human populations (observed by Maeda *et al.* in 1983). By comparison, the b-globin pseudogene has several related haplotypes and the d-globin locus has a single major allele. These data imply that linkage disequilibrium varies greatly within the b-globin gene complex as a consequence of the evolutionary interplay of recombination, mutation and genetic drift.

Program Nr: 2276 from the 1999 ASHG Annual Meeting

Haplotype based diagnosis of 3-Methylglutaconic aciduria type 3 (Costeff syndrome). *Y. Weigl[1], E. Gak[1], D. Lev[2,3], L. Peleg[1,3], B. Goldman[1,3], M. Frydman[1,3].* 1) Medical Genetics, Danek Gertner Institute, Tel Hashomer, Israel; 2) Medical Genetics, Wolfsaon Hospital Holon; 3) Sackler School of Medicine, Tel Aviv University, Israel.

Costeff syndrome is an autosomal recessive condition characterized by infantile optic atrophy, an early onset, spastic paraplegia, mild ataxia, mild cognitive deficiency, dysarthria and 3-methylglutaconic aciduria. Recently linkage disequilibrium with the myotonic dystrophy protein kinase gene on 19q was reported in Iraqi Jews (Nystuen et al, Hum Mol Genet 1997 6:563-9). Microsatellites ERRC2CA6 and D15S908 are tightly linked to the disease locus, and allele # 1 of both microsatellites is in full linkage disequilibrium with the mutation. Using these microsatellites we studied 6 families at risk and 37 unselected and unrelated individuals of Iraqi Jewish origin. None of the 74 chromosomes of unrelated individuals carried allele 1 of markers ERRC2CA6 and D15S908. In addition 10 normal chromosomes of obligatory carries and 4 chromosomes of distant relatives were studied and were not carrying allele # 1 in either locus. In one mating of a disease haplotype carrier and his unrelated spouse, a healthy offspring, homozygous to allele # 1 at both loci was found. This individual either carries the background haplotype or an historic recombinant haplotype. In the 6 families reported by Nystuen et al, 13 normal chromosomes were found, neither carrying a disease associated allele at the two loci we studied. The prevalence of the disease haplotype in the Iraqi Jewish population is < 1/74. The prevalence of the background haplotype is 1/ 113. With a prevalence of < 0.01 for either allele, the prevalence of the haplotype should be < 0.0001. Thus, the detection of this haplotype in an individual of Iraqi origin is almost certainly an indication that this individual carries a 3MGA mutation. In the 6 families at risk, all the affected individuals were homozygotes to the 1-1 haplotype. Two singelton and one twin pregnancies were monitored. 3 fetuse were heterozygote carriers and one a homozygote normal.

Program Nr: 2277 from the 1999 ASHG Annual Meeting

Association of the interleukin-1 receptor antagonist IL1RN*1 allele with systemic lupus erythematosus (SLE) clinical phenotypes. *A. Weinreb[1,2], J.M. Grossman[2], R.M. Cantor[3], N. Theophilov[2], D.J. Wallace[4], B.H. Hahn[2], B.P. Tsao[2]*. 1) Division of Rheumatology, VA GLAHS, Los Angeles, CA; 2) Division of Rheumatology,UCLA, Los Angeles, CA; 3) Division of Human Genetics, UCLA, Los Angeles, CA; 4) Cedars-Sinai Medical Center, Los Angeles, CA.

SLE is a complex autoimmune inflammatory disease characterized by autoantibody production in which multiple genetic and environmental factors contribute to its pathogenesis. Interleukin-1 receptor antagonist (IL1RN), a competitive inhibitor of interleukin-1 (IL-1) that downregulates inflammation, may contribute both to SLE susceptibility and severity. The IL1RN*1 allele has previously been associated with SLE susceptibility and severity in both English and Swedish cohorts. We tested SLE clinical phenotypes in a North-American Caucasian cohort of 72 unrelated individuals for associations with IL1RN alleles. The SLE clinical phenotypes tested included malar rash, discoid rash, serositis, nephritis, hematologic abnormalities (hemolytic anemia, leukopenia/lymphopenia, and/or thrombocytopenia), neurologic abnormalities (seizures and psychoses), and vasculitis. Alleles at this locus were not associated with SLE itself. However, the distribution of the IL1RN allele frequencies in SLE patients with neurologic abnormalities differed from SLE patients with none ($p=0.021$ by Fisher's Exact Test). The distribution of IL1RN allele frequencies in SLE patients with hematologic abnormalities also differed from SLE patients with none ($p=0.001$), which was significant after a correction for multiple testing. In particular, the IL1RN1 allele frequency was increased in those with hematologic abnormalities (0.74 vs. 0.46, $p<0.001$). SLE patients with hematologic abnormalities had a significantly increased IL1RN*1 homozygote frequency compared to those patients with none (0.50 vs. 0.12, $p=0.001$). Stratification of SLE clinical phenotypes has identified a novel association of the IL1RN*1 allele with hematologic abnormalities, suggesting that the IL1RN gene functions as an SLE disease-modifier in this North-American Caucasian SLE cohort.

Program Nr: 2278 from the 1999 ASHG Annual Meeting

Cardiovascular risk factors in stroke cases, stroke family history positive, and stroke family history negative siblings: The HyperGEN Study. *J.B. Wilk[1], R.C. Ellison[1], D.K. Arnett[2], S.C. Hunt[3], S.S. Rich[4], Y. Hong[5], R.H. Myers[1]*. 1) Boston University School of Medicine, Boston, MA; 2) University of Minnesota School of Public Health, Minneapolis, MN; 3) University of Utah, Salt Lake City, UT; 4) Wake Forest University School of Medicine, Winston-Salem, NC; 5) Washington University, St. Louis, MO.

The goal of this study was to examine the differences in cardiovascular risk factors among three groups defined by their personal and family history of stroke. The participants were part of the HyperGEN study, a cohort of sibships ascertained for two or more hypertensive siblings, supported as part of the NHLBI Family Blood Pressure Program. The three groups compared were 1) (FamHx-) no family history and no diagnosis of stroke or transient ischemic attack (TIA); 2) (FamHx+) a family history of stroke or TIA, but no diagnosis of stroke or TIA; and 3) (stroke) any diagnosis of stroke or TIA. Mean levels of total cholesterol, high density lipoprotein (HDL) cholesterol, triglycerides (TG), glucose, and uric acid were calculated for the three groups stratified on gender. Adjusted group means were also calculated separately for men and women to account for correlated observations between siblings and the effect of age, BMI (kg/m^2), alcohol use (yes/no), and physical activity (per week). Adjusted TG levels were significantly different in the three groups for both men and women. TGs increased from the lowest levels in the FamHx- group (men: 150 mg/dl, women: 131 mg/dl), intermediate levels associated with FamHx+ (166 mg/dl, 147 mg/dl), and the greatest levels associated with stroke (177 mg/dl, 158 mg/dl). For mean total cholesterol and glucose, the stroke group had significantly higher levels, and the mean levels in the FamHx- and FamHx+ groups were not significantly different. The stroke group had significantly lower adjusted mean HDL cholesterol levels, and HDL levels in the FamHx- and FamHx+ groups were not significantly different. Mean adjusted uric acid levels did not vary significantly across the three groups. These results suggest that a family history of stroke is associated with elevated TG levels in families with hypertensive siblings.

Program Nr: 2279 from the 1999 ASHG Annual Meeting

Multilocus SNP disequilibrium is associated with hypertension in a Ghanaian population. *S.M. Williams[1], J.H. Addy[2], J.A. Phillps III[3], M. Murray[1], L.-J. Wong[4], P.A. Jose[4], R.A. Felder[5]*. 1) Meharry Med Col, Nashville, TN; 2) Univ Ghana Med Sch; 3) Vanderbilt Univ Sch Med; 4) Georgetown Univ; 5) Univ Virginia.

Hypertension (HT) has been associated with SNPs or other mutations in components of the renin-angiotensin system (e.g., ACE, angiotensin-I-converting enzyme, AGT, angiotensinogen and AT1R, angiotensin II type I receptor) in separate studies of various populations. We hypothesized that multiple, non-allelic interactions at these loci might show stronger associations with HT than do separate alleles. A total of 126 HT and 51 non HT Ghanaian subjects were ascertained, phenotyped and their DNAs genotyped for the ACE ins/del, AGT T174M and M235T and AT1R A1166C alleles. Multilocus Hardy-Weinberg (H-W) analyses were performed to detect genetic associations between 2-4 of these loci. The ACE gene ins/del and the AT1R alleles were in H-W disequilibrium in the HT but not the non HT class ($p=0.01$ and 0.04, respectively). ACE genotypes showed an excess of heterozygotes ($f=-0.22$), while AT1R genotypes had a deficiency of heterozygotes ($f=0.39$) in the HT class. The AGT alleles showed no differences individually. However, significant multilocus interactions were observed in HTs in 2/11 multilocus comparisons, both involving AGT alleles: M235T and ACE ($p=0.02$) and T174M and AT1R ($p=0.02$). No significant differences were detected between the HT and non HT classes in allele or genotype frequencies at any locus and no significant deviations from H-W equilibrium were observed in the non HT class. Three SNPs at an additional, unreported locus exhibited even stronger disequilibrium. In summary: 17 of 120 (14%) possible multilocus comparisons across all 7 sites showed significant interactions ($p<0.05$) and 8 other comparisons had $0.05<p<0.10$ in the HT class, but no interactions with $p<0.24$ were observed in the non HT class. Our data indicate that a large number of multilocus comparisons showed significant linkage disequilibrium in the HT but not in the non HT classes. We infer that non-allelic interactions may be associated with HT and that multilocus SNP disequilibrium analysis may be useful in studies of the cause(s) of HT and other complex human diseases.

Program Nr: 2280 from the 1999 ASHG Annual Meeting

Population genetic inferences from nucleotide-sequence variation in human a **chain of the interleukin-4 receptor (*IL4RA*).** *X. Wu[1,2], A. Di Rienzo[1], M.S. McPeek[2], C. Ober[1].* 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Department of Statistics, The University of Chicago, Chicago, IL.

Variants in the *IL4RA* gene have been associated with asthma and allergy in ethnically diverse populations, including inbred Hutterites, outbred Caucasians, African Americans, Hispanic and Japanese. Here we report the initial results of a population genetic study of *IL4RA* variants in healthy individuals (72 chromosomes) from three ethnic groups: African Americans (24), Caucasians (24), and East Asians (24). A 3-kb region, including part of intron 8, entire exon 9, and the 3'UTR was sequenced. The sequence has a total of 23 polymorphic sites, including two new nonsynonymous substitutions, yielding a nucleotide diversity of 0.0018. Tajima's D was calculated to determine if the variants in this region are selectively neutral. The overall Tajima's D (0.42107) is not significant ($P > 0.1$), however D is positive (1.03352) for African Americans but negative for Caucasians (-0.50695) and East Asians (-0.73624), perhaps reflecting the different selective pressures in these populations. Comparisons between human and chimp yielded a total of 25 fixed differences in this region. The HKA Test was used to test for homogeneity of the evolutionary forces acting on different portion of the sequenced region. The result was not significant ($P = 0.7$), indicating that the evolution of the sequences in the intron, exon 9, and 3'UTR does not differ measurably. To further test the neutral hypothesis, we compared the divergence and polymorphism levels of nonsynonymous versus synonymous substitutions using the McDonald-Kreitman Test. There were 9 nonsynonymous and 4 synonymous sites in exon 9 in the human samples, whereas there were 8 nonsynonymous and 6 synonymous sites between human and chimpanzee (Fisher's exact test, $P = 0.69$). Although the test is not significant based on this data set, the high ratio of nonsynonymous to synonymous changes (2.25) may suggest that natural selection operated on this gene. Furthermore, this study further documents the presence of extensive variation in genes associated with common diseases. (Supported by NIH grants HL 49596, HL 56399 and NSF grant GIG DMS 97-09696).

Program Nr: 2281 from the 1999 ASHG Annual Meeting

Genetic Relationships of 15 Southeast Asian populations: mtDNA evidence. *C. Xiao[1,2], B. Su[2], M. Seielstad[3], E. Kangwanpong[4], H. Xiao[1], B. Wen[1], L. Jin[2].* 1) Department of Biology, Yunnan University, Kunming, Yunnan, China; 2) Human Genetics Center, University of Texas - Houston, Houston, TX; 3) Program for Population Genetics, Harvard School of Public Health, Boston, MA; 4) Department of Biology, Chiang Mai University, Chiang Mai, Thailand.

Sino-Tibetan, Hmong-Mien, and Austro-Asiatic are the major language families spoken in mainland Southeast Asia. In this study, we sampled 15 populations (6 Sino-Tibetan, 4 Hmong-Mien, and 5 Austro-Asiatic, 363 individuals in total) from China, Thailand and Vietnam in order to investigate the genetic relationships of those populations. Our results showed that the frequencies of mitochondrial DNA 9bp deletions vary drastically among different populations, ranging from 0 to 41.5%, and populations in the same language family tend to share similar 9bp-del frequencies, implying the concordance between the linguistic and genetic relationship in this area. In addition, we also sequenced the two highly variable segments (HVS-I and HVS-II) in the control region of individuals with the 9-bp deletion (70 samples). The so-called Polynesian motif (16217C, 16247G and 16261T), which was found exclusively in Polynesian populations, was not found in our samples. However, the intermediate ancestral haplotype (16217C, 16247A and 16261T) of the Polynesian motif were found in several populations, especially in Yao populations residing both in mainland China and in Thailand (23.1% in average). This observation makes Southeast Asia another possible homeland of the origin of pro-Polynesian people and therefore challenges the validity of the Taiwan homeland hypothesis on Polynesian origin.

Program Nr: 2282 from the 1999 ASHG Annual Meeting

High frequency of the FMR-1 INV10+14c/t polymorphism in Asians, and its association with the Fragile X Syndrome in Caucasians. *B. Xu[1,2], J.M. Schoof[2], N.E. Buroker[1], C.R. Scott[1,2], S.-H. Chen[1,2]*. 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Children's Hospital & Regional Medical Center, Seattle, WA.

Expansion of the CGG repeats in the FMR 1 gene is responsible for the fragile X syndrome. We have investigated an FMR I intragenic polymorphic site (IVS10+14c/t) in Asian, Caucasian and African-American populations in Seattle. A pair of primers (IVS10F: 5'-AGAAGAGGTATGTTACAGCG and IVS10R: 5'-ACTGCATTAGAGGACAGAGA) were synthesized and used for amplifying a fragment of DNA (187 bps) of intron 10 to target a BstU I (5'CGCG) recognition site. The PCR product of IVS10+14c was digested by the enzyme and generated two fragments of 167 and 20 bps. The enzyme did not digest IVS10+14t. We genotyped a total of 779 normal chromosomes for the polymorphism in 312 Asians, 208 Caucasians, and 159 African-Americans. The frequency of IVS10+14t in the Asians was 63.78%, higher than the frequency found in Caucasian (9.13%) and African-American (10.69%) samples. The high frequency of the polymorphism in the Asian population indicates this site is a useful marker for genetic analysis; but contrary to what has been suggested by others, it is unlikely to be a determining factor for fragile X syndrome in Asians. Analysis of the IVS10+14 polymorphic site in 50 Caucasian fragile X chromosomes showed that 4 were IVS10+14t. The chi-square test (x2) for these data was 0.13, with a p-value of >>0.05. This value was not different from the one predicted by random association in the Caucasian population. By contrast, tests of two other closely linked markers (DXS548 and FRAXAC1) showed that the fragile X chromosomes were associated with specific haplotypes.

Program Nr: 2283 from the 1999 ASHG Annual Meeting

Association of a polymorphism in the gene for MMP13 with atherosclerosis. *S. Yoon[1], G. Tromp[1], J. Olson[3], G. Malcom[4], J. Strong[4], H. Kuivaniemi[1,2].* 1) Center for Molecular Medicine and Genetics,Wayne State University School of Medicine, Detroit, MI; 2) Department of Surgery, Wayne State University School of Medicine, Detroit, MI; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio; 4) Department of Pathology, Louisiana State University Medical Center, New Orleans, LA.

Atherosclerosis causes more than 700,000 deaths per year from myocardial infarction and stroke in the USA. It is therefore the leading cause of death, accounting for 50% of all mortality. Atherosclerosis progresses through three stages: fatty streak, fibrous plaque, and complex lesion. Transition from fatty streak to other stages involves an inflammatory fibro-proliferative response that is accompanied by tissue remodeling. Several members of the matrix metalloproteinase (MMP) family, major extracellular matrix degrading enzymes, are highly expressed in atherosclerotic lesions. We identified a polymorphism of either 11 or 12 As at nt -291 in the MMP13 promoter. It is located upstream of an AP-1 binding site and spans sequences with similarity to consensus sequences for nuclear factors HFH-2 and Hb. We tested for association between the polymorphism and atherosclerosis in a subsample of the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) collection because of the unbiased collection and thorough pathological evaluation of atherosclerosis. The PDAY study was a multicenter autopsy study that examined risk factors for coronary artery disease, including smoking, hypertension, diabetes, and lipid profiles. DNA for genotyping was isolated from frozen liver specimens. We analyzed the MMP13 genotypes from 193 individuals with fibrous plaque and 268 without. Our logistic regression model included age, sex, race, and their interactions and yielded a p-value of 0.18, which was within our liberal criterion for a first stage of screening. Subgroup analyses, controlling for age, showed that the effect is almost exclusively due to black males, p-value < 0.01. Supported by a grant from American Heart Association-MI affiliate.

Program Nr: 2284 from the 1999 ASHG Annual Meeting

Statistical Methods for Examining Association Between Recombination and Non-disjunction. *K. Yu*[1], *E. Feingold*[2]. 1) Biostatistics, University of Pittsburgh, Pittsburgh, PA; 2) Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Recent studies have found an association between altered recombination and meiotic non-disjunction leading to trisomy. Attempts to better understand this association have included using recombination data to estimate frequencies of various patterns of exchange on the tetrad, in order to see which particular exchange patterns are associated with non-disjunction. These studies have been somewhat hampered by limitations in the available statistical methods. We have developed improved statistical methods for this type of analysis based on the E-M algorithm and the bootstrap. Our methods allow better parameter estimation, including confidence intervals, and also allow statistical hypothesis testing. We have applied our methods to several published datasets, and compared our results with those in the original papers. For the most part the conclusions reached by previous methods stand up under more rigorous statistical examination, but there are some exceptions.

Program Nr: 2285 from the 1999 ASHG Annual Meeting

Molecular studies in a sample of Iranian phenylketonuria patients. *N. Zarrin-Khameh, S.M. Hosseini-Mazinani, J. Koochmeshgi, N. Hosein Pur.* Molecular Genetics, National Research Center for Genetic Engineering and Biotechnology, Tehran, Iran.

Phenylketonuria (PKU) is the most common error of amino acid metabolism. This autosomal recessive disorder is caused by a large variety of mutations in the phenylalanine hydroxylase (PAH) gene. To date, more than 300 different mutations in the PAH gene have been identified in patients from various ethnic groups. These mutations exhibit a high degree of association with specific RFLP and VNTR haplotypes in different populations. The study of PAH mutations in diverse populations contributes to our knowledge about population, history, and genetic variation in this locus. In a preliminary study of the PAH mutations in Iran , 10 unrelated Iranian classical PKU patients were screened for 5 known mutations: R261Q, R261X, R408Q, R408W, and IVS10nt546. The R261X mutation was observed in one patient and the IVS10nt546 mutation in two patients.All three were homozygous for the mutations. The R261X mutation involves a CpG doublet and has been found in Caucasians and East Asians but in association with different haplotypes. IVS10nt546, a splice junction mutation strongly associated with RFLP haplotype 6, is the most prevalent mutation in the PAH gene causing phenylketonuria in Mediterranean populations. It accounts for about 40% of mutant alleles in Iran's neighboring country, Turkey. Various and alternative hypotheses have been proposed concerning the geographical origin and pattern of diffusion of this mutation in this region of the world. Continued mutation screening and haplotyping in Iran will contribute to resolving this and other problems in the population genetics of phenylketonuria.

Program Nr: 2286 from the 1999 ASHG Annual Meeting

Effects of Cancer Chemotherapy on Frequencies of Minisatellite Mutations in Human Sperm. *N. Zheng[1,2], D.G. Monckton[1], G. Wilson[1], L. Ramagli[1], M.J. Siciliano[1], M.L. Meistrich[1].* 1) M.D. Anderson Cancer Center, Houston, TX; 2) Univ. Texas School of Public Health, Houston, TX.

Minisatellite repeat number changes have been proposed to be sensitive biomarkers for mutagenic effects of radiation and genotoxic chemicals in the human germ line. To test this hypothesis, we analyzed the frequencies of length change mutations at the MS205 locus in human sperm using small-pool PCR, with which we can screen 8000 sperm per sample and detect mutations in individual sperm. Sperm were obtained from patients before, during, and after cancer chemotherapy. Previously we showed that the mutation frequency after chemotherapy with, NOVP, which lacks alkylating agents, was the same as before treatment indicating no induction of mutations in stem spermatogonia. In the present study we measured the frequencies of mutations induced in primary spermatocytes by collecting sperm during chemotherapy. The results from three Hodgkin's disease patients treated with either NOVP or ABVD, another regimen that lacks alkylating agents with high testicular toxicity, indicated that repeat number mutation frequencies at MS205 during chemotherapy were identical to baseline values (before or after treatment). To analyze the effects of more highly mutagenic agents, sperm were obtained from three patients 9 to 15 years after MOPP or CVPP-ABDIC chemotherapy, which contain strong alkylating agents. The MS205 mutation frequencies in the two patients who received CVPP-ABDIC (3 to 4 cycles of each) were identical before and after chemotherapy. However the patient receiving 6 cycles of MOPP chemotherapy had a significantly higher repeat number mutation frequency of 1.14% at 15 years after treatment, compared to 0.79% before chemotherapy. Thus very high doses of alkylating agents can induce a significant increase in repeat number mutation frequencies at minisatellite loci but the increase at MS205 was not very large. From these data we conclude that either MS205 is not a very sensitive locus, or that repeat number changes at minisatellite loci are not sensitive indicators for detecting mutagenic changes, or that chemotherapy does not induce many DNA sequence mutations in germ cells.

Program Nr: 2287 from the 1999 ASHG Annual Meeting

Candidate Gene Loci for Endogenous Sex Steroid Hormones. *J.M. Zmuda, J.A. Cauley, L.H. Kuller, M.M. Johns, X. Zhang, M. Lee, R.E. Ferrell.* University of Pittsburgh, Pittsburgh, PA.

Endogenous sex steroid hormones may have a prominent role in the etiology of several age-related diseases in men including atherosclerosis, osteoporosis, and prostate cancer. A familial influence on sex steroid hormone levels has been demonstrated, but the specific genes and allelic variants contributing to their interindividual variation have not been defined. Thus, we quantified the association between allelic variation at four sex steroid metabolism genes and fasting levels of bioavailable testosterone (BT) and estradiol (BE) in 279 community-dwelling men aged 58-91 years who were not taking drugs known to affect sex steroid hormone metabolism. Unlinked marker loci at genes encoding the androgen receptor (*AR*; CAG repeat in exon 1), estrogen receptor alpha (*ESRA*; A®G in intron 1), cytochrome P450c17a (*CYP17*; T®C at position -34 bp), and aromatase (*CYP19*; Arg264Cys) were studied. Observed genotype frequencies did not deviate significantly from Hardy-Weinberg expectations. Hormone levels were adjusted for age and body mass index using multiple regression. Mean BT was 123±45 ng/dl and mean BE was 14.1±5.1 pg/ml. BT increased by 5.4% per copy of the *CYP17*C* and *ESRA*A* alleles ($p<.05$ for both), and by 1.0% per 6 CAG repeats in *AR* ($p=.01$). BT was 21.0% lower in carriers than non-carriers of the Arg264Cys mutation in *CYP19* ($p=.005$). BE increased by 1.1% per 6 CAG repeats in *AR* ($p=.01$) and was 18.5% lower in carriers of the Arg264Cys mutation in *CYP19* ($p=.03$). Candidate gene loci collectively explained 6.2% of the variance in BT and 3.8% of the variance in BE levels. We conclude that marker alleles at key sex steroid metabolic loci are significantly associated with circulating androgen and estrogen levels in older men. Additional studies are needed to determine the contributions of these marker loci to the risk of androgen and estrogen dependent disease.

Program Nr: 2288 from the 1999 ASHG Annual Meeting

Interpretation of molecular diagnostic testing in facioscapulohumeral muscular dystrophy (FSHD). *P.W. Lunt[1], A. Stephenson[2], L. Middleton[2], L.A. Tyfield[2].* 1) Clin Genet, Inst Child Hlth, Bristol Childrens Hosp; 2) Mol Genet, Southmead Hosp, Bristol, UK.

In offering a molecular diagnostic service for FSHD, DNA samples are received for exclusion of diagnosis as well as for confirmation. In the absence of any known affected gene product, diagnostic testing will for the foreseeable future be based on identifying a shortened array of 3.3kb repeats at 4q35 on one copy of chromosome 4. Distinction from the two copies of the homologous repeat array at 10q26 cannot yet be achieved with certainty owing to polymorphic exchange between these repeat arrays, thereby resulting in a lower sensitivity than specificity of testing, and lower confidence for exclusion than for confirmation of diagnosis. Use of pulse field gel electrophoresis (PFGE), or of a recently developed fragment-type dosage test, can determine the ratio of Bln-resistant : Bln-sensitive repeat arrays. Published data suggests 20% of the population are polymorphic for the exchange, with 19% of controls and 90% of FSHD having a fragment <32kb, and with hybrid repeats or deletion of p13E-11 hybridisation site found in 1-2% of cases. Based on this we present a table of likelihood for a D4F104S1 fragment to be associated with FSHD or not, according to its size, Bln-sensitivity, and ratio of Bln-resistant : Bln-sensitive fragments present. Meaningful interpretation of a molecular test result can then be achieved by combining this likelihood figure in Bayes calculation with an estimate of the prior likelihood for the subject to have FSHD. For this it is essential to have adequate clinical information, and close liaison with a clinician expert in FSHD.

For example: Bln-sensitive (E) fragments <32kb are predicted in 4.7%of FSHD and 19% of controls. With this a fragment ratio of 1 Bln-resistant(EB):2-3 Bln-sensitive (E) fragments gives a likelihood ratio (LR) for FSHD:control of 2:1, whereas a reverse fragment ratio of 2-3EB:1E would give LR of 1:60. A 2EB:2E fragment ratio would give a LR of 1:30. For a 32-38 kb Bln-resistant fragment, the same fragment ratios as above would give LRs of 80:1, 1:2 and 40:1 respectively.

Program Nr: 2289 from the 1999 ASHG Annual Meeting

Detection of a *de novo* mutation using the STR 44 marker in a Duchenne muscular dystrophy family. *M. Maheshwari, M. Kabra, S.S. Shastri, S. Arora, P.S.N. Menon.* Genetics Unit, Dept.Of Pediatrics, All India Institute Of Medical Sciences, New Delhi 110029, India.

Duchenne muscular dystrophy (DMD) is an X-linked recessive genetic disorder characterized by progressive muscle weakness. It affects about one in 3500 males. The female relatives of affected boys are at risk of carrying the disease allele. Since females have two X chromosomes, detection of the carrier status by deletion screening of mutant allele poses a problem due to the presence of one normal X chromosome which masks the effect of the other chromosome. Short tandem repeat polymorphic markers play an important role in carrier testing and detection of *de novo* mutations as they are inherited in Mendelian fashion. It is possible to identify the females at risk of being carriers for the disease allele by family linkage studies of DNA polymorphic sites within the dystrophin gene. We report here a case of *de novo* mutation with the use of dinucleotide repeat marker STR 44. A 25-year-old female consulted us to know her carrier status and the likelihood of development of DMD in her 3-year old son. Her brother was diagnosed as having DMD. Deletion screening by multiplex PCR showed deletion of exon 44 in her brother and not in her son. Carrier testing was performed by family linkage studies using STR markers. PCR products were run on an 8% polyacrylamide gel and silver stained. Analysis with STR marker 44 revealed deletion of this marker in her brother but not in her, her son and her mother. Heterozygocity at the STR 44 locus in her and her mother suggest a non-carrier status for them. Intron deletion in her brother and no deletion in her son suggest a *de novo* mutation in her brother and the improbability of development of DMD in her son.

Program Nr: 2290 from the 1999 ASHG Annual Meeting

Prevalence of factor V Leiden mutation in 241 Hellenic patients with homozygous b**-thalassemia.** *C.G. Makatsoris[1,3], T. Hatzis[2], H. Karageorgiou[3], F. Karabatsos[4], C. Fragodimitri[4], G. Makatsoris[1], C. Pantos[3], T. Antoniadi[1], H. Vrettou[5], M. Karagiorga-Lagana[4], M.B. Petersen[1], E. Economou-Petersen[5]*. 1) Department of Genetics & Molecular Biology, "Mitera" Maternity & Surgical Center, Athens, Greece; 2) Department of Hematology, "Mitera" Maternity & Surgical Center, Athens, Greece; 3) Department of Pharmacology, University of Athens Medical School, Athens, Greece; 4) Thallasemia Center, "Agia Sophia" Children's Hospital, Athens, Greece; 5) Thallasemia Treatment Unit, Drakpoulion Blood Bank Center, Athens, Greece.

Several clinical manifestations are associated with thromboembolic events which are frequently observed in b-thalassemic patients, such as deep venous thrombosis, arterial occlusions, pulmonary thromboembolism, etc. A key mechanism involved in the pathophysiology of thrombosis is a mutation localized in exon 10 of the factor V gene. Several studies have shown that there is a high incidence of this mutation among Hellenic individuals; one of the highest incidence rates in Europe. It's for these reasons that we conducted our study in 241 thalassemic major patients of Hellenic origin. The objective was to determine whether the 1691 G®A mutation of the factor V gene plays a role or has a synergistic effect for the development of thrombosis in b- thalassemia. In 241 patients, 3 were found to be heterozygotes for the FV Leiden mutation and one homozygote (carrier frequency 1.6; allele frequency 1.1). This is comparatively lower from the allele frequency found in healthy Hellenic blood donors which we have previously demonstrated to be 2.5%. An explanation could be that thallasemic patients having the FV Leiden mutation carry a heavy survival disadvantage and possibly have already deceased. This coincides with the hypothesis that in b-thalassemic patients the prevalence of Factor V Leiden is low due to negative selection.

Program Nr: 2291 from the 1999 ASHG Annual Meeting

Rapid mutational screening of the Menkes/Occipital horn syndrome locus. *P.E. McAndrew[1], L.A. Keppen[2], S.G. Kaler[1,3]*. 1) Res Ctr for Genetic Medicine, Children's Research Institute; Washington, DC; 2) Univ So Dakota; Sioux Falls, SD; 3) Clin Neurocardiology Section NINDS/NIH; Bethesda, MD.

Menkes disease (MD)is an X-linked recessive neurodegenerative disorder of copper (Cu) transport. MD patients are unable to absorb and utilize Cu, and most clinical features can be explained by malfunction of essential cuproenzymes. The MD gene encodes a copper-transporting P-type ATPase, and lack or dysfunction of this protein leads to death in early childhood for 95% of classical MD patients. Occipital horn syndrome (OHS), an allelic variant of MD, has a milder neurological presentation and is associated with connective tissue abnormalities.'

'Mutation analyses by several groups demonstrated that approximately 20% of MD patients have large deletions in the MD/OHS gene, while the majority have small insertions/deletions, nonsense, missense, or splice site mutations. OHS patients typically have mutations at non-consensus splice site positions and maintain some proper splicing. Our laboratory is interested in defining mutations in Menkes and OHS patients in order to (1) better understand the molecular basis of this disorder; (2) understand the structure/function relationships (3) correlate molecular data with response to copper histidine treatment;(4) provide information for families interested in carrier detection and prenatal diagnosis of this fatal disorder.'

'Each of the 23 Menkes/OHS exons and flanking sequence is PCR amplified from genomic DNA and used for heteroduplex analysis as an initial screen to identify novel mutations. A multiplex PCR reaction is also being developed as an efficient method to detect gene deletions. In 1 at-risk male infant born prematurely at 28 wks gestation, we detected a deletion of exons 7-19 and used long PCR to identify a '»'3 kb junction fragment in him and his obligate carrier mother. He began treatment with copper histidine injections on day 9 of life. At 8 mo of age (5 mo corrected for prematurity), he shows developmental delays, failure to thrive, and hypertension related to renal artery aneurysms.

Program Nr: 2292 from the 1999 ASHG Annual Meeting

Advances in Bone Marrow Transplant Monitoring. *L.K. McGlynn-Steele, L.S. Horrocks, Y. Yang, C.A. Ryan, P.N. Ray.* Dept Pediatrics & Lab Med, Hosp Sick Children, Toronto, ON, Canada M5G 1X8.

The monitoring of bone marrow transplant (BMT) or peripheral donor blood infusion (PDBI) is essential to ensuring that the donor cells have successfully replaced either cancerous cells or cells deficient for certain genetic components. Previously, the ratio of donor to recipient cells present in the post-transplant sample was determined by examining the sex chromosomes of recipient cells. However, this method is very labor intensive and only useful when the sex of the donor and recipient were different. Molecular genetics offers new methods for monitoring BMT or PDBI patients. This new methodology involves using the GenePrintTM Fluorescent STR DNA fingerprinting procedure. The sample requirements for molecular analysis include a sample from the recipient pre- and post-transplant, as well as a sample from the donor. A total of eight microsatellite autosomal markers are examined in a multiplex-PCR reaction, in addition to both X- and Y-specific marker analyses using the AMELX/Y locus. This analysis allows the detection of admixtures of DNA down to the level of ~10%. We have tested more than 150 cases in a 1 year period. The advantages of this methodology over conventional cytogenetics include: 1) 3-fold less workload 2) the majority of BMT cases are informative 3) as little as 1ng DNA is required as starting material and 4) results can be obtained in time. Our results have provided invaluable information to clinicians by determining the status of the transplant and hence have had a positive impact on patient management. Examples from 4 BMT-monitoring cases will be presented here. These cases illustrate the importance of this method in the careful monitoring of the cell transition and long-term clinical prognosis.

Program Nr: 2293 from the 1999 ASHG Annual Meeting

Connexin-26 (Cx-26) gene mutation detection using Guthrie cards from subsequently identified deaf children.

J.M. Milunsky[1], E. Yosunkaya[1], T.A. Maher[1], B.R. Vohr[2]. 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Women&Infants Hosp, Dept Ped, Brown Univ Sch Medicine, Prov., Rhode Island.

Prelingual sensorineural hearing loss (SNHL) affects approximately 1 in 500 children. Inherited deafness has been demonstrated to account for 50-60% of all SNHL. About 70% of inherited deafness is non-syndromic, the majority having autosomal recessive (AR) inheritance. About 50-80% of all AR deafness may be due to mutations in the Cx-26 gene. The 35delG mutation in this gene accounts for about 90% of all mutations characterized thus far.

Rhode Island established universal neonatal hearing screening in 1993. About 32 children per year are identified, about half with bilateral deafness needing amplification by 2 months of age. The aim of this study was to determine the efficacy and utility of Cx-26 gene analysis from DNA isolated from Guthrie cards and to precisely define a major cause of prelingual non-syndromic SNHL in those children requiring amplification and detected in this program.

50 deaf children were identified as non-syndromic in the last 5 years with no known cause for their hearing loss. 49 Guthrie cards were obtained from the RI State Lab following informed consent. 3 children were identified as 35delG homozygotes. 3 children were identified as 35delG heterozygotes. 38 children tested negative for the common 35delG mutation.There was no amplification of DNA or uninterpretable results using 5 Guthrie cards. 12% of children were identified with at least one Cx-26 mutation. The Cx-26 gene of the 3 heterozygous children is being sequenced.

Cx-26 analysis is an important test that identifies a major cause of prelingual non-syndromic deafness. Linkage to newborn screening programs will be important in identifying this major cause of deafness, facilitating genetic counseling and carrier detection in these families. Failures with Guthrie cards may make use of other methods preferable.

Program Nr: 2294 from the 1999 ASHG Annual Meeting

A brazilian study of FRAXE mutation in mentally retarded patients using OxE18 probe. *M.V. Mulatinho[1], J.C. Llerena[2], M.M.G. Pimentel[1]*. 1) Cell and Genetic Biology, UERJ, Rio de Janeiro, Brazil; 2) Instituto Fernandes Figueira, IFF/FIOCRUZ, Rio de Janeiro Brazil.

The expansion of trinucleotide repeats within the transcribed regions of genes has been associated to several genetics human disorders. Besides FRAXA, a second fragile site, FRAXE, that lies ~ 600 kb distal to the fragile X syndrome (FRAXA), has been characterized at Xq27.8, which is associated with a non-syndromic form of mental retardation (MR). The FRAXE prevalence is calculated as 1:50000 livebirths. Since 1996, the Human Genetic Service of State University of Rio de Janeiro, Brazil (UERJ), have been searching for FRAXA and FRAXE mutations by molecular technique in MR patients. The screening for FMR1 gene, has been based in standards protocols using EcoRI digests on Southern blots and hybridized with StB12.3 probe. For FRAXE mutation we have been using a molecular protocol for OxE18 probe, in the DNA samples digested with EcoRI . In this sample, 144 negative FRAXA patients (52 sporadic cases, 7 familial cases and 85 institutionalized patients) were tested by this methodology and no FRAXE mutation was detected. In our investigation 40 ng of OxE18 probe labeled with [a32P]dCTP 3000 Ci/mmol (Amersham)by random priming was left hybridizing overnight in 50 % of formamide in the same blots used for FRAXA screening, followed by 3xSSC, 1x SSC, 0,5x SSC washes at 42C. The autoradiograms showed a normal pattern of 2,5 kb for males and 2,5/8,5 kb for females showing the practical use to test FRAXA and FRAXE in a large amount of patients. The OxE18 is an alternative probe to investigate FRAXE mutation as it offers several advantages since it can be used to detect FRAXE locus expansion in the same Eco RI blots used for FRAXA screenings. This work was supported by CNPq, CAPES, FAPERJ, CEPUERJ.

Program Nr: 2295 from the 1999 ASHG Annual Meeting

California's Legislative Response to Genetic Discrimination. *A.M. Musial[1], J.A. Kopczynski[2]*. 1) Perinatal Practice Management, Walnut Creek, CA; 2) San Francisco, CA.

Recent advances in genetic research have increased both the availability and number of genetic tests for the health care consumer. A negative consequence of these promising technological advances, however, is that asymptomatic individuals identified as having disease genes are experiencing discrimination by their employers, health insurers, and health maintenance organizations based solely on their predisposition for such diseases. As a result of such acts of discrimination, many patients are compromising their health care by declining genetic testing that may help guide the patient and physician in choosing appropriate surveillance and medical interventions. Beginning in 1994 and continuing through 1998, the California Legislature responded by passing vanguard pieces of legislation prohibiting discrimination on the basis of one's genetic characteristics. This series of California laws specifically targets discrimination by employers, insurers, health plans and HMOs, and attempts to fill significant voids left by comparable federal genetic discrimination laws. As incidents of genetic discrimination become increasingly more prevalent in a society on the verge of fully mapping the human genome, California citizens now have legal recourse available to protect against these types of abuses by their employers, insurers, and HMOs. However, the existence, specifics and limitations of these laws are relatively unknown to the public. By applying this relatively recent body of California law to several hypothetical factual scenarios of discrimination based on recent case studies, California health care providers and citizens will be made aware of a patient's legal rights and remedies in this new era of discrimination on the basis of one's genetic information.

Program Nr: 2296 from the 1999 ASHG Annual Meeting

Trends in predictive and prenatal testing for Huntington disease, 1993-1999. *M.A. Nance[1], R.H. Myers[2], US Huntington Disease Genetic Testing Group[3]*. 1) Park Nicollet Clinic, St Louis Park, MN; 2) Boston University School of Medicine, Boston, MA; 3) Multiple Institutions, US.

Direct analysis of the CAG repeat sequence in the huntingtin gene has been used for predictive and prenatal testing of Huntington disease (HD) since 1993. To monitor the use of, and problems associated with, this gene test, the United States HD Genetic Testing Group, a consortium of clinical centers and laboratories providing the test, was formed in 1995. This group surveys its members yearly to determine how many tests have been performed, to identify unusual cases, and to obtain detailed information about any social complications of testing, such as employment or insurance discrimination, or litigation related to predictive testing.

The 1999 survey obtained information from 31 clinical centers or clinical centers with affiliated laboratories, and 2 commercial laboratories. Responding clinical centers had an average of 4.5 years of experience with testing, and had performed 1353 predictive tests, of which 57.9% were normal (no CAG repeat expansion), 39.9% showed an expansion (CAG repeat number >39), and 4.1% yielded a result in the incomplete penetrance range (36-39 CAG repeats). The 31 centers performed between 220 and 300 tests each year between 1994-1998. Only 20 prenatal tests have been performed by these centers since 1993. Social complications known to the test centers will be reviewed. Anonymous testing was performed by about one third of the centers in 1998.

The uptake of prenatal genetic testing for HD is currently very low. This study included about half of the US testing centers. Assuming that the other centers are performing a similar number of tests and that some tests are taking place outside of established centers, about 500-600 predictive tests are performed in the US each year, representing about 0.5% of the estimated 120,000 at-risk individuals per year, or up to 1 percent of at-risk adults under age 60.

Program Nr: 2297 from the 1999 ASHG Annual Meeting

Analysis of both *TSC1* and *TSC2* for germline mutations in 126 unrelated patients with tuberous sclerosis. *Y. Niida[1], N. Lawrence-Smith[1], J. Lewis[1], R.L. Beauchamp[1], K. Sims[2], V. Ramesh[1], L. Ozelius[3].* 1) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown, MA; 2) Department of Neurology, Massachusetts General Hospital, Charlestown, MA; 3) Molecular Genetics, Albert Einstein College of Medicine, Bronx, NY.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder characterized by the development of multiple hamartomas involving many organs. About two-thirds of the cases are sporadic and appear to represent new mutations. With the cloning of two causative genes, *TSC1* and *TSC2*, it is now possible to analyze both genes in TSC patients and identify germline mutations. Here we report the mutational analysis of the entire coding region of both *TSC1* and *TSC2* genes in 126 unrelated TSC patient, including 40 familial and 86 sporadic cases, by single stranded conformational polymorphism (SSCP) analysis followed by direct sequencing. Mutations were identified in a total of 74 (59%) cases, including 16 *TSC1* mutations (5 sporadic and 11 familial cases) and 58 *TSC2* mutations (42 sporadic and 16 familial cases). Overall, significantly more *TSC2* mutations were found in our population ($c2 = 12.963$, $p = 0.00032$), with a relatively equal distribution of mutations between *TSC1* and *TSC2* among the familial cases, but a marked underrepresentation of *TSC1* mutations among the sporadic cases ($p = 0.0035$, Fisher's exact test). All *TSC1* mutations were predicted to be protein truncating. However in *TSC2*, 13 missense mutations were found, five clustering in the GAP-related domain and three others occurring in exon 16. Upon comparison of clinical manifestations, including the incidence of mental retardation, we could not find any observable differences between TSC1 and TSC2 patients. Our data helps define the distribution and spectrum of mutations associated with the TSC loci and will be useful for both understanding the function of these genes as well as genetic counseling in patients with the disease.

Program Nr: 2298 from the 1999 ASHG Annual Meeting

Use of fast high pressure liquid chromatography for analysis of thrombophilic mutations. *S.B. Parks[1], E. Gerber[2], R. Hatch[2], R. Foss[2], R.A. Luhm[3], M.J. Hessner[3], D.B. Bellissimo[3], R. Press[1], B. Popovich[1]*. 1) Oregon Health Sci Univ, Portland, OR; 2) Varian Inc, Walnut Cove, CA; 3) Blood Center of Southeastern Wisconsin, Milwaukee, WI.

In DNA diagnostic labs, analysis of thrombophilic mutations constitutes a growing percentage of the tests conducted. In an effort to increase clinical laboratory efficiency, we have evaluated the application of semi-automated fast high pressure liquid chromatography (F-HPLC) as an alternative to gel electrophoresis for analysis of PCR-amplified DNA fragments. In a blinded study, we have used the standard *Mnl* I RFLP followed by F-HPLC to analyze 112 patient samples for the factor V Leiden mutation, and have found all F-HPLC genotypes to be consistent with those generated by electrophoresis. Analyzing each sample for approximately 7 minutes (after PCR and digestion), we were able to visualize amplicon fragments ranging from 67 to 587 bp. Two notable advantages of F-HPLC are the automated analysis and the resulting electronic data. Once initiated, no further supervision is required during the analysis. Linking clinical laboratory computer systems with the electronic record generated for each sample can reduce the risks of transcription and interpretation errors. Our experience indicates that F-HPLC generates accurate, consistent, and reliable results, and can serve as a replacement for the gel electrophoresis of most PCR RFLP assays in the clinical setting.

We are currently conducting a blinded study analyzing 100 patient samples for the thrombophilic factor V Leiden, prothrombin G20210A, and MTHFR C677T mutations, using a multiplex ASO PCR in conjunction with F-HPLC. The ASO PCR detects all three mutations simultaneously without the need for restriction digestion. Coupling this technique with F-HPLC will provide a fast, efficient, semi-automated means of simultaneously detecting these three primary thrombophilic mutations in a clinical diagnostic setting. In conclusion, we believe that F-HPLC represents a promising new approach to molecular diagnostics by providing a semi-automated method of DNA analysis for RFLP-based or ASO PCR based protocols.

Program Nr: 2299 from the 1999 ASHG Annual Meeting

Measuring distress in individuals presenting for cancer genetic testing: A single interview question versus standard measures. *A.F. Patenaude[1,2], M. Dorval[1], L. DiGianni[1], K. Kalkbrenner[1], K.A. Schneider[1], S.A. Kieffer[1], J.E. Garber[1,2]*. 1) Dana Farber Cancer Inst, Boston, MA; 2) Harvard Medical School, Boston, MA.

Measurement of distress in persons presenting for genetic testing is important for clinical safety and evaluation of psychological outcomes. Depressed individuals may be at increased risk for adverse outcomes. Research programs have utilized interviews and standard psychological measures. In clinical settings, however, limits on time and personnel restrict assessment options.

We compare use of a single question assessing depressive affect with standard depression measures in 2 cancer genetics counseling programs. For 31 LFS family members seeking *p53* testing, the single question, "During the past month, have you experienced any periods of depression or consistent unhappiness?" correctly identified all subjects with T-scores of ≥63 on the Symptom Checklist-90R (sensitivity 100%), and identified 75% of those not meeting criteria for depression (specificity). Among 47*BRCA1*testing program participants, specificity of the single item remained high (85%), but sensitivity was lower (67%) when compared to Depression T-scores (≥63)on the Brief Symptom Inventory, a short version of the SCL-90R. Implications for affective assessment in clinical and research programs of cancer genetic testing are discussed.

Program Nr: 2300 from the 1999 ASHG Annual Meeting

Mutation detection for Epidermolysis Bullosa in a global population. *E.G. Pfendner[1,2], A. Nakano[1,2], K. Nielsen[1,2], L. Pulkkinen[1,2], J. Uitto[1,2].* 1) Dermatology and Cutaneous Biology; 2) DebRA Molecular Diagnostics Laboratory, Thomas Jefferson University Phila., PA.

Epidermolysis Bullosa (EB) is a group of heritable skin blistering disorders marked by extreme fragility of the skin and separation of epidermal layers within the cutaneous basement membrane zone either below the lamina densa (dystrophic EB, DEB), within the lamina lucida (junctional EB, JEB) or within the basal keratinocytes (EB Simplex). Molecular diagnosis for DEB and JEB has been performed for a group of patients from an international referral base representing patients from Africa, Asia, Australia, Europe and the Americas. To date, a total of 266 samples have been submitted which meet the diagnostic criteria for analysis; among these cases 144 are DEB and 122 are JEB. Of the patients in the DEB category, 19 were known to have dominant and 125 recessive inheritance patterns, while all known JEB cases were recessive. Using heteroduplex analysis followed by nucleotide sequencing, the mutation detection rate was 64% for DEB and 80% for JEB. DEB mutations have been detected in the COL7A1 gene in five categories; splice junctions (19.6%), missense (4.5%), nonsense (16.9%), insertion/deletion (32.1%) and glycine substitutions (26.8%). Recurrent DEB mutations have been identified at 4 sites comprising 6.2% of the total population surveyed. JEB mutations have been identified in six different genes; LAMA3, LAMB3, LAMC2, a6 and b4 integrin (ITGA6 and ITGB4) and BPAG2 (COL17A1). JEB mutations were identified in splice junction (15.6%), missense (6.4%), nonsense (37.7%) and insertion/deletion (40.2%) categories. Recurrent LAMB3 mutations accounted for 54.0% of all LAMB3 mutations and 32.5% of all JEB mutations. R635X was the predominant LAMB3 mutation comprising 41.1% of all JEB mutations. These molecular analyses lead to prenatal diagnosis for 58 pregnancies, 39 DEB and 19 JEB. Linkage analysis was used for prenatal diagnosis in another 10 DEB families. In 65 pregnancies genotype was correctly predicted. Three pregnancies are ongoing. These results indicate that DNA based prenatal testing is expedient and reliable in predicting genotype in pregnancies at risk for recurrence of EB.ab.

Program Nr: 2301 from the 1999 ASHG Annual Meeting

High-Throughput Mutation Detection at the Australian Genome Research Facility. *K.F. Poetter[1], S. Foote[1], J. Barlow[1], A. Wirapati[1], G. Myers[1], R. Cotton[2].* 1) AGRF, Walter & Eliza Hall Institute, Parkville, VIC, AUSTRALIA; 2) Mutation Research Center, St. Vincent's Hospital, Fitzroy, VIC, AUSTRALIA cotton@ariel.its.unimelb.edu.au.

Genomic research is rapidly changing the scope as well as focus of genetic research into causes of inherited diseases. With the rapid increase in primary DNA sequence information, the direct comparison of test DNA to known sequence as a way to characterise mutations is a methodology in need of development. To this end, the Australian Genome Research Facility (AGRF) has developed high throughput (> 2000 samples per day) protocols for chemical cleavage of mismatch (CCM) mutation detection. This report describes the robotic controls for CCM as well as rates the method on speed, accuracy (both false negative and false positive rates) and cost. Two main technical advances of this work are the development of **solid phase supports** for the chemical modification and cleavage steps of CCM and the **computerized automated subtraction protocols** which allow quick and accurate allele calling. Proof of principle and proof of practice experiments using a set of 15 Brca1 patients whose genotypes were determined by other investigators were analyzed by both CCM and direct sequencing. We have found that CCM can identify mutations with a low false negative rate. DNA sequencing of all amplimers of all patients failed to identify mutations which were unexpected from CCM results.

Program Nr: 2302 from the 1999 ASHG Annual Meeting

SMA carrier testing: the Ohio State University experience. *T.W. Prior[1], D.W. Parsons[1], J.W. Heinz[1], A.C. Papp[1], R.W. Schafer[1], M.S. Sedra[1], P.J. Snyder[1], A.H.M. Burghes[2], P.E. McAndrew[1].* 1) Department of Pathology, Ohio State University, Columbus, OH; 2) Department of Neurology, Ohio State University, Columbus, OH.

Autosomal recessive spinal muscular atrophy (SMA) is caused by homozygous loss of the telomeric survival motor neuron gene (telSMN) in ~95% of SMA patients. A quantitative competitive PCR assay for the determination of telSMN copy number was developed in our laboratory. This test allows the accurate identification of SMA and has been offered to SMA families in which a homozygous telSMN deletion has been ascertained. We now report the results of the first two years of clinical SMA carrier testing at our institution.

The assay has been performed on 181 individuals, most frequently spouses of SMA carriers or patients (n=52) and aunts/uncles (n=48) or parents (n=44) of SMA patients. The test results for our patient population closely resemble those expected for an autosomal recessive disorder: 12 of 16 siblings (75%) of SMA patients and 20 of 48 (42%) aunts/uncles of patients were determined to be carriers. Two of 52 unrelated spouses of SMA carriers or patients were found to be carriers, which is not significantly different from the estimated SMA carrier frequency of 1/40 to 1/50 individuals. Consistent with a reported new mutation rate of 2%, 1 of 44 parents of SMA patients was revealed to possess two copies of telSMN.

These results demonstrate the presence of significant interest in SMA carrier testing, and confirm that this assay can reliably identify carriers of SMA as previously established. Furthermore, no asymptomatic individuals were found to be homozygously deleted for telSMN in our patient population, indicating that this phenomenon is a rare occurrence and does not affect carrier studies significantly. In families of SMA patients with homozygous loss of the telSMN gene (and not individuals with telSMN point mutations or other neuromuscular disorders), this test provides an accurate means of determining SMA carrier status and allows at-risk individuals to make informed family planning decisions.

Program Nr: 2303 from the 1999 ASHG Annual Meeting

Attitudes to genetic testing in childhood in England and Wales. *A.M. Procter, A.J. Clarke, P.S. Harper.* Institute of Medical Genetics, Uni Wales College of Medicine, Cardiff, U.K.

It is 5 years since the survey carried out by a Working Party of the UK Clinical Genetics Society contributed to its report entitled "The Genetic Testing of Children". Since that time, the debate has continued, particularly with regard to the desirability and organisation of such tests. As the range of tests available has increased, so has public awareness of genetic issues. This interest has been fostered by increased ease of access to medical and scientific information which has in turn generated new pressures upon individuals involved in genetic counseling. In collaboration with the Department of Health and the Advisory Committee on Genetic Testing, we have instituted a survey which aims to assess current opinion among the various groups of professionals involved in the genetic testing of children. Two thousand questionnaires have been circulated to clinicians and senior scientists in molecular and cytogenetic laboratories throughout England and Wales. Those returned (more than 700) have allowed us to gain some insight into current trends both in professional practice and in attitudes to the use of genetic tests in childhood.

Program Nr: 2304 from the 1999 ASHG Annual Meeting

Screening of the C282Y mutation in the HFE gene in Italy by Taqman technology. *G. Restagno[1], A.M. Gomez[1], L. Sbaiz[1], S. Bosso[1], C. Negro[1], P. Fortina[2], P. Gasparini[3], M. Cicilano[4], M. De Gobbi[4], C. Camaschella[4].* 1) Clinical Genetics, A. O. O.I.R.M.-S. ANNA, Torino, Italy; 2) Department of Pediatrics, The Children Hospital of Phildelphia PA; 3) Medical Genetics Service, IRCCS, San Giovanni Rotondo, Foggia, Italy; 4) Department of Clinical and Biological Sciences, University of Torino.

Hereditary Hemocromatosis (HH) is a common autosomal recessive disorder of iron metabolism. Homozigosity for a C282Y mutation in the Hemocromatosis gene (HFE) is the underlying defect in approximately 64-95% of patients with HH. Carrier frequency in Caucasians ranges between 3-13%. Gene frequency in a cohort of italian newborns using a new assay based on the use of two fluorescent dyes (a reporter and a quencher) both attached to the probe. Fluorescence is read with the ABI Prism 7700 Sequence detection System. The C282Y mutation was evaluated in 554 newborns. No newborns were homozygous for the C282Y; there were 18 C282Y heterozygotes which translates into a carrier frequency of 3,2%. In order to asses the presence of genotypes at risk other than C282Y homozygosity, the mutation H63D was investigated in 18 heterozygotes and 3 resulted compound heterozygotes (5,4/1000). However the risk of compound heterozygotes is rather low. The frequency of C282Y in Italy is lower than that described in Brittany, where the homozygote frequency was 5/1000 and heterozygote frequency was 12%. This may be explained because HH is considered as the most frequent disease in the population of Northern Europe origin; the origin of heterozygous newborns described in our work was mixed (North, Center and South of Italy) with the exception of 5 cases from Northern Italy. Since the current study is done blindy, we expect that the frequency of the C282Y mutation is not biased. The use of Guthrie spots coupled with the Taqman methodology proved to be semi-automatable, rapid and suitable for screenings of the general population.

Program Nr: 2305 from the 1999 ASHG Annual Meeting

Testing for an Inherited Susceptibility to Breast-Ovarian Cancer: Consequences One Year Later. *P.T. Rowley, S. Loader, J.C. Levenkron, C.G. Shields.* University of Rochester, Rochester, NY.

Concern has been expressed about the consequences of BRCA testing. Will women in whom a mutation is found be excessively worried? Will women in whom no mutation is found be inappropriately reassured and reduce surveillance?

We conducted a trial in which free genetic counseling and BRCA testing were offered to any woman in the care of a Monroe County physician who had two or more first- or second-degree relatives with breast or ovarian cancer. Of 140 women qualifying, 112 came for individual pretest education (averaging 90 min.), and, after hearing about risks and limitations as well as benefits, 98 chose to be tested. Of the women having cancer from 87 families actually tested, 13 had a deleterious BRCA1 or BRCA2 mutation and were given information about recommended surveillance and optional prophylactic surgery.

At 1 mo. and at 1 yr. after receiving their test result, patients were evaluated by structured interview and questionnaires. Knowledge of genetic risks for breast cancer was significantly greater at 1 mo. than before education ($p < .001$) and was well maintained at 1 yr. Breast Cancer Worry score did not significantly rise in any test result group, even in those found to have a mutation. At 1 yr., Breast Cancer Worry score was higher in women who perceived breast cancer as more serious, but not in women who perceived themselves as more susceptible. Scores for self-assessed breast cancer surveillance at 1 yr. did not differ among test result groups. Of the 87 women tested, 41 were very satisfied, 19 somewhat satisfied, and only 13 neutral or dissatisfied with the testing program. Compared to 1 mo., satisfaction at 1 yr. was increased in 40 cases, unchanged in 13 cases, and decreased in 9 cases.

Thus, at 1 yr., we observed that knowledge had been retained, worry about breast cancer had not risen even in those found to have a mutation, surveillance was satisfactory, and most were satisfied with the testing program. We attribute these favorable results in part to a significant investment in pretest education, generating realistic expectations among those choosing testing and permitting others to choose no testing.

Program Nr: 2306 from the 1999 ASHG Annual Meeting

Under utilization of genetics services in a poor urban population . *H.M. Saal[1], L. Hoechstetter[1], C. Hetteberg[2], E.K Schorry[1]*. 1) Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH; 2) College of Nursing, University of Cincinnati.

The Division of Human Genetics is the sole provider of genetics services in southwest Ohio, serving a population of 1.9 million. We successfully provide outreach services in 7 distant rural counties. In our own county, which is urban, we have identified a significantly under served poor population, which, for various reasons has had limited utilization of specialty services. Analysis of the utilization of genetic services revealed startling differences when comparing individuals from the wealthiest and poorest zip codes in our community. The median income for the wealthy zip code (WZP) was $43,375 compared to $8,824 for the poor zip code (PZP). The racial distribution for the WZP was 91% Caucasian and for the PZP 77% African American. During fiscal year 1997 there were 37 patient visits from the WZP compared to only 12 from the PZP, and only one patient had private insurance. For genetic encounters, individuals from combined wealthier communities were seen predominantly for outpatient visits (88%), whereas inpatient consultations accounted for almost 50% of genetics visits for persons from poor communities. In order to identify the reasons for the differences in provision of clinical genetics services to these poor communities, we have embarked on a project to study the barriers to genetics services in three urban primary care clinics. The study includes educational programs for primary care health providers, as well as assessing the role of case management in provision of genetics services. Since the initiation of the project, we have seen patients with a wide variety of conditions. Early data have identified a lack of understanding of the role of clinical genetics in the health care management of children with genetic disorders by both the lay public and primary healthcare providers along with an under-identification of individuals who would benefit from genetics services. From these data it is clear that we must address the modes of provision of genetics services to poor urban populations. Supported by Maternal and Child Health Bureau grant MCHG 98-07.

Program Nr: 2307 from the 1999 ASHG Annual Meeting

Economical analysis of mutation detection: DHPLC as contract services to enhance discovery in the Human Genome Variability. *M. Sanders[1], B. Lobos[2], R. Todd[2].* 1) Psychiatry, GeneShop Inc., Washington Univ, St Louis, MO; 2) Psychiatry Department, Washington University School of Medicine, St. Louis, MO.

A growing need to detect de novo sequence variants in newly discovered human genes presents challenges to the research community for rapid and accurate delivery of data. We analyze various mutation detection techniques and discuss DHPLC as a contract service available to the human genetics laboratories. DHPLC employs the formation of heteroduplexes between wild-type (reference) and mutated DNA, which are efficiently separated on the WAVE DNA Fragment Analysis System (Transgenomic Inc., San Jose, CA). GeneShop Inc. offers services for mutation/SNPs discovery, which are competitive in price and complementary to sequencing, thus reducing research costs in search of sequence variants. Temperatures, maintained by the WAVE oven, finely mediate partial melting (denaturation) of the heteroduplexes at mismatch sites. The melted domains in the heteroduplex molecular species cause them to be retained less strongly on the DNASep micropellicular matrix of the WAVE analytical cartridge than the double-stranded homoduplex molecules. We demonstrate the superiority of this approach to gel-based techniques and sequence-it-all projects. For additional info geneshop3@hotmail.com, Tel. 314 362 8650.

Program Nr: 2308 from the 1999 ASHG Annual Meeting

Molecular diagnosis of congenital deafness: novel mutations in the GJB2 gene. *L. Sbaiz, A.M. Gomez, C. Carbonara, S. Bosso, C. Negro, G. Restagno.* Clinical Pathology, A.O. O.I.R.M.-S.Anna, Torino, Torino, Italy.

The most common form of inherited and apparently sporadic congenital deafness is due to mutations in the connexin-26 gap junction protein B2 (GJB2) on human chromosome 13q11 (DFNB1). The 35delG frameshift mutation accounts for 60% of the DNFB1 alleles in the Mediterranean population, representing the most common mutation . We search for GJB2 mutations in congenital deaf and in potential carriers within their families using a direct sequencing approach.In the present study we report on the molecular analysis of the Cx26 gene in a group of 25 patients and 59 potential carriers. Analysis of the complete coding region of the GJB2 gene revealed seven different mutations: one frameshift (35 delG) three stop codons (E47X, W24X, and a novel mutation, E114X) and three aminoacid substitutions (R127H, the novel mutations Q80P and V153I). An additional novel mutation (V37I, aminoacid substitution) has been found in a three generation autosomal dominant family, with a form of late onset (45 years of age) sensorineuronal deafness: the mutation segregates in all the seven affected members. Nine patients (36%) were found to be 35delG homozygous, 2 patients were compound heterozygous E47X/35delG, and one E114X/35delG; four patients showed only one mutation and 9 (36%) showed no mutations. Severe deafness or hearing impairment is the most prevalent inherited sensory disorder, affecting about one in 1000 children. Although many cases of congenital deafness are tough to be recessively inherited, the nature of sporadic cases is unknown, which makes genetic counselling and the diagnosis of deafness difficult. Mutations in the GJB2 gene represent a major cause of congenital deafness; the characterization of 35delG and other mutations facilitates population screening and diagnosis and counselling in families with affected members.

Program Nr: 2309 from the 1999 ASHG Annual Meeting

Impact of neonatal screening and prenatal diagnosis for cystic fibrosis in Brittany, France. *V. Scotet[1], M. De Braekeleer[2], M. Roussey[3], G. Rault[3], P. Parent[3], M. Dagorn[3], H. Journel[3], A. Lemoigne[3], J.P. Codet[4], M. Catheline[4], V. David[5], A. Chaventre[2], C. Verlingue[1], I. Quere[1], B. Mercier[1], M.P. Audrezet[1], C. Ferec[1]*. 1) Department of Molecular Genetics, ETSBO - UBO, BREST; 2) Department of Genetic Anthropology and Demography - BORDEAUX; 3) Departments of Paediatrics of Brittany; 4) Departments of Nuclear Medicine of Brittany; 5) Department of Genetics, RENNES, FRANCE.

Cystic fibrosis (CF) is the commonest severe autosomal recessive disease in white population of Caucasian origin. Cloning of the gene responsible for CF and identification of its mutations with their ethnical and geographical distribution enabled to implement efficient strategies of molecular diagnosis and prevention. This study assessed the ten years of neonatal screening and prenatal diagnosis practice and studied their influence on CF incidence in Brittany, a French area of 2 millions of inhabitants of Celtic origin. Over the decade, 343.756 newborns were screened by measurement of immunoreactive typsin. 118 CF children were identified, leading to an incidence of 1/2913 which did not decrease significantly over the period. All the prenatal diagnoses performed over these ten years were registered : 62 diagnoses were realised in families related to a screened child, 102 in the relatives of a child born before the introduction of screening and 118 in couples who presented abnormal ultrasound scan. Through early detection of patients, neonatal screening allowed 12 couples to use prenatal diagnosis for future pregnancies whereas the screened child was still asymptomatic. Prenatal diagnosis, which identified 60 affected fetuses, allowed the birth of 222 healthy children and the termination of 54 pregnancies (a pregnancy termination level of 90%). Taking into account pregnancy terminations, incidence was 1/1999. However 50% of couples would not have extended their family without the existence of prenatal diagnosis; so 32 births were really avoided. Prevention strategies led to a modification of 21% in CF incidence in Brittany, and awaiting more efficient pharmacological or gene therapy-based treatments, prevention remains an important aspect in management of CF.

Program Nr: 2310 from the 1999 ASHG Annual Meeting

Mutation detection for Congenital Adrenal Hyperplasia: Analysis of 117 Dutch patients and comparison of existing methods for mutation screening in the CYP21 gene. *E.A. Sistermans, I.J. de Wijs, L.H. Hoefsloot.* Dept Human Genetics, Univ Hosp Nijmegen, Nijmegen, Netherlands.

Congenital Adrenal Hyperplasia (CAH) is a relatively common recessive disorder with a carrier frequency of approximately 1:50. It is characterised by excessive virilisation, and 70% of the classical cases show potentially fatal salt wasting. The disease is caused by mutations in the 21-hydroxylase (CYP21) gene located in the class III HLA region on chromosome 6. The gene is part of a 30 kb tandemly duplicated fragment, with an almost identical pseudogene (CYP21P) on the second segment. This particular structure determines the spectrum of mutations found in CAH, which consists of gross deletions/conversions and of small mutations derived from the pseudogene. We analysed 117 independent patients from the Netherlands for mutations in the CYP21 gene. In 103 patients, mutations were found on both alleles, whereas 7 patients had a common mutation on only one allele. No mutation was found in the remaining 7 patients, in all these cases the clinical diagnosis was uncertain. An overview of all mutations found will be presented. Analysis of deletions and large conversions in the CYP21 gene is generally performed by Southern blot analysis, whereas PCR-based techniques like allele specific PCR are used to detect the smaller mutations. At least ten independent tests have to be performed to cover all common mutations. Therefore, completion of mutation screening takes much time, which is not always available, for instance in the case of a pregnancy or when imbedded in a neonatal screening program. To overcome this problem, we started working on a new method that allows fast and reliable parallel detection of small mutations.

Program Nr: 2311 from the 1999 ASHG Annual Meeting

Genetic tests, screening and priorities in health care. *J.H. Solbakk, H.S. Hasan.* Centre for Medical Ethics, University of Oslo, Oslo, Norway.

Genetic testing has been developed in order to benefit individuals who are susceptible to genetic conditions which when manifested will either lead to the loss of quality of life or the loss of life or both. Genetic screening and the problem of priorities in relation to genetic testing will be the main focus of attention in this paper. A Socratic approach will be tried out, implying that several impertinent questions will be raised and some answers provided. The first question addressed is the purpose of genetic testing. The second question is which of these genetic tests should be given priority.

Five clusters of preliminary questions are also addressed: the question of the identity of different interest groups in the field of genetic testing (Who are they?); second, the nature of genetic counselling; third, the relation between legitimate and illegitimate interests in the field of genetic testing; fourth, the relation between self-evident and hidden concepts and values in the practice of genetic testing (What is meant by 'genetic disease', 'genetic susceptibility', to be 'at risk', 'low risk', 'high risk' etc.? Who has the authority to fill out the definitions of these concepts, and whose interests are at stake in the process of prescribing this new language? Last but not least, what are the potential effects and side effects of genetic testing and screening programs?

Norway was the first country worldwide to provide a system of priorities in healthcare in 1987. In various forms, other states and countries (Oregon, 1991; The Netherlands 1991; Sweden, 1991-95; Finland, 1994; Denmark, 1996 and New Zealand, 1992) have followed similar models, at least in terms of defining a core set of principles (severity of the disease, effectiveness, cost-effectiveness, and need) by which prioritisation decisions should be made.

We have applied these core principles to propose a model for genetic testing and screening programs.

Program Nr: 2312 from the 1999 ASHG Annual Meeting

A polymorphism in HFE promotes misdiagnosis of hereditary hemochromatosis. *M.J. Somerville, K.A. Sprysak, M. Hicks, B.G. Elyas, L. Vicen-Wyhony.* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

Hereditary hemochromatosis (HH) is an autosomal recessive disorder of iron metabolism that is estimated to affect approximately 1 in 300 individuals. Two mutations in the HFE gene have been identified (C282Y and H63D) that contribute to HH (Feder et al. 1996), and screening for the C282Y mutation in particular, is used to identify carriers and affected individuals. We have obtained anomalous results in 8 out of 202 unrelated individuals tested for the C282Y mutation. PCR amplification followed by restriction digest in these individuals gave a C282Y homozygote digestion pattern with trace amounts of undigested DNA. Increased restriction enzyme and incubation time, as well as resampling of these cases did not resolve the anomalous results. Increased PCR stringency eliminated the normal product. Reanalysis of these cases using two alternative primers that flank the Feder et al. primer sites, gave a C282Y heterozygote pattern in all 8 samples. Sequencing of HFE revealed a G->A substitution (892+48G->A) in intron 4, 5 bases from the 3 terminus of the reverse primer site identified by Feder et al. This is not predicted to disrupt normal HFE splicing. In all 8 cases this mutation was on a non-C282Y, non-H63D chromosome. PCR using this reverse primer can result in dramatically reduced amplification of the polymorphic allele, such that a C282Y carrier will appear to be a C282Y homozygote. These 8 cases were obtained from a total of 43 unrelated C282Y (non-H63D) carriers, and in addition to 44 unrelated C282Y homozygotes. The estimated frequency of this allele in our population is, therefore, 8/43 = 0.186. If the assumption of homozygosity along with access to parental genotypes had been made in all polymorphic and homozygous cases, this would have led to an apparent 8% rate of non-paternity. The frequency of this polymorphism is high enough to warrant concern that the interpretation of homozygosity in these cases will result in an overestimate of the C282Y allele frequency, in misdiagnosis of this condition, in an underestimate of C282Y penetrance, and in an incorrect assumption of non-paternity in some families. Feder JN, et al. (1996) Nature Genet 13: 399.

Program Nr: 2313 from the 1999 ASHG Annual Meeting

An Empiric Method to Determine Sensitivity and Allele Frequency for Cystic Fibrosis Genetic Testing. *P. Srinivasan[1], J. McClellan[2], M.E. Nunes[2].* 1) University of Texas Medical Branch, Galveston, TX; 2) USAF Medical Genetics Center, Keesler AFB,MS.

The American College of Medical Genetics (ACMG) 1997 Statement on Genetic Testing for Cystic Fibrosis (CF) suggests that adequate experience with sensitivity and specificity in target populations be obtained prior to universal offering of preconception/prenatal CF genetic testing. The majority of *GeneTests*$_{TM}$ (*Helix*) listed laboratories which offer CF testing determine their sensitivity by adding individual allele frequencies derived from CF Consortium tabulated data for each mutation in their test panel. Reported sensitivities for Caucasians using equivalent mutation panels range from 80% to 90%. We report a simple empiric method to independently determine sensitivity and allele frequencies for CF mutations in clinical laboratories, regardless of the molecular methodology used. The predicted number of independently ascertained CF chromosomes in the test pool, *C*, can be determined from clinical information provided in the test requisition form and applying the following formula: $\mathbf{C = 2a + S(R \times b)_i + S(2pq \times c)_i}$ where *a* is the number of known CF cases, *R* the probability of being a carrier based on pedigree analysis (in most cases the coeffecient of relationship), *b* the number of at risk carriers at each probability, *2pq* the carrier frequency for a given ethnic population, and *c* the number of individuals without family history of CF of given ethnicity. Our molecular diagnostic laboratory offers a 21 CF mutation panel. A two year period covered 393 cases, which correcting for shared parental chromosomes represented 526 independent chromosomes. Applying the above formula predicts 84.6 independent CF chromosomes. From this sample, 67 mutations were detected (sensitivity = 67/84.6 = 79.20%): 61 DF508 (allele frequency = 61/84.6 = 0.728), two G542X (0.024), and one each R553X, N1303K, G551D,and R560T (0.012 each). Using the formula it should be possible for any laboratory to empirically determine overall test sensitivity. With a large enough sample size, specific sensitivities and allele frequencies for different ethnic and racial groups can readily be determined as well.

Program Nr: 2314 from the 1999 ASHG Annual Meeting

Predictive testing for the dominantly inherited corneal dystrophies. *H.S. Stewart[1], G. Black[1,2], G. Hall[1], D. Donnai[1], A.E.A. Ridgway[2], D. Craufurd[1]*. 1) Department of Medical Genetics, St Mary's Hospital, Manchester, UK; 2) Manchester Royal Eye Hospital, Oxford Road, Manchester, UK.

Introduction: The autosomal dominantly inherited corneal dystrophies (CD's) form a heterogeneous group, clinically and genetically. They vary in their age of onset and the severity of the problems they cause. Reis-Bucklers dystrophy has a childhood onset of recurrent, painful corneal erosion and there is a rapid loss of visual acuity necessitating corneal transplantation by the second decade. In contrast, late-onset lattice CD causes less severe visual problems, though corneal transplantation may eventually be necessary due to loss of visual acuity. Since the BIG-H3 gene on chromosome 5q31 has been shown to cause a number of CD's, genetic testing prenatally, pre-symptomatically and to confirm a suspected diagnosis are all theoretically possible. Purpose: We aimed to assess the psychological burden of being at risk in people at 50% risk of CD by virtue of their family history and assess their attitudes to predictive testing. We compared this with other late onset diseases such as Huntington's disease and familial cancer, for which predictive testing is possible. Patients with CD are primarily managed by ophthalmologists. Comparisons were made with the attitudes of the people at risk and the corneal surgeons. Methods: Individuals from 24 CD families were invited to complete telephone questionnaires. Postal questionnaires were sent to 119 surgeons. Results: Being at risk of developing CD is not a major psychological burden. Predictive testing was favoured 100% responding patients and 80% of surgeons. Advantages of testing were cited as career planning and to clarify the risk to children. Ethical considerations such testing in childhood and testing people at 25% risk were poorly understood. Conclusions: The International Guidelines for predictive testing, based on the models of Huntington's disease and familial cancer, may need to be modified for late onset diseases that cause less psychological burden. Interdisciplinary debate is necessary to devise such modified guidelines.

Program Nr: 2315 from the 1999 ASHG Annual Meeting

Development of an improved molecular assay for detection of mutations causing Tay-Sachs disease. *T.L. Stockley, G. Koultchitski, P.N. Ray.* Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada.

Tay-Sachs disease is an inherited lysosomal storage disorder caused by deficiency of the enzyme hexosaminidase A and is most prevalent in the Ashkenazi Jewish population (carrier rate 1/30). Carrier screening for Tay-Sachs is available by biochemical analysis of hexosaminidase activity in blood. However, the biochemical assay is complicated by several difficulties, such as inaccurate results for women who are pregnant or using birth control pills. As well, individuals who carry non-pathogenic pseudodeficiency mutations are reported as Tay-Sachs carriers by use of the biochemical assay. Due to these difficulties, molecular analysis of mutations in the HEXA gene is an important compliment to biochemical screening. However, many common current methods for detection of mutations in HEXA are laborious and are not suitable for molecular analysis of large numbers of individuals.

We have developed a molecular assay which simultaneously detects five common HEXA mutations. The mutations detected in this assay include three pathogenic mutations, 1278insTATC, IVS12(+1)G®C and 805G®A (G269S), which account for 96% of HEXA mutations in the Ashkenazi Jewish population. The assay also detects two pseudodeficiency mutations, 739C®T (R247W) and 745C®T (R249W), which are common in the non-Jewish population. The assay is based on the Amplification Refractory Mutation System (ARMS), which relies on the fact that primers which have a mismatch at the 3' terminal nucleotide will not function in PCR. We have adapted the ARMS methodology to detection of HEXA mutations by designing fluorescent dye labelled ARMS primers specific to either the normal or the mutant DNA sequence for each of the five mutations to be detected. This assay is an improvement on previous molecular assays for Tay-Sachs as it simultaneously detects five HEXA mutations in a single tube, thus reducing the labor and cost associated with molecular testing for Tay-Sachs disease.

Program Nr: 2316 from the 1999 ASHG Annual Meeting

Detection of genomic mutations and polymorphisms of Protein C (PROC) gene using denaturing high performance liquid chromatography (DHPLC). *M.R. Taliani[1,2], S.C. Roberts[1], R.K. Pruthi[1], W.L. Nichols[1], J.A. Heit[1]*. 1) Hematology Research, Mayo Clinic and Foundation, Rochester, MN; 2) Institute of Internal and Vascular Medicine, University of Perugia, Italy.

Background: Genomic abnormalities responsible for the deficiency of PROC have been extensively studied in the last years providing important insights into the PROC structure-function relationship. Unlike other hereditary defects of antithrombotic mechanisms, the PROC gene abnormalities are heterogeneous. Thus it is difficult and expensive to identify the genomic abnormality in a given patient, since each exon has to be amplified and sequenced. At present, there are a number of available techniques wich allow screening large populations for sequence variations, but they present some disadvantages such as lack of sensitivity, high costs and labor intensity. DHPLC has been recently described as a new, rapid, automated, scanning method of unknown mutations. **Objective**: To evaluate the sensitivity and the specificity of DHPLC as a method for rapid screening of unknown mutations within the PROC gene of patients with PROC deficiency. **Study population**: Patients (n=24) with a history of venous thromboembolism referred to the Mayo Clinic Special Coagulation Laboratory and found to have PROC deficiency. **Methods**: Protein C activity was determined by chromogenic assay using Protac and protein C antigen level was determined by ELISA. For each patient, a minimum of 4 kb of the PROC gene was amplified by PCR and sequenced using fluorescence-based Perkin-Elmer ABI methodology. After a denaturing and reannealing step, 5-10 ml of each PCR product were analyzed by DHPLC (Transgenomic Wave DNA Fragment Analysis System). A blinded analysis of the chromatograms obtained from the DHPLC was performed by an independent reader. These results were then compared to the sequence data. **Results**: On the basis of number, width and separation of chromatogram peaks, a total of 47/47 heterozygous mutations and heterozygous polymorphism patterns were correctly identified as were 193/193 homozygous wildtype alleles. **Conclusion**: We conclude that DHPLC is a highly sensitive and specific method for the rapid detection of unknown mutations.

Program Nr: 2317 from the 1999 ASHG Annual Meeting

The Effects of Race, Maternal Age, Income, and Timing of First Prenatal Care on the Utilization of Prenatal Diagnosis and the Percent Reduction of Live Births with Down Syndrome in California, 1992 - 1995. *J.M. Tepe[1], C.A. Huether[1], C. Torfs[2], L. Feuchtbaum[3]*. 1) Biological Sciences, University of Cincinnati, Cincinnati, OH; 2) California Birth Defects Monitoring Program, Emeryville, CA; 3) Genetic Diseases Branch, California Department of Health Services, Berkeley, CA.

Two significant factors that affect the incidence rate of Down syndrome are maternal age and utilization of prenatal diagnosis with elective termination. Additionally, there are sometimes differences in incidence rates seen among races. These differences most likely occur due to the above two factors, with the differing utilization rates most likely due to varying sociologic factors.

This study examines the effects of race, maternal age, income, and timing of first prenatal care on the utilization rates of prenatal diagnosis and their resulting effects on the percent reduction of Down syndrome. As a retrospective study, the data have been abstracted from two Californian databases, the California Birth Defects Monitoring Program and the Genetic Diseases Branch of the Department of Health Services for the time period 1992 - 1995. By combining these two sources, a comprehensive cohort of all fetuses with Down syndrome is obtained. The four-year period yields 1,441 live births and 842 terminations. Preliminary analysis indicates that the overall reduction in live births with Down syndrome was approximately 30.2% over the four years of the study. The percent reductions by race categories are as follows: Asian American, 46.9%; African American, 22.7%; Hispanic, 15.1%; Caucasian, 51.9%; and Other, 34.6%. The magnitude of effect of each of the four independent variables, and their interactions, on both the utilization rates of prenatal diagnosis and the percent reduction of Down syndrome will be presented. The results will provide an increased understanding about the differences in utilization of prenatal diagnosis among races. Given the impact of individuals with Down syndrome on the health care and educational establishments, these results are of importance to health and education providers.

Program Nr: 2318 from the 1999 ASHG Annual Meeting

The Effect Of One Genetic Support Group On Research For A Rare Disease. *S.F. Terry[1], P.F. Terry[1], L.G. Bercovitch[1,2].* 1) PXE International, Inc, Sharon, MA; 2) Department of Dermatology, Brown University, Providence, RI.

A patient support organization can accelerate and focus research on a rare disorder. Research on a rare genetic disorder is limited by lack of data about its manifestations, natural history and epidemiology. Often the very lack of large numbers of individuals with the disorder limits the funding possibilities and makes the acquisition of patient samples and data difficult. Further, the agenda of researchers and participants can diverge in ways that ultimately delay progress toward a treatment and cure.

Pseudoxanthoma elasticum (PXE) is a rare genetic disorder. PXE International, a support organization founded in 1995, initiates, supports and funds research. Also providing support for affected members and their families, it has focused and accelerated research on this disorder. As a lay support organization it is has established a database of 1500 affected individuals and 250 pedigrees, created a blood and tissue bank housing 900 DNA samples and 90 tissue samples, collected detailed epidemiological data from 400 individuals, initiated several research projects, and described these and other projects to patients in a direct and expedient manner. PXE International has expended 80% of its operating budget on direct and indirect costs of research. It sponsored regular research meetings for studying PXE and related basic science to encourage expedient definition of problems and to open new avenues for further research.

The results of the efforts made by PXE International are a 15 laboratory consortium, an International Centennial Meeting on Pseudoxanthoma Elasticum cosponsored by the NIH, a multidisciplinary approach forging collaborations amongst many specialists, a focused agenda which accelerates research in the service of the interests of the patient population, and increased congressional awareness for real outcomes of medical research funding. The organization is also uniquely able to safeguard confidentiality by acting as a 'firewall' between researchers and participants. Genetic support groups using this model can greatly benefit both research and patient populations, furthering both the common and divergent goals of each.

Program Nr: 2319 from the 1999 ASHG Annual Meeting

Implication of Screening for FMR1 and FMR2 Gene Mutation in Individuals with Nonspecific Mental Retardation in Taiwan. *C.C. Tzeng[1,2], P.Y. Tzeng[2], H.S. Sun[2], R.M. Chen[1,2], S.J. Lin[2,3].* 1) Departments of Pathology; 2) Molecular Medicine; 3) Pediatrics, National Cheng-Kung University Hospital, Tainan, Taiwan, R.O.C.

Fragile X syndrome (FXS) is the most common familial mental retardation (MR), attributable to (CGG)n expansion in the FMR1 gene. FRAXE is less frequent, associated with a similar mutation of FMR2 gene. Both disorders are as yet not treatable but can be prevented by prenatal genetic examination. However, screening of all pregnant women for carriers is thus far technically not cost-effective. In this study we attempted to ascertain the prevalence of both disorders in MR population in Taiwan, as well as to develop a method to effectively find carriers. We screened 321 nonspecific MR patients for the FMR1 and FMR2 mutation. Four (1.9%) out of 206 males and one (0.9%) in 115 females were identified as FXS patients. All four FXS males could be detected by Southern blot analysis, as well as by a simple nonradioactive PCR. None of the 206 males had FMR2 full mutation. This confirmed the low incidence of the FRAXE in Chinese. FXS patients appears to be more prevalent among mildly MR, since 4 of the 5 FXS were from the 115 mildly MR (3.5%) and only one from the other 206 severely MR (0.5%). All five FXS were maternally inherited. Further search of other family members for carriers was rather resistant. Worthy to note is that none of these mothers had discernible premarital family history of MR. Thus the negative family history could not preclude a woman from being a carrier. How to identify female carriers of childbearing age, beyond the scope of family history, is thus worthy to be further explored. We here demonstrated a simple and inexpensive PCR procedure suitable for wide screening of males, at a cost of US$ 6.00 per case. It could reliably classify males as possible FXS, PM, or normal. Although normal transmitting males have no immediate risk of having a diseased child, tracing them and FXS patients would easily identify more carrier women at or before childbearing age for more preventive measures.

Program Nr: 2320 from the 1999 ASHG Annual Meeting

Denaturing High Performance Liquid Chromatography (DHPLC) for PMM2 mutation screening in CDG type 1A patients. *A. Uller[1], H. Stibler[2], B. Kristiansson[3], J. Wahlstrom[1], T. Martinsson[1]*. 1) Dept Clin Genet, Gothenburg Univ, Sahlgrenska Univ Hosp, Gothenburg, Sweden; 2) Dept Neurology, Karolinska hosp, Stockholm, Sweden; 3) Dept Pediatr, Sahlgrenska Univ Hosp, Gothenburg, Sweden.

The phosphomannomutase 2 gene (PMM2) has been identified as the carbohydrate-deficient glycoprotein syndrome type 1A gene (CDG type 1A). The gene spans 8 exons and 741 bps of coding DNA. Previously, we have identified 20 different mutations in the PMM2 gene using mutation screening with SSCP (single-stranded conformation polymorphism) and sequencing of DNA from 61 CDG type 1A patients. Since seven of these could not be detected by SSCP in this first study, we were not satisfied with the sensitivity of the mutation detection technique used. Thus, we wanted to investigate if DHPLC was a more suitable mutation screening method for PMM2. DHPLC was set up for PMM2 by optimizing eight different PCR fragments, one fragment for each exon. The mutation detection was optimized empirically with PCR fragments from wild-type controls. First, wild-type samples were run at a universal-gradient and after modifying and shortening of the gradient, also run at ten different temperatures, 50-70oC with 2 degrees interval, to enable setting of the temperature with the highest resolution. Then, PCR products with known mutations from the previous study, were loaded and the results were compared to the wild-type chromatograms for aberrations. We detected 19/20 mutations with DHPLC. Several mutations not detected by earlier techniques were readily detected by dHPLC. In conclusion, the use of DHPLC here shown to detect 95% of the mutations in the PMM2 gene is likely to provide a powerful tool for diagnostics for CDG type 1A patients and families in terms of sensitivity, reliability and automation.

Program Nr: 2321 from the 1999 ASHG Annual Meeting

Genetic Diagnosis Challenge: Experience at the National Institute of Pediatrics in Mexico city. *N. Urraca, MC. Esmer, V. Del Castillo.* Genetics, Institute National Pediatrics, Mexico, city, Mexico.

The diagnosis of a genetic disease depends on the capacity of the geneticist and on the availability of biochemical, radiological, chromosomal and molecular tests. We studied 400 charts to investigate our frequency of undiagnosis, we analyzed 1992 and 1996 to asses whether there was a change on frequency with the access to computerized systems and to molecular tools. The mean age of onset was 8.8 months, and the average on patients attendance to consultation was at 30.2 months of age. In 68% of all patients had a diagnosis, 37% of them were diagnosed by other specialists and the remainder at the genetic consultation: history and physical examination helped on 26%, laboratory studies on 34%, the academic meetings, literature search and the computerized systems on minor grade. The diagnostic frequency was significatively high in 1992, more patients arrived diagnosed in 1996, probably on the later years the easier and recognizable disorders are not seen, therefore it is possible that the complexity of the disease is increasing at this level of attention. Almost one third of the patients with a diagnosis had a mendelian disorder or an entity with unknown etiology. 108 different diagnosis were made on 274 patients. The most prevalent were oculo-auriculo-vertebral spectrum (OAVS), non-syndromic cleft lip and palate (CLP), Down's syndrome, myelomeningocele and neurofibromatosis. Although 30&% of the patients with unknown diagnosis had a suspicion disorder, it couldn't be confirmed probably because the patients didn't return to complete their studies or due to the absence of confirmatory resources. 11.9% had only mental retardation, which itself represents a clinical challenge to establish a etiologic diagnosis needing the performance of magnetic resonance and molecular tests that are not always available. 23% have abnormalities that probably encompass a syndrome not yet described. This study confirms the need for the clinical geneticist to have complementary tools that improve the study of these patients in order to lesser the anxiety of the family.

Program Nr: 2322 from the 1999 ASHG Annual Meeting

A DGGE system for comprehensive mutation screening of the complete coding regions of BRCA1 and BRCA2 outside exons 11. *A.H. van der Hout, I.M. Mulder, Y. Wu, P. van der Vlies, M. Huisman, J.C. Oosterwijk, C.H.C.M. Buys, R.M.W. Hofstra.* Medical Genetics, University of Groningen, Groningen, The Netherlands.

A family history of breast and/or ovarian cancer is one of the strongest risk factors for breast cancer. A substantial portion of all hereditary breast and/or ovarian cancer is associated with germline mutations in BRCA1 and BRCA2. We have used PTT for screening on a routine basis patients from breast/ovarian cancer prone families for truncating mutations in the large exons (exon 11 of BRCA1 and exons 10 and 11 of BRCA2). Moreover, we screened by PCR analysis for the in the Dutch population frequently occurring deletions of exon 13 or 22 of BRCA1. Mutations were found in 37/218 families (17%). To scan the remaining part of the coding sequences of both genes for all possible small mutations we have designed a DGGE system in which we divide the coding region of both genes outside exon 11 plus the first and last 500 bp of the exons 11 into 81 amplicons. These are combined in 22 pools which are subjected to DGGE in a 9% PAA gel for 16 hours, 120V, with a urea/formamide gradient of 20-65% at 59°C (BRCA1) or 30-65% at 55°C (BRCA2). We use DGGE because we have shown in other diseases that with an appropriate design the sensitivity of this technique is virtually 100%. With this system all known Dutch mutations in BRCA1 and BRCA2 outside exons 11 (n=16) were indeed easily detected. Until now we screened 14 families in which no mutation was found with PTT/deletion analysis. In three families frameshift mutations were found, one of these not reported previously in the BIC database. Moreover, a number of unclassified variants and polymorphisms were detected. Thus, a combination of PTT and this DGGE system allows a relatively easy and fast scanning of the complete coding sequences of BRCA1 and BRCA2 for mutations on a routine basis.

Program Nr: 2323 from the 1999 ASHG Annual Meeting

PCR-based methylation testing of archived fixed cell suspensions from individuals previously tested by cytogenetics/FISH for Prader-Willi or Angelman syndromes. *M. Velinov[1], H. Gu[1], M. Genovese[1], C. Duncan[1], W.T. Brown[2], E. Jenkins[1]*. 1) Dept Cytogenetics; 2) Dept Human Genetics, IBRDD,Staten Island.

Until recently most diagnostic evaluations for Prader-Willi (PWS)and Angelman (AS)syndromes consisted of a combination of high resolution banding and FISH analyses to look for microdeletions in the proximal long arm of chromosome 15. However cytogenetic and FISH microdeletion analysis can only identify about 70% of individuals suspected for PWS or AS. In contrast, DNA methylation testing identifies nearly 100% of PWS and 75% of AS individuals. Thus methylation testing was recommended for individuals with suspected PWS or AS and negative FISH analysis (AJHG, 58: 1085-1088, 1996). We have carried out methylation testing on standard cytogenetic fixed cell suspensions from people previously tested for PWS or AS with negative cytogenetic/FISH findings. These specimens were refrigerated after FISH analysis for 0-4 years. We used two PCR-based methylation tests: methylation specific PCR (mPCR), which was reported previously (Kubota et al. Nat. Genet.;16:16,1997) and a bisulfite restriction analysis(BRA) method that we recently developed (Velinov et al. Gen.Med.1(2):75,1999,A124). The mPCR and BRA tests were initially standardized using specimens from individuals with known PWS and AS as well as normal controls. The mPCR method was successful in testing 15 out of the 16 fixed cell suspensions. One specimen failed to amplify with the primers used, possibly due to insufficient amount/quality of the genomic DNA tested. All fixed cell suspensions showed normal methylation patterns, thus ruling out PWS or AS. Since BRA was only successful with larger amounts of template, we were able to test only 5 out of the 16 specimens studied. All the BRA results supported the mPCR findings. We thus showed for the first time that archived fixed cell suspensions from individuals suspected for PWS/AS that were negative for cytogenetic/FISH microdeletions,can now be re-evaluated with PCR-based methylation tests without requesting additional specimens from the previously studied individuals. This work was supported in part by the NYS Office of Mental Retardation and Developmental Disabilities.

Program Nr: 2324 from the 1999 ASHG Annual Meeting

Multiplex PCR for Down's diagnosis. *D.Y. Venable[1], X. Li[1], X. Hou[2], L. Zhang[2], G. Feng[2], F. Song[2], B. Qi[2], J. Han[1].* 1) Genaco Biomedical Products, Inc., Huntsville, AL; 2) ShenYang Maternal Child Care Hospital, Liaoning, PR.China.

Down's syndrome is the most common chromosome disease. In the West, prenatal diagnosis is relying on cytogenetic analysis. This method, however, is not widely available in many developing countries. In China, for example, over 90% of the population still do not have access to prenatal genetic services. The limitations can be technical or economical. Technically, lack of reliable products and proper training lead to a low amniotic cell culture success rate (less than 75%); Economically, if imported products (such as culture media and consumables) were used, most consumers could not afford the service. To make prenatal Down's diagnosis more accessible to people in developing countries, we have developed an accurate, easy, and affordable molecular diagnostic kit. The kit used multiplex PCR to amplify three chromosome 21 specific polymorphic loci. The biotin-labeled PCR products were separated with gel electrophoresis and transferred onto nylon membrane for color detection. Relatively high detection rate is achieved by this multi-allelic system. Down's diagnosis can be made either qualitatively (about 95% of Down's patients can be recognized as having three alleles) or quantitatively (two alleles, but with a 2:1 intensity ratio). The kit is easy to use and its application requires only a thermal-cycler and gel apparatus.

Program Nr: 2325 from the 1999 ASHG Annual Meeting

Health-related quality of life indices for breast cancer treatments and genetic testing options. *S. Verma[1], M. Cappelli[2], L. Surh[2], L. Humphreys[2], D. Logan[1], A. Hunter[2], J. Allanson[2].* 1) Ottawa Regional Cancer Centre - Genreal Division; 2) Children's Hospital of Eastern Ontario.

In establishing decision models for the treatment and prevention of breast cancer, it is important to evaluate the health-related quality of life afforded to patients by such interventions. The objectives of the present study were: (i) to characterize women's preferences for breast cancer treatments and BRCA1/BRCA2 testing, using the rating scale and standard gamble techniques for eliciting health state utilities ranging between 0 (death) and 1 (perfect health); and (ii) to identify factors associated with these quality-of-life indices. Data were collected from: 60 women diagnosed with breast cancer before 50 years of age; 58 unaffected, high-risk female relatives of women with early-onset breast cancer; and 51 unaffected women in the general population. Multivariate analyses of variance (MANOVAs) and factorial analyses of variance (ANOVAs) revealed that health state utilities did not differ according to group membership or whether or not participants intended to undergo genetic testing in the near future. There was, however, a trend for married women to evaluate certain health states more highly than unmarried women, and for women with a higher level of education to value preventive drug therapy more highly than women with less than a university education. It was concluded that women's preferences for various breast cancer treatment and prevention options are not related to the degree of experience they have with the disease, nor are they related to women's choices about receiving BRCA testing in the near future. Certain demographic factors may play a role, however. Results of this study provide valuable information regarding the quality of life attributed by affected and unaffected women with respect to breast cancer genetic testing and treatment outcomes.

Program Nr: 2326 from the 1999 ASHG Annual Meeting

Identification of Novel Mutations in Hispanic Cystic Fibrosis Patients. *J. Wang[1], M. Bowman[2], E. Hsu[2], K. Wertz[2], L. Wong[1]*. 1) Inst Molecular & Human Gen, Georgetown Univ Medical Ctr, Washington, DC; 2) Department of Pediatrics, Children's Hospictal Los Angeles, California.

Cystic fibrosis (CF) is a common autosomal recessive genetic disorder, with a carrier frequency of about 1:25 in Caucasians. More than 800 mutations have been found in the CF gene. The mutation spectrum varies among different ethnic groups. In Ashkenazic Jewish, five mutations account for more than 90% of CF alleles. However, only about 58% of Hispanic CF mutations have been identified. Here we report the use of temporal temperature gradient gel electrophoresis (TTGE) method to scan the mutations in CFTR gene. 32 Hispanic CF patients who have been screened for a panel of 70 common mutations and have at least one unidentified mutant allele were studied by TTGE. Each of the 27 exons of CFTR and the flanking intron regions was PCR amplified followed by TTGE analysis, which separates the homo- and heteroduplexes formed between mutant and wild type DNA based on their melting behavior. Seven novel mutations were identified, in addition to two polymorphisms. Three of these mutations were found heterozygous in more than two unrelated CF Hispanic patients. They are 3876delA, 935delA and 406-1G>A. 3876delA was found in seven patients and each of the other two in two patients, respectively. Both 3876delA and 935delA mutations are associated with growth retardation, lung and intestine impairment and pancreatic insufficiency. In addition, both patients heterozygous for 935delA had meconium ileus. Other symptoms include early deaths, liver disease, cor pulmonale and diabetes. These clinical findings suggest that 3876delA and 935delA mutations are associated with severe CF phenotype. Our results demonstrate that TTGE is an effective method for screening unknown sequence variations. The 3876delA mutation was found in about 15% of our Hispanic patients. Both 935delA and 406-1G>A are recurrent. This information will be useful for genetic counseling to Hispanic patients. *cor pulmonale*.

Program Nr: 2327 from the 1999 ASHG Annual Meeting

Public attitudes regarding the donation and storage of blood specimens for genetic research. *S.S. Wang[1], F. Fridinger[1], K.M. Sheedy[1], H. Linnan[2], M.J. Khoury[1]*. 1) Office of Genetics & Disease Prevention, CDC, Atlanta, GA; 2) Office of Communication, CDC, Atlanta, GA.

As sequencing of the human genome progresses, the demand will increase for population-based genetic research to assess allele frequencies and associations between specific polymorphisms and human diseases. Such research will include large population-based cross-sectional and cohort studies that collect and store blood samples for DNA studies. In order to assess the current climate towards donating and storing blood for genetic research, the authors examined data from the 1998 American Healthstyles Survey. Individuals participating in this survey of health attitudes and behavior are representative of adults in the U.S. with regard to age, gender, marital status, race, income, region, household income, and population density. As part of this extensive survey, a series of questions regarding blood donation and storage for genetic research was posed to the participants. Of 3,130 survey participants, 2,621 (84%) completed questions regarding blood donation and use of stored blood for genetic research. We found that 42% were in favor of both blood donation and long term storage for genetic research; 10% were willing to donate blood for genetic research but not for long term storage; 27% were not willing to donate blood but would consider it under certain circumstances (confidentially or anonymously); and 21% were not willing to donate or store blood for genetic research under any circumstance. Factors affecting the likelihood of respondents to be in favor of blood donation for genetic research and long term storage include: higher education, higher income, positive family history for a genetic disorder, individuals living in the pacific and mountain regions of the U.S., Caucasians, and individuals 30-64 years old ($p<0.05$). These results indicate a wide range of public opinion on donation and storage of blood specimens for genetic research. Further understanding of the multiple factors which contribute to attitudes regarding genetic research will contribute to future actions in communicating genetic research goals to the public and recruitment for population-based genetic studies.

Program Nr: 2328 from the 1999 ASHG Annual Meeting

SCA 8 in the Scottish population. *J.P. Warner, L.H. Barron, M.E. Porteous.* Molecular Genetics Service, Western General Hosp, Edinburgh, Scotland.

A CTG expansion in the 3' UTR of a gene in 13q21 has recently been described as the cause of SCA 8. This (CTG)n expanded sequence is preceded by a polymorphic stretch of (CTA)n. We describe PCR amplification methods which allow accurate independent size determinations of both trinucleotide repeats. Allele frequencies for both repeats are presented for the Scottish normal population. New TP-PCR primers are presented which help identify the presence of large difficult to amplify expanded alleles. Since 1989 a cohort of over 100 individuals with cerebellar ataxia of unknown origin has been referred to us by local neurologists for testing. The majority of these patients have no family history of ataxia and have previously been tested for SCA 1, 2, 3, 6, 7, DRPLA and Friedreich's ataxia. We present clinical details for individuals found with a combined CTG/CTA repeat at the upper end of the reported affected range for SCA 8. SCA 8 is currently the most common cause of spino cerebellar ataxia in our population.

Program Nr: 2329 from the 1999 ASHG Annual Meeting

Mutations and associated polymorphisms in Saudi -thalassaemia patients. *A.S. Warsy[1], M.A. El-Hazmi[2].* 1) Biochemistry, King Saud University, Riyad, Saudi Arabia; 2) Medical Biochemistry, King Khalid Hospital,King Saud University,Riyadh,Saudi Arabia.

The -thalassaemias are frequently encountered in the Saudi population with a diverse clinical picture. We investigated the -thalassaemia mutations in 98 Saudi patients using ARMS, dot blot analysis and DNA sequencing, using ABI 310 prism Sequencer. The spectrum of the mutations covered IVS-I-110 (GA), IVS-II-I (GA), IVS-I-5 (GC), CD 39 (CT), IVS-I-3' (-25bp) and CD 6 (-A), CD 8 (+1), Cap+1 (-25 bp), CD 5 (CCTC--), IVS-I-6 (TC); IVS-I-1 (GA) and IVS-II-848. Of interest is the findings of extensive polymorphic sites. The polymorphic sites identified included: IVS-II-26, IVS-II-244, IVS-II-76, CD 2, IVS-II-81, IVS-II-666, IVS-II-16 and IVS-II-74, as heterozygotes, homozygotes and double homozygous states. In addition, multiple polymorphic sites, upto 6 polymorphic sites in the same patient, were frequently encountered with variable prevalence. The paper will highlight the molecular pathogenesis of -thal. in Saudis and the associated multiple polymorphisms. The modulation of clinical presentation of -thalassaemias in Saudis, a phenomenon of frequent occurrence in Saudi sickle cell disease, and the relation to the polymorphism will be discussed.

Program Nr: 2330 from the 1999 ASHG Annual Meeting

Comparison Between Two Methods For Human Buccal Cell DNA Extraction: A High Throughput Method Versus One That Generates Ultra-pure DNA. *J.B. Watson, H. Grunenwald.* Epicentre Technologies, Madison, WI., U.S.

The use of human buccal cells as a convenient, non-invasive source of DNA has increased dramatically over the last decade. In this study we compared two methods for isolating DNA from buccal cells. The first uses a heat and amplify method that generates PCR amplifiable DNA using an extraction solution containing a PCR enhancer and a PCR inhibitor chelator. The yield using this method varies from 1-10 g of DNA and generates enough sample for up to 250 PCR amplifications. The primary advantage of this system is that the entire extraction is performed within a closed tube, which minimizes hands on manipulation, assures no cross contamination during the extraction process and allows hundreds of samples to be processed in a single day. We compared this heat and amplify method with a ultrapure protocol that generates highly purified DNA from buccal cells using a simple salting out procedure that does not require hazardous reagents. DNA yields using this method were also between 1-10 g of DNA; but the DNA was free from contaminating protein as assayed by O.D. 260/280 ratios. The primary advantage of the ultrapure method compared to the heat and amplify method was that the DNA is precipitated and therefore can be diluted to any desired concentration after isolation. To determine which method is preferable for different applications, PCR amplifications were performed using primers that amplified regions of the Fragile X gene, the hemochromatosis gene, the cystic fibrosis transmembrane receptor gene, and the apolipoprotein E gene. To determine their usefulness in forensics applications a set of short tandem repeat primers were amplified. It was found that PCR amplicons for all the genes could be generated using either method. The ultrapure DNA protocol generated more consistent PCR bands suggesting that if the PCR amplification is from a difficult template such as those with high GC content, the protocol that generates clean DNA is preferred. If the PCR will be performed on a large number of samples, and the PCR has been well-optimized, then the simpler heat and amplify method would be more efficient for these high throughput or automated applications.

Program Nr: 2331 from the 1999 ASHG Annual Meeting

A reverse hybridisation assay for molecular genetic diagnosis of familial mediterranean fever (FMF). *A.S. Weinhaeusel[1], C. Oberkanins[2], F. Kury[2], O.A. Haas[1].* 1) CCRI, St. Anna Children's Hospital, Vienna, Austria; 2) ViennaLab Labordiagnostika GmbH, Vienna, Austria.

Familial Mediterranean Fever (FMF; MIM 249100) is an autosomal recessive inherited disorder that is characterized by short, recurrent bouts of fever accompanied by pain in the abdomen, chest, or joints, and an erysipela-like erythema. In addition, renal amyloidosis can develop in patients with FMF. With a heterozygote frequency of 1/5 to 1/30 in the mediterranean area, the disease is widespread in North African, Jewish, Armenian, Turkish and Arab populations and individuals with their ethnic origin in these countries. FMF is caused by point mutations in the marenostrin gene located on chromosome 16(p13). The currently known mutations in exons 2, 5 and 10 cover at least 94 percent of disease-relevant mutations. Owing to the rather unspecific clinical symptoms, molecular genetic analysis significantly improves the diagnosis of this disease and, by that, facilitates correct treatment of homozygous and compound herterozygous mutation carriers with colchicine. Based on these prerequisites, we have developed a rapid and reliable assay for the molecular genetic detection of the most common FMF-mutations. The test is based on the reverse-hybridization principle and covers more than 94% of mutations that are found in the Mediterranean populations. Some essential improvements over published procedures have been introduced to facilitate the use of this test as a tool for routine diagnosis: (I) a single multiplex amplification reaction is used to amplify exon 2, 5 and 10 of the FMF gene; (II) premade, ready-to-use test strips are provided that contain oligonucleotide probes for each wild type and mutated allele immobilized as parallel lines. It is therefore possible from one single strip to discriminate heterozygous, compound heterozygous, and homozygous individuals; (III) the entire procedure from blood sampling to the identification of mutations can easily be carried out within a single working day. The test may be automated on equipments, such as the TECAN profiBlot.

Program Nr: 2332 from the 1999 ASHG Annual Meeting

The use of cheek brush DNA and allele specific oligonucleotides in screening for the APC I1307K allelic variant in Ashkenazim. *A. Whetsell[1], M. Wright[1], D. Shrag[2], J. Garber[2], S. Syngal[2], G.A. Miller[1], R.J. Pomponio[1].* 1) Molecular Profiling Laboratory, Genzyme, Framingham, MA; 2) Dana Farber Cancer Institute, Boston, MA.

The I1307K allelic variant in the Adenomatous Polyposis Coli gene (APC) has been reported to occur in about 6-7% of Ashkenazi Jewish individuals has been implicated as promoting increased susceptibility to colorectal and breast cancer.

As part of an ongoing study, we utilized DNA extracted from standard cytology cheekbrushes collected from 448 unrelated Ashkenazi Jewish patients with a history of either colorectal cancer, polyposis or adenomas. The samples were PCR amplified, dot-blotted, and analyzed for the presence or absence of the I1307K allele using allele specific oligonucleotides (ASOs). Eleven patients failed to PCR amplify, possibly due to improper cheek cell collection. Thirty-eight individuals (8.7%) were found to carry the I1307K allele variant, and of these, 2 were homozygous.

This data demonstrates the feasibility of large scale testing for the I1307K allele using bucal swab deried DNA.

.

Program Nr: 2333 from the 1999 ASHG Annual Meeting

Scorpions™ primers - a novel method for use in single-tube genotyping. *D. Whitcombe, S. Kelly, J. Mann, J. Theaker, C. Jones, S. Little.* AstraZeneca Diagnostics, Northwich, Cheshire, UK.

The application of SNP and point mutation analysis in a clinical setting needs simple, cheap and reliable test formats. With this in mind we have developed a novel genotyping method which requires only a single addition of a DNA sample to a single tube to perform the assay.

The method employs PCR primers with integral tail sequences which we call Scorpions primers. The tail is complementary to part of the primer extension product, carries a fluorophore quencher pair and incorporates a blocking sequence to prevent it being copied during PCR. This allows the Scorpions primer to signal when it has been incorporated into the appropriate amplicon via a uni-molecular rearrangement which separates the fluorophore from the quencher. The system has substantial benefits in terms of kinetics, thermodynamics, assay design and reliability. We have combined Scorpions signalling with ARMS™ allele specific amplification to generate single tube genotyping tests.

The method has been used to develop single tube genotyping tests for SNPs and point mutations in a number of genes including CFTR, AAT, IL1a, BRCA1,VCAM, MLH1, HFE and also several non-genic SNPs. The utility of the system has been demonstrated by performing over 3,000 genotyping reactions.

Program Nr: 2334 from the 1999 ASHG Annual Meeting

The APEX SNP Identity Chip and the *IDENTI*PLEX™ STR Identity Testing System. *L.D. White[1,2], J.J. Tollett[2], L.A. Liles[1], J.P. Teske[1], J.H. Warren[1], R.W. Staub[1]*. 1) Molecular Genetics, Identigene, Inc, Houston, TX; 2) Dept. Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

We have developed a 50 locus microarray for human identity testing at Identigene, Inc. based upon single nucleotide polymorphisms (SNPs). The 50 SNPs were chosen based on reported allele frequencies of approximately 50%. Using Arrayed Primer Extension (APEX) on the 50 locus chip, we are able to genotype individuals at 50 loci simultaneously. APEX involves the template specific extension of an oligonucleotide primer (bound to a silanized glass surface) using a thermostable DNA polymerase and fluorescently labeled ddNTP terminators. Amplification of the 50 SNP sites was performed with multiplex PCR technology (5 reactions/50 sites). The fluorescently labeled SNP sites were detected on an Avalanche Microscanner™ (Amersham Pharmacia Biotech/Molecular Dynamics) that was modified for 4-color detection. Current testing protocols at Identigene, Inc. include multiplex PCR amplification of 11 short tandem repeat (STR) loci with fluorescently labeled primers and electrophoresis of the resulting gene fragments on an ABI Prism™ 377 Automatic DNA Sequencer. We tested 20 families from the American Black population on both the 50 SNP Identity Chip and on the *IDENTI*PLEX™ STR ABI Prism™ 377 System. Comparisons were made between the relative combined paternity indices, powers of exclusion, accuracy, and turnaround time of the two methods.

Program Nr: 2335 from the 1999 ASHG Annual Meeting

Genetic Testing for Friedreich Ataxia. *M.J. Wick[1], V.L. Matthias Hagen[1], D.J. Allingham-Hawkins[2], M.A. Nance[3], N.T. Potter[4], for the Ataxia Molecular Diagnostic Testing Group[5]*. 1) Dept Lab Medicine & Pathology, Univ Minnesota, Minneapolis, MN; 2) Genetics Program, North York General Hospital, North York, Ontario, Canada; 3) Dept Neurosciences, Park Nicollet Clinic, St. Louis Park, MN; 4) Neurogenetics Laboratory, University of Tennessee Medical Center, Knoxville, TN; 5) Multiple Institutions.

The Ataxia Molecular Diagnostic Testing Group (AMDTG) was established to provide proficiency testing and outcomes data for the inherited ataxias and DRPLA. The AMDTG has previously presented data regarding proficiency testing for the autosomal dominant ataxias (SCA1-3, 6 and 7) and DRPLA (AJHG 1998;63:A239). Here we report data from the AMDTG proficiency testing for Friedreich Ataxia (FRDA). Of the 22 laboratories listed in GeneTests™ for clinical FRDA testing, 19(86%) agreed to participate in the study, and 15(68%) completed the proficiency testing. Each laboratory analyzed four specimens and responded to a questionnaire regarding methods and result interpretation. Inter-laboratory agreement of allele sizes was best for the sample with two expanded alleles, and expanded alleles were almost always distinguished from normal alleles, but normal and premutation sized alleles were not always reliably distinguished from each other. Differences in separation methods and molecular weight markers, and in (GAA)n repeat reference ranges used for result interpretation appear to be responsible for this variability. These results, which will be discussed by the AMDTG-associated laboratories, suggest the need to 1.) establish uniform repeat reference ranges, perhaps through a multi-center genotype/phenotype study, and 2.) standardize methods which allow for appropriate resolution and sizing of alleles with repeats ranging from 7 to over 1000 GAA repeats. (Supported in part by a grant from the National Ataxia Foundation).

Program Nr: 2336 from the 1999 ASHG Annual Meeting

Immunofluorescent staining for emerin in hair roots distinguishes Emery-Dreifuss muscular dystrophy patients and carriers from normal individuals. *G.R. Wilmot[1], S.T. Warren[2,3].* 1) Department of Neurology; 2) Departments of Biochemistry, Genetics, and Pediatrics, Emory University School of Medicine; 3) Howard Hughes Medical Institute.

Emery-Dreifuss Muscular Dystrophy (EDMD) is an X-linked inherited myopathy characterized by muscle weakness, joint contractures and cardiac conduction defects. The disease is caused by mutations in the EDMD gene which lead to a loss of the protein product emerin, which localizes to the inner nuclear membrane. The diagnosis can be established either by screening for EDMD mutations, of which over 70 are currently known, or by establishing the absence of emerin expression by immunofluorescent staining of tissue or less invasively by Western blot analysis of leukocytes. Although Western blots work well in EDMD patients where emerin is completely absent, they are less efficient for diagnosing carrier status where intermediate emerin levels are seen due to X-inactivation. We have therefore explored whether individual hair roots, which are clonally-derived following X-inactivation, can be immunostained for emerin in order to diagnose EDMD carriers and affected individuals. Hair roots (5-20 from each individual) were collected from normal control subjects (n= 4), genetically-confirmed EDMD patients (n= 4) and EDMD carriers (n= 3), fixed in acetone and processed for indirect immunofluorescence with a monoclonal antibody to emerin. Each root was scored as negative (no emerin staining), positive (>70% cells stained), or intermediate (1-70% cells stained). EDMD patients demonstrated negative staining in all roots (n=20), while normal controls were positive in 23 out of 24 roots. Of 30 total roots taken from EDMD carriers, 14 were negative, 6 were intermediate and 10 were positive, clearly distinguishing them from normal individuals. Thus, the analysis of emerin immunoreactivity in hair roots offers a convenient, efficient, and minimally-invasive method for diagnosing EDMD patients and carriers.

Program Nr: 2337 from the 1999 ASHG Annual Meeting

Detection of FMR1 Genotypes, Sex Chromosome Abnormalities, and Deletion Mutations by PCR Products With an automated DNA Sequencer. *M. Winkler, M. McGill, L. Jones, T. Tubman, H. Hamdan, R. Fenwick.* Quest Diagnostics, Inc., Nichols Institute, San Juan Capistrano, CA.

The molecular diagnosis of Fragile X syndrome is performed using PCR and Southern blot analyses to determine the size of the CGG repeat in the FMR1 gene. For the last two years we have used a non-radioactive PCR protocol to co-amplify the FMR1 CGG repeat and the CAG repeat in the androgen receptor gene from clinical samples. Fluorescently labeled PCR products are analyzed in an automated DNA sequencing system (ALFExpress). The size of each PCR product is determined relative to a set of molecular size standards using 'Fragment Manager TM' software (Hamdan et al., 1997, Molec. Diag. 4:259). The use of betaine in the PCR eliminates 'stuttering' often observed with amplification of triple repeats (Papp et al., 1996. Molec. Diag. 1:59). This improvement coupled with the resolution obtained with the automated sequencer allows us to define the FMR1 genotypes of both male and female individuals and has also allowed detection of X chromosome aneuploidies. Migration of the fluorescently labeled PCR products in the sequencing gel is detected after laser excitation and the results are presented as a chromatogram. Measurement of the number and heights or areas of the peaks allows discrimination of normal and abnormal alleles plus estimation of gene dosage. Through our normal assay we have been able to identify 47,XXX, 48,XXXY and 46,X (Turners syndrome) individuals. Two patients affected by Kleinfelters syndrome were also identified with this method, one of whom carried a Fragile X syndrome premuatation. We were also able to discriminate a FMR1 deletion mutation in a female hemizygous for the FMR1 gene. Detection of these abnormal alleles would have been very difficult if the conventional radioactive PCR and autoradiographic detection method had been used. This non-radioactive and semi-automated method is also conducive to improving the efficiency of the Fragile X syndrome assay since each diagnostic assay can accommodate 35 patients plus the appropriate controls.*FMR1*^{TM}.

Program Nr: 2338 from the 1999 ASHG Annual Meeting

Hemoglobin Alpha chain deletions may select for Factor V Leiden. *K. Yanamandra, D. Napper, H. Chen, D.W. Jalanivich III, T.F. Thurmon, M. Susla, M. Jeroudi, J.A. Bocchini, jr.* Dept Pediatrics, LSU Medical Ctr, Shreveport, LA.

Hemoglobin Bart's (Hb Bart's) is found in 5% to 12% of newborns. The amount may be as low as 1% when one alpha chain is inactivated (mostly in Africans) or as high as 25% when three are inactivated (mostly in Orientals). Factor V Leiden is usually caused by a G to A transistion at position 1691 in the Factor V gene. That results in an arg506gln amino acid residue change in the Factor V clotting factor protein, which renders it resistant to inactivation. The frequency of Factor V Leiden ranges from near 0 among Africans and Orientals to 15% in Greeks. *If Factor V Leiden is present in a locale,* frequencies have been found to be higher among persons selected for various types of thrombophilia or for frequent spontaneous abortions.

Our local population has an ethnic mix typical of US urban areas. In our newborn screening program, about 4% have Factor V Leiden, and about 14% of African-Americans have Hb Bart's. However, we found that, among newborns with Factor V Leiden, 28% have Hb Bart's. The alpha chain deletions that result in the presence of Hb Bart's *also change hematologic indices.* This may ameliorate prenatal thrombotic events stemming from Factor V Leiden, resulting in differential survival. We will present our figures to date, along with statistical analysis.

Program Nr: 2339 from the 1999 ASHG Annual Meeting

Negative Impact of Missed Appointments on Clinical Genetics Service Delivery. *A. Zimak, A. Hunter, L. Humphreys, M. Cappelli.* Genetics, Children's Hosp. Eas. Ontario, Ottawa, Ontario, Canada.

Patients who miss appointments or cancel with short notice cause significant disruption in the delivery of clinical genetic services, and they become relatively more important as the demands on limited genetic resources grow. Our purpose was to examine the problem of non-attendance at genetic clinics and to examine existing interventions used by genetic centres to improve the attendance rate. This study looked at non-attendance rates at 21 genetic centres across Canada. The participants were sorted into groups of: Small (<500 visits/yr; n = 8); Medium (500-2000 visits/yr; n = 7); Large(>2000 visits/yr; n = 6). All participants completed a survey concerning their no show rate for physician and genetic counsellor appointments; cancellation rates; perceived importance of their no show rate; and interventions used to improve attendance. The non-attendance rate for physician appointments at all of the centres was 6%, compared to 5.7% for counselling appointments. The cancellation rate was 12% for physicians and 7.5% for counsellors, and the total non-attendance and cancellation rate for all appointments was 10%. Sixty-five percent of the centres stated that non-attendance was a problem. Seventy-five percent of the centres were using three or more interventions such as reminder calls, letters to referring physicians, and notices of missed appointments, which had mixed results in reducing missed appointments. As a follow-up to these results, a second study using a patient-based questionnaire was conducted to examine reasons for non-attendance at a genetics clinic. The findings from both studies will be used to develop targeted interventions to reduce both no-show and late cancellations of appointments. Evaluating the outcomes of these interventions will likely be useful for other genetic and outpatient health centres experiencing similar problems.

Program Nr: 2340 from the 1999 ASHG Annual Meeting

The German Human Genome Project (DHGP). *J. Maurer.* Managing Office of the Scientific Coordinating Committee, German Human Genome Project, Heubnerweg 6, D-14095 Berlin, Germany.

The German Human Genome Project (DHGP) is a joint effort between the German Federal Ministry of Education and Research (BMBF) and the Deutsche Forschungsgemeinschaft (DFG). The scientific work started in 1996. Since then, the DHGP has had an increasing impact on the international activities of the Human Genome Project. The project is represented by a scientific coordinating committee (elected members: Rudi Balling, Munich; Hans Lehrach, Berlin; Jens Reich, Berlin). Projects cover large scale genetic linkage analysis with an emphasis on multifactorial and complex traits, physical mapping (focused on chromosomes 17, 21, and X), sequencing (particularly 7, 21, X, and full length cDNA), expression studies, bioinformatics, studies of model organisms (e.g. large scale ENU mouse mutagenesis screen), and human evolution. A major research interest is to reveal the function of genes, especially those with medical relevance. Currently the second phase of funding is about to begin. It is expected that the emphasis will be shifted to high throughput functional genomics. For a comprehensive listing of current projects please refer to http://www.dhgp.de/. Currently, more than 50 projects are funded that were selected by an internationally composed scientific advisory board. For the whole initiative about DM 45 Mio (roughly US$ 25 Mio) per year are available. To promote and channel the application of the obtained scientific results a patent and licensing agency was established that supports scientists in patent affairs (www.pst.fhg.de/pla/). The Resource Center (funded by BMBF) at the Max Planck Institute for Molecular Genetics, Berlin, and the Deutsches Krebsforschungszentrum, Heidelberg, constitutes the central structural unit. It generates, collects and files standardized reference materials and distributes them among all groups participating in the DHGP. Its extensive service can, however, also be obtained by all researchers world-wide (for information please refer to http://www.rzpd.de/).

Program Nr: 2341 from the 1999 ASHG Annual Meeting

Pericentromeric region of human chromosome 22: Boundary between duplication segments and gene-rich region. *H.E. McDermid[1], B. Roe[2], P. Brinkman-Mills[1], M.A. Riazi[1], L. Bridgland[1], S. Maier[1], G. Banting[1], L. Ray[2], T. Nguyen[2], S. Minoshima[3], N. Shimizu[3], T. Footz[1].* 1) Dept Biological Sci, Univ Alberta, Edmonton, AB, Canada; 2) Dept Chemistry & Biochemistry, Univ Oklahoma, Norman, OK; 3) Dept Molecular Biology, Keio Univ School of Medicine, Tokyo, Japan.

Cat eye syndrome (eye, anal, heart, kidney and facial defects and mental retardation) results from the presence of four copies of the pericentromeric 2 Mb of human chromosome 22q. Recent analyses of sequence from the pericentromeric regions of chromosomes 2 and 16 (Horvath et al, 1998) and 10 (Jackson et al, 1999) reveal a complex mosaic of duplication segments from elsewhere in the genome. Mapping of the pericentromeric region of chromosome 22 has indicated a similar pattern (Minoshima et al, 1998). We have constructed and sequenced a BAC/PAC contig spanning the second Mb of pericentromeric 22q. Sequence analysis of the proximal half of this contig reveals a transition from complex duplication segments to a unique gene-rich region. The duplication segments include the unprocessed pseudogene of the von Willebrand factor (F8VWFP) and a number of fragments of the kappa light chain immunoglobulin variable region. Also present are segments from chromosomes 2, 10, 11, 16, 21, X and Y, as well as a fragment of the lambda light chain immunoglobulin variable region duplicated from elsewhere on chromosome 22. Interspersed repeats found throughout this region show an unusual distribution which favours LINES over SINES, the opposite pattern of the more distal gene-rich region. The latter contains at least 9 chromosome 22-specific putative genes. These genes are present in four copies in cat eye syndrome and are therefore being investigated as candidate genes. However, the complex of repeats proximal to this gene-rich region contains many gene fragments duplicated from throughout the genome. This may result in the creation of new genes which could also be candidates for involvement in cat eye syndrome.

Program Nr: 2342 from the 1999 ASHG Annual Meeting

Physical and transcript mapping of human chromosome 14q32. *D.A. McFadyen, B. Kraus, L. Read, D.W. Cox.* Dept Medical Genetics, Univ Alberta, Edmonton, AB, Canada.

We are constructing a physical and transcript map of the most distal region of chromosome 14, and have sequence-ready material for the region. The 14q32 region contains genes for Usher syndrome, retinitis pigmentosa, and neuroblastoma. The interval of interest encompasses the cytogenetic band 14q32 and is flanked by the serine protease inhibitor gene cluster at the centromeric end, and by the immunoglobulin heavy chain (IGH) gene cluster at the telomeric end. By FISH mapping of markers throughout the region and physical data, we have estimated the total length to be approximately 7.8 Mb, considerably smaller than anticipated by linkage analysis. A YAC contig of 5.5 Mb extending from D14S81 (in the serine protease inhibitor gene cluster) to D14S293 has been constructed. The STS and EST content of the YAC contig distal to D14S78 and extending to D14S293, an estimated 1.8 Mb, has been used as a source of probes for the isolation of BAC and PAC clones from this region. The approximately 2.3 Mb region distal to D14S293 is underrepresented in YAC libraries and we have used linkage and radiation hybrid maps to develop probes for clone recovery. The region is currently represented by six contigs, consisting of 113 clones, from which bidirectional chromosome walking has been undertaken, using probes derived from the sequenced ends of clones, to close the gaps. The construction of a transcript map of 14q32 is being facilitated by the use of software that generates a non-redundant in silico library of ESTs that have been reported to map to this region of chromosome 14. Presently, 23 STSs and 36 ESTs have been placed on the contig. We have determined more precisely the order of some of the genes previously mapped to the region, including: EMAP, YY1, HSPCAL4, TNFAIP2, CDC42BPB, XRCC3, CKB, DNCL, AKT, DLK, JAG2, CRIP2, and ELK2. The comprehensive map that we are developing will assist in disease gene discovery in this region.

Program Nr: 2343 from the 1999 ASHG Annual Meeting

An Integrated Linkage-Radiation Hybrid Map of theCanine Genome. *C.S Mellersh[1], C. Hitte[2], M. Richman[1], F. Vignaux[2], C. Priat[2], S. Jouquand[2], P. Werner[3], C. Andr[2], S. DeRose[1], D.F. Patterson[3], E.A. Ostrander[1], F. Galibert[2].*
1) Clinical Research D4-100, Fred Hutchinson Cancer Res Ctr, Seattle, WA; 2) UPR 41 CNRS, Recombinaisons Gntiques, Facult de Mdecine, 35043 Rennes Cdex, France; 3) Section of Medical Genetics and Center for Comparative Medical Genetics, University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA 19104.

Purebred dogs are a unique resource for dissecting the molecular basis of simple and complex genetic diseases and traits. As a result of strong selection for physical and behavioral characteristics among the 300 established breeds, modern dogs are characterized by high levels of interbreed variation, complemented by significant intrabreed homogeneity. A high resolution map of the canine genome that contains both type I and type II markers is necessary to establish the syntenic relationship between the dog and other mammalian genomes and thus exploit the mapping power of this unusual resource. To this end we have constructed a radiation hybrid (RH) map of the canine genome and have integrated it with the most recent version of the canine linkage map. The map contains more than 600 markers, of which approxiately two thirds are microsatellites and one third are genes. The map likely identifies a syntenic group (a linkage group aligned with its corresponding RH group(s)) for each canine chromosome and is estimated to cover in excess of 95% of the genome. Partial alignment of the canine and human maps enables conservation of synteny between dog and human chromosomes to be investigated and also offers the opportunity for candidate gene studies suggested by initial linkages deduced from the primary linkage map.

Program Nr: 2344 from the 1999 ASHG Annual Meeting

Genomic sequencing and identification of 190 genes on human chromosome 22q11.1-q11.2. *S. Minoshima, T. Sasaki, K. Kawasaki, A. Shintani, K. Shibuya, S. Asakawa, N. Aoki, Y. Yoshizaki, J. Kudoh, N. Shimizu.* Dept Molecular Biol, Keio Univ Sch Medicine, Tokyo, Japan.

We have been analyzing genomic sequence of 3 regions on chromosome 22q11.1-q11.2. These include the proximal half of the cat eye syndrome (CES) region (D22S458-D22S50, 1.1 Mb), a 1.8-Mb contiguous region from Velo-Cardio-Facial syndrome (VCFS) "distal repeat" to immunoglobulin l gene locus (IGL) (BCRL2-GNAZ), and another contiguous 1.5-Mb region from BCR to the IGL-like gene (IGLL) region (BCR-TOP1P2). The total length of these regions is 4.4 Mb corresponding to 10% of the chromosome 22q. To date, we have completed a total of 3.6 Mb of genome sequencing for these regions. For the CES region covered with 4 BAC and 26 cosmid clones, 0.9 Mb has been processed. The sequence analysis predicted at least 7 genes, including neurofibromatosis type 1 (NF1)-like, g-glutamyl transpeptidase (GGT)-like, adrenoleukodystrophy (ALD)-like, CESK1, and von Willebrand factor-pseudogene (F8VWFP). For the IGL locus, a contiguous sequence of 1,025,415 bp was determined. The detailed analysis revealed 36 potentially active immunoglobulin V genes, 83 V pseudogenes, 7 J genes and 7 C genes. Thirteen non-immunoglobulin genes and pseudogenes were identified, including a gene belonging to phosphatase 2C family, topoisomerase 3b, VpreB, and melanoma antigen PRIME (Genome Res. 7: 250-261, 1997). For the VCFS distal repeat region, GGT.2, GGT-rel, BCRL2, POM121, the E2F factor 6 pseudogene, and a new gene which matches with 18 ESTs were found. For the IGLL region, a total of 25 genes were identified, including a suppressor gene for a malignant Rhabdoid tumor, hSNF5/INI1, both an active gene and a pseudogene for IGLL, glutathione S-transferase q (GSTT), 4 D-dopachrome tautomerase (DDCT), BCR, GGT, and GGT-related. GSTT and DDCT were found as a large cluster consisting of 9 GSTT and 4 DDCT genes/pseudogenes. A deletion of GSTT1 was found in one of 2 alleles. It is noteworthy that the GSTT1 deletion was homozygously found in 16% of the Caucasian and that it is associated with an increased rate for cancer.

Program Nr: 2345 from the 1999 ASHG Annual Meeting

Are common fragile sites preferential targets for the integration of mitochondrial DNA during evolution? *D. Mishmar[1], C. Kilger[2], T. Haaf[3], A. Rahat[1], S. Paabo[4], B. Kerem[1]*. 1) Genetics, Hebrew University, Jerusalem, Israel; 2) Lion Bioscience AG, Heidelberg, Germany; 3) Max Planck Institute for Molecular Genetics, Berlin, Germany; 4) Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.

Fragile sites are specific unstable chromosomal loci characterized by gaps and constrictions on chromosomes from cells exposed to specific chemical conditions. In humans there are >100 fragile sites, classified as rare and common according to their prevalence in the population and mode of induction. Common fragile sites (cFS) are considered part of the normal chromosome structure and exhibit some characteristics of instability: gene amplification, chromosomal rearrangements and foreign DNA integration. Three cFS have been identified at the molecular level, all shown to be targets for viral DNA integration indicating that fragile sites are unstable genomic regions which tend to rearrange. Despite their instability, evolutionary conservation was found for several cFS, indicating that these sites might play an important biological role. The nuclear DNA of various organisms contains mitochondrial DNA (mtDNA) homologous sequences. These sequences are thought to arise by the integration of mtDNA into the nuclear genome during evolution. We have identified >90 mtDNA integration sites in the human genome by screening PAC libraries with mtDNA. Here we investigated the possibility that cFS might have been preferential targets for these integration events. We have studied four of the PAC clones which map to chromosomal regions (4q31, 3p22-23, 9q22, 13q31-32) known to harbor cFS (FRA4C, FRA3A, FRA9D and FRA13D, respectively). FISH analysis using these PAC clones was performed on metaphase chromosomes expressing cFS. Three of the clones (from 4q31, 3p22-23, 9q22) appeared to span a fragile site gap (FRA4C, FRA3A and FRA9D respectively), hence on different chromosomes from the same preparation their hybridization signals appeared centromeric, telomeric, or crossed the fragile region. These results suggest that mtDNA integration might have occurred preferentially at cFS. Thus, cFS might play a major role in chromosomal evolution.

Program Nr: 2346 from the 1999 ASHG Annual Meeting

Physical mapping of the candidate region for the gene causing Limb-Girdle Muscular Dystrophy type 2G (LGMD2G). *E.S. Moreira[1], T. Wiltshire[2], M. Vainzof[1], R.H. Reeves[3], M. Zatz[1], M.R. Passos-Bueno[1]*. 1) Depto. de Biologia, Instituto de Biociências, Universidade de São Paulo, Brasil; 2) Dept. of Psychiatry, University of Pennsylvania, Philadelphia, PA, USA; 3) Dept. of Physiology, Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Limb-Girdle Muscular Dystrophy type 2G (LGMD2G), one of the 8 forms of Autosomal Recessive (AR) LGMD, was recently mapped by us to 17q11-12 through a genome-wide scan in one Brazilian family. Only 2 of 29 other Brazilian AR LGMD families tested with 17q11-12 markers are possibly linked to the LGMD2G locus, suggesting that this form of muscular dystrophy is rare in our population. The candidate interval for the LGMD2G gene, based on recombination analysis, was delimited between D17S1867 and D17S1814, which are estimated to be 3 cM apart. We are now constructing a BAC/PAC contig of this region. The clones have been selected either by screening of genomic DNA libraries or through scanning the Whitehead Institute web-site, using 28 STSs mapped to 17q11-12. Identification of overlaps between clones was performed using STS mapping and EcoRI fingerprinting. So far, we have been able to construct 3 contigs, including a minimum of 21 clones. Two of them are approximately 700kb and 500kb and harbor the proximal and distal flanking markers D17S1867 and D17S1814, respectively. The largest one, covering a region of about 900kb, comprises microsatellites D17S250, D17S1851, D17S946 and D17S1814, which are known to be non-recombinant in the LGMD2G families. Three novel microsatellites have been identified within the 900kb contig, all of them being polymorphic in our population. Genotyping of these markers in the LGMD2G families showed no recombination between any of them and the disease gene. In conclusion, the contigs are ordered as 700kb-900kb-500kb and the candidate region has a minimum of 900kb. Presently, we are conducting end sequence STS generation in order to close the remaining two gaps. Completion of this physical map will provide the framework necessary for the positional cloning of the LGMD2G gene. Supported by FAPESP, HHMI, CNPq, PRONEX.

Program Nr: 2347 from the 1999 ASHG Annual Meeting

Improving the Efficiency of Targeted Mutagenesis Using Bacteriophage l **Vectors.** *M.L. Mosaico, K. Woltjen, M.W.T. Unger, G. Bain, D.E. Rancourt.* Biochemistry & Molecular Biology, University of Calgary, Calgary, Canada, T2N 4N1.

Targeted mutagenesis is a pervasive biomedical technology that allows the engineering of specific mutations into the mouse genome. Its utility to human genetics is in the generation of animal models of disease and in the validation of drug targets. In the emerging functional genomics phase of the human genome project, it is anticipated that over 100,000 genes in the mammalian genome will need to be mutated. Following this agenda, we have initiated experiments to improve the efficiency of the targeted mutagenesis using bacteriophage l as a vector system. We have developed methods to streamline the construction of targeting vectors (TVs) by building them in bacteriophage l using phage-plasmid recombination. Using a recombination-proficient gene targeting phage, l2TK, we are able to introduce modification cassettes to desired sites using double-crossover recombination, thus obviating limitations in TV design, including restriction site availability. Using a novel mutagenesis method, custom mutations can be transferred from oligonucleotides to phage TVs using a plasmid interface. By developing a 129-ES cell genomic library in lTK, gene targeting phage can be rapidly isolated using recombination and modified as above. We have also explored whether intact bacteriophage may be used as a medium for introducing lTK TVs into ES cells. Typically TVs are introduced into ES cells by electroporation. While this is an effective method of delivery, it causes DNA shearing and can affect targeting efficiency either by reducing the total homology length or by severing the negative selection marker. We have electroporated TVs in phage capsids to potentially overcome these problems. We find that bacteriophage-mediated TV delivery yields targeted clones at efficiencies comparable to conventional methods. More importantly, we observe that two orders of magnitude less DNA-equivalents are required when using phage. These results suggest that phage-mediated TV delivery can significantly increase the absolute efficiency of gene targeting. As bacteriophage appear to be benign in ES cells, these observations indicate a possible future role for these vectors in human gene therapy.

Program Nr: 2348 from the 1999 ASHG Annual Meeting

A systematic approach for investigating primary iron overloads : Generation of iron-related SNPs. *J. Mosser[1], N. Soriano[1], F. Wojcik[1], V. Douabin[1], H. Ferran[1], S. Sachot[1], D. Lavenier[2], R. Moirand[3], Y. Deugnier[3], J-Y. Le Gall[1], V. David[1]*. 1) Faculty of Medicine, UPR 41 CNRS, RENNES, FRANCE; 2) IRISA, CNRS INRIA,Rennes, France; 3) Clinique des maladies du foie,CHU Pontchaillou, Rennes, France.

Hemochromatosis is essentially related to alteration of the HFE gene. In north european populations, the patients are mostly homozygous for the C282Y mutation but an incomplete penetrance of this mutation is suspected. Indeed systematic population screening studies showed that the frequency of the C282Y homozygotes was higher than that reported for the disease in the corresponding region. These discrepancies could be explained by the existence of modifier genetic factors. To identify these genes, we decided to use a candidate gene approach. As a first step of this study, we developped an informatic system to characterize putative SNP within genes involved in iron metabolism. This system provides a link between nucleotidic databases (UNIGENE clusters, Genbank ...) and EST trace data and then performs base calling and sequence assembly of all the sequences related to each gene of interest. The SNPs are selected when a mismatch of high-quality base calling occurs within a sequence identical to that of the assembling consensus. Among the 20 iron-related genes, 17 contained potential SNPs (average of 5 SNPs for each gene). Experimental SNP validation, performed by PCR-sequencing on 20 unrelated Breton control DNAs, revealed at most 50% reliability in SNP prediction. Further validations are required to define empirical threshold values for efficient SNP extractions. In parallel, we used both these validated SNPs and already known polymorphic markers to conduct systematic genotyping of families with C282Y incomplete penetrance. In the end, we expect that systematic genotyping will provide the characterization of some discriminative haplotypes in iron overloads or iron deficiencies.

Program Nr: 2349 from the 1999 ASHG Annual Meeting

***in silico* differential display.** *H. Murakami[1,2], T. Suzuki[2,3], J. Goto[1,2], S.-Y. Jeong[1,2], H. Hashida[1,2], N. Masuda[1,2], I. Kanazawa[1,2].* 1) Dept Neurology, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 2) CREST, Japan Sci. and Tech. Copy., Tokyo, Japan; 3) Dept Medical Zoologyarasitology, Grad Sch Med, Nagoya City Univ.

Differential display (DD) is a powerful method to show the lineage-related gene expressions. We developed Computer programs predicting the result of the experiments of DD.
Analyzing and comparing with actual data, the band patterns of DD can increase the specificity of the result. The novel system of computer simulations for DD results is being used with the genetic database and some specific primers. We prefer to name it, "*in silico* Differential Display".;

The following are a list of components that the program is specifically designed to handle;.

1. Checking the cDNA database of a species in the Genbank and create a new database file to use *in silico* DD.
2. Adding the predicted PCR products in to the database file and make suitable landmarks for a band in a DD experiment.
3. Calculating the specific DD pattern by an input of the gene ID.

The band that is both observed in *in silico* DD and in the actual DD image are highly likely to be the area interest. If not, the unpredicted band in the actual DD is likely to be a novel gene.

In silico DD method has the advantage of having a low running cost and labor in comparison to the DNA array technique particularly. This method is likely to bring about greater efficiency for research involving the routine DD method.

Program Nr: 2350 from the 1999 ASHG Annual Meeting

Using the Invader™ Squared FRET Assay on a Panel of 24 Genomic Samples to Detect Single Base Changes at Multiple Loci. *B.P. Neri, D.M. Marshall, B. Aizenstein, E.L. Beaty, S.M. Law, K.W. Nichols, M. de Arruda.* Third Wave Technologies, Inc., Madison, WI.

As more of the human genome sequence is determined, a large number of single nucleotide polymorphisms (SNPs) are being discovered. It is becoming evident that SNPs are associated with certain medical disorders, response to drug therapies, and risk for some diseases. Therefore, the ability to detect SNPs in genomic DNA samples has important clinical and pharmacogenomic applications. The Invader™ Squared Assay employing FRET detection is a sensitive, low cost, and easy to use method that is capable of discriminating single base changes, insertions, and deletions directly on genomic DNA **without** the use of PCR. The components of the assay are two target specific oligonucleotides (termed the Invader and the signal probe), a FRET oligonucleotide, and the Cleavase® enzyme. The Invader and signal probe hybridize to the target, forming an overlapping complex only if the base of interest at the site of the SNP is present. This complex is a substrate for the structure specific Cleavase enzyme. The product of the cleavage event induces another cleavage event on the FRET probe which frees the signal fluorophore from the nearby quenching dye. Both reactions occur near the melting point of the oligonucleotides involved, so that multiple hybridization and cleavage events occur for each target molecule present, eliminating the need to amplify the target of interest. We will present data detecting single nucleotide changes at multiple loci on a panel of genomic DNA samples from 24 ethnically diverse individuals. All reactions involved the addition of less than 100 ng of genomic DNA (< 30,000 target molecules) and occurred in 96-well reaction plates that contained lyophilized reagents. Following a denaturation step, the reaction plates were incubated for 4 hours isothermally. The fluorescence signal was detected directly on the reaction plates without the need for any further sample manipulation. This demonstration shows that the Invader Assay is a versatile, simple, and low cost method that is suitable for the high throughput screening of SNPs.

Program Nr: 2351 from the 1999 ASHG Annual Meeting

Expression of non-deleted genes in the 18q- syndrome. *P. O'Connell[1], S.G. Hilsenbeck[2], J.D. Cody[3], Z. Wang[3], R.J. Leach[3]*. 1) Cell Biology, Baylor College of Medicine, Houston, TX; 2) Medicine, Baylor College of Medicine, Houston, TX; 3) Cellular and Structural Biology, University of Texas Health Science Center at San Antonio, San Antonio, TX.

The molecular mechanisms of disease pathogenesis in monosomic syndromes are poorly understood. Our recent studies of the 18q- monosomy indicate that while reduced gene expression of the deleted genes is common, some deleted genes can express at normal levels due to dosage compensation, and may influence the disease phenotype (Wang et al., Hum. Genet., in press). In the present study, we investigated whether alterations in the expression of non-deleted genes is also a feature of this disorder. This hypothesis was explored using two commercially available complementary DNA (cDNA)-based gene arrays interrogated with cDNA derived from poly-A+ RNA from either an 18q- patient or a normal control. The poly-A+ RNA was recovered from lymphoblastiod cell lines. The observed patterns of gene expression were subjected to statistical analysis utilizing a principle components-based approach, and genes known to be deleted in the 18q- patient exhibited appropriately reduced gene expression levels. Variations of gene expression between 18q- patients and normal controls were confirmed by a quantitative reverse-transcription polymerase chain reaction (RT-PCR) method tested on an expanded group of patients with 18q- syndrome and additional normal controls. These experiments indicate that altered gene expression of non-18q genes in 18q- patients was rare. A few genes (approximately 1%) showed up to two-fold increases or decreases in levels of gene expression in a subset of patients. These changes in gene expression in the non-deleted genes are of the same magnitude as seen for genes deleted in 18q- patients. These data support the notion that monosomic phenotypes can result from haploinsufficiency of deleted genes, but do not rule out a role for low magnitude variations of gene expression of certain non-deleted genes in some patients. These genetic variations may play a role in the variability of the phenotypic presentation of monosomies from patent to patient, even when their deletion breakpoints are similar.

Program Nr: 2352 from the 1999 ASHG Annual Meeting

Denaturing High Performance Liquid Chromatography (DHPLC) Detects *BRCA1* and *BRCA2* Mutations with High Sensitivity. *P. Oefner[1], D. Stoppa-Lyonnet[3], E. Fleischmann[2], D. Muhr[2], S. Pages[3], T. Sandberg[4], V. Caux[3], R. Moeslinger[2], G. Langbauer[2], A. Borg[4], T. Wagner[2]*. 1) Biochemistry, Univ Stanford, Palo Alto, CA; 2) Dept OB / GYN, Div Senology, Univ Vienna, Vienna, Austria; 3) Unite Genetique Oncologique, Inst Gustave Roussy, Villejuif, France; 4) Dept Oncology, Lund University, Lund, Sweden.

Denaturing high performance liquid chromatography (DHPLC) is a recently developed method of comparative sequencing based upon heteroduplex detection. To assess the sensitivity of this method 180 mutations in BRCA1 and BRCA2 were tested: First, we analyzed 131 different mutations (50 deletions, 9 insertions and 70 single base substitutions) that had been identified originally by DGGE, PTT, SSCP or direct sequencing. Second, 49 different mutations (46 single base substitutions, 2 deletions and 3 insertions) that had been reported previously were identified by DHPLC in the process of screening 183 HBOC families and 111 control individuals from world wide populations. Third, 30 index individuals with complete direct sequencing analysis of BRCA1 were reanalyzed by DHPLC. Fourth, 41 index individuals were concomitantly analyzed by both DGGE and DHPLC. All 180 different BRCA1 and BRCA2 mutations showed heterozygous DHPLC elution profiles. The reanalysis of 30 index individuals revealed 1 splice site mutation initially missed by direct sequencing. The concomitant analysis of 41 index cases showed that 4 out of 4 probably disease associated mutations were identified by DHPLC and 3 out of 4 by DGGE. We conclude that DHPLC is as sensitive as direct sequencing but significantly less expensive and less labor intensive.

Program Nr: 2353 from the 1999 ASHG Annual Meeting

An STS, EST/gene and YAC/PAC based physical map of the Split hand-Split foot type 3 (SHFM3) critical region on chromosome band 10q24. *R.S. Ozen[1], B.E. Baysal[2], F.E. Orkunoglu[1], B. Devlin[2], C.W. Richard III[3]*. 1) Dept Medical Genetics, Gulhane Med Academy Med Fac, Ankara, Turkey; 2) Department of Psychiatry, University of Pittsburgh Medical Center, Pittsburgh, PA; 3) Wyeth-Ayerst Research, Radnor, PA.

Split-hand/split foot malformation (SHFM, ectrodactyly) is a human limb malformation characterized by aberrant development of central digital rays with absence of fingers and toes, a deep median cleft and fusion of remaining digits. SHFM is clinically and genetically heterogeneous. Three SHFM disease loci have been genetically mapped to chromosomes 7q21 (SHFM1), Xq26 (SHFM2), and 10q24 (SHFM3). We have previously confined the SHFM3 locus to an approximate 2 Mb interval between D10S1147 and D10S1240 by analysis of a multigenerational Turkish family. We have also shown that SHFM3 displays transmission distortion. The mutant allele is preferentially transmitted from affected fathers to his offspring. The SHFM3 critical interval harbors other known disease loci including infantile onset spinocerebellar ataxia (IOSCA) and renal coloboma syndrome, which is caused by mutations in the PAX2 gene. To facilitate the identification of SHFM3, we have built a physical map across the critical region. We have analyzed and ordered 16 CEPH mega-YACs, which are selected based on the regional framework map from Whitehead Institute physical mapping database. Eight PAC clones were selected from previous physical mapping studies on the IOSCA locus. These clones are ordered by STS content mapping. A total of 39 STSs have been used to refine the physical map. Using the constructed map, we have further tested and mapped numerous ESTs and regionally localized known genes, including FGF8, PAX2, CYP17, HOX11 and LBX. We have localized FGF8, PAX2 and CYP17 and three anonymous ESTs (WI-3735, WI-6750 and WI-16946) within the SHF3 critical region. Mapping of additional transcribed sequences and further refinement of the map is underway. This physical map will help in the identification of SHFM3 and other disease loci on chromosome band 10q24, as well as in the elucidation of mechanism of transmission distortion.*SHFM1SHFM2SHFM3IOSCAPAX2*.

Program Nr: 2354 from the 1999 ASHG Annual Meeting

Optimizing full-length gene isolation by PCR based methods. *D. Patzak, M.S. Wehnert.* Institute of Human Genetics, Greifswald, Germany.

The structure of human genes can be detected from the genomic sequence and expressed sequences. Large-scale analysis of expressed clones (e. g. ESTs, SAGE) is often limited to partial sequences. Still the extension to of full-length expressed genes from pieces is a bottleneck for further functional analysis and disease association. Thus we tried to optimize the isolation of whole expressed genes from partial sequences. For this we used partial cDNA clones obtained from a human heart cDNA-library by reciprocal probing including the ribosomal protein L31 (as a control) and two unknown X-chromosomal cDNAs. The two unknown human cDNAs were used to screen the "I.M.A.G.E. consortium clone collection" by filter hybridization (RZPD Berlin and Heidelberg). No positive clones could be verified although EST entries (GenBank) indicate their presence. Spurred by some disadvantages of library screenings (e. g. missing signals, effort, incomplete cDNAs) we focussed on RACE-PCR (rapid amplification of cDNA ends). Using a commercial system (CLONTECH, Marathon-Ready cDNA) to amplify adaptor-ligated templates in both directions (5' and 3' extension) we could isolate differently spliced cDNAs in one case but only artifacts and parts of non-related genes in the other case. We developed modifications in order to overcome some disadvantages of the commercial RACE system (e. g. amplification of non-related genes, amplification of shorter ends). These modifications include: (i) adaptor-ligation to a PCR-product obtained from a specifically prepared full-length cDNA (ii) nuclease-digestion after the first cycle of PCR to prepare a more specific template for the following cycles and (iii) usage of end-primers (without adaptor-ligation) that preferentially work together with gene specific primers. Modification (i) and the combination of (ii) and (iii) were found to get the best results for specific amplification of 5' and 3' cDNA-ends.

Program Nr: 2355 from the 1999 ASHG Annual Meeting

Functional Mapping of the Human 17 Syntenic Region on Mouse Chromosome 11. *M.A Pershouse, W.W Cai, J. Klysik, W.M. Di, E.K. Brundage, A. Bradley, A.C. Chinault.* Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Even with the completion of the sequencing of the human genome in the near future, there will exist functional data for only a small fraction of the 80,000 to 100,000 genes. The overall goal of this project is to provide functional evidence for genes mapping to human chromosome 17, a linkage group which is conserved on mouse chromosome 11. Our collaborators will employ phenotype-driven screens in mice or cell lines which have been manipulated by *loxP/Cre* chromosomal engineering techniques to contain large regions of segmental haploidy. These regions will be further targeted for ENU mutation to uncover recessive alleles. Our laboratory's role in this project is to establish a high resolution BAC map of this region. The map will be used for a number of purposes, but primarily to aid in finding the genes responsible for phenotypes seen in deletion or mutation mice. Mapping has been initially concentrated in the region from 56-66.5 cM to coordinate with initial deletion studies, but will eventually cover the entire 33-80 cM region. Mapping was accomplished by screening with labelled overgo primers designed against available STS markers and 3' and 5' UTRs. Gap closure was facilitated by BAC end sequencing, primer design, and rescreening of the library. Restriction digest fingerprints were used to optimize the rescreening process. To date, we have identified 299 BAC clones using 115 markers, with 605 total hits, or approximately 2 hits per BAC. We have also developed a high-throughput BAC prep which generates sequence-ready template, and have sequenced over 16 kb of BAC ends to date. Approximately 25% of our BAC end sequences map within known genes or to cDNAs within Unigene clusters, suggesting the usefulness of this data not only in probe generation, but in gap closure. Detailed maps of this region will be presented.

Program Nr: 2356 from the 1999 ASHG Annual Meeting

Comprehensive Transcript Analysis in Small Quantities of mRNA by SAGE-Lite. *D.G. Peters[1], A.B. Kassam[2], E. Heidrich-O'Hare[1], H. Yonas[2], R.E. Ferrell[1], A. Brufsky[3].* 1) Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Neurosurgery, Univ Pittsburgh, Pittsburgh, PA; 3) Hematology/Oncology, Univ Pittsburgh, Pittsburgh, PA.

Serial Analysis of Gene Expression (SAGE) is a powerful technique for global analysis of gene expression in a tissue or cell type of interest. Its chief advantage over other methods is that SAGE does not require prior knowledge of the genes of interest and provides quantitative and qualitative data of potentially every transcribed sequence in a cell or tissue type. Furthermore, SAGE can quantify low abundance transcripts and reliably detect small changes in transcript abundance between cell populations. However, SAGE demands high levels of mRNA which are often unavailable, particularly when studying human disease. To overcome this limitation, we have developed a modification of SAGE that allows detailed global analysis of gene expression in extremely small quantities of tissue. We have called this approach "SAGE-Lite". This technique was used for the global analysis of transcription in samples of normal and pathological human cerebrovasculature to study the molecular pathology of intracranial aneurysms (ICA). These samples, which are obtained during operative surgical repair, are typically no bigger than 1 or 2 mm^2 and yield <50 ng of total RNA. In addition, we show that SAGE-Lite allows simple and rapid isolation of long cDNA fragments from short (14 bp) SAGE sequence tags.

Program Nr: 2357 from the 1999 ASHG Annual Meeting

5' nuclease assay as a tool for SNP haplotype studies of cancer genes. *R.J. Peterson[1], V.J. Clark[1,3], M.W. Smith[2], M. Dean[1]*. 1) Laboratory of Genomic Diversity, NCI-FCRDC, Frederick, MD; 2) SAIC, Frederick, MD; 3) Graduate Program in Genetics, PSU, University Park, PA.

Genetic background influences a person's vulnerability to cancer. An important fraction of this background is functional variation due to Single Nucleotide Polymorphisms (SNPs). As part of the Cancer Genome Anatomy Project, the goal of this study is to investigate the effect of SNPs on the initiation and progression of cancer. Linkage disequilibrium analyses for a large number of candidate genes require scoring many SNPs. However, SNP analysis using traditional gel electrophoresis is slow and costly. Because of this, we have investigated the 5' nuclease assay (TaqMan, PE) as a way to rapidly query many SNPs. In this fluorescent method, discrimination occurs during PCR due to allele-specific probes that, when hybridized to template, are cleaved by the 5' nuclease activity of Taq polymerase. Cleavage results in increased emission of a reporter dye (VIC or FAM) that otherwise is quenched by the dye TAMRA. Eighteen SNP assays were designed using PE's Primer Express software and tested on the PE Prism 7700 Sequence Detection System. The genes queried were: *CCR2, CCR5, GPR15, SDF1, XRCC1, JAK3, CDH1, GSTP1, CYP17* and *ATM*. Sixteen of the eighteen SNP assays yielded excellent discrimination using a single set of reagent concentrations and thermal cycling parameters. Genotypes for SNPs in *CCR2, CCR5, GPR15* and *SDF1* were concordant with genotypes collected using restriction enzymes and SSCP. Consistent Mendelian transmission was observed in 40 3-generation CEPH pedigrees comprising 489 individuals. Allele frequencies were obtained in thirty each of Europeans, African-Americans, Hispanics, and Asians. Preliminary results indicate that cluster and discriminate analysis allow allele calling for data pooled across multiple plates. Association analyses are being performed for *XRCC1, JAK3, CDH1, GSTP1,* and *CYP17* in case/control cohorts for lung cancer (n=271), breast cancer (n=196), AIDS-related lymphoma (n=200), and AIDS-related Kaposi's sarcoma (n=200). The success rate reported here of the 5' nuclease assay indicates that it is a useful tool for haplotype studies.

Program Nr: 2358 from the 1999 ASHG Annual Meeting

Assessment of quantity and quality of DNA from formalin-fixed paraffin- embedded tissue using real time rapid cycle DNA amplification. *K. Pindolia[1], G. Pals[2], M.J. Worsham[1]*. 1) Cancer Genetics Research, Pathology, Henry Ford Health Systems, Detroit, MI; 2) Free Univeristy, Amsterdam, The Netherlands.

DNA analysis from archival tissue permits retrospective characterization of disease and has facilitated molecular data gathering from large population-based epidemiological study cohorts. Reliable quantification of paraffin DNA for PCR is problematic even with the more recent DNA extraction kits that provide better DNA quality and yield. We evaluated a real-time rapid cycle PCR approach to quantitate DNA from formalin-fixed paraffin tissue employing PCR of the beta-globulin gene using DNA-binding dye SYBR Green I or hybridization probes specific for the beta-globulin gene. The amount of paraffin DNA was measured as the number of copies of the beta-globulin gene. The specific hybridization probe for the beta-globulin gene was more reliable and accurate than PCR incorporating SYBR Green 1. Melting curve analysis permitted confirmation of the PCR product. DNA from formalin-fixed archival tissue can be reliably assessed for quality, quantity and confirmation of specific PCR products using real time PCR. This approach allows the use of more accurate sample dilutions to achieve optimal PCR.

Program Nr: 2359 from the 1999 ASHG Annual Meeting

The use of DNA microarray to study genes affecting a phenotype related with schizophrenia in a mouse model. *Y. Qiu, J. Cheng.* Genome Science Department, Lawrence Berkeley National Lab, Berkeley, CA.

It has been established that mice treated with the psychotomimetic drug phencyclidine (PCP or angel dust) mimic both positive and negative symptoms of schizophrenia. The schizophrenic phenotype in mice can be measured using the pre-pulse inhibition (PPI) of the startle response. We have shown that the PPI of C57bl/6J mice was reduced to ~50% of the normal level by administrating 10 mg/kg of PCP of acute dosage. The disrupted PPI in C57bl/6J mice was found to be restored by the appropriate dosage of antipsychotic drug clozapine. Clozapine alone did not change the PPI of the mice. A DNA microarray containing more than 3,000 mouse genes is used to assay the expression changes in the brain of mice induced by the drugs. Three specific brain regions (ventral midbrain, hippocampus, and cerebellum) have been assayed. The RNAs are extracted from each of the regions after each treatment of PCP, PCP+clozapine, or clozapine alone. The gene expression profiles are also followed at several time points after the drug treatments. The genes that are found to be consistently induced or suppressed by PCP but restored by clozapine are identified as candidate genes.

Program Nr: 2360 from the 1999 ASHG Annual Meeting

Denaturing High-performance Liquid Chromatography (dHPLC) Analysis of Pooled PCR Samples for High-throughput Screening for DNA Sequence Variants of Human Populations. *M. Radel, R. Aragon, C. Mazzanti, B. Kolachana, J. Vanakoski, J. Rudolph, D. Goldman.* Laboratory of Neurogenetics, NIAAA, NIH, Rockville, MD 20852.

Oefner and colleagues (1996) have detected DNA sequence variants using reverse phase HPLC in the presence of an ion-pairing agent. At the appropriate temperature, partially melted DNA heteroduplexes have relatively reduced affinity to the hydrophobic matrix, enabling DNA variants to be detected with high sensitivity. Here we report for the first systematic detection of single nucleotide polymorphisms (SNPs) in pooled PCRs from human genomic DNA samples and using the Eclipse HP dsDNA column in an 8.5 min run. Evaluation of dHPLC pooling was conducted in blind fashion, using one standardized dHPLC method, and a single temperature for variant in each DNA amplicon. The temperature for dHLPC variant detection was selected based on an initial temperature optimization conducted independently of observation of genetic variation. Three SNPs were evaluated: 5-HT5A , GABRA6 1031G>C and GABRA6 1236C>T and the amplicons were, respectively, 196, 233, and 365 bp in size. The individually amplified genomic DNAs from eight individuals chosen for their previously known genotype were pooled, melted and reannealed to form mixtures of homo- and heteroduplexes. For the three SNPs, detection was accurately accomplished at a level of one heterozygous individual mixed with seven homozygotes, in other words, one part (allele) in sixteen. An advantage of SNP detection in pooled DNAs is that the denatured rarer allele strands have a greater chance to reanneal to DNA strands corresponding to the more abundant allele, augmenting the heteroduplex DNA signal. Sample pooling conserves template DNA and enhances the efficiency of dHPLC for automated high-throughput detection of DNA variants.

Program Nr: 2361 from the 1999 ASHG Annual Meeting

MGD: A Comparative Mapping Resource. *S. Ramachandran, J.A. Blake, J.A. Kadin, J.E. Richardson, M.T. Davisson, J.T. Eppig, and the Mouse Genome Informatics Group.* The Jackson Laboratory, Bar Harbor, ME.

An extensive catalogue of genes will be available when the Human Genome Project is completed. But information pertaining to gene function, genome organization and evolution will not be obtained immediately. Studying similar genes in different organisms can generate this information. Comparative maps provide data on gene neighbors, gene environment and evolution, thus allowing greater insight into the wider processes of genetics and disease. Candidate disease loci and complex disease trait information can sometimes be transferred across species and aid in the development of animal models of human disease.

The Mouse Genome Database (MGD) is a community resource of mouse genetic and biological information. MGD includes a scientifically curated data set designed to provide the scientific community with access to comparative genomic data. Homology assertions are extracted from literature, Chromosome Committee reports and personal communications and integrated into MGD where they can be accessed by the user.

Information can be retrieved from MGD in several ways. The web interface allows users to query the database using a simple, flexible form. A concise homology assertion table listing species, gene symbols, chromosomal assignments, supporting references and hypertext links to online species databases comprises the query result. Several different comparative map displays can also be generated. Comparative maps can be displayed directly on a web browser or created as postscript files suitable for printing. Oxford Grid displays are also available as a genome-wide graphical display tool. The user can thus visualize evolutionarily conserved regions between two species.

MGD encourages community submissions of data supporting novel homology relationships and updates to existing information.

Program Nr: 2362 from the 1999 ASHG Annual Meeting

Mapping and characterisation of an X-linked mental retardation locus (MRX) within Xp11.2. *F.L Raymond[1], J. Bonnington[1], S. Clegg[2], L. Willatt[1], D. Trump[1].* 1) Medical Genetics, Cambridge Institute for Medical Research, Cambridge University, Cambridge, UK; 2) Sanger Centre, Hinxton, Cambridge, UK.

There are over 60 families reported with non-syndromic X linked mental retardation. No gene in Xp11.2 has yet been identified that causes non-specific mental retardation although linkage to this region is described. We present 2 cases of MRX one with a familial interstitial deletion of Xp11.2 and the other with a de novo X autosome translocation with the X breakpoint at Xp11.2. The familial interstitial deletion was ascertained through a boy who presented with severe developmental delay. His mother also had learning difficulties but was less severely affected, although they both had similar behavioural phenotypes. The deletion was identified on G-banding and has been further defined by fluorescent in situ hybridisation using PACs from the region (http://www.sanger.ac.uk). The breakpoints lie between PACs dJ154P24(telomeric) and dJ1158B12(centromeric). Mapping of the boundaries of the deletion using further PACs, BACs and STS markers over this region has narrowed the candidate interval for defining a further MRX gene. The de novo translocation was found in an adult with profound mental retardation, unable to live independently. G banding analysis identified the X chromosome breakpoint to be also within Xp11.2. Fine mapping by fluorescent in situ hybridisation with PACs locates the breakpoint telomeric to the first case and lies between dJ8N8(telomeric) and dJ154P24(centromeric). This suggests there are at least 2 locii for MRX within Xp11.2 which lie on either side of dJ154P24.

Program Nr: 2363 from the 1999 ASHG Annual Meeting

Updates to VariationView: an applet to record and manage variation data, and its application to the tuberous sclerosis genes. *M.P. Reeve[1], V. Whittemore[2], D. Kwiatkowski[3].* 1) Genetics & Bioinformatics, Walter & Eliza Hall Institute, Parkville, Victoria, Australia; 2) National Tuberous Sclerosis Association, Landover, MD; 3) Genetics Laboratory, Hematology Division, Brigham & Women's Hospital, Boston, MA.

The VariationView java applet provides an intuitive graphical interface for entering insertions, deletions, and single-base changes in genomic and coding DNA context. The user can view the spectrum of variations from the exon or sequence level and by clicking on a variation see the effect of the change on the DNA and coding level. Variations are input by selecting the base(s) in question and the index and correct nomenclature are automatically.

In the process of collecting the mutations and polymorphisms for the tuberous sclerosis genes TSC1 and TSC2 a number of updates have been made to VariationView. These include new ways of filtering data for viewing, expanded storage of clinical information, an exon overview of variations by effect on coding sequence, inclusion of polymorphisms, and new output and printing features. An overview of TSC1 and TSC2 published variations will also be presented.

The VariationView should be generically applicable to other variation projects. As input it can take coding, genomic DNA, or a combination of the two, and existing variations can be loaded in batch format. Data is stored in MiniSQL, a light-weight relational database, and accessed from the applet through JDBC.

VariationView has been developed with the support of the National Tuberous Sclerosis Association and is currently being used as a repository for the published mutations in TSC1 and TSC2. The database can be viewed at http://zk.bwh.harvard.edu/ts.

.

Program Nr: 2364 from the 1999 ASHG Annual Meeting

Refined mapping of human chromosomal region 9p22 distal to the interferon gene cluster and construction of a transcript map of 1.2 Mb surrounding RP S6 gene. *A. Reigo[1,2], T. Lushnikova[1], I. Laanpere[1,2], R. Ilisson[1], A. Metspalu[1,2]*. 1) Dept.of Biotechnology, Tartu University Institute of Molecular and Cell Biology, Tartu, Estonia; 2) Estonian Biocentre, Tartu, Estonia.

The area telomeric of interferon gene cluster on human chromosome 9p has been shown to be involved in tumor growth regulation by several authors. Aiming to find new disease-related genes in this region, we have constructed an undisrupted double-linked 4.5 Mb YAC contig (12 clones) between D9S2016 (IFNB)and D9S157, based on restriction analysis with 10 rare-cutting enzymes, end-clone hybridisation and polymorphic marker PCR. The refined order of 13 markers included in the contig differs from published data (Bouzyk 1997; Kenmochi 1998). 10 YACs connecting the two above-mentioned well-known chromosomal landmarks were screened for the presence of 18 anonymous DNA markers selected from databases (radiation hybrids of the best likelihood) and for 17 newly-generated markers, increasing the mean density of reliable markers in this area to 8 per 1 Mb. Current stage of our project focuses on expression mapping of a 1.2 Mb subregion covered by RP S6-containing YAC clone 804B9, which was used as a probe for screening a chromosome 9 specific cosmid library and also for direct cDNA selection from a human fetal brain cDNA library. The localisation of this YAC clone on 9p22 was confirmed by FISH. 86 cosmid clones from the primary selection have been organized into a full length coverage contig with 3 minimal gaps according to their restriction fragment and L1-fingerprints. Analysis of 52 positive cDNA clones (end-sequencing, database similarity search, dot-blot and Southern hybridisation to the selected cosmid clones) has revealed 14 cDNAs of interest. 6 of them (one with no highly similar matches in database, one 94% similar to neurodegeneration-related protein mRNA, two including protein kinase domains and two similar to anonymous ESTs) are subjects to tissue expression analysis as most promising to represent new genes in this functionally interesting human chromosomal region.

Program Nr: 2365 from the 1999 ASHG Annual Meeting

Upstream cloning methods applied to intronic sequence: cloning the insertion point of the partial duplication of the a**-7 nicotinic cholinergic receptor subunit (CHRNA7) gene on chromosome 15q13-q14.** *B.P. Riley[1], A.M. Makoff[1], M. Mogudi-Carter[2], T.J. Jenkins[3], R. Williamson[4], D.A. Collier[1], R.M. Murray[1]*. 1) Dept. of Psychological Medicine, Inst Psychiatry, London, England; 2) Dept. of Psychiatry, Baragwanath Hospital, Soweto, South Africa; 3) Dept. of Human Genetics, University of the Witwatersrand, Johannesburg, South Africa; 4) The Murdoch Institute, Royal Childrens' Hospital, Melbourne, Australia.

Recent reports have strongly linked the a-7 nicotinic cholinergic receptor gene (CHRNA7) on chromosome 15q13-q14 to a sensory gating deficit common in schizophrenics, and have shown suggestive results linking this receptor gene to the primary phenotype of schizophrenia in two samples of North American families. We have previously shown suggestive results for linkage to schizophrenia using the same map of markers as the original report in South African Bantu families. A partial duplication of exons 7 to 10 with at least four novel upstream exons has been identified in the same chromosome region. In order to generate further markers in the region and to test for variability in the duplication, we wished to clone the insertion point of the duplication. Promoter cloning methods provide an efficient alternative to subcloning large genomic clones for upstream walking. Using the Genome Walker upstream promoter cloning kit with two DNA polymerases and nested primers in known sequence at the 5' end of exon 5, we generated a set of 21 fragments from ten reactions varying from 0.4 to 3 kilobases (Kb) in length. Nine of these fragments were ligated into pGEM directly from the reaction mixture. Three larger fragments (1.4-3 Kb) required gel purification before ligation. Sequencing of these fragments reveals two species, one with an uninterrupted, and one with an interrupted, Alu repeat sequence. All clones are positive for either known exon 5 sequence or for intron 4 sequences previously obtained by direct sequencing of two P1 clones positive for exons 5-10 of CHRNA7. An assay for the breakpoint is currently being developed.

Program Nr: 2366 from the 1999 ASHG Annual Meeting

GENINTER/GENAROM, a new version of GENATLAS to represent and simulate genetic and molecular interactions. *M. Roux-Rouquie[1], C. Capponi[2], M. Page[3], C. Mugnier[1], M-L. Chauvet[1], J. Frezal[1]*. 1) Genetique Medicale U393, INSERM Enfants-Malades, Paris Cedex 15, France; 2) Laboratoire dInformatique de Marseille, UP, France; 3) INRIA Rhne-Alpes UPMF Grenoble France.

GENAROM, the knowledge base dedicated to the representation and simulation of genetic and molecular interactions, is currently under development using a new knowledge representation (KR) system called AROM. AROM introduces novel features in the world of KR systems, two of which are especially important in the context of interactions. Firstly, AROM (acronym of Associating Relations and Objects for Modeling) deals with relations as well as objects. Relations are very powerful for representing knowledge in domains where objects are highly interconnected, as it is the case in biology for interactions. Secondly, AROM uses an explicit model of time, allowing one to model and simulate dynamic systems like interactions networks, a task currently out of the scope of existing KR systems. In addition, AROM allows one to categorize objects (genes and/or products) as well as relations among these objects. As a first step to construct GENAROM, we are involved in concept identification and vocabulary characterization, and currently two kinds of ontologies are under development, which refer to structures and processes. The internal structure of these ontologies consist of tree-like conceptual hierarchies with multiple inheritance (composition and specialization). Once ontologies have been identified and represented in the knowledge base GENAROM, they will be used as a basis for the categorization of new structures and processes. AROM does provide us with interactive mechanisms which are of great help to classify some new knowledge among the identified classes and relationships of ontologies. Automatic programs are planned to transfer the knowledge represented in GENAROM toward data represented in GENINTER of which structure was deduced from GENAROM. Referring to ontologies, biological functions will be modeled and represented, mainly as relationships among structures and/or processes.

Program Nr: 2367 from the 1999 ASHG Annual Meeting

Physical and transcript map of CCM1 candidate interval on chromosome 7q. *T. Sahoo[1], J.W. Thomas[2], S.-Q. Lee-Lin[2], P.M. Kuehl[2], C. Dokken[3], E.W. Johnson[3], E.D. Green[2], D.A. Marchuk[1]*. 1) Dept Genetics, Duke Univ Medical Ctr, Durham, NC; 2) NHGRI, NIH, Bethesda, MD; 3) Barrow Neurological Institute, Phoenix, AZ.

Cerebral cavernous malformations (CCM) are congenital vascular anomalies of the brain responsible for significant neurologic disability. Autosomal dominant forms of CCM have been described, and we and others have shown that a gene for CCM (CCM1) maps to chromosome 7q. The current CCM1 candidate interval encompassing a 1.9 Mb region on Chr 7q as defined by a common hispanic haplotype and additional recombinants has been completely sequenced. This has enabled us to construct a complete physical map of the CCM1 interval. We are using a sequence-based strategy to identify candidate genes. This involves computational analysis of the sequence using BLAST to search for known genes/transcripts, as well as the gene prediction programs GRAIL II, GENESCAN, and MZEF to identify putative coding regions within raw genomic sequence. Exons thus identified by computer analysis of genomic sequence are being amplified from our panel of patient genomic DNAs and subsequently sequenced to identify authentic mutations. We have so far identified and analyzed approximately 200 putative exons effectively covering about 960 Kb of genomic sequence. A number of known genes (CDK6, KRIT1, AKAP450, YOTIAO, PFTAIRE) that we have identified as mapping within the CCM1 interval are also being analyzed at the genomic sequence level. We have not yet identified any mutations in the CDK6 and AKAP450 genes. We are also including a strategy to detect micro- or macro-deletions that may be present in this region of Chr7q in CCM1 patients using somatic cell hybrids generated using isolated affected or unaffected Chr 7 from a number of our patients. Identification of the CCM1 gene and the nature of the mutations will be the first step towards achieving a better understanding of the pathogenesis of this disorder.

Program Nr: 2368 from the 1999 ASHG Annual Meeting

Automated method to construct high-throughput BAC physical maps. *J. Sainz, S. Gudjonsson, O. Gustafsson, H. Magnusson, G. Arnason, K. Benediktsson, G. Ludviksson, K. Stefansson, J. Gulcher*. Decode Genetics, Reykjavik, Iceland.

We have developed a highly automated method to rapidly construct large physical maps of BAC clones. At present we are constructing human BAC maps, spanning up to 40-Mb regions with a 0.1 Mb average density of markers, in less than 10 working days/person. The method is based on a two-step hybridization approach of pooled oligomers of genetic markers against a RPCI-11 BAC library with 12X genomic coverage robotically gridded in 6x6 density. Prior to the hybridizations, the primers are analyzed for repeat, E. coli and vector sequence content, and discarded according to the percentage and/or the melting temperature of the homology. The whole sequence analysis process is performed automatically by a computer program. The first hybridization step is based in two pools of primers, forward and reverse, and only the coincident signals in both hybridizations are selected as positive clones. This approach is very robust and, according to our data, has reduced the number of false positives below 5%. In the second step, the primers are pooled in rows and columns or in a binary approach and hybridized against the re-arrayed and gridded positive clones from the first step. Reading of positives is performed in both steps automatically by a computer program from scans of autoradiograms or phosphorimager files. The results provided by the computer program can be edited manually, if necessary, to improve the quality of the readings. Analysis of data to provide marker/BAC assignments and a graphical display of the physical map is also computerized. BAC/markers associations are confirmed by PCR and all the information is stored in a database that can detect clones contained in more than one chromosomal region as a quality control. The gaps are closed using the same method with new markers obtained from the BAC-ends or from data-mined sequences.

Program Nr: 2369 from the 1999 ASHG Annual Meeting

Localizing, ordering and orienting mouse collagen genes by high resolution FISH. *R. Sallinen[1], A.-P. Kvist[2], A. Latvanlehto[2], M. Rehn[2], I. Eerola[3], M.-L. Chu[4], P. Bonaldo[5], G.M. Bressan[5], B. Saitta[4], T. Pihlajaniemi[2], E. Vuorio[3], A. Palotie[1], M. Wessman[1], N. Horelli-Kuitunen[1].* 1) Departments of Clinical Chemistry and Biosciences, University of Helsinki, Helsinki, Finland; 2) Department of Medical Biochemistry, University of Oulu, Oulu, Finland; 3) Department of Medical Biochemistry and Molecular Biology, University of Turku, Turku, Finland; 4) Thomas Jefferson University, Philadelphia, USA; 5) Institute of Histology and Embryology, University of Padova, Padova, Italy.

High resolution fluorescence *in situ* hybridization (FISH) enables accurate ordering and distance measurements as well as determination of transcriptional orientation of genes. So far, high resolution FISH has mostly been used in human genome mapping but was here applied to the mouse genome.

We have used mouse metaphase chromosomes, mechanically stretched chromosomes and free DNA fibers for localizing, ordering and orienting five collagen genes by FISH. This was the first time mechanically stretched mouse chromosomes were used for physical mapping. Using metaphase FISH *Col6a1*, *Col6a2* and *Col18a1* were localized to mouse chromosome 10B5-C1, *Col13a1* to 10B4 and *Col10a1* to 10B1-B3 confirming the earlier linkage results. These regions are known to be homologous between human and mouse chromosomes. Mechanically stretched mouse chromosomes were used to determine the order of these five collagen genes and also to determine the transcriptional orientation of *Col13a1* and *Col18a1*. The most likely order of these genes on chromosome 10 is cen-*Col10a1*-*Col13a1*-*Col6a2*-*Col6a1*-*Col18a1*-tel. The transcriptional orientation of *Col6a1*, *Col6a2*, *Col13a1* and *Col18a1* is head to tail from telomere to centromere.

The comparison of the physical mapping results of human and mouse homologous collagen genes demonstrated that these five genes are clustered in mouse unlike in human. Chromosomal rearrangements and coincidence could together be the reason for clustering of these collagen genes in mouse. *Col6a1*, *Col6a2* and *Col18a1* might also share some transcriptional elements based on the short distance separating them.

Program Nr: 2370 from the 1999 ASHG Annual Meeting

High-density EST map of the rat. *T.E. Scheetz[1], M. Raymond[1], J. Zhang[1], A.M. McClain[1], C.A. Roberts[3], D.Y. Nishimura[1], T.L. Casavant[3], M.B. Soares[1,2], V.C. Sheffield[1]*. 1) Pediatrics and HHMI, University of Iowa, Iowa City, IA; 2) Physiology, University of Iowa, Iowa City, IA; 3) Electrical and Computer Engineering, University of Iowa, Iowa City, IA.

We are in the process of generating a high density EST map of the rat, placed on a framework of genetic markers. We have generated duplicate radiation hybrid mapping data on nearly 9000 nonredundant ESTs identified by our Rat Gene Discovery and Mapping Project (http://ratEST.uiowa.edu). We are placing these ESTs on published framework maps of genetic markers (1,2) as well as maps being constructed locally. Our ability to maintain a rate of novel EST discovery relies upon the method of serial subtraction of pooled, normalized 3' cDNA libraries (3). To date, we have been able to sustain a novelty rate of over 45% across more than 59,000 3' end reads, yielding over 27,000 novel clusters of 3' EST sequences.

To date, we have mapped, in duplicate, nearly 9000 novel rat ESTs, and have placed over 7000 of those ESTs on our frameworks maps. The chromosome framework maps have an aggregate total size of 11,000 cR, yielding an average physical correspondance of 270 kb per cM. Duplicate scores were used to create a consensus vector for every EST mapped. Discordant vectors were not utilized. The frameworks were built, and the placement maps created, using the RHMAPPER software package from MIT. Genetic marker order derived in the frameworks was compared with existing genetic maps available from the Whitehead Institute.

This EST map of the rat will be a valuable resource for constructing human-rat and mouse-rat syntenic maps, as well as aiding in the positional cloning of genes for rat models of human diseases. A web-based interface to the maps is available at http://ratEST.uiowa.edu/rat-map.

Program Nr: 2371 from the 1999 ASHG Annual Meeting

Comparative transcriptional mapping of human chromosome 20q13 segment and identification of new genes as candidate for imprinting. *D. Schlote[1], S. Kussmann[1], A. Hehr[1], K. Koerber[1], H. Miller[2], J. Peters[2], I. Hansmann[1].* 1) Institut fuer Humangenetik, Universitaet Halle, Halle/Saale, FRG; 2) Medical Research Council, Harwell, UK.

The mouse chromosome 2 segment (MMU2) corresponding to human chromosome 20 (HSA20) is known to be involved in both, maternal as well as paternal noncomplementation (genomic imprinting). Uniparental disomies for distinct regions of MMU2 result in different neonatal lethalities with opposite anomalous phenotypes, strongly suggesting the presence of imprinted genes in this region. These chromosomal regions show a conserved synteny of gene loci to human 20q13 segment, predicting the presence of imprinted genes in this chromosomal region. Two mouse models have been generated carrying reciprocal translocations (T1Goe and T30H) which served to define chromosomal segments of the parental source effect. Based on two contigs (YAC, P1) covering a 2Mb imprinting region 1 (IR1) and a 5Mb imprinting region 2 (IR2), we have assigned several human ESTs into this chromosomal segment, by means of Southern hybridization to PFGE blots of mouse YACs. These EST markers were used to screen a human BAC library by PCR. Altogether 17 BACs have been arranged into a preliminary map of 550 kb in length for the 20q13 region suspected to carry imprinted genes. Successful sequencing of isolated BAC inserts representing genomic DNA of this chromosomal region results in defining further novel STS sites in this segment. To investigate the expression pattern multiple tissue Northern blot analysis has been done as well as RT-PCR of all assigned ESTs classified as unidentified transcripts by the means of sequence homologies. Based on these results we have already isolated several complete cDNA clones mapping in the region of interest using a marathon ready cDNA library and a PCR screenable cDNA library (RZPD, Berlin). Subfragments of the BAC clones carrying these sequences are being isolated for cloning the corresponding human gene which would serve as candidates to search for their monoallelic expression in mouse and man as well as their potential association with a given human disease. This work was supported by a grant of the DHGP.

Program Nr: 2372 from the 1999 ASHG Annual Meeting

Genomic Structure of the Human Machado-Joseph Disease (MJD/SCA3) Locus on Chromosome 14q32.1. *C. Sell, C. Cemal, S. Chamberlain.* Molecular Genetics, Imperial College of Science, Technology and Medicine, London, UK.

Machado-Joseph disease (MJD) or spinocerebellar ataxia 3 (SCA3) is an autosomal dominantly-inherited neurodegenerative disorder caused by pathological expansion of a (CAG)n repeat motif present within the coding sequence of the MJD1 gene. We report here the genomic organisation of the human disease locus, determined as the consequence of the strategy to generate a representative mouse model of the human disease using YAC transgenesis. In the original description of the disease gene, subdivision of the sequence into four exons was reported . We now demonstrate that the putative exon 1 and 3 sequences actually comprise three and two exons respectively, with the CAG repeat motif now located in exon 7. Exonic sizes range from 45 to 869 bp. Exon-intron structure and primer sequences designed to facilitate full characterisation of each exon are described. It is possible that the latter may be useful for systematic screening of individuals with sporadic cerebellar ataxia for conventional non-triplet repeat expansion mutations present within the gene sequence.

Program Nr: 2373 from the 1999 ASHG Annual Meeting

Physical and transcript mapping of the *CLN6* critcal region on chromosome 15q22-23. *J.D. Sharp[1], R.B. Wheeler[1], R.A. Schultz[2], J.M. Joslin[2], B.D. Lake[3], M. Fox[4], S.E. Mole[1], R.E. Williams[1], R.M. Gardiner[1]*. 1) Dept. of Paediatrics, Royal Free and University College Medical School, UCL, London, UK; 2) Eugene McDermott Center for Human Growth and Development, UTSWMC, Dallas, USA; 3) Dept. of Histopathology, Great Ormond Street Hospital for Sick Children, London, UK; 4) MRC Human Biochemical Genetics Unit, UCL, London, UK.

The neuronal ceroid lipofuscinoses (NCLs) are a group of progressive neurodegenerative disorders characterised by visual failure, epilepsy and the accumulation of an autofluorescent lipopigment in neurones and other cells.

The *CLN6* gene codes for a variant form of late infantile NCL and has been mapped to chromosome 15q22-23 by homozygosity mapping. Using a YAC and PAC contig the critical region was narrowed to approximately 200 Kb spanned by two PACs. These have been sequenced as part of the chromosome 15 sequencing project at UTSWMC. The sequence is being analysed using traditional gene identification methods including cDNA library screening and 5' RACE. In addition we are also using a range of gene prediction programmes from the NIX database at HGMP (http://www.hgmp.mrc.ac.uk/NIX/) including GENSCAN, MZEF, GRAIL-2. Two known genes, *MEK5* and *hnRNP* core protein A1 have been identified in the region. In addition at least two novel transcripts are present within the critical region and are being analysed as candidates for *CLN6*.

Program Nr: 2374 from the 1999 ASHG Annual Meeting

Gene Ontology: a controlled vocabulary to describe the function, biological process and cellular location of gene products in genome databases. *D.R. Shaw[1], M. Ashburner[2], J.A. Blake[1], R.M. Baldarelli[1], D. Botstein[3], A.P. Davis[1], J.M. Cherry[3], S. Lewis[4], C.M. Lutz[1], J.E. Richardson[1], J.T. Eppig[1].* 1) Mouse Genome Database, The Jackson Laboratory, Bar Harbor, ME; 2) FlyBase/European Bioinformatics Institute, Hinxton, Cambridge, UK; 3) Saccharomyces Genome Database, Dept. of Genetics, Stanford University, Stanford, CA; 4) Berkeley Drosophila Genome Project/FlyBase, Berkeley, CA.

The Gene Ontology (GO) project is a collaboration between research groups at three model organism databases (see institutions, above). The goals are to develop controlled vocabularies to describe the functions, biological processes and cellular locations of gene products and to annotate genes in the respective databases. A gene product may be one or more RNAs or proteins, and each of these may have more than one function, and could be localized to more than one cellular component. For mouse and human, gene nomenclature has been used frequently to describe gene products. While the gene name should be a unique designation, trying to attach significant biological information to the name can be problematic. Through the use of GO terms to associate a gene's products with its functions, multiple relationships can be captured and new or more precise functions can be added as more is learned. The GO vocabulary contains functional descriptions including broad terms such as "enzyme" or "aminosugar metabolism" and more specific terms such as "glucosamine catabolism" or "Toll receptor ligand." Over 5000 terms have been added to the GO vocabulary, though it is far from complete. Definitions of terms are included. A hierarchical list of the terms is available online at http://www.ebi.ac.uk/~ashburn/GO/. We hope that this controlled vocabulary will be adopted by other genome databases and become a community-wide effort. The GO vocabulary and its associated search tools should facilitate complex cross-species functional queries across the contributing databases. The Mouse Genome Database, http://www.informatics.jax.org/, has begun supplementing its gene descriptions with the GO vocabulary. MGD is supported by NIH grant HG00330.

Program Nr: 2375 from the 1999 ASHG Annual Meeting

Measurements of relative expression levels on microarrays using gene copy numbers as internal reference. *J. Shi, D. Che, P. Bao, U. Müller.* Advanced Technology, Vysis, Inc., Downers Grove, IL.

Determination of relative gene copy number differences between differentially labeled sample DNA and reference DNA is the basis for Comparative Genomic Hybridization and has been demonstrated to work equally well in formats employing DNA microarrays. A similar approach has been used for array based expression analyses, whereby differentially labeled cDNAs are co-hybridized to the chip. We have developed an assay format by which differentially labeled cDNA from a test tissue is co-hybridized with genomic DNA (gDNA) from the same test tissue and the gDNA from a reference tissue. The assay involves extraction of both genomic DNA and mRNA from the same cell line or tissue. The gDNA was labeled with SpectrumGreen-C-4-dCTP (Vysis), and the mRNA was converted to cDNA by reverse transcription in the presence of Cy-5-dCTP (Amersham). Competitive simultaneous hybridization of gDNA, cDNA, total human reference DNA (labeled with SpectrumOrange, Vysis) and Cot1 DNA (to suppress repeat sequences) was carried out on chromium coated glass chips containing microarrays of genomic clones (BAC, PAC, or P1 clones). Ratios of Green to Orange and Cy-5 to Orange, respectively, were determined for each target spot with a large field multi-color imaging system. Results with two tumor cell lines containing known gene amplifications suggest that this method establishes a correlation between gene copy number and expression level, and with further improvements may allow a much better comparison of expression levels between 2 or more cell types. Program Nr: 2376 from the 1999 ASHG Annual Meeting

Sequencing analysis of deletion mutations in the giant Parkin gene. *N. Shimizu[1], N. Hattori[2], A. Shintani[1], K. Kawasaki[1], T. Kitada[1,2], S. Minoshima[1], Y. Mizuno[2], S. Asakawa[1]*. 1) Department of Molecular Biology, Keio University School of Medicine, Shinjuku-ku, Tokyo Japan 160-8582; 2) Department of Neurology, Juntendo University School of Medicine, Bunkyo-ku, Tokyo Japan 113-8421.

Recently, we identified and cloned a novel gene named Parkin which is responsible for the pathogenesis of the autosomal recessive juvenile parkinsonism (AR-JP). AR-JP patients are found to develop highly selective neuronal degeneration in the substantia nigra of brain. The Parkin gene consists of 12 exons and span over 1 Mb on the q25.2-q27 region of human chromosome 6. A variety of mutations have been found in the Parkin gene of AR-JP patients of different ethnic origins. Interestingly, the majority (75%) of Japanese AR-JP patients had large exonic deletions and mutations in the rest of patients have not been identified by the current PCR-based exon amplification assay. These unveiled mutations may include heterozygous exonic deletions, promoter mutations and others. Thus, it was desired to design appropriate PCR primers to amplify the sequence corresponding to the exact breakpoints of each deletion and the sequence of promoter region of Parkin gene. It was also necessary to design appropriate probes to detect these mutations using non-PCR methods such as FISH and Southern blotting. For this, we started sequencing the entire Parkin gene of over 1 Mb in sharing the task with The Sanger Centre. We constructed a BAC contig covering the entire Parkin gene and began sequencing the two selected regions covering exon 1 and exon 3 through exon 7. The Sanger Centre is in charge of the other two regions covering exon 2 and exon 8 through exon 12. Based on the sequences so far determined for exon 2 through exon 4, we designed 71 pairs of PCR primer and generated a detailed deletion map using DNAs from 23 Japanese AR-JP patients. We also determined the flamking sequences of the breakpoints in two patients. Moreover, we were able to design FISH probes to detect genomic DNA segments flanking each deleted exon. Molecular natures of these large deletions will be discussed.

Program Nr: 2377 from the 1999 ASHG Annual Meeting

Comparative Analysis of the Human Genome Using Primers Specific for Avian Expressed Sequence Tag Sites.

E.J. Smith[1], E. Powell[1], L. Shi[1], P. Drummond[1], R. Zahorchak[2]. 1) Comparative Genomics Program, Tuskegee Univ, Tuskegee, AL; 2) Research Genetics, Inc. Huntsville, AL, 35801.

Gene discovery and SNP identification remain major priorities of the human genetics community. In the present project, 120 primers specific for chicken embryo and turkey pituitary expressed sequence tags were used to amplify fragments in humans that were sequenced and analyzed for homology and nucleotide variants. Though seventy percent of the primers amplified products, only 15% of the amplified fragments showed significant homology to the source avian sequence. However, 90% of the human sequences showed significant homology to previously reported DNA sequences in GenBank. Five of the ESTs were mapped in the human genome using the Gene Bridge 4 radiation hybrid panel. Of the 28 SNPs discovered in the analyzed sequences, 80% were validated by allele-specific PCR and the sequencing of a second PCR product. The validated SNPs have been submitted to NCBI's dbSNP. The sequences, as well as the SNPs, provide a resource for additional comparative genome analysis of avians and humans. This information may be useful for the understanding of such processes as human development by studying the chick.

Program Nr: 2378 from the 1999 ASHG Annual Meeting

Physical/transcript map of the hereditary prostate cancer locus at Xq27.3-q28. *D.A. Stephan[1], L. Malechek[1], D. Gildea[1], J. Smith[1], M. Heiskanen[1], M.I. Quesenberry[1], J. Schleutker[1], R. Sood[1], H. Pinket[1], C.M. Robbins[1], N. Scott[1], J.D. Carpten[1], P. Meltzer[1], O. Kallioniemi[1], W.B. Isaacs[2], J.M. Trent[1]*. 1) Lab Of Cancer Genetics, NIH/NHGRI, Bethesda, MD; 2) Department of Urology, Johns Hopkins University, Baltimore, MD.

Recent identification of a hereditary prostate cancer locus at Xq27.3-q28 (HPCX) by linkage analysis in several large cohorts (Xu et al. 1998) has prompted physical mapping of the region. The maximum multipoint LOD score is at marker DXS1200 and extends several cM in either direction. Given the high phenocopy rate, we were unable to definitively localize the boundaries with trustworthy recombinants. We have therefore built a physical map of the 12 Mb region surrounding DXS1200 (DXS1192-DXS1193) in YACs, BACs and PACs, a region which extends over the entire positive LOD score. Prexisting YAC contigs were utilized as framework maps to place STSs. These STSs were used to screen BAC/PAC libraries by PCR and hybridization to identify preliminary contigs. Joins were made by BAC/PAC end-sequencing and further rounds of screening with end-STSs. Overlaps were reconfirmed by fingerprinting of all clones. ESTs and transcripts were mapped to high resolution by placement onto the BAC/PAC contig by PCR. Finally, finished sequence from the region was annotated by BLAST and exon-prediction analysis to yield further coding sequence. We have extended to full-length and characterized several of the ESTs in this interval. The analysis has shown several regions of high gene density in a mostly gene poor region. Complex genomic events such as inverted duplications have been seen and investigated by fiber-FISH. We present a sequence-ready BAC/PAC contig of 12Mb of Xq27.3-q28, a region of the genome harboring many disease-causing genes, as a resource for the identification of the HPCX gene.

Program Nr: 2379 from the 1999 ASHG Annual Meeting

Construction of a physical map of 2cen-q13 critical region containing the Primary Open Angle Glaucoma (GLC1B) locus and mutation screening of nine candidate genes. *D. Stoilova[1], A. Child[2], G. Brice[2], M. Rocchi[3], M. Sarfarazi[1]*. 1) Molecular Ophthalmic Genetics Laboratory, University of Connecticut Health Center, Farmington, CT; 2) Department of Cardiological Sciences, St. George's Hospital, London, UK; 3) Instituto Di Genetica, Universita di Bari, Bari, Italy.

Glaucoma is an ocular neuropathy affecting over sixty million individuals worldwide. Primary Open Angle Glaucoma (POAG), the most frequent form, is characterized by optic nerve damage, visual field loss and often elevated intraocular pressures. Six POAG loci have already been reported, but only mutations in the TIGR/MYOC gene are known to be associated with the glaucoma phenotype at the GLC1A locus. In order to assist the identification of causative gene for the GLC1B locus on 2cen-q13, a detailed STS-based physical map of the region has been assembled. This map consists of 38 YACs, 18 chromosome 2 specific Radiation Hybrid (RH) clones, 42 STRPs/STSs, 69 ESTs and 23 known genes. Two potential gaps in the YAC coverage have been identified in the vicinity of centromere. The first gap is between WI-9976 and WI-8267 and the second one is between GATA6GO2 and SHGC-33807. Two internal deletions were also identified for YACs 914H7 and 937D1. The physical map constructed here, localized a number of new genes and ESTs at much better resolution and made it possible to evaluate their candidacy for the GLC1B phenotype. Ten genes were mapped outside of the critical region and 17 others were mapped within the GLC1B minimum interval. Since the flanking region of GLC1B is around 9 cM, the number of potential candidate genes still remains large. A total of 9 genes from the GLC1B minimum interval, including Beta-Centractin, COX5B and ADRA2B were screened for mutations by direct sequencing but no causative mutations were identified. However, a number of polymorphisms were detected that can serve as SNPs. Screening of the 8 remaining genes is currently in progress. As more of the existing candidate genes are being excluded, identification of the causative GLC1B gene may have to rely on positional cloning. The new integrated YAC/STS and RH map provides a useful tool for this purpose. Support: EY-09947, IGA, InSite Vision, Inc.

Program Nr: 2380 from the 1999 ASHG Annual Meeting

Analysis of gene-expression profiles of single cells. *T. Suzuki[1,2,3], H. Hashida[1,2], Z. Jeong[1,2], N. Masuda[1,2], H. Murakami[2], K. Ogata[2], J. Goto[1,2], I. Kanazawa[1,2].* 1) CREST, Japan Science and Technology Corporation, Tokyo, Japan; 2) Department of Neurology, Graduate School of Medicine, Tokyo, japan; 3) Laboratory of Medical Zoology, Nagoya City Medical School, Nagoya, Japan.

In order to analyze gene-expression profiles of single cells, we have developed laser-dissection system and differential display method that can be applied to single cells. In this system, we mark target cells of freeze-dried sections on computer and laser cut out those cells automatically. For differential display of 100 cells-level RNA, increasing the cycles of PCR up to 40 cycles was revealed to be effective, while not to be effective for differential display of single-cell level RNA. For clarifying the gene-expression profiles of single cells, the "2nd round of PCR" was shown to be effective. In brief, after the 1st round of 30 cycles of cDNA amplification, nested FITC-labeled primer was used for 2nd round of differential PCR of 30 cycles. This method was successfully applied to analyses of gene expression of human and rat Purkinje cells and African Trypanosomes, protozoan parasites.

Program Nr: 2381 from the 1999 ASHG Annual Meeting

SPG4: a recombination event narrows the minimum candidate region. *I.K. Svenson[1], M.A. Nance[2], J.L. Haines[3], W.K. Scott[1], M.A. Pericak-Vance[1], D.A. Marchuk[1]*. 1) Duke University Medical Center, Durham, NC; 2) Park Nicollet Clinic, Minneapolis, MN; 3) Vanderbilt University Medical Center, Nashville, TN.

The hereditary spastic paraplegias (SPGs) are a clinically and genetically heterogeneous group of neurodegenerative disorders characterized primarily by progressive weakness and spasticity of the lower limbs. A genetic locus for the most common form of autosomal dominant SPG, SPG4, has been mapped to a 3cM interval bounded by D2S352 and D2S367 on the short arm of chromosome 2. We have identified a recombination event in a previously described family (Nance et al., Hum. Hered. 48:169-178, 1998) that narrows the SPG4 minimum candidate region (MCR) by placing its centromeric boundary at D2S2347. The markers used in the haplotype analysis in this family include seven that map between D2S352 and D2S367, with marker order determined by physical mapping to a contig of 28 YACs that span the new MCR with at least eight-fold coverage. A minimum tiling path across the new MCR consists of two overlapping megabase-sized YACs. We have mapped a total of 22 polymorphic and nonpolymorphic markers to the new MCR on the YAC contig, of which 13 are ESTs and two are associated with known genes.

Program Nr: 2382 from the 1999 ASHG Annual Meeting

Consortium to clone, map, and study human mitochondrial ribosomal protein genes. *J.E. Sylvester[1], H.-R. Graack[2], J. Liu[3], E.B. Mougey[1], B.A. Maguire[1], N. Fischel-Ghodsian[4], B. Wittmann-Liebold[5], T.W. O'Brien[3]*. 1) Nemours Children's Clinic, Jacksonville, FL; 2) Institute for Genetics, AG Kress, Free University of Berlin, Germany; 3) University of Florida, Gainesville, FL; 4) Cedars-Sinai Medical Center, Los Angeles, CA; 5) Max-Delbruck-Center for Molecular Medicine, Berlin, Germany.

Mammalian mitochondria have their own separate translation system comprised of components distinct from their cytoplasmic counterparts. Whereas mitochondrial DNA encodes tRNAs and two rRNAs, the remaining genes for the translation system are found in nuclear DNA. Upward of 100 mitochondrial ribosomal proteins (MRPs) are imported into the mitochondria, assembled into ribosomes which are responsible for translating the 13 mRNAs for oxidative phosphorylation proteins. Since mutations in mitochondrial tRNA and rRNA can cause various pathological states, we hypothesize that mutations in MRP genes are also candidates for human disorders. Therefore, the first step is to identify, clone, and map the gene for each human MRP. Our approach is to use N-terminal and internal amino acid sequence data obtained from purified bovine or rat MRPs (Goldschmidt-Reisin, et al., J.Biol.Chem. 273: 34828, 1998) to search EST databases. A representative I.M.A.G.E. clone (ATTC) is purchased and used to screen a human lambda genomic library. Chromosome map positions are ascertained by using *in silico* methods to search Genbank and GeneMap through NCBI, by *in situ* hybridization (FISH) with genomic sequences, and/or by radiation hybrid mapping. At present, we have over 30 different human MRPs at various stages of characterization and have established a consortium of investigators to complete the project. We are currently investigating one MRP as a potential candidate for Russell-Silver Syndrome (RSS)(see abstract, Mougey, et al., this meeting). In addition to studying their clinical relevance, long term characterization of MRP genes should lead to important insights into mammalian evolution, coordinant regulation of nuclear and mitochondrial gene expression, and ribosome function. [Supported by NIH RO1-04092 (NFG, TWO) and Nemours Research Programs (JES, EBM, BAM)].

Program Nr: 2383 from the 1999 ASHG Annual Meeting

Fiber-FISH physical mapping in the PGL1 interval involved in hereditary paragangliomas of the head and neck region. *P.E.M. Taschner[1], B.E. Baysal[2], J.G. Dauwerse[1], A. Bosch[1], J.C. Jansen[3], A.G.L. Van der Mey[3], C.J. Cornelisse[4], B. Devlin[2], P. Devilee[1,4].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Department of Psychiatry, Western Psychiatric Institute and Clinic, University of Pittsburgh Medical Center, Pittsburgh, PA; 3) Department of Otorhinolaryngology,Leiden University Medical Center, Leiden, Netherlands; 4) Department of Pathology, Leiden University Medical Center, Leiden, Netherlands.

Hereditary paragangliomas (MIM 168000) of the head and neck region are benign slow-growing tumors of the parasympathetic paraganglion system. The inheritance pattern is autosomal dominant with imprinting: only paternal transmission of the mutation results in tumor development. Paragangliomas are genetically heterogeneous. Most cases are linked to the PGL1 locus on chromosome 11q23. While the PGL1 gene was previously localized to a 7 cM interval between D11S1647 and D11S622, recent advances by our group refined the critical region to 1.5 Mb, between D11S1986 and D11S1347 (Hum. Genet. 104: 219 (1999)). Baysal et al (unpublished) built a YAC-BAC-PAC map of this region. More than half of the region is covered in BACs and PACs; there is complete coverage over the telomeric part, which preliminary evidence suggests contains PGL1. The continuity of the PGL1 contig could be confirmed by pulsed field gel electrophoresis of digested human DNA, followed by Southern blot hybridization using genomic clones as probes. Here, we decided to use the more efficient fiber-FISH method to refine the order and overlap of clones from the telomeric region. No chimeric clones were found by metaphase FISH. Fiber-FISH with probes in different colors confirmed the order determined by STS-based methods. Overlaps for each clone with at least one other were observed, except for the most telomeric clone. STS-PCR and Southern blotting suggested that this clone was separated from the next by a gap of 50-100 kb. No gap between these clones was seen on DNA fibers, suggesting that the gap is 5 kb at most. Fiber-FISH experiments using patient cell lines have yet to reveal any rearrangements as the cause of paraganglioma.

Program Nr: 2384 from the 1999 ASHG Annual Meeting

MICROMAX: A complete system for rapid high sensitivity gene expression analysis. *W.W. Tian, B.A. Brown, J. Killian.* Nen Life Science Products Inc, Boston, MA.

The rapid study of the entire panorama of mRNA expression in a wide range types of samples, from cell culture to clinical micro-metastasis has been enabled by the development of differential gene expression on cDNA microarrays and related chip technology utilizing oligonucleotides. However, full acceptance of this technology has been hindered by a number of factors; unavailability of genes and spotting capability, lack of adequate sensitivity, poor reproducibility, complex lengthy protocols and cost. NEN, in collaboration with AlphaGene, have introduced MICROMAX; a complete cDNA microarray system for high through put, high sensitivity differential gene expression, available to all researchers. AlphaGene provides the capability of producing high quality full length genes, with state of the art bioinformatics characterization as well as a fully optimized and reproducible cDNA microarray manufacture. NEN brings extensive assay development capability and the patented Tyramide Signal Amplification (TSA) to provide unparalleled sensitivity and convenience to cDNA microarrays. Utilizing the first product, an array of 2400 known human genes, collaborators have been able to reduce the amount of starting total RNA from the typical 100 ug to as little as 1-4 ug while gaining the capability of detecting a single copy mRNA from samples as small of 105 cells without the need to amplify the mRNA. The linear range of the response in MICROMAX is over 2 orders of magnitude and for genes that have been reported in the literature, the results with human tissue samples and cell lines agree with published Northern analysis. The reproducibility is such that significant changes in expression levels are as little as two fold. The reading of a MICROMAX slide is by standard microarray readers as it is developed with the traditional cyanine 3 and cyanine 5 dyes, though a slide reading service is available for those who do not have access to that instrumentation. With MICROMAX, any researcher can take advantage of the potential of microarray analysis of differential gene expression with a minimal investment in capital instrumentation or in the time required for optimization.

Program Nr: 2385 from the 1999 ASHG Annual Meeting

Cosmid-contig construction from the bipolar disease region at 18q21.33-q22. *F. Tissir, S. Villafurte, D. Goossens, C. Van Broeckhoven, J. Del-Favero.* Flanders Interuniversity Institute for Biotechnology (VIB),University of Antwerp, Department of Biochemistry, Psychiatric Genetics group, Antwerp, Belgium.

Linkage of bipolar disorder (BP) to chromosome 18 has been reported by several independent studies. To replicate these findings, linkage analysis with chromosome 18 markers in 10 Belgian families with a BP proband was performed. In one family, MAD 31, we found suggestive linkage to chromosome 18q21.33-q23. Multipoint linkage analysis gave the highest lod scores in a 12 cM interval between D18S51 and D18S61. Additional markers within this interval were typed in MAD 31 and the candidate region was refined to 8.9 cM. A YAC-contig map was constructed for this region with an estimated physical length of 5 Mb. Three YACs identifying the minimal tiling path were characterized by metaphase FISH analysis and shown to be chromosome 18q21.33-18q23 specific. These YACs were subcloned in the multiple exon trap cosmid vector wich is used for region specific isolation of novel expressed sequences. The cosmid libraries with a 5-8 times coverage were screened for all available markers by radioactive oligonucleotide hybridization and subsequently confirmed by PCR. To construct a cosmid-contig, DNA prepared from 96 cosmid clones is simultaneously digested and fluorescently labelled in one tube reaction. The digestion products are analysed using the fingerprinted contigs (FPC) software.

Program Nr: 2386 from the 1999 ASHG Annual Meeting

Parallel expression analyses of DNA repair genes in adult mouse brain and testis using cDNA microarrays. *L.M Tomascik Cheeseman[1,2], R. Raja[1], X. Lowe[1], J. Nath[2], A.J. Wyrobek[1]*. 1) Biology and Biotechnology Research Program, Lawrence Livermore National Laboratory, Livermore, CA; 2) Genetics and Developmental Biology Program, West Virginia University, Morgantown, WV.

The objective of this research was to investigate functional variations in the expression of DNA repair genes using cDNA expression microarrays. These arrays were comprised of expressed sequence tags (ESTs) representing genes involved in double strand break repair, nucleotide excision repair, base excision repair, mismatch repair, direct reversal of damage, damage response, cell cycle regulation and apoptosis. Pooled mRNA was extracted from the adult mouse testis and adult mouse brain, reverse transcribed, fluorescently labeled with Alexa-red and Alexa-green and hybridized onto the arrays. Several genes showed differential expression (ranging from 2 to 11 fold) between the two tissues. For selected genes, northern blot analyses were performed to confirm differential gene expression between the testis and the brain. These findings have contributed to our understanding of the multiple functions of DNA repair genes in various tissues and may also have implications for cancer and aging. [This work was conducted under the auspices of the U.S. DOE by the Lawrence Livermore National Lab. under contract W-7405-ENG-48 with support from the National Institutes of Health grant ES09117-02, the University of California and West Virginia University.].

Program Nr: 2387 from the 1999 ASHG Annual Meeting

Chromosomal localization by PRINS of single copy genes SRY and SOX3. *Y. Tunca, J.S.. Kadandale, A.T. Tharapel.* Clinical and Molecular Cytogenetics Laboratory, Department of Pediatrics, University of Tennessee, Memphis, TN.

Single copy gene sequences are frequently identified with the polymerase chain reaction (PCR). Primed in situ labeling (PRINS), a specific and sensitive technique, can be adapted to the localization of single copy genes and DNA segments. Using PRINS, we have localized the 2.1kb SRY and 2.4kb SOX3 genes at bands Yp11.31p11.32 (ISCN 1995) and Xq26-q27, respectively. The SRY and SOX3 genes were selected because of their relatively small size, single exon nature and lack of commercial probes for conventional FISH. We used locus-specific oligonucleotide primers; annealing and extension were performed on day-old chromosome preparations on microscope slides, in the presence of dATP, dCTP, dGTP, dTTP and digoxigenin-11-dUTP, Tris-HCl, KCl, MgCl2, BSA and Taq DNA polymerase . The SRY signals were detected in about 95% of metaphase spreads and in about 90% of nuclei. None were detected in females. SOX3 showed one signal on the X chromosome in males and two signals on the X chromosomes in females. The PRINS technique used in this study is faster, more specific and more sensitive than conventional FISH and can be employed in cytogenetics and molecular genetics laboratories. With appropriate oligonucleotide primers, PRINS can be used for the analysis of gene deletions known in clinical entities, and for rapid localization of DNA segments.

Program Nr: 2388 from the 1999 ASHG Annual Meeting

The low-copy repeats flanking the WBS deletion and other regions in chromosome 7 contain truncated copies of *STAG3*, a gene involved in meiotic chromosome pairing. *M.C. Valero[1], N. Pezzi[2], I. Prieto[2], J.L. Barbero[2], L.A. Pérez Jurado[1]*. 1) Serv. Genética, Hosp. Univ. La Paz, Madrid, Spain; 2) Dept. Inmunología y Oncología, CNB, Madrid, Spain.

Williams-Beuren syndrome (WBS) is a contiguous gene syndrome caused by a microdeletion in chromosome band 7q11.23. It occurs with a estimated frequency of 1 in 20000 live births. Most cases are sporadic indicating a deletion rate ~ 0.5×10^{-5}. A duplicated genomic region flanks the WBS deletion interval and contains at least two genes at the telomeric block (*GTF2I* and *NCF1*), and one or more copies of their pseudogenes at the centromeric block. In addition, low-copy repeats containing genes related to the mismatch repair gene *PMS2* map to those duplications and to other chromosome 7 locations. We have identified truncated copies of another gene that are also part of the low-copy repeats. The ancestral gene, *STAG3*, encodes a meiotic-specific protein with a evolutionarily conserved domain, the stromalin conservative domain (SCD), that is involved in chromosome pairing and maintenance of the synaptonemal complex. The *STAG3* locus consists of 34 exons encompassing > 40 kb and maps to chromosome 7q22. *STAG3*-like genes consist of different sets of *STAG3* exons displaying 90-95% sequence identity and are ubiquitously expressed in all tissues tested. The *STAG3*-like loci are located in the vicinity of the 7q11.23 WBS deletion breakpoints, containing the *D7S489A* and *C* loci, as well as in 7q22. Some *STAG3L* cDNAs have short potential ORFs that might encode 134 aa proteins with the SCD. The *STAG3*-like genes are transcribed from the opposite strand of PMS2-like genes, using a common promoter region embedded in a CpG island. The mouse *Stag3* locus is single copy and maps to chromosome 5, in a region of conserved synteny with human 7q22. The presence of large duplicated segments on human chromosome 7q that are absent in mouse suggest a mechanism of chromosome evolution through subsequent duplications and provides a mechanism for unequal homologous recombination that may mediate the rearrangements responsible for WBS deletions and other cytogenetic abnormalities.

Program Nr: 2389 from the 1999 ASHG Annual Meeting

Resource Center / Primary Database of the German Human Genome Project. *A. Vente, P. Kioschis, B. Korn, C. Maurer, G. Zehetner, A. Poustka, H. Lehrach.* Resource Center German Human Genome Project, Berlin & Heidelberg, Germany.

Since 1995 the the Resource Center / Primary Database (RZPD) serves as a central infrastructural unit of the German Human Genome Project (DHGP), which was launched by the Federal Ministry of Education and Science (BMBF) and the Deutsche Forschungsgemeinschaft (DFG) for the systematical identification and characterization of the structure, function and regulation of human genes, in particular those of medical relevance. Currently approximately 50 research projects within the various fields of gene technology are supported. Established at the Max Planck Institute for Molecular Genetics, Berlin, and the German Cancer Research Center, Heidelberg, the RZPD serves as a central source of standardized reference materials for all the different DHGP projects as well as academical and industrial research groups from all over the world. Amongst the main tasks of the RZPD are the construction and collection of genomic and cDNA clone libraries from human or various model organisms and the distribution of single clones as well as high density colony filters or clone pools for the screening of these libraries. The RZPD offers a unique resource for the analysis of the human genome: Filters and DNA-pools for more than 50 human cDNA libraries from different organs and developmental stages and high density protein arrays for the screening of proteins encoded by cDNA expression libraries are available at the RZPD. The RZPD also offers a custom screening service and a service for the custom rearraying of gridded libraries. To support the various high throughput methods for the expression profiling of genes, non-redundant EST sets of different model organisms were either imported or set up at the Resource Center. The RZPD has access to clone sets for human (35,000 ESTs), mouse (25,000 ESTs), rat (25,000 ESTs), zebrafish (24,000 ESTs) and arabidopsis (12,000 ESTs). DNA-filters of these EST-sets can be requested from the Resource Center. Experimental data generated by the users of the different materials are collected by the Primary Database. These data are publicly available after an optional period of confidentiality. World Wide Web: http://www.rzpd.de email: info@rzpd.de.

Program Nr: 2390 from the 1999 ASHG Annual Meeting

Physical map of the RP11 locus for autosomal dominant retinitis pigmentosa and investigation of a candidate gene. *E.N. Vithana[1], M. al-Maghtheh[1], N. Kenmochi[2], S. Higa[2], S.S Bhattacharya[1]*. 1) Dept of Molecular Genetics, Inst of Ophthalmology, University College London, London, England; 2) Dept of Biochemistry, School of Medicine, University of the Ryukyus, Japan.

Autosomal dominant Retinitis Pigmentosa (adRP) is an inherited progressive retinal degeneration characterised by night blindness and constricted visual fields. adRP is genetically heterogeneous, whilst mutations have only been found in four genes to date genetic linkage studies have implicated at least six further loci. adRP locus on chromosome 19q13.4 (RP11) was first reported in a single large British pedigree in our laboratory. We have subsequently identified four other British families, plus a Russian and a Pakistani family linked to the chromosome 19q locus. These data together with the publication of a Japanese and three other American families also linked to 19q implicate RP11 as a major adRP locus. All linked families exhibit incomplete penetrance, individuals with the disease haplotype were either severely affected or asymptomatic. Recombination events in our RP11 families have localised the disease gene to a 3cM genetic interval between the markers D19S927(proximal) and D19S781.2(distal). In the effort to find the disease gene we have established a DNA contig spanning the RP11 interval composed of YAC, BAC, PAC and cosmid clones. Altogether the RP11 contig orders 27 STSs from a wide range of sources, including 14 microsatellite markers, 6 end clones, 3 expressed sequence tags (ESTs), 7 STS, and three known genes within a 2Mb genomic interval. The gene for ribosomal protein S9 (*RPS9*) located within the disease interval show expression in the retina but has yet undefined function. We characterised *RPS9*, which consists of 5 exons, and screened it for mutations in all RP11 linked families by direct sequencing. Apart from several polymorphisms in the non coding regions no disease causing mutations were identified thus leading to the exclusion of *RPS9*. Currently the physical map is being used to map ESTs to be evaluated as candidates for RP11.

Program Nr: 2391 from the 1999 ASHG Annual Meeting

Discovery of single nucleotide polymorphisms (SNPs) in biochemical pathway genes as risk factors for cancer.

A.K. Voltz[1], A. Cassidy[2], K. Cleverly[1], M. Edmonson[1], M. Gandolph[1], E. Harkins[1], Y. Hu[1], J. Kelley[1], R. Michielli[2], T. Scherpbier-Heddema[1], K.H. Buetow[1]. 1) Laboratory of Population Genetics NIH/NCI/DCEG, Bethesda, MD; 2) Fox Chase Cancer Center Philadelphia, PA.

We are discovering novel single nucleotide polymorphisms (SNPs) in genes relevant to cancer. Our goal is to determine the potential relationship between these variants and cancers of the liver, breast, ovary and prostate. We are taking a "pathway-directed" approach, targeting genes for SNP characterization that are part of well described biochemical pathways that determine how an individual responds to endogenous and exogenous exposures.

The SNPs are found by data mining of publicly available DNA sequences. Trace files are retrieved from the Wash. U. Genome Sequencing Center based on significant identity with a "seed" DNA sequence for each gene of interest. A suite of software tools, previously described as the "SNP pipeline" (Nature Genetics, 21, 323-325, 1999) is used to detect single nucleotide variants in the resulting sequence assemblies. Primers are designed to flank the predicted SNP, which are validated by restriction enzyme digestion or sequencing of individuals in CEPH families. Variants are designated as "confirmed SNPs" following observation of Mendelian transmission in CEPH families and placement on reference genetic maps.

We have predicted and confirmed single nucleotide polymorphisms in several genes implicated in liver, breast, ovarian and prostate cancer. These include previously undescribed variants in the catechol-O-methyltransferase (COMT) gene resulting in silent mutations (His62His, Leu136Leu), and variants in the 3' UTR of GSTA4 and GSTT1. In addition to the identification of novel SNPs, we have also observed several previously described polymorphisms, including functional mutations within COMT (Val158Met), GST pi (Ala114Val) and GST zeta (Gly42Arg, Thr82Met) and variants within the 3' UTR of CYP19 and GSTT2. Detection of known single nucleotide polymorphisms in these genes supports the validity of this approach in the discovery of new variants.

Program Nr: 2392 from the 1999 ASHG Annual Meeting

Transcript map of a genetic locus at 11q23 linked to hypoalphalipoproteinemia. *S. Wagner[1], W. Ding[1], H. Wang[1], H. Goldfine[1], T. Rigley[1], R. Kehrer[1], M. Frodsham[1], M. Hess[1], J. Malandro[1], K. Eddington[1], B. Miao[1], M. Chen[1], K. Harshman[1], C. Schumacher[2], P. Chen[2], N. Lyons[2], D. Duricka[2], B.R. Bowen[2], M. Skolnick[1], D. Ballinger[1]*. 1) Myriad Genetics, Inc., Salt Lake City, UT; 2) Novartis Institute for Biomedical Research, Summit, NJ.

Epidemiological evidence shows a strong inverse correlation between the level of plasma high-density lipoprotein (HDL) and the incidence of heart disease. It has been suggested that HDL has a protective effect against cardiovascular disease, and hypoalphalipoproteinemia is considered a potent predictor of coronary heart disease. Several genetic deficiencies have been linked to extreme hypoalphalipoproteinemia, however no variants that account for the more common forms of low HDL have been described. Genetic analysis of Utah pedigrees with familial coronary heart disease located a susceptibility locus for hypoalphalipoproteinemia in a 10cM region on 11q23. Initial genetic mapping defined a region between D11S924 and D11S934 which was further refined by recombinants to a 2Mb minimal interval between D11S1353 and D11S933. Physical mapping of the minimal region assembled a minimal tiling path of 16 BACs and PACs. Transcription units were identified by a combination of large scale automated sequencing and a set of complementary methods for the isolation of transcribed sequences. We describe here an integrated physical and transcript map of the minimal recombination interval. Fourteen genes and one pseudogene were identified and characterized. Five genes were identical to mRNAs described in Genbank (SP17, neurogranin, BCSC-1, ZNF202, CTH). One transcript shows strong similarity to the mouse gene for sialic-acid acetyl-esterase and most likely represents the human homolog. One gene shares strong homologies with the b subunits of known sodium channel proteins, but appears to be a novel gene. Seven transcripts are novel genes of unknown function. A cluster of putative olfactory receptor genes is located in the center of the region including a number of pseudogenes. Biochemical evidence suggests that ZNF202 is a potent regulator of lipid metabolism and a strong candidate for a hypoalphalipoproteinemia predisposition gene.

Program Nr: 2393 from the 1999 ASHG Annual Meeting

Physical and transcript mapping of the Blau syndrome susceptibility locus. *X. Wang[1], G. Tromp[1], H. Kuivaniemi[1], L. Molina[2], L. Serrano de la Peña[2], C.J. Williams[2].* 1) Ctr. Molec. Med. and Genet., Wayne State University, Detroit, MI; 2) Div. Rheumatology, Thomas Jefferson University, Philadelphia, PA.

Blau syndrome is a multi-system inflammatory disease that is characterized by the development of granulomas in the joints, eyes, and/or skin. The disease is inherited in an autosomal dominant manner and we have used genetic linkage analysis to map the disease susceptibility locus to the long arm of chromosome 16. The most likely disease interval resides in an 8 cM region demarcated by the microsatellite markers D16S411 and D16S415, and coincides with a Crohn's disease locus linked to chromosome 16q. Although chromosome 16 is one of the most well-characterized of the human chromosomes, there appears to be some inconsistency with regard to the order of polymorphic markers in the candidate interval; this inconsistency has hampered our efforts at refined linkage mapping. To alleviate these discrepancies, we have undertaken refined mapping of the markers in and around the susceptibility interval using high and medium resolution radiation hybrid panels (TNG4 and G3) and by concurrently constructing a low resolution YAC contig and a high resolution BAC contig of the interval. We have also used these resources to refine the chromosomal location of several potential candidate genes for Blau syndrome: we have determined that the genes for the matrix metalloproteinases MMP2 and MMP15 reside outside of the susceptibility interval, as does the gene for carboxyesterase 1 (CES1). We will continue to utilize the physical mapping resources in the Blau susceptibility interval to fine map additional potential candidate genes, as well as ESTs that have been provisionally assigned to the locus. (Supported by a Biomedical Science Grant from the Arthritis Foundation).

Program Nr: 2394 from the 1999 ASHG Annual Meeting

An 8kb deletion/insertion polymorphism in the Van der Woude syndrome critical region at 1q32-q41. *Y. Watanabe[1], B.C. Bjork[1], P.-W Chiang[2], S.G. Gregory[3], D.M. Kurnit[2], J.C. Murray[1], B.C. Schutte[1].* 1) Dept. of Pediatrics, University of Iowa, Iowa City, IA; 2) Dept. of Pediatrics, University of Michigan, Ann Arbor, MI; 3) Sanger Centre, Hinxton, Cambridgeshire, UK.

VWS is an autosomal dominant disorder whose cardinal features are cleft lip and/or palate and lip pits. The VWS gene was localized to a 1.6cM region of 1q32-q41 flanked by markers D1S491 and D1S205. A contig of BAC and PAC clones was constructed across the VWS critical region (B. Bjork et al., submitted). Eleven overlapping BAC and PAC clones, spanning approximately 1.1 Mb, were selected for high-throughput genomic (HTG) sequence analysis by the Sanger Centre (UK). From sequence analysis the BAC clone 321i20 and the PAC clone 782d21 overlap, however the clone 321i20 was missing a 7922 bp region. Imbedded in this 7922 bp region was a short tandem repeat (STR). To verify that this nearly 8kb deletion in the clone 321i20 was not a cloning artifact, we genotyped unaffected control samples using two sets of PCR primers, 186/7 that flank the STR and 583/4 that flank the putative 8 kb deleted sequence. The genotype data with 186/7 showed that the STR was polymorphic. The genotype data with 583/4 showed that the 8 kb deletion mutation was present in 54% of the chromosomes tested. The presence of the 8 kb deletion in the control samples was confirmed by QPCR. These results demonstrate the presence of an STRP within a common 8 kb deletion/insertion at the distal end of the VWS critical region. In addition, the deletion breakpoint sequences from 11 unrelated individuals were identical, suggesting that the 8 kb deletion/insertion may be an old mutation. Since this polymorphism is present in control samples and appears to be an old mutation, it is not a mutation that is etiologic for VWS. However, it is located near the distal breakpoints for two known microdeletions that are etiologic for VWS, providing additional evidence that this may be a region of genetic instability.

Program Nr: 2395 from the 1999 ASHG Annual Meeting

Physical and genetic mapping of the CT locus on dog 10q26. *C. Wijmenga[1], B. van de Sluis[1], J. Rothuizen[2], B.A. van Oost[2], P.L. Pearson[1].* 1) Dept Medical Genetics, University Medical Center, Utrecht, Netherlands; 2) Dept. Veterinary Sciences, Utrecht University, Utrecht, the Netherlands.

Copper toxicosis (CT) in Bedlington terriers is an autosomal recessive disorder characterised by accumulation of copper in the liver. This terrier might be an interesting animal model for human diseases associated with hepatic copper overload, such as idiopathic copper toxicosis (ICT). The anonymous microsatellite marker C04107, which is closely linked to CT in Bedlington terriers, was isolated in a canine BAC clone and mapped to dog chromosome10q26 by FISH. Sample sequencing of the C04107 BAC revealed a subclone with high homology to one exon of the human MURR1 gene, which was used to show conservation of synteny with human 2p13-p16. Genes and ESTs known to map to human 2p13-16 are currently mapped onto the dog genome and are being used to isolate BAC clones for the construction of a physical map. Polymorphic markers from the 10q26 region have been used to locate the CT locus between two markers that are 30 cM apart. Currently, new polymorphic markers are being developed to construct a high resolution genetic map.

Program Nr: 2396 from the 1999 ASHG Annual Meeting

Single Nucleotide Polymorphism (SNP) Mapping of a Type 2 Diabetes-linked Region on Human Chromosome 1q21-q23. *J.K. Wolford, R.L. Hanson, C. Bogardus, P. Permana, M. Prochazka.* NIDDK/PECRB, NIH, Phoenix, AZ.

Type 2 diabetes mellitus is a complex heritable disease. A genetic basis for the disease is especially evident in the Pima Indians of Arizona, who have the world's highest reported prevalence of this disease. We have previously demonstrated evidence for linkage of diabetes in the Pimas in a 30 cM region on 1q21-q23 with a maximum multipoint LOD score (2.5) at *D1S1677*. This region has also been linked to type 2 diabetes in a Caucasian population (*Diabetes* 48: 1175-1182, 1999). To narrow the area of linkage and identify potential candidate genes, we are evaluating densely spaced SNP markers by association analysis in 117 Pima sib-pairs discordant for diabetes and in 100 unrelated Pimas, including 50 affected and 50 unaffected subjects. We are utilizing a contig of 65 overlapping YACs that encompasses the region of linkage and spans approximately 34 cM between markers *D1S442 and D1S452*. Using a combination of automated sequencing, DHPLC, PCR-RFLP, and AD-PCR, we have analyzed 36 SNPs. These SNPs include 13 previously reported markers and 23 novel, gene-specific markers (in *ATP1A2, ATP1B1, CRABP2, FCER1A, FCGR2A, FLG, GBA, LMX1, MCL, PEA15, RXRG, SPRR1B* and *USF1*) which were identified as polymorphic in Pimas. Four SNPs in the *GIRK3* gene are associated with diabetes (p=0.0003 in discordant sib-pairs; p=0.003 in the affected/unaffected group). *GIRK3*, located approximately 3 cM centromeric from the linkage peak at *D1S1677*, encodes a G-protein-coupled inwardly rectifying potassium channel protein. The GIRK3 protein is known to regulate ion flow and hormone secretion in some tissues and thus represents a candidate gene for diabetes susceptibility. We are scanning the *GIRK3* gene for mutations in Pimas and constructing a BAC contig through the *GIRK3-D1S1677* region to concomitantly identify additional candidate genes and locate novel SNPs for use in haplotype analysis.

Program Nr: 2397 from the 1999 ASHG Annual Meeting

Construction of a BAC Contig for Murine Chromosome 11 (32-34 cM): The Region Homologous to the Smith-Magenis Syndrome Common Deletion. *J. Yan, C.F. Boerkoel, K. Walz, J.R. Lupski.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Smith-Magenis syndrome (SMS) is one of the most frequent contiguous gene deletion syndromes and is characterized by mental retardation and multiple anomalies. In humans, the common deletion region is 17p11.2, which is syntenic to the 32-34 cM region of murine chromosome 11. Several genes have been mapped to both the mouse and human regions of synteny. By using 21 probes specific for these genes and genetic markers in this region, we screened the mouse RPCI-23 BAC library and isolated 96 positive clones. After PCR verification, we constructed a BAC contig spanning the mouse syntenic region. These BACs are being mapped into a sequence ready contig. In addition, we found that this region does not have sequences homologous to the human repeated gene cluster (SMS-REP) that flanks the SMS common deletion region. These unique specific low-copy repeats are a substrate for homologous recombination resulting in unequal crossing over and consequent deletion in humans. This indicates that the occurrence of SMS-REP is a recent event in mammalian genome evolution. Our physical mapping effort will enable genomic characterization of this region and is critical for constructing a mouse model for SMS.

Program Nr: 2398 from the 1999 ASHG Annual Meeting

A practical application of sample sequencing strategy and the GeneHunting software tools in positional cloning of progressive epilepsy with mental retardation (EPMR) and laryngeal carcinoma cancer region at chromosome 8p23. *Y. Zhang[1], X. Ye[1], S. Ranta[2, 3], B. Ross[1], Y. Tao[1], M. Chien[1], A. de la Chapelle[3, 4], A. Lehesjoki[2], P. Zhang[1], T. Gilliam[1]*. 1) Columbia Genome Ctr, Columbia Univ, New York, NY; 2) Dept. of Medical Genetics, University of Helsinki,; 3) Folkhälsan Institute of Genetics, Helsinki, Finland; 4) Comprehensive Cancer Center, Ohio Sate University, Columbus, OH.

One of the challenges of positional cloning is to quickly identify genes in the defined disease region. We describe a strategy that combines sample sequencing and automated computational analysis to quickly and effectively generate a transcript map. We sought to determine the extent of sequencing coverage necessary to generate a transcription map equivalent to or better than that currently available by standard molecular cloning and hybridization methods. In order to handle the large amount of sequencing data efficiently, we developed a software package, GeneHunting, on the UNIX client for DNA sequence assembling and editing, contig assembling, automatic database searching and annotation, cDNA versus Genomic DNA alignment, exon prediction, statistical report and graphic view with a user-friendly web interface. The scaffolding for the program includes PHRED/PHRAP, CONSED, CROSSMATCH, Network BLAST and GENESCAN. In addition, we integrate these tools using scripts written with PERL and JAVA. The data is automatically processed at each night. The final reports are output in HTML format and the end users can view the results with a standard web browser. Using the data that we generated in the EPMR study, we found that 1.5 X sequencing data generated comparable, or better, transcript coverage than the traditional exon trapping and cDNA selection methods. Sample sequencing combining with our GeneHunting tools provides advantages of automation, greater cost and time saving over the traditional methods. Detailed comparison of our strategy and the traditional ones, as well as the description GeneHunting interface and functionality will be presented.

Program Nr: 2399 from the 1999 ASHG Annual Meeting

Molecular characterization of FRA7E - a common fragile site on human chromosome 7. *E. Zlotorynski[1], S.W. Scherer[2], D. Mishmar[1], J. Skaug[2], A. Rahat[1], L.-P. Tsui[2], B. Kerem[1].* 1) Genetics, Life Sciences, Jerusalem, Israel; 2) Genetics, Hospital for sick children, Toronto, Canada.

Common fragile sites are specific unstable loci characterized as constrictions, gaps or breaks on chromosomes from cells exposed to replication stress. These sites were implicated in chromosomal rearrangements (both constitutive and in cancer), gene amplification, sister chromatid exchange and integration of foreign DNA. Only three common fragile sites, FRA3B, FRA7G and FRA7H, all induced by aphidicolin, have been characterized at the molecular level. In contrast to rare fragile sites, expanded repeats had not been found in common fragile sites, and the molecular basis for their fragility remains obscure. Here we report the identification and characterization of another common fragile site, FRA7E, on the long arm of human chromosome 7. Contigs of YAC, PAC and BAC clones from 7q21 were used as probes in a FISH analysis on metaphase chromosomes expressing fragile sites. Identification of hybridization signals telomeric, centromeric or on both sides of the gaps and constrictions of FRA7E, enabled us to map and define a region of ~500 kb encompassing this fragile site. Using STS markers from that region, we were able to construct a contig of >1 Mb (with only two small gaps, tens of kb long each), out of published PAC and BAC sequences, encompassing the FRA7E region. No expanded repeat sequences were identified in the sequenced region, confirming previous results indicating that the molecular basis of aphidicolin induced common fragile sites differs from that of rare fragile sites. Analysis of ORFs and potential non-B DNA structures within the region will be discussed. Interestingly, FRA7E resides a few Mb proximally to the PGY (MDR) genes, known to be amplified in various types of cancer, and underlying their resistance to chemotherapy. The involvement of FRA7E in these amplification events is currently under investigation.

Program Nr: 2400 from the 1999 ASHG Annual Meeting

Acute, fatal presentation of ornithine transcarbamylase deficiency in a 62-year-old man. *D. Kostiner, K. Weisiger, E. Moffatt, N. Linderman, R. Lamb, G. Lopez, F. Sharp, S. Goodman, M. Tuchman, S. Packman.* Medical Genetics, U. of California, San Francisco, CA.

Ornithine transcarbamylase (OTC) deficiency is an X-linked urea cycle defect. While hemizygous males typically present with hyperammonemic coma in infancy, there are case reports of late-onset presentations with poor outcomes in males 6-58 years old. Interestingly, relatives carrying the same mutations often remain asymptomatic. Multifactorial influences clearly affect disease penetrance and expressivity. We present a patient with late-onset OTC deficiency to educate clinicians about urea cycle defects in adults and to consider environmental factors that may have impacted disease expression in this patient. A previously healthy, intelligent 62-year-old man developed mental slowing, vision changes, emesis, refractory seizures and coma over a 10-day period. History was remarkable for recent use of home-gardening fertilizers and pesticides. Evaluations for drug and alcohol use, infections, and liver disease were negative. Aggressive treatment including hemodialysis was initiated for ammonia level of 457 uM (nl 11-35). Despite therapy, ammonia peaked at 2050 uM and patient expired from cerebral edema and cerebellar herniation. Urine orotic acid was 473 MMol/Mol CR (nl 0-3). Analysis of the OTC gene showed a Pro-225-Thr change in exon 7. This mutation has been previously implicated in causing OTC deficiency. Family history revealed a sister with arrested cognitive maturity at puberty and 3 normal brothers. Mutation testing of siblings is currently underway. We conclude the following: 1) Pro-225-Thr mutation can be associated with late onset OTC deficiency. 2) Exposure to pesticides and fertilizers might have contributed to onset of symptoms in this patient. Tissue levels of these organic compounds are currently being assessed. 3) Acute, severe hyperammonemia in a previously healthy adult might be due to OTC deficiency. Physician awareness of this possibility can lead to rapid treatment and appropriate genetic counseling.

Program Nr: 2401 from the 1999 ASHG Annual Meeting

Molecular pathology of bovine b**-mannosidosis.** *S.A. Kraemer[1], J.R. Leipprandt[1], M.Z. Jones[1], K.H. Friderici[2]*. 1) Division of Human Pathology, Michigan State University, East Lansing, MI; 2) Department of Microbiology, Michigan State University, East Lansing, MI.

b-Mannosidosis, a disease with autosomal recessive inheritance, results from the deficiency of lysosomal b-mannosidase activity. This deficiency is associated with severe prenatal and neonatal neurological and skeletal deformities in the naturally-occurring Salers cattle model. Although bovine b-mannosidase RNA levels in the affected animal were comparable to those in the normal control, no residual enzyme activity or protein was detected in tissues of affected animals, suggesting a total loss of function mutation, with a post-transcriptional mechanism, may cause this disease. A nonsense mutation, G2574A, associated with the bovine disease was identified. This mutation is predicted to result in the deletion of only the C-terminal 22 amino acids of the 879 amino acid bovine b-mannosidase, a region not previously predicted to be critical in the catalytic function of the enzyme. To explore the molecular basis underlying bovine b-mannosidosis, wild-type and mutant bovine b-mannosidase were expressed in CHO-K1 cells. Wild-type transfectants had significantly elevated b-mannosidase enzyme activity in both intracellular and secreted fractions; however, no activity was detected in either fraction of the mutant transfectants. Following metabolic labeling with ^{35}S-methionine and immunoprecipitation using a polyclonal anti-bovine b-mannosidase antibody, both wild-type and mutant b-mannosidase proteins were detected in the intracellular fraction. Both intracellular proteins appeared to be subjected to similar post-translational carbohydrate modification, and had similar stability. On the other hand, unlike the wild-type recombinant protein, the mutant recombinant protein was absent in the secreted fraction. These results suggest that the mutation associated with bovine b-mannosidase does not appear to interfere with proper translation or intracellular glycosylation of the protein. However, the C-terminal 22 amino acids of b-mannosidase apparently play an unforseen role in the activity, secretion and/or extracellular stability of the enzyme.

Program Nr: 2402 from the 1999 ASHG Annual Meeting

Clinical Manifestations in Three American Adult Patients with Carbohydrate-deficient Glycoprotein Syndrome.
D. Krasnewich[1], E. Orvisky[2], O. Goker[3], W. Introne[1], K. Peters[1], K. Dietrich[1], E. Ginns[2], E. Sidransky[2]. 1) MGB/NHGRI; 2) NSB/NIMH; 3) HCB/NICHD National Institutes of Health, Bethesda, MD.

CDGS is a group of multisystemic disorders resulting from defective N-linked oligosaccharide synthesis. 60-70 cases of CDGS have been diagnosed in the United States over the past 5 years. Only three American adult CDGS cases have been recognized; a 24 year old woman and her 25 year old brother, and a 30 year old man, the oldest recognized American CDGS patient. All are CDGS type 1 patients, as determined by diagnostic serum transferrin isoelectric focusing. The siblings are CDGS type 1A, the most common CDGS type, as defined by lymphoblast phosphomannomutase (PMM) deficiency; PMM assay is pending in the third case. All had unremarkable birth histories followed by failure to thrive, developmental delay and esotropia recognized in the first few months of life. Their infantile medical histories revealed only mildly elevated liver function tests which persisted during their first few years of life. Hypotonia and ataxia were pronounced throughout their development; none achieved independent standing, the third patient briefly walked with a walker. Scoliosis, kyphosis and striking truncal shortening have been progressive throughout the teenage and adult years. Because of ataxia and profound skeletal involvement, currently all are wheelchair bound. All have the previously reported peripheral neuropathy with only the oldest patient having progressive muscle wasting (Stibler, 1994). Muscle strength is good, with the siblings atypically maintaining normal muscle mass. All three patients have retinitis pigmentosa (RP) and cerebellar hypoplasia/atrophy. The men have normal adult genitalia; the woman has no breast development. Their cognitive abilities are remarkable, while severely dysarthric all three carry on conversations punctuated with good natured joking. The oldest is in an assisted living setting and describes himself as an "eclectic music lover". The clinical description of these adults cautiously support a more positive cognitive prognosis in children with CDGS type1. CDGS should be considered in any adult patient with mental retardation, ataxia, truncal shortening and RP.

Program Nr: 2403 from the 1999 ASHG Annual Meeting

Polymorphisms in the CBS gene associated with increased risk of heart disease and decreased responsiveness to homocysteine lowering by folate. *W.D. Kruger[1], L. Wang[1], A.A. Evans[1], M.R. Malinow[2], P.B. Duell[2], D.L. Hess[3], R.A. Gluckman[4], P.C. Block[4], P.H. Anderson[4], B. Upson[4].* 1) Population Sci, Fox Chase Cancer Ctr, Philadelphia, PA; 2) Department of Medicine, Oregon Health Sciences Unversity, Portland Or; 3) Reproductive Sciences, Oregon Regional Primate Research Center, Beaverton Or; 4) Providence St. Vincent Medical Center, Portland Or.

Elevated total plasma homocysteine (tHcy) is an established risk factor in the development of vascular disease. Folic acid supplements can generally lower tHcy levels but individual response is highly variable. In this case-control study we have examined various genetic polymorphisms in homocysteine metabolizing genes and their relationship to incidence of coronary artery disease (CAD), tHcy levels, and lowering of tHcy levels in response to folic acid supplementation. We have found that two polymorphisms in the cystathionine beta synthase (*CBS*) gene, 699c and 1080t, are associated with increased incidence of CAD and decreased folate responsiveness. Individuals homozygous for either 699c or 1080t are over represented in CAD patients and show decreased tHcy lowering in response to treatment by folate. The two polymorphisms in *CBS* are third codon changes and would not be predicted to affect the underlying protein. Interestingly there is strong linkage disequilibrium between these two positions, suggesting that they may also be linked to other as yet unidentified polymorphisms within the *CBS* gene. These observations suggest that specific *CBS* alleles are a risk factor for the development of vascular disease. In addition, it may be possible with genetic information to predict *apriori* an individuals response to folic acid supplementation.

Program Nr: 2404 from the 1999 ASHG Annual Meeting

Perinuclear localization of hephaestin suggest exocytic intestinal iron export. *Y. Kuo[1], C.D. Vulpe[2], G.J. Anderson[3], J.G. Gitschier[1,4].* 1) Department of Pediatrics, University of California, San Francisco, CA 94143; 2) Department of Nutritional Sciences, University of California, Berkeley, CA 94720; 3) Joint Clinical Sciences Program, Queensland Institute of Medical Research and University of Queensland, Queensland, 4029; 4) Howard Hughes Medical Institute, U.C.S.F., CA 94143.

Hephaestin encodes a transmembrane-bound ceruloplasmin homolog, which is mutant in the *sla* mouse and is highly expressed in the intestine. We suggest that hephaestin is a multi-copper ferroxidase necessary for iron egress from intestinal enterocytes into the circulation. Hephaestin was localized in the mouse small intestine using affinity-purified hephaestin antiserum. The antiserum was raised in rabbits to a peptide corresponding to amino acids in the predicted cytoplasmic domain at the C-terminus. By RNA *in situ* hybridization, hephaestin is highly expressed throughout the intestinal villi but absent in the crypt cells. However, by immunostaining hephaestin is within the enterocytes of the intestinal villi in a perinuclear location. When the antiserum was preabsorbed with the peptide used for immunization, there was no detectable staining indicating the staining specificity for hephaestin protein. Perinuclear localization was confirmed by double staining with the nuclear marker propidium iodide. Double staining with anti-Na^+K^+- ATPase antibody, a marker for the plasma membrane, clearly shows that hephaestin does not localize to the plasma membrane. We conclude that in iron replete adult animals at steady state, hephaestin resides in a perinuclear compartment rather than directly on the basolateral cell surface of the enterocytes. Other proteins involved in intestinal metal export , such as ATP7A, the copper transporting ATPase defective in Menkes disease and the mottled mouse, also localizes to an intracellular compartment (trans-Golgi) within the cell. The intracellular localization of hephaestin suggests that iron export from the intestine proceeds via transport into an intracellular compartment followed by exocytosis of vesicle-bound iron. Hephaestin localization in *sla* and mottled mutant mice will also be discussed.

Program Nr: 2405 from the 1999 ASHG Annual Meeting

The arsenite-stimulated ATPase (hASNA-I) interacts with metallothionein-II and modifies the human cellular response to arsenite. *B. Kurdi-Haidar, L. Fink, D.K. Hom, D. Heath.* UCSD Cancer Center, Univ California San Diego, La Jolla, CA.

The physiologic role of metallothionein (MT), as a metal binding protein affecting zinc and copper cellular homeostasis, in human genetic disorders of Cu metabolism has been described. The human arsenite-stimulated ATPase (hASNA-I) was recently identified as a human paralogue of the ATPase component of the arsenite efflux system in E. coli. Using the hASNA-I cDNA as bait in a yeast two-hybrid system, metallothionein II (MT-II) was identified as a cellular protein interacting with hASNA-I. Three lines of evidence verified that MT-II is a true partner of hASNA-I. First, hASNA-I can be covalently cross-linked to purified MT-II. Second, GST-hASNA-1 fusion protein selectively captured both purified and cellular hMT-II in a glutathione-dependent manner. Third, affinity mass spectrometry based on surface enhanced laser desorption/ionization showed binding of purified MT-II to hASNA-I. Glutathione markedly diminished the binding of MT-II to hASNA-I. The physiological consequence of the interaction between the two proteins on the sensitivity to arsenite was investigated by over-expression of either hASNA-I or hMT-II alone or together in human squamous head and neck carcinoma UMSCC10b cells. No change in arsenite sensitivity was observed when the two proteins were expressed separately, but over-expression of both together resulted in an increase in arsenite sensitivity by a factor of 1.9-fold (p=0.02). Thus, hASNA-I appears to be a modulator of the sensitivity of human cells to arsenite in the presence of MT-II. Studies of the effect of the interaction between hASNA-I and MT-II on the cellular sensitivity to Cu are underway. The current findings raise the possibilities that: 1) hASNA-I might influence the genetic susceptibility of individuals to arsenite carcinogenesis; and, 2) the physiological role of MT in disorders of Cu metabolism could also be mediated through its interaction with other cellular partners such as hASNA-I. *E. colihASNA-IhASNA-IhMT-II*.

Program Nr: 2406 from the 1999 ASHG Annual Meeting

Nonketotic hyperglycinemia: Mutation spectra of the GLDC and AMT genes in Finnish and non-Finnish populations. *S. Kure[1], M. Takayanagi[1], Y. Kurihara[1], J. Leisti[2], D. Zalai[3], G. Chuck[4], K. Tada[5], Y. Matsubara[1], K. Narisawa[1]*. 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 2) Department of Clinical Genetics, Oulu University Central Hospital, Oulu, Finland; 3) Department of Pediatrics, Semmelweis University School of Medicine, Budapest, Hungary; 4) Division of Pediatric Neurology, Children's Hospital Medical Center, Cincinnati, Ohio; 5) NTT Tohoku Hospital, Sendai, Japan.

Nonketotic hyperglycinemia (NKH) is an inborn error of metabolism characterized by accumulation of a large amount of glycine in body fluid. Incidence of NKH is estimated as 1 in 250,000 births in many countries while it is unusually high in northern Finland (1 in 6,000 births). NKH is caused by deficiency of the glycine cleavage system (GCS), which consists of four individual components referred to as P, T, H, and L-proteins. Three and six mutations have been reported in the genes encoding P-protein (GLDC) and the T-protein (AMT), respectively. To elucidate the mutation spectra of NKH in Finnish and non-Finnish population we screened 27 Finnish and 33 non-Finnish patients for mutations in the GLDC and AMT genes by direct sequencing analysis of each exon. In Finnish patients we identified two prevalent mutations in the GLDC gene, S564I and G761R. The two mutations accounted for 42 of 54 Finnish mutant alleles (78 percent) and no mutation was found in the AMT gene. In non-Finnish patients, 20 and 8 patients were identified to have mutations in the GLDC and AMT genes, respectively, and no mutation was detected in 5 patients. The mutations were heterogeneous: there were 24 and 12 mutations in the GLDC and AMT genes. There results suggest a sharp contrast of genetic background of NKH in Finnish and non-Finnish populations.

Program Nr: 2407 from the 1999 ASHG Annual Meeting

The N370S/N370S glucocerebrosidase genotype is associated with low chitotriosidase activity. *L.M.W.G. Lacerda[1], O.M.O. Amaral[1], E.M. Pinto[1], E. Silva[1], P. Oliveira[2], M.C.P. Sa Miranda[1].* 1) Genetic Neurobiology, IBMC-University of Porto, Porto, Portugal; 2) Department of Production and Systems, University of Minho, Braga, Portugal.

Gaucher disease (GD), the most prevalent lysosomal storage disease, is an autosomal recessive disorder of glycosphingolipid metabolism. It is characterised by accumulation of glucosylceramide in macrophages (Gaucher cells) due to the glucocerebrosidase deficient activity. Chitotriosidase is a human chitinase produced by these cells in tissues and organs and may thus reflect the severity of the disease. Although the glucocerebrosidase (GBA) gene mutations have been extensively characterised, no correlation can be easily established between GBA genotype and the clinical expression of the disease. In this work we attempted to correlate the clinical severity, reflected by chitotriosidase activity, with GBA genotype. Patients were also screened for the frequent 24bp chitotriosidase duplication. Sixty-three Portuguese type 1 GD patients were studied and the mean chitotriosidase activity of the 38 GD patients not carrying the chitotriosidase gene mutation was 15282/-16367, ranging from 1265-68394. From these, a group of 7 patients who were homozygotes for the N370S GBA gene mutation (mean chitotriosidase activity 4223/-1895) presented significantly lower chitotriosidase activity than that presented by the 31 patients with other GBA genotypes (mean chitotriosidase activity 17780+/-17166). This finding substantiates further our previous prediction of mild clinical presentation in this genotype group. Twenty-five GD patients are under enzyme supplementation therapy and the biochemical follow-up was done by comparing changes of plasma chitotriosidase activity. The importance for the establishment of the chitotriosidase deficiency carrier status was manifold: to evaluate the starting dose/regimen, on the basis the initial chitotriosidase activity (which reflects the overall Gaucher cell burden in the body); to establish the lowest effective dose, by making use the of maximal reduction of chitotriosidase activity as a marker of the correction and/or prevention of ongoing formation of Gaucher cells.

Program Nr: 2408 from the 1999 ASHG Annual Meeting

Tissue-Specific Regulation of Human Galactose-1-Phosphate Uridyltransferase (GALT). *K. Lai, C.A. Presley, S.D. Langley, L.J. Elsas.* Dept Ped, Div Medical Genetics, Emory Univ, Atlanta, GA.

Classic Galactosemia in humans is an inherited metabolic disorder caused by deficiency of GALT. While a galactose-restricted diet can prevent a lethal hepatotoxic syndrome, long-term complications such as verbal dyspraxia, ataxia, mental & growth retardation, and premature ovarian failure may occur. We have defined differences in organ expression of GALT enzyme activity (Lai *et al.*, 1996, *J. Pediatrics* v128: 89-95). By Northern blot analysis, GALT mRNA abundance varies. We found abundant GALT message in liver, ovary, brain, heart, while little or no message is in pancreas, skeletal muscle. To understand the molecular mechanisms for tissue-specific expression of the human GALT gene, we cloned and sequenced 4 kb of DNA 5' to the translation start site. Using the TRANSFAC v3.2 program, we found numerous putative binding sites for tissue-specific and developmentally-regulated transcriptional factors such as HNF-3, HNF4, HNF-5, IRF-1. No TATA box was found. Primer extension analysis using RNA harvested from normal human fibroblasts, and liver tissues, as well as three tissue-specific cell lines HEK293 (embryonic kidney), NIH-OVCAR-3 (ovary) and HepG2 (liver) indicated numerous transcription initiation sites. The strongest mRNA start signal was at a GC-rich region located at -80 nucleotide (nt) relative to the ATG start site. Functional analyses of the GALT gene promoter using a luciferase reporter gene system and the tissue-specific cell lines showed predominant promoter elements within the 166 nucleotides (-1nt to -166nt) 5' to the ATG start. A fibroblast-specific repressor binding site was between -166nt and -366nt. Using a construct containing -1nt to -698nt, we found 100 fold higher reporter activity in the embryonic kidney cell lines compared to liver, ovary and fibroblasts. We conclude that the human GALT gene expression is regulated in a tissue-specific and developmental manner.

Program Nr: 2409 from the 1999 ASHG Annual Meeting

A rapid and direct detection for the CYP21P/CYP21 chimeric gene in steroid 21-hydroxylase deficiency: an analysis for PCR dropout. *H.H. Lee[1], J.G. Chang[1], C.H. Tsai[1], B.c. Chung[2]*. 1) Deptment of Medical Research, China Medical college Hospital, Taichung, Taiwan, R.O.C; 2) Institute of molecular Biology, Academia Sinica, Nankang, Taipei, Taiwan, R.O.C.

We have developed a rapid and direct method to detect chimeric CYP21P/CYP21 gene, which resulting from gene crossover, in congenital adrenal hyperplasia (CAH) using a PCR-based assay. The strategy was to use primers containing a 3' specific primer for the CYP21 gene and two different 5' primers for both the normal CYP21 and the CYP21P of the chimeric CYP21P/CYP21 genes in the PCR amplification. For detecting gene crossover region, a secondary PCR was performed using another set of primers which included one 5' primer specific for the chimeric gene and the other for the normal CYP21 gene. The size of the PCR products was able to differentiate chimeric gene from the normal gene. By adding a CYP21/CYP21P specific primer for the 8 base-deleted region (codon 111-113) in intron 2, we were able to amplify and detect both the chimeric homozygous and heterozygous genes. Otherwise, by using primer for the CYP21 gene, only the CYP21 could be amplified, and most of time the CYP21/CYP21P chimeric gene will not be amplified. This will lead to a diagnostic discordance and result in false results. From our studies, we have shown that the lack of specific primer for this molecule missed the detection CYP21/CYP21P chimeric gene, which commonly occurs in the heterozygous CAH carrier population. Since the PCR amplification was a competition reaction, PCR dropout in detecting intron 2 nucleotides 656 of the chimeric gene was due to unequal concentration of the PCR template. Therefore, this PCR-based assay is a more effective way to analyze the mutation of CAH.

Program Nr: 2410 from the 1999 ASHG Annual Meeting

Molecular analysis in patients with MPS I: Two major common mutations and multiple single nucleotide polymorphic alleles in the IDUA gene. *P. Li, J.N. Thompson.* Department of Human Genetics, Univ. Alabama at Birmingham, Birmingham, AL.

Mucopolysaccharidosis type I (MPS I, MIM 252800) is an autosomal recessive disorder resulting from a deficiency of the lysosomal glycosidase, a-L-iduronidase (IDUA, EC 3.2.1.76). Patients with MPS I present with variable clinical manifestations ranging from severe type (Hurler syndrome), intermediate type (Hurler/Scheie syndrome), to mild type (Scheie syndrome). The clinical heterogeneity of MPS I has been suggested to reflect the allelic heterogeneity of the IDUA gene. In the present investigation, molecular analysis of the IDUA gene defects was performed for 10 patients who were enzymatically diagnosed with MPS I by the demonstration of IDUA deficiency. Total RNA and DNA samples were extracted from peripheral blood leukocytes or cultured fibroblasts. An experimental approach coupling RT-PCR based full-length cDNA sequencing with PCR based genomic DNA analysis was used for detecting mutations in the IDUA gene. Results of the analysis showed that one patient was a homozygote for a common mutation Q70X (CAG to TAG), one patient was a homozygote for another common mutation W402X (TGG to TAG), two patients were compound heterozygotes for Q70X/W402X, one patient was a compound heterozygote for Q70X and a novel missense mutation G208D (GGT to GAT), one patient was a compound heterozygote for R363C (CGC to TGC) and W402X, and one patient was a compound heterzygote for a novel missense mutation R162I (AGA to ATA) and a nonsense mutation R621X (CGA to TGA). The remaining three patients contained the W402X allele and an unidentified mutant allele. In addition, several single nucleotide polymorphic (SNP) alleles, coexisting with the disease-causing mutations, were detected. These SNP alleles included A8, A20, Q33H, L118, N181, A314, A361T, T388, and T410. The multiple IDUA SNP alleles could be useful for intragenic haplotyping in carrier detection and pedigree analysis. The present results and our previous data (Li. et al., Am J Hum Genet, 61:1490, Suppl.) indicated that the Q70X and W402X are found in about 25% and 40% of IDUA mutant alleles, respectively. Therefore, these two common mutations account for about 60% of mutant alleles in the IDUA gene.

Program Nr: 2411 from the 1999 ASHG Annual Meeting

Deficiencies in the Glucose-6-phosphate Transporter Cause Glycogen Storage Disease Type 1b but Not 1c. *B. Lin, H. Hiraiwa, C.-J. Pan, J.Y. Chou.* Heritable Disorders Branch, NICHD/NIH, Bethesda, MD.

Glycogen storage disease type 1 (GSD-1) is a group of autosomal recessive disorders caused by deficiencies in glucose-6-phosphatase (G6Pase) and the associated substrate/product transporters. Molecular genetic studies have demonstrated that GSD-1a and GSD-1b are defective in the G6Pase enzyme and a glucose-6-phosphate transporter (G6PT), respectively. While kinetic studies of G6Pase catalysis predict that the index GSD-1c patient is deficient in a pyrophosphate/phosphate transporter, the existence of a separate locus for GSD-1c remains unclear. We have previously shown that the G6Pase gene of the index GSD-1c patient is intact, we now show that the G6PT gene of this patient is normal. Further, we have uncovered five novel G6PT mutations among fourteen GSD-1b patients. We demonstrate that all fifteen missense G6PT mutations reported to date as well as the F93 and the prevalent 1211delCT G6PT mutations completely abolish or greatly reduce glucose-6-phosphate (G6P) transport activity. Our data establish the molecular basis of GSD-1b and strongly suggest the existence of a distinct GSD-1c locus.

Program Nr: 2412 from the 1999 ASHG Annual Meeting

Regulation of the human cystathionine beta-synthase (CBS) gene. *K.N. Maclean, M. Janosik, E. Kraus, J.P. Kraus.* Dept of Pediatrics, C-233,University of Colorado school of medicine , Denver, CO.

Cystathionine beta-synthase (CBS; L-serine hydro-lyase (adding homocysteine), EC 4.2.1.22) catalyzes the condensation of serine with homocysteine to form cystathionine, which is subsequently converted to cysteine. Homozygous CBS deficiency is the most common cause of classical homocystinuria, while partial deficiency of CBS has been proposed to cause mild hyperhomocysteinemia, considered an independent risk factor for arteriosclerosis. The CBS gene has multiple transcription initiation sites with the 5' UTR being encoded by five alternatively used exons (-1a through -1e) and an invariably present exon 0. We have identified two separate promoters in the human CBS gene designated -1a and -1b, respectively. Using CBS activity assays it was found that the level of CBS activity in normal skin fibroblast, HepG2 (hepatoma) and SK-N-MC (neuroepithelioma) cells is coordinately regulated with proliferation. Maximal activity was detected during exponential growth and a 2 to 5-fold reduction of activity (depending upon cell type) occurred when cells became quiescent or were growth arrested in response to the addition of cytotoxic compounds or serum withdrawal. This finding was further investigated at the transcriptional level using -1a and -1b specific promoter constructs fused to a luciferase reporter gene and transiently transfected into HepG2 cells. In both cases, CBS promoter activity was coordinately regulated with proliferation as a function of nutrient depletion, growth rate, serum deprivation or the presence of cytotoxic compounds. A preliminary investigation has suggested that the second messenger compound cAMP is involved in the proliferation specific regulation of human CBS. The ability of insulin to repress CBS transcription from the -1b reporter construct, which lacks any known insulin response sequence elements, suggests that this regulation may be mediated by the intracellular concentration of cAMP. This hypothesis is supported by the observations that insulin specific repression of CBS was only detectable in actively proliferating cells and that the adenylate cyclase activator compound forskolin, up-regulates the -1b promoter in HepG2 cells.

Program Nr: 2413 from the 1999 ASHG Annual Meeting

Co-incidence of PKU and propionic acidemia in an Amish girl. *S.E. McCandless[1,3], J.W. McConnell[2], D.S. Kerr[2].* 1) Dept of Pediatrics, Univ of North Carolina; 2) Rainbow Babies and Children's Hosp, and; 3) Dept of Genetics, Univ Hospitals of Cleveland/Case Western Reserve Univ.

Propionic acidemia (PA) was recently diagnosed in an Amish female infant in whom PKU had been diagnosed by routine newborn screening (initial phe concentration 38 mg/dl). In addition to products of phe metabolism, methylcitrate and tiglylglycine were unexpectedly found in the urine organic acid analysis. Plasma and urine contained large amounts of propionylcarnitine. Enzyme analysis (fibroblasts) demonstrated very low propionyl-CoA carboxylase activity with normal activity of pyruvate and methylcrotonyl-CoA carboxylases. Urine pteridines were normal, as were serum biotinidase and RBC dihydropteridine reductase activities. At age 2 months, prior to treatment, she developed vomiting, decreased appetite and irritability, with metabolic acidosis and hyperammonemia (155mM). •• Management required combining two different amino-acid restricted formulas and oral carnitine (50 mg/kg/day). With treatment, phe was typically 2-6 mg/dl. At 6 months of age growth and development were normal. During this time of rapid growth the combination of the 2 formulas has met her requirements for essential amino acids without causing significant accumulation of phe or metabolites of propionyl-CoA. ••• There were several individuals with PKU on both sides of the family, but no recognized cases of PA nor consanguinity in the 4-generation pedigree. A 2-year-old sister of the proband with hypotonia and global developmental delay was tested and found to have PA but not PKU. That child had no episodes of serious illness, coma, blood dyscrasias or acidosis. •••• We are not aware of previous reports of co-incidence of these two rare metabolic diseases. This case alerts physicians to the possibility that rare genetic disorders may co-exist in a member of an in-bred group. The use of broader confirmatory testing enabled subclinical detection of PA in this case, and raises awareness of the usefulness of broader newborn screening, particularly in in-bred populations. The combined restriction of phe and propiogenic amino acids has been workable and effective, resulting in normal growth and development to date.

Program Nr: 2414 from the 1999 ASHG Annual Meeting

Immunolocalization Studies and Mutational Analysis of Acid a**-Glucosidase in Danon Disease.** *A.J. McVie-Wylie[1], P.W.K. Wong[2], S.G. Pophal[2], E.R. Rodriguez[3], V.J. Ferrans[4], D. van Leenen[5], A.J.J. Reuser[5], Y.T. Chen[1]*. 1) Dept. of Pediatrics, DUMC, Durham, NC; 2) Dept. of Pediatrics, RPSLMC, Chicago, IL; 3) Dept. of Pathology, RPSLMC, Chicago, IL; 4) Pathology Section, NBHLI, Bethesda, MD; 5) Dept. of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

Glycogen storage disease type II (GSD II) is an autosomal recessive disease in which deficiency of lysosomal a-glucosidase (GAA) results in massive accumulation of glycogen. This disorder presents with a spectrum of clinical findings ranging from severe cardiomyopathy in infants to mild muscle weakness in adults. Danon disease resembles GSD II histopathologically, however, biochemical analysis indicates that GAA levels are within the normal range. This condition is characterized clinically by severe cardiomyopathy, mild myopathy and mild to moderate mental retardation. We describe a 5 year old male who mimics the clinical observations reported and has normal GAA activity in muscle and skin fibroblasts. The histological changes detected are consistent with previous findings, including faint perinuclear material within the myocardial muscle fibers, increased PAS staining in both skeletal and myocardial tissue, and intra-lysosomal and cytoplasmic glycogen accumulation. The biochemical defect in this disorder remains unknown. It has been postulated that the intracellular processing and routing of GAA may be defective. Human GAA is synthesized as a 110kDa precursor, which is subsequently cleaved during transport to the lysosomes. Western blot analysis indicates that our patient not only produces mature GAA but in quantities similar to normal controls, demonstrating normal GAA synthesis and processing. Immunolocalization staining in patient skin fibroblasts reveals a typical punctate pattern consistent with lysosomal localization. These data contradict the theory that abnormal GAA processing or misrouting may be responsible for this disorder. Furthermore, sequencing analysis revealed no deleterious mutations in the GAA cDNA coding region. We therefore conclude that GAA may not be integral in the pathomechanism of Danon disease and that other pathophysiologic changes may be critical in the etiology of this disorder.

Program Nr: 2415 from the 1999 ASHG Annual Meeting

Molecular characterization in Niemann-Pick type C: insights into phenotypic variablility. *V. Meiner[1], S. Shpitzen[2], M. Zeigler[1], A. Lossos[3], H. Mandel[4], G. Bach[1], E. Leitersdorf[2].* 1) Dept Genetics, Hadassah Univ Hosp, Jerusalem, Israel; 2) Center for Research, Prevention, and Treatment of Atherosclerosis, Hadassah Univ Hosp, Jerusalem, Israel; 3) Dept of Neurology, Hadassah Univ Hosp, Jerusalem, Israel; 4) Dept of Pediatrics, Rambam Medical Center, Haifa, Israel.

Niemann-Pick disease type C (NP-C) is an autosomal recessive lipid storage disease manifested by an impairment in cellular cholesterol homeostasis. The disease is clinically characterized by progressive degeneration of the central nervous system with accumulation of cholesterol and sphingomyelin. The clinical phenotype of NP-C is extremely variable ranging from an acute neonatal form to an adult-late onset presentation. To facilitate phenotype-genotype studies, we have analyzed multiple families with a clinical phenotype of NP-C. Clinical diagnosis in these families was supported by cholesterol esterification assays and filipin staining of cellular free cholesterol. The severity of the disease was assessed by age at onset of first symptoms, clinical progression, and cholesterol esterification studies. We screened for mutations in the entire NPC1 coding sequence and identified 2 novel mutations localized either within or between the putative transmembrane domains. A dinucleotide deletion predicted to result in a truncated 1120 aa protein was found in patients with a rapidly progressive fatal disease. In contrast, a novel missense mutation (A927V) was associated with an adult-onset, slowly progressive phenotype accompanied by a 23% to 58% block in the induced cholesterol esterification assays. These results, further support a possible link between the severity of the phenotype and the characteristics of the specific NPC1 mutation and may help to clarify the roles of putative critical domains in the NP-C protein.

Program Nr: 2416 from the 1999 ASHG Annual Meeting

Polyendocrinopathy, skeletal dysplasia, organomegaly, and distinctive facies associated with a novel, widely-expressed Gsa **mutation.** *K.A. Mockridge[1], M.A. Levine[2], L.A. Reed[1], E. Post[1], F.S. Kaplan[3], S.M. Jan de Beur[2], Z. Deng[2], C. Ding[2], C. Howard[1], R.E. Schnur[1]*. 1) Cooper Hosp./UMDNJ at Camden; 2) Johns Hopkins Univ. School of Medicine, Baltimore, MD; 3) Univ. of Pennsylvania School of Medicine, Philadelphia.

McCune Albright syndrome (MAS) is comprised of the clinical triad of polyostotic fibrous dysplasia, polyendocrinopathy, and café au lait macules. MAS is caused by somatic mosaicism for activating mutations of GNAS1, specifically at residues Arg201 and Gln227 in exons 8 and 9. We report a 2 yr old African American male with developmental delay and a variant MAS phenotype associated with a novel Gsa mutation that is apparently constitutional, rather than mosaic. Skeletal abnormalities include metaphyseal chondrodysplasia, with disproportionate, short limbs, bony effects of his hyperparathyroidism (demineralization, spontaneous fractures), slipped capital femoral epiphyses and advanced bone age. In addition, he has precocious puberty and increased testosterone, IGF-BP3, and somatomedin-C levels. He also has features suggestive of a storage disorder (hepatosplenomegaly, cardiomyopathy, thick skin and gums, increased urinary excretion of heparan and dermatan sulfate). Dysmorphic facial features include wide fontanel, epicanthi, hypertelorism, preauricular tags and sinuses, flat nasal bridge, short septum, tented upper lip, and deep philtrum. He has had therapy-resistant tinea versicolor, thrush, and monilial rash. He also has bilateral hydroceles. His cutaneous pigmentation is darker than either parent's, but he has no discrete café au lait macules. Because of the polyendocrinopathy, DNA was analyzed for mutations in the GNAS1 gene. A novel arginine to leucine mutation (CGT®CTT) was detected at residue 201. The mutation and the wild type allele appear to be present in equal proportions in DNA from both blood and fibroblasts and are equally expressed by RT-PCR of mRNA from these tissues. R201L is thus the first probably constitutional, non-mosaic GNAS1 mutation to be identified in association with a variant form of MAS. *GNAS1GNAS1GNAS1*.

Program Nr: 2417 from the 1999 ASHG Annual Meeting

I-Cell disease in a patient with unusual biochemical findings. *E.T. Morava Kozicz[1], G. Toth[1], E. Paschke[3], K.E. Jackson[2], Gy. Kosztolanyi[1]*. 1) Inst Medical Gen/Child Dev, Univ Medical Sch Pecs, Pecs, Hungary; 2) Human Genetics Program, Tulane University School of Medicine, New Orleans, LA; 3) Pediatric Hospital, Graz, Austria.

I-cell disease is a Hurler-like condition with coarse face, clear corneas, hyperplastic gums, severe growth deficiency, congenital hip dislocation, thoracic and vertebral deformities and restricted joint mobility. Retarded psychomotor development becomes evident in early infancy. We report a patient with typical clinical features of I-cell disease, who had unusual biochemical findings. Enzyme studies including arylsulfatase, hexosaminidase, iduronidase-sulfatase and beta-galactosidase showed normal activity in lysosomes, fibroblasts and serum. We found a pronounced decrease in the lysosomal activity of beta-glucoronidase (50%) with a 25 times increased activity in serum. Other metabolic findings including urinary excretion of sialic acid and no detectable GAG supported the diagnosis of I-cell disease. Since the mother is pregnant, prenatal diagnosis was performed, and no elevation of beta-glucoronidase or hexosaminidase A was found in the amniotic fluid, and the ratio of the enzyme activity in amniotic cells and culture media was comparable to controls.

Program Nr: 2418 from the 1999 ASHG Annual Meeting

Real defect of Ampd1 accompanied with myopathy: New missense mutations found in a Japanese patient. *T. Morisaki[1], H. Morisaki[1], I. Higuchi[2], M. Osame[2], M. Abe[3]*. 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Third Dept Medicine, Kagoshima Univ Med School, Kagoshima, Kagoshima, Japan; 3) Dept Medicine, Kagoshima Redcross Hosp, Kagoshima, Kagoshima, Japan.

AMPD (AMP deaminase) deficiency of skeletal muscle is one of the most common inherited defects in the Caucasian. Approximately 2 % of Caucasians are homozygotes for a nonsense mutation (C34T) in exon 2 of the AMPD1 gene. Alternative splicing of exon 2 in individuals who have inherited this defect is thought to provide a mechanism for phenotypic rescue and variations in clinical symptoms. Here we have studied the first case with real defect of AMPD1 gene in a Japanese patient with myopathy. Forty-six year-old female presented muscle weakness in lower extremities. The muscle biopsy showed negative staining for AMPD in addition to changes in fiber size and mild degeneration in myofiber. Muscle lysate showed very little AMPD activity (0.2 % of control). cDNA synthesized from the biopsied muscle indicated comparable amount of AMPD1 transcripts in the patient. Direct sequencing of cDNA identified two missense mutations in exon 9 and exon 10 of AMPD1. These mutations cause amino acid substitutions (R388W and R425H) in the conserved domain of AMPD1, and they were confirmed to be located in the different alleles by PCR analysis of genomic DNA. Prokaryotic expression showed comparable amount of AMPD1 peptide and undetectable AMPD activity in the constructs with these mutations. It has not been verified whether mutation of AMPD1 gene would indeed cause muscle dysfunction, since alternative splicing may restore the function of AMPD1 gene with C34T mutation. From this study, we conclude that this patient is a compound heterozygote for AMPD1 mutant allele and the first case of real dysfunction of AMPD1 gene product, suggesting that AMPD1 has indeed a key role in muscle metabolism and function.

Program Nr: 2419 from the 1999 ASHG Annual Meeting

Targeted disruption of the mouse iduronate sulfatase gene. *J. Muenzer, H. Fu.* Department of Pediatrics, University of North Carolina, Chapel Hill, NC.

Hunter syndrome (MPS II) is a lysosomal storage disorder due to a deficiency of the enzyme iduronate sulfatase (IdS). Deficiency of IdS results in lysosomal accumulation of dermatan and heparan sulfate, with progressive tissue and organ dysfunction, and in the severe form, premature death. A knockout mouse has been generated by homologous recombination. The targeting vector was designed to create a null mutation in the IdS gene. A replacement vector (JNS2) containing 9.2 kb of mouse genomic DNA was constructed in which a portion of exon 4 and all of exon 5 of the IdS gene (a 1.5 kb deletion) was replaced by a neomycin-resistance gene expression cassette. The targeting vector JNS2E8 was injected into E14TG2a embyronic stem cells and G-418 resistant clones were screened for homologous recombination. A targeting frequency of about 1:18 was obtained. Embyronic stem cells clones were injected into blastocysts that resulted in highly chimeric male mice which produced germline transmission of the mutated allele. Heterozygous female and hemizygous male mice were identified by Southern analysis and/or by a PCR assay which detects both the normal exon 4 and the recombinant exon 4 alleles. Offspring of heterozygous female mice yield the expected number of mutant male mice. The MPS II mice appeared normal at birth. The mutant male mice have no detectable IdS activity in liver or brain. Light microscopic analysis revealed vacuolated cells in liver and brain. Glycosaminoglycan content at 6 to 8 months of age was increased at least 2-fold in the seven tissues measured, with liver being greater than 6-fold elevated. Radiographs at 6 months of age revealed widened and thickened ribs. The IdS deficient mice should be useful in the study of the pathophysiology of Hunter syndrome and for the development of new therapies, such as enzyme replacement and gene therapy.

Program Nr: 2420 from the 1999 ASHG Annual Meeting

Difficult Prenatal Diagnosis of a Fetus Affected with Mild Smith-Lemli-Opitz syndrome (SLOS). *M.J.M. Nowaczyk[1,2], T.W. Heshka[2], L.E. Kratz[3], R.I. Kelley[3].* 1) Dept. Pathology & Molecular Medicine, McMaster University, Hamilton, ON, Canada; 2) Hamilton Regional Laboratory Medicine Program, Hamilton, Canada; 3) Kennedy Krieger Institute, Division of Metabolism, Baltimore, MD.

We recently diagnosed SLOS in two brothers minimal physical findings and mental retardation; their cholesterol levels were 2.30 and 2.34 mmol/l, and 7DHC levels were 134 and 183 mmol/l. We now present our experience with prenatal diagnosis of a third affected sib. The mother reported her pregnancy at 5 weeks of gestation, at which time oral cholesterol supplementation of 1000 mg/day was started. The couple underwent prenatal diagnosis by CVS at 11 2/7 weeks. The karyotype was 46,XY. Direct analysis of CVS material was performed according to previously published methods. The 7DHC/chol ratio was 3.76%, [normal controls: 0.06% ± 0.02% (SD), (n=7), unaffected at-risk: 0.08% ± 0.03% (SD)(n=7)]. This ratio was significantly lower than that found in CVS of three fetuses in whom SLOS was diagnosed prenatally [27.6% ± 4.5% (SD)] raising the possibility of a heterozygote fetus. The couple stopped the pregnancy at 13 2/7 weeks. The level of 7DHC in amniotic fluid obtained at that time was 151 ng/ml [normal value: 6 ± 3 (SD) ng/ml, (n=89)] and the 7DHC/chol ratio in fetal tissue was 69±37; [normal control 0.037±37;]. These results clearly established a diagnosis of SLOS.

This case illustrates the potential difficulties of interpreting results in fetuses with mild variants of SLOS. Although the 7DHC/chol ratio was »50 times normal, as it was much lower than the ratio in CVS tissue of other affected SLOS pregnancies, and because the cultured cells of some SLOS parents have had atypically high 7DHC/chol ratios, we could not be certain whether the intermediate value reflected heterozygote status or a fetus affected with mild SLOS variant. Also possible is that maternal chol supplementation for 6 weeks prior to CVS lowered the 7DHC/chol ratio in the CVS sample. As the clinical spectrum of SLOS expands to include cases with very mild biochemical abnormalities, the interpretation of the results of biochemical testing of fetuses affected with milder biochemical variants may be more difficult.

Program Nr: 2421 from the 1999 ASHG Annual Meeting

Glucosylsphingosine accumulation in patients with Gaucher disease. *E. Orvisky, E.I. Ginns, E. Sidransky.*
DHHS/PHS, NIH/NIMH, Bethesda, MD.

Gaucher disease results from the inherited deficiency of lysosomal glucocerebrosidase and presents with a wide spectrum of clinical manifestations including neuronopathic and non-neuronopathic forms. While patients and the null allele Gaucher mouse store the lipid glucocerebroside, elevated levels of a second and highly toxic substrate, glucosylsphingosine, have also been reported. Using high performance liquid chromotography with a 4-fluoro-7-nitrobenzofurazan-generated autofluorescent derivative, glucosylsphingosine levels were measured in tissues from patients with type 1, 2, and 3 Gaucher disease and correlated with patient phenotype. Glucosylsphingosine was measured in 13 spleen samples (5 type 1, 3 type 2, and 5 type 3) and levels ranged from 54 to 417ng/mg protein in the type 1 patients, 133 to 1200 ng/mg protein in the type 2 patients and 102 to 1298 ng/mg protein in the type 3 cases. The levels of glucosylsphingosine in these spleens bore no relation to the type of Gaucher disease, the age of the patient, the genotype, nor the clinical course; but tended to be highest in the largest and most abnormal spleens. In the same patients, glucosylsphingosine levels in liver were somewhat lower than those in spleen. Glucosylsphingosine was also measured in brains from 7 patients (1 type 1, 5 type 2, 1 type 3). While no elevation of glucosylsphingosine was found in the brain from the type 1 patient, the level in the type 3 patient was 8.89 ng/mg protein. The level in the type 2 patients ranged from 9.8 to 437 ng/mg protein, with the highest values detected in 2 fetuses with hydrops fetalis. The elevated levels found in brains from neuronopathic, but not type 1 Gaucher patients, support the hypothesis that glucosylsphingosine may contribute to the nervous system involvement in these patients.

Program Nr: 2422 from the 1999 ASHG Annual Meeting

Compound heterozygosity for Fp subunit mutations causes complex II deficiency in a patient with encephalomyopathy. *B. Parfait, D. Chretien, A. Munnich, P. Rustin, A. Rotig.* INSERM U393, Hosp Necker, Paris, France.

Complex II of the mitochondrial respiratory chain is made up of four subunits in human. All four subunits are nuclearly encoded. The Fp (flavoprotein) gene is present in two copies on human genome, one on chromosome 5p15 and the second on chromosome 3q29 and the specific role of each copy remains unclear. We have sequenced the exon-intron boundaries of the two Fp copies by using somatic hybrids harboring either human chromosome 3 or chromosome 5. This allowed us to identify one base pair deletion creating a frameshift in the 3q29 copy and confirming that this gene is a pseudogene. Here, we report a patient with SDH deficiency presenting with encephalomyopathy. Sequencing the Fp SDH cDNA allowed to identify two heterozygous mutations. One allele carried a C to T transition changing an alanine into a valine in the protein. This transition was found in the patient's father but was absent from 150 controls. Transfection of the mutant cDNA in human SDH-deficient cells failed to restore normal SDH activity confirming the deleterious nature of this mutation. The second allele, inherited from the mother, carried an A to C substitution changing the methionine translation initiation codon into a leucine. The mutated transcript represented only 20% of total Fp transcripts suggesting instability of this transcript. This new case of SDH Fp mutation adds further support to the view that nuclear genes are involved in respiratory chain deficiencies in human.

Program Nr: 2423 from the 1999 ASHG Annual Meeting

Regulated expression of the mouse acid b **glucosidase (GCase) gene.** *E. Ponce[1], A. Hung[2], D. Witte[1], G.A. Grabowski[1]*. 1) Children's Hospital Medical Center, Cincinnati, OH; 2) Escuela de Medicina J.M. Vargas UCV, Caracas, Venezuela.

The hydrolysis of glucosylceramide to ceramide and glucose occurs by the action of the lysosomal enzyme GCase. In Gaucher disease, an autosomal recessive inherited disorder, the deficiency of this enzyme results in the accumulation of glucocerebrosides in spleen, liver and bone marrow and CNS manifestations in severe variants. Although GCase activity is ubiquitously distributed in mammalian tissues, the pattern of mRNA expression has not been reported. *In situ* hybridization studies of mouse early postnatal (2, 4 days old) and adult tissues were conducted to evaluate the spectrum of GCase mRNA expression. mRNA signals were present in all tissues and cell types examined, consistent with the distribution of GCase activity. Distinct patterns of differential expression were identified in specific tissues, cell types, and developmental stages. In the CNS, low intensity signals evenly distributed between neurons and glia at early postnatal times, were much lower in adult tissues. The highest expressing cells were in the GI tract. Intense signals were localized to the forestomach and esophagus squamous epithelia and intestinal cell lining. In the liver, the greatest signals were present in hepatocytes. Discrete signals were present in the capsule of lymph nodes and cells lining the sinusoidal spaces. The highest intensity signals in the spleen were in cells of the germinal centers. The thymus had diffuse signal. In the kidney, the signals were localized to the cortex, nephrogenic zone and immature tubules cells while in the lungs the cell involvement was generalized. Distinct low intensity signals were evident in Sertoli cells of the testis. Skeletal and cardiac muscle cells had very low level signals. Interestingly, the bone showed no detectable signal in hematopoietic cells but distinct low intensity signal was present in cells of the young trabeculae within the cartilage to bone conversion zone. These results show tissue, cell and developmental stage specific regulation of the GCase locus at the transcriptional level with no direct correlation to the tissue specific manifestations of Gaucher disease.

Program Nr: 2424 from the 1999 ASHG Annual Meeting

Early phenotyping in phenylketonuria by genotyping and screening procedures. *A. Ponzone[1], O. Guardamagna[1], S. Ferraris[1], G.B. Ferrero[1], C. Carbonara[1], R. Ponzone[2], S. Giannattasio[3], M. Spada[1]*. 1) Dipartimento di Pediatria, Univ. di Torino, Torino, Italia; 2) Dipartimento Scienze Ostetriche e Ginecologiche, Univ. Torino; 3) Centro di Studio su Mitocondri e Metabolismo Energetico, Bari, Italy.

The clinical spectrum of phenylketonuria (PKU) encompasses a continuum of phenotypes with different severity, which have been separated into four arbitrary classes of phenylalanine hydroxylase (PAH) deficiency: severe, moderate, mild, and benign. As early patient phenotyping is of crucial interest for the immediate therapeutic option as well as for the long-term prognosis, we report the informations drawn from the study of 26 PKU patients, all genotyped for their causal mutations at the PAH locus. They were analyzed in the neonatal period and subsequently re-evaluated for several biochemical parameters: blood phenylalanine (Phe) level at the screening test, pre-treatment plasma Phe concentration and Phe/tyrosine ratio, velocity of plasma Phe normalization after a Phe-free diet was started, maximal and minimal dietary Phe tolerance. A total of 20 PKU mutations were detected in the 52 chromosomes, of which 12 were known as null, 4 as mild, and 4 as benign. On the basis of their allelic combination, 11 patient were assigned to the severe, 4 to the moderate, 6 to the mild, and 5 to the benign class of PAH deficiency. Within the examined metabolic parameters, only the value of dietary Phe tolerance, both maximal and minimal , showed a precise correlation with the predicted and observed phenotype. Contrary to previous opinion, the values of blood Phe concentration at the initial screening test and at the pre-treatment time, though reflecting allelic differences at the PAH locus, were not fully predictive of the inherent phenotype, sharing consistent overlap with one or more of the adjacent classes. Since the value of minimal dietary Phe tolerance can be assessed in patients as early as by the first month of life, it allows to anticipate a clinic-based and reliable PKU phenotyping.

Program Nr: 2425 from the 1999 ASHG Annual Meeting

Long term follow up study and linkage analysis of hepatic Carnitine Palmitoyl Transferase-1 (CPT1A) deficiency in a Canadian and American Hutterite kindred: evidence for a founder effect. *C. Prasad[1], L. Dilling[1], M. Innes[1], N. Buist[2], O. Hamilton[3], L. Beischel[3], J.P. Johnson[3]*. 1) Dept. of Genetics, Childrens Hosp, Winnipeg, MB, Canada; 2) OHSU, Portland, OR, USA; 3) Shodair Hospital, Helena, MT, USA.

CPT1A deficiency is a rare autosomal recessive defect of mitochondrial beta-oxidation presenting with hypoketotic hypoglycemia, hepatomegaly, seizures, and coma. We describe 5 patients with CPT1A deficiency who are all members of the Hutterite Brethren, 3 of whom have been reported previously (Haworth et al., J. Pediatr 1992). All presented with recurrent episodes of encephalopathy associated with hypoglycemia, hyperammonemia, and hepatomegaly. Diagnosis was confirmed by low enzyme activity (CPT1A) in cultured skin fibroblasts. Extended follow up shows that both index patients have ongoing seizures and developmental delay as consequences of delayed diagnosis and hypoglycemic brain injury. The patients in whom the diagnosis was suspected earlier show normal neurodevelopmental progress. The Canadian patients belong to an extended inbred Hutterite family (a brother, sister and their second cousin), while the American patients are sibs. Linkage analysis was undertaken in the American family. We used 7 polymorphic DNA markers near CPT1A on chromosome 11q13, including D11S987, reported to be within 1 Mb of the gene (Britton et al., Genomics 1997). Results showed the 2 sibs were homozygous for a haplotype of 5 loci over approximately 10 cM. This haplotype was present in both grandfathers, who were first cousins. This indicates a common ancestor in the fifth generation preceding the affected sibs. A founder effect was further confirmed by finding homozygosity for haplotypes identical at 4 of the 5 loci in the 3 Canadian patients. The Canadian and American Hutterite families share a common ancestor around 1812, about 60 years before the Hutterites arrived in North America. Mutation analysis on the Canadian patients has been carried out and is presented in a separate submission. Given the presumed identity by descent of the CPT1A mutations in these two families, we expect identical mutations in both.

Program Nr: 2426 from the 1999 ASHG Annual Meeting

The ALD-Related gene: of functional redundancy and mouse model for adrenoleukodystrophy. *A. Pujol, E. Metzger, N. Troffer-Charlier, C. Kretz, J.L. Mandel.* Human Molecular Genetics, IGBMC, Strasbourg, France.

X-linked adrenoleukodystrophy (X-ALD), is a severe demyelinating disease associated with impaired beta-oxidation of very-long-chain fatty acids. The gene responsible for the disorder encodes a peroxisomal half-ABC transporter, the ALD protein. ALD is characterized by a very high phenotypic variability within the same kindred, a fact that suggests the existence of modifier genes. An animal model of the disease is not available yet, since ALD knock-out (KO) mice do indeed show a biochemical phenotype (accumulation in organs of VLCFAs) but no demyelination. We have characterised the human ALDR gene structure, the closest homolog to the ALD gene (66% identity at the aa level). The ALDR gene has been shown to complement the biochemical phenotype of X-ALD patients fibroblasts [1]. We aim at demonstrating the in vivo capacity of the ALDR gene for functional rescue of the ALD KO mouse's biochemical phenotype. Therefore we have constructed transgenic mice expressing the mALDR cDNA under the control of an ubiquitous promoter (chicken beta actin); a line showing high expression of the transgene in several tissues has been obtained and crossed with ALD KO mice. VLCFA's levels and beta-oxidation capacity of these mice will be determined. Furthermore we believe on the hypothesis of some functional redundancy between the ALD and ALDR genes, and intend the creation of a mouse model of the disease by generating a double ALD/ALDR KO. For the ALDR KO, we have disrupted the ALDR gene in the mouse, and found that homozygous mice (ALDR-/-) are not viable. Analysis of ALDR KO embrios will help to gain insight into the function of the ALDR gene, and possibly into the issue of functional redundancy at the peroxisomal membrane. [1] Kemp et al, Nature Med 4, (1998), 1261.

Program Nr: 2427 from the 1999 ASHG Annual Meeting

Cystinuria type I: Identification of nine new mutations by RNA-SSCP and two large deletions by multiplex QF-PCR in *SLC3A1*. *J. Purroy[1], L. Bisceglia[2], L. Feliubadaló[1,3], F. Rousaud[4], L. Zelante[2], A. Zorzano[3], X. Estivill[1], M. Palacín[3], P. Gasparini[2], V. Nunes[1]*. 1) Centre de Genètica Mèdica i Molecular-IRO, Barcelona, Catalonia, Spain; 2) SGM-Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; 3) Departament de Bioquímica i Fisiologia, Facultat de Biologia, UB, Barcelona, Catalonia, Spain; 4) Servei de Nefrologia, Fundació Puigvert, Barcelona, Catalonia, Spain.

Cystinuria type I is caused by mutations in *SLC3A1*, although only half of the patients studied show mutations in this gene. Here we describe nine new mutations in *SLC3A1* (S168X, M190T, 765+1G>T, F266S, R452Q, Y461X, S547W, L564F and C673W) detected after studying 38 chromosomes (24 type I and 14 from non fully determined patients) by RNA-SSCP. To detect large deletions we set up a method combining multiplex and semi-quantitative fluorescent PCR. By a simultaneous amplification of the 10 exons of *SLC3A1* we detected two large deletions in a Belgian family: one comprising exon 10 and another comprising exons 2 to 10 and beyond. We have found mutations in 60% (23 out of 38) of the chromosomes studied. These results are consistent with the 60% of cystinuria type I chromosomes that have been explained so far in different studies by mutations in *SLC3A1*. The large number of non-explained chromosomes may be accounted for by the existence of mutations in the promoter or other less studied areas, by the difficulty of distinguishing between type I and type III phenotypes or by the existence of a second gene for cystinuria type I.

Program Nr: 2428 from the 1999 ASHG Annual Meeting

Quantitative amino acid analysis using a Beckman System Gold HPLC 126AA analyzer. *Y. Qu[1], R.H. Slocum[2], W.E. Rasmussen[1], N.J. Carpenter[1], J.G. Coldwell[3], B. Say[1].* 1) H A Chapman Inst Med Genetics, Tulsa, OK; 2) Eltanin Inc., San Francisco, CA; 3) Children's Medical Center, Tulsa, OK.

Beckman System 6300 and 7300 Amino Acid Analyzers are no longer available on the market. To develop a quantitative amino acid analysis program for diagnosis and management of patients with amino acidemias, a Beckman System Gold HPLC ion-exchange system was used. The analysis system includes Solvent Module 126 AA, Post Column Reactor 232, Detector 166, Autosampler 507, and a 3mm X 250mm spherogel AA Lithium column. The Lithium column eluents and Trione Nihydrin Reagent were from Pickering Laboratories.

In the first stage, a 30-min isothermal, isocratic HPLC chromatograph was developed for quantitative analysis of valine (val), methionine (met), isoleucine (ile), leucine (leu), phenylalanine (phe) and tyrosine (tyr) using both plasma and dried blood spots. The quantitation of met, leu, and phe was validated by the Centers for Disease Control Newborn Screening quality assurance program from dried blood spots. This short program was successfully used for confirmatory testing for hyperphenylalaninemia patients from State Newborn Screening program. In addition, the program was used to monitor dietary management for phenylketonuria and tyrosinemia type 2 patients. It also has the potential to be used for diagnosis and management of patients with maple syrup urine disease and homocystinuria. The second stage of development involved screening 42 amino acids from phosphoserine to arginine. The separation was achieved by using three temperatures and a step gradient with three Pickering Lithium eluents. The chromatogram was comparable to that obtained from a Beckman System 6300 Amino Acid Analyzer. At 500 nm wavelength, all primary amino acids and hydroxyproline and proline were separated and detected in a single run. This running system provides a less expensive and reliable way to analyze amino acids for patients with amino acidopathies.

Program Nr: 2429 from the 1999 ASHG Annual Meeting

Functional implications of intramolecular alterations on human galactocerebrosidase. *M.A. Rafi, H.Z. Rao, P. Luzi, D.A. Wenger.* Dept Neurology, Thomas Jefferson Univ, Philadelphia, PA.

Galactocerebrosidase (GALC) is the enzyme responsible for lysosomal degradation of galactosylceramide and lack of GALC activity results in Krabbe disease. Its expression in normal cells is governed by a weak promoter, and sub-optimal initiation sequences. This results in a small but sufficient amount GALC in normal cells. The enzyme is very hydrophobic, with strong tendency to aggregate in a very high molecular weight complex. These biochemical and biological peculiarities render the purification of GALC extremely difficult. However generating sufficient amount of this enzyme is critical to obtain a polyclonal antibody, which in turn is pivotal to investigate many physiologic processes including enzyme processing. We designed a wide range of plasmid constructs, to increase the yield of recombinant GALC, and facilitate its intracellular detection. Alterations introduced in our pcDNA3-GALC construct include: addition of sequences for green fluorescent protein (GFP) at the 3'end, tagging the protein with a short stretch of peptide containing a polyhistidine tract, entrokinase specific cleavage site, and c-myc epitope at N- and C-terminals of GALC, and finally replacing original leader peptide with leader sequence for mouse Ig kappa chain. The GALC activities were then evaluated in COS-1 cells. Low GALC activity was detected when GFP was fused at its C-terminal but normal activity was restored when an IRBS was introduced in the construct between coding sequences for GALC and GFP. GALC tagged with short segment of peptide containing the polyhistidine tract, entrokinase specific cleavage site, and c-myc epitope preserved its activity when this segment was located at either the N- or C-terminal of the GALC. A construct with the leader sequence from mouse Ig kappa chain failed to increase GALC secretion, but surprisingly demonstrated slightly higher intracellular GALC activity compare to one with the original leader sequence. These findings are leading to experiments using retroviral vectors where the overproduced GALC could be easily purified using a nickel affinity column followed by release of GALC by treatment with entrokinase.

Program Nr: 2430 from the 1999 ASHG Annual Meeting

Characterization of the gene encoding a**-aminoadipic semialdehyde synthase.** *K.A. Sacksteder[1], B.J. Biery[2], J.C. Morrell[1], B.V. Geisbrecht[1], R.P. Cox[3], S.J. Gould[1], M.T. Geraghty[2].* 1) Dept Biological Chemistry, Johns Hopkins Univ, Baltimore, MD; 2) Dept. Pediatrics, Johns Hopkins Univ, Baltimore, MD; 3) Univ. of Texas Southwestern Medical Center, Dallas, Texas.

A-aminoadipic semialdehyde synthase is a bifunctional enzyme which catalyzes the conversion of lysine to a-aminoadipic acid. The enzyme is associated with both lysine-ketoglutarate reductase and saccharopine dehydrogenase activities. Defects in the bifunctional protein result in familial hyperlysinemia, an autosomal recessive condition characterized by hyperlysinemia, lysinuria and variable saccharopinuria. We used sequences from *S. cerevisiae*, namely the LYS1 gene which encodes saccharopine dehydrogenase activity and the LYS9 gene which encodes lysine-ketoglutarate reductase activity to search the EST database and subsequently cloned a full length cDNA encoding the bifunctional enzyme. The cDNA contains an ORF of 2781 bp predicted to encode 927 amino acids. The cDNA is arranged such that the 5' end is homologous to the yeast saccharopine dehydrogenase, while the 3' end of the cDNA is similar to the yeast lysine-ketoglutarate reductase. In Northern blot analysis the cDNA crosshybridizes to several transcripts. These are most highly expressed in liver and to a lesser extent in most other tissues. The genomic structure consist of 24 exons scattered over 68 kb and maps to chromosome 7q 31-32. We sequenced the genomic DNA from a patient (JJa) who has been previously reported with familial hyperlysinemia and who is the product of a consanguineous mating. The patient has a homozygous out of frame 9 bp deletion in exon 15 which results in a premature stop codon at position 534 of the protein.

Program Nr: 2431 from the 1999 ASHG Annual Meeting

Type IV 3-methylglutaconic aciduria associated with isolated complex II and IV deficiencies . *F. Scaglia[1], V.R. Sutton[1], H. Vogel[2], S.K. Shapira[1].* 1) Depts. of Molecular and Human Genetics; 2) and Pathology, Baylor College of Medicine, Houston, TX.

Type IV 3-methylglutaconic aciduria (Mc Kusik 250951) has been described in children who present during the first year of life with hypotonia, developmental delay, seizures, cerebellar dysgenesis, retinal pathology, hypertrophic cardiomyopathy, hepatic dysfunction, and dysmorphic features. Some of these patients have had complex I, IV, and/or V deficiencies, or Pearson syndrome, suggesting that 3-methylglutaconic aciduria may be associated with mitochondrial dysfunction. Furthermore some cases have been associated with mitochondrial DNA depletion. We report a three year old boy who lost developmental milestones after four months of age. His presentation revealed psychomotor retardation, dystonic movements, and hypotonia, prompting a genetic evaluation. Urine organic acids analysis revealed large amounts of glutaric acid, 3-hydroxyglutaric acid, and glutaconic acid, suggesting the diagnosis of glutaric acidemia type I. Enzyme assay for glutaryl-CoA dehydrogenase was normal. Additional studies were performed, excluding glutaric acidemia type II. While on treatment with carnitine and riboflavin, urine organic acids analyses showed a different pattern from initial studies, with large amounts of 3-methylglutaconic and 3-methylglutaric acids. Assay for 3-methylglutaconyl-CoA hydratase was normal. On muscle biopsy the electron microscopy showed Z-disc streaming, and abnormal cristal configurations within the mitochondria. Respiratory chain enzyme analysis showed partial deficiency of complex II and IV activities. Evaluation for a possible mitochondrial DNA depletion is currently underway. This is the first report of a patient with 3-methylglutaconic aciduria associated with isolated complex II and IV deficiencies. The 3-methylglutaconic aciduria observed in this patient most likely represents a secondary phenomenon, and it is unlikely to be the cause of the clinical phenotype. However it appears to be a useful indicator of an underlying defect in the respiratory chain, which should prompt future studies toward elucidating the molecular cause of type IV 3-methylglutaconic aciduria.

Program Nr: 2432 from the 1999 ASHG Annual Meeting

Genomic organisation of the human phosphomannose-isomerase (PMI) gene and mutation analysis in patients with the carbohydrate-deficient glycoprotein syndrome type Ib (CDGS1b). *E. SCHOLLEN[1], L. DORLAND[2], J.B.C. DE KLERK[3], O.P. VAN DIGGELEN[3], G. MATTHIJS[1]*. 1) Center for Human Genetics, University of Leuven, Leuven, Belgium; 2) Wilhelmina Kinderziekenhuis, Utrecht, Nederland; 3) Academic Hospital Rotterdam, Rotterdam, Nederland.

The carbohydrate-deficient glycoprotein (CDGS) syndromes are a group of multi-system disorders, characterised by incomplete glycosylation of glycoproteins. Two subtypes relate to defects in the synthesis of GDP-mannose, in the earliest steps of N-glycosylation: a deficiency of phosphomannomutase in type Ia (CDGS1a) and a deficiency of phosphomanno-isomerase in the recently discovered type Ib (CDGS1b). CDGS1b patients present with intestinal symptoms, including protein-losing enteropathy and liver disease, sometimes with fatal outcome, and coagulation problems. We determined the genomic structure of the phosphomannose-isomerase (PMI) gene, to allow mutation analysis at the genomic level and to prepare for screening. The human PMI gene consists of 8 exons and spans 7 kb, in contrast to the mouse gene that comprises only 6 exons. Two patients in two consanguineous families were found to be homozygous respectively for the M51T and R152Q mutation. In a third patient, only one mutation (R152Q) was found; the second mutation must be located outside the coding region. This is reminiscent of a prior case, in which a second mutation could not be found, in spite of a biochemically proven carrier-status in both parents. We are currently focussing on the promoter sequence of the gene in an attempt to identify regulatory mutations. The disease is treatable with mannose, and therapy has been started in these patients. Because the disease seems to be largely unrecognized, it is important to also try and raise awareness on this disease.

Program Nr: 2433 from the 1999 ASHG Annual Meeting

Short Chain Acyl-CoA Dehydrogenase Deficiency (SCADD) - An Under-Reported Disorder? *P.H. Schwartz, S.A. Stein.* Neurology and Brain/Tissue Bank Dev Disorder, Children's Hosp Orange County, Orange, CA.

SCAD, an intramitochondrial enzyme of the beta-oxidation spiral, catalyzes the oxidation of 6- and 4-carbon acyl-CoA fatty acid esters to release electrons and give rise to the corresponding 2-trans-enoyl-CoA fatty acid esters. The clinical presentations and laboratory findings of patients with deficiencies of SCAD are highly variable and may include hypoketotic hypoglycemia, myopathy with or without myoglobinuria, elevations in lactate (L), butyrate (Bu), ethylmalonate (EtM), or methylsuccinate (MeS), and low plasma or muscle carnitine. Post-mortem/biopsy findings have revealed hepatosplenomegaly with fatty changes or minor generalized lipid accumulation in type I myofibers. We present four patients with enzymatically-verified SCADD whose findings further broaden the phenotypes of SCADD. The salient features of each patient are: Patient 1: severe neonatal weakness/floppiness, mild cardiomegaly, and glaucoma; mild elevation of EtM and Kreb's cycle intermediates; numerous intramyofibrillar lipid droplets with increased size and number of mitochondria. Patient 2: delayed language, facial weakness, slow motor and intellectual development; mild elevations of L, EtM; slightly low plasma carnitine; normal muscle biopsy findings. Patient 3: neonatal weakness and hypotonia, mild dysmorphism; normal development; low plasma carnitine; type II myofiber size disproportion; mild increase in EtM, and MeS. Patient 4: normal birth and development; severe cerebral edema after RSV infection and SVT; normal pathological and laboratory findings. All four of these cases were tentatively diagnosed because of a high index of suspicion using the Fatty Acid Oxidation Defects screen of Charles Roe at Baylor. Only in Patient 1 were the clinical and laboratory findings relatively consistent with what is felt to be the salient findings in disorders of fatty acid metabolism; the remainder of the patients represent new phenotypes of SCADD. This indicates that SCADD may be an under-reported genetic disease and may not have any clinically observable symptoms. SCADD, like other metabolic disorders such as GA I, may only become apparent under metabolically demanding circumstances.

Program Nr: 2434 from the 1999 ASHG Annual Meeting

Detection of enzyme deficiencies by Electrospray Ionization Mass Spectroscopy (ES/MS). *C.R. Scott, S. Gerber, F. Turecek, M. Gelb.* Depts of Chemistry and Pediatrics, Univ Washington, Seattle, WA.

We have developed a sensitive, specific, rapid and general approach for measuring enzyme activity in crude cell lysates using ES/MS as the detection system. The strategy consists of synthesizing substrates consisting of biotin-sarcosine-polyethylene glycol-glycoside. Biotin is linked to sarcosine to provide an affinity handle for selective capture and simple purification by streptavidin-agarose. Sarcosinyl biotin forms an N-methyl biotinamide motif that blocks cleavage by biotinidase and affords rapid elution from streptavidin. The PEG diamine linker provides water solubility, contains a basic residue for protonation by electrospray (high sensitivity), allows for conjugate differentiation of coincident mass by insertion or deletion of a PEG unit, and provides a location for introduction of stable isotopes for synthesis of internal standards. Finally, the PEG linker is coupled to a clinically revelant substrate to form the complete substrate conjugate. Following incubation with cell lysates the substrate and product are captured and then seperated and quantitated by ES/MS. We have applied the method to identifying disorders of lysosomal storage and have verified deficiency of B-galactosidase and N-acetylglucosaminidase in patients with GM1-gangiosidosis and Sanfillipo syndrome, respectively. The method can measure more than one enzyme reaction simultaneously (multiplexing) and can be developed to identify the enzyme deficiency of a disorder that has a common phenotype, but caused by different enzyme deficiencies.

Program Nr: 2435 from the 1999 ASHG Annual Meeting

Diagnosis of familial juvenile hyperuricaemic nephropathy. *I. Sebesta, B. Stiburkova, S. Kmoch.*
Dept.Clin.Biochem.,Inst.Inher.Metab. Dis.,1st Fac.Med., Charles Univ., Prague, Czech Republic.

Hyperuricaemia and/or gout are uncommon in children and adolescents. Familial juvenile hyperuricaemic nephropathy (FJHN) is a disorder characterized by progressive renal disease affecting young men, women and children equally. Gout is not a constant feature. The most striking finding is progressive renal disease with early onset. This presentation distinguishes FJHN from the more prevalent primary gout. The biochemical hallmark is hyperuricaemia arising from a reduced excretion fraction of uric acid. Autosomal mode of inheritance was observed, but the gene(s) responsible for the renal impairment is (are) still unknown. The diagnosis depends on clinical and biochemical evaluation. Complete laboratory investigations were set up. These include: evaluation of uric acid in plasma and especially in urine, quantification of purine metabolites in urine and assays of purine enzymes: hypoxanthine phosphoribosyltransferase (HPRT) and phosphoribosylpyrophosphate synthetase (PRPPs). The concentrations of urinary uric acid were expressed on creatinine and creatinine clearance basis. More than 400 patients with unexplained hyperuricaemia were investigated and 12 new patients with FJHN spanning two and three generations in two Czech families were found. Detailed studies of the relatives in the previously described family revealed four additional patients. The youngest patient was 6-year-old girl and six other patients were under the age of twenty. The patients suffered from nonspecific interstitial nephropathy. Three young patients have mildly impaired renal function. Our patients show the evidence of early onset of this disorder. Moreover,we found that the detailed purine investigations are essential for the exclusion of hyperuricaemia due to defect of HPRT or PRPPs, particularly in older patients with renal impairment. The need for DNA marker for presymptomatic detection is of prime importance. Taking to account our and other described patients with FJHN the indications for purine metabolic work up are: unexplained hyperuricaemia in children or young adults found within family members.(Supported by grant 27-3 Ministry of Health,CZ; EC grant ERBIC20CT98-0212).

Program Nr: 2436 from the 1999 ASHG Annual Meeting

Cloning, expression and characterization of human guanine deaminase (GDA) and identification of the *E. coli* homolog. *F.F. Snyder, R.G. Yuan, W.J. Paramchuk, J.C. Bin, J.T. Maynes.* Department of Medical Genetics, University of Calgary, Calgary, Alberta, T2N 4N1, Canada.

Guanine deaminase is an aminohydrolase that converts guanine to xanthine and ammonia. The reaction removes the guanine base from the pool of guanine containing metabolites and may play a role in the regulation of cellular GTP. We purified the mouse guanine deaminase protein to homogeneity and obtained partial amino acid sequence. BLAST analysis facilitated the retrieval of human EST clones. We subsequently cloned and sequenced the cDNA for human brain guanine deaminase, having an open reading frame of 1365 nucleotides and encoding a 51.0 kDa protein. The corresponding homolog in the *E. coli* genome was identified at 65.2 minutes as a functionally unassigned 1317 nucleotide open reading frame encoding a 50.2 kDa protein that is 36% identical to the human enzyme. Expression and purification of the recombinant proteins gave K_m's for the human and *E. coli* enzymes of 9.5 and 18 mM respectively. The enzymes share a 9 residue motif, PG[FL]VDTHIH, characterised as a class II zinc site, with no less than 10 other amino- and amido-hydrolases. The human and mouse motifs are identical with L at the variable position versus F for the *E. coli* enzyme. Atomic absoprtion demonstrated that both the human and *E. coli* enzymes have approximately 1 atom of Zn per guanine deaminase subunit and the activity was abolished by exposure to the divalent metal ion chelating agent, phenanthroline. Analysis of tissue expression shows high levels of guanine deaminase mRNA in the brain, liver, kidney and digestive tract. There is essentially no expression in cardiac tissue, skeletal muscle, reproductive or lymphoid systems. The pattern of expression in the brain was complex with expression in the cerebral cortex, frontal, parietal and occipital lobes, and maximal levels in the temporal lobe and amygdala. Southern analysis reveals the human guanine deaminase gene to span approximately 33 Kb. Supported by the Medical Research Council of Canada.

Program Nr: 2437 from the 1999 ASHG Annual Meeting

“Age related” Stargardt disease accounted for by heterozygote truncating mutations in the ABCR gene questiones autosomal recessive inheritance. *E. Souied[1, 2], J.-M. Rozet[1], D. Ducroq[1], S. Gerber[1], I. Perrault[1], G. Coscas[2], G. Soubrane[2], A. Munnich[1], J. Kaplan[1]*. 1) Unité de Recherches sur les Handicaps Génétiques de l'Enfant, INSERM U393, Hôpital Necker, Paris, France; 2) Clinique Ophtalmologique Universitaire, Centre Hospitalier Intercommunal, Créteil, France.

Stargardt disease (STGD) and late-onset *fundus flavimaculatus* (FFM) are autosomal recessive macular dystrophies with perimacular flecks of childhood and adulthood respectively. The STGD and the FFM genes have been independently mapped to 1p22.1 and mutations of the ATP binding cassette retinal specific (ABCR) have been shown to account for both phenotypes. In addition, heterozygous mutations of the ABCR gene have been identified in patients with age related macular dystrophies (ARMD), raising the hypothesis that the ABCR gene acts as a susceptibility factor in this condition. We report here the ABCR gene analysis of two unrelated patients affected with “age related” Stargardt disease with an onset at 70 and 65 years of age respectively. For this reason, the patients could have been misdiagnosed as ARMD. Nevertheless, both displayed typical angiographic features of Stargardt disease, namely macular atrophy, perimacular fluorescent flecks and silent choroid. The ABCR gene was entirely analyzed by direct sequencing in the two patients. In the first one, an heterozygote C to T transition at nucleotide 450 was identified resulting in the substitution of an arginine to a stop codon at position 152. In the second, an heterozygote splice mutation at the acceptor site of exon 35 (4849-1 G®C) was identified. The 49 other exons and the promoter region of both patients were extensively sequenced, but no deleterious base change has been detected on the second allele. Although we cannot totally exclude an overlooked mutation in the two patients, our results strongly suggest that this late-onset phenotype is accounted for by heterozygous truncating mutations in the ABCR gene and opens the debate of inheritance patterns of the ophthalmologic disorders related to the ABCR gene.

Program Nr: 2438 from the 1999 ASHG Annual Meeting

Investigating the pathogenesis of mucolipidosis IV using subtractive hybridization. *M. Sun, R. Schiffmann, E. Goldin.* Developmental and Metabolic Neurology Branch, NINDS, NIH, Bethesda, MD.

Mucolipidosis IV is an autosomal recessive metabolic disorder affecting the development of motor and communicational functions. Progressive loss of vision is evident in most patients. Vacuolization of certain epithelial cells, neurons, and fibroblasts is manifested. The gene mutation and the cause of the apparent neurodevelopmental arrest are not known. To better understand the defects underlying the cellular pathology in mucolipidosis IV we analyzed gene expression using subtractive hybridization. Fibroblast cDNA was prepared from purified mRNA and subtractive library was created using PCR-Select subtraction kit from Clontech. We subtracted RNA of normal fibroblasts from that of patients, and vice versa. The initial subtraction resulted in over 8000 colonies in the patient over-expressed library, and 3000 in the under-expressed library. The clones obtained from these subtractions were then screened against the products of subtraction of 3 other patient and normal cultures. Over 500 clones of genes over-expressed in patients and100 clones of genes under-expressed in patients were sequenced. Among the over-expressed genes, fibronectin was the most prominent, appearing in 200 clones. Other over-expressed genes were also part of the extracellular matrix or genes involved in cellular stress. Several over-expressed genes were related to vesicular transport, which taken together with vacuolization of cells, suggest that abnormal vesicular transport pathways play an important role in the pathogenesis of mucolipidosis IV. In the group of under-expressed genes the most prominent was insulin-like growth factor binding protein 3 (IGFBP3) appearing in 14 clones. Other genes in this group included integrin related proteins and stress related genes. The fact that over-expressed and under-expressed gene populations were substantially different adds to the credibility of technique used in our experiments. Overall, the changes in gene expression in cultured mucolipidosis IV fibroblasts serves as a reliable indicator for the cellular pathology in this devastating disorder.

Program Nr: 2439 from the 1999 ASHG Annual Meeting

Relationship between kinetic properties of mutant enzyme and biochemical and clinical responsiveness to biotin in holocarboxylase synthetase deficiency. *Y. Suzuki[1], O. Sakamoto[1], X. Li[1], Y. Aoki[1], M. Hiratsuka[1], T. Suormala[2], R.E. Baumgartner[2], K.M. Gibson[3], K. Narisawa[1].* 1) Dept of Medical Genetics, Tohoku Univ School of Medicine, Sendai, Japan; 2) Metabolic Unit, University Children's Hospital, Basel, Switzerland; 3) Biochemical Genetics Laboratory, Dept of Molecular and Medical Genetics, Oregon Health Sciences University, Portland, OR.

Holocarboxylase synthetase (HCS) deficiency is a metabolic disorder that causes a biotin-responsive multiple carboxylase deficiency. We analyzed the kinetic properties of seven mutant HCS proteins. Two of these enzymes harbored mutations within the putative biotin-binding region of HCS and showed elevated Km values for biotin compared to that of the wild-type form (Km mutant; Gly581Ser: 45 times, delThr610: 3 times). The remaining five mutations (Arg183Pro, Leu216Arg, Leu237Pro, Val333Glu, and Val363Asp) were located outside the biotin-binding region. The enzymes containing these mutations showed normal or low Km values for biotin (non-Km mutant). Symptoms of patients who have the non-Km mutants, as well as those of patients who have the Km mutants, responded to biotin therapy. This is probably because the Km value for biotin of normal HCS is higher than the physiological concentration of biotin in human cells. The Vmax values of all mutant HCS proteins were considerably decreased, but to a variable degree. The responsiveness to biotin supplementation of propionyl-CoA carboxylase activity in cultured cells bearing the mutations correlated well with the degree of reduction in the Vmax of HCS. Patients who have mutant HCS proteins with lower Vmax showed poorer clinical and biochemical responses to biotin therapy. These observations suggest that the reduction of Vmax is an essential factor for pathophysiology and prognosis of HCS deficiency under treatment with large amounts of biotin. The determination of HCS genotype can be valuable for characterizing the clinical phenotype in HCS deficient patients.

Program Nr: 2440 from the 1999 ASHG Annual Meeting

Novel mutations of the Glutaryl-CoA Dehydrogenase Gene in Three Chinese patients with Glutaric aciduria Type I. *N.L.S. Tang[1], L.K. Law[1], J. Hui[2], K.L. Cheung[2], Y.Y. Lam[3], W.L. Yeung[2], T.F. Fok[2].* 1) Department of Chemical Pathology, The Chinese University of Hong Kong, Hong Kong SAR, China; 2) Department of Paediatrics, The Chinese University of Hong Kong, Hong Kong SAR, China; 3) Department of Paediatrics, Kwong Wah Hospital, Hong Kong.

Glutaric aciduria Type I (GA-I) is an autosomal recessive disorder caused by inheritance of defective glutaryl-CoA dehydrogenase (GCDH). The enzyme converts glutaryl-CoA to crotonyl-CoA in the breakdown of lysine, hydroxylysine and tryptophan. GCDH deficiency led to urine excretion of glutaric acid. Patients present with progressive neurologic mansifestations or acute encephalopathic crisis. Mutations in GCDH gene were responsible for GA-I. Genetic heterogeneity was reported and more than 60 mutations had been reported. We reported here the GCDH mutations in three Chinese patients with GA-I. All patients excreted significant amount of glutaric acid in urine and were picked up by urine organic acid study. Two of them had also been confirmed by fibroblast enzyme assay. The 11 exons were amplified by intron-based primers and examined by SSCP and then sequencing of SSCP variants. Five mutations were found and four of them were novel. R355H was a previously reported mutation. Three mutations were missense including; A219T, A298T, R386G. One patient who is the second child of a consanguineous marriage is homozygote for a splicing mutation, IVS10-2A->C. This mutation is predicted to results in a GCDH without exon 11. We did not find a common mutation in the Chinese population. The absence of a common mutation is also a feature in other ethnic groups. All mutations were found downstream of exon 6. It may be related to the hypothesis that the carboxyl end of the enzyme contains important catalytic sites.

.

Program Nr: 2441 from the 1999 ASHG Annual Meeting

Linkage Analysis Of A Family With Autosomal Recessive Vitamin B12 Deficiency. *M.K. Tayeh[1], J. Al-Alami[1], M.Y. Al-Sheyyab[1], S.M. Leal[2], H.E. El-Shanti[1].* 1) Jordan University of Science & Technology, Irbid, Jordan; 2) The Rockefeller University, New York, NY, USA.

Inherited disorders of vitamin B12 metabolism are known as single gene defects, mostly transmitted in an autosomal recessive mode. They affect absorption, transport, or intracellular metabolism of vitamin B12. Patients with vitamin B12 absorption and transport defects demonstrate at least megaloblastic anemia as a characteristic change besides other manifestations. We identified a large inbred kindred with congenital megaloblastic anemia from Northern Jordan. Linkage analysis was undertaken to map the locus responsible for the disease in this family. The first attempt was at excluding linkage to three known loci responsible for a similar clinical picture. These loci are the MGA1 locus causing Imerslund-Grasbeck syndrome (IGS), the intrinsic factor causing congenital pernicious anemia (CPA), and TCII causing transcobalamin II deficiency. Exclusion of linkage to these three candidate loci on chromosome 10, 11, and 22 was indicated by absence of homozygosity in the affected individuals and the significant LOD scores (less than -2 at different recombination fractions) for all the used markers. It is then highly suggested that the disorder in this family is not due to IF, MGA1 or TCII gene defects. This finding either demonstrates that CPA or IGS is genetically heterogeneous with more than the two expected loci involved or it indicates that there might be another unidentified step involved in the absorption or transport of vitamin B12.

Program Nr: 2442 from the 1999 ASHG Annual Meeting

Molecular prenatal diagnosis of carnitine palmitoyltransferase 2 deficiency. *L. Thuillier[1], H. Belbachir[1], G. Royer-Legrain[2], T. Attie-Bitach[2], A. Driben[2], N. Abadi[1], P. Kamoun[1], J.M. Saudubray[3], A. Munnich[2], J.P. Bonnefont[1, 2]*. 1) Genetic Biochemistry Unit; 2) Department of Genetics; 3) Department of Pediatrics, Hopital Necker-Enfants Malades, Paris, France.

Carnitine palmitoyltransferase 2 (CPT2) deficiency is one of the most common inherited disorders of mitochondrial long-chain fatty acid oxidation. This disease has two clinical presentations: the “muscle“ phenotype is a benign condition affecting teenagers and young adults, while the “hepatocardiomuscular“ form exposes to a high risk of sudden death in neonates or infants. We were asked for genetic counseling in a couple of first cousins whose first child was affected with CPT2 deficiency. Clinical features included hypoketotic hypoglycemia, hepatomegaly, cardiomyopathy with heart beat disorders, and tubulopathy at one day of life. After initial recovery, the child suddenly died at 22 months of age. CPT2 activity was less than 5% of control values in fibroblasts. Analysis of the full-length coding sequence of the CPT2 gene by DGGE-sequencing revealed a homozygous A®G transition at nt 1500, predicting an Asp®Gly substitution. This substitution of an aminoacid highly conserved across species and CPT isoforms was not found in 50 control DNAs, thus suggesting it was the disease-causing mutation. During next pregnancy, genomic DNA from a chorion villus sampling was submitted to both D328G detection and indirect study using polymorphic markers linked to the CPT2 locus at 1p32. Both approaches established that the fetus had inherited the mutant CPT2 allele in a heterozygous state, and was therefore CPT2 deficient. Parents chose not to terminate the pregnancy, and delivery should occur within next months. This is to our knowledge the first report establishing that DNA analysis is a convenient approach to an early prenatal diagnosis of CPT2 deficiency.

Program Nr: 2443 from the 1999 ASHG Annual Meeting

Mutation of the thermolabile variant of MTHFR enzyme in a family with vascular events and neural tube defects. *G. Toth[1], E. Morava[1], K.E. Jackson[2], A. Horváth[3], M. Czakó[1], Gy. Kosztolányi[1]*. 1) Department of Medical Genetics & Child Development, POTE, Pecs, Hungary; 2) Human Genetics Program, Tulane University School of Medicine, New Orleans, LA; 3) Department of Gynecology, POTE, Pecs, Hungary.

Homozygous mutation of the thermolabile variant of methylene tetrahydrofolate reductase (MTHFR) may result in hyperhomocystinemia leading to an increased risk for cardiovascular accidents and neural tube defects. According to recent studies heterozygosity for MTHFR enzyme mutation is also more frequent in patients with thrombotic disease compared to that in the average population. We report a family with different types of early vascular disease in three consecutive generations. MTHFR heterozygosity was detected in the proband and in her mother and grandfather. The patient's aunt died of spina bifida shortly after birth. Our patient's sister with spina bifida occulta also carries the same mutation, as does her daughter who is asymptomatic. In the other asymptomatic members of the family no mutations were found. Unexpectedly, hyperhomocystinemia was detected in the heterozygote individuals. On continuous folate supplementation of 1 mg/day, no homocystinemia is detectable. Our study demonstrates the necessity for folic acid therapy in mutation carriers to prevent early vascular events, and also to reduce the risk of neural tube defects in a preconception setting.

Program Nr: 2444 from the 1999 ASHG Annual Meeting

Xenomitochondrial mouse cell cybrid models of multiple respiratory chain complex deficiency. *I. Trounce, M. McKenzie.* Mutation Research Centre, Melbourne, Victoria, Australia.

The lack of mouse cell mtDNA mutants presents a barrier to producing cell culture and mouse models of mitochondrial DNA disease. We have used a similar approach to that recently reported for primate/human cybrids (Kenyon & Moraes, PNAS,94:9131,1997), to produce xenomitochondrial mouse cybrids. Fusion of enucleated hamster cells (Mus/hamster divergence was around 16 m.y.b.p.) with *Mus domesticus* rho-zero cells followed by selection for respiratory competence failed to produce any cybrids. Similar crosses with *Rattus norvegicus* cells (*Mus/Rattus* divergence was around 10 m.y.b.p.) and *Mus spretus* cells (divergence around 1 m.y.b.p.) produced cybrids at a high frequency (around one cybrid per 1,000 cells). *Rattus* cybrids grew more slowly and acidified media more quickly than *M. spretus* cybrids or *M. domesticus* reconstituted cells. Polarographic analysis revealed a severe respiratory deficiency of NADH-linked and FAD-linked substrate oxidation in the *Rattus* cybrids compared with preserved function in the *M. spretus* and control cybrids. Spectrophotometric analysis of individual respiratory chain complexes in the cybrids showed the *Rattus* respiratory defect to result from partial deficiencies of complexes I (60% control), III (20%) and IV (60%). The *M. spretus* cybrid showed partial defects of complexes I (60%) and IV (60%) which did not impact on overall flux as measured with the polarograph. Metabolic labeling of mitochondrial translation products using labelled methionine in the presence of cyclohexamide showed normal or increased production of mtDNA-encoded proteins in the *Rattus* cybrids. Using oxidation of the peroxide-sensitive probe DCFDA-H2 as a measure of hydrogen peroxide production, we found that the amount of peroxide produced per unit of oxygen consumed was increased in the *Rattus* and *M. spretus* cybrids. We conclude that the *Rattus* xenocybrids exhibit a model of multiple respiratory chain dysfunction as seen in some severe human mitochondrial DNA diseases. The defects in this model can be used to investigate nuclear-mitochondrial subunit interactions in respiratory complex assembly and function.

Program Nr: 2445 from the 1999 ASHG Annual Meeting

De novo purine biosynthesis enzyme interactions: yeast two hybrid studies. *G.N. Vacano, D. Patterson.* Patterson Lab, Eleanor Roosevelt Inst, Denver, CO.

Purines are fundamental biological molecules that serve a number of roles, including components of nucleic acids, neurotransmitters, vasodilators, second messengers, coenzymes, and key molecules in cellular energy metabolism. Errors in purine metabolism can result in mental retardation, autism, sensorineural deafness, and arthritis. The major source of purines, the de novo pathway, has not been well characterized at the molecular level. There is evidence, including co-sedimentation through sucrose gradients and co-purification gel chromatography, which suggests that the enzymes in the de novo pathway may form multi-enzyme complexes. These experiments have not conclusively demonstrated the existence of a classical enzyme complex, because of the weakness of the interactions. To investigate the nature of protein interactions involving the de novo pathway enzymes, bait and prey vectors containing entire or partial cDNA sequences were constructed, and these were used in yeast two hybrid studies to identify and characterize discrete interactions.

Program Nr: 2446 from the 1999 ASHG Annual Meeting

A MITOCHONDRIAL CYTOCHROME b MUTATION BUT NO MUTATIONS OF NUCLEARLY ENCODED SUBUNITS IN UBIQUINOL CYTOCHROME c REDUCTASE (COMPLEX III) DEFICIENCY. *I. Valnot, D. Chretien, P. de Lonlay, A. Munnich, P. Rustin, A. Rotig.* INSERM U393, Hosp Necker, Paris, France.

Ubiquinol cytochrome c reductase (complex III) deficiency represents a clinically heterogeneous group of mitochondrial respiratory chain disorders which can theoretically be subject to either a nuclear or a mitochondrial mode of inheritance. In an attempt to elucidate the molecular bases of the disease, we first determined the nucleotide sequence of three unknown subunits (9.5 kDa, 7.2 kDa, 6.4 kDa) by cyberscreening of human EST data bases and we sequenced the 11 cDNA subunits encoding complex III in five patients with isolated complex III deficiency. No mutation in the nuclearly encoded complex III subunits was observed but a mutation in the cd2 helix of the mitochondrial (mt) cytochrome b gene was found to alter the conformation of the bc1 complex in one patient with severe hypertrophic cardiomyopathy. The present study is highly relevant to genetic counseling as absence of mtDNA mutations in all but one patient in our series strongly supports autosomal rather than maternal inheritance in the majority of patients with complex III deficiency.

Program Nr: 2447 from the 1999 ASHG Annual Meeting

Biochemical, genetic and immunoblot analyses of 17 patients with an isolated cytochrome c oxidase deficiency. *J. Von Kleist-Retzow[1], E. Vial[1], K. Chantrel-Groussard[1], A. Rotig[1], A. Munnic[1], P. Rustin[1], J.W. Taanman[2].* 1) INSERM U393, Hosp Necker, Paris, France; 2) Royal Free and University College Medical School, Dep of Clinical Neurosciences, Rowland Hill Street, London NW3 2PF, UK.

Mitochondrial respiratory chain defects involving cytochrome c oxidase (COX) are found in a clinically heterogeneous group of diseases yet the molecular basis of these disorders have been determined in only a limited number of cases. Here, we report the clinical, biochemical and molecular findings in 17 patients who all had isolated COX deficiency and expressed the defect in cultured skin fibroblasts. Immunoblot analysis of mitochondrial fractions with nine subunit specific monoclonal antibodies revealed that in most patients, including in a patient with a novel mutation in the SURF1 gene, steady-state levels of all investigated COX subunits were decreased. Distinct subunit expression patterns were found, however, in different patients. The severity of the enzymatic defect matched the decrease in immunoreactive material in these patients, suggesting that the remnant enzyme activity reflects the amount of remaining holo-enzyme. Four patients presented with a clear defect of COX activity but had near normal levels of COX subunits. An increased affinity for cytochrome c was observed in one of these patients. Our findings indicate a genetic heterogeneity of COX deficiencies and are suggestive of a prominent involvement of nuclear genes acting on the assembly and maintenance of cytochrome c oxidase.

Program Nr: 2448 from the 1999 ASHG Annual Meeting

Subdural hematomas and retinal hemmorhages: Glutaric Aciduria type 1 or Shaken Baby Syndrome? *I.R. WALSH, G.W. HORNIG, A.H. GETTEL, M.J. DASOUKI.* PEDIATRICS, CHILDREN MERCY HOSPITAL, KANSAS CITY, MO.

A 10 month old boy presented with increasing head circumference, irritability, ataxia and frequent falls. A head CT scan showed bilateral subdural hematomas while a previuos study a week earlier was normal. Physical examination was significant for macrocephaly, hypotnia and retinal hemorrhages. Urine organic acid and plasma acyl carnitine profiles showed extremely elevated glutaric, 3-hydroxyglutaric acids and C5-dicarboxylic acylcarnitine while free and total carnitines were extremely low. A skeletal survey was normal. Normal CPK, mild hepatic dysfunction and mild hyperammonemia were also seen. At 14 months of age, his head MRI showed abnormal brain myelination, global atrophy espcially in the frontotemporal region and signal abnormality within the basal ganglia and periventricular white matter and centrum semiovale. Despite prompt evacuation of his subdural hematomas, early institution of restricted protein diet, carnitine and riboflavin supplementation, he progressed to develop seizures, severe irritability and dystonia. Initially, Lorazepam, Carbidopa/Levodopa, clonidine and midazolam had little effect on his irritability and dystonia. Multiple Botulinum toxin (Botox) intramuscular injections produced the best response for the dystonia. Glutraic aciduria type 1 is an autosomal recessive inborn error of metabolism of tryptophan, lysine and hydroxylysine that results from glutaryl CoA dehydrogenase (GDD) deficiency. Clinical presentation is variable ranging from no symptoms to acute encephalopathic metabolic crisis. Among a variety of radiologic findings including frontotemporal atrophy and basal ganglia changes are most characteristic. While subdural effusions are not uncommon in GA1, isolated subdural hematomas were reported in a few patiens with GA1 and only in 1 patient had both retinal hemorrhages and subdural hematoma. The absence of subdural effusion in our patient demonstrates that an effusion is not requried for the hematoma formation. Also, the lack of signs of non-accidental trauma suggests that the combination of subdural hematomas and retinal hemorrhages is etiologically related to GA1.

Program Nr: 2449 from the 1999 ASHG Annual Meeting

Hormone-Sensitive Lipase (HSL) is Not Essential for Adipose Tissue Lipolysis. *S.P. Wang[1], N. Laurin[1], L. Pan[1], M.F. Robert[1], M. Ashmarina[1], L. Oligny[1], J.M. Trasler[2], M.A. Rudnicki[3], L. Hermo[2], E. Levy[1], G.A. Mitchell[1]*. 1) Serv Genet Med and Gastroent (EL) and Dept Pathol (LO), Hop Sainte-Justine, Montreal, Canada; 2) Montreal Children's Hosp (JT) and Dept Anat (LH), McGill U, Montreal; 3) Inst Molec Biol & Biotech, McMaster U, Hamilton.

HSL is felt to be necessary for fat release from adipose tissue. HSL can hydrolyse a variety of fatty acyl esters other than triglycerides, including cholesteryl esters. It is also expressed in many nonadipose sites including pancreatic beta cells, macrophages and steroid-synthesizing tissues like adrenals and gonads. To directly assess the biological importance of HSL, we performed constitutive gene targeting at the HSL locus in mice. Unexpectedly, HSL-deficient mutant (mut) mice had normal body weight, abdominal fat mass and adipose tissue histology. Adipocytes isolated from perigonadal fat of HSL-deficient mice were small (cell diameter 70 ± 3.7 mm vs 77 ± 5.7 in heterozygotes (het) and 81 ± 7.6 in wild type (wt) mice) and basal lipolysis was increased (4.45 ± 0.85 nmol glycerol/10^8 mm^2/h vs 3.35 ± 1.40 in hets and 2.75 ± 1.05 in wt mice; $p<0.03$, mut vs wt). As expected, however, adrenergic stimulation of lipolysis by the beta-3 agonist CL316,243 was undetectable for mutant mice (1.08 ± 0.12-fold vs 4.31 ± 1.26 for hets and 6.49 ± 1.65 for wt; $p<0.01$, mut vs wt). We are currently investigating the function of other organs in which HSL is expressed. Our results suggest a previously-unsuspected redundency in adipocyte lipolysis, in which HSL mediates hormone-responsive lipolysis and an HSL-independent pathway mediates basal lipolysis. HSL may be important in fasting and the fight-or-flight response, in which lipolysis is activated in a hormone-dependent fashion. The delineation of the HSL-independent pathway and of its interaction with HSL may be relevant to obesity.

Program Nr: 2450 from the 1999 ASHG Annual Meeting

Missense mutations in the organic cation transporter OCTN2 in patients with primary carnitine deficiency. *Y. Wang[1], F. Taroni[2], B. Garavaglia[2], T. Cowan[3], J. Ye[1], N. Longo[1]*. 1) Medical Genetics/Pediatrics, Emory University, Atlanta, GA; 2) Istituto Nazionale Neurologico C.Besta, Milano, Italy; 3) University of Maryland, Baltimore, MD.

Primary carnitine deficiency (OMIM 212 140) is an autosomal recessive disorder of fatty acid oxidation caused by defective carnitine transport. This disease presents early in life with hypoketotic hypoglycemia or later in life with skeletal myopathy or cardiomyopathy. The transporter defective in primary carnitine deficiency is named Organic Cation Transporter with Nucleoside binding site-2 (OCTN2) and mutations abolishing its function were recently demonstrated in a few patients. Here we extend mutational analysis of OCTN2 to additional families with primary carnitine deficiency. Fibroblasts obtained from different patients expressed the OCTN2 gene and had either completely absent or impaired (2-4% of control) saturable carnitine transport. Fibroblasts from two patients with absent carnitine transport were homozygous or compound heterozygous for mutations producing premature STOP codons (R282X, Y401X, and 458X). Fibroblasts from four patients retained residual carnitine transport and carried missense mutations (R169W, G242V, W351R, E452K). Two mutations (G242V and W351R) affected transmembrane domains, while two others (R169W and E452K) were in intracellular loops. The R169W mutation was found in two unrelated families and occurred on two different RFLP haplotypes in an apparently homozygous patient. Expression studies in CHO cells indicated that the E452K-mutant OCTN2 cDNA impaired carnitine transport to levels corresponding to 3% of those measured with the normal OCTN2 cDNA, correlating well with the transport data in homozygous human fibroblasts. As expected, no increase in carnitine transport was observed in CHO cells expressing nonsense mutations in the OCTN2 cDNA. These results indicate that nonsense mutations in OCTN2 abolish saturable carnitine transport, while some missense mutations retain residual carnitine transport. The incomplete impairment of transporter function caused by missense mutations may be important in determining the severity of phenotypic expression.

Program Nr: 2451 from the 1999 ASHG Annual Meeting

Cellular and Molecular Studies of Smith-Lemli-Opitz Syndrome. *C.A. Wassif[1], P.A. Krakowiak[1], N. Nwokoro[1], M. Tsokos[3], W.E. Connor[2], C.M. Maslen[2], R.D. Steiner[2], F.D. Porter[1]*. 1) HBD, NICHD/NIH, Bethesda, MD; 2) Oregon Health Sciences University, Portland, OR; 3) NCI, NIH, Bethesda, MD.

The Smith-Lemli-Opitz Syndrome (SLOS) is an autosomal recessive malformation syndrome due to mutations in the 7-dehydrocholesterol reductase gene. In the last step of endogenous cholesterol biosynthesis 7-dehydrocholesterol reductase catalyzes the conversion of 7-dehydrocholesterol to cholesterol. Individuals with SLOS have elevated levels of 7-dehydrocholesterol. The molecular, biochemical and cellular mechanisms by which this inborn error of metabolism cause the SLOS phenotype have not been determined. In order to establish a genotype/phenotype correlation for this malformation syndrome we have cloned the human 7-dehydrocholesterol reductase gene and identified multiple mutations in patients with SLOS. The most common mutation is G to C transversion at the -1 position of a splice acceptor. When homozygous, this mutation gives rise to a severe phenotype. All of the mutations result in elevated levels of 7-dehydrocholesterol. These abnormal levels of 7-DHC appear to perturb the function of proteins that contain sterol sensing domains. The sonic hedgehog receptor Patched and the Neiman Pick type C (NPC) gene both encode sterol sensing domains. Previously it has been shown that inhibitors of cholesterol biosynthesis impair the signaling of sonic hedgehog through Patched. SLOS has phenotypic overlap with sonic hedgehog mutations. Thus, abnormal sterol biosynthesis in SLOS may perturb Patched signaling during development and thereby may explain the genesis of some of the developmental malformations. We now demonstrate that SLOS fibroblasts have a secondary defect in intracellular LDL cholesterol metabolism. Like NPC cells, SLOS fibroblasts show increased filipin staining, and can develop lysosomal inclusion bodies similar to those seen in NPC. In addition, SLOS fibroblasts have impaired LDL degradation. We propose that these findings are due to inhibition of NPC1 function through its sterol sensing domains. Clinically, this secondary defect in LDL cholesterol transport may limit the effectiveness of the current dietary therapy.

Program Nr: 2452 from the 1999 ASHG Annual Meeting

Analysis of the N-Acetyl-a-D-glucosaminidase gene in four patients with Sanfilippo syndrome type B: Identification of three novel mutations and correlation of enzymatic activity with genotype in two families. *T.C. Wood, J.N. Thompson.* Dept Human Genetics, Univ Alabama at Birmingham, Birmingham, AL.

Mucopolysaccharidosis IIIB (Sanfilippo Syndrome Type B, MIM 252920) is caused by a deficiency in the lysosomal enzyme N-acetyl-a-D-glucosaminidase (NAG). This enzyme is involved in the breakdown of heparan sulfate and a deficiency in the enzyme causes the lysosomal storage of partially degraded substrate. Over time this storage disrupts normal cellular function causing the disease phenotype. MPS IIIB individuals are characterized by mild somatic features and degenerative neurological problems that can include a wide spectrum of behavioral disturbances. The NAG gene has been localized to chromosome 17q21.1 and the complete sequence of the gene has been reported. In the present study, we report the identification of 3 previously described mutations (R297X, R643H, Y140C) and 3 novel mutations (W103R, S500I, P604L) from 4 patients enzymatically diagnosed with MPS IIIB. Each novel mutation occurs at an amino acid that is conserved between human and mouse. Family analysis from a R297X homozygote showed the brother of the proband to be a carrier of the R297X mutation. Using cultured fibroblast homogenates NAG activity was not detected in the homozygous individual while his brother was found to have only 20% of the activity of the control. In addition, analysis of a family in which the proband was a compound heterozygote for the Y140C and W103R mutations showed the father, brother, and sister to be carriers of the W103R mutation. The mother and maternal aunt of the proband both contained the Y140C mutation. Serum NAG activity for each carrier was found to be only 24-36% of control values while the affected individual had no detectable serum activity. These findings support the observations of Vance et al. (1981 Clinical Genetics 20:135-140) that serum NAG activity is significantly decreased in heterozygous individuals.

Program Nr: 2453 from the 1999 ASHG Annual Meeting

Further characterization of Wilson disease in Taiwan: identification of two novel mutations and high correlation between haplotype and mutation. *J.Y. Wu[1], F.J. Tsai[2], C.C. Lee[3], J.G. Chang[1], C.H. Tsai[2].* 1) Dept Medical Research, China Medical Col Hosp, Taichung, Taiwan; 2) Dept Pediatrics, China Medical Col Hosp, Taichung, Taiwan; 3) Dept Neurology, China Medical Col Hosp, Taichung, Taiwan.

Wilson disease is caused by the deficiency of copper-transporting enzyme, P-type ATPase (ATP7B). Twelve different mutations had previously been identified in Taiwanese Wilson disease chromosomes. We report here the finding of four newly identified missense mutations in Taiwanese Wilson disease chromosomes, two of which are novel. We also did haplotype analysis of Taiwanese WND chromosomes by the use of three well-characterized STR markers (haplotype was assigned in the order of D13S314-D13S301-D13S316). We found association between some mutations and their respective haplotypes. R778L was found to be associated with haplotypes 8-4-4 and 8-4-5.5. P992L was found to be associated with haplotypes 8.5-6.5-2 and 8.5-6.5-6.5. R778Q and G943D were found to be exclusively associated with haplotype 7.5-0.5-5.5 and haplotype 11-1.5-5.5, respectively. The haplotype deduced pedigree analysis was shown to be helpful in mutation analysis of WND chromosomes and in molecular assessment of either pre-symptomatic WND patients or carriers. Given the complexity and heterogeneity of mutation spectrum of ATP7B, haplotype data is important in assisting mutation analysis and carrier detection of Wilson disease.

Program Nr: 2454 from the 1999 ASHG Annual Meeting

Molecular characterisation of two mutations that cause severe and intermediate Sanfilippo syndrome type B. *G. Yogalingam, B. Weber, J.J. Hopwood.* Lysosomal Diseases Research Unit, Department of Chemical Pathology, Women's and Children's Hospital, North Adelaide, SA, 5006, Australia.

To investigate the relationship between genotype, cellular biochemistry and clinical phenotype in A-N-acetylglucosaminidase (NAG) deficient mucopolysaccharidoses type IIIB (MPS IIIB) patients, two mutations, F48L and R297X, which are associated with intermediate and severe Sanfilippo phenotypes respectively, were engineered into the wild-type NAG cDNA. The R297X allele displayed no detectable NAG activity when expressed in Chinese hamster ovary (CHO-KI) cells (CHOR297X) and was observed only as a 34 kDa truncated polypeptide that was rapidly degraded. Skin fibroblasts obtained from a R297X/R297X homozygous patient contained no detectable NAG activity and a twelve-fold elevated level of ^{35}S-labelled glycosaminoglycan (GAG) storage when compared with normal fibroblasts. The lack of detectable NAG activity in CHOR297X cells and R297X homozygous skin fibroblasts and the highly elevated levels of ^{35}S-labelled GAG storage in R297X homozygous skin fibroblasts are consistent with the clinically severe phenotype associated with the R297X allele. When over-expressed in CHO-KI cells, F48L NAG was detected as a 89 kDa precursor polypeptide that was not cleaved to the mature 79 kDa form or secreted into the medium. When expressed via retroviral-mediated gene transfer in R297X homozygous MPS IIIB skin fibroblasts, intracellular F48L NAG activity corresponded to 3.75 % of NAG activity levels in wild-type NAG-transduced MPS IIIB fibroblasts. This residual level of NAG activity was sufficient to metabolise 34 % of intracellular ^{35}S-labelled GAG storage suggesting that some F48L NAG is being correctly sorted to the lysosomal compartment. The residual level of F48L NAG activity in the lysosomes of F48L NAG-transduced MPS IIIB fibroblasts and subsequent partial turn-over of GAG is consistent with the intermediate clinical phenotype associated with the F48L allele.

Program Nr: 2455 from the 1999 ASHG Annual Meeting

Two Korean patients with citrullinemia presenting with a stroke-like episode. *H. Yoo[1], H. Kim[2]*. 1) Dept Pediatrics, Asan Medical Ctr, Seoul, Republic of Korea; 2) Dept Pediatrics, Ulsan Univ Hosp, Ulsan, Republic of Korea.

Urea cycle disorders are characterized by encephalopathy, respiratory alkalosis and hyperammonemia. A urea cycle disorder should be considered as a diagnosis in a patient with occult encephalopathy regardless of age. The most common central nervous system pathology is cerebral edema. The cerebral edema is caused by astrocyte swelling secondary to hyperammonemia and intracellular glutamine accumulation. Strokes in children occur in conjunction with cardiac disease, hematologic disorders, mitochondrial encephalopathy, trauma, intracranial infection, and rarely inborn errors of metabolism. To our knowledge, there have been several reports on patients with ornithine transcarbamylase deficiency presenting with strokes. However, a case of citrullinemia presenting with a stroke-like episode has not been described previously. We report two unrelated Korean infants with citrullinemia with an initial clinical manifestation of stroke, emphasizing their clinical features, brain MR imaging and their genotypes. The differential diagnosis for unexplained strokes should include inborn errors of urea cycle metabolism.

Program Nr: 2456 from the 1999 ASHG Annual Meeting

Cytochrome P450 2A6 (CYP2A6): a population genetics study using a new genotyping approach. *C.P. Zabetian[1,2], J. Gelernter[1,2], H.R. Kranzler[3], J.F. Cubells[1,2].* 1) Dept. of Psychiatry, Yale University, New Haven, CT; 2) Dept. of Psychiatry, VA CT Healthcare System, West Haven, CT; 3) Dept. of Psychiatry, U. Conn. Health Ctr., Farmington, CT.

CYP2A6 is the predominant enzyme responsible for the metabolism of nicotine to cotinine. Several alleles at the CYP2A6 locus have been identified including CYP2A6*1, which encodes an active enzyme, and two null alleles (CYP2A6*2 and *3) encoding inactive proteins. It has been proposed that the presence of one or more null alleles may protect against tobacco-dependence (Pianezza et al., Nature 393: 750, 1998). However, different laboratories have reported widely disparate CYP2A6 allele frequencies in Caucasians. This could be due to either actual allele frequency differences, or to methodological differences. We therefore developed an improved method to genotype CYP2A6*1, *2 and *3, and assessed allele frequencies in populations of diverse geographic origin.

Avoiding coamplification of two genes (CYP2A7, CYP2A13) and two pseudogenes that bear >90% sequence homology to CYP2A6 is critical in obtaining accurate results. Using a combination of novel and previously described primers, nested PCR, and differential restriction enzyme digestion, we developed a method that offers the following advantages. 1) All primers are anchored in exonic regions, decreasing the likelihood of allele dropout from primer mismatches in more polymorphic untranslated areas. 2) The first PCR product is shorter, and thus technically easier to amplify. 3) Both of the null alleles discussed above are detected.

We ascertained CYP2A6 genotypes in samples from European-Americans (EAs), African- Americans, Japanese, Ashkenazi and Ethiopian Jews, and Bedouins. The combined null allele frequency in EAs was 2-3%, and did not exceed 6% in the remaining 5 populations. Although these results confirm the presence of population variation in CYP2A6 allele frequencies, they suggest the null alleles CYP2A6*2 and *3 are less common than previously reported by most authors. Further study of the population genetics of CYP2A6 is critical in evaluating the role of this gene in nicotine addiction.

Program Nr: 2457 from the 1999 ASHG Annual Meeting

Refined localization of hKCA3/KCNN3 gene by haplotype analysis and allele sizing to 1q21, between D1S506 and the Duffy gene. *S. Hanz[1,2], N. Parasol[1], N.S. Kosower[1], R. Navon[1,2].* 1) Dept Human Genetics, Tel-Aviv Univ, Tel-Aviv, Israel; 2) Molecular Genetics, Meir Hospital, Sapir Medical Center, Kfar Sava, Israel.

The chromosomal localization of hKCA3/KCNN3, a neuronal small conductance calcium-activated potassium channel gene, was recently mapped by us to 1q21 using FISH analysis. It was recently reported that the hKCA3/KCNN3 gene might be involved in schizophrenia. The gene contains two adjacent polyglutamine repeats arrays in its N-terminal region. The second repeat is highly polymorphic in Caucasian European and North American populations. In a previous work we studied the involvement of 1q in schizophrenia. To establish haplotypes of members from schizophrenic families, we used 15 markers from 1cen-1q23, most of them highly polymorphic microsatellite CA repeats probes. Haplotype analysis and allele sizing of the polymorphic CAG repeats on 84 members of 8 non-Ashkenazi Jewish families enabled us to refine the localization of hKCA3/KCNN3 gene. The localization was mainly based on one family, containing multiple cross-overs. Combination of the two methods, haplotype analysis and allele sizing, enabled us to refine the localization of the hKCA3/KCNN3 gene to the region between the marker D1S506 and the Duffy gene. The localization was consistent with the haplotypes of other informative families tested.

Program Nr: 2458 from the 1999 ASHG Annual Meeting

Chromosome 14 linkage analysis for atopic asthma in Italian families, and mutation study of two serpin genes. *G. Malerba[1], C. Patuzzo[1], E. Trabetti[1], C. Lauciello[1], R. Galavotti[1], M. Wahlen[1], T. Scherpbier[2], R. Levitt[2], L. Pescollderungg[3], G. Zanoni[4], A.L. Boner[1], P.F. Pignatti[1].* 1) Mother-Child and Biol-Genet, University of Verona, Italy; 2) Magainin Inst. Mol. Med., Plymouth Meeting, PA; 3) Istitute of Paediatrics, Hospital of Bolzano, Italy; 4) Dept. of Pathology, University of Verona, Italy.

In order to identify genetic factors for susceptibility to atopy and asthma in childhood we have collected 116 families (560 subjects) with at least one affected sibpairs, from a restricted geographic area in North East Italy. All the subjects were characterized for the following phenotypes: atopy, total serum IgE, Skin Prick Test (SPT), Bronchial Hyperresponsiveness (BHR) to methacoline and clinical asthma. Atopy was defined as increased IgE and/or positive SPT. A chromosome 14 region of 118 cM has been studied with 14 DNA markers (D14S742, D14S1280, D14S608, D14S306, D14S583, D14S587, D14S588, D14S606, D14S616, D14S617, D14S1434, D14S605, D14S614, D14S1426). Multipoint analysis indicated linkage of BHR with D14S617 (NPL=2.22, p=0.013). TDT analysis displayed a significant disequilibrium of D14S617 alleles and BHR (p=0.02). The region in which D14S617 is located (14q32) is different from that reported to be linked to asthma in 14q11.2-13 (CSGA, Nat Genet. 1997; 15:389). Alpha 1 antitrypsin (AT) and alpha 1 antichymotrypsin (ACT) genes map at 1 Mb from D14S617. These serine protease inhibitors have been reported to be associated with chronic obstructive pulmonary disease. We have analyzed Z, S, and the Taq I mutations in the AT gene and the Thr-15Ala signal peptide polymorphism in the ACT gene. Linkage of any of the 4 mutations with any phenotype did not show any significant result. A transmission disequilibrium was observed between the Thr-15Ala mutation and total IgE (p=0.014), asthma (p=0.027) or BHR (p=0.05). In conclusion, the alpha 1 antichymotrypsin gene or a closely located gene may be involved in susceptibility to atopic asthma in this group of patients.

Program Nr: 2459 from the 1999 ASHG Annual Meeting

Mapping of a new autosomal dominant non-syndromic hearing loss to chromosome 15q26. *M. Mangino[1], F. Sangiuolo[1], F. Capon[1], G. Novelli[1], E. Carraro[2], F. Gualandi[3], M. Mazzoli[2], A. Martini[2], B. Dallapiccola[1,4]*. 1) Department of Biopathology, Tor Vergata University of Rome and CSS Mendel Institute, Rome; 2) ENT Department, University of Ferrara, Italy; 3) Department of Genetics, University of Ferrara, Italy; 4) IRCCS, CSS, S.Giovanni Rotondo, Italy.

Hearing loss is the most frequent sensory defect characterized by wide heterogeneity. We analyzed a four-generation Italian family in which a non-syndromic hearing impairment is transmitted as an autosomal dominant trait. Patients showed a sensorineural hearing impairment involving middle and high frequencies, moderate to severe grade. The hearing impairment starts at the end of the first decade, rapidly progressive till the fourth decade, then it becomes stable. After excluding known DFNA loci using markers listed on the Hereditary Hearing Loss Homepage (URL: http://dnalab-www.uia.ac.be/dnalab/hhh), we performed a genome wide scan with 358 highly informative microsatellite markers using the ABI PRISM Linkage Mapping Set (PE Applied Biosistem,USA). Significant linkage (Zmax=3.37;q=0) was obtained with markers of chromosome 15q26. Haplotype analysis from genotype of affected and unaffected individuals defined a 20cM disease-gene interval. Fine mapping and identification of candidate genes are in progress.

Program Nr: 2460 from the 1999 ASHG Annual Meeting

The gene for Cherubism maps to chromosome 4p16.3. *J. Mangion[1], N. Rahman[1], S. Edkins[1], R. Barfoot[1], T. Nguyen[1], A. Sigurdsson[1], J.V. Townend[2], D.R. Fitzpatrick[3], A.M. Flannagan[4], M.R. Stratton[1]*. 1) Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, UK; 2) Department of Maxillofacial Surgery, St Richard's Trust, Chichester, West Sussex PO 19 4SE, UK; 3) Human and Clinical Genetics Unit, Molecular Medicine Centre, Western General Hospitals Trust, Edinburgh EH4 2XU, Scotland, UK; 4) Department of Histopathology, Imperial College School of Medicine at St Mary's. Norfolk Place, London W2 1PG, UK.

Cherubism is a rare autosomal dominant disease of childhood characterised by proliferative lesions within the mandible and maxilla leading to prominence of the lower face and appearances reminiscent of Renaissance cherubs. Resolution of these bony abnormalities is often observed after puberty. Using two families with clinically, radiologically and/or histologically proven Cherubism, we have performed a genome wide linkage search and localised the gene to chromosome 4p16.3 with a maximum multipoint LOD score of 5.64. Both families showed evidence of linkage to this locus. Critical meiotic recombinants place the gene in a 3cM interval between D4S127 and 4p-telomere. Within this region a strong candidate is the gene for fibroblast growth factor receptor 3 (*FGFR3*), mutations in which have been implicated in a diverse set of disorders of bone development. Having screened a total of 7 families of cherubism by conformation-sensitive gel electerophoresis (CSGE), we have found no evidence of mutations within *FGFR3*. We also found no evidence for loss of heterozygosity (LOH) within this region when we analysed 13 mandibular biopsies with the characteristic features of cherubism from 8 affected individuals, indicating that cherubism is unlikely to be due to the inactivation of a tumor supressor gene. We are currently in the process of collecting further families, so that we can perform allelic association studies on approximately 20 families.

Program Nr: 2461 from the 1999 ASHG Annual Meeting

Faster multipoint linkage analysis through state space reduction. *K.G. Markianos, L. Kruglyak, M.A. Eberle.*
Molecular Medicine, Fred Hunchinson Cancer Research Center, Seattle, WA.

Computational constraints currently limit exact multipoint linkage analysis to pedigrees of moderate size. We are developing new algorithms that allow analysis of larger pedigrees by reducing CPU and memory requirements of the computation. The algorithms are being implemented in a new version of the software package GENEHUNTER. One algorithm uses the observed pedigree genotypes to reduce the inheritance vector space. Performing the calculation in the reduced vector space increases the efficiency of multipoint analysis several times both in terms of computational speed and memory requirements. Specifically, we introduce the following improvements:

1) Identification of the COMPLETE set of illegal inheritance vectors.
2) Computation of prior probabilities only for legal inheritance patterns.
3) Efficient computation of the Whittemore & Halpern statistic used for nonparametric (NPL) linkage analysis.
4) Computation and storage of cumulative transition probabilities only for states compatible with the observed genotypes.

We will present performance data for the new version of GENEHUNTER.

.

Program Nr: 2462 from the 1999 ASHG Annual Meeting

A weighted sibship disequilibrium test for linkage and association in discordant sibships. *E.R. Martin[1], S.A. Monks[2], N.L. Kaplan[3].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) Biostatistics Branch, NIEHS, Research Triangle Park, NC.

For a data set consisting of discordant sib pairs, with one affected and one unaffected child, Horvath & Laird (1998) presented two statistics that can be used to test the null hypothesis of no linkage or no association between a biallelic marker and a disease locus. For a discordant sib pair, let d denote the difference between the number of copies of marker allele 1 in the affected sib and unaffected sib. T_1 is based on sgn(d), where sgn(d) is +1 or -1 depending on whether d is positive or negative, while T_2 is simply based on d. In a sample of discordant sib pairs the test with T_2 is the same as both Curtis's test and the S-TDT (Curtis 1997, Spielman & Ewens 1998). Under the null hypothesis, both statistics are asymptotically normal with mean 0 and variance 1. Horvath & Laird (1998) showed that, when testing for association in the presence of linkage, the two tests have similar power in most situations, with neither test uniformly most powerful. These statistics can also be used to construct tests for association and linkage in larger sibships. For a larger sibship, Horvath & Laird (1998) defined $d = m_A - m_U$, where m_A and m_U are the mean numbers of copies of marker allele 1 in the affected and unaffected sibs, respectively. With this more general definition of d, their sibship disequilibrium test (SDT) uses T_1. Just as for sib pairs, a test could also be based on T_2, and we refer to the test as the weighted sibship disequilibrium test (WSDT), since the sign of the difference is weighted by the magnitude of this difference in the calculation of T_2. We have conducted computer simulations to examine the power of the WSDT. Our simulation results suggest that, unlike for sib pairs, for larger sibships the test with T_2 is often more powerful than the test with T_1 when testing for association in the presence of linkage, particularly when sibships contain multiple affected siblings. We also discuss extensions of the WSDT to multiallelic markers and multiple marker loci.

Program Nr: 2463 from the 1999 ASHG Annual Meeting

Likelihood methods for model-free linkage analysis of multiple-affected sibships. *M.M. Martinez, Z. Uhry, F. Demenais.* Genetique des Maladies Humaines, Hopital St Louis, INSERM U358, Paris, France.

Several likelihood methods have been proposed to test for linkage using Affected Sib-Pairs. The ASP-MLS (Risch 1990, Holmans 1993) method maximizes the likelihood as a function of two zj's parameters (probability for a sib-pair to share j marker alleles Identical By Descent). The distribution of the statistic, 2ln(10)MLS, is a mixture of chi-squares with 1 and 2 df. For sibships with multiple affected sibs, type I and type II errors of the ASP-MLS statistic are not well defined. An other approach, recently proposed, can be applied to the whole sibship of affecteds (Terwilliger 1994; Abel 1998). The statistic (MLB) is assumed to be a linear function of y (IBD sharing rate). The MLB approach is equivalent to the lod score maximized as a function of r (recombination fraction between the disease and the marker locus), assuming a recessive mode of transmission with complete penetrance and no phenocopies (f2=1, f1=f0=0) and setting parental phenotypes to unaffected (Knapp 1994). We propose the Z-mod likelihood method to test for linkage without linear constraint (as with the general MLS model) while analyzing sibships of affected sibs. The Z-mod is the lod score function maximized as a function of the genetic parameters (q, f2, f1 and f0) with r=0 and with parental phenotypes being set to unknown. We investigated the statistical distribution of the Z-mod when families have s=2, 3 or 4 affected sibs. We computed the expected maximum of Z-mod and MLB statistics and their exact sample distributions for different sample sizes (n) of families, under different hypotheses on linkage (r=0.5 vs. 0) and on the effects of the disease locus. We considered a fully informative marker. For families with two affected sibs only, Z-mod is equivalent to the MLS method. For the genetic effects considered, the linkage test has greater power using Z-mod than using MLB methods, particularly when s increases. The Z-mod approach can be easily generalized to non-parametric linkage analysis incorporating covariate effects. These situations will be further explored by Monte-Carlo simulations.

Program Nr: 2464 from the 1999 ASHG Annual Meeting

MAP-O-MAT: marker-based linkage mapping on the World Wide Web. *T.C. Matise, J.A. Gitlin.* Lab of Statistical Genetics, Rockefeller University, New York, NY.

Genetic linkage maps are commonly used in many types of genetic analyses, including parametric and non-parametric linkage analyses searching for genes for both simple Mendelian as well as complex, oligogenic traits. Although 2-5 cM linkage maps have been available for over 3 years, no single map contains all available polymorphic markers. In addition, on any map only a portion of the markers are placed in single map positions with high statistical support while most can only be localized to larger bins. Therefore, it can still be a difficult and tedious exercise to determine the order and map distances for any given set of polymorphic markers.

We have developed a Web-based server (MAP-O-MAT) for automated linkage mapping of polymorphic DNA markers. MAP-O-MAT facilitates verification of order and map distances for custom mapping sets, eliminating the need to download genotype data and compute likelihoods locally. MAP-O-MAT uses the CEPH genotype database version 8.2 comprising nearly 12,000 markers scored in the CEPH reference pedigrees. The CRI-MAP program (Lander and Green, 1987) is used for likelihood calculations and some mapping algorithms. For any given set of ordered markers, MAP-O-MAT can compute map distances using either the Haldane or Kosambi map functions, run CRI-MAP's FLIPS analysis to evaluate local support for order, and can determine the location and corresponding statistical support of additional markers on the given map. MAP-O-MAT also allows evaluation and comparison of statistical support for multiple user-specified marker orders. MAP-O-MAT has a special feature which localizes marker(s) of interest on the Genemap '99 framework map, thus facilitating identification of regions of interest on the Genemap. In addition, MAP-O-MAT provides marker-specific information not easily found elsewhere, including observed heterozygosity, the number of families genotyped, the number of meioses, the number of informative meioses, and the number of phase-known meioses available for each marker. MAP-O-MAT is a Java servlet and is located at http://linkage.rockefeller.edu/tara/mapomat. Development of MAP-O-MAT is funded by NIH grants R29HG01691 and HG00008.

Program Nr: 2465 from the 1999 ASHG Annual Meeting

Consistency of nominal and empirical p-values in QTL linkage analysis. *R.C. McEachin, W.L. Duren, R.M. Watanabe, M. Boehnke, The FUSION study group.* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Quantitative trait locus (QTL) linkage analysis is a tool for localizing genes responsible for quantitative traits. Variance components methods provide a powerful approach to QTL analysis, using intact pedigrees. Given independent pedigrees of identical structure, normally-distributed data, and observed identity-by-descent states for all pairs of family members, QTL LOD scores are asymptotically distributed as a 1/2:1/2 mixture of chi-square on one degree of freedom and point mass at zero, under the null hypothesis of no linkage. Given finite samples and the likely violation of most of these assumptions, we tested how well this distribution fits actual data. We examined results from the FUSION study, in which we are trying to map and identify genes for type 2 diabetes and diabetes-related quantitative traits. For each of 39 analyses in which we obtained a QTL LOD score ³ 2.5, we used computer simulation to assess empirical p-values (Pe). In these simulations, we used the same family structures, genetic maps, and markers as in FUSION. For each of 10,000 or 100,000 replicate samples, we simulated marker genotypes for all family members, assuming that no trait-affecting gene was present. We then estimated Pe as the proportion of replicates yielding LOD scores at least as large as we observed in the real data. We compared the resulting Pe values to the nominal p-values (Pn) obtained under the assumed mixture distribution. In 36 of the 39 analyses, Pn was within the 95% exact binomial confidence interval for Pe. Of the three outside the interval, two were on the boundary. On average, the Pe values were slightly larger than Pn, suggesting that the nominal p-value tends to overstate slightly the true linkage evidence. We note that for all 39 analyses, we transformed the data to approximate univariate normality prior to QTL linkage analysis. Without this step, the nominal p-values likely would have been far less accurate. These results suggest that using the nominal p-value in an initial screen is appropriate but, for results of interest, computer simulation to assess the actual significance level should be used.

Program Nr: 2466 from the 1999 ASHG Annual Meeting

Refinement of the genetic mapping of the hemochromatosis gene by use of haplotype sharing analysis, and application of this method to Multiple Sclerosis. *G.J.te Meerman[1], I.M. Nolte[1], G.T. Spijker[1], M. Boon[1,2]*. 1) Medical Genetics, University of Groningen, the Netherlands; 2) Department of Neurology, University Hospital Groningen, the Netherlands.

Thomas et al. (1998) and Ajioka et al. (1997) have analyzed the single and multilocus marker association between repeat markers and the hemochromatosis gene. It appeared that the marker that was most closely linked was less associated with the disease than markers at greater distance from the gene. One reason that there may be a discrepancy between the strength of association and linkage is that a mutation occurs on a chromosome with a unique marker allele that is further away than a nearby marker allele that occurs without the mutant allele. Especially with SNPs such a situation is likely. If marker alleles are used that are in linkage disequilibrium haplotype agreement will be an indication for identity by descent. Analyzing the overlap between all pairs of haplotypes will then give an indication for the identity by descent status of intervals between markers. The interval where the probability of identity by descent has the strongest contrast between cases and controls will then most likely contain the mutant allele(s). We applied a method of haplotype by haplotype comparison to the data sets of Thomas and Ajioka and found that the most linked marker allele was indicated. We also applied this method to our own data on Multiple Sclerosis and found that while the association analysis was inconclusive with respect to the gene position only one marker interval was indicated to harbour mutant alleles. Ajioka, R.S. et al. Haplotype analysis of hemochromatosis: evaluation of different linkage-disequilibrium approaches and evolution of disease chromosomes. Am. J. Hum. Genet. 60, 139-1447 (1997) Thomas, W. et al. A haplotype and linkage disequilibrium analysis of the hereditary hemochromatosis gene region. Hum. Genet. 102, 517-525 (1998).

Program Nr: 2467 from the 1999 ASHG Annual Meeting

Genetic studies on generalized Osteoarthritis. *I. Meulenbelt[1, 2], C. Bijkerk[3, 1], J.J. Houwing-Duistermaat[3], F.C. Breedveld[2], C.M. van Duijn[3], P.E. Slagboom[1].* 1) Vascular/Connective Tissue Res, TNO-Prevention & Health, Leiden, Z-H, Netherlands; 2) Dept. of Rheumatology, Leiden University Medical Center, Leiden; 3) Dept. of Epidemiology & Biostatistics Erasmus University Medical School, Rotterdam.

Osteoarthritis (OA) is characterized by degradation of articular cartilage and formation of new bone. Previously, genetic linkage analysis was performed a Dutch family in which primary generalized OA (GOA) without dysplasia occurred at an early age of onset (20-35 years). Most candidate genes that were tested in this family were excluded to cause the development of GOA (1). Among these loci, were genes encoding matrix components (COL2A1, COL9A1, COL9A2, COL11A1, COL11A2, COMP, and CRTL-1), and factors involved in cartilage remodeling (MMP3). To identify new OA genes a genome wide search was performed using this and 3 additional Dutch families. In all families OA occurred at early ages of onset in multiple joint sites simultaneously and was inherited in a dominant Mendelian fashion. Together these families consisted of 75 individuals of which 35 were affected. A genome wide search was performed using 300 Weber markers from set 8/8a with an 18-cM spacing. Linkage was observed only for a single chromosomal region with a maximum LOD-score of 2.2. Our genome wide search indicates a chromosomal region that may contain a gene involved in early onset generalized OA. 1) Meulenbelt I. et al. (1997) J Med Genet 34:1024-1027.

Program Nr: 2468 from the 1999 ASHG Annual Meeting

Non-hyperandrogenic polycystic ovarian syndrome is associated with short CAG repeats in the androgen receptor. *A. Mifsud[1], B. Rodrigez[2], E.L. Yong[1]*. 1) Obstetrics and Gynaecology, National University of Singapore, Singapore; 2) Pedriatics, National University of Singapore, Singapore.

Polycystic ovary syndrome (PCOS) is a heterogeneous endocrine disorder, which is considered to be the commonest cause of anovulatory infertility. The mode of inheritance of PCOS is uncertain but the disease is clustered in families. Although PCOS is responsible for at least 85% of women with hirsutism the percentage of hirsute women with elevated levels of testosterone seems to be lower. The mode of action of androgens is in conjunction with the AR. The exon 1 of the AR contains a polymorphic region with a variable number of CAG repeats. We looked at the role that the number of CAG repeats in the AR plays in the etiology of PCOS. We have examined the CAG repeat segment from 91 patients with ultrasound diagnosis of PCOS associated with irregular infrequent menstrual cycles and compared them to 112 controls of proven fertility and who have normal regular cycles. Patients were 83% Chinese and 17% Indians while that of the controls were 92% Chinese and 8% Indians. We found no differences between the mean CAG repeats length in patients compared to controls being the mean 22.97 and 23.09 respectively. Because each female has two X-chromosomes we then performed the analysis on the short and long alleles separately. Since there is a subset of PCOS whose androgens are normal we wondered whether there were any differences in CAG length between those with normal or low T compared to those whose T was high. The mean T in the normal population was 0.5 ng/ml. We divided the patients into two groups, those with T less than 0.5 and those with T more than 0.5. There was difference in the short alleles in between patients with low T compared to those with high T ($p=0.004$). There was no difference in the long alleles of patients with low or high T. There were still differences in the short CAG allele when Chinese and Indians patients were analyzed separately. There were also ethnic differences in our data. The mean of average CAG length in combined patients and controls were significantly different between for Chinese and Indians, being 23.16 and 22.08 respectively ($p=0.035$).

Program Nr: 2469 from the 1999 ASHG Annual Meeting

The gene for X-linked Vacuolated Myopathy (XVM), is located in a 14 cM span of Xq28. *BA. Minassian[1], MP. Auranen[2], SW. Scherer[1], M. Villanova[3], F. Muntoni[4], M. Fardeau[5], H. Kalimo[2].* 1) Departments of Pediatrics and Genetics, Hospital for Sick Children, Toronto, M5G 1X8, Canada; 2) Department of Human Molecular Genetics, National Public Health Institute, Helsinki, and Department of Pathology, Turku University, Finland; 3) Laboratorio di Patologia Neuromuscolare Istituto Ortopedico "Rizzoli",Bologna, Italy; 4) Department of Paediatrics & Neonatal Medicine, Hammersmith Hospital, London, UK; 5) Inserm U.153, Paris, France.

X-linked vacuolated myopathy (XVM), also known as X-linked myopathy with excessive autophagy (XMEA), was first described by Kalimo et al. in 1988. XMEA/XVM is characterized clinically by slowly progressive muscle weakness, mainly in lower limbs, and histopathologically by vacuolation of myofibers. The pathogenesis of this myopathy was suggested to be a sublethal intrinsic defect of myofibers which led to abundant autophagy as well as exocytosis of the phagocytosed debris, deposited between multiplied basement membranes around the injured myofibers (the intrinsic hypothesis). Since then, Muntoni et al. (1994) and Villanova et al. (1995) have described several other families and the latter showed that the vacuoles in this disease are unique among vacuolar myopathies in that they are lined by plasma and basement membrane and have strong deposition of the complement C5b-9 membrane attack complex (MAC). An alternate hypothesis was thus proposed whereby MAC attack causes invaginations of the plasma membrane leading to the formation of the vacuoles (the extrinsic hypothesis).

We have embarked on a project aimed at identifying the gene responsible for XMEA/XVM. We have so far recruited seven families three of which independantly prove linkage to chromosome Xq28. Based on a number of recombinations, we have been able to narrow the gene locus to 14 cM. At present, we are collecting new families and analyzing candidate genes for mutations. Identifying the gene responsible for XMEA/XVM and characterizing its protein product should provide important insights into the pathogenesis of this unique genetic form of vacuolar myopathies and into the physiology of muscle.

Program Nr: 2470 from the 1999 ASHG Annual Meeting

The -308 promoter polymorphism in the tumor necrosis factor-a **gene is associated with higher body mass index in white girls during adolescence.** *S.P. Moffett[1], S.Y.S Kimm[2], N.W. Glynn[2], C.E. Aston[1], R.E. Ferrell[1].* 1) Dept. of Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) School of Medicine, Univ of Pittsburgh, Pittsburgh, PA.

Tumor necrosis factor-a (TNF-a) is a modulator of gene expression in adipose and muscle tissues. Elevated levels of TNF-a are implicated in the development of both cachexia (loss of muscle and adipose tissue seen in inflammatory states and cancer) and obesity. This report examines the effect of variation in the TNF-a gene on measures of body composition in a biracial cohort of girls followed from ages 9-10 (Yr 1) to 18-19 (Yr 10). Body composition measures included body mass index (BMI, kg/m^2), sum of skinfolds at the triceps, subscapular and suprailiac sites (SSF) and lean body mass (LBM, assessed by bioelectrical impedance). The -308 TNF-a polymorphism, a G (TNF*1) to A (TNF*2) substitution in the promoter region reported to alter TNF-a expression, was typed in 642 black girls and 641 white girls participating in the NHLBI Growth and Health Study, a longitudinal study of obesity development during adolescence. Allele frequencies did not differ between the two races (q=0.181 in black girls; q=0.176 in white girls) and were in Hardy-Weinberg equilibrium. Cross-sectional analysis by age showed a significant association between the TNF 2-2 genotype and higher BMI in white girls (TNF 1-1=23.1 vs. TNF 2-2=25.4, p=0.0085 at Yr 10). Also, those with the TNF 2-2 genotype had a 4 kg greater LBM compared to TNF 1-1 or 1-2 (Yr10, p=0.0004). No such relationship was seen in black girls. No significant association was found between TNF-a genotype and SSF in either group. In summary, these results show a significant association between the -308 TNF-a polymorphism and BMI in white girls. Since no associations were found between TNF-a and body fat, the association with BMI is most likely a reflection of the effect of TNF-a on LBM.

Program Nr: 2471 from the 1999 ASHG Annual Meeting

Hepatocyte Nuclear Factor-6: Studies of Associations between Genetic Variability and Type 2 Diabetes or Estimates of Insulin Secretion. *A.M. Moller[1], J. Ek[1], S. Durviaux[2], S.A. Urhammer[1], J.O. Clausen[1], H. Eiberg[3], T. Hansen[1], G.G. Rousseau[2], F.P. Lemaigre[2], O. Pedersen[1].* 1) Steno Diabetes Ctr, Copenhagen, Denmark; 2) Hormone and Metabolic Research Unit, Université Catholique de Louvain and Christian de Duve Institute of Cellular Pathology, B-1200 Brussels, Belgium; 3) University Institute of Medical Biochemistry and Genetics, University of Copenhagen, Copenhagen, Denmark.

Since the transcription factor hepatocyte nuclear factor (HNF)-6 is an upstream regulator of several genes involved in the pathogenesis of maturity-onset diabetes of the young (MODY), we have tested the hypothesis that variability in the HNF-6 gene is associated with subsets of type 2 diabetes or estimates of insulin secretion. We cloned the coding region as well as the intron-exon boundaries of the two exons of the human HNF-6 gene. We then examined them on genomic DNA in six MODY probands without mutations in the MODY1, MODY3 and MODY4 genes and 54 patients with late-onset type 2 diabetes by combined SSCP-heteroduplex analysis followed by direct sequencing of identified variants. We found two silent variants (Pro94Pro, Gly287Gly) and one missense variant (Pro75Ala). In an association study the allelic frequency of the Pro75Ala polymorphism was 3.2% (95% confidence interval, 1.9-4.5) in 330 type 2 diabetic patients and 4.2% (2.4-6.0) in 238 age-matched glucose tolerant control subjects. There were no differences between carriers (N=19) and noncarriers (N=219) of this polymorphism in glucose-induced serum insulin and C-peptide release during an oral glucose tolerance test in 238 middle-aged, glucose tolerant subjects. Moreover, in genotype-phenotype interaction studies of 226 glucose tolerant off-spring of type 2 diabetic patients and of 367 young healthy subjects, the carriers (N=21 and N=15, respectively) of the polymorphism did not differ from non-carriers (N=205 and N=352, respectively) in acute (0-8 min) serum insulin or C-peptide responses during an intravenous glucose tolerance test. In conclusion, mutations in the coding region of the HNF-6 gene are not associated with type 2 diabetes or with changes in insulin secretion among the Caucasians examined.

Program Nr: 2472 from the 1999 ASHG Annual Meeting

Dizygotic twinning is not linked to variation at the a**-inhibin locus.** *G.W. Montgomery[1], D.L. Duffy[1], B.R. Haddon[1], M. Kudo[2], E.A. McGee[2], J.S. Palmer[1], A.J. Hsueh[2], D.I. Boomsma[3], N.G. Martin[1].* 1) Genetic Epidemiology Unit, Queensland Institute of Medical Research and Joint Genetics Program, The University of Queensland, Brisbane, Queensland, Australia; 2) Division of Reproductive Biology, Department of Gynecology and Obstetrics, Stanford University Medical Center, USA; 3) Psychology Department, Free University, Amsterdam, Netherlands.

Natural multiple pregnancy in women leading to dizygotic (DZ) twins is familial and varies across racial groups suggesting a genetic predisposition. Mothers of DZ twins have a higher incidence of spontaneous multiple ovulation and several studies report elevated follicle-stimulating hormone (FSH) concentrations in mothers of twins. Release of FSH is controlled by feedback of inhibin peptides from the ovary. Inhibin peptides are heterodimers of a common a-subunit and either bA- or bB-inhibin subunits. Immunization against inhibin a-subunit results in increased ovulation rate in animals and the inhibin a-subunit is therefore a candidate gene for mutations that may increase the frequency of DZ twinning.

A C/T polymorphism at base pair 128 was identified in exon 1 of the human a- inhibin gene. Restriction digests of a PCR product from exon 1 with the enzyme *Spe* I detects two alleles of 447 bp and 124 bp. The polymorphism was typed in 1328 individuals from 325 pedigrees of sister pairs that all had at least one set of DZ twins. The frequencies for the 447 bp and 124 bp alleles were 0.802 and 0.198 respectively. Analysis using a dominant model excluded linkage between the a- inhibin locus and DZ twinning in this population (LOD score -2.81 at theta equals zero). TDT and case control based association tests were also negative. We conclude that dizygotic twinning is not linked to variation in the a-inhibin locus.

Program Nr: 2473 from the 1999 ASHG Annual Meeting

Childhood absence epilepsy in 8q24: haplotypes, recombinations, and construction of physical map. *R. Morita[1,2], Y. Sugimoto[2], G.C.Y. Fong[1], P.U. Shah[3], I.P. Castroviejo[4], S. Khan[1,5], K. Yamakawa[2], A.V. Delgado-Escueta[1]*. 1) Epilepsy Genomics laboratories, Comprehensive Epilepsy Program, UCLA School of Med and West L.A. DVA Medical Center, Los Angeles, CA; 2) Lab for Neurogenet, Brain Sci Inst, The Inst of Physical & Chemical Res, Saitama, Japan; 3) K.E.M. Hospital & Seth G.S. Medical College, Bombay, India; 4) Pediatric Neurology University Hospital La Paz, Madrid, Spain; 5) Neurosciences Dept, Riyadh Armed Forces Hospital, Riyadh, Saudi Arabia.

Childhood Absence Epilepsy (CAE) is a common form of idiopathic generalized epilepsy accounting for 5 to 15% of all epilepsies. In 1998, we mapped the locus responsible for CAE and tonic-clonic seizures to chromosome 8q24 (*ECA1*; MIM No. 600131) by linkage analysis using a five-generation family from India and five medium sized multiplex families from USA, Argentina, Spain, and Saudi Arabia (Fong et al., 1998). Haplotype analyses suggested a 3.2 cM interval flanked by D8S1710 and D8S502. We excluded two candidate genes, *KCNQ3*(voltage gated potassium channel) and *JRK* (human homologue of mouse jerky) located on 8q24 by their location and mutation analyses (Morita et al., in press). As a further step to isolate the *ECA1* gene, we screened a BAC library with 16 STS markers on 8q24 and expanded the contigs by BAC end walking to create a physical map, composed by 17 BACs and two YACs. These clones spanned about 3Mb from D8S1710 to D8S523, and provided the correct order of markers around the *ECA1* gene. We used the physical map to reorder marker positions, and further studied haplotypes and recombinations in CAE families with additional markers. We identified consanguinity in the first and second generations of the Indian family. Both individuals of the first generation were first cousins and one of their sons married his aunt. Consanguinity and identical haplotypes suggested all relatives in the first and the second generations had the same *ECA1* mutation that segregated with affected members through five generations. Our present results reduced the size of *ECA1* region to 700kb bounded by D8S1753 and D8S502. Large scale sequencing of BACs is on going looking for candidate genes for *ECA1*.

Program Nr: 2474 from the 1999 ASHG Annual Meeting

Mega2, a data-handling program for facilitating genetic linkage and association analyses. *N. Mukhopadhyay[1], L. Almasy[1], M. Schroeder[2], W.P. Mulvihill[3], D.E. Weeks[1]*. 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Stanford University, Stanford, CA; 3) Carleton College, Northfield, MN.

During a linkage analysis project, it can be quite difficult to get one's data in the proper format required by each different computer program. Not only must the data be converted to the proper format, but also the loci must be reordered into their proper order. To address this problem, we created Mega2.

A typical linkage-analysis study requires information regarding pedigree structure, trait phenotypes, and genetic marker data. One commonly-used data format is the one used by the LINKAGE programs. LINKAGE-format files come in pairs: the "datain.dat" contains the locus information (disease model, allele frequencies, numbers of alleles, etc.), while the "pedin.dat" contains the pedigree structure information and phenotypes. However, the original LINKAGE format made no provisions for locus names nor for marker map information. So Mega2 uses as input a trio of files which remedy these omissions: 1) the locus file modified to contain locus name information; 2) the pedigree file; and 3) the map file. Mega2 then takes this trio of input files and, via a menu-driven interface, transforms them into various other file formats, thus greatly facilitating a variety of different analyses. In addition, for many of these options, it also sets up a C-shell script that can then automatically run these analyses. Programs that are currently supported include SIMWALK2, MENDEL, ASPEX, APM, SLINK, SPLINK, SIMULATE, SAGE, GeneHunter, GeneHunter-Plus, TDTMax, SOLAR, and Guo and Thompson's program for testing for Hardy-Weinberg equilibrium. In addition, Mega2 can generate summaries about pedigree structures and allele frequencies, as well as can convert larger pedigrees to their component nuclear families.

Mega2 currently uses a textual interface. We plan to use it as the engine behind some more graphical interfaces under development. Mega2 is available via our web site http://watson.hgen.pitt.edu/.

This work was supported in part by the following NIH grants: HG00932, AG16989, AG16992, EY09859, and DK55406.

Program Nr: 2475 from the 1999 ASHG Annual Meeting

The TDT/sib-TDT procedure applied to the study of the 5HT1Dbeta receptor gene and Obsessive-Compulsive Disorder. *E. Mundo[1], M.A. Richter[2], K. Hood[2], F. Sam[1], F. Macciardi[1], J.L. Kennedy[1].* 1) Neurogenetics Section, CAMH,University of Toronto, Toronto, Ontario, Canada; 2) Anxiety Disorders Clinic, CAMH,University of Toronto, Toronto, Ontario, Canada.

Obsessive-Compulsive Disorder (OCD) is a complex psychiatric disease with a strong genetic component (Pauls et al, 1995; Billet et al, 1998). Data from challenge studies and from pharmacological trials have pointed to the involvement of serotonin (5HT) in the pathogenesis of OCD (Barr et al, 1992; Mundo et al, 1995, 1999). As for other complex diseases, investigating for the presence of linkage disequilibrium is a particularly useful strategy in identifying genes that may contribute to disease susceptibility, particularly when genes are of small effect. Recently an extension of the Transmission Disequilibrium Test (TDT) (Spielman et al, 1993) has been developed, the sib-TDT (Spielman and Ewens,1998), which compares marker genotypes in affected and unaffected offspring. The combination of the two procedures in one test, named TDT/sib-TDT (Spielman and Ewens, 1998) allows the incorporation of families with known parental genotypes together with families having known unaffected sibs' genotypes and unknown parental genotypes. We applied this procedure to a set of data from 67 probands diagnosed as affected by OCD according to DSM-IV criteria (APA, 1994) and their living parents or siblings, genotyped for the G861C polymorphism of the 5HT1Dbeta autoreceptor gene (Lappalainen et al, 1995). This receptor is particularly interesting in OCD as data from recent studies have shown that the 5HT1Dbeta selective ligand sumatriptan may improve symptoms in OCD patients resistant to conventional pharmacotherapy (Stern et al, 1998). Thirty-two families were informative for the analysis. Results showed a preferential transmission of the G allele to the affected subjects ($z=2.524$, $p<.01$). Our findings need to be replicated on larger samples. If confirmed, the 5HT1Dbeta receptor gene will be implicated in either the pathogenesis of OCD, or in the mechanism of the pharmacological response.

Program Nr: 2476 from the 1999 ASHG Annual Meeting

Silver syndrome, a distinct form of hereditary spastic paraplegia (HSP), is not linked to any of the known HSP loci. *V.A. Murday[1], H. Patel[1], P. Hart[2], T. Warner[2], I. Allen[1], H. Phillimore[1], M. Patton[1], A.H. Crosby[1]*. 1) Dept Medical Genetics, St Georges Hosp Medical Sch, London, England; 2) Dept Neurology, Royal Free Hospital, London, England.

The hereditary spastic paraplegias are a clinically and genetically diverse group of disorders which share the primary feature of a progressive and severe lower extremity spasticity. The HSPs have been divided into 'pure' and 'complicated' forms depending upon the absence or presence of secondary neurological abnormalities. Silver syndrome is a particularly disabling autosomal dominant form of complicated HSP in which the leg spasticity is associated with wasting of the hand muscles. In view of the fact that genes for hereditary spastic paraplegia can produce highly variable phenotypes, the five known autosomal dominant loci were investigated for linkage to Silver syndrome. However, genotyping of these loci in 2 large multigeneration families was incompatible with linkage to any of these regions, suggesting that an additional locus is responsible for this syndrome.

Program Nr: 2477 from the 1999 ASHG Annual Meeting

Fine-scale mapping of the Congenital Fibrosis of the Extraocular Muscles type 2 (CFEOM2) gene region. *M. Nakano, E.C. Engle.* Dept Genetics, Children's Hospital, Boston, MA.

The syndromes known as congenital fibroses of the extraocular muscles (CFEOM) are congenital ocular-motility disorders manifested as restrictive ophthalmoplegias with ptosis. CFEOM2 (MIM 602078) is an autosomal recessive form of this disorder characterized by bilateral ptosis, with the eyes frozen in an exotropic (outward) position. Three consanguineous Saudi Arabian families have been identified with CFEOM2, and we have previously mapped their disease gene to a 2.5 cM region of distal 11q13 between D11S4162 and D11S4184. Two of the three families share a common disease-associated haplotype, suggesting a founder effect for CFEOM2.

Toward our goal of narrowing the critical region and cloning the CFEOM2 gene, we have constructed a BAC contig across the ~1300kb CFEOM2 critical region. This map contains 40 BAC clones with a minimal tiling path of 6 BACs. Through di- and tetra-nucleotide repeat oligonucleotide hybridization we have, to date, identified 25 new short tandem repeat polymorphisms in the region and have mapped them onto the BAC contig. We are currently testing these markers for recombination events in family members and for evidence of a common haplotype shared by all three CFEOM2 families. In addition, we have mapped 15 new EST/genes to the region, in addition to the 5 genes already present on the existing YAC map. These ESTs/genes, as well as any others identified by exon trapping, will be analyzed as candidate CFEOM2 disease genes.

Although the CFEOM syndromes are thought to arise from dysfunction of the oculomotor nerve, their molecular etiology remains unknown. Identifying the CFEOM2 gene will reveal the genetic mechanism underlying this recessive form of CFEOM, and should be valuable to our understanding of the CFEOM disease process and the role these genes play in the normal development of the oculomotor system. In addition, this relatively gene rich region of distal 11q13 is not currently covered by the Human Genome Project, and thus our positional cloning project will contribute to this larger effort.

Program Nr: 2478 from the 1999 ASHG Annual Meeting

Genome Coverage and Fidelity of Whole Genome Amplification. *K.C. Neal, A.C. Lidral.* Orthodontics, Ohio State University, Columbus, OH.

For most studies of human genetics, sample DNA is a limiting resource, particularly when tissue or blood samples are minimal. In these cases, the amount of DNA restricts analysis to a small number of experiments, thus preventing genome wide linkage or linkage disequilibrium mapping. In addition, with the advent of SNP's a larger amount of initial template will be necessary to permit genome wide coverage. A variety of whole genome amplification (WGA) techniques have been developed to circumvent this problem. These include inter-Alu PCR and a variety of degenerate oligonucleotide PCR's. Previous studies using WGA have shown complete genome coverage at cytogenetic resolution. However, to date, there are no comprehensive studies to address the issues of genome coverage or amplification fidelity to validate the use of WGA for mapping and sequencing purposes. The purpose of this study was to evaluate the genome coverage and the loss of heterozygosity (LOH) following WGA. DNA from 90 CEPH individuals was subjected to WGA performed by a modified degenerate oligonucleotide primed PCR protocol of Zhang et al. (PNAS 89:5847, 1992). The amplified DNA was subsequently genotyped using a low density set of microsatellite markers from the Weber 8 Mapping Panel. Genotyping results were compared to published genotypes for the CEPH individuals (www.cephb.fr). Preliminary analysis of 8 markers from 5 chromosomes revealed a loss of heterozygousity (LOH) rate of 5.3% with the loss of larger alleles being more frequent. The LOH rate was inconsistent with several markers giving higher rates while others were reasonably low. The LOH rates were not correlated with the size or sequence of the repeat marker. The percentage of samples with incorrect genotypes compared to published results for CEPH individuals was 0.8%. The percentage of sample amplification was 97.1% and 1.3% of the amplified samples were too ambiguous to be scored which is comparable to published results. This preliminary data suggests that WGA exhibits a variable rate of fidelity that may prove to be acceptable for a majority of markers. Experiments are ongoing to determine if the coverage and fidelity of WGA would permit genotyping using a 20 cM mapping panel.

Program Nr: 2479 from the 1999 ASHG Annual Meeting

***NIDDM1* is associated with diabetes and body fat distribution in the Hutterites.** *D.L. Newman[1], A. Tsalenko[1], N.J. Cox[1,2], C. Ober[1]*. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL.

Non-insulin-dependent diabetes (NIDDM) is a complex disease with widespread health implications. Hanis et al. (1996, Nat Genet 13:161-166) reported significant evidence for linkage between NIDDM in Mexican-Americans and a marker at 2qter (*NIDDM1*). A single variable site, SNP43, completely partitioned the evidence for linkage in those data. Here we report that the *NIDDM1* locus is also associated with NIDDM in the Hutterites of South Dakota, an inbred Caucasian population. We examined SNP43 as well as a variable site 11 bp away, SNP44, using the TDT. The common allele of SNP44 (T) was overtransmitted to affected individuals (15T:3U), while the common allele of SNP43 (G) did not show significant excess transmission (27T:22U). The common SNP44-SNP43 haplotype (T-G) was overtransmitted (42T:27U) while the two other observed haplotypes (T-A and C-G) were undertransmitted (24T:30U and 7T:16U, respectively) to affected individuals, suggesting that both SNPs contribute to NIDDM susceptibility. In addition, although the T-G haplotype was associated with lower BMI and percent body fat, females homozygous for the common variant of SNP44 (T/T) or carrying the common haplotype (T-G) had a higher mean waist-to-hip ratio ($P = 0.018$ and $P = 0.013$, respectively). A high waist-to-hip ratio is a significant risk factor for developing NIDDM. Overall, these data are consistent with the hypothesis that variation at *NIDDM1* influences both diabetes susceptibility and body fat distribution in the Hutterites. (Supported by NIH grants HL56399 and HL07237.).

Program Nr: 2480 from the 1999 ASHG Annual Meeting

Localization of FEVE (Familial Enteropathy with Villous Edema) to Human Chromosome 11 (11q23.1). *A.Y. Ng[1], M. Hicks[1], S.M. Haase[1], T. Johnson[1], J.S. Bamforth[1], H.F. Pabst[2], M.A. Walter[1], K.A. Sprysak[1], B.G. Elyas[1], L.M. Vicen-Wyhony[1], M.J. Somerville[1]*. 1) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Pediatrics, University of Alberta, Edmonton, Alberta, Canada.

Familial enteropathy with villous edema (FEVE [MIM 600351]) is an autosomal dominant disorder with variable penetrance (Smith et al., 1994). It is characterized by episodes of life-threathening secretory diarrhea with persistent jejunal histologic abnormalities associated with IgG2 deficiency. Patients present with a sudden onset of mild symptoms which include fever and occasional abdominal pain. These symptoms progress within 5 to 6 hours to intense nausea, persistent vomiting and very profuse watery diarrhea which leads to severe dehydration and hypovolemic shock. The age of onset of these symptoms varies from 6 months to 20 years and in all cases the episodes are less frequent in the teenage years with no family member having an episode after the age of 21 years. We have obtained blood samples from a large Mennonite kindred from Alberta, Canada which exhibits this syndrome. Two-point linkage analysis was conducted with a genome-wide screen for linked markers using the LINKAGE analysis program (Lathrop et al., 1985). DNA was genotyped on an Applied Biosytems model 377 (ABI PRISM Linkage Mapping Set Version 2; Perkin Elmer Applied Biosystems) using fluorescent-based microsatellite sets that included 400 markers defining a ~10 cM resolution human index map. 190 polymorphic markers from various panels were screened and a region on the long arm of chromosome 11 gave significant LOD scores. A maximum LOD score of 6.2 at theta = 0 was obtained with marker D11S908, and is localized to 11q23.1. This portion of chromosome 11 is currently under investigation with a higher density microsatellite array. Candidate genes in this region include: SCN2B, MMP12, CD3D, CD3E, CD3G, TAGLN, and IL10RA. Smith LJ, et al. (1994) J Pediatr 125: 541-548, Lathrop et al. (1985) Am. J. Hum Genet. 37: 82-498.

Program Nr: 2481 from the 1999 ASHG Annual Meeting

Association of neuropeptide Y receptor polymorphisms with obesity in a diabetic Ashkenaze population. *E.M. Nolin[1], T. Guillemette[1], J. Rennich[1], S. Lewitzky[1], X. Wang[1], J. Meyer[1], B. Glaser[2], M.A. Permut[3], A. Parker[1]*. 1) Human Genetics, Millennium Pharmaceuticals, Inc., Cambridge, MA; 2) Hadassah Medical Center, Jerusalem, Israel; 3) Washington University, St. Louis, MO.

The neuropeptide Y receptors (NPYR) located on chromosome 4q31-q32 are members of the G protein-coupled receptor superfamily and have been proposed as metabolic disease candidate genes owing to the role of NPY in appetite regulation. We investigated their association with non-insulin-dependent diabetes (NIDDM), an adult-onset polygenic disorder strongly associated with obesity. We screened NPY1R, NPY2R, and NPY5R for mutations using single-stranded conformation polymorphism (SSCP) and denaturing HPLC (DHPLC). Six polymorphisms were identified: in NPY1R, 2538 (A-G) in the 3' UTR and 640 (indel AAAT) 5' of the exon 1A promoter, in NPY2R, 2838 (A-G) in the 3'UTR and Ile195Ile (ATT-ATC) in exon 2, in NPY5R, Cys230Cys (TGT-TGC) and Gly426Gly (GGG-GGA) in exon 2. We typed four of these polymorphisms, 2538 (A-G) of NPY1R, 2838 (A-G) and Ile195Ile of NPY2R, and Gly426Gly of NPY5R, in a sample of Ashkenaze individuals collected in Israel, including 235 nuclear families characterized by one or more sibling pairs affected with NIDDM, 35 randomly ascertained trios, and 138 superunaffected controls (N=1074). We evaluated allelic and genotypic association of each marker with an obese diabetic phenotype. No significant association was observed, although genotypic associations with two markers, NPY1R 2538 (A-G) (p=0.102) and NPY5R Gly426Gly (p= 0.086), approached significance. There was no evidence of linkage disequilibrium between these two markers (p=0.49), nor association between two marker haplotypes and disease (p=0.24). We conclude that our sample shows no evidence of association between the neuropeptide Y receptors and obesity in the Ashkenaze diabetic population. This research was partially supported by Roche Pharmaceuticals, Inc.

Program Nr: 2482 from the 1999 ASHG Annual Meeting

Gilles de la Tourette syndrome: a replication study using family-based analyses of loci associated in an Afrikaner Population. *D.R. Nyholt[1], I. Simonic[2], G.S. Gericke[2], D. Gordon[1], J. Ott[1], J.L. Weber[3]*. 1) Laboratory of Statistical Genetics, Rockefeller University, New York, NY; 2) University of Stellenbosch, Matieland, South Africa; 3) Center for Medical Genetics, Marshfield Medical Research Foundation, Marshfield, WI.

Gilles de la Tourette syndrome (GTS) is a childhood-onset neurologic disorder characterized by motor and vocal tics and associated with behavioral abnormalities. Evidence supporting genetic determination of GTS comes from several lines of evidence including twin and family studies. However, gene-mapping efforts using large kindreds have generally proved unsuccessful. Subsequently, efforts are being redirected toward association studies in young, genetically isolated populations. Recently, we performed a genome scan using DNA samples from GTS patients and unaffected control subjects from the South Afrikaner population, and identified a number of regions significantly associated with GTS (Simonic et al. AJHG 63:839-846).

In the present study, five chromosomal regions previously showing evidence for association (p-values 10^{-1} to 10^{-6}), were examined in 91 unrelated nuclear families, using family-based tests for linkage and association. Single marker transmission disequilibrium (TDT) and haplotype relative risk (HRR) analysis (Terwilliger, AJHG 56:777-787) showed evidence for linkage or association with p-values of around 0.05. To further examine the presence of shared haplotypes among GTS individuals, two and three marker haplotypes were tested for excess transmission using an extended HRR contingency test, with significance determined by calculating exact p-values using Monte Carlo simulation. Extended haplotype analysis improved evidence for linkage disequilibrium at some regions ($P = 0.01$). As this study was designed to replicate previously significant results, our p-values of 0.05 or 0.01 represent significant replication and strong evidence for susceptibility loci in some genomic regions, although our sample size was relatively small.

Program Nr: 2483 from the 1999 ASHG Annual Meeting

Deterministic haplotyping algorithms for pedigree analysis and error checking. *J.R. O'Connell*[1,2]. 1) University of Pittsburgh, Pittsburgh, PA; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, England.

As genetic maps using SNPs become more dense, researchers will incorporate more tightly spaced biallelic markers into their analyses, and thus increase the importance of haplotype information. Haplotypes allow geneticists to reconstruct gene flow within a pedigree, which can dramatically increasese the information content available for linkage analysis and positional cloning. Given a small region of the genome spanned by tightly linked markers of interest where no recombination is expected, we have developed a deterministic algorithm based on multilocus genotype elimination that can determine whether the pedigree has a haplotype configuration with zero recombinants. Moreover, if such a pedigree exists, then our algorithm can determine all such possible zero-recombinant haplotyped pedigrees. These configurations can then be used to estimate the haplotype frequencies for the pedigree data to test for linkage disequilibrium and also to perform a cladistic/measured haplotype analysis. The cladistic analysis constructs a haplotype tree to account for the most common haplotypes to try to find ancestral recombination events. Measured haplotype analysis then models the effect of a quantitative trait associated with particular haplotypes to estimate trait variability. Haplotype analysis can also be very useful for detecting the presence of genotyping errors in pedigrees that do not cause inconsistencies in Mendelian inheritance by detecting the presence of an excess of recombination events among closely spaced markers. We present a deterministic algorithm based on a technique called set-genotype elimimination that finds all consistent haplotype configurations for groups of two and three markers even in the presence of recombinants. In particular, if no zero-recombinant pedigree configuration exists, the algorithm can find pedigree configurations with the smallest number of recombinants and identify any haplotypes that contain obligate double recombinants. We present examples of our algorithms applied to real pedigree data. The work was supported in part by funds from NIH grant HG00932, NIA grant AG16992-01 and BIOMED EC grant PL 96 2532.

Program Nr: 2484 from the 1999 ASHG Annual Meeting

Analysis of Single Nucleotide Polymorphisms in Candidate Genes for Hypertension and Insulin Resistance. *M. Olivier[1,2], H.-H.W. Sheu[2], C.-Y. Jeng[2], C.-F. Hsiao[2], Y.-Z. Tseng[2], K. Ranade[1,2], Y.-D.I. Chen[2], R. Olshen[2], D. Curb[2], R. Pratt[2], N. Jarvis[3], M. De Arruda Indig[3], N. Risch[1,2], D.R. Cox[1,2]*. 1) Genetics, Stanford University, Stanford, CA; 2) SAPPHIRe Project; 3) Third Wave Technologies, Madison, WI.

The Stanford-Asian Pacific Program in Hypertension and Insulin Resistance (SAPPHIRe) is collecting Chinese and Japanese sib-pairs to map major genetic loci underlying hypertension. To date, 1,263 sib-pairs between 35 and 60 years have been collected. The cohort consists of 686 concordant hypertensive pairs, 179 concordant hypotensive pairs, and 577 discordant pairs. Both concordant and discordant sib-pairs are being used for analysis of polymorphisms in candidate genes hypothesized to play a role in hypertension.

We selected 5 genes reported to affect blood pressure regulation (11b-hydroxylase, aldosterone synthase, mineralocorticoid receptor) or insulin resistance (CD36, PTP-1b) in both humans and rats. For all genes, the sequence of the human exons and partial intronic sequences were known. We designed primers to amplify the exons and adjacent intronic sequences for each gene from 24 individuals (16 hypertensives and 8 hypotensives from the SAPPHIRe cohort). The resulting amplicons, which were between 400 and 550 bp in size, were subsequently sequenced. All obtained sequences were analyzed by PolyPhred to detect potential single nucleotide polymorphisms (SNPs).

We identified a total of 16 SNPs with a frequency greater than 10%, 10 of which are located in introns. Additional potential SNPs of lower frequency were not investigated further. Only one of the SNPs identified in this screen results in a change in the amino acid sequence. For all genes, at least one SNP was identified.

We have developed allelic discrimination assays (Taqman assays, PE Biosystems) or invader assays (Third Wave Technologies) to facilitate genotyping of the SAPPHIRe cohort. These assays will be used for our ongoing genotyping and association studies.

Program Nr: 2485 from the 1999 ASHG Annual Meeting

A general conditional logistic model for affected relative pair linkage studies. *J.M. Olson.* Epid/Biostat,MetroHlth Med Ctr, Case Western Reserve Univ, Cleveland, OH.

Model-free lod-score methods are often employed to detect linkage between marker loci and complex diseases, using samples of affected sib pairs. Although extentions of the basic one-disease-locus model have been proposed that allow separate inclusion of addition disease loci, covariates, discordant sib pairs, or other types of affected relative pairs, a common framework that can handle simultaneously all of these features has been lacking. I propose a conditional logistic parameterization that generalizes easily to include all of these features. The Risch single-locus affected-sib-pair model is reparameterized in terms of the logarithms of the offspring and monozygotic twin relative risks and written in a form that is generally applicable to all types of affected relative pairs, provided one can compute the relative pair's marker allele-sharing probabilities. Multilocus models are parameterized in terms of the logarithms of joint-allele-sharing-specific relative risks and are easily written in general, multiplicative, and mixed forms. Covariates can be included in both the single- and multilocus models under the assumption that the covariate acts multiplicatively on the relative risks, that is, additively on the log relative risks. Discordant pairs can be added to the model by the addition of a third parameter. Examples using diabetes and simulated data are given to demonstrate uses of the model.

Program Nr: 2486 from the 1999 ASHG Annual Meeting

Genome-wide population genetic mapping of severe bipolar disorder in a Costa Rican isolate. *R. Ophoff[1], M. Escamilla[2], M. Spesny[3], S. Service[1], W. Poon[1], D. Meshi[1], J. Molina[3], R. Ramirez[3], R. Mendez[3], S. Silva[3], M. Ramirez[3], E. Fournier[3], S. Batki[1], C. Matthews[1], T. Neylan[1], E. Roche[1], V. Reus[1], P. Leon[3], L. Sandkuijl[4], N. Freimer[1]*. 1) Dept Psychiatry/Neurogenetics, Univ California, San Francisco, San Francisco, CA; 2) Department of Psychiatry, University of Texas Health Science Center at San Antonio, San Antonio, Texas; 3) Cell and Molecular Biology Research Center and Escuela de Medicina, Universidad de Costa Rica, San Jose, Costa Rica; 4) Department of Human Genetics, Leiden University, Leiden, the Netherlands.

In recent years linkage disequilibrium (LD) analysis has been promoted as a method of mapping disease genes, particularly in isolated populations. So far whole-genome LD strategies have been applied only to simple monogenic traits. Application of such LD strategies to complex traits has awaited development of both sufficiently dense marker maps and powerful statistical methods. We have now completed an initial genome-wide LD screen for a complex trait, namely severe bipolar mood disorder (BP-I). Unrelated affected individuals (n=109) with at least one parent available were collected from the isolated population of the Costa Rican Central Valley. Patients selected for the study had at least 2 hospitalizations, age of onset by age 50 and at least 6 of 8 great-grandparents born in the Central Valley. All individuals, (patients and availble parents, n=288) were genotyped for a set of 1020 microsatellite markers with an average spacing of less than 4 cM. LD was assessed via a two-point method and by an approach that uses haplotypes.

Program Nr: 2487 from the 1999 ASHG Annual Meeting

Mutations and their effect on linkage disequilibrium mapping. *V.S. Pankratz[1], M. Kimmel[2], R. Chakraborty[3]*. 1) Section of Biostatistics, Mayo Clinic, Rochester, MN; 2) Statistics Department, Rice University, Houston, TX; 3) Human Genetics Center, U. Texas School of Public Health, Houston, TX.

The use of linkage disequilibrium to map disease genes in the absence of familial data is of great interest. It provides a framework that can produce refined estimates of the location of disease mutations within a map of marker loci. Its use is especially appealing as disequilibrium can be measured from individuals who are not related. While it is recognized that recombination, drift, mutation and other factors influence genetic associations, many methods of linkage disequilibrium mapping of necessity ignore every component but recombination. However, to obtain good information from population-based data, it is important to utilize methods that account for the genetic characteristics of the population in question. We describe a general approach that allows for the incorporation of mutation processes into two distinct population models that can be used for linkage disequilibrium mapping with one or more marker loci. Using these models, we examine the utility of modeling mutations jointly with recombination. For linkage disequilibrium mapping with a single marker, mutation and recombination events are confounded, as they are indistinguishable in population samples. However, when several marker loci are used jointly to map the position of a disease gene, allowing for mutations provides definite benefits. First, mutations can account for heterogeneity among marker loci. Second, they provide a structure that can describe the addition of new disease genes to the population. Third, mutations serve to smooth multi-point composite likelihoods, improving their properties in genomic regions densely populated by marker loci. Illustrations of these benefits, based on published and simulated data, are provided. (Research supported by grant DMS 9409909 from the NSF, GM 53545 from the NIH, and NLM 1T15LM07093-04 from the National Library of Medicine through the Keck Center for Computational Biology).

Program Nr: 2488 from the 1999 ASHG Annual Meeting

No IL4R alfa gene linkage or association detected in Italian families with atopic asthma by the analysis of 3 mutations. *C. Patuzzo[1], G. Malerba[1], C. Migliaccio[1], E. Trabetti[1], R. Galavotti[1], L. Pescollderungg[2], G. Zanoni[3], A.L. Boner[3], P.F. Pignatti[1]*. 1) Moth-Child,Biology and Genet., Section of Biol. and Genetics,University of Verona, Italy; 2) Division of Pediatrics, Hospital of Bolzano, Italy; 3) Dpt. of Patology, University of Verona, Italy.

As IL4 mediates IgE production by interacting with its receptor, the gene for its receptor is a potential candidate in studies of genetic factors involved in atopic asthma. Two different IL4R alpha gene mutations increase IgE syntesis in vitro and are significatively associated with increased response to some common allergens in a North American population (Q576R, NEJM 1997; 337: 1720), or in a Japanese population (I50V, Nat.Genet.1998; 19: 119). These two mutations, and a third mutation (E375A, B.B.R.C. 1997; 231: 696), were studied in a sample of 851 individuals belonging to 192 Italian families with affected sib-pairs. The following phenotypes were examined: skin prick test (SPT) positivity, total serum IgE, Bronchial Hyperresponsiveness (BHR) to metacholine, and clinical asthma. Atopy was defined as elevated circulating total IgE and/or positive SPT. Non parametric linkage analysis and TDT tests were performed. The following results were obtained. Mutations Q576R and E375A: No allele sharing increase for any phenotype was observed. The frequency of allele 576R was 0.18 (PIC=0.25). The frequency of allele 375A was 0.06 (PIC=0.11). Regression analysis on these two mutations indicated an association with total serum IgE level in sib pairs. Mutation I50V : preliminary data do not show any association with any phenotype.No particular 3 points haplotype was associated with any phenotype.In conclusion, the IL-4Ra gene, in contrast with what reported for other populations, does not seem to be involved in atopic asthma in the Italian population investigated in this study.

Program Nr: 2489 from the 1999 ASHG Annual Meeting

A complete genome screen in sib-pairs affected with the Gilles de la Tourette syndrome. *D. Pauls[1], The Tourette Syndrome Association International Consortium for Genetics[2]*. 1) Child Study Center, Yale University School of Medicine, New Haven, CT; 2) Tourette Syndrome Association Inc., Bayside, Queens, New York, NY.

Gilles de la Tourette syndrome is a neuropsychiatric disorder characterized by waxing and waning multiple motor and phonic tics. Segregation analyses of several family samples have suggested that the mode of inheritance is complex but that genes of major effect appear to be important for the expression of the syndrome. Previous attempts using large multigenerational families to localize susceptibility loci have been unsuccessful. In this report, the results of the first systematic genome scan using 76 affected sib-pair families with a total of 110 sib-pairs will be presented. While no results reached acceptable statistical significance, the multipoint maximum likelihood scores (MLS) for two regions (chromosomes 4q and 8p) were suggestive (MLS > 2.0). Four additional genomic regions, on chromosomes 1, 10, 13 and 19 also gave multipoint MLS scores between 1.0 and 2.0. Subsequent analyses of additional families have yielded supportive evidence for the regions on 8p and 19p. Genotyping is continuing and the most recent results will be presented.

Program Nr: 2490 from the 1999 ASHG Annual Meeting

Localisation of a Gene for Autosomal Recessive Cone-Rod Dystrophy to Chromosome 17p12-13.3. *A.M. Payne[1], S. Khaliq[2], A. Hameed[2], M. Ismail[2], D.A.R. Bessant[1], S.Q. Mehdi[2], S.S. Bhattacharya[1].* 1) Dept Molec Genetics, Inst Ophthalmology, London, England; 2) Research Laboratories, Biomedical and Genetic Engineering Division, Islamabad, Pakistan.

The cone-rod dystrophies (CRDs) are a severe form of inherited retinal dystrophy characterised by the simultaneous involvement of both the cone and rod photoreceptors. CRD can be inherited as an autosomal dominant or recessive, or X-linked trait. Autosomal recessive cone-rod dystrophy (arCRD) is a genetically heterogeneous disease with mutations in the ABCR gene, and many unidentified loci associated with the disease phenotype. In this study linkage analysis was performed on a three generation Pakistani family with arCRD. All the previously reported loci were excluded as the disease region in this family. Significant linkage to the disease gene was obtained with 5 microsatellite markers across a locus situated on chromosome 17p12-13.3. A maximum two point lod score of 3.56 was obtained with marker D17S799 establishing linkage of the disease in our family to this part of chromosome 17p. Recombination events positioned the between D17S938 and D17S921 an estimated genetic distance of 22.3 cM. This new locus (only the second reported for this phenotype) is close to the disease regions of Leber congenital amaurosis, autosomal dominant cone-rod and cone dystrophy and central areolar choroidal dystrophy (RetNet). Ret-GC1 which has been shown to be implicated in Leber congenital amaurosis (Perrault et al., 1998) and autosomal dominant cone-rod dystrophy (Kelsell et al., 1998) and Na K ATPase b 2-subunit, a retinally expressed membrane bound protein responsible for maintaining the K+ and Na+ intracellular concentrations, both map to this region. On screening affected family members for disease causing mutations none were detected in either gene. The disease gene for this novel locus is therefore yet to be identified.

Program Nr: 2491 from the 1999 ASHG Annual Meeting

Automated fragment analysis of capillary electrophoresis data. *M.W. Perlin*[1,2,3]. 1) Cybergenetics, Co., Pittsburgh, PA; 2) School of Computer Science, Carnegie Mellon University, Pittsburgh, PA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

High-throughput capillary electrophoresis (CE) sequencers such as the ABI/3700 and MD/MegaBACE have become more widely available. These highly parallel CE devices have the potential to greatly increase throughput and reduce labor in genotyping studies that use multiplexed fluorescent microsatellite, SNP, and other genetic markers. However, a key obstacle remains -- the tedious human review of data required for identifying data artifacts. We recently developed a CE processing software module that automatically eliminates certain data artifacts, and have integrated this module into our TrueAllele(TM) automated genotyping software.

The module: (1) Acquires the one dimensional (1D) data of a single capillary for all fluorescent detection channels from the sequencer's data files. (2) Performs initial 1D signal processing (filtering, baseline removal). (3) Automatically classifies the dye colors for a subset of nonprimer peaks, and uses this information to dynamically determine a color separation matrix that is uniquely adapted to the individual capillary run; it separates the dye colors by applying this matrix to the spectrally overlapped data channels in the 1D capillary. (4) Removes the primer region from the data. (5) Tracks the size standard peaks by matching the expected size distribution to the observed peaks. (6) Combines the genetic data traces with the size standard calibration to recast the sampled 1D CE data into a uniformly sized coordinate system. The processed CE traces are then stored for downstream automated genotyping analysis.

At each processing step, the program computes quality measures that can be used to flag problematic data (e.g., low signal, bleedthrough, or incorrect sizing). Interestingly, the third processing step (our new data-adaptive color separation) virtually eliminates the bleedthrough artifact that has complicated multiplexed genetic analysis. Complete data processing for one capillary takes 5-10 seconds on an iMAC computer; the software runs on Macintosh, Windows, and UNIX computers.

Program Nr: 2492 from the 1999 ASHG Annual Meeting

Genetic linkage analysis of prostate cancer families to Xq27-28. *M.A. Peters[1], G.P Jarvik[2], M. Janer[2], L. Chakrabarti[2], S. Kolb[1], E.L. Goode[1,2], M. Gibbs[1], C.C. DuBois[1], E.F. Schuster[2], L. Hood[2], E.A. Ostrander[1], J.L. Stanford[1,2].* 1) Fred Hutchinson Cancer Research Center, Seattle, WA, USA; 2) University of Washington, Seattle, WA, USA.

A family history of prostate cancer has been consistently associated with at least a doubling of risk in first-degree relatives and segregation analysis studies have suggested the existence of an inherited predisposition to prostate cancer. Thus far, four prostate cancer susceptibility loci have been suggested by linkage studies of high-risk prostate cancer families. In the current investigation, we have analyzed families participating in the Prostate Cancer Genetic Research Study (PROGRESS) for linkage to the recently described hereditary prostate cancer locus, HPCX (Nat Genet 20:175-179). PROGRESS is an ongoing Seattle-based study that recruits high-risk prostate cancer families from throughout North America and several other countries.

In this study 129 PROGRESS families have been genotyped at 8 polymorphic markers spanning 15-cM of the HPCX region. These include markers DXS1200 and DXS297, which define the region of the maximum multipoint LOD score as observed in the original HPCX study. Analysis of the total dataset resulted in positive two-point LOD scores at only two markers, DXS984 and DXS1200, with scores of 0.952 at q=0.32 and 0.067 at q=0.38 respectively. In the original HPCX study families without evidence of male-to-male transmission had higher LOD scores at Xq27-28 than those with. Excluding pedigrees with evidence of male-to-male transmission from the PROGRESS families increased the evidence of linkage at DXS1200 (LOD=0.408 at q=0.30), while an additional elimination of families with an unknown mode of transmission resulted in positive LOD scores across a larger portion of the HPCX region. This is consistent with an X-linked locus and locus heterogeneity.

Although, this analysis did not show statistically significant evidence of linkage to the HPCX locus in these 129 PROGRESS families, the results were consistent with a small percentage of the PROGRESS families being linked to this region.

Program Nr: 2493 from the 1999 ASHG Annual Meeting

Power for mapping by admixture linkgage disequilibrium: a case/control simulation study. *C.L Pfaff, M.D Shriver.* Penn State University, University Park, PA.

Admixture between genetically distinct populations creates association between loci. After a few generations, the linkage disequilibrium between unlinked loci decays, and the remaining disequilibrium can be used to map genes (Mapping by Admixture Linkage Disequilibrium). In order to characterize the behavior of MALD, we designed a simulation program that determines the power for MALD depending on a set of parameter values (e.g. number of generations since admixture, proportion of admixture, recombination fraction (q), sample size, and marker and disease allele frequencies). This program examines the power of a case/control study to detect linkage disequilibrium between a marker and a disease allele. Our results show that microsatellite markers are, on average, more powerful than SNPs for MALD. The average power for a SNP marker is 56% (q=0.01, N=300 case, 300 control), whereas an average microsatellite marker achieves >90% power under the same conditions. This difference is mainly due to higher d_C levels (the sum of all positive allele frequency differentials at a locus) at microsatellite loci than at SNP loci. We have found that a high d_C value is the most important characteristic of a good marker for MALD. For example, a marker with a d_C value of 0.71 achieves a power of almost 90% when q=0.06, whereas a marker with a d_C value of 0.38 attains a power of only 57% at the same q. Similarly, markers with high d_C levels demonstrate powers of 89% with only 5% admixture (q=0.001) whereas markers with lower d_C values have powers of 48% under the same conditions. We estimate the average d_C value for microsatellites to be 0.42. Values of d_C above 0.20 generate power estimations >85% at $q \leq 0.01$. Thus, for candidate gene mapping, most microsatellites and many SNPs will provide suitable power. However, for genome-scan mapping a panel of high d markers must be chosen to achieve sufficient power. The results of these simulations indicate that MALD can and should be an important technique for mapping complex disease genes, and has more statistical power than other mapping methods. The results of current efforts comparing the power of MALD to the power of affected sib-pair mapping will also be discussed.

Program Nr: 2494 from the 1999 ASHG Annual Meeting

Role of candidate regions for asthma susceptibility on Sardinian population. *G. Pilia[1,2], N. Olla[1], L. Balaci[1,2], C. Spada[2], M. Fattori[2], M.P. Pinna[2], D. Altea[1,2], G. Sole[1], V. Brancolini[3], M. Devoto[3], A. Cao[1,2].* 1) Istituto di Clinica e Biologia Eta' Evolutiva, Universita' di Cagliari, Cagliari, Italy; 2) Istituto di Ricerca sulle Talassemie ed Anemie Mediterranee, CNR, Cagliari, Italy; 3) Dipartimento di Oncologia, Biologia e Genetica, Universita' di Genova, Genova, Italy.

Asthma is one of the most common chronic diseases in all industrialized countries, affecting 2-4% of the population. Several attempts have already been made to identify genes responsible for asthma susceptibility, but, unfortunately, we are still far from the full characterization of the genes that underlie this complex condition. A problem that is often encountered when dealing with complex traits is the presence of genetic heterogeneity, both of loci and of alleles, which lowers the power to detect linkage. Such a problem is alleviated and may be virtually eliminated when one analyzes an isolated population, in which we expect restricted number of loci and number of mutations to have occurred. Sardinians are one such population. On 100 affected sib-pairs (from 80 Sardinian families with two or more affected sibs) genotyping of 61 markers from the following candidate regions has been performed: Ch.4q33-35, 5q31-q33, 6p21.3, 7p21-15, 11pter-p15, 13q14.1-q14.2 and 16q22.1-q22.1. We carried out an affected sib-pair analysis with the MAPMAKERS/SIBS program. Our results support the view that Ch.4, 5, 11, and 13 may contain genes relevant to asthma. A single region produced suggestive (and nearly significant) evidence of linkage: the region near D13S164 on Ch.13 yielded a single-point lod-score of 3.1. Despite the genetic complexity of asthma, it is therefore possible that our population may provide the resolving power to identify the gene(s) responsible for linkage in each positive candidate regions. This encouraging outcome of our project shows also that the size of the already available Sardinian sample collection is large enough to be used as a primary sample for a whole genome linkage analysis.

Program Nr: 2495 from the 1999 ASHG Annual Meeting

Alpha-2-macroglobulin (Val1000Ile) polymorphism in Finnish late onset Alzheimer's disease patients. *M. Pirskanen[1, 2], M. Hiltunen[1, 2], S. Helisalmi[1, 2], A. Mannermaa[2], A.M. Koivisto[1], M. Lehtovirta[1], I. Alafuzoff[1, 3], H. Soininen[1]*. 1) Department of Neurology, Kuopio University Hospital, Kuopio, Finland; 2) Chromosome and DNA laboratory, Kuopio University Hospital, Kuopio, Finland; 3) Department of Pathology, Kuopio Univ, Kuopio, Finland.

Alpha-2-macroglobulin (a-2M; encoded by the gene A2M) is a serum pan-protease inhibitor that has been implicated in Alzheimer disease (AD) based on its ability to mediate the clearance and degeneration of Ab, the major component of senile plaques characteristic in AD. Recently it was suggested that the A2M polymorphism, Val1000(GTC)/Ile1000(ATC) is associated with the AD. The aim of this study was to find out whether there is an association with A2M and Finnish late onset AD patients. Alpha-2-macroglobulin polymorphism (Val1000Ile) was genotyped from 47 clinically defined late onset AD patients (>65 years) and 50 age matched controls from Eastern-Finland. Genotyping was done with standard PCR and RFLP methods. No association (c2, p = 0.79) was found between AD (A/A 0.33, A/G 0.5, G/G 0.17) and control (A/A 0.28, A/G 0.5 G/G 0.22) genotype. The allele frequencies did not differ statistically (c2, p = 0.56) between groups as the frequencies of A- and G-allele were 0.58 and 0.42 in AD, and 0.53 and 0.47 in controls, respectively. Combining the A/A and A/G or G/G and A/G genotypes to the same category did not reveal differences between AD and control groups (c2, p = 0.62, OR 1.24 (0.49-3.69) and c2, p = 0.67, OR 0.8 (0.33-1.92)). This preliminary data suggests no association between A2M polymorphism (Val1000Ile) and Finnish late onset AD patients.

Program Nr: 2496 from the 1999 ASHG Annual Meeting

Genome-wide screen for the autosomal dominant familial adult myoclonus epilepsy (*fame*) locus. *N.M. Plaster[1], E. Uyama[2], L.J. Ptacek[1]*. 1) Human Genetics, University of Utah, Salt Lake City, UT; 2) Dept. of Neurology, Kumamoto University School of Medicine, Kumamoto, Japan.

Epilepsy is a complex group of disorders affecting approximately 1-3% of the population. The contribution of genetic factors to epilepsy is well recognized. We have collected four familial adult myoclonus epilepsy (FAME) families from Japan, including 22 affected individuals. These individuals' affected status is characterized by autosomal dominant, adult onset, myoclonus of the extremities, and rare generalized tonic-clonic seizures. To determine the location of the *fame* locus, we have performed a genome-wide linkage screen with 65 microsatellite markers spaced 40 to 60 cM apart. The results of linkage analysis indicate four regions of the genome on chromosomes 9, 12, and 13, in which the LOD scores are 0.7 to 1.2. Additional markers flanking these regions are being investigated further, to identify the *fame* locus. Concurrently, we are increasing our marker coverage for the genome-wide screen to a spacing of 20 to 40 cM (>100 markers total), in order to determine additional regions of interest. Identification of the *fame* gene will provide invaluable insights into the etiology of FAME and possibly, phenotypically similar disorders such as juvenile myoclonus epilepsy. Furthermore, investigation of the FAME protein will help us better understand the molecular mechanisms of neuronal hyperexcitability and the etiology of epilepsy.

Program Nr: 2497 from the 1999 ASHG Annual Meeting

High frequency of mutations in the WFS1 (wolframin) gene in patients with Type 1 diabetes. *F. Pociot, Z.M. Larsen, J. Nerup.* Steno Diabetes Ctr, Gentofte, Denmark.

Type 1 diabetes is a multifactorial disease. It has become evident that Type 1 diabetes may be much more heterogeneous than previously assumed. No disease specific mutations have been identified so far. Candidate gene(s) may be derived from knowledge of other diseases where an impaired beta-cell function is observed. Wolfram syndrome is sometimes referred to as DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness). Insulin-dependent, non-autoimmune diabetes is required for establishing the diagnosis. Pronounced clinical heterogeneity exists in Wolfram syndrome. Therefore, genetic variation(s) leading to only the diabetic phenotype may exist. Recently, the Wolfram syndrome gene was mapped to 4p16. The gene, WFS1 (wolframin), encodes a predicted 890-amino acid transmembrane protein. WFS1 appears to function in survival of islet beta-cells and neurons. Most mutations of WFS1 related to Wolfram syndrome have been located in exon 8. We sequenced exon 8 of 29 Type 1 diabetics, all with age-at-onset less than 10 years, and negative for autoantibodies (GAD65 and IA-2). We have so far identified 5 mutations of the coding part of exon 8, two of which result in amino acid substitutions, and 3 mutations of the 3UTR part of exon 8. In total, we found mutations in 21 of the 29 individuals investigated. Four of the five mutations of the coding region, including one of the missense mutations, were found in at least four non-related individuals, making them potential SNPs useful for large linkage and/or association studies.

Program Nr: 2498 from the 1999 ASHG Annual Meeting

Candidate gene analysis of TGFA, EDN-1, and MTHFR, and the influence of maternal smoking in nonsyndromic cleft lip and palate. *NJ. Prescott, D. Kelberman, MM. Lees, RM. Winter, S. Malcolm.* Molecular and Clinical Genetics, Institute of Child Health, London, UK.

Nonsyndromic cleft lip with or without cleft palate (CL/P) is a common malformation of the face affecting at least 1 in 1000 Caucasian live births. This complex multifactorial disorder exhibits heritability, demonstrated by a high sibling relative risk (l_s»30) where between 2-10 susceptibility loci may have an effect. Factors such as smoking and maternal nutrition are also thought to influence lip and palate formation, interacting with genetic factors to produce the resulting cleft phenotype.

Traditionally, genetic dissection of this complex trait has been via candidate gene selection. We have adopted a genome wide approach for selecting candidate loci. We recently completed a genome search of 91 affected sibpairs and highlighted several areas which deserve further investigation. These include the TGFA locus (p=0.04), previously associated with CL/P, and thought to interact with maternal smoking, 6p24-23 (p=0.008), originally identified through chromosomal breakpoints in cleft individuals, and a third area at 1p36 (p=0.009) which harbours the Methylenetetrahydrofolate Reductase (MTHFR) gene involved in folate metabolism.

For the second phase of this study we have used 72 affected sib pair pedigrees and 48 trios in an ongoing candidate gene evaluation, to examine polymorphic variants of TGFA(2p13), Endothelin-1(6p24-23), and MTHFR(1p36) by T/DT and determine the interaction of maternal smoking. We have demonstrated skewed transmission of the uncommon alleles of TGFA TaqI RFLP, EDN-1 TaqI RFLP and the MTHFR heat labile variant, although sufficient significance has not yet been obtained (p=0.062, p=0.076, p=0.075 respectively),probably due to the limited size of the cohort. Preliminary findings suggest the prevalence of these alleles in cleft offspring do not appear to be significantly associated with maternal smoking. This is an ongoing study and we are continuing to recruit families for T/DT analysis of these and other candidate genes.

Program Nr: 2499 from the 1999 ASHG Annual Meeting

Familial clustering for extreme longevity in humans. *A.A. Puca[1], S.J. Brewster[1], J. Bowen[2], E. Joyce[2], S.B. Ridge[2], M. Shea[2], M. Daly[3], T. Perls[2], L. Kunkel[1].* 1) Genetics Division, Howard Hughes Medical Institute, Children's Hospital and Harvard Medical School, Boston, MA; 2) Gerontology Division, Beth Israel Deaconess Medical Center, Harvard Division on Aging, Boston, MA; 3) Center for Genome Research at the Whitehead Institute for Biomedical Research, Cambridge, MA.

Twin studies of people reaching the age of 85 have previously concluded that genetics play only a minor role in life expectancy. Here we describe 4 families (A-D) which clearly show the segregation of extreme old age.

Family A is composed of 2 males and 4 females aged 100 or greater living in the 17th and 18th centuries. In family B there are 7 individuals, including males, who have lived to at least the age of 101. In family C, you have an sibship of 13 children with 8 reaching extreme old age including a female who is currently 102 years old. The remaining 5 siblings are >80 years of age and in good health. Family D is composed of two branches linked together by a marriage in the 3rd generation. In the 3rd generation, one sees 23/46 individuals living to extreme old age. Of these individuals, 2 lived to the age of 100 or older.

In order to confirm the hypothesis that human longevity is in fact a genetically determined condition, a binomial analysis has been performed for the single most impressive generation of each family. Cohort life tables for the years 1900, 1850 and 1801 were used to estimate the probability of individuals from families A-D to survive to their specified ages. These specific probabilities were then used to calculate a binomial probability of obtaining N individuals achieving their specified ages from a random sample of M individuals belonging to specific birth cohorts. This analysis clearly demonstrates that there is familial aggregation that cannot be explained by random chance but only by the genetic determination of extreme longevity.

Additional families need to be recruited in which there are living individuals of extreme old age in order for linkage analysis to be performed.

Program Nr: 2500 from the 1999 ASHG Annual Meeting

Evidence for the genetic heterogeneity of human papillomavirus-associated epidermodysplasia verruciformis: susceptibility loci on 2p and 17qter. *N. RAMOZ[1], A. TAIEB[2], L.-A. RUEDA[3], M.-J. RUEDA[3], M. FAVRE[1], G. ORTH[1].*
1) Unité mixte PAPILLOMAVIRUS/U190 INSERM, INSTITUT PASTEUR, PARIS, FRANCE; 2) Unité de DERMATOLOGIE PEDIATRIQUE, Hôpital PELLEGRIN-ENFANTS, BORDEAUX, FRANCE; 3) Unidad DERMATOLOGICA, SANTAFE DE BOGOTA, DC COLOMBIA.

Epidermodysplasia verruciformis (EV; MIM#226400) is a rare genodermatosis with an autosomal recessive mode of transmission. The disease is characterized by an abnormal genetic susceptibility to infection with a specific group of related human papillomavirus (HPV) genotypes, including the oncogenic HPV5 associated with the skin carcinomas observed in about half of the patients. EV is thus a model to understand the genetic factors involved in the control of infections with HPVs, in particular the widespread oncogenic HPV genotypes associated with invasive cervical carcinoma. The genes involved in the predisposition to EV HPV infections remain to be identified. By homozygosity mapping in three consanguineous EV families, we recently localized a first EV locus (EV1) to a 1-centiMorgan (cM) interval on chromosome 17qter in a region containing a locus for the susceptibility to familial psoriasis. We had reported that psoriatic patients are likely to constitute a reservoir of HPV5. This suggests that distinct defects of the same gene might be involved in the two skin disorders.

Analysis of microsatellite markers encompassing EV1 locus in two additional consanguineous EV families confirmed the linkage with EV1 in a single family. A genome-wide search in the second family disclosed a new disease locus (EV2) on chromosome 2p. Segregation analysis with microsatellite markers and recombination events allowed to limit the EV2 locus to a 8-cM interval. The disclosure of two distinct susceptibility loci for EV provides evidence for the genetic heterogeneity of the disease and for the multiplicity of controls in infection by oncogenic HPV genotypes.

Program Nr: 2501 from the 1999 ASHG Annual Meeting

Linkage Analysis of Human Systematic Lupus Erythematosus Related Traits. *S. Rao[1], JaneM. Olson[1], C. Gray-McGuire[2], K.L. Moser[2], J.B. Harley[2].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH 44109; 2) Arthritis and Immunology Program and Protein Study Program, Oklahoma Medical Research Foundation, Oklahoma City, OK 73004.

Systematic lupus erythematosus (SLE) is an autoimmune disorder characterized by the production of autoantibodies against intracellular antigens, including DNA. Several organ systems may be affected but there is considerable variability among SLE patients in the clinical manifestation of the disease. Little is known about whether observed clinical variability is due to environmental effects, heterogeneity of SLE loci, or modifying genes. We studied 101 SLE affected sib pairs for presence or absence of dermatological (DM), renal (RN), immunological (IM), hematological (HM), neurological (NR), cardiopulmonary (CP) and arthritic (AR) symptoms. Of these, renal and cardiopulmonary showed the strongest evidence of familial aggregation. For multivariate linkage analysis, we obtained nine principal components from the seven traits plus race and age-at-onset. We analyzed genome scan data using the multivariate version of the new Haseman-Elston regression model (SIBPAL2). The largest signal for an individual trait was on chromosome 2 (IM, P=0.00048). The largest multivariate signal was on chromosome 7 (P=0.0029). Of the individual organ systems, DM had the largest effect (P=0.0083) at this location. Because DM is negatively correlated with most other traits, this result might indicate the presence of gene that is responsible for a subtype of SLE or modifying the SLE phenotype.

Program Nr: 2502 from the 1999 ASHG Annual Meeting

Genetic heterogeneity of X-linked thrombocytopenia mapping to Xp11-12. *W. Raskind[1], K. Niakan[1], J. Wolff[1], M. Matsushita[1], T. Vaughan[1], C. Watanabe[2], J. Rios[2], H. Ochs[2].* 1) Dept of Medicine and; 2) Dept of Pediatrics, Univ of Washington, Seattle, WA.

X-linked thrombocytopenia and thalassemia (XLTT, OMIM 314050) is a rare disorder characterized by thrombocytopenia, platelet dysfunction, splenomegaly, reticulocytosis, and unbalanced hemoglobin chain synthesis resembling b-thalassemia trait. In a 4-generation family, we mapped XLTT to chromosome Xp11-12. The maximum lod score possible in this family, 2.39, was obtained for DXS8054 and DXS1003 at q = 0. Recombination events observed for XLTT and DXS8080 and DXS991 define a critical region of 7.65 KcM containing the *WASP* gene responsible for Wiskott-Aldrich Syndrome (WAS, OMIM 301000) and its allelic variant X-linked thrombocytopenia (XLT, OMIM 313900). The manifestations of WAS include thrombocytopenia, eczema and immunodeficiency. In contrast to WAS/XLT in which the platelets are small and bleeding is proportional to the degree of thrombocytopenia, in XLTT platelet morphology is normal and the bleeding time is disproportionately prolonged. To evaluate WASP as a candidate gene for XLTT, cDNA from affected males was examined by ddF. No alterations were seen in the ddF pattern. Western blot and flow cytometric analyses revealed the presence of normal amounts of normal sized WASP protein. Finally, no sequence alteration was found in the 12 WASP exons. X-inactivation patterns were evaluated using methylation differences in the HUMARA locus. As has been reported for WAS and some cases of XLT, almost total inactivation of the XLTT-bearing chromosome was observed in granulocytes and mononuclear cells from one asymptomatic obligate carrier. The only XLTT carrier previously found to have an elevated a:b hemoglobin chain ratio had a skewed pattern favoring activity of the abnormal allele. These findings make it very unlikely that XLTT is another allelic variant of WAS/XLT and strongly suggest that X-linked thrombocytopenia is a genetically heterogeneous disorder. An X-linked syndrome of mental retardation and a-thalassemia (ATR-X, OMIM 300032) is caused by mutations in the helicase gene XNP in Xq13. The possibility that the XLTT gene is a transcription regulator is being investigated.

Program Nr: 2503 from the 1999 ASHG Annual Meeting

Localization of a gene for adult-onset primary open-angle glaucoma to the *GLC1B* locus at chromosome 2cen-q13 in a French-Canadian family. *V. Raymond[1], M. Faucher[1], S. Dubois[1], G. CÔté[2], J.L. Anctil[2], J. Morissette[1]*. 1) Molecular Endocrinology, Laval University Hospital (CHUL) Research Ctr, Quebec, PQ, Canada; 2) Dept. of Ophthalmology, Laval University, Quebec, PQ.

Genetic factors play a major role in the etiology of primary open-angle glaucoma (POAG) and hereditary forms of the disorder have been mapped to at least 7 loci. To counteract this important genetic heterogeneity, we have recruited 24 large French-Canadian glaucoma families showing potential founder effects. One of these kindreds comprised 132 individuals over 4 living generations. To identify the location of the disease-causing gene, we performed a genetic linkage study and an haplotype analysis. Criteria for POAG were: intraocular pressures (IOP) > 22 mm Hg, optic nerve degeneration and open-angle gonioscopy. Out of the 28 persons who were investigated, 7 were diagnosed with autosomal dominant POAG and 2 showed ocular hypertension (OHT) with bilateral IOPs > 22 mm Hg. Age at onset, defined as age at which OHT was first detected, ranged from 38 to 58 years old. Genotyping was performed using Généthon markers selected to cover 9 candidate regions: *GLC1A* at 1q23-q25, *GLC1B* at 2cen-q13, *GLC1C* at 3q21-q24, *GLC1D* at 8q23, *GLC1E* at 10p14-p15, *GLC1F* at 7q35, *IRID1* at 6p25, *IRID2* at 4q25 and 11p13. For linkage analyses, OHT and POAG patients were considered affected. Evidence of linkage was observed between the affected phenotype and markers located at *GLC1B*. Two-point lod score values reached a maximum of 2.97 with marker AFMa333vh5 (D2S388) at q=0. Preliminary multipoint analyses supported these data with lod score values near 3. The same characteristic haplotype comprising 12 markers was recognized in all persons affected by either POAG or OHT. Two key affected recombinants confined the disease region within an interval of less than 8 cM. These findings demonstrated that the *GLC1B* locus is associated with adult-onset POAG in at least one French-Canadian family. These observations also confirmed the mapping of a glaucoma locus at 2cen-q13 in families ascertained in the United Kingdom (Stoilova & al., Genomics 1996, 36:142-150).

Program Nr: 2504 from the 1999 ASHG Annual Meeting

Association of a CD14 promoter polymorphism and atopic phenotypes. *N.E. Reijmerink[1], G.H. Koppelman[1,2], O.C. Stine[3], D.G. Wiesch[3], D.A. Meyers[3], E.R. Bleecker[3], D.S. Postma[1]*. 1) University Hospital Groningen,; 2) Beatrixoord Rehabilitation Center, The Netherlands; 3) Center for the Genetics of Asthma and Complex Diseases, University of Maryland, Baltimore, USA.

Background: Asthma, a serious chronic airway disease characterized by bronchial hyperresponsiveness and airway inflammation is a complex disease with major a genetic component. Atopy, an immunologic state of hypersensitivity to environmental allergens characterized by high levels of IgE is a very important aspect in asthma. A recent study suggests that a polymorphism in the promoter region of CD14 may have a central role in regulating atopic phenotypes, such as high levels of IgE and positive skintest responsiveness. CD14 is a multifunctional surface receptor, localized on monocytes and macrophages. One of its functions is to bind lipopolysaccharide (LPS). After binding to LPS, CD14 may inhibit IgE production.

Methods:A case-controle study was used and phenotypes related to atopy as well as asthma were studied.159 adult patients with asthma and 158 spouses (n=317) from a restricted Dutch population were analyzed with restriction enzyme *AVA*II, for a polymorphism in the promoter region of the CD14 gene (a C to T transition at position -159).

Results: Allele frequencies for CC were 25.9%, CT 50.8% and TT 23.3%. In a recessive model, CC homozygotes had higher levels of serum total IgE (p=0.036) and higher numbers of positive skintests (p=0.008). There was no significant association between this polymorphism and asthmatic phenotypes.

Conclusion: This study suggests that the CD14 gene plays an important role in regulating atopic phenotypes.

We thank Dr.F.Martinez for the use of the primers. Supported by the Netherlands Asthma Foundation, the Jan Kornelis de Cock-Stichting and the National Institute of Health(HL48341).

Program Nr: 2505 from the 1999 ASHG Annual Meeting

Modification of a YAC deletion vector aids SNP detection and mapping. *J.H Riley, K. Lewis, R. Khakhar, L. Hosking, I.J. Purvis.* Molecular Genetics, Glaxo Wellcome Medicines Research Centre, Stevenage, Hertfordshire, U.K.

A yeast artificial chromosome (YAC) deletion method has been developed to aid the isolation and mapping of single nucleotide polymorphisms (SNPs) across two complex disease loci. The method exploits recombination in the yeast cell between the linearised YAC deletion vector, pBCL and the human insert of the YAC. The recombination is directed via human alu repeats which undergo random recombination and subsequent deletion of the YAC to generate sets of deletion derivatives from the parental YAC. Ends of deletants can be captured, sequenced and SNPs subsequently identified and physically mapped. Initial experimentation generated deletion derivatives containing large gaps between the deletants of up to 500kb and very few deleted YACs of less than 150kb. To improve the coverage and hence the mapping, modifications to the vector were made. A vector containing an inverted alu was constructed and a further four vectors containing different alu family members were created. The experiments were designed to enable the specificity of the recombination event to be determined and to generate a nested set of deletants with a largest gap size of no greater than 250kb and an average gap size of 100kb. This technology was applied in two complex disease loci mapping to different chromosomes. YAC contigs were generated for each. Across both loci YACs were subjected to the deletion protocol using pBCL alone. The recombination for one YAC clearly showed a large number of deletants of the same size. However, when the deletion experiment was repeated with the newly constructed vectors, a range of different sized deletion derivatives was observed. This demonstrates the specificity of the recombination event and the advantage of utilising more than one vector. The YAC deletion technology not only provides a tool for accurate mapping of SNPs but it also enables sequences to be generated at specific points across a locus by end capture of the deletion derivatives.

Program Nr: 2506 from the 1999 ASHG Annual Meeting

DataTracker: Comprehensive software for data quality control protocols in complex disease studies. *J.B. Rimmler, C.S. Haynes, J.G. McDowell, J.E. Stajich, C.S. Adams, B.D. Slotterbeck, A.R. Rogala, S.G. West, J.R. Gilbert, E.R. Hauser, J.M. Vance, M.A. Pericak-Vance.* Center For Human Genetics, Duke University Medical Center, Durham, NC.

The study of human disease traits of complex genetic architecture is a rapidly expanding area. High throughput genotyping is now the norm. The structure of families under analysis is smaller and more variable and sample sizes are increasing. Protocols dealing with quality control [QC] issues of these data, however, have lagged behind technological advancement. Thus, we have designed and implemented a series of protocols for each of the critical steps in the processing of the associated laboratory data. In addition we have developed a program, DATATRACKER, to perform the quality control [QC] assessments of these data. Specifically, an auxillary program, ScreenKey_Create, uses DNA sample lists to automatically generate gel plate loading diagrams, gel reader template files, and QC sample keys. QC Samples (or duplicated samples) are positioned on a gel [6 per gel] and DNA is dispensed robotically for analysis. Technicians are blinded with respect to the location of the QC duplicates to avoid bias in interpretation of results. These steps serve to ensure the consistency of readings and to identify problems such as misloads, gel reading errors, and sample mix-ups across gels.

Once the initial genotype generation is complete, the results undergo a series of QC checks that identify problems such as incorrect formatting, typographical errors, inconsistancy of CEPH standards, and low efficiency levels. Problems are automatically e-mailed to the technician and QC supervisor for re-examination and correction. QC summary statistics are databased by projects and markers, and summary reports automatically produced. Statistics databased include the genotyping list used, date of QC analysis, marker efficiency, % QC match, technician, and date data passed all QC checks. Specific protocols, report examples and summary statistics will be presented for this system as a prototype for other researchers involved in the study of complex traits.

Program Nr: 2507 from the 1999 ASHG Annual Meeting

Familial congenital isolated ptosis with dominant inheritance and equal expression in males and females: a new truly dominant X linked condition. *D.O. Robinson[1], A.G. Tyers[2], T.F.W. McMullan[1,2]*. 1) Wessex Regional Genetics Lab, Salisbury District Hosp, Wiltshire, England; 2) Dept. of Ophthalmology, Salisbury District Hosp., Wiltshire, England.

Ptosis (blepharoptosis) is defined as the abnormal drooping of the upper eyelid and results in reduction of the field of vision. The condition is a feature of many syndromes and can be both unilateral or bilateral, congenital or acquired. Ptosis can also be present as a sole feature with no other abnormalities. We have studied a family from Wessex in the UK in which dominantly inherited congenital ptosis is segregating. Ptosis is present as a sole feature, is bilateral and equal in severity in males and females. DNA samples from 28 family members including 15 affected individuals have been analysed by linkage analysis. No male to male inheritance was evident so analysis was carried out using markers along the whole length of the X chromosome at 10-15cM intervals. Linkage to Xq25-27.1 was established with a LOD score of 2.7 at DXS1212 with no recombination. Two females in the pedigree have the at risk haplotype but do not have ptosis. This could be either due to double recombination or to non-penetrance. In one of these females unilateral X inactivation was shown in DNA from blood which could be the cause of non-expression of the phenotype. The only other documented pedigree with ptosis as the sole feature and with genetic linkage data is that of Engle et al (Am J Hum Genet 1997, 60, 1150-1157). They established linkage to chromosome 1p32-34.1 in an American family with dominant inheritance. We have therefore identified a second gene for isolated ptosis and defined a new condition namely X-linked dominant congenital isolated ptosis. Furthermore there appears to be equal expression of ptosis in both males and females which is very unusual. For most X linked dominant conditions males are affected more severely than females. This therefore defines a truly dominant X linked condition.

Program Nr: 2508 from the 1999 ASHG Annual Meeting

Autosomal dominant pure Spastic Paraplegia in a Brazilian family: Linkage to chromosome 8q and study of muscle syntrophin b**1.** *P.S. Rocco[1], M. Vainzof[1,2], S.C. Froehner[3], S.K.N. Marie[2], L.M. Kunkel[4], M.R. Passos-Bueno[1], M. Zatz[1]*. 1) Centro de Estudos do Genoma Humano, Dept. of Biology, IB-USP, Sao Paulo, Brazil; 2) Dept. of Neurology, FMUSP; 3) Dept. of Cell and Molecular Physiology, School of Medicine, UNC-Chapel Hill, PH, USA; 4) Division of Genetics and the Howard Hughes Medical Institute, Childrens Hospital, Boston, USA.

Autosomal Dominant hereditary spastic paraplegia (AD-HSP) include a genetically heterogeneous group of degenerative disorders of the central motor system, characterized by progressive spasticity of the lower limbs. AD-HSP may be sub classified into pure and complicated forms based on the presence of additional neurological features. Four loci for pure AD-HSP have been identified up to date: SPG3 on chromosome 14q, SPG4 on chromosome 2p, SPG6 on chromosome 15q, and more recently SPG8 on chromosome 8q (Hedera et al., 1999). We have analyzed a Brazilian family with 15 affected individuals by pure AD-HSP (8 males and 7 females) who developed insidiously progressive gait disturbance with onset at age 18-26 years. Linkage analysis performed with 13 family members (6 affected and 7 normal) excluded SPG3, SPG4 and SPG6 as candidate regions. However, positive LOD scores were obtained with markers close to the SPG8 locus (Z max=3.01 at theta=0 for D8S1804, D8S568, and MYC). In this region lies syntrophin b1 gene (SNT2B1), a widely expressed dystrophin-associated protein and therefore a good positional and functional candidate for this disease. We performed immunohistochemical (IF) and Western Blot (WB) studies using an antibody to syntrophin b1 in a muscle biopsy from one affected male. The distribution, expression and MW of the protein were comparable to normal control. Therefore, it is unlikely that defects in this protein is causing SPG8, at least in the present family. Additional DNA studies will be performed to definitively exclude the SNT2B1 gene as a candidate for SPG8. We are also currently performing linkage analysis with other markers and including other 4 affected individuals in an attempt to narrow down the previous mapped region. Supported by FAPESP, CNPq, PRONEX and CAPES.

Program Nr: 2509 from the 1999 ASHG Annual Meeting

Localization of genes predisposing to acute leukemia in Down syndrome. *P.K. Rogan[1], D.W Sabol[2], P. Close[3].* 1) Section of Medical Genetics & Molecular Medicine, The Children's Mercy Hospital and Clinics, Kansas City, MO; 2) Phylogenetix Laboratories, Pittsburgh, PA; 3) Division of Pediatric Hematology/Oncology, Harbor-UCLA Medical Center, Torrance, CA.

Constitutional chromosome 21 aneuploidy in blasts from children with Down syndrome can predispose to additional segregation errors resulting in either increased gene dosage or loss of heterozygosity (LOH). Eight of 16 patients enrolled in protocol CCG-B957 exhibited reduction to germline homozygosity at one or more loci on the non-disjoined chromosome. Three genetic intervals displayed disomic homozygosity and significant linkage to the disease locus in a cohort of patients with acute lymphocytic leukemia (ALL; n=5), and acute myeloid leukemia (AML; n=3). Linkage to centromeric 21q loci (Z_{max}=2.41)confirmed and refined the interval associated with transient leukemoid reaction and AML-type M7 in this population. LOH at D21S16 and D21S13 on the normally disjoined chromosome (a possible second hit) was also detected in 2 individuals who exhibited disomic homozygosity within this interval. The second interval (Z_{max}=3.30) overlapped the region containing a familial platelet disorder disease locus (FPDMM). The third interval spanned HMG14 through D21S266 (Z_{max}=3.01). Somatic LOH was also detected in 2 patients at D21S1434 and D21S1436, respectively, and in 3 patients at D21S1280 and D21S262, both of which are linked to the TIAM1 gene. Patients may carry homozygous recessive alleles on non-disjoined chromosomes that are sometimes unmasked by somatic mutations on the normally disjoined chromosome.

Program Nr: 2510 from the 1999 ASHG Annual Meeting

FRAGMENT ANALYSIS PERFORMANCE ON THE ABI PRISM® 3700 DNA ANALYZER. *M. Roque-Biewer, Y. Wang, K. Rogers, A. Wheaton, M. Rivera, N. Caffo, P. Dong.* Genetic Analysis, PE Biosystems, Foster City, CA.

The 3700 DNA Analyzer is a fully automated high-throughput capillary array instrument designed to operate in a 24-hr unattended mode that can process hundreds of samples daily. In fragment analysis, the current dye set uses 6FAM, HEX, NED and ROX. The use of 4 dyes in a single lane for fragment analysis allows the generation of up to 400 genotypes per day on the ABI PRISM 310 Genetic Analyzer and 4,500 genotypes per day on the ABI PRISM 377 DNA Sequencer (96-lanes/3runs per day). The new 3700 DNA Analyzer, will be able to generate up to 15,000 genotypes in a 24-hr period. We have optimized the 3700 DNA Analyzer for microsatellite applications. We will show resolution and sizing precision across the capillary array under standard and varying conditions (run voltage, injection time, injection voltage, etc.). Utilizing the associated GeneScan NT and Genotyper NT software, we will show that the system can assign a size in nucleotide (nt) to a fragment with standard deviation of < 0.15 nt up to 300 nt. We will also show compatibility of the linkage mapping suite of reagents with the instrument.

Program Nr: 2511 from the 1999 ASHG Annual Meeting

Linkage of a Large Family with Hereditary Spastic Paraplegia to Chromosome 2p. *D.R. Rosen[1], N.H. Chapman[2], C. He[1], T.F. Thurmon[3], E.M. Wijsman[2, 4].* 1) Div Genetic Disorders, Wadsworth Ctr, Albany, NY; 2) Dept. of Biostatistics, University of Washington Seattle, WA; 3) Louisiana State University Medical Center, Shreveport, LA; 4) Division of Medical Genetics, University of Washington Seattle, WA.

Hereditary spastic paraplegia (HSP) is a group of disorders caused by the degeneration of corticospinal motor neurons, resulting in loss of strength and coordination of the legs. We have performed linkage analysis on a large American family with uncomplicated hereditary spastic paraplegia. Clinical features of this family's HSP include gait disturbances and hyperreflexia; the family is remarkable in that leg spasticity and a positive Babinski sign are not obligate features of the disorder. The mode of inheritance in this family is autosomal dominant. Current size of this family is greater than 600 individuals covering 9 generations. Of these, 49 cases of HSP have been documented. Blood samples from 38 family members, including 13 HSP-affected individuals, were collected. Linkage analysis was performed on a total of 83 family members, including this set of 38 individuals, for four previously reported HSP loci at chromosomes 2p, 8q, 14q, and 15q. Negative lod scores were obtained for 2 markers at 8q, 3 markers at 14q, and 3 markers at 15q. Positive lod scores were obtained for 13 DNA markers on chromosome 2p. A peak lod score of 3.87 at a recombination fraction of 0.001 was obtained for D2S2374. These results suggest that this family has a mutation linked to the SPG4 locus on chromosome 2. Because the HSP in this family was previously demonstrated to exhibit anticipation, further evidence for a dynamic mutation at the SPG4 locus is suggested.

Program Nr: 2512 from the 1999 ASHG Annual Meeting

Genetic Mapping of a Locus for Amish Microcephaly. *M. Rosenberg[1], R. Agarwala[4], M.S. Hilliard[1], J. Weber[5], D.H. Morton[3], A.A. Schaffer[4], R.I.. Kelley[2], L.G. Biesecker[1].* 1) GDRB, NHGRI/NIH, Bethesda, MD; 2) Kennedy-Krieger Inst, Baltimore, MD; 3) The Clinic for Special Children, Strasbourg, PA; 4) NCBI, NLM, NIH, Bethesda, MD; 5) Marshfield Clinic, WI.

Amish microcephaly is a syndrome that includes severe congenital microcephaly, hypertonia, irritability, and premature death, usually at six to 15 months of age. The disorder is inherited in an autosomal recessive pattern and is only known to occur in Old Order Amish who have ancestors in Lancaster County, Pennsylvania. We analyzed an extended kindred with this condition that included 21 nuclear families who had an affected child. A single pedigree was constructed that connected all of these nuclear families in a systematic and automatic manner using PedHunter software, the Steiner tree software package of T. Kock and A. Martin and the Amish Genealogy Database. A whole genome linkage scan was performed on a subset of eight families using semi-automated fluorescent genotyping. Two-point LOD scores were calculated for all markers and the phenotype using a model of autosomal recessive inheritance and full penetrance with the FASTLINK software package 4.0P. Positive markers with a LOD > 3 or (LOD > 2 and an adjacent locus with LOD > 1) were further analyzed by typing additional flanking markers and additional samples. Ten markers met these criteria and additional manual genotyping excluded all but one of these loci. The remaining positive screening marker was D17S1301. We mapped the disease locus to chromosome 17q with a three-point LOD score of 3.87 using markers D17S1603 and D17S1301 and a pedigree with six consanguinity loops. We conclude that Amish microcephaly is a single gene disorder that perturbs prenatal CNS development and the gene for this disorder maps to distal chromosome 17q.

Program Nr: 2513 from the 1999 ASHG Annual Meeting

Candidate regions in MS monitored using SNP microarray. *J. Saarela[1], H.M Frostad Riise[1], T. Pastinen[2], M. Schoenberg Fejzo[1], D. Chen[1], S. Kuokkanen[3], L. Peltonen[1].* 1) Human Genetics, UCLA, school of medicine, Los Angeles, CA; 2) University of Helsinki and National Public Health Institute, Dept. of Molecular Genetics, Helsinki, Finland; 3) Cancer Genetic Branch, NHGRI, NIH, Bethesda, MD, 20892.

Multiple sclerosis (MS) is a demyelinating disorder of the central nervous system with a putative autoimmune etiology. It is the most common cause of acquired neurological dysfunction of young adults. Genetic susceptibility to MS is implicated on the basis of twin and family studies. Several putative susceptibility loci have been identified by other groups and us but only the HLA region on chromosome 6p has repeatedly shown definitive association to MS. Among the interesting, putative loci are two relatively wide chromosomal regions on chromosomes 5p14-p12 and 17q22-q24, which are syntenic to mouse chromosomes 15 and 11, respectively, and harbor susceptibility loci for murine EAE. To restrict these chromosomal areas by identifying a shared haplotype between affected individuals, we produced a microarray for genotyping SNPs spanning these regions. In the first SNP microarray we used 22 SNPs on chromosome 5 and 17 on chromosome 17 from existing databases. The second SNP array contains novel, intragenic SNPs created from ESTs mapped to these regions. We have also sequenced several candidate genes on 17q22-q24 including ICAM-2, PECAM 1, myeloperoxidase, and apolipoprotein H and identified several novel polymorphisms. Our SNP array utilizes specificity of the RNA reverse transcriptase to detect the variable nucleotide. PCR products from genomic DNA containing either T3 or T7 RNA polymerase transcription start sites, are *in vitro* transcribed to RNA, and subsequently converted to cDNA with the RT enzyme and one of the detection primers attached to the slide having the right variable nucleotide as the most 3' nucleotide. The RT enzyme incorporates CYP-labeled nucleotides to cDNAs which are detected by a laser scanner. In the Finnish MS study material we will monitor for association between MS and SNPs on the linked chromosomal regions. This approach should aid us in identification of predisposing genes for MS.

Program Nr: 2514 from the 1999 ASHG Annual Meeting

An Updated Genome Screen for Platelet Monoamine Oxidase (MAO) Activity. *N.L. Saccone[1], J.P. Rice[1], N. Rochberg[1], J.T. Williams[2], A. Goate[1], T. Reich[1], S. Shears[1], W. Wu[1], J.I. Nurnberger Jr.[3], T. Foroud[3], H.J. Edenberg[3], T.-K. Li[3]*. 1) Washington University School of Medicine, St Louis, MO; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Indiana University School of Medicine, Indianapolis, IN.

We have performed new linkage analyses for platelet MAO-B activity on three samples: a previously analyzed sample (wave 1, 95 extended families containing 827 phenotyped members), a distinct sample (wave 2, 120 extended families containing 797 phenotyped members), and the combined sample. These families were recruited for the Collaborative Study on the Genetics of Alcoholism (COGA). Sibpair-based analyses were performed using MAPMAKER/SIBS; variance component analyses of extended pedigrees were performed using SOLAR. Platelet MAO-B activities were measured using a tryptamine assay, and values were corrected according to subjects' cigarette smoking status, gender, and center where blood was drawn.

Variance component analysis gave lod scores of 1.5, 2.3 and 3.2 in the respective samples in a region of chromosome 9 near D9S261; the lod score in the combined data was 1.4 greater than the next highest in the genome. Sib pair analyses of chromosome 9 with independent pairs gave respective lod scores of 0.8, 1.1 and 1.6, which in the combined data was the second largest signal in the genome via this method.

Haseman-Elston based regression using independent sib pairs found suggestive linkage on chromosome 2 (lod=2.0, 2.5 and 2.8 in the respective samples); variance component analysis gave lod scores of 0.8, 0.5 and 1.3, respectively, in this region.

The consistency across datasets and methods for the chromosome 9 finding is exciting. Variance component analysis supports a potential linkage of MAO activity to chromosome 9 with a lod over 3 in the combined sample; this finding may reflect the information gained by jointly considering all pedigree relationships. Further analyses are underway to understand the differences in results obtained by the two methods on chromosome 2.

Program Nr: 2515 from the 1999 ASHG Annual Meeting

A novel locus DFNA23 for prelingual autosomal dominant hearing loss maps to 14q in a Swiss German kindred.

A.A. Salam[1], F.M. Häfner[2], T. Linder[2], A. Baumer[3], D. Balmer[3], T. Spillmann[2], A. Schinzel[3], S.M. Leal[1]. 1) Laboratory of Statistical Genetics, The Rockefeller University, New York, NY; 2) Department of Otohinlaryngology and Head and Neck Surgery, University Hospital of Zurich, Zurich, Switzerland; 3) Institute of Medical Genetics, University of Zurich, Zurich, Switzerland.

A novel locus for non-syndromic hearing loss has been identified in a Swiss German kindred with autosomal dominant bilateral sensorineural hearing loss. A total of 25 members of this family over three generations were ascertained for study. Eleven of the family members were considered affected, 13 family members unaffected and one family member was excluded from analysis due to uncertain affection status. No evidence for acquired risk factors predisposing to hearing loss was observed for any of the affected individuals. The history and records of the patients suggested a prelingual onset (at birth or in the first years of life). The majority of the affected family members did not display progression of hearing loss during a follow up period which varied between 6 and 32 years. In only two cases the hearing loss showed progression. Audiometry displayed a bilateral and symmetrical hearing loss. In 6 cases there existed a conductive component (which produced an air-bone-gap between 10 dB and 40 dB). All audiograms showed sloping curves with normal hearing ability to mild hearing loss in low frequencies, normal to profound hearing loss in mid frequencies and moderate to profound hearing loss in high frequencies.

A genome scan was carried out in this family and a maximum multipoint los score of 3.9 was obtained. The locus which segregates in this family maps to 14q and does not overlap with DFNA9. Additional work is being carried out to further refine the genetic region for this novel locus.

This work was supported by the NHLBI Mammalian genotyping service, NIH-NIDCD grant DC03594 and the American Hearing Research Foundation. .

Program Nr: 2516 from the 1999 ASHG Annual Meeting

Two regions of linkage on chromosome 8 in Type 1 diabetes. *M.M. Sale[1], J.C. Charlesworth[2], C.C. Simpson[1], G. Morahan[3], J. Pendleton[4], D.W. Bowden[4].* 1) Menzies Centre for Population Health Research, University of Tasmania, Hobart, Australia; 2) Dept Biochemistry, University of Tasmania, Hobart, Australia; 3) The Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia; 4) Wake Forest University School of Medicine, Winston-Salem NC.

While several Type 1 diabetes susceptibility loci besides HLA and the insulin gene have been reported, other loci remain to be identified to account for the familial clustering observed. We have identified two regions suggestive of linkage on chromosome 8 in a U.S. Type 1 diabetes population of 137 affected sibling pairs derived from 121 families. Using multipoint analysis, the first region of linkage centred on D8S281 produced a non-parametric LOD score (NPL) of 3.0 (p=0.001). When combined with 45 Australian families, the NPL rose to 3.3 (p=0.0005). Conditioning on HLA and sex indicated a bias to HLA-discordant sibs and families with predominantly male offspring in both American and Australian populations. Linkage was not observed in 140 British IDDM families. Located approximately 20cM proximal to this peak, a second region of linkage was observed at D8S271 with a NPL of 3.1 (p=0.0008) in the U.S. families alone. Linkage at this locus was not detected in the British population, and was equivocal in the Australian families. Significant results using the transmission disequilibrium test (p=0.024 and 0.002) were obtained with alleles at the two peak loci. A positional cloning approach will be used to localise and identify two possible Type 1 diabetes susceptibility genes.

Program Nr: 2517 from the 1999 ASHG Annual Meeting

Linkage to the Lipoprotein Lipase Gene in an Extended Utah Kindred with Hypoalphalipoproteinemia: The -93G/D9N variant predisposes to low HDL. *M. Samuels[1], K. Forbey[1], A. Bandley[1], K. Bulka[1], B. Wardell[1], J. Reid[1], P. Hopkins[2], S. Hunt[2], D. Ballinger[1], M. Skolnick[1], S. Wagner[1]*. 1) Myriad Genetics, Salt Lake City, UT; 2) Department of Cardiovascular Genetics, University of Utah, Salt Lake City, UT.

Defects in the lipoprotein lipase (LPL) gene have been associated with dyslipidemia in the general population. Several rare mutations in the gene, as well as two common coding region polymorphisms, D9N and N291S, exhibit deleterious effects on circulating lipid levels. Such mutations have generally been discovered by random screening of probands. Using a linkage-based approach, we have identified a large Utah kindred segregating the D9N variant. The variant shows significant causal evidence for dyslipidemia in the kindred by multipoint linkage analysis. The variant shows the most penetrance for an hypoalphalipoproteinemia phenotype, but is also associated with hypertriglyceridemia. This is the first example using genetic linkage analysis to identify a specific mutation causing predisposition for dyslipidemia.

Program Nr: 2518 from the 1999 ASHG Annual Meeting

A genome-wide search for genes predisposing to familial psoriasis using a stratification approach. *L. Samuelsson[1], F. Enlund[1], A. Torinsson[1], A. Inerot[2], C. Enerback[2], J. Wahlstrom[1], G. Swanbeck[2], T. Martinsson[1]*. 1) Dept of Clinical Genetics, Univ Gothenburg, Sahlgrenska University Hospital/East, Gothenburg, Sweden ÅÅ; 2) Dept of Dermatology and Venereology, Univ Gothenburg, Sahlgrenska University Hospital, Gothenburg, Sweden.

In the search for psoriasis susceptibility loci, we have performed a genome scan using microsatellite markers spaced by 10 cM and a family set of 134 affected sibling pairs. Genotyping results were analyzed for non-random excessive allele-sharing between sib pairs, using GENEHUNTER ver 1.1. A stratification approach was applied to increase the homogeneity of the material by use of an operational definition of joint complaints among affected individuals. Significant linkage to the HLA-region on chromosome 6p in a cohort including 42 families without joint complaints (NPL-value of 2.83, p=0.002) supports the validity of this operational definition as it replicates results from earlier linkage reports using similar stratification criteria. New candidate regions on chromosome 3 and 15 were identified. The highest NPL-values in this study, 2.96 (p=0.0017) and 2.89 (p=0.0020), were reached on chromosome 15 in a subgroup with joint complaints and on chromosome 3 in a subgroup without joint complaints. In addition, confirmation of previously reported loci was established on chromosomes 6p, 14q, 17q and 20p. This study indicates that distinct disease loci might be involved in psoriasis etiology for various phenotypes.

Program Nr: 2519 from the 1999 ASHG Annual Meeting

Robust regression methods for complex traits: Simultaneous linkage and linkage disequilibrium. *D.J. Schaid, C.M. Rowland.* Section Biostatistics, Mayo Clinic, Rochester, MN.

Robust methods to evaluate genetic linkage of markers with complex traits typically do not allow for the possibility of linkage disequilibrium (*LD*), which can result in a loss of power if *LD* exists. The transmission/disequilibrium test (*TDT*) takes advantage of both linkage and *LD*, and provides a valid test for linkage in the presence of *LD*. However, the *TDT* has several limitations: typically, it is applied to only affected offspring, whereas more complex traits may be relevant, such as ordinal or continuous traits; it does not allow for multiple siblings when testing for *LD* in the presence of linkage; and it does not allow for environmental covariates.

To take advantage of both linkage and *LD*, we propose a new regression method that uses marker allele sharing between sibships, to capture *LD* and use it to impute parental linkage phase, and allele sharing within sibships, to account for linkage. The proposed method extends the binomial mixture likelihood for linkage by (1) incorporation of *LD* with an arbitrary number of marker alleles via regression parameters that account for between-family sharing of marker alleles, and hence incorporates different parental phase probabilities, and (2) having the probability of transmission of parental marker alleles depend on the offsprings' traits. This general regression method allows for simple traits (affected/unaffected) as well as more complex traits (continuous; multiple traits) and covariates.

Our proposed method evaluates the transmission of alleles from each heterozygous parent to their offspring, irregardless of whether parents are from the same family. The advantage of considering parents separately is a gain in robustness, without need to consider mode of inheritance, but requires pseudo-likelihood methods to account for dependencies of allele transmission between parents of the same offspring. This approach, as well as a method that considers both parents jointly, will be presented, as well as simulations demonstrating the statistical properties of these methods.

Program Nr: 2520 from the 1999 ASHG Annual Meeting

Fine mapping asthma- and atopy-susceptibility loci on chromosome 5q23-31 in the Hutterites. *D. Schneider[1], A. Tselenko[1], J. Andal[1], D.M. Hoki[1], R. Daniel[1], K. True[1], E.L. Sorensen[1], S. Willadsen[1], N.J. Cox[1,2], C. Ober[1]*. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL.

The cytokine gene cluster on 5q23-31 includes a plethora of loci that are functional candidates for asthma and atopy susceptibility alleles. Thus, it is not surprising that many candidate gene and linkage studies of asthma and atopy have identified this region as housing genes that influence these phenotypes. We previously reported linkage to this region in the Hutterites, a founder population of European ancestry. D5S1480 showed evidence of linkage to asthma by both the likelihood ratio test (LR) and the TDT (P = 0.0079and 0.0091, respectively) (Ober et al., 1998, *Hum Molec Genet* 7:1393) and D5S642 showed evidence of linkage to atopy by the TDT (P = 0.0082) (Ober et al., 1999, *Clin Exp Allergy*, in press). To identify the 5q-linked asthma and atopy susceptibility loci, we genotyped a sample of 750 Hutterites for 24 markers spanning 30 cM (average spacing 1.25 cM), including one or more STRPs or SNPs in the following candidate genes: *IL4*, *IL9*, *CD14*, *B2ADR*, and *CSF1R*. A region of <2 cM and including D5S1480 shows the strongest evidence of linkage with asthma. None of the candidate genes examined account for our evidence of linkage to asthma in this region, suggesting that an as yet unidentified gene on 5q31 confers susceptibility to asthma. Furthermore, a haplotype comprised of alleles at D5S1480 and D5S210 is associated with asthma (P = 0.019), identifying a haplotype that likely carries the 5q-linked asthma susceptibility allele in the Hutterites. The candidate gene, CD14, showed significant association with atopy, measured by positive skin prick test (+SPT) to ³1 of 14 allergens (P = 0.0009), suggesting that this gene may be the atopy-susceptibility locus on 5q in the Hutterites. (Supported by HL49596 and HL56399).

Program Nr: 2521 from the 1999 ASHG Annual Meeting

Integrated map of chromosome 17q critical region in multiple sclerosis. *M. Schoenberg-Fejzo[1], J. Saarela[1], D. Chen[1], M. Parkkonen[1], S. Kuokkanen[2], A. Palotie[1], L. Peltonen[1].* 1) Department of Human Genetics, Univ California, Los Angeles, CA 90095; 2) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD, 20892.

Multiple sclerosis (MS) is a neurological disease characterized by inflammatory demyelination of the CNS with a typical onset in the second to the fourth decades of life. In the past, multiple studies have revealed evidence for a genetic component to MS and genome-wide screens have identified several suggestive chromosomal regions. Of particular interest, studies of Finnish and British MS-families singled out chromosome 17q22-q24 as an area for further study. We have screened 32 additional markers mapping to 17q22-q24 in the original Finnish MS-families. D17S1825 has a maximum two point LOD score of 3.42. All other markers in the region of about 20 cM also generated positive lod scores. Multipoint analysis with 23 ordered markers using Genehunter and Simwalk2 would position the putative MS locus within a 5 cM region flanked by markers D17S807 and CHLC.GATA108A5. An integrated map over the 17q critical region in MS has been created using 60 markers covering an approximately 15 Mb/10 cM region. The map was built using multiple technologies including PCR to clone contigs, web-search based approaches, radiation hybrid mapping, and FISH methodology. Markers were screened against 37 YACs and 12 BAC, PAC, or P1 clones to create a physical map of the region. All markers have been blasted to the NCBI database and 30/60 hit 17 additional sequenced clones. 22 markers have been studied on the G3 and 19 on the TNG4 radiation hybrid panels to order the markers. In addition, we have performed FISH on 27 clones to metaphase chromosomes to confirm their map locations. We are in the process of identifying and studying candidate genes in the region and comparing these genes to the syntenic region in murine EAE7 on mouse chromosome 11. This work will aid in the discovery of a susceptibility locus for multiple sclerosis and may be of interest for other diseases such as breast cancer that show frequent amplification events in this chromosomal area.

Program Nr: 2522 from the 1999 ASHG Annual Meeting

Screening endothelin-1 by SSCP analysis for mutations associated with nonsyndromic cleft lip and palate in individuals of Filipino origin. *R.E. Schultz, A. McColley, J.C. Murray.* Dept. of Pediatrics, Univ.of Iowa, Iowa City, IA.

Cleft lip and palate (CL/P) is a congenital abnormality present in approximately 1/1000 live births. About 30% of cases of CL/P are syndromic, with causes such as Mendelian disorders, chromosomal anomalies, or known teratogen exposure. The remaining 70% are nonsyndromic (NS), meaning that the affected individual has no other physical abnormalities or known teratogen exposure. Previous studies have shown linkage for NS CL/P to a locus at 6p23, which contains the candidate gene endothelin-1. Mice knockouts for endothelin-1 show CL/P, and endothelin-1 is also hypothesized to be involved in the epithelial-mesenchymal transformation. Endothelin-1 consists of 5 exons. Primers were designed to screen all of the the coding sequence and the intron-exon boundaries of endothelin-1 for mutations via SSCP analysis. 73 Filipino individuals with nonsyndromic CL/P and both unaffected parents were the samples used for SSCP analysis. A primer to exon 2 identified an SSCP variant. Out of the 73 triads (unaffected parents and affected child), there were 62 in which all three members were homozygous for the wildtype allele. 11 triads contained a G to A mutation at bp 426 of the coding sequence. Of these 11 triads, 8 showed the mutation in both a parent and the affected child, while 3 showed the mutation only in a parent. The p-value for the transmission disequilibrium test was 0.1243, indicating a trend towards significance. The mutation at position 426 was a silent mutation. Because the bp 426 change is a silent mutation, it is less likely that this polymorphism is a disease-causing mutation. However, it is possible that it is linked to a disease-causing mutation elsewhere in the gene, for example in the promoter or an intron, or in a nearby gene. These possibilities should be investigated. Further study on this SSCP variant will be carried out by screening further affected Filipino individuals and their unaffected parents, screening other populations, and sequencing other individuals with the SSCP variant. With a larger population, the results might reach greater significance.

Program Nr: 2523 from the 1999 ASHG Annual Meeting

The autosomal recessive non-syndromic deafness loci, DFNB8 and DFNB10 on human chromosome 21q22.3, are distinct loci. *H.S. Scott[1], A. Berry[2], M. Korostishevsky[2], I. Talior[2], C. Barras[1], C. Gehrig[1], F. Younus[3], A. Veske[4], A. Mohyuddin[3], S. Qasim Mehdi[3], A. Gal[4], J. Kudoh[5], N. Shimizu[5], B. Bonne-Tamir[2], S.E. Antonarakis[1].* 1) Division of Medical Genetics, Univ Geneva Medical School, Geneva, Switzerland; 2) Department of Human Genetics and Molecular Medicine, Sackler School of Medicine, Tel Aviv University, Israel; 3) Biomedical and Genetic Engineering Division, Khan Research Laboratories, Islamabad, Pakistan; 4) Institut fur Humangenetik, Universitats-Krankenhaus Eppendorf, Germany; 5) Department of Molecular Biology, Keio University School of Medicine, Japan.

Deafness affects approximately 1/1,000 newborns. Approximately 50% of early-onset deafness cases are genetic and approximately 50% of these are recessively inherited. Nineteen recessive non-syndromic deafness loci have been identified to date, but only 5 have been cloned. Cloning of deafness genes will shed new light on the biology of the ear, hearing and deafness. Two families with autosomal recessive non-syndromic deafness have previously been independently reported with linkage to the distal chromosome 21q. A Pakistani family (DFNB8) revealed a likely localization telomeric to D21S212 while the disease locus (DFNB10) in a large Palestinian family maps to a 12-cM region in 21q22.3 with homozygosity of only the most telomeric marker, D21S1259. It was not clear if these two loci were in fact the same. By using additional markers (precisely mapped on BAC/cosmid contigs) on critical meioses and additional family members, we have delineated DFNB8 from DFNB10 as being telomeric and centromeric to D21S1885 respectively. This result is perhaps not surprising as the Pakistani and Palestinian kindreds, while both having recessive non-syndromic deafness, are phenotypically different, having childhood-onset and congenital deafness respectively. Several candidate genes for both loci have been excluded by mutation analyses. Ongoing studies will help identify the minimal critical regions for positional cloning efforts.

Program Nr: 2524 from the 1999 ASHG Annual Meeting

Examination of association between *LRP1* and late-onset Alzheimer disease using single nucleotide polymorphisms (SNPs). *W.K. Scott[1], E.H. Lai[2], J.M. Grubber[1], E.R. Martin[1], D.M. Hill[1], S.H. Poulton[1], M.M. Menold[1], L.A. Farrer[3], P.M. Conneally[4], G.W. Small[3], A.M. Saunders[1], A.D. Roses[2], J.R. Gilbert[1], J.L. Haines[5], M.A. Pericak-Vance[1]*. 1) Duke Univ. Medical Center, Durham, NC; 2) GlaxoWellcome Research & Development, RTP, NC; 3) Boston Univ. School of Medicine (LAF); Univ. of California at Los Angeles (GWS); 4) Indiana Univ. School of Medicine, Indianapolis; 5) Vanderbilt Univ. Medical Center, Nashville, TN.

The associations of a 5' tetranucleotide repeat and a non-coding SNP in exon 3 of the low density lipoprotein receptor-related protein (*LRP1*) gene with late-onset AD have been controversial. One potential explanation for these conflicting results is that varying degrees of linkage disequilibrium (LD) exist between these polymorphisms and the pathogenic variation. *LRP1* is an attractive candidate gene due to its function as a receptor for apoE as well as its location in the region on chromosome 12 recently linked to late-onset familial AD. Thus, these conflicting results necessitate more detailed study. The potential variation in LD across this large gene (89 exons) requires that several intragenic markers be examined. We conducted a more thorough examination of association and linkage between *LRP1* and AD by generating SNPs in 2 introns (38 and 78) and 3 exons (44, 54, and 56) for analysis with the previously described exon 3 SNP. To avoid bias by population stratification, we used the S-TDT and SDT family based association methods to test for linkage and association in 183 discordant sibships from late-onset AD families ascertained by Duke, the NIMH AD Genetics Initiative, and the Indiana Univ. AD Cell Repository. Logistic regression was used to examine association in 265 cases of sporadic AD and 276 controls ascertained at Duke and Boston Univ. Family-based tests of association (S-TDT and SDT) failed to detect statistically significant evidence of linkage disequilibrium at any of the 6 SNPs. Logistic regression analysis of the unmatched case-control data set, controlling for age, sex, and APOE, also found no statistically significant evidence for association. These data suggest that *LRP1* is not likely a significant risk factor for AD.

Program Nr: 2525 from the 1999 ASHG Annual Meeting

Fine mapping of the 11q13 Bardet-Biedl Syndrome1 (BBS1) locus and use of the rat EST map to identify BBS1 candidate genes. *M.D. Shastri[1], T.E. Scheetz[1], D. Nishimura[1], A.S. Cornier[2], G.F. Cox[3], A.B. Fulton[4], E.M. Stone[1], V.C. Sheffield[1]*. 1) Pediatrics, HHMI, University of Iowa, Iowa city, IA; 2) Ponce School of Medicine, Puerto Rico, PR; 3) Div. of Genetics, Children's Hospital, Boston, MA; 4) Dept. of Opthalmology, Harvard Medical School, Boston, MA.

Bardet-Biedl Syndrome (BBS) is an autosomal recessive disease characterized by retinal degeneration, polydactyly, obesity, mental retardation, and hypogonadism. BBS is genetically heterogenous showing linkage to 5 loci on chromosomes 2, 3, 11, 15, and 16. BBS1 was initially mapped using small pedigrees to a large interval around PYGM on 11q13 (Leppert et.al., 1994). We have analyzed a number of large families and refined the genetic interval. YACs, BACs, and PACs have been used to construct a physical contig across the BBS1 interval. In addition to the work on BBS1, we are in the process of constructing a dense EST map of the rat genome and are taking advantage of this map for the positional cloning of the BBS1 gene. Comparison of human ESTs in the BBS1 interval from the GeneMap99 with the rat EST placement map from the University of Iowa Rat Gene Discovery and Mapping Project (ratest.uiowa.edu) identifies an area of synteny between rat and human. More than 50 non-redundant rat ESTs were identified in the BBS1 syntenic region. Many of these ESTs were determined to be novel based on BLAST analysis using a threshold E-value of e^{-10}. This work shows that utilization of the rat EST data is an effective approach for identifying novel candidate genes. We are in the process of performing similar analysis on the other known BBS intervals. Comparison of genes between intervals is expected to aid in the identification and prioritization of BBS candidates for mutation screening by identifying genes of similar function. Refernce Leppert, M., et. al., (1994) Nature Genetics 7:108-112.

Program Nr: 2526 from the 1999 ASHG Annual Meeting

Selective Sib Pairs for Mapping QTL in Humans Using Identity in State Versus Identity by Descent. *S.S. Shete.* Epidemiology and Biostatistics, CWRU, Cleveland, OH.

A modification of the Risch-Zhang method of linkage analysis is proposed for two different models. First we consider a model in which the marker locus itself is the trait locus, called the candidate locus model. In the second model we assume that the trait locus and the marker locus are two distinct loci with a recombination fraction of q. These proposed procedures are based on identity in state relations between sib pairs. It is shown that with the proposed modification also, like the Risch-Zhang method, sib pairs with extreme discordant/concordant phenotypic values are more useful and powerful for linkage than sib pairs with intermediate phenotypic values. One of the advantages of the proposed procedures is that we do not need information about the parents and hence it is a good alternative for diseases with late age of onset, where parental information may not be available. A comparison through the number of sib pairs required to have given power is made for both these models with the Risch-Zhang method which is based on the ibd status of the sib pairs. We found that for this allele sharing procedure the iis based method has more power in the case of the candidate locus model, but has less power when the trait locus and the marker locus are two different loci. Possible implications of these results are discussed.

Program Nr: 2527 from the 1999 ASHG Annual Meeting

Linkage analysis of autosomal dominant polycystic kidney disease in the Japanese population. *Y. Shimizu[1], M. Mizoguchi[1,2], T. Kimura[1], A. Yamaki[1], T. Tamura[1], E. Higashihara[3]*. 1) Medical Genetics, Kyorin Univ, Tokyo, Japan; 2) Dept. Nursing, Sch. Health Sci., Tokai Univ; 3) Dept. Urology, Sch. Med., Kyorin Univ.

At least three different genes are thought to be causative for autosomal dominant polycystic kidney disease (ADPKD). They are PKD1 at 16p13.3, PKD2 at 4q21-q23 and PKD3 at the unknown locus. The mutations of PKD1and PKD2 have been reported at a variety of sites but only a small fraction of ADPKD patients. We have performed linkage analysis to clarify the ADPKD genetic heterogeneity in the Japanese population. To assess linkage to PKD1 and PKD2, we used two intragenic (KG8 and I42) and four flanking markers (D16S521, 16AC2.5, CW2, SM7) of PKD1 and six flanking markers (D4S231, D4S1534, D4S1542, D4S1563, D4S41544, D4S414) of PKD2. The analysis showed that 22 families linked to PKD1, one family to PKD2, and two families (family 68 and family 79) linked to neither PKD1 nor PKD2. We found an abnormal band in three out of four patients of family 68 by PCR-SSCP analysis. The direct sequence analysis revealed a nonsense mutation, C12581T (Gln4124stop), in exon 45 in this family except one patient. Thus we assume that the nonsense mutation and an additional unknown sporadic mutation may exist in family 68. In family 79, we obtained the maximum lod scores 2.01 with PKD1 markers and 3.39 with PKD2 markers from linkage analysis and no mutation was found in exons 36 through 46. These findings suggests the existence of the third genetic locus for ADPKD in family 79.

Program Nr: 2528 from the 1999 ASHG Annual Meeting

BIPOLAR AFFECTIVE DISORDER SUSCEPTIBILITY LOCI ON CHROMOSOME 5 AND 12 IN A HOMOGENOUS POPULATION IN QUEBEC. *E. Shink[1], J. Morissette[1], A. Villeneuve[2], L. Bordeleau[1], D. Rochette[3], V. Raymond[1], B. Gagné[1], C. Laprise[1], G. Bouchard[4], M. Plante[1], N. Barden[1].* 1) Neuroscience, CHUL research center, Ste-Foy, Québec, Canada; 2) Clinique Roy-Rousseau, Québec; 3) Complexe Hospitalier de la Sagamie, Chicoutimi, Québec; 4) Université du Québec a Chicoutimi.

A complete genome-wide scan at approximately 11 cM was conducted in a very large multiplex family with bipolar affective disorder from the Saguenay-Lac-St-Jean region of Qubec. We have already reported that this pedigree, which included more than 130 living members, suggests linkage with bipolar affective disorder in one region of chromosome 12 (Z=2.87). Using a more restrictive definition of affected status, the same genome survey pointed to two different regions on chromosome 5. Under this definition, bipolar disorder, type I, schizo-affective disorder, bipolar type and bipolar disorder, type II were considered as affected, whereas single or recurrent major depressive episodes were classified as unknown. All other diagnoses were considered as unaffected. The GENEHUNTER multipoint nonparametric analysis suggested the presence of a susceptibility locus at the 5q33-34 region (NPL score=2.6 with p=0.022). This region, delimited by markers D5S673 and D5S422, was also supported by parametric analysis (Z=2.15) and by SimAPM (p=0.014) at marker D5S412. Additionally, another chromosome 5 area, delimited by D5S406 and D5S432, was pointed too by the affected sib-pair test with p-values less than 5% for these two successive markers. To analyze the linkage heterogeneity, the whole pedigree was broken down into 5 branches. Two of these branches, which were the most linked to the 12q23-24 region, gave also some support for the chromosome 5p loci, whereas the two others informative branches supported the 5q region. Others independent research teams also reported positive finding in these regions: Kelsoe et al. observed positive LOD scores on 5p15 near the dopamine transporter locus and Macciardi et al. found linkage disequilibrium between the GABRA1 gene (5q34-q35) and bipolar disorder. These results suggest that more than one susceptibility locus may be involved in transmission of bipolar disorder in this community.

Program Nr: 2529 from the 1999 ASHG Annual Meeting

Detection of linkage for quantitative trait loci. *D.O. Siegmund, H.-K. Tang.* Dept Statistics, Stanford Univ, Stanford, CA.

We present a self-contained discussion and comparison of strategies for mapping quantitative trait loci, with emphasis on situations where there are thought to be gene/gene or gene/environment interactions. Beginning with a simple general treatment of certain issues of study design that have recently received attention, e.g., genotyping only selected pedigrees, the comparative value of large pedigrees versus sib pairs, we then introduce and study simultaneous and conditional search to detect linkage when there is thought to be gene/gene or gene/environment interaction. By using a particular parameterization of the genetic effects and the framework of local alternatives employed in large sample statistical theory, we obtain simple explicit expressions for asymptotic noncentralilty parameters. From these expressions, with negligible computational effort we can compare the power of different strategies. ~.

Program Nr: 2530 from the 1999 ASHG Annual Meeting

Identification and analysis of polymorphic loci in and around the a**-synuclein and synphilin genes in Parkinson's disease and dementia with Lewy bodies.** *A.B Singleton[1], S. Lincoln[1], D. Dickson[2], J. Hardy[1], M. Farrer[1].* 1) Neurogenetics, Mayo Clinic Jacksonville, Jacksonville, FL; 2) Mayo Clinic Jacksonville, Jacksonville, FL.

The pathobiological significance of a-synuclein has recently become an area of much interest to researchers working in the field of neurodegenerative disease. This protein has long been known to be a component of Alzheimers disease senile plaques and is now known to be a major depositing protein within Lewy bodies. Lewy bodies are seen in numerous neurodegenerative disorders most notably dementia with Lewy bodies (DLB) and Parkinson's disease (PD). Although the physiological function of this protein is unknown the pathogenic importance of the a-synuclein gene has been emphasized by the discovery that it harbors mutations in some rare cases of familial PD. A novel a-synuclein interacting protein, synphilin, has recently been identified and cloned.

In order to find novel single nucleotide polymorphisms in the a-synuclein and synphilin genes we used a direct sequencing approach in twenty mixed PD, DLB and control cases. We have identified two novel polymorphisms in the a-synuclein gene, within and 5' to exon 5. Examination of the synphilin gene demonstrated the presence of 3 informative single nucleotide polymorphisms in exon 1, 25bp 5' to exon 4 and 21bp 5' to exon 6. In addition we have identified a polymorphic $(CA)_{14\text{-}19}$ repeat 5' to exon 5 of this gene.

In order to examine any putative role that the a-synuclein and synphilin genes may have to play in Lewy body disorders we have determined the frequencies of these polymorphisms and a known imperfect repeat in the 5'UTR of the a-synuclein gene in a large series of PD, DLB and control cases.

Program Nr: 2531 from the 1999 ASHG Annual Meeting

SIMPLE: A linkage program that incorporates interference. *Z. Skrivanek[1], M. Irwin[1], S. Lin[1], F.A. Wright[2]*. 1) Department of Statistics, Ohio State University, Columbus, OH; 2) Human Cancer Genetics Program, Ohio State University, Columbus, OH.

Although chiasma interference is known to occur in human meiosis, it is typically ignored in order to facilitate the calculation of multipoint likelihoods in linkage analysis. This gain in computational ease often occurs at the expense of power to accurately construct a genetic map. Linkage analysis programs that have incorporated interference models to date are limited to either small pedigrees or a small number of loci. We present a software package, SIMPLE (Sequential Imputation for Multi Point Linkage Estimation), that can handle both large simple pedigrees and a moderate number of markers and easily incorporates almost any interference model. SIMPLE uses Sequential Imputation, a Monte Carlo method, giving it the power and flexibility to achieve these ends. To demonstrate the advantages of SIMPLE, we perform linkage analysis on simulated data sets from large pedigrees with a moderate number of loci. We model the chiasma interference using the chi-squared model: chiasmata are treated as events from a stationary renewal process with inter-event distances following a chi-squared distribution. We simultaneously analyze the same data with no interference and compare the two methods in terms of power, size and lod scores. The advantages of SIMPLE are the flexibility it offers in facilitating a wide range of interference models and the ability to handle large simple pedigrees and a moderate number of loci at the same time.

Program Nr: 2532 from the 1999 ASHG Annual Meeting

Multipoint linkage analysis of complex traits with Markov chain Monte Carlo linkage analysis. *G. Snow[1], E. Wijsman[1], E. Thompson[1], S. Heath[2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Rockefeller University, New York, NY.

Lod scores for multipoint linkage analysis can be difficult or impossible to compute for large and/or complex pedigrees when there are many multiallelic markers. Markov chain Monte Carlo (MCMC) methods offer one computationally tractable solution. MCMC methods are based on realization of dependent samples of genotypes, from which desired parameters and likelihood ratios can be estimated. Earlier MCMC samplers for lod score computations are based on single-genotype updating (e.g., the Gibbs sampler), which tends to be relatively inefficient thus limiting practical utility.

Here we show that use of a sampler which simultaneously updates all genotypes at each locus in turn is much more efficient. We also incorporate a mixed-model for the trait locus, thus allowing for a more complex model. We applied this approach to a 101-member simple-structure pedigree with simulated trait and marker data, and compare results to those obtained by Vitesse by combining environmental and polygenic variance. For 4 markers spaced at 20 cM intervals, a linked quantitative trait with major gene heritability .69 and polygenic heritability .15, the peak lod score (5.6) for the MCMC analysis is virtually identical to that obtained by Vitesse (5.7), and both peaks occur at the correct location. However, the MCMC approach provides more accurate localization (1 lod support interval ~50% that provided by analysis with Vitesse) and requires less CPU time. When 10% of the pedigree is unobserved, for 4 markers Vitesse requires 115 minutes vs.20 minutes for the MCMC approach; for 5 markers, Vitesse requires >12 hours, while < 30 minutes are required for the MCMC approach. This demonstrates the practical utility of this approach for multipoint linkage analysis of large pedigrees.

A comparison of the power of haplotype sharing analysis and two locus association analysis for fine-mapping of genes contributing to complex genetic disease. *G.T. Spijker, I.M. Nolte, G.J. te Meerman.* Medical Genetics, University of Groningen, the Netherlands.

Fine-mapping of genes that contribute to complex disease presents a major challenge to geneticists. At a density of genes of perhaps one gene per 15 kb of DNA, association between genetic markers and disease alleles may be insufficient to achieve sufficient accuracy of fine mapping. We propose that systematic haplotype comparison offers an improved perspective on genetic fine mapping, by using all information of haplotype by haplotype comparison. The physical model underlying haplotype similarity is haplotype decay starting from the position of an original mutant allele. It is likely that the highest similarity between patient haplotypes is found at the marker interval containing the risk allele. This similarity is reflected by an excess sharing between pairs of haplotypes containing the risk allele. We have developed an analysis method that systematically investigates this haplotype sharing. We expect this method to be less sensitive to differences in marker informativity than one and two locus association methods, especially when allelic heterogeneity is present. The goal of this study is to investigate the properties of haplotype sharing analysis with regard to power and accuracy of fine mapping and to compare them with one and two locus chi-square association tests. We present results pertaining to empirical and simulated data sets. The independent variables are degree of allelic heterogeneity, marker densities and the number of unknown alleles. Dependent variables are sample size and accuracy of mapping.

Program Nr: 2534 from the 1999 ASHG Annual Meeting

CCR5 Does Not Influence Genetic Susceptibility to Multiple Sclerosis in the Canadian Population. *J.L. Steckley[1], K. Cousin[2], A.D. Sadovnick[3], N. Risch[4], G.C. Ebers[1], The Canadian Collaborative Study Group[5]*. 1) University of Oxford, Department of Clinical Neurology, Radcliffe Infirmary, Woodstock Road, Oxford, England; 2) The Department of Clinical Neurological Sciences, London Health Sciences Centre, University Campus, London, ON,; 3) The Department of Medical Genetics, University of British Columbia, Vancouver, BC; 4) The Department of Genetics, Stanford University, Palo Alto, California.

Chemokines are thought to be important for the establishment of inflammatory processes in putative autoimmune diseases such as multiple sclerosis (MS). There is a growing body of evidence for the involvement of macrophage inflammatory protein (MIP)-1a and its main receptor, CCR5 in the development of MS. A common 32bp deletion (D32bp) in the CCR5 gene prevents CCR5 receptor expression on the surface of cells. There have been a number of attempts to implicate a retroviral etiology in MS and thus D32bp could protect against viral infection. Two-hundred and ninety families with MS that were obtained as part of the Canadian Collaborative Project on Genetic Susceptibility to Multiple Sclerosis (CCPGSMS) were analyzed for the D32bp mutation. We analyzed the D32bp genotype, as well as the genotype of two neighbouring microsatellite markers (D3S4580 and D3S4579) for linkage and linkage disequilibrium with the ASPEX linkage package. Eleven MS patients were found to be homozygous for the D32bp mutation, showing that the absence of the CCR5 receptor on the cell surface does not protect from the development of MS. Further, the transmission disequilibrium test (TDT) showed no preferential transmission of the D32 mutation to affected offspring and linkage analysis excluded the D32bp mutation from contributing to MS susceptibility at a l value of 1.50. There was no excess transmission of alleles to affected offspring for the microsatellite markers and multipoint linkage analysis excluded the CCR5 gene. We conclude that CCR5 polymorphism does not influence susceptibility to MS in the Canadian population.

Program Nr: 2535 from the 1999 ASHG Annual Meeting

Multiple origins of the spinocerebellar ataxia (SCA7) mutation revealed by linkage disequilibrium studies with closely flanking markers, including an intragenic polymorphism ($G^{3145}TG/A^{3145}TG$). *G. Stevanin[1], G. David[1], A. Durr[1], P. Giunti[2], A. Benomar[3], M. Abada-Bendib[4], M.S. Lee[5], A.S. Lebre[1], Y. Agid[1], A. Brice[1]*. 1) INSERM U289, Hopital la Salpetriere, Paris, France; 2) Institute of Neurology, Queen Square, London, UK; 3) Service de Neurologie, Hopital des Specialites, Rabat, Morocco; 4) Service de Neurologie, Hopital de Ben-Aknoum, CHU Alger-Ouest, Algiers, Algeria; 5) Department of Neurology, Yongdong Severance Hospital, Seoul, Korea.

Spinocerebellar ataxia (SCA7) is a neurodegenerative disease characterised by cerebellar ataxia and progressive macular degeneration. The cause of the disease is a (CAG)n repeat expansion in the coding sequence of the SCA7 gene on chromosome 3p. De novo mutations occur on intermediate sized alleles carrying from 28 to 35 CAG repeats. Neomutations explain the persistence of the disease in spite of the great instability of the repeat sequence. This is the biological base for the marked anticipation that characterises this disease that results in the appearance of juvenile onset patients and its extinction within families. This rare disorder has been reported in a large number of countries and ethnic groups. We have selected 41 SCA7 families of different origins and determined the haplotypes segregating with the mutation at several microsatellite markers close to the SCA7 gene as well as at a newly described intragenic polymorphism ($G^{3145}TG/A^{3145}TG$). Four different haplotypes were observed for centromeric markers ($G^{3145}TG/A^{3145}TG$ - D3S1287 - D3S3635) in the majority of the kindreds from 4 different geographical regions: A-2-4 in Korea; A-3-6 in North-Africa, B-3-6 in continental Europe and A-4-6 in UK and USA. The haplotypes segregating in the Jamaican, Filipino, Brazilian and German families were different, and suggest that independent regional founders are at the origin of the SCA7 mutation in each population. Two different haplotypes were observed, however, in two families from the same rural area in central Italy in which de novo SCA7 mutation have been observed. These results suggest the existence of different pools of at-risk chromosomes in this population.

Program Nr: 2536 from the 1999 ASHG Annual Meeting

Stocco dos Santos XLMR Syndrome: Clinical Update and Linkage Analysis. *R.C. Stocco dos Santos[1], L.M. Holmes[2], C.J. Lindsey[3], H.A. Lubs[4], D.T. Horne[2], R.C. Recouso[1], R.E. Stevenson[2], C.E. Schwartz[2].* 1) Laboratorio de Genetica, Instituto Butantan, São Paulo, São Paulo, Brazil; 2) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC,29646; 3) Departamento de Biofisica, UNIFESP, São Paulo, São Paulo, Brazil; 4) Department of Pediatrics, University of Miami School of Medicine, Miami, FL.

The Stocco dos Santos XLMR syndrome was originally described in 1991 (Am J Med Genet 39:133) as a condition in which the affected males had mental retardation, bilateral hip luxation and short stature. Three of the four affected males also had a variant of G6PD. Recently, we re-examined the family. In addition to the original clinical features, the affected males were found to now have kyphosis, seizures, strabismus, hyperactivity and possible premature aging. Linkage analysis was conducted using 4 normal males and 4 carrier females in addition to the 4 affected males. Tight linkage was found between the loci DXS983 and AR (zero recombination with a lod score of 3.13) and the XLMR. Recombination was detected at DXS1003 (Xp11.3) and DXS8077 (Xq21.1) thereby localizing the syndrome to the pericentric region. Furthermore, the female carriers were found to have skewed X-inactivation. Based on the combination of these findings, the XNP gene has been screened for mutations; to date no alterations have been observed. Other potential XLMR genes located in the linkage interval, such as OPHN1, are also being screened for mutations. (Supported in part by NIH grant HD26202 to H.A.L. and C.E.S. and by the South Carolina Department of Disabilities and Special Needs.).

Program Nr: 2537 from the 1999 ASHG Annual Meeting

Genetic Heterogeneity in Carney Complex (OMIM 160980): Contributions of loci at chromosomes 2 and 17 in its genetics. *C.A. Stratakis[1], L.S. Kirschner[1], S.E. Taymans[1], C.J. Vaughan[2], C.J. Hatcher[2], M. Casey[2], J.A. Carney[3], C.T. Basson[2]*. 1) Unit on Genetics & Endocrinology, NICHD, NIH, Bethesda, MD; 2) Div. of Cardiology, Dept. of Medicine, Cornell University Medical College, The New York Hospital, New York, NY; 3) Mayo Clinic, Rochester, MN.

Carney complex (CNC) is an autosomal dominant disorder characterized by spotty skin pigmentation, myxomas of the skin, heart, breast and other sites, and other tumors. Despite its unique phenotype, which suggested a single causative gene, CNC has been linked to two different locations of the human genome. At first, 10 families collected by the National Institutes of Health (NIH) and the Mayo Clinic (MC) were mapped to chromosomal region 2p15-16; subsequently, 5 families [1 from the NIH study and 4 collected from Cornell University (CU)], were mapped to 17q22-24. We reexamined the evidence for linkage to 2p15-16 in 16 families, including 3 previously unreported families, as well as the previously described families from the NIH, MC and CU collection. 150 individuals (84 affected) were genotyped for 11 polymorphic markers on 2p15-16 and for 4 markers on 17q22-24. LOD score analysis demonstrated that 5 families were linked to 17q22-24. In 5 families, haplotype analysis showed at least one recombination with the chromosome 17 locus; 4 of these families showed no recombination with 2 tightly linked markers on 2p15-16 with summed pairwise LOD scores (Z) 3.82 and 3.67 for D2S2156 and CA2, respectively. HOMOG revealed no heterogeneity amongst these 4 families. The maximum summed multipoint LOD score (MMLS) for marker D2S2156 was 3.8; overall, MMLS for 2p15-16 was 4.1 (centered between markers CA-7 and D2S1352). One family had recombinations with both loci; 4 families had no recombinations for either locus or were uninformative. Two families that demonstrated recombinations with 2p15-16 segregated with markers from 17q22-24. These observations confirm locus heterogeneity in CNC. Of 16 families studied, we predict that 7 map to 17q22-24 and 4 to 2p15-16. Four families could not be definitely mapped, and a third locus for CNC in the genome may exist, because one family exhibited recombinations with both loci.

Program Nr: 2538 from the 1999 ASHG Annual Meeting

Lod scores for disease mapping in the presence of marker map uncertainty. *H.M. Stringham, M. Boehnke.* Department of Biostatistics, University of Michigan, Ann Arbor.

Multipoint lod scores are typically calculated for a grid of locus positions, moving the putative disease locus across a fixed genetic marker map. The resulting multipoint lod score curve is then plotted against this map. Changing the order of a set of markers and/or the distances between the markers can make a substantial difference in the lod score curve. Given densely-spaced markers, there may not be a single clearly best marker order, and the maximum lod score and estimated disease gene location may differ depending on which marker order is used. There is need for a method to deal with this uncertainty in the map, provide a single multipoint lod score which accurately reflects the evidence for linkage, and give an appropriate estimate of disease gene location.

We propose three weighted multipoint lod score statistics that make use of information from all plausible marker orders. In each of these statistics, the information conditional on a particular marker order is weighted by the posterior probability of that order. The first statistic is a lod score formed from weighted likelihoods. The second is a weighted average of the lod scores themselves. For the third statistic, we calculate a weighted significance level and then back transform to its lod score equivalent. We illustrate the use of these three lod score statistics with an example and evaluate their properties based on results from simulated data. We consider the type I error, power, and bias in the estimate of location for the disease locus and compare these results to those obtained using the best maximum likelihood map and the true genetic map.

Program Nr: 2539 from the 1999 ASHG Annual Meeting

Efficiency of Various Methodologies for Estimating Penetrance. *M.D. Swartz[1], C.I. Amos[2].* 1) Department of Statistics, Rice University, Houston, TX; 2) Department of Epidemiology, The University of Texas M.D. Anderson Cancer Center, Houston, TX.

Statistical methods to estimate the penetrance of a complex disease include segregation analysis without a linked marker, joint segregation and linkage analysis, and maximizing the LOD score over the penetrance (the MOD approach). For back cross matings, analytic studies [Liang et al., (1996)Genetic Epidemiology 13:575-593, Amos & Rubin (1995) Exp Clin Immunogenet 12:141-155] have compared the efficiency of parameter estimation between combined segregation and linkage and segregation analaysis. These studies showed that the increase in efficiency to estimate the penetrance comparing combined segregation and linkage to segregation analysis depended strongly on the ratio of the penetrance in the carriers versus the noncarriers. The MOD score approach has been suggested whenever ascertainment correction cannot be accomplished, but the MOD score method has been criticized as having low efficiency for parameter estimation. Here we analytically study these three methods of penetrance estimation for an autosomal locus using sib pairs with unknown phase. We study these methods while varying not only the penetrance of the carriers but also the penetrance of the noncarriers. Contrary to statements in the literature, the MOD score approach only performs poorly relative to combined segregation and linkage when the relative penetrance of carriers to noncarriers is low. Thus, for highly penetrant (usually rare) alleles, the MOD score approach provides a reliable estimate of penetrance, yet, for alleles having low penetrance, the MOD score approach performs very poorly. These results can be used for deciding which sampling scheme to use in studying a disease, whether population based with well described ascertainment criteria or registry based with a poorly defined ascertainment process.

Program Nr: 2540 from the 1999 ASHG Annual Meeting

Evidence for extensive linkage disequilibrium on the X chromosome. *P. Taillon-Miller[1], I. Bauer-Sardina[1], N.L. Saccone[2], G. Pilia[3], J. Kere[4], J.P. Rice[2], P-Y. Kwok[1]*. 1) Washington University, Dermatology; 2) Washington University, Psychiatry; 3) University of Cagliari, Pediatrics; 4) University of Helsinki, Department of Medical Genetics.

Evidence for extensive linkage disequilibrium on the X chromosome Patricia Taillon-Miller, Irma Bauer-Sardia, Nancy L. Saccone, Giuseppe Pilia, Juha Kere, John P. Rice and Pui-Yan Kwok Washington University, Dermatology, Psychiatry, University of Cagliari, Pediatrics, University of Helsinki, Department of Medical Genetics To date most investigators have looked at linkage disequilibrium (LD) in humans as a means to discover the cause of a specific genetic disease. As we develop a large number of single nucleotide polymorphism (SNP) markers and begin to look at the genetic origin of complex diseases using association studies it will be important to understand the amount and the location of regions of LD across the genome. To approach this problem we have developed a set of closely spaced (less than 100 kb apart) SNPs markers in Xq25-28. The X chromosome is an ideal region in which to begin these studies. It is a well-characterized chromosome and by genotyping only males, we can easily determine haplotypes across the chromosome. We have typed 90 males in 3 populations; the CEPH, Finnish, and Sardinian populations. Linkage disequilibrium was determined by using pairwise comparisons. We have found 2 extended regions of LD ($p<.0.005$) in all populations examined to date. The first is 550 kb in length in Xq25 and the second in Xq28 (340 kb). In addition, we have also found regions that exhibit no LD giving strong support to the theory that LD is not a monotonic function of the distance between markers but is dependent on the region of the chromosome. . These results are in sharp contrast to recent simulations that have concluded that a useful level of LD is unlikely to extend beyond a distance of 3 kb in the general population.

Program Nr: 2541 from the 1999 ASHG Annual Meeting

Fine mapping of the gene for familial cylindromatosis. *M. Takahashi, G. Bignell, E. Rapley, S. Seal, C. Brown, P. Biggs, W. Warren, M. Stratton.* Cancer Genetics, Inst of Cancer Research, Sutton, Surrey, England.

Familial cylindromatosis is a rare autosomal dominant disease characterised by the development of multiple benign tumours of skin adnexal structures. The gene responsible, *Cyld1*, has been mapped to chromosome 16q12.1-q13 and is likely to be a tumor suppressor gene. Seventeen cylindromatosis families have now been analysed using markers within the *Cyld1* region and all are consistent with linkage to the *Cyld1* region. Therefore there is no evidence for genetic heterogeneity. YAC and PAC contigs have been constructed through the region between D16S517 and D16S416 known to harbor the cylindromatosis gene and new polymorphic microsatellite markers isolated. Further recombinant mapping using these markers has reduced the interval to less than 1Mb. There is some evidence for similarity between segregating haplotypes found in independently ascertained families. More detailed characterisation of this potential allelic association is in progress and may result in further reduction of the interval.

Program Nr: 2542 from the 1999 ASHG Annual Meeting

A study of phenotype-genotype correlation in two DPHL families with different missence mutation in the KCNQ4 gene. *Z. Talebizadeh[1], P.M. Kelley[1], J.B. Kenyon[1], G. Haynatzki[2], M. McGlynn[1], S.D. Smith[1].* 1) Genetics, Boys Town Natl Res Hosp, Omaha, NE; 2) Biochemistry, Creighton Univ, Omaha, NE.

We have studied two kindreds ,family 616 and 2177,with dominant progressive nonsyndromic sensorineural hearing loss. Heteroduplex analysis and sequencing analysis have been used for mutation detection. Two missence mutations, L281S and G285S, in the voltage-gated potassium channel KCNQ4 gene have been detected as the etiology of the hearing loss in these families. The two families were compared with respect to hearing level (dB), taking into account three factors: (1) Ear; (2) Age; and (3) Frequency. We avaraged the data on the two ears for each affected individual to increse the precision of the measurements. A Repeated Measures ANOVA and fitting a linear regression model for each family were used for compairing the respective intercepts and slops. The results have indicated the overall level of hearing loss is not significantly different in two families. However, review of the audiograms revealed considerable differences in age of onset and level of hearing loss, in some affected members. This observation suggested involvement of another factor as a secondary cause that produces more severe hearing loss in these subjects. It has been proven that mutations in Connexin 26 could account for 50% of childhood hearing loss, with a carrier rate of 2.8% (Kelley 1998). Abe et al., (1999) found mutation in Connexin 26 among some families with the A1555G mitochondrial DNA mutation. Individuals with both mutations had more severe hearing loss. Thus, it is reasonable to hypothesize that Connexin 26 mutaions or other nuclear or mitochondrial genes play similar roles in causing the clinical variation in some affected individuals with mutaiton in the KCNQ4 gene. To investigate this hypothesis, we have screened the affected individuals in both families for mutaion in Connexin 26, and known mutaions resulting hearing loss in the mitochondrial DNA.

Program Nr: 2543 from the 1999 ASHG Annual Meeting

Mapping of a gene responsible for dermatitis of NOA (Naruto Research Institute Otsuka Atrichia) mice, an animal model of allergic dermatitis. *M. TAMARI[1], O. WATANABE[1], Y. ONOUCHI[1], K. NATORI[1], Y. SHIOMOTO[2], S. KUBO[2], Y. NAKAMURA[1]*. 1) Laboratory of Molecular Medicine, Institute of Medical Science, University of Tokyo,MINATO-ku, Tokyo, Japan; 2) 2Naruto Research Institute, Otsuka Pharmaceutical Factory, Inc., Naruto, Tokushima, Japan.

Atopy and atopic disorders are considered to be multifactorial diseases caused by abnormalities in the immune system. Although a large number of genetic and immunological studies of atopic disorders have been performed, genes predisposing to or developing these diseases are still not well understood because of the etiological complexity in humans. The NOA (Naruto Research Institute Otsuka Atrichia) mouse is an animal model of allergic or atopic dermatitis, a condition characterized by ulcerative skin lesions with accumulation of mast cells and increased serum IgE. These features of the murine disease closely resemble human atopy and atopic disorders. We performed linkage analysis in NOA back-cross progeny, as a step toward identifying and isolating a gene responsible for the NOA phenotype. We crossed NOA mice with five other murine strains (C57BL/6J, IQI, C3H/HeJ, DBA/2J, and BALB/cByJ) and then bred back-cross animals. Using 241 microsatellite markers, we scanned the entire genome of 559 N2 offspring from the five parental strains. Linkage analysis revealed a significant association between ulcerative skin lesions and markers on murine chromosome 14. Statistical analysis indicated the critical region to be the vicinity of D14Mit236 and D14Mit160 ($c2=86.89$, $p<0.001$ for D14Mit236 and $c2=86.62$, $p<0.001$ for D14Mit160). Since this 15-cM region of murine chromosome 14 must contain dozens of genes, it will be useful to construct a more detailed genetic map with a view toward positional cloning of the putative dermatitis-associated gene.

Program Nr: 2544 from the 1999 ASHG Annual Meeting

Identification and genetic mapping of zebrafish circadian clock mutants. *Y. Tan, J. DeBruyne, M.W. Hurd, D.E. Wells, G.M. Cahill.* Biology and Biochemistry, University of Houston, Houston, TX.

We have initiated a screen for dominant mutations that affect the periodicity of behavioral circadian rhythms of larval zebrafish. Random point mutations were induced in male spermatogonial stem cells using N-ethyl-N-nitrosourea. Treated males were then crossed to wild type females, and the resulting (G1) progeny are each heterozygous for a unique set of mutations. The swimming activity in constant conditions of G1 larvae (days 10-17 post fertilization) was measured continuously with an automated video image analysis system, and the average time of the circadian activity peaks from days 5-6 was measured. Among the first 1275 G1 individuals screened, we have identified two mutants that transmit short period phenotypes to their progeny. When these G1 mutants were outcrossed to wild type, the distribution of F1 period phenotypes was consistent with a 1:1 ratio. F2 progeny generated from an F1 mutant intercross had a phenotype distribution ratio consistent with 1:2:1. This is consistent with a semi-dominant mutation. Periods of heterozygous individuals for either mutation were shortened by 0.5-1 hours and the periods of homozygous individuals were shortened by 1-1.5 hours. We tested the effect of one mutation on the period of melatonin production rhythms from cultured pineal glands. Pineals from homozygotes had a significantly shorter period (23.8 0.1 hours, n=7) than pineals from wild type siblings (24.4 0.1 hours, n=7). This indicates that this mutation affects circadian rhythmicity at the tissue level, as well as the behavioral level. Linkage mapping using simple sequence length polymorphisms indicates that one mutation is on linkage group 20 close to the centromere while the other mutation has been narrowed down to a 4cM region on linkage group 7. Together, these findings demonstrate that behavioral rhythmicity provides an efficient screen for zebrafish clock mutants. This work was funded by grants from AFOSR and the Texas Advanced Research Program.

Program Nr: 2545 from the 1999 ASHG Annual Meeting

Computer prediction of optimal temperature and gradient conditions for mutation detection by DHPLC. *P.D. Taylor, D.T. Gjerde, J. Walter, A. Kuklin, R. Haefele.* Transgenomic, Inc., San Jose, CA.

Denaturing high performance liquid chromatography (DHPLC) is a fully automated technique for scanning for novel mutations. The mutant and wild-type sequences are first hybridized to form a heteroduplex containing one or more mismatched bases and then injected onto a polymeric cartridge at a temperature which is slightly denaturing, in order to separate the heteroduplex from the homoduplex. The method is more appropriately termed temperature modulated heteroduplex analysis (TMHA) and takes around 6 minutes per sample. The optimal temperature at which the entire fragment may be scanned for novel mutations, varies with the sequence of the sample, typically within the range of 54 to 68^{o}C. This temperature can be determined experimentally by systematic analysis at 1^{o}C increments although this is time consuming. Alternatively the temperature can be calculated directly from the sequence, using the Fixman-Friere modification of the Poland algorithm. The parameters used in this model have been re-determined for the solvent conditions used for TMHA and applied in a computer program operating in the Windows® environment. The temperatures predicted by this computer program are compared here with those obtained experimentally. The program also predicts more than one temperature when this is required to obtain complete coverage of a sequence which has highly disparate melting domains. Finally, the gradient composition of the two eluents required for separation at the selected temperature is predicted and compared with experimental results.

Program Nr: 2546 from the 1999 ASHG Annual Meeting

Genetic dissection of metabolic pathways. *B.A. Thiel[1], M. Stoll[2], A.W. Cowley[2], A.E. Kwitek-Black[2], H.J. Jacob[2], N.J. Schork[1,3]*. 1) Dept. of Epidemiology/Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Department of Physiology, The Medical College of Wisconsin, Milwaukee, WI; 3) The Genset Corporation, La Jolla, CA.

The translation of genotypic variability into high level phenotypic differences is of tremendous interest in contemporary genetics research. Given that a single gene may have an effect on a whole class of measureable phenotypes, analyzing these phenotypes together may provide more compelling insight into gene function than analyzing any one trait individually. In an effort to try and understand the genetic components of multiple phenotypes in complex physiologic pathways, we have used data from genetic crosses using rats to look at the relationships between multiple trait variables and marker genotypes across the genome. These types of analyses are also applicable to, and have been implemented in, human studies.

Our analysis methods involved the use of factor analysis, principal components analysis and cluster analysis to explore the relationships between multiple traits. Our methods also allow one to take advantage of graphical techniques to depict physiological heirarchies under genetic control. We will discuss the assumptions and limitations of these statistical methods for detecting genetic effects.

Program Nr: 2547 from the 1999 ASHG Annual Meeting

A two-stage test of transmission/disequilibrium for quantitative traits in pedigree data. *H.K. Tiwari*[1], *R.C. Elston*[1], *V. George*[2]. 1) Dept Epidemiology/Biostatistic, Case Western Univ, Cleveland, OH; 2) Medical College of Wisconsin, Milwaukee, WI.

The transmission/disequilibrium test (TDT), originally proposed by Spielman et al. for binary traits, is a powerful method for detecting linkage between a marker locus and a trait locus in the presence of allelic association. The TDT uses information on the parent-to-offspring transmission status of the associated allele at a marker locus to assess linkage or association in the presence of the other. All TDT methods are valid tests for linkage, but they only have power in the presence of population association. Recently, George et al. proposed a regression-based TDT for linkage between a marker locus and a quantitative trait locus by modeling the trait as the dependent variable and the transmission status as one of the independent variables, along with other predictors and confounders, in a linear regression model. We propose a two-stage regression-based TDT procedure, specifically for quantitative traits from pedigree data, in which at the first stage a test of population association is performed, and then, if significant association is found, a test for linkage is performed at the second stage. The association test is performed using all members in the pedigree, whereas the linkage test in the second stage is performed using only the informative offspring. We investigate the statistical properties of the procedure by simulating markers, having various levels of association with the trait, at different recombination fractions from the trait locus. The two-stage procedure leads to more definitive conclusions regarding association and linkage, and its power, relative to the single-stage procedure, increases as the number of alleles at the marker locus increases.

Program Nr: 2548 from the 1999 ASHG Annual Meeting

A Gene Responsible for Paroxysmal Kinesigenic Choreoathetosis Mapped to Chromosome 16p11.2-q12.1. *H. Tomita[1], K. Yamada[1], N. Niikawa[1], Y. Nakane[2], S. Nagamitsu[3], T. Matsuishi[3], K. Wakui[4], Y. Fukushima[4], N. Kato[5]*. 1) Dept. of Human Genetics, Nagasaki Univ. School of Medicine, Nagasaki, Japan; 2) Dept. of Neuropsychiatry, Nagasaki Univ. School of Medicine., Nagasaki, Japan; 3) Dept. of Pediatrics and Child Health, Kurume Univ. School of Medicine., Kurume, Japan; 4) Dept. of Hygiene and Medical Genetics, Shinshu Univ. School of Medicine, Matsumoto, Japan; 5) Dept. of Neuropsychiatry, Faculty of Medicine., Univ. of Tokyo, Tokyo, Japan.

Paroxysmal kinesigenic choreoathetosis (PKC) [MIM 128200], a major form of paroxysmal dyskinesias, is characterized by brief attacks of involuntary movements induced by sudden voluntary movements. Although another form, paroxysmal dystonic choreoathetosis, was mapped to 2q33-35, the localization of the PKC gene has not been known. To localize it, we performed linkage analysis on eight Japanese families with autosomal dominant PKC. Two-point linkage analysis provided a maximum LOD score of 10.27 (recombination fraction = 0.00, penetrance; $p = 0.7$) at *D16S3081*, and a maximum multipoint LOD score for a subset of markers was calculated to be 11.51 ($p = 0.8$) at *D16S3080*. Haplotype analysis defined the disease locus within a region of ~12.4 cM between *D16S3093* and *D16S416*. To determine the chromosomal localization, we isolated P1-derived artificial chromosome clones 104-G-3 and 83-D-21 that correspond to the *D16S3093* and *D16S416* loci, and mapped them by FISH to 16p11.2 and 16q12.1, respectively. Thus, the PKC critical region (PKCR) in the eight families studied is assigned to 16p11.2-q12.1. The PKCR overlaps the region responsible for infantile convulsion and paroxysmal choreoathetosis [MIM 602066], a recently recognized clinical entity as a combination of benign infantile convulsion and non-kinesigenic form of paroxysmal dyskinesias.

Program Nr: 2549 from the 1999 ASHG Annual Meeting

One SNP - two alleles - three different complex diseases. *A.H. Torinsson[1], S. Nilsson[3], L. Samuelsson[1], A. Gudjònsdottir[2], B. Hallberg[1], T. Martinsson[1], H. Ascher[2], B. Kristiansson[2], L.M. Sollid[4], J. Ek[5], J. Wahlström[1].* 1) Clinical Genetics, SU/Östra sjukhuset, Göteborg, Sweden; 2) Peadiatrics, SU/Östra sjukhuset, Göteborg, Sweden; 3) Chalmers University of Technology, Göteborg, Sweden; 4) Inst. of Transplantational Immunology, Oslo, Norway; 5) Buskerud Central Hospital, Drammen, Norway.

Insulin Dependent Diabetes Mellitius(IDDM),Coeliac disease(CD) and Multiple Sclerosis(MS) are three complex diseases who all show allelic association to an A/G substitution at the +49 position of the Cytotoxic T-lymphocyte Associated(CTLA4)gene. While several studies show association between IDDM and the G-allele of this polymorphism, association to CD has been described to the A-allele, [Djilali-Saiah 1998]. This association with CD is now confirmed by our group in a Scandinavian population. In our study, Linkage and association analysis by the transmission disequilibrium test(TDT) were used on a total of 108 nuclear families. The TDT showed 115 trans- mitted vs. 78 non-transmitted A-alleles ($p<0.005$). Our results and the other studies all point to one conclusion; true disease gene associations. Interestingly since some of these IDDM and CD associations have been shown in the same population the association to the different alleles means that the potential gene or genes that are involved at 2q33 have different functions in the two diseases. There's an even more intriguing situation when one considers the recent results from a Norwegian study on MS. An association only to the heterozygote(A/G) was shown. Does this mean that perhaps one would need both of these factors interacting to show predisposition to MS?

.

Program Nr: 2550 from the 1999 ASHG Annual Meeting

A transmission disequilibrium test for discrete and continuous traits. *D.L. Tritchler[1, 3], S.B. Bull[2, 3], Y. Liu[3]*. 1) Ontario Cancer Institute; 2) Samuel Lunenfeld Research Institute of Mount Sinai Hospital; 3) Department of Public Health Sciences, University of Toronto, Toronto, Ontario, Canada.

A transmission disequilibrium test is derived for traits following any statistical distribution belonging to the exponential family, which includes the normal, Poisson, binomial, gamma, and inverse Gaussian distributions. A general score test statistic is derived which handles all the above cases. The score statistic is linear and leads to an analysis using regression methods, which facilitates outlier detection and model criticism. The model is flexible enough to handle additive and dominance effects, transmission distortion, covariates, and gene-gene and gene-environment interaction. Designs in which observations are sampled based on trait value are accommodated.

Program Nr: 2551 from the 1999 ASHG Annual Meeting

Detection of linkage disequilibrium using information from unlinked regions. *A.M Tsalenko, N.J Cox.* Department of Human Genetics, The University of Chicago, Chicago, IL.

It has been suggested that genome-wide linkage disequilibrium/association (LD/A) studies will become more prominent in the identification of susceptibility loci for common, complex disorders as denser marker maps are developed. The power to detect linkage in the presence of LD is a complex function of the linkage disequilibrium between the susceptibility allele and the marker allele examined, the correspondence between the frequencies of these two alleles, and the magnitude of the contribution the susceptibility locus makes to the liability to disease. In order to determine whether considering the contribution from two or more unlinked regions at a time might improve the power to detect susceptibility loci using LD/A mapping, we have developed a simple screening approach for considering the contributions from two unlinked markers simultaneously. Consider two bi-allelic markers, and the 3x3 matrix corresponding to the genotypes of affected individuals at these two markers. The deviation of the observed matrix from the null matrix computed using the allele frequencies of the markers can be used to determine whether there is evidence for LD and interaction between the markers. We simulated data using two interacting loci and two additional independent susceptibility loci, using recessive models for both the two loci with the epistatic interaction and the two additional independent susceptibility loci (total Kp = 0.13, 0.06 for the epistatic and 0.07 for the independent loci), and compared results of single locus TDT analyses and analyses of the 3x3 matrix for linkage disequilibrium (D') between marker and disease susceptibility alleles ranging from 0.0 to 1.0. We found that the deviation of the 3x3 matrix from its null expectation (under no LD) was detected at lower values of LD than was significant overtransmission of the associated allele via TDT, at least for these models. Moreover, the matrices behave differently in the case of interacting and non-interacting loci. Supported by 1R01 DK55889-01, HL49596 and HL56399.

Program Nr: 2552 from the 1999 ASHG Annual Meeting

Linkage analysis of hemiplegic migraine loci and ChrXq28 in 29 families with familial migraine. *P. van Galen[1], K. Gardner[3], J. Pascual[2], M. Barmada[1], J. Badger[3], M. Soso[3], E. Hoffman[4].* 1) Department of Human Genetics, University of Pittsburgh, PA; 2) Department of Neurology, University Hospital Marques de Valdecilla Santander, Spain; 3) Department of Neurology, University of Pittsburgh, Pittsburgh, PA; 4) Children's National Medical Center,Washington, DC.

Objective: Evaluate familial migraine (with and without aura) for evidence of linkage to the dominant familial hemiplegic migraine (FHM) loci and to a possible X-linked familial migraine locus. Background: Linkage has been previously established for FHM to Chr19p13, Chr1q21-23 and Chr1q31. An X-linked dominant locus spanning a large region around Xq28 has also been suggested for familial migraine. Methods: Probands of 29 migraine families with and without aura were ascertained from Spain (16 families, 69 affected patients) and USA (13 families, 40 affected patients) for a total of 85 sibpairs by neurologists (JP,KG,MS). Additional family members were evaluated directly (Spain) or by questionnaire and clinic or phone interview (USA). DNA was extracted from blood specimens and genotyped with markers D1S422, D1S413, D1S2745, D1S2707, D1S2635, D19S1150, D19S394, DXS1123, DXS1001, DXS1192 and DXS8043 from the four regions using standard PCR, gel electrophoresis and autoradiograms. Alleles were scored, aligned and several different methods of linkage analysis were used, including two-point VITESSE and MMLS with varying penetrance, phenocopy rate and inheritance models; multipoint GENEHUNTER and HOMOG. Results: Of the 29 families evaluated, two point analysis showed a highest LOD of 1.38, theta = 0.0 in a single family for region Chr1q21-23, using a recessive, 50% penetrant model, phenocopy 0%. The highest NPL score for a single family was 1.4 and 1.26, p values 0.043 for markers D1S2635 and D1S2707 at the proximal Chr1q21-23 FHM locus. The highest p value for combined families was 0.0885 at the Chr1q21-23 locus. Conclusion: There is no evidence of significant linkage among 29 familial migraine families to any of the three FHM loci or to the ChrX28 region.

Program Nr: 2553 from the 1999 ASHG Annual Meeting

Study of the apolipoprotein E promoter for Alzheimer's disease in a French population. *P. Verpillat[1], L. Zurutuza[2], G. Raux[2], D. Hannequin[2], A. Brice[3], D. Campion[2], F. Clerget-Darpoux[1], T. Frebourg[2]*. 1) Epidémiologie génétique, INSERM U155, Paris, France; 2) INSERM EPI 9906, Faculté de Médecine et de Pharmacie, IFRMP Rouen, France; 3) INSERM U289, Hôpital de la Salpêtrière, Paris, France.

The apolipoprotein E gene (APOE) is an uncontested genetic risk factor in Alzheimer's disease (AD). The involvement of his promoter has recently been suggested by several studies. Indeed, three polymorphisms of the APOE regulatory region (-186 G/T, -427 C/T and -491 A/T) have been found associated with AD even after adjustment on the APOE status. We analyzed the association of these three promoter polymorphisms on AD in a large French case-control study (388 AD cases and 386 controls). We found that the -427 T and -491 A alleles were associated with an increased risk of developing AD, but not the -186 G/T polymorphism. However, a strong linkage disequilibrium was observed between the alleles of these promoter polymorphisms and the APOE alleles. Consequently, association was retested after adjustment on APOE. Then, only the association with the -427 T allele remained significant. Our study reinforce the idea of a role of the APOE promoter in AD. However, it is important to emphasize that the observed associated alleles differ from one study to another. This may be explained by the different geographical origin of the used samples and by the difference in the linkage disequilibrium found between the alleles of the promoter polymorphisms and the ones of the APOE gene.

Program Nr: 2554 from the 1999 ASHG Annual Meeting

A new linkage analysis method for complex disorders based on multiple sets of data. *V.J. Vieland[1], K. Wang[2], J. Huang[1]*. 1) Univ Iowa, Iowa City, IA; 2) Univ Alabama at Birmingham.

For complex disorders, power to detect linkage in one set of data may be low, and power in follow-up samples may be lower. It is therefore essential to have rigorous methods for 'meta-analysis' based on multiple sets of data. We have developed a novel sequential Bayesian (SB) approach, based on sequential access to data collected at different sites or points in time. Using a prior distribution for the recombination fraction q based on the genetic map, a marginal posterior density for q is estimated while allowing for locus heterogeneity and other covariates. This posterior density is then used as the prior in analyzing a subsequent set of data, in which covariates can be independently modeled. The process can be applied repeatedly as new data become available. This provides a computationally efficient way to model important covariates within data sets while allowing them to vary across data sets. The result can be summarized by the posterior probability of linkage (PPL). Based on simulation of ASP data, we show that the PPL has better power to detect linkage, compared to the standard heterogeneity lod (HLOD), when follow-up data sets have a small proportion of "linked" families. The table shows power based on two data sets (D_1, D_2) of 100 ASP's each, for a simple dominant model (p=.01; penetrance=.5), as a function of the proportion of linked families a_i in D_i. Results are shown for a 0.001 size test; a_1=50%.

Power as a function of the proportion of linked families a2 in D_2

	a2=0.5	a2=0.4	a2=0.3	a2=0.2	a2=0.1
PPL	0.94	0.86	0.74	0.64	0.55
HLOD	0.93	0.84	0.69	0.53	0.35

These results illustrate (i) that for complex disorders, power can actually drop as the sample size increases; and (ii) that the PPL can be a more robust tool for linkage detection in such circumstances.

Program Nr: 2555 from the 1999 ASHG Annual Meeting

Analysis of the human T locus as a candidate gene for neural tube defects. *K.D. Viles[1], C. Drake[1], E. Melvin[1], A. Franklin[1], T.M. George[1], J.M. Vance[1], M.A. Pericak-Vance[1], J. Nye[2], J. Gilbert[1], M.C. Speer[1], NTD Collaborative Group[1]*. 1) Dept Medicine/Med Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Northwestern University Medical School, Dept. of Pediatrics, Chicago , IL.

Neural tube defects (NTDs) are among the most common birth defects. Mouse mutants that show NTDs provide good models for human NTD candidate gene investigation. The T (Brachyury) mutant mouse is one such model. The protein product of the T gene is critical for axis elongation, and heterozygous T mutants have short or absent tails due to abnormal posterior mesoderm development (Morrison, et al 1996). DNA was obtained from ninety-six caucasian patients- seventy-two sporadic cases and twenty-four multiplex cases- affected with lumbosacral myelomeningocele. This DNA was used to examine the human homolog T gene for its possible role as a susceptibility factor for NTDs. Eighty normal, causcasian, unrelated, control samples were also included in the analysis. Primers flanking each of the eight exons were designed from the published human T gene sequence. Each exon was amplified using pcr and analyzed for variants using single-strand conformation polymorphism. Each product showing a mobility shift was sequenced to determine the nucleotide change. All previously reported polymorphisms (Papapetrou et al 1997, Papapetrou et al 1999), including those in exons two, three, seven, and eight, were detected. The DNA sequencing identified a C363T nucleotide change in exon two and a G1176A change in exon eight. Neither of these resulted in an amino acid change. In exon seven, a rare C1013T (Ala338Val) variation was detected in one of the sporadic cases and not at all in the multiplex cases or in the controls. A second variant in exon eight was also detected. This A1106G (Asn369Ser) transition was seen in 15% of the case samples and 21% of the control samples. A third G1066A (Gly356Ser) change in exon eight is still being examined. Further analysis of this gene, including a novel variant in exon five, is in process.

Program Nr: 2556 from the 1999 ASHG Annual Meeting

Linkage of X-linked Myopathy with Excessive Autophagy (XMEA) to Xq28. *L. Villard[1], V. des Portes[2], N. Levy[1], J.P. Louboutin[3], D. Recan[2], M. Coquet[4], B. Chabrol[5], D. Figarella-Branger[5], J. Chelly[2], J.F. Pellissier[5], M. Fontes[1]*. 1) INSERM U491, Fac de Médecine La Timone, Marseille, France; 2) INSERM U129, Fac de Médecine Cochin, 75014 Paris; 3) CJF INSERM 96-01, Hôpital GR Laennec, Nantes; 4) Lab d'Anatomie Pathologique, Hôpital Pellegrin, Bordeaux; 5) Lab de Biopathologie Nerveuse et Musculaire, Fac de Médecine La Timone, Marseille.

X-linked myopathy with excessive autophagy (XMEA, MIM 310440) is a rare inherited mild myopathy segregating as an X-linked trait. This condition is characterized by juvenile onset and slow progression of the disorder, which seems to predominantly affect proximal muscles. Upon histological studies, the muscle does not display acute necrosis but shows an excess of autophagic processes and exocytosis of the phagocytosed material. This condition is named X-linked Myopathy with Excessive Autophagy (XMEA). So far, no extensive genetic analysis of this disorder has been performed, even though a potential lod score to the tip of long arm of X chromosome has been suggested by Saviranta et al. (Zmax=0.9). We have used 32 polymorphic markers spanning the entire X chromosome to exclude most of the chromosome except the Xq28 region in a large XMEA family. Using three additional families for linkage analysis, we have obtained a significant two-point lod score with marker DXS1183 (Z=2.69 at theta=0). A proximal recombinant has been detected between DXS1193 and DXS8011, which places the XMEA locus between DXS1193 and the telomere of the long arm of the X chromosome. Multipoint linkage analysis confirmed the assignment of the disease locus with a maximal lod score of 2.74 obtained at recombination fraction zero. Linkage of XMEA to the Xq28 region is thus firmly established. Several other inherited diseases with muscular involvment have been localized to this region of the human X chromosome and in particular the Emery-Dreifuss muscular dystrophy. We have ruled out the Emery-Dreifuss muscular dystrophy to be allelic with XMEA by direct sequencing of the emerin gene in three of our families.

Program Nr: 2557 from the 1999 ASHG Annual Meeting

Genomic mapping of a fourth gene involved in familial hypercholesterolemia. *L. Villéger[1], M. Varret[1], J-P. Rabès[1], B. Saint-Jore[1], A. Cenarro[2], M. Devillers[1], M. Krempf[3], M.J. Kotze[4], G.M. Kostner[5], M. Farnier[3], M. Martinez[1], C. Junien[1], C. Boileau[1]*. 1) INSERM U383 and U358, Paris, France; 2) Universidad de Zaragoza, Spain; 3) CHU Hôtel Dieu, Nantes and Point Médical, Dijon, France; 4) MRC Cape Heart Group, Tygerberg, South Africa; 5) University of Graz, Austria.

Autosomal Dominant Hypercholesterolemia (ADH) is one of the most common hereditary diseases, characterized by a selective increase of LDL particles, giving rise to premature mortality from cardiovascular complications. ADH results from molecular defects in either of two genes: mutations in the LDLR gene (FH1) lead to FH (Familial Hypercholesterolemia), and 3 mutations in the APOB gene (FH2) lead to FDB (Familial ligand-Defective apolipoprotein B-100). We showed the involvement of a third gene in ADH named FH3 and we localized it at 1p32-p34.1. The genetic linkage homogeneity test at the FH3 locus estimated that 73% out of the 13 nonLDLR/nonAPOB ADH families we studied were not linked to this locus, but to a fourth gene (or group of genes): FH4. We identified a large French ADH family (HC6) in which the involvement of the LDLR, APOB and FH3 genes had been excluded by using both genetic and biochemical approaches, suggesting the existence of this fourth locus. We undertook the identification of the FH4 locus using linkage analysis in family HC6. First, a candidate region approach was used: 30 candidate genes encoding proteins involved in cholesterol metabolism were tested, and linkage was excluded between theses markers and ADH in the family. Then, we undertook an exclusion mapping approach: 220 new microsatellite markers located throughout the genome were tested. To date, 80% of the genome has been excluded and a suggestive linkage was obtained with a Lod score of 2.6 (q=0). Suggestive linkage was also obtained for 3 other nonLDLR/nonAPOB/nonFH3 families [respective Lod scores of 1.17, 0.56 and 0.30 (q=0)] conforting the localization of the FH4 locus in this genomic region. Finally, a critical region of 4.3 cM was defined which probably contains the FH4 gene.

Program Nr: 2558 from the 1999 ASHG Annual Meeting

Autosomal Recessive Distal Spinal Muscular Atrophy with Diaphragmatic Palsy in Childhood is not linked to 5q13-SMA locus. *L. Viollet[1], A. Barois[2], P. Burlet[1], S. Bertrandy[1], E. Vial[1], S. Lefebvre[1], A. Munnich[1]*. 1) INSERM U-393, Hopital Necker, Paris, France; 2) Service de Pediatrie, Hopital Raymond Poincare, 92380 Garches, France.

Distal Spinal Muscular Atrophy with Diaphragmatic Palsy (DSMADP) in childhood is a rare neuromuscular disorder characterized by progressive motor weakness predominating on the distal part of the limbs and involving diaphragmatic dysfunction. Although fatal neonatal cases have been previously described, DSMADP with later onset and survival has not been reported. Symptoms begin after the age of one year, with a disability to walk, progressive course and relative stabilization in adulthood. Symmetric distal motor weakness and amyotrophy predominates in lower limbs and is associated with a later proximal involvement, causing walking missing by the age of five and serious orthopedic complications, such as joint contractures, clubfeet, clawhands and kyphoscoliosis. By contrast to Proximal Spinal Muscular Atrophy (SMA), severe and evolutive diaphragmatic palsy is constant, leading to restrictive respiratory insufficiency, requiring respiratory assistance. Electrophysiological nerve studies show evidence of pure motor neurogenic disorder, of "spinal" type. We report here a pedigree of three DSMADP children born to unaffected parents, consistent with autosomal recessive inheritance. No deletion of SMN exon 7-responsible for Proximal SMA- was detected in the affected cases. Analysis of DNA markers flanking the SMN locus on chromosome 5q13 revealed that two of the affected sibs were discordant for their haplotypes at the SMN locus. These data support the view that, in this family, DSMADP is not linked to chromosome 5q13. Recruitment of more informative DSMADP families will allow to undertake the genetic mapping of the disease and identification of the disease gene will hopefully help understanding the mechanisms of anterior horn cell degeneration in spinal muscular atrophies.

Program Nr: 2559 from the 1999 ASHG Annual Meeting

Genetic Mapping of Multiple Sclerosis in a Large American Pedigree. *E. Vitale[1, 5], M. Devoto[2], R. Sun[1], C. Rohowsky-Kochan[3], D. Nathanson[4], M. Schwalb[1], S. Cook[3].* 1) Dept Microbiology & Molecular Genetics, UMDNJ-New Jersey Medical School, Newark, NJ; 2) University of Genova, Genova, Italy; 3) Dept Neurosciences UMDNJ-New Jersey Medical School, Newark NJ; 4) Dept Neuroscience Sacred Heart Hospital Allentown, PA; 5) Institute of Molecular Genetics , CNR Alghero (SS), Italy.

There is evidence supporting the view that multiple sclerosis (MS) is a complex trait determined by genetic, environmental and autoimmune factors. Association and/or linkage studies to candidate genes have produced many reports of significant genetic effects including those for the major histocompatability complex (MHC), immunoglobulin heavy chain (IgH), T-cell receptor (TCR) and myelin basic protein (MBP) loci. With the exception of MHC, however these results have been difficult to replicate beyond isolated populations. We identified a large pedigree from Pennsylvania, with segregation of MS compatible with a fully penetrant dominant transmission with either an autosomal or X-linked mode of inheritance. We have collected and carefully phenotypically characterized 16 members from this family. Seven members show the typical findings in MS using clinical and magnetic resonance scanning (MRI) criteria. This family presents a unique opportunity to search for genes predisposing to MS by linkage analysis. Analysis of chromosome 6 has already excluded linkage to the HLA region. A first-stage genome screen using markers spaced at an average distance of 10-15 cM produced several lod-scores larger than 1, namely on chromosomes 1, 2, 3, 8, 10, 11, 12, 14, 16, 17, 18, 19. These regions are now being saturated with more markers in order to identify the region of true positive linkage.

Program Nr: 2560 from the 1999 ASHG Annual Meeting

Refined mapping and mutation screening of candidate genes for Welander distal myopathy. *D. von Tell[1,2], A-C. Thelander[1,2], M. Anvret[1], G. Ahlberg[1,2].* 1) Molecular Medicine, Karolinska Hospital, Stockholm, Sweden; 2) Clinical Neuroscience, Karolinska Hospital, Stockholm, Sweden.

Objective: Narrowing of the candidate gene region by refined mapping and screening of candidate genes for Welander distal myopathy(WDM). Background: WDM is a well-described autosomal dominant distal myopathy that is mainly seen in Sweden. Onset is late, between the ages of 40 and 60 and typical manifestations include weakness of long extensor muscles of hands and feet. Cardiac involvement is not seen and patients have normal life expectancy. Linkage studies have mapped the disease locus to chromosome 2p13. The region has been restricted to 2.4 cM through recombinations and a common shared haplotype. Material and Methods: DNA has been isolated from peripheral leukocytes from 122 individuals, 62 affected (9 families). Additional microsatellite markers were genotyped. Candidate genes were screened for mutations by single stranded conformation polymorphisms and direct fluorescent automated sequencing of the PCR products. Results: Recombinations for dysferlin intragenic microsatellite markers reduce the candidate region and exclude dysferlin as a candidate gene. Mutation screening was performed for the following candidate genes: dynactin (DCTN), dysferlin (DYSF), rab1 (RAB1), and adducin (ADD2). Antibodies towards dysferlin were used in Western blotting to screen for defective dysferlin protein product but no abnormalities were found. Discussion: Through new recombinations with markers CY172-H32 and 104-sat the region of the gene locus can further be narrowed down to below 2.4 cM. Further, there are several SNPs within our candidate region that will be investigated in order to minimize the region. No mutations have so far been identified within the screened candidate genes. A number of highly interesting candidate genes and ESTs with neuromuscular expression pattern remain to be screened within the candidate region. A positional cloning effort has been initiated.

Program Nr: 2561 from the 1999 ASHG Annual Meeting

Demonstration of a founder effect in British and Danish pedigrees mapping to the dominant optic atrophy locus on 3q28-qter. *M. Votruba[1,2], D. Thiselton[1], A.T. Moore[2], S.S. Bhattacharya[1], B. Kjer[3], T. Rosenberg[3], H. Eiberg[4]*. 1) Dept of Molecular Genetics, Institute of Ophthalmology, London, UK; 2) Moorfields Eye Hospital, London, UK; 3) National Eye Clinic, Hellerup, Denmark; 4) Dept of Medical Biochemistry and Genetics, The Panum Institute, University of Copenhagen, Denmark.

Dominant optic atrophy (DOA, gene-*OPA1*), a hereditary optic neuropathy causing decreased visual acuity, colour vision deficits, a centro-caecal scotoma and optic nerve pallor, has been mapped to a genetic interval of 1.4 cM between loci D3S3669 and D3S3562 on chromosome 3q28-qter. In order to further refine the critical disease interval, and to test the power of haplotype analysis and linkage disequilibrium mapping, we identified a total of 48 families with DOA, unrelated on the basis of genealogy, from a database of genetic eye disease families. 38 families originated from the British Isles and 10 families from Denmark, and all showed evidence of linkage to the *OPA1* locus. They were genotyped with 9 highly polymorphic microsatellite markers spanning a region of 12 cM around the *OPA1* locus. Allelic frequency analysis [(Chi-squared test, Likely-hood Ratio Test (LRT) and p values)] and haplotype parsimony analysis showed evidence of a founder effect. Five markers (D3S1314, D3S3669, D3S1523, D3S2305 and D3S3562), spanning 4.4 cM across the disease-associated region, demonstrated significant linkage disequilibrium by LRT ($p<0.05$). A peak LRT of 31.64 ($p<0.00000001$, $l=0.64$), and a peak chi-sq of 37.06 ($p<0.00003$) occurred at D3S1523. From haplotype parsimony analysis of the Danish pedigrees alone, it would appear that 7 out of 10 of the Danish pedigrees are party to the founder effect. Analysis of the British pedigrees alone has previously indicated that 36 out of 38 pedigrees were likely to be ancestrally related. This new data suggests that the UK and the Danish populations with dominant optic atrophy may share a common core founder haplotype.

Program Nr: 2562 from the 1999 ASHG Annual Meeting

Hypomagnesemia with secondary hypocalcemia (HSH): Narrowing the Disease Region on Chromosome 9. *R.Y. Walder[1], Z. Borochowitz[4], H. Shalev[5], R. Carmi[5], K. Elbedour[5], D.A. Scott[2], E.M. Stone[3], V.C. Sheffield[2].* 1) Dept Internal Medicine, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics; 3) Dept Ophthalmology; 4) Simon Winter Institute for Human Genetics, Haifa, Israel; 5) Genetics Institute, Soroka Medical Center, Ben Gurion University of Negev, Beer-Sheva, Israel.

Familial hypomagnesemia is an autosomal recessive disorder associated with secondary hypocalcemia (OMIM 602014). Affected individuals have extremely low levels of magnesium in the blood, and are frequently characterized by muscle weakness, tetany and seizures. Earlier work from our laboratory using DNA samples from three inbred Bedouin kindreds, containing 13 affected individuals, 11 males and 2 females, identified a region on chromosome 9 (9q12-9q22.2) linked to the disease. The linked interval spanned 14 cM and contained a large region of homozygosity, flanked by proximal marker D9S1874 and distal marker D9S1807. Several markers within this interval were linked with a LOD >3.0, with a maximum LOD of 7.14 for D9S284 at O= 0. Two unaffected individuals from the Bedouin kindreds showed recombinations within the HSH disease interval, narrowing the proximal flank to D9S1115. This narrowed genetic region is approximately 2.8 cM. In the present study, we describe two additional families, unrelated to the Bedouin kindreds, which are linked to the same interval on chromosome 9. There is no evidence of genetic heterogeneity in all of the HSH containing families that we have tested. One of these additional families contains two affected individuals with observed recombinations for D9S276 and D9S175. These recombinant individuals allow us to refine the interval to less than 1 cM, flanked by D9S1115 and D9S175. We have developed a YAC contig across the narrowest interval and using BACs and RH mapping, constructed a fine physical map of the HSH disease region. This map was used to search for ESTs in the interval. Selected BAC clones were sample sequenced to identify putative candidate genes from the region. This map will facilitate the positional cloning of the gene for HSH.
>q.

Program Nr: 2563 from the 1999 ASHG Annual Meeting

Genome scan for generalised nodal osteoarthritis susceptibility loci. *G.A. Wallis[1], R. Varhol[1], M.E. Grant[1], S. Eyre[1,2], P. Roby[1,2], W.O. Ollier[2], M. Doherty[3].* 1) Sch Biological Sci, Univ Manchester, Manchester, UK; 2) ARC ERU, Univ Manchester, Manchester, UK; 3) Dept Rheumatology, Univ Nottingham, Nottingham, UK.

Osteoarthritis (OA) is a heterogeneous disorder which represents the most common form of human joint disease. There is evidence that environmental and genetic factors contribute to the aetiology of the condition. Of the common subsets of idiopathic OA, generalised, nodal OA (GNOA) has the strongest familial predisposition and we therefore chose this form of OA for our search for OA susceptibility genes. For this purpose, families were recruited where there was at least one affected sibling pair (ASP) and the affected individuals had definite nodes on two or more distal interphalangeal joints of each hand plus radiographically confirmed OA in at least two sites (hands being one site). In a first stage genome scan, we have genotyped 249 individuals from 90 families including 187 affected females, 30 affected males and 163 ASP combinations using a standard set of microsatellite markers that span the genome. Analysis of the data using non-parametric pair wise linkage analysis identified 3 loci with a p less than 0.05: 2q24 (lod 1.45), 5cent (lod 0.8) and 8q24 (lod 1.4). Linkage between these loci and GNOA is currently being examined by inclusion of an additional 103 families (194 ASP combinations) and markers that span these loci in multipoint analyses.

Program Nr: 2564 from the 1999 ASHG Annual Meeting

construction of a physical and transcript map for a 1 Mb genomic region containing the urofacial (Ochoa) syndrome gene on 10q23-q24 and localization of the disease gene within two overlapping BAC clones. *C.Y. Wang, J.D. Sh1, Y.Q. Huang, P.E. Cruz, A. Davoodi-semiromi, J.X. She.* Dept Pathology/Immunol/Lab Med, Univ Florida, Gainesville, FL.

The urofacial (Ochoa) syndrome is an autosomal recessive disease characterized by distorted facial expression and urinary abnormalities. Previously, we mapped the UFS gene to chromosome 10q23-q24 and narrowed the interval to one YAC clone of 1,410kb. Here, we have constructed a BAC/PAC contig of the 1 Mb region using STS content mapping with 42 BAC/PAC-end sequences, 9 previously reported and 16 newly identified microsatellite markers and 14 EST markers. A total of 26 polymorphic microsatellite markers were genotyped for 31 UFS patients from Colombia and 2 patients from the US. Haplotype analyses suggest that the UFS gene is located within two overlapping BAC clones, a region of less than 360kb of DNA sequences. We tested 42 EST markers previously mapped to the D10S1709-D10S603 interval against the BAC/PAC contig and identified 11 ESTs located in the 1Mb region. Four of the 11 ESTs mapped to the 360kb UFS critical region. Shotgun sequencing of the two BAC clones and BLASTN search of the EST databases revealed three other ESTs contained in the UFS critical region. These results will facilitate the cloning and identification of the UFS gene.

Program Nr: 2565 from the 1999 ASHG Annual Meeting

Genome-Wide Linkage Analysis of Type 2 Diabetes-Related Quantitative Traits in the FUSION Study. *R.M. Watanabe[1], C.D. Langefeld[1], M. Epstein[1], T. Valle[1], S. Ghosh[1], F.S. Collins[1], R.N. Bergman[4], M. Boehnke[1], The FUSION Study Investigators[1,2,3,4].* 1) Dept. of Biostatistics, Univ. of Michigan School of Public Health, Ann Arbor, MI; 2) National Public Health Institutes, Helsinki, Finland; 3) National Human Genome Research Insititute, Bethesda, MD; 4) Dept. of Physiology & Biophysics, Univ. of Southern California, Los Angeles, CA.

The FUSION study is an effort to positionally clone genes for type 2 diabetes and related quantitative traits in a Finnish cohort. We sampled 580 families with type 2 diabetes (1240 affected subjects, 2095 total subjects) ascertained through affected sibling pairs, and have genotyped these subjects for >400 genetic markers spaced ~10 cM apart throughout the genome. Quantitative trait locus (QTL) linkage analysis was performed using variance components (VC) analysis of intact families using the program USERFQTL which combines elements of SIBLINK for identity-by-descent estimation in relative pairs and FISHER for VC estimation. We analyzed body mass index (BMI), waist-to-hip ratio (WHR), fasting and 2-hour glucose (GLU) and insulin (INS), fasting C-peptide, minimal model-derived measures of glucose effectiveness and insulin resistance, and acute insulin response (AIR) after adjusting for age and gender. Analyses were also done with and without additional adjustment for BMI or WHR, due to the known relationship between adiposity and type 2 diabetes. Affected (AFF) and unaffected (UAF) individuals were analyzed independently, because disease status may differentially affect trait values. Also, unaffected offspring (OFF) were analyzed as an additional "at-risk" group. Our most interesting results to date include: AIR on chr. 10 (UAF, LOD=3.11, distance from pter d=21 cM), fasting INS on chr. 14 (AFF, LOD=2.67, d=102 cM), fasting GLU on chr. 14 (OFF, LOD=2.66, d=23 cM), 2-hour GLU on chr. 20 (OFF, LOD=2.11, d=9.5 cM). These initial results provide evidence for several quantitative trait loci along the genome. In addition, because these traits are closely related to type 2 diabetes, these QTL linkage results may provide information regarding the location of type 2 diabetes susceptibility loci.

Program Nr: 2566 from the 1999 ASHG Annual Meeting

High throughput whole genome polymorphism scans. *J.L. Weber, W. Dickinson, T.A. Kronenwetter-Koepel, L. Ott, T.L. Rusch, D.A. Vaske, C. Zhao.* Center for Medical Genetics, Marshfield Medical Research Foundation, Marshfield, WI.

Human whole genome polymorphism scans are currently used widely in linkage mapping and in the future will also likely find broad clinical application. While diallelic polymorphisms have received a great deal of attention and hold great potential, no one has yet been able to devise an effective means of employing diallelic polymorphisms in whole genome scans. Fortunately, genotyping of multiallelic short tandem repeat polymorphisms (STRPs) continues to steadily improve. In 1999, whole genome scans using about 400 STRPs will be completed at Marshfield on over 13,000 individuals at a total cost, including indirect costs, of about $150 per individual (< $0.40 per genotype). Genotyping quality has remained fairly constant during productivity improvement. Genotyping completeness averages about 97.5%; and genotyping accuracy about 99.5%. Primary sources of cost reductions have been experience of laboratory members, use of optimal markers, economies of scale, and, most importantly, improvements in technology. Major and minor improvements have been made in the laboratory processes for genotyping, in the instruments used in the genotyping process, and in the software and computer systems for allele calling and data management. Our large capacity water bath thermal cyclers have proven highly reliable and cost effective. Our Scanning FlUorescent Detectors (SCAFUDs) currently utilize 200 lane gels and 16 channel PMT array detectors, so that up to 7 different visible fluorescent dyes and 33,600 genotypes can be obtained in each gel run. Excluding dropouts, our allele calling software currently has an accuracy of about 95%. A new screening set of 400 STRPs (Screening Set 10), recently developed by D. Vaske, eliminates markers which were particularly difficult to score, and provides improved spacing of markers along the chromosomes and better coverage of telomeres. Many additional improvements in STRP genotyping are in progress. Within two-three years it is likely that 400 marker total genotyping scan costs can be reduced to to $100 or less per individual ($0.25 per genotype). Plans are also in place to steadily expand our marker screening set to 800-1,000 STRPs.

Program Nr: 2567 from the 1999 ASHG Annual Meeting

Refinement of the Limb Girdle Muscular Dystrophy Type 2H (LGMD2H) Candidate Region. *T. Weiler[1], T. Sudha[1], E. Nylen[1], T.M. Fujiwara[2], K. Morgan[2], C.R. Greenberg[1], K. Wrogemann[1]*. 1) Univ. Manitoba, Winnipeg, MB, Canada; 2) McGill Univ., Montreal, PQ, Canada.

Limb girdle muscular dystrophy type 2H (LGMD2H) is an autosomal recessive disorder initially described by Shokeir and Kobrinsky in 1976 in Manitoba Hutterites (Clin. Genet. 9:197-202, 1976). We have recently mapped the location of this gene to chromosome 9q31-q33 in a 4.4 Mbp region (Genetic Location Database, LDB), flanked by *D9S302* and *D9S1850* (AJHG 63:140-147, 1998). Here we report the identification of additional Manitoba Hutterite families affected with LGMD2H, the refinement of the *LGMD2H* candidate interval, extensive re-ordering of the region on the basis of YAC contigs, genomic sequences, radiation hybrid (RH) mapping and recombination events in LGMD2H & CEPH families.

Two new nuclear families with 3 LGMD patients have been identified and analyzed. Two of these patients are in their late 50's with a history of elevated creatine kinase (CK) levels. Both are now wheelchair bound. The other patient is 40 yrs old, exhibits proximal weakness and has an elevated CK level. These two families as well as the four previously reported families have been genotyped with 17 additional markers located between *D9S302* and *D9S1850*. Analysis of haplotypes revealed recombination events in this region in five individuals refining the *LGMD2H* candidate region to an area flanked by *D9S1855* and *D9S1802*. The order of the markers in this region however, based on the LDB, Marshfield and GeneMap '99 maps and 1 Mbp of genomic sequence, is not in agreement. Hence, haplotypes of CEPH individuals and a YAC contig were constructed and RH mapping using the TNG panel from the Stanford Human Genome Centre (SHGC) was performed. The high resolution TNG panel has been screened for all the markers in the candidate region. Together, the 6 recombinant chromosomes, the YAC contig, the 9q32 genomic sequence and the RH map of the *LGMD2H* region have served to order the markers and have reduced the size of the candidate area.

Program Nr: 2568 from the 1999 ASHG Annual Meeting

Linkage Mapping Set-HD5 on ABI Prism® 377, 310 and 3700 DNA Analyzers. *A. Wheaton, K. Rogers, M. Roque-Biewer, Y. Wang, M. Rivera, N. Caffo, P. Dong.* Genetic Analysis R&D, PE Biosystems, Foster City, CA.

The newly introduced Linkage Mapping Set-HD5 (LMS-HD5) is a set of optimized microsatellite markers originally identified in the Genethon Human Linkage Map (Dib et al. 1996 Nature 380:A1-138), that provides an average 5 cM genome-wide coverage. LMS-HD5 utilizes the dye set 6-FAM, HEX, NED, and ROX, and the reverse primers are tailed on the 5 end to minimize plus A inconsistencies. The set incorporates the 400 markers originally in the Linkage Mapping Set-MD10 (previously LMS V2) and 411 newly designed markers, for a total of 811 markers. We will demonstrate the cross-platform performance of the Linkage Mapping Set -HD5 on the ABI Prism 377, 310 DNA sequencers, and the ABI Prism 3700 DNA analyzer. We will describe optimized pooling ratios of PCR products for each platform as well as demonstrate sizing accuracy across platforms. As expected sizing estimates of the same DNA fragment can vary across instrument platforms. We will show that the sizing precision is within a +/- 0.15bp standard deviation on all instrument platforms.

Program Nr: 2569 from the 1999 ASHG Annual Meeting

The insulin receptor related receptor gene (*IRR*) is mapped to chromosome 1q21-q23: A candidate diabetes susceptibility locus. *T.E. Whitmore, M.F. Maurer, H.L. Day, A.C. Jelmberg, M.M. Dasovich, S.K. Burkhead, M.D. Heipel, S.R. Jaspers, R.D. Holly, S. Lok.* ZymoGenetics Inc., Seattle, WA.

The insulin receptor related receptor (IRR) is an orphan member of the insulin receptor family. The receptor is a heterotetrameric glycoprotein consisting of extracellullar alpha-subunits comprising the ligand binding domain that are disulfide-bonded to beta-subunits spanning the cell membrane and contain a cytoplasmic tyrosine kinase which is activated upon ligand binding. *IRR* is expressed in sensory and sympathetic neurons, renal epithelial cells, enterochromaffin-like cells of the fundic stomach and islet beta cells where it has been proposed to regulate the physiological function of insulin secreting cells (Ozaki 1998, Eur. J. Endocrinol. 139: 244). While a ligand for IRR has not been identified, the IRR signaling pathway includes the phosphorylation of insulin receptor substrate-2 (Hirayama et al. 1999, Diabetes 48: 1237), a cytosolic docking protein believed to regulate compensatory increase in pancreatic beta-cell mass (Withers et al. 1998, Nature 391: 900). As a first step to assess a possible role of *IRR* in heritable forms of diabetes, we carried out a regional mapping of the human *IRR* locus. The *IRR* locus was mapped to chromosome 1 using the Stanford G3 Radiation Hybrid Mapping Panel. The results showed linkage of *IRR* to chromosome 1 marker *SHGC-69054* with a LOD score of 11.39 and a distance of 0 cR from the marker. Comparison with the surrounding cytogenetically mapped genes positions *IRR* in the 1q21-q23 region of chromosome 1. The *IRR* locus is approximately 1.5 Mb proximal to *APOA2*, in a region that is implicated for a major recessive diabetes locus identified from a new genome-wide search of susceptibility genes in multigenerational families of Northern European ancestry (Elbein et al. 1999, Diabetes 48: 1175). Additionally, a genomic scan for loci linked to type II diabetes and body-mass index in Pima Indians has also indicated a potential diabetes susceptibility locus in the 1q21-q23 region (Hanson et al. 1998, Am. J. Hum. Genet. 63: 1130). These results support *IRR* as a strong candidate for a diabetes susceptibility gene locus residing on chromosome 1q21-q23.

Program Nr: 2570 from the 1999 ASHG Annual Meeting

Genomic screen for primary open angle glaucoma susceptibility genes. *J.L. Wiggs[1], J.L. Haines[2], A.M. Hossain[2], J. Kern[1], E.A. del Bono[1], B. Broomer[3], F.L. Graham[3], M.A. Pericak-Vance[3], R.R. Allingham[3].* 1) Depts of Ophthalmology and Genetics, New England Medical Ctr, Boston, MA; 2) Dept of Genetics, Vanderbilt University, Nashville, TN; 3) Depts of Ophthalmology and Genetics, Duke University, Durham, NC.

Primary open angle glaucoma (POAG) is the leading cause of irreversible blindness worldwide. POAG is characterized by progressive optic nerve atrophy, visual field loss, and often elevated intraocular pressure. Onset is usually after the fifth decade. A family history of POAG is a significant risk factor for the disease and indicates a genetic etiology. Previous studies have suggested that multiple genetic and possibly environmental factors may participate in the disease process. To locate genes that may be associated with POAG, we have completed an initial genome screen using 103 affected sibpairs (121 affected individuals). POAG was defined as: age of diagnosis greater than 35, IOP greater than 22mmHg in both eyes, glaucomatous optic nerve damage in both eyes and visual field loss in at least one eye. Individuals with secondary causes of glaucoma were excluded. Four hundred and forty-five markers spanning the human genome at approximately 7 cM intervals were analyzed. Linkage analysis was performed using both model-dependent (lod score) and model-independent affected relative pair, and sibpair methods. Sixteen regions on chromosomes 1, 2, 3, 4, 5, 6, 8, 9, 10, 11, 12, 14, 15, 17, and 19 showed interesting results (p-value <0.05 and/or a lod score >1.0). Using a second pedigree set of 69 affected sibpairs (81 affected individuals) continued positive results have been found for four of these regions (chromosomes 2, 9, 14 and 19). The region identified on chromosome 2 may correspond to a previously identified glaucoma susceptibility locus (GLC1B), while the other regions are novel. Further follow-up studies are in progress.

Program Nr: 2571 from the 1999 ASHG Annual Meeting

Chromosome 12 and late onset Alzheimer's disease. *E.M. Wijsman[1], E.W. Daw[1], E.J. Nemens[2], H. Payami[3], T.D. Bird[2], G.D. Schellenberg[2]*. 1) Dept Medical Genetics, Univ Washington Sch Medicine, Seattle, WA; 2) VA Medical Center, Seattle, WA; 3) Oregon Health Sciences University, Portland, OR.

While 3 genes have been identified that play a role in early onset Alzheimer's disease (AD) only ApoE has been definitively associated with late-onset AD (LOAD). Recently, reports of linkage and combined linkage and association studies have implicated genes on chromosome 12, including the region between D12S273 and D12S390, and the genes LRP and A2M. These await confirmation.

We have performed analyses of 67 LOAD families ranging in size from 4 to 53 individuals (685 total individuals) with 23 chromosome 12 markers, plus LRP and A2M. ApoE was included as a major-gene covariate. The method of analysis was Monte Carlo Markov chain joint oligogenic segregation and linkage analysis which gives accurate localization even in the presence of genetic heterogeneity. Observed age-of-onset or censoring was used as the phenotype. Covariate effects were estimated as shifts in age-of-onset. Evidence for linkage was assessed by the ratio of observed to expected placements of trait loci. We found modest evidence for linkage (~4 fold increase in trait locus placements over baseline) at about 38cM on the Marshfield map. We found no evidence for linkage between D12S273 and D12S390. In a joint major gene covariate analysis of LRP, A2M and ApoE, ApoE genotype effects were as previously reported, but there was no evidence that LRP genotypes differed in age-of-onset (mean difference, d, between the heterozygote and common homozygote of d=0.0033 yrs, sd=1.64 yrs). For A2M, there was a modest decrease in age-of-onset for the heterozygote relative to the most common homozygote (d=.85 yrs, sd=1.62 yrs) and no difference between the heterozygote and rare homozygote. The common allele was reported previously to be associated with increased AD risk, while here the risk associated with this allele decreased. Our results provide little or no evidence supporting the role of LRP and A2M in AD risk, exclude linkage from one region of chromosome 12, and provide at best weak evidence for linkage to the other region. Supported by NIH AG05136 and GM46255.

Program Nr: 2572 from the 1999 ASHG Annual Meeting

A genome-wide scan in 72 sib-pair families with schizophrenia reveals suggestive evidence for 7 potential susceptibility loci. *D.B. Wildenauer[1], S.G. Schwab[1], J. Hallmayer[2], B. Lerer[3], K. Kanyas[3], M. Albus[4], G.N. Eckstein[1], M. Borrmann[4], M. Rietschel[1], D. Lichtermann[1], M. Trixler[5], W. Maier[1]*. 1) Dept Psych, Univ Bonn, Germany; 2) Graylands Hospital/University of Western Australia, Mt Claremont, Australia; 3) Dept Psych, Hadassah University Medical Center, Jerusalem, Israel; 4) Mental State Hospital, Haar, Germany; 5) Dept Psych, University Medical School of Pecs, Hungary.

Schizophrenia is a devastating mental disorder which affects worldwide up to 1% of the population. A role of genetic factors in development of the illness is documented by family-, twin-, and adoption studies. These studies and the failure to detect Mendelian inheritance by segregation analysis suggests polygenic inheritance and environmental influences. We have ascertained 72 families (470 individuals) through a schizophrenic or chronic schizoaffective (RDC) index patient, each family having at least 2 affected siblings and parental information (67 families with both parents, 5 with one parent and unaffected siblings). 13 families were from Israel, 59 from Germany. The sample comprises a total of 87 (n-1) and 107 (n(n-1)1/2) sib-pair combinations for affected sib-pair analysis, identity by descent. 415 fluorescence labeled microsatellite marker have been used for genotyping in approximately 10 cM average distance. In addition to previously in our sample detected potential susceptibility loci on 6p22,23, 10p14-11, 22q12,13 (supported by other groups in independent samples),18p11.2 (supported by linkage disequilibrium and by overlapping with findings in bipolar disorder), suggestive evidence was obtained for 4q (NPL=2.7, p=0.003 around D4S2917) and 6q (NPL=2.4, p=0.008 around marker D6S1613). A potential locus on 5q31 (around D5S399) which had been previously detected in a subsample of 44 families was not supported in the genome scan sample of 72 families (mlod = 0.64 for D5S399). However, 25 cM telomeric to D5S399, a mlod of 1.68 (NPL=2.5, p=0.006) was obtained for marker D5S422. The study demonstrates difficulties in mapping susceptibility loci for schizophrenia, but provides also suggestive evidence for regions which may be screened for candidate genes.

Program Nr: 2573 from the 1999 ASHG Annual Meeting

Confirmation of linkage between the HLA-DR locus and multiple sclerosis in two unusually large MS families.

C.J. Willer[1], D.A. Dyment[1], A.D. Sadovnick[2], N. Risch[3], G.C. Ebers[1], Canadian Collaborative Project on Genetic Susceptibility to Multiple Sclerosis[2]. 1) University of Oxford, Department of Clinical Neurology, Radcliffe Infirmary, Woodstock Road,Oxford England; 2) The Department of Medical Genetics, University of British Columbia, Vancouver, BC; 3) The Department of Genetics, Stanford University, Palo Alto, CA.

Multiple sclerosis (MS) is a complex trait. Genetic analysis of MS has typically been approached with an affected relative pair analysis. Complexity seems certain and even the large numbers of sibling pairs available may not find all susceptibility genes by linkage methods. Previous association studies have implicated the human leukocyte antigen (HLA) genes within the major histocompatibility complex (MHC) on 6p21 as being involved in MS susceptibility. Four recent genome scans using sibling pairs have demonstrated the involvement of the MHC region in MS susceptibility. However, evidence for other loci remains modest. One approach to the problem of complexity is to examine isolated pedigrees with a high recurrence rate.

The Canadian Collaborative Project on the Genetic Susceptibility to Multiple Sclerosis (CCPGSMS) has ascertained over 15,000 individuals with MS. The CCPGSMS has identified over 1,000 families with at least two affected individuals and blood samples from 900 families have been collected. 110 Pedigrees with more than four affected family members were chosen for possible genetic study. The two largest families, with 14 and 9 affected individuals respectively, detected linkage to the HLA-DR locus with a lod score of 2. This supports the suggestion based on clinical findings that these families have a type of MS in which the MHC plays a similar role in susceptibility to that seen in families with one or two affected individuals.

Future studies of multiple sclerosis may be aided by focusing on large kindreds to confirm or identify regions of susceptibility to MS. Aside from the labour and cost advantages, large kindreds are more likely to be homogeneous than populations of affected relative pairs.

Program Nr: 2574 from the 1999 ASHG Annual Meeting

Linkage of a Gene Causing Familial Focal Segmental Glomerulosclerosis. *M.P. Winn[1], P.J. Conlon[2], K.L. Lynn[3], D.N. Howell[4], B.D. Slotterbeck[1,5], A.H. Smith[3], F.L. Graham[1,5], M.L. Bembe[1,5], L.D. Quarles[1], M.A. Pericak-Vance[1,5], J.M. Vance[1,5]*. 1) Medicine, Duke University Medical Center, Durham, NC; 2) Nephrology, Beaumont Hospital, Dublin, Ireland; 3) Nephrology, Christchurch Hospital, New Zealand; 4) Pathology, Duke University Medical Center, Durham, NC; 5) Center for Human Genetics, Duke University Medical Center, Durham, NC.

Focal segmental glomerulosclerosis (FSGS) is a pathological entity characterized by proteinuria, nephrotic syndrome and the progressive loss of renal function. It is a common cause of end-stage renal disease (ESRD). Autosomal dominant and recessive forms of FSGS have been identified as well as types associated with congenital syndromes. Two families with autosomal dominant FSGS were evaluated for linkage using 351 genomic microsatellite markers. Linkage, multipoint analysis, and tests for heterogeneity were performed on the subsequent results. In addition, three small families were utilized for haplotype analysis. Evidence for linkage was found on chromosome 11q21-22 for the largest family, with a maximum LOD score of 9.89. The gene is currently localized to an approximately 8 cM area between flanking markers D11S919 and D11S1986. The disease in a second family was not linked to this locus, or to a previously described locus on chromosome 19q13. There were no shared haplotypes among affected individuals in the three smaller families. Our findings demonstrate that genetic heterogeneity is prevalent in FSGS in that at least three genes cause the FSGS phenotype. Identification of the genes which cause familial FSGS will provide valuable insights into the molecular basis and pathophysiology of FSGS.

Program Nr: 2575 from the 1999 ASHG Annual Meeting

Linkage analysis of candidate regions in Swedish non-syndromic cleft lip and palate families. *F.K. Wong[1,2], C. Hagberg[2], A. Karsten[2], O. Larson[3], J. Huggare[2], C. Larsson[1], B.T. Teh[1], S. Linder-Aronson[2].* 1) Molecular Medicine, Karolinska Hospital , Stockholm, Sweden; 2) Orthodontics, Karolinska Institutet, Stockholm, Sweden; 3) Reconstructive Plastic Surgery, Karolinska Hospital, Stockholm, Sweden.

Objective: To analyze linkage of four candidate regions for non-syndromic cleft lip and palate (CLP) on chromosome 2p13, 4q, 6p23 and 19q13; in addition chromosome 1q32, the locus for van der Woude syndrome (VWS), on Swedish CLP families. Design: Three to five linked microsatellite markers were selected from each candidate region. Polymerase chain reaction (PCR) with fluorescent labeled markers was performed on DNA samples from the participating families. Electrophoresis of the PCR products was performed on a laser-fluorescent DNA sequencer. The genotype data was analyzed with multi-point linkage analysis. Mode of inheritance tested included two autosomal dominant, an autosomal recessive and a non-parametric model. Multi-point LOD scores were also calculated by assuming genetic heterogeneity. Participants: Nineteen Swedish families each with at least two members affected with CLP. Results: Cumulative multi-point LOD scores calculated under autosomal dominant modes of inheritance were less than -2 except chromosome 6p23. LOD scores calculated under recesive inheritance and the non-parametric model were inconclusive. There was no significant evidence of genetic heterogeneity among the sample group. Conclusions: Linkage of the Swedish CLP families to the candidate regions (1q32, 2p13, 4q, 6p23 and 19q13) could not be established. This may suggest a new but yet unknown CLP locus or loci in the Swedish families. The results may, however, reflect the heterogeneity of CLP which is difficult to confirm statistically in this sample group. The families collected and the linkage results from this study will form the base for future genetic studies of CLP in this population.

Program Nr: 2576 from the 1999 ASHG Annual Meeting

Mapping of Familial Partial Epilepsy with Variable Foci to 22q12 and Genotype-Phenotype Correlation. *L. Xiong[1,2], M. Labuda[1], J.C. Mulley[5], D.S. Li[1], R. Desbiens[3], S. Verret[3], P. Langevin[3], S. Mercho[2], M.H. Seni[2], F. Dubeau[2], S.F. Berkovic[1,4], J. Serrotosa[6], F. Andermann[2], E. Andermann[2], M. Pandolfo[1,2].* 1) Notre Dame Hospital, CHUM, Montreal, Quebec, Canada; 2) Dept Neurology & Neurosurgery, Montreal Neurological Inst, Montreal, PQ, Canada; 3) CHUQ, Quebec, Quebec, Canada; 4) Austin and Repatriation Medical Centre, Melbourne, Australia; 5) Women's and Children's Hospital, North Adelaide, Australia; 6) Neurology Service, Fundacion Jimenez, Madrid, Spain.

We previously described three large French Canadian families presenting with a clinically homogeneous phenotype of familial partial epilepsy with variable foci (FPEVF). Genotyping, using polymorphic microsatellite markers and linkage analysis by maximum-likelihood parametric approach and a dominant model with 50% penetrance was carried out. Candidate loci were tested and a whole genome scan was performed. We identified linked markers to chromosome 22q12 for the two largst families with a combined lod score of 6.58. Another French Canadian family with 7 affected individuals presenting with the same phenotype was subsequently identified showing linkage to the same locus and sharing the same haplotype. By analysis of recombination events, the disease locus was localized within a 3.7 cM interval. A Spanish family with a similar phenotype also showed evidence of linkage (lod score=2.8), but with a different haplotype. Genotype-phenotype correlation revealed that the phenotypic spectrum within the three families includes partial seizures arising from frontal, temporal or occipital foci in different affected individuals, with age of onset varying from 3 to 25 years. Individuals with symptomatic epilepsy, isolated deja vu symptoms, other episodic disorders were not found to carry the disease haplotype. One of the probands was found to be homozygous for the linked haplotype. None of 21 additional families presenting with various familial partial epilepsies showed linkage to the same locus.Mutation analysis excluded a few candidate genes within the region, including 14-3-3 protein, RRP22 protein, etc.. Our results support the view that familial partial epilepsy can be caused by syndrome-specific genes with Mendelian inheritance.

Program Nr: 2577 from the 1999 ASHG Annual Meeting

Determination of SNP Allele Frequency by A DNA Pooling Method. *C. Xu, C. Donnelly, D. Montgomery, C. Allan, I. Purvis.* Dept Molecular Genetics, Glaxo Wellcome R&D, Hertfordshire, England.

Allelic association study is one of the most powerful methods for mapping genes that contribute to complex diseases. However, due to the large number of markers and DNA samples required, it is very labour-intensive and expensive to carry out such studies. DNA pooling has been shown to be an effective preliminary screen method for allelic association studies, which can reduce the labour and cost significantly. We described a TaqMan method to determine the allele frequencies of single nucleotide polymorphisms by DNA pooling. The allele frequencies of 3 SNPs were determined in a pool consisting of 80 individuals. These estimated allele frequencies by DNA pooling were then compared to that calculated from the genotype of each individual. Accurate estimation was also obtained even at very low concentrations of DNA. In addition, this method detected small increases or decreases in allele frequencies of SNPs within the pool indicating that it is a feasible way to determine allele frequencies in association studies. Our results showed that Taqman is an effective and efficient method in determining SNP allele frequencies in a DNA pool.

Program Nr: 2578 from the 1999 ASHG Annual Meeting

A genome-wide search for Crohn's disease susceptibility loci in Ashkenazi Jewish families pooled from four U.S. IBD research groups. *H. Yang[1], J.H. Cho[2], R.H. Duerr[3], K.D. Taylor[1], Y.C. Lin[1], J.I. Rotter[1], S.R. Brant[4].* 1) Div. Med Genetics, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) Univ. of Chicago, Chicago, IL; 3) Univ. of Pittsburgh, Pittsburgh, PA; 4) Johns Hopkins Univ., Baltimore, MD.

Background/Aims: Chronic inflammatory bowel disease (IBD) presents as two major clinical forms, Crohn's disease (CD) and ulcerative colitis (UC). The Ashkenazi Jewish population has a 3-4-fold greater risk for IBD than non-Jewish Caucasians. The estimated relative risk to siblings is much greater for CD (30) than that for UC (15). The aim of this study is to identify specific susceptibility loci for CD in Ashkenazi Jewish families with a genome-wide search approach. **Methods:** A total of 63 CD only families (13 extended and 50 sib-pair) from four IBD research groups were studied. The genotyping in these families was part of a whole genome scan effort in each group with different marker panels (ABI linkage panel 1 and 2, Weber screening set 8.0). To perform linkage analysis in the combined sample, we integrated all markers by using the Broman et al map (1998). Approximately 350 microsatellite markers with an average interval of 10 cM were used by each group. Multipoint linkage analysis was performed using GENEHUNTER2.0 and GENEHUNTER- PLUS1.1. **Results:** For the combined screen, evidence for linkage was strongest at chr 16p12 (multipoint logarithm of the odds, MLod=2.0, NPL=2.4, p=0.008), 30cM p-telomeric to the previously reported *IBD1* region. In addition, nominal evidence for linkage was observed at chr. 2p, 3q, 4q, 5q, and 17qter (Mlod>1.2, NPL>2, p<0.02). The 3q and 4q peaks overlie the same regions reported previously by Cho et al. (1998). No evidence was present for the *IBD2* locus on chr. 12 reported by Satsangi et al. (1996). **Conclusion:** These results provide evidence for potential susceptibility loci contributing to the risk of CD specifically in Ashkenazi Jewish families. *IBD1* may be more p-telomeric relative to previous reports or there is a 2nd chr 16 susceptibility locus. Further fine mapping is required to narrow the region and identify positional candidate genes which may be relevant to the pathogenesis of CD.

Program Nr: 2579 from the 1999 ASHG Annual Meeting

Sequence-based polymorphisms in members of the apoptosis Bcl-2 gene family and their association with hematocrit level. *J. Yankowitz[1], S. Zeng[1], J.C. Murray[2], J.A. Widness[2], R.G. Strauss[3]*. 1) Dept OB/GYN; 2) Dept Peds; 3) Dept Path, Univ Iowa Hosp & Clinics, Iowa City, IA.

Apoptosis, or programmed cell death, is an active process which controls cell number and quality. Apoptosis may play a role in hematopoiesis. The Bcl-2 gene family includes anti-apoptotic (bcl-2, bcl-xL, bclw) and pro-apoptotic (bcl-xS, Bak, Bax) genes. Members of the Bcl-2 family have been shown to mediate survival of erythroid cells. Deregulation of the Bcl-2 family may lead to an increase in red cell destruction and anemia. We sought to find polymorphisms in the bcl-x, Bax and bclw genes and determine whether they were linked to hematocrit.

We screened the 5'- and 3'-regions of bcl-x, Bax, and bclw using PCR and SSCP analysis. One sequence-based polymorphic locus was found in each 5'-region of Bax and bclw having 3 and 2 alleles respectively. No polymorphism was found for bcl-x. Strong linkage between the Bax polymorphism and several markers on chromosome 19 was seen. The bclw polymorphism was strongly linked to D14S50. Direct sequencing showed the Bax polymorphism to be caused by variation in adenine nucleotide repeat number (19, 25, 27) starting at position 360 and the bclw polymorphism is the result of a G to A transition at 550. The allelic frequencies for Bax were, 0.2 for A1, 0.08 for A2, 0.78 for A3, and for bclw 0.24 A and 0.76 for G. Both are in are in Hardy-Weinberg equilibrium. Using these Bax and bclw polymorphic markers, we genotyped 200 subjects with high or low hematocrit (Hct) selected from a population of 819 healthy Iowans. A comparison of the allelic frequencies and distribution of each polymorphism was made in the low vs high Hct, male vs female, male low vs male high Hct, female low vs female high Hct, male high vs female high Hct and male low vs female low Hct group. Statistical analysis indicated that the allelic frequencies of the polymorphic loci were not significantly different in any of the comparisons ($P>0.05$). Nucleotide variation at the 5-region of Bax or Bcl-w does not appear to be related to human Hct level. These polymorphisms can be a powerful tool to study other events which may be linked to the Bax and bclw genes.

Program Nr: 2580 from the 1999 ASHG Annual Meeting

Further refinement of the MYP2 locus for autosomal dominant high myopia by linkage disequilibrium analysis.
T.L. Young, S.M. Ronan, A.B. Alvear, S.C. Wildenberg, A.T. DeWan, J. Peterson, W.S. Oetting, L.D. Atwood, R.A. King.
Univ Minnesota, Minneapolis, MN.

High myopia (> -6.00 diopters) is a complex common disorder that predisposes individuals to retinal detachment, glaucoma, macular degeneration, and premature cataracts. Recent linkage analysis of 7 families with autosomal dominant high myopia has identified one locus (MYP2) for this disorder on chromosome 18p11.31 (AJHG 63:109;1998). Haplotype analysis revealed an initial interval of 7.6 cM.

We performed transmission disequilibrium testing (TDT) using both the S.A.G.E. 3.1 TDTEX and GENEHUNTER 2 programs of chromosome 18p marker alleles. The following p values were obtained for these markers in marker order used for fine mapping in this region; D18S1146 (p = 0.227), D18S481 (p = 0.001), D18S63 (p = 0.062), D18S1138 (p = 0.0004), D18S52 (p = 1.79 x 10-6), and D18S62 (p = 0.141) by S.A.G.E. analysis. GENEHUNTER 2 TDT analysis revealed the p values for the linked allele for the following markers; D18S1146 (allele 2, p = 0.083), D18S481 (allele 1, p = 0.108), D18S63 (allele 11, p = 0.034), D18S1138 (allele 6, p = 0.011), D18S52 (allele 4, p = 0.007), and D18S62 (allele 3, p = 0.479).

The data from both tests suggest that the gene for 18p11.31 linked high myopia is most proximal to marker D18S52, with a likely interval of 0.8 cM between markers D18S63 and D18S52. Due to the contraction of the interval size by TDT testing, it is now possible to begin physical mapping and gene identification in the MYP2 locus.

Homozygosity and Linkage-Disequilibrium Mapping of Bardet-Biedl Syndrome Type 1 (BBS1). *T. Young[1], M.O. Woods[1], P.S. Parfrey[1], J.S. Green[1], D. Hefferton[1], W.S. Davidson[2].* 1) Fac Medicine, Memorial Univ Newfoundland, St John's, NF, Canada; 2) Dept Biochem, Memorial Univ Newfoundland, St John's, NF, Canada.

Bardet-Biedl syndrome (BBS; OMIM 209900) is a rare, autosomal recessive disorder of unknown etiology that exhibits phenotypic and genetic heterogeneity. The syndrome is characterized by retinal dystrophy, dysmorphic extremities, obesity, male hypogenitalism and renal anomalies. Five genetic loci have been mapped by genome-wide scanning in (i) a collection of North American families of North European descent (BBS1, 11q); (ii) three unrelated Bedouin kindreds from Kuwait (BBS2, 16q; BBS3, 3p; BBS4, 15q); (iii) a kindred of North European descent from Newfoundland, Canada (BBS5, 2q). So far, none of the BBS genes have been cloned. We have extended haplotypes within the 13 cM BBS1 critical region for 10 BBS patients and their families representing three BBS1-linked and three unassigned families from the recently founded Newfoundland population. All 10 patients were homozygous for overlapping portions of a rare, disease-associated ancestral haplotype. Linkage disequilibrium analysis of the overlapping ancestral haplotypes significantly reduced the BBS1 critical region and should aid in the positional cloning of the BBS1 gene.

Program Nr: 2582 from the 1999 ASHG Annual Meeting

Evidence for Linkage to 10q21-22 for Mitral Valve Prolapse Phenotype in a Dilated Cardiomyopathy Family. *B. Yuan[1], S.H. Duan[1], G. Schonfeld[1], Y. Von Kodolitsch[2], M. Bourdius[2], M. Malkowski[2], R.E. Pyeritz[2].* 1) Department of Internal Medicine, Washington University School of Medicine, St. Louis, MO, USA; 2) Department of Human Genetics, MCP Hahnemann School of Medicine, Pittsburgh, PA, USA.

Mitral valve prolapse (MVP) is the most common form of valvular defect with a prevalence of 4-6%. Idiopathic dilated cardiomyopathy (DCM) is the most common form of heart disease with Mendelian inheritance. We evaluated a family showing autosomal dominant transmission of DCM associated with MVP through at least 3 generations (7 affected). Echocardiography in the youngest 2 generations showed MVP in all 3 instances of DCM; however, 4 young individuals with normal left ventricular dimensions and function had MVP; 3 also had mild mitral regurgitation (MR). None had signs of a systemic disorder of connective tissue, conduction abnormality or rhythm disturbance. Genetic mapping using polymorphic markers around previously reported loci for familial DCM showed a positive LOD score only for markers at 10q21-22. The 2-point LOD for D10S556 was 3.3 (q = 0; penetrance = 0.99). Multipoint non-parametric analyses (GENEHUNTER v1.2) showed a maximal peak of NPL=6.27 (p=0.005) in the 6 cM region bounded by D10S1650 and D10S607. MVP phenotype was used in both of the analysis. There was no linkage detected to this locus with DCM phenotype. Analysis showed that MVP in this family segregated with a distinct haplotype. In another family, DCM associated with MVP was previously mapped to the same region. Our results suggest, first, that in some forms of DCM, MVP is an early manifestation of the basic defect, and second, that a locus exists at 10q21-22 that encodes a product that is essential for long-term myocardial function. While MVP and MR can be a consequence of left ventricular dilatation, dysfunction, or both, our family suggests that at least one structural abnormality of the MV apparatus is a primary component of this DCM phenotype. A variety of genes encoding cytoskeletal proteins map to the region and a search for mutations will ensue.

Program Nr: 2583 from the 1999 ASHG Annual Meeting

On a Unified Transmission/Disequilibrium Test. *H. Zhao[1], F. Sun[2]*. 1) Epidemiology & Public Health, Yale Univ Sch Medicine, New Haven, CT; 2) Department of Genetics, Emory UNiversity, Atlanta, GA.

The transmission/disequilibrium test (TDT), which is based on the unequal probability of transmission of different marker alleles from parents to the affected offspring, may have greater power to detect linkage for complex traits than traditional family-based linkage methods. Since the original TDT was proposed for studying families with both parents available, the TDT has been extended to analyzing sibships without parents and one affected child with only one parent. However, these extensions are still restricted to limited family structures. For example, these methods cannot analyze the following two cases: (1) a set of affected siblings without parents; and (2) multiple sibs with one available parent. Because the real data do not necessarily fall into the types studied so far in the literature, there is a real need to develop a unified approach to analyzing families of different structures. We have recently developed a likelihood-based approach to studying transmission disequilibrium that simultaneously uses nuclear families of different structures. This approach borrows information across all the families to infer mating types for each pair of parents (genotypes available or not). As a result, this approach extracts more genetic information from family data and is more efficient than existing methods. Simulation studies under different population structures and disease models also demonstrated the greater power of the proposed method. For example, in the case of analyzing affected-unaffected sib pairs, the proposed approach can increase the statistical power to detect linkage by 50% compared to the method proposed by Spielman and Ewens (1998) for these discordant sibling pairs. Statistical properties of this unified likelihood-based approach will also be discussed. Supported in part by NIH grant GM59507.

Program Nr: 2584 from the 1999 ASHG Annual Meeting

Type 2 diabetes susceptibility loci maps on chromosomes 1 and 20 in Chinese Han families. *J.Y. Zhao[1,2], M.M. Xiong[2], W. Huang[3], H. Wang[4], J. Zuo[1], Z. Chen[3], B.Q. Qiang[5], M.L. Zhang[1], W.N. Du[1], J.L. Chen[3], W. Ding[3], W.T. Yuan[3], Y. Zhao[3], H.Y. Xu[3], L. Jin[2], Y.X. Li[4], Q. Sun[4], Q.Y. Liu[4], F.D. Fang[1]*. 1) Biochemistry and Molecular Biology, Institue of Basic Medical Science, Chinese Academy of Medical Science, Beijing, 100005, P. R. China; 2) Human Genetics Center, University of Texas-Houston, Houston, TX 77225; 3) Chinese National Genome Center at Shanghai, 201203, P. R. China; 4) Department of Endocrinology, Peking Union Medical Hospital, Beijing, 100730, China; 5) Chinese National Genome Center at Beijing, Beijing, 100005, China.

As a part of genome-wide scan for identifying genes that contribute to type 2 diabetes in samples of 32 Chinese Han families, we studied chromosomes 1 and 20. Thirty six markers at an average of 8cM on chromosome 1 and eight markers at an average of 12.5cM on chromosome 20 were genotyped. Linkage analysis was performed by use of two point and multipoint parametric and nonparametric methods in GENEHUNTER. Two point linkage analysis identified marker D1S193 on chromosome 1 and marker D20S118 on chromosome 20 showing significant evidence for linkage with LOD=6.1477 (P=5.2 X10-8) and NPL Z=4.1733 (P=1.5 X10-5), and LOD = 4.677 (P=1.73 X10-6) and NPL Z=2.8997 (P=0.00187), respectively. Two point lod score calculations also demonstrated suggestive linkage for the marker D20S115 with LOD=1.93 (P=0.0014).

Program Nr: 2585 from the 1999 ASHG Annual Meeting

Multipoint Linkage Analysis Using a Mapping Function, with an Application to Mapping IDDM. *L.P. Zhao, R.L. Prentice.* Division of Public Health Sciences, Fred Hutchinson Cancer Res Ctr, Seattle, WA.

The advances made in genomic technologies as well as in the construction of the human genome map will provide invaluable tools for discovering disease genes via genome scan studies with hundreds or even thousands of markers. A large array of markers is expected to be highly informative, but methods, handling multiple markers are relatively undeveloped to date. In this paper, we introduce a two-staged method for multipoint linkage analysis. At the first stage, the method estimates recombination fractions of putative disease genes with all individual marker loci using, for example, the semiparametric method recently proposed (Zhao et al. 1998a,b,c). Then, at the second stage, the method integrates estimated RFs based upon the genomic structure underlying all marker loci on a chromosome, using a mapping function to form a likelihood function. The likelihood can be used to construct test statistics for assessing the genome-wide significance, for estimating the number of disease genes, and for estimating locations of such genes along with confidence intervals for estimated locations. Under the assumed likelihood, the estimation procedure is expected to be efficient. Furthermore, it separates the calculation involving pedigrees from that dealing with multiple markers, and thus ensures practical computation for large pedigrees with a large array of markers. Scientifically, this method allows one to incorporate any partial knowledge about the disease phenotype under investigation. To illustrate this method, we apply this approach to a simulation experiment as well as to mapping study of insulin-dependent diabetes mellitus (IDDM) conducted in the United Kingdom. The IDDM data from the United Kingdom study and other studies will be more fully explored in a companion paper, and the result supports the presence of two major disease genes in chromosome 6q25-27. These positive findings, which remain to be proven ultimately via cloning, also support the utility of an affected sib pairs research strategy.

Program Nr: 2586 from the 1999 ASHG Annual Meeting

Genome-wide scanning for loci linked to essential hypertension in Chinese families. *D. Zhu[1], M. Xiong[2], S. Chu[1,2], L. Jin[2,3,4], G. Wang[3], W. Yuan[1], Y. Zhan[1], W. Zhang[1], S. Dong[1], P. Gao[1], G. Zhao[1], W. Huang[3]*. 1) Shanghai Institute of Hypertension, Ruijin Hospital, Shanghai Second Medical University, Shanghai, China; 2) Human Genetics Center, University of Texas-Houston, Houston, TX, USA; 3) National Human Genomic Center in Shanghai, Shanghai, China; 4) Institute of Genetics, Fudan University, Shanghai, China.

Essential hypertension is a complex, polygenic disease in which many genetic and environmental factors are involved and they may interact with each other in unpredictable ways in its development. To elucidate the genetic mechanisms of essential hypertension, 79 Chinese nuclear families residing in Shanghai were recruited in a genome-wide scanning study. 283 affected sib-pairs were counted in those families with 279 patients with essential hypertension. 393 family members were genotyped using ABI PRISM^{TM} Mapping Set Version 2 including 240 microsatellite markers with an average distance of 15 cM. Non-parametric linkage analyses (SIBPAIR and GENEHUNTER/NPL) gave statistically significant evidence for eight predisposing loci on Chromosome 2, 3, 7, 8 and 18. Among them, three markers (D2S168, D2S142 and D2S151) were on Chromosome 2. A replication study is needed to weed out the false positive linkage and to reduce the size of the candidate regions identified in this study.

Program Nr: 2587 from the 1999 ASHG Annual Meeting

Ventricular arrhythmia and dilated cardiomyopathy is linked to chromosome 2. *X. Zhu[1], D. Dreher[1], K. Hoang[2], J. Tan[2], S. Hunt[2], R.H Vagelos[2], M. Fowler[2], E.M. McNally[1].* 1) Medicine/Cardiology, University of Chicago, Chicago, IL; 2) Stanford University, Palo Alto, CA.

Eight different genetic loci (1p11, 1p32, 2q31, 3p22, 6q23, 9q13-22, 10q22, and 15q14) have been linked to the development of autosomal dominant familial dilated cardiomyopathy (FDC). Phenotypically, patients with FDC show enlargement of all four chambers of the heart and development of congestive heart failure with or without cardiac conduction system defects. However, the molecular etiology and the relationship between ventricular arrhythmias and the progression of dilated cardiomyopathy are not well understood. To this end, we have identified a large pedigree with ventricular arrhythmias and, in some instances, dilated cardiomyopathy whose phenotype segregates as an autosomal dominant disorder. The disorder is progressive and has an age of onset that ranges from the third to the sixth decade. The penetrance of this disorder for individuals in their sixth decade is estimated at 95%. A genome wide linkage scan was conducted using the Weber 8 markers on an ABI 377. Genotypes were scored blinded to phenotype and data was analyzed using FASTLINK 5.1. Approximately 50% of the genome was excluded before two point LOD score analyses identified markers on the long arm of chromosome 2 that showed maximal LOD scores of 3.50 at q =0, identifying ventricular arrhythmias with cardiomyopathy as a genetically distinct disorder. Haplotype analysis identified centromeric and telomeric recombination events. Thus, the interval containing the gene for ventricular arrhythmias and dilated cardiomyopathy was refined to 13 cM. Several interesting candidate genes including translin, brain-derived phosphotase 1, RAS-related protein RAB6, and a G-protein coupled receptor gene are currently being evaluated. Haplotype analysis also excluded nebulin, an important muscle-expressed gene in this region. This study demonstrates a new genetic locus associated with ventricular arrhythmia and dilated cardiomyopathy.

Program Nr: 2588 from the 1999 ASHG Annual Meeting

The Interleukin-4 receptor variants I50V and Q576R in atopic children. *S. ZIANI[1], N. Chavernoz[1], G. Morgant[1], A. Grimfeld[2], P. Aymard[1], D. Feldmann[1].* 1) Dpt of Biochemistry, Hopital A Trousseau, Paris, France; 2) Dpt of Allergology, Hopital A Trousseau, Paris, France.

Atopy is a very common disease with genetic predisposition. Interleukin-4 (IL4) and IL4 receptor (IL4R) play a central role in the regulation of IgE synthesis. Recently, two polymorphisms in the gene coding for IL4R alpha chain have been identified : I50V and Q576R or Q551R. The gain of function of IL4R alpha chain baring a residue Ile50 or Arg576 and the association of I50V or Q576R variants with atopy or asthma is still controversial. So, We have studied the two variants in a population of atopic children. We have studied 93 atopic patients (1-16y) with elevated serum IgE and a positive screening test for pulmonary allergy (Phadiatop, Pharmacia) and/or a positive radioimmunoadsorbent test (score>3) in respons to one or more allergens, and 92 non atopic controls (1-20y) with normal serum IgE and negative screening test for pulmonary allergy. I50V and Q576R polymorphisms were studied by PCR mediated site directed mutagenesis. Frequency of I50 allele was not different in atopic (40%) and control (43%) children. Frequency of homozygotes I50 was 31.6% in atopic patients and 30% in controls. Q576R variant was detected in 49 atopic patients (R576 allele frequency : 36%) and in 41 controls (R576 allele frequency : 24%). Frequency of homozygotes R576 was 20% in atopic and 3% in controls ($p<0.001$ $chi2=13.5$ $DL=2$). In conclusion, an increase of homozygotes R576 was observed in our atopic population versus non atopic subjects. This result suggest that R756 variant of IL4R gene could play a role in the genetic predisposition of atopy.

Program Nr: 2589 from the 1999 ASHG Annual Meeting

Fine-mapping of the cystic fibrosis modifier locus on human chromosome 19. *J.S. Zielenski, D. Markiewicz, M. Corey, I. Aznarez, J. Shin, R. Rozmahel, P. Durie, L.C. Tsui, and. the CF Modifier Collaborative Group.* The Hospital for Sick Children, Toronto, Ontario, Canada.

Clinical phenotype in CF is influenced by mutations at the *CFTR* locus as well as secondary genetic modifiers. We have recently obtained strong evidence indicating the presence of a CF modifier locus (*CFM1*) on human chromosome 19, region q13.2. The linkage was demonstrated by identity by descent analysis with polymorphic markers. *CFM1* appeared to contribute to the predisposition of meconium ileus (MI) which is a severe form of intestinal obstruction in the perinatal period. The strongest linkage was detected for markers in a 3.75 Mb interval between markers *D19S408* and *D19S412*. To narrow the critical region for *CFM1*, we have performed transmission disequilibrium test (TDT) for markers in the above interval. The study population included 33 families with at least one CF child with MI from the original linkage study. In addition, we recruited 124 "trios", i.e., CF patients with MI and their parents, for the analysis. To date, we tested 17 markers: *D19S408-40867/DraI -APOC2-APOC1/HpaI-2050/AvaII-31237(GT)n-10080(GT)n-D19S219-DM(GCT)n-D19S112-CALM3(178+66C/T)- D19S412-STD(-910C/A)-D19S902-D19S604-D19S246-KLK1*. Two computer programs, GASSOC and GENEHUNTER, were used to assess a linkage disequilibrium. Studies were performed with 142 families for 3 microsatellite markers, *31237(GT)n*, *10080(GT)n*, and *DM(GCT)n*, spanning a 500-kb region within the interval of strong linkage. Intragenic SNPs for *CALM3(178+66C/T)* and *STD(-910C/A)* were also studied in 93 families. No transmission disequilibrium could be detected for any of these markers by either computer programs. The most significant association was detected for *APOC2* (GASSOC *P*=0.002), with GENEHUNTER pointing to two specific alleles (*P*=0.01), but the number of families tested was small (n=33). Additional studies are in progress, particularly with markers surrounding the *APOC2* locus. The CF Modifier Collaborative Group: T. Casals, D. Bozon, A. Krebsowa, M. Claustres, B. Marshall, E. Bjorck, B. Mercier, A. Palacio, E. Langfelder, J. Bal, G. Cutting, S. Larriba, L. Chertkoff, C. Ferec, B. Strandvik, M. Macek Jr., X. Estivill.

Program Nr: 2590 from the 1999 ASHG Annual Meeting

Missense mutations in the cystic fibrosis gene in adult patients with asthma. *C. Lazaro[1], R. de Cid[1], J. Sunyer[2], J. Soriano[2], J. Gimenez[1], M. Alvarez[1], T. Casals[1], J.M. Anto[2], X. Estivill[1].* 1) Medical and Molecular Genetics Center-IRO, Barcelona, Spain; 2) Respiratory and Environmental Health Research Unit-IMIM, Barcelona, Spain.

Asthma is a multifactorial disorder with a complex phenotype that affects 5% of adults and 10% of children worldwide. As a complex genetic disorder, it is hypothesized that genetic and environmental factors play complementary roles. There is evidence to suggest a link between asthma and cystic fibrosis (CF) although first attempts to assess an association between asthma and the CFTR gene led to inconsistent results. Thus, the characterization of the CFTR coding region in a well defined asthma population has so far not been reported. Here we present the complete analysis of the CFTR gene, by using multiplex denaturing gradient gel electrophoresis (DGGE) and single strand conformation analysis (SSCA) in a sample of adult patients with asthma and in subjects from the general population. This characterization identified missense mutations in 15% of 144 unrelated adult patients with asthma, but in none of 41 subjects from the general population (P = 0.005). Some of these changes (R75Q, G576A, R668C and L997F) have also been found in an extended sample of individuals from the general population, in similar proportions. There were no major differences in the asthma-related phenotypes according to the presence of missense mutations. The distribution of genotypes for the 470M/V variant was significantly different between the patients with asthma bearing CFTR mutations and those without, the M470 variant being detected in 90% of the patients with asthma and amino acid variants, but in 63% of those without amino acid changes (P=0.01) and in 63% of subjects from the general population (P=0.02). None of the patients with missense mutations had the 5T allele of intron 8 of CFTR, responsible for low CFTR levels, while it was detected in 8% of asthma patients without CFTR mutations and in 9% of subjects from the general population. These findings suggest a putative role of the CFTR gene in the genetic variability of asthma.

Program Nr: 2591 from the 1999 ASHG Annual Meeting

Endogenous huntingtin modulates the cellular toxicity of mutant huntingtin. *B.R. Leavitt[1], A. Hackam[1], C.A. Gutekunst[2], K. McCutcheon[1], A. Yassa[1], R. Singaraja[1], G. Kimel[3], S. Hersch[2], W. Vogl[3], M.R. Hayden[1].* 1) CMMT, UBC, Vancouver, BC, Canada; 2) Emory U. School of Medicine, Atlanta, GA, USA; 3) Dept. of Anatomy, UBC, Vancouver, BC, Canada.

We have developed yeast artificial chromosome (YAC) transgenic mice expressing normal (YAC18 CAG) and mutant (YAC46 and YAC72 CAG) human huntingtin (htt) in a developmental and tissue specific manner identical to endogenous htt. YAC72 mice develop a behavioral phenotype and selective degeneration of medium spiny neurons in the striatum similar to that observed in HD. YAC transgenic mice expressing human htt can compensate for the loss of endogenous htt, and rescue the embryonic lethality of htt knockout mice. Decreasing the levels of endogenous htt in YAC46 and YAC72 mice, but not YAC18 mice, leads to a novel phenotype characterized by testicular atrophy, inability of male mice to breed, and massive cell loss in the testes. Ultrastructural analysis (EM) of the testes of YAC72 mice lacking endogenous htt revealed massive spermatocyte loss, phagocytosis of dying cells, and intracellular inclusions not seen in YAC72 mice with normal endogenous huntingtin levels, or in YAC18 mice lacking endogenous htt. The cell death in the testes is due to increased apoptosis (TUNEL staining) and is modulated by level of endogenous htt. Testicular cell death is also CAG repeat size dependent with a greater effect in YAC72 vs. YAC46 and no effect in YAC18 mice. Co-expression of mutant and normal htt in a neuronal cell culture model leads to decreased neuronal death, less huntingtin aggregation, and less htt cleavage than seen with co-expression of mutant htt and vector alone. Protection from neuronal death is seen with C-terminal htt fragments but not N-terminal fragments of htt, suggesting that the C-terminal region of htt is responsible for this effect. These data provide evidence that endogenous htt modulates the cellular toxicity of mutant htt, and suggest that normal htt may be an anti-apoptotic protein with therapeutic potential.

Program Nr: 2592 from the 1999 ASHG Annual Meeting

Spinocerebellar ataxia 7 (SCA7) : cellular localization and search for partners of ataxin-7. *A.S. Lebre[1], G. Cancel[1], C. Zander[1], G. Yvert[2], C. Duyckaerts[3], P. Kussel[4], J.H. Camonis[5], A. Brice[1].* 1) INSERM U289, Hopital de la Salpetriere, Paris, cedex 13, France; 2) IGBMC, Illkirch, CU de Strasbourg, France; 3) Laboratoire de Neuropathologie, Hopital de la Salpetriere, Paris, France; 4) Institut Pasteur, Paris, France; 5) Institut Curie, Paris, France.

Spinocerebellar ataxia 7 is a progressive neurodegenerative disease caused by an expansion of a CAG repeat in the coding region of the gene. The distinct neuropathological feature of SCA7 is degeneration of optic pathways and the retina. Ataxin-7 is a protein of unknown function which contains a bipartite nuclear localization signal, four polyproline domains (SH3-binding domains), and a serine-rich C-terminus. It is expressed in various tissues including CNS (David et al., 1997). The mutated protein has been reported to be nuclear, as analyzed by Western blot on cell fractions of lymphoblasts from SCA7 patients. We have carried out immunocytochemical studies in transfected Cos7 cells, and showed a strong/almost exclusive nuclear localization of both wild type and mutated ataxin-7. In contrast, expression of ataxin-7 is predominantly cytoplasmic in normal human brain. Confocal microscopy studies are underway to localize ataxin-7 more precisely. In contrast to its ubiquitous expression, SCA7 mutations lead to a selective neuronal death. This phenotype could be explained by an interaction with a specific partner. Using a two-hybrid approach, we screened a human neural retina cDNA library for ataxin-7 binding proteins. Screening with the mutated ataxin-7 (100 Glutamines) yielded 21 different clones that interact with normal and mutated ataxin-7. BLAST analysis identified 17 known proteins, 2 EST and 2 unknown proteins. One partner interacts more strongly with mutated than normal ataxin-7. This latter protein and three others have been selected for further studies on the basis of their expression in the CNS as assessed by Northern blot. GST pull down studies are underway to confirm the (direct) interaction between ataxin-7 and these partners. Immunoprecipitation and immunochemistry studies will be performed to determine whether these proteins do meet in vivo, and in which (sub)cellular compartment.

Program Nr: 2593 from the 1999 ASHG Annual Meeting

Construction of an imprinting status transcript map of 15q11-q13. *S. Lee, R. Wevrick.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Human chromosome bands 15q11-q13 are prone to interstitial deletions. This region contains a group of imprinted, uniparentally expressed genes. Genomic imprinting is the epigenetic modification of DNA that results in differential expression of the paternal and maternal alleles of a gene. Deletions of either the paternal or maternal copy of 15q11-q13 are the predominant cause of two imprinted disorders, Prader-Willi Syndrome (PWS) and Angelman Syndrome (AS). PWS is a neurobehavioural disorder characterized by neonatal hypotonia, developmental delay, and hyperphagia. PWS is due to the loss of expression of one or more paternally expressed genes, most commonly as a result of deletions on the paternal copy of chromosome 15. AS is characterized by developmental delay and ataxia. AS is caused by the absence of expression of a single, maternally expressed gene, *UBE3A*, usually as a result of deletions on the maternal copy of the chromosome. Studies suggest that imprinted genes may be clustered into domains, suggesting a regional method of gene regulation. Currently, 5 imprinted genes, *ZNF127*, *NDN*, *SNRPN*, *IPW* and *UBE3A*, and 4 nonimprinted genes have been identified within this 4 Mb deletion region. We hypothesize that there are additional genes in the 15q11-q13 region and that some of these genes are imprinted. We have physically mapped at least 5 Expressed Sequence Tags (ESTs) from the GeneMap 98 database which do not correspond to known genes to a YAC contig spanning the 15q11-q13 region. We have analyzed the GeneMap 98 ESTs and additional ESTs mapped to the region by other groups for uniparental expression by RT-PCR. Lymphoblast and brain RNA were collected from normal, PWS and AS patients. Fibroblast RNA from normal and PWS were also used in the analysis. Using this method, we have established that a subset of the ESTs examined are paternally expressed and may correspond to genes that are involved in PWS. Results from this analysis will give an overview of the imprinting status of a large number of ESTs 15q11-q13, and may provide insights into the organization and control of this imprinting domain.

Program Nr: 2594 from the 1999 ASHG Annual Meeting

Analysis of Familial Combined Hyperlipidemia with chromosome 1q21-q23 markers and the APOAI/CIII/AIV gene cluster in the NHLBI Family Heart Study. *M.F. Leppert[1], H. Coon[1], I.B. Borecki[2], D.K. Arnett[3], S.C. Hunt[1], M.A. Province[2], L. Djoussé[4], R.H. Myers[4]*. 1) Depts of Human Genetics, Psychiatry and Cardiovascular Genetics, Univ Utah, Salt Lake City, UT; 2) Division of Biostatistics, Washington Univ, St. Louis, MO; 3) Division of Epidemiology, Univ of MN, Minneapolis, MN; 4) Section of Preventive Medicine and Epidemiology, Boston Univ, Framingham, MA.

FCHL is the most common familial dyslipidemia with a prevalence of 1%-2%, and is implicated in up to 20% of cases of premature coronary heart disease. Although underlying mutations for FCHL have yet to be identified, Pajukanta et al. (1998) recently published positive linkage to chromosome 1q markers, with the highest lod score of 5.93 occurring between D1S104 and D1S1677. Using the same diagnostic criteria, the Family Heart Study has defined 71 FCHL families comprising 170 cases for a total of 137 possible affected sibling pairs. The FCHL criteria require elevation in both serum LDL cholesterol and triglycerides within the family, with at lease two affected first degree relatives. Markers D1S104 and D1S1677 were typed as a replication attempt. Suggestive allele sharing was found in FCHL sibships with these markers (multipoint NPL score = 2.26, p = 0.01). In addition, previously reported linkage of FCHL to apolipoprotein AI/CIII/AIV (Wojciechowski et al., 1991) has been investigated in FHS families. Results revealed positive but nonsignificant allele sharing among FCHL sibships with AI/CIII/AIV using marker D11S4127 (p = 0.19).

Program Nr: 2595 from the 1999 ASHG Annual Meeting

Transmission of skewed X-inactivation in familial Rett Syndrome. *N. Levy[1,2], L. Villard[1], F. Xiang[3], V. Labelle[2], M. Tardieu[4], J. Chelly[5], M. Fontés[1]*. 1) Inserm U491, "Génétique médicale et développement, Faculté de médecine de la Timone, Marseille, France; 2) Département de génétique médicale, Hôpital d'enfants de la Timone, Marseille, France; 3) Department of molecular medicine, Karolinska hospital, Stockholm, Sweden; 4) CRI9612, "Virus, neurone et immunité", UFR Kremlin Bicêtre, Paris, France; 5) InsermU129,"physiologie et pathologie génétiques et moléculaires, CHU Cochin-Port-Royal, Paris, France.

Rett syndrome (MIM312750) is a disease of unknown origin which essentially affects girls. Based on clinical features, this disorder seems to have a neurodevelopmental origin, since affected patients present an arrest in brain's development. More than 99% of affected patients correspond to sporadic cases with no other relatives affected even in large families. In most of the rare families reported so far, the disease appears as a classical Rett phenotype in girls from the same sibship. A genetic linkage to Xq28 has been proposed (Xiang et al., 1998; Siriani et al., 1998; Webb et al., 1998). In a recent report, Siriani et al. (1998) suggested that a skewed X inactivation could be a necessary event in the transmission of Rett syndrome from carrier mothers to affected girls. Indeed, they observed in one family a carrier mother having a preferential inactivation of the morbid allele, even though her daughters had a random inactivation pattern. In order to test the liability of this hypothesis, we explored more families and analysed the X inactivation status in the mothers and daughters. Surprisingly, an important bias of inactivation was observed both in mothers and affected daughters. These observations clearly raises the question of the relationships between X inactivation bias and the Rett mutation in familial cases, as well as the localization of the RETT mutation. Hypothesis will be presented, which could reconciliate the transmission of the disease in familial forms with the sporadic cases occurrence. In these hypothesis, the role of a second event, the skewed X inactivation is taking a major role.

Program Nr: 2596 from the 1999 ASHG Annual Meeting

Investigation of the *TSC2* locus in lymphangioleiomyomatois (LAM) patients. *H. Li[1], H. Basterrechea[2], M. Glassberg[1], L. Baumbach[2]*. 1) Medicine, Univ of Miami School of Med, Miami, FL; 2) Pediatrics, Univ. of Miami Scool of Med, Miami, FL.

Pulmonary lymphangioleiomyomatois (LAM) is a fatal lung disease that predominantly affects women in their child-bearing years. The disease is characterized by the focal accumulation of airway mesenchymal cells ("LAM cells") and dense collagen deposition associated with air-filled cysts within affected lung tissue. Little is known about its pathogenesis, but the symptoms, radiographic findings, and histopathologic descriptions of LAM are identical to those of a subset (1-5%) of female tuberous sclerosis patients (TSC). The only report to address a possible genetic relationship between TSC and LAM detected somatic loss of heterozygosity at *TSC2* in 7/13 renal angiomyolipomas from LAM patients.

Our studies are focused on the possible identification of germline DNA sequence variations in *TSC2* in genomic DNA from LAM patients with and without features of TSC We first analyzed the *TSC2* GAP-binding region (exons 34-41) in genomic DNA samples isolated from peripheral blood samples from 20 LAM patients (14 with additional symptoms resembling TSC) and 7 unrelated age-matched controls, through the development of an exon-specific PCR amplification assay. No gross exon alterations were detected. These initial studies were followed by SSCP analysis of each exon, scanning for possible genetic variations in the GAP-binding region. SSCP variants were further analyzed by DNA sequencing, and DNA sequences compared to the published wild-type *TSC2* sequence. Although several SSCP variants were detected in 2 LAM patients in this region, DNA sequencing of SSCP variant bands and genomic DNA-PCR products detected only wild-type DNA sequence in these patients. These results suggest that germline mutations in, at least, the *TSC2* GAP-binding domain, are not a contributory factor to the association between TSC and LAM.

Program Nr: 2597 from the 1999 ASHG Annual Meeting

Imprinting study of Prader-Willi syndrome with methylation-specific PCR(MSPCR). *L.Y Li, M.H Song, J.J Fu, X.R Li, G.X Lu.* Human reproductive engineering laboratory, Hunan Medical University, Changsha, Hunan, P.R.China.

In this paper reported here that we used a faster,more efficient method to diagnose Prader-Willi syndrome(PWS). Differential DNA methylation at several sites in the PWS critical region exists inwhich the maternalhomologue is methylated and inactive while the paternal homologue is unmethylated and transcriptionally active.MSPCR is based on sodium bisulfite treatment of DNA, which converts unmethylated, but not methylatedcytosine residues to uracil, and PCR primers specific for the maternal and the paternal allele. Methylation analysis by Southernblot isusedto validate the MSPCR result. The results indicated Bisulfite-modified DNA from PWSpatients amplified only with methylated allele-specific primer pair whichshowed only maternal 174-bp PCR product. MSPCR and PW71B methylation studies showed an abnormal pattern consistent with the clinic diagnosis of PWS. Untreated DNA does not produce a PCR product. Conclusion:It is proved that MSPCR be able to detect all presently testable causes of PWS(deletion, uniparental disomy (UPD), or imprinting mutation) in an efficient first step for stepwise dignostic testing, comparing to either Southernblot analysis which is more timeconsuming, or fluorescence in situ hybridization(FISH) which can not detect UPD or imprinting mutation. [Key words] Methylation-specific PCR Methylation Prader-willi syndrome.

Program Nr: 2598 from the 1999 ASHG Annual Meeting

Novel mtDNA mutations detected by TTGE. *M.-H. Liang, J.J. Wang, T.J. Chen, W. Fan, L.-J. Wong.* Georgetown University Medical Center, Institute for Molecular and Human Genetics, Washington, DC.

Most reported pathogenic mtDNA mutations are heteroplasmic. Our recent studies using TTGE to scan mutation in 3 regions containing $tRNA^{Leu}$(L), $tRNA^{Lys}$(K), and penta-$tRNA^{Trp, Ala, Asn, Cys, Tyr}$(WANCY) regions suggested that heteroplasmic mtDNA may be more common than previously reported(Chen et al., 1999). In this study, two hundred and eighteen specimens suspected of mitochondrial disorders are screened for mtDNA mutations in ten regions containing 21 tRNAs and part of the mRNAs, totaling 37% of the entire mitochondrial genome by temporal temperature gradient gel electrophoresis (TTGE). These specimens were negative for 11 common point mutations (MELAS,MERRF, NARP, LHON, cardiomyopathy) and large deletions (KSS, Pearson). Our results demonstrate that 6.9% (15/218) of the specimens showed multiple bands on TTGE analysis suggesting heteroplasmic base substitutions. The heteroplasmic mutations occur most frequently (1.9%) in the WANCY region. They were not detected in L and G/ND3/R ($tRNA^{Gly, Arg}$) regions. Sequencing results confirmed several mutations responsible for the molecular state of heteroplasmy. Novel mutations identified include T5580C ($tRNA^{Trp}$+1), G5821A ($tRNA^{Cys}$), C5840T($tRNA^{Tyr}$), C7476T($tRNA^{Ser}$), A12333G ($tRNA^{Leu(CUN)}$), and T4454C($tRNA^{Met}$). Two hundred and fifty three homoplasmic band shifts have been detected in 8 different regions. In conclusion, TTGE has been effectively used to scan mtDNA. It will be suitable for the mutational analysis of the entire mitochondrial genome.

Program Nr: 2599 from the 1999 ASHG Annual Meeting

A candidate gene study in Finnish families with premature coronary heart disease and low HDL-cholesterol. *H.E Lilja[1,2], P. Pajukanta[2], A. Soro[3], L. Peltonen[1,2], M.-R. Taskinen[3]*. 1) Human Molecular Genetics, Nat. Public Health Institute, Helsinki, Finland; 2) Department of Human Genetics, University of California, Los Angeles; 3) Department of Medicine, University of Helsinki, Finland.

Low serum high density lipoprotein cholesterol (HDL-C) is one of the most important risk factors for coronary heart disease (CHD). The prevalence of familial low HDL disorder is approximately 4% in patients with premature CHD and at least 50% of the variation in HDL-C levels is estimated to be genetically determined. However, the genetic component of low HDL is still largely unknown. Most likely low HDL-C disorder is a complex trait, in which multiple genes and environmental factors are playing a role. To explore the genetic backround of low HDL-C in the genetically isolated Finnish population, we have so far collected 14 well-documented Finnish pedigrees with premature CHD and isolated low HDL-C. Inclusion criteria for the proband are the following: age of 30-60 years, angiographically or clinically verified CHD and HDL-C level below to that of the age- and sex-specific 10th percentile. To focus on isolated low HDL families, strict limits for serum total cholesterol and triglycerides are used. We selected a candidate gene approach and analyzed genes encoding proteins involved in metabolic pathways of HDL-C, such as apolipoproteins and lipolytic enzymes, using intragenic and flanking microsatellite markers. We genotyped 94 individuals, of whom 59 are affected fulfilling the strict criteria. Both parametric linkage and nonparametric affected sibpair (ASP) analyses were performed to avoid disadvantages of each of the methods alone. Because we used a candidate gene approach, we accepted $p<.05$ to test for significance. Our preliminare data indicate that there is suggestive evidence of linkage emerged with the markers on the apolipoprotein A2 and lipoprotein lipase genes and the low HDL-C trait in ASP analyses, with p-values of 0,019 and 0,045. We are currently performing a genome scan to define the genome wide significance of these findings and to identify other genetic loci.

Program Nr: 2600 from the 1999 ASHG Annual Meeting

The human *SRA1* gene maps proximal of the Prader-Willi/Angelman syndrome domain in 15q11 and is non-imprinted. *D.P. Locke[1], T. Ohta[1], J.H.M. Knoll[2], R.D. Nicholls[1]*. 1) Case Western Reserve University, Cleveland, OH; 2) Children's Mercy Hospital, Kansas City, MO.

Sra1, the product of the *SRA1* (KIAA0068) gene, is found in association with Rac1, a Rho GTPase family member (JBC 273:291, 1998). Sra1 interacts with Rac1 and F-actin and is implicated in membrane ruffling. The murine homolog, *Sra1* (formerly *Shyc*), is activated during neuroectodermal differentiation of P19 cells (Neuro Lett 252:69, 1998). Phylogenetic comparisons indicate high conservation between the human, murine and putative *C. elegans* homologs. Data from the G3/GB4 radiation hybrid panel (www.ncbi.nlm.nih.gov/genemap98/) suggested *SRA1* mapped to 15q11-q12 close to, or within, the Prader-Willi/Angelman syndrome (PWS/AS) imprinted domain. We confirmed this location by somatic cell hybrid mapping the *SRA1* 3'-UTR, and by FISH localization of *SRA1* with a BAC probe. FISH also demonstrated that *SRA1* is likely a single copy gene. Further mapping of the 3'-UTR to YACs 931C4 and 124A3 places *SRA1* proximal of the *HERC2*-duplicons associated with PWS/AS deletion breakpoint 2 (Amos-Landgraf, AJHG in press), and hence proximal of the known PWS/AS imprinted domain. We found that *SRA1* is biallelically expressed using RT-PCR with somatic cell hybrid RNA (PNAS 95:14857, 1998) as well as RNA isolated from PWS/AS imprinting mutation patients. A murine BAC containing the *Sra1* 3'-UTR was isolated and mapped by FISH to the syntenic chromosome 7C location, within a deletion of the PWS/AS-homologous domain (Gabriel, PNAS in press). Murine imprinting assays indicate *Sra1* is non-imprinted. We are currently assessing the location of *SRA1* in Class I and II PWS/AS deletions, and whether *SRA1* shows asynchronous replication timing as for the PWS/AS domain. We conclude that *SRA1* is a single copy gene located outside the PWS/AS imprinted domain with biallelic expression in human and mouse. The location of this nonimprinted gene defines one boundary of the PWS/AS imprinted domain. Further study of the interval between *ZNF127*, the closest imprinted gene, and *SRA1* in human and mouse will allow identification of epigenetic control elements that regulate the boundary of this imprinted domain.

Program Nr: 2601 from the 1999 ASHG Annual Meeting

Examination of Collagen Genes in Kindred with Developmental Dislocation of the Hip. *A.L Lonkar[1], K.E Murphy[2]*. 1) Microbiology & Molecular Cell Sciences, University of Memphis, Memphis, TN; 2) Veterinary Pathobiology, College of Veterinary Medicine, Texas A&M University, College Station, TX.

Work from several laboratories has shown that mutations in various genes encoding collagen proteins cause hip joint hypermobility, which is a characteristic of several developmental diseases. Because hip joint malformation is the primary feature of developmental dislocation of the hip (DDH), we are investigating the possibility that mutations within those genes are contributing factors to this heritable disease. Interestingly, an appropriate canine model, canine hip dysplasia (CHD), is available. Published findings have indicated an abnormal collagen III:I ratio in dogs with CHD and a similar abnormal ratio has been reported in DDH patients. These data suggest DDH may result, in part, from aberrant metabolism of collagens I and III. Furthermore, considerable data demonstrate that certain regions spanning exons and introns within the human *col*1A2 gene harbor mutations leading to abnormal hip joint development. To date, we have identified by PCR and direct sequencing an extensive polymorphism within one of our subject families. Analyses of this polymorphism within subject A-1 has shown multiple point mutations within exons 9, 10 and 11 of the *col*1A2 gene not present within any other subjects (families A, B, C or controls). It has been determined that there is an amino acid switch from P to A in exon 9 caused by this polymorphism but the implications of this amino acid alteration have yet to be determined.

Program Nr: 2602 from the 1999 ASHG Annual Meeting

Toll-4 mutations D299G and P714H give reduced levels of NFkB activation in transfected CHO/CD14 cells. *E. Lorenz, K.L. Schneider, N.C. Arbour, D.A. Schwartz.* Dept Int Med, Univ Iowa, Iowa City, IA.

We identified a common (allelic frequency 5-10%) mutation in the extracellular domain of toll-4 (D299G) in humans. Similar to the missense P712H mutation in murine toll-4 seen in strain C3H/HeJ mice (amino acid residue 714 in humans), the D299G mutation in humans is associated with an LPS hyporesponsive phenotype. We used site-directed mutagenesis to recreate both mutations in plasmids for use in in vitro transfection studies in CHO/CD14 cells. Amino acid 299 is part of the extracellular domain, while amino acid 714 is part of the intracellular domain of toll-4. Both residues 299 and 714 in humans are highly conserved between mice and humans. Using NFkB as a reporter gene, the wild type gave a 2-fold activation in response to 100 ng/ml of LPS for 5 hours. The mutation corresponding to the one identified in mouse strain C3H/HeJ gave no activation in response to the same dose of LPS, while the D299G mutation gave intermediate levels of LPS response. This is the first in vitro proof that the mutation in mouse strain C3H/HeJ abolishes the response to LPS. In addition, this result proves that mutations in both the extracellular domain, as well as the intracellular domain, of toll-4 affect LPS responsiveness in vitro.

Program Nr: 2603 from the 1999 ASHG Annual Meeting

Examination of 15q11-13 DNA methylation and expression imprints in prolonged lymphoblastoid cell culture.
A.C. Lossie, K. Dopp, M.M. Whitney, D.J. Driscoll. RC Philips Unit, Pediatric Genetics, University of Florida, Gainesville, FL.

One of the best studied imprinted regions in humans is the Angelman (AS)/Prader-Willi (PWS) domain located within 15q11-13. AS and PWS are distinct neurobehavioral disorders arising from the lack of a maternal (AS) or paternal (PWS) genetic contribution from 15q11-13. The imprinting center (IC), which overlaps exon 1 of *SNRPN* establishes methylation and expression imprints along the 2Mb AS/PWS domain. Several loci within 15q11-13 have DNA methylation imprints in peripheral blood leukocyte (PBL) DNA. Methylation analyses of 5' *SNRPN*, PW71, *NECDIN* and *ZNF127* indicate that the maternal alleles are preferentially methylated, while the paternal copies remain largely unmethylated in PBL DNA. In correlation with DNA methylation, these genes are preferentially expressed from the paternal chromosome.

Lymphoblastoid cell lines (LB) from AS and PWS patients are commonly used for genetic analysis. However, evidence for the stability of DNA methylation in LB cultures is questionable. We hypothesized that: 1) DNA methylation imprints in B-cell derived LB cell lines would be faithfully maintained within the IC, but would relax with increasing distance from the IC. 2) Changes in DNA methylation would correlate with expression.

We established LB cell lines from AS, PWS and control samples. During 12 months of continuous culture, samples were collected every 4 months; DNA and RNA were isolated at each time point. At the 4, 8 and 12 month time points, changes in methylation occurred at 5' *SNRPN*, PW71 and *ZNF127*, but not at *NECDIN*. However, RT-PCR showed that the demethylation at 5' *SNRPN* did not correlate with expression. Surprisingly, DNA methylation imprints in LB cultures are not faithfully maintained at regions within the IC, and methylation at the 3' end of the CpG island of 5' *SNRPN* is not crucial for maintenance of imprinted expression of *SNRPN*. Expression analyses of *ZNF127* and *NECDIN* are ongoing and should provide further insight into the role that DNA methylation plays in the transcriptional regulation of the AS/PWS imprinted domain.

Program Nr: 2604 from the 1999 ASHG Annual Meeting

Allelic variation of the fibulin-1 gene in age related macular degeneration. *A.J. Lotery, K. Vandenburgh, H. Haines, L. Streb, R. Hockey, G. Beck, V. Sheffield, E.M. Stone.* Department of Ophthalmology, University of Iowa, Iowa City, IA 52242.

Introduction: We recently demonstrated that the EFEMP1 gene is mutated in Malattia Leventinese and Doyne Honeycomb Retinal Dystrophy. These diseases are familial drusen syndromes and are phenotypically similar to the more common drusen disorder known as age related macular degeneration (AMD). EFEMP1 was not found to be associated with AMD. However EFEMP1 is homologous at the protein level to the fibulin gene family and indeed has previously been known as fibulin-3. Because of this homology we screened fibulin-1 for mutations in patients with AMD. Methods: The genomic structure of fibulin-1 exons 2 to 20 were ascertained from genomic databases and suitable SSCP primers were synthesized. 190 control patients and 494 patients affected with AMD from the University of Iowa retinal clinic were screened for sequence variation. The coding region of exons 2 to 20 were screened by single strand conformation polymorphism analysis (SSCP). Amplimers showing a band-shift were reamplified and sequenced bidirectionally using an ABI 377 automated sequencer and dye-terminator chemistry. Results: 11/190 control patients (5.7%) and 28/494 AMD patients (5.7%) were found to have missense changes in the fibulin-1 gene. In 8 cases these sequence variations were non-conservative. Conclusions: Fibulin-1 sequence variation was not significantly associated with the AMD phenotype in this study.

Program Nr: 2605 from the 1999 ASHG Annual Meeting

Neural Tube Defects and the 13q Deletion Syndrome: Delineation of a Critical Region for Neural Tube Defects in 13q33-34. *J. Luo[1,2], J. Charrow[3], J.F. Sarwark[2], J.S. Nye[1,3].* 1) Dept of Molecular Pharmacology, Northwestern University; 2) Dept of Orthopaedics, Northwestern University and Children's Memorial Hospital; 3) Dept of Pediatrics, Children's Memorial Hospital, Chicago, IL.

Neural tube defects (NTDs) are a variable feature in the 13q- syndrome. However, the relationship between the 13q- syndrome and NTDs is poorly understood. We present a case with both a characteristic 13q deletion phenotype and lumbosacral myelomeningocoele. The proband was a boy with severe mental retardation, microcephaly, hypertelorism, prominent cheek bones and incisors, short neck, hypoplastic fifth digits, club feet, and ambiguous genitalia. Cytogenetic analysis revealed 46,XY,del(13)(q33.2®qter). FISH studies with a total chromosome 13 probe showed hybridization to both chromosome 13s with no visible translocation. Parental chromosomes were normal. Using microsatellite markers, the deletion breakpoint was shown to be of paternal origin and was mapped to a 350kb region between D13S274 and D13S1311. Multiple proximal microsatellites were heterozygous and distal microsatellites were hemizygous.

This case is distinct from reported cases because the patient has multiple major malformations consistent with the 13q deletion phenotype, but the deletion is distal to and non-overlapping with the previously defined critical region in 13q32 (Brown et al., AJHG 57:859-866, 1995). In addition, an extensive literature search has suggested that many cases of 13q- and NTD have in common a deletion distal to 13q32. These results suggest that one or more genes in 13q33-13q34 are responsible for NTDs and some of the characteristic phenotypes of 13q- syndrome when hemizygous. Further work will elucidate the relationship of distal 13q deletions and neural tube defects. Supported by NINDS
.

Program Nr: 2606 from the 1999 ASHG Annual Meeting

Generation and analysis of a BAC/PAC contig for the chromosome 15q11-q13 Autistic Disorder candidate gene region. *L.O. Maddox, M.M. Menold, L. Zaeem, M.P. Bass, M.A. Pericak-Vance, J.M. Vance, J.R. Gilbert.* Duke University Medical Center, Durham, NC.

Autistic Disorder (AD) is a complex neurodevelopmental disorder that affects approximately 2-10/10,000 individuals. Epidemiological studies have consistently implicated genetic factors in the etiology of AD, and it is estimated that as many as 2-10 genes may underlay this etiology. Evidence for an AD genetic risk factor on chromosome 15 is based on the following: 1) associated cytogenetic abnormalities; 2) increased recombination frequency in this region in AD versus non-AD families; 3) suggestive linkage results with markers D15S156, D15S219, and GABRB3; and 4) significant linkage/association with polymorphisms in the GABRB3 gene.

To isolate the 15q11-q13 candidate AD gene, a genomic contig and physical map of the 1.2 Mb region from the g-aminobutyric acid (GABA) gene cluster to the OCA2 locus was generated (cen-GABRB3-GABRA5-GABRG3-APBA2-OCA2-tel). Twenty-one BAC clones, 32 PAC clones, and 2 P1 clones have been isolated using markers D15S540, GABRB3, GABRA5, GABRG3, D15S822, D15S975, D15S156, D15S219, D15S217, and 32 novel markers developed from the end sequences of BAC/PAC clones. Analysis of critical markers in the contig utilizing the GeneBridge 4 radiation hybrid panel verified the chromosome 15 localization of clones creating a minimum tiling path of the candidate gene region. Six clones create a minimum tiling path from GABRB3 to GABRA5. The contig from GABRA5 exon 7 extending to exon 24 of the OCA 2 gene has a minimum tiling path of 11 clones. The region is rich in repetitive DNA elements including retrotransposons, LINEs, SINEs, and retroviruses. The D15S822 and D15S975 markers have been localized within the GABRG3 gene. The GABRG3 gene, which was previously reported as greater than 50 kb, has been shown to be approximately 250 kb. Not I and numerous Eag I restriction enzyme cut sites were identified by PFGE of clones in this region. The genomic contig of the candidate gene region will serve as a resource for the characterization of genes in individuals with AD.

Program Nr: 2607 from the 1999 ASHG Annual Meeting

Molecular basis of diabetic embryopathy: Mutation analysis of left-right axis determining genes in NOD mouse.

K. Maeyama[1], R. Kosaki[1,2], H. Yoshihashi[1], B. Casey[3], K. Kosaki[1,4], N. Matsuo[1]. 1) Dept of Peds, Keio Univ Sch of Med; 2) Health Ctr, Keio Univ, Tokyo, Japan; 3) Dept of Path, Baylor Col of Med; 4) Pharmacia-Upjohn Fund for Growth& Development Research.

As a model system to study gene-environmental interaction in the pathogenesis of birth defects, we investigated diabetic embryopathy in the offspring of symptomatic NOD [non-obese diabetic] mouse strain. The incidence of left-right axis malformations among offspring of diabetic dams varies depending on the genetic background of the fetus: When diabetic NOD dams were mated with sires of different strains, the incidence of left-right axis abnormalities is 65 and 7 percent among F1 of varies NOD x NOD, and among NOD x C57BL/6J, respectively [Morishima et al., Teratology 54:183, 1996]. We hypothesized that mutations of the key molecules involved in the normal development of left-right axis could account for the variable incidence and undertook systematic mutation analysis of NOD, and C57BL/6J. Genomic structures of murine Nodal, HNF3beta, Smad2, Acvr2b were determined by either long range PCR amplification across exons or by the rapid-amplification-of-genomic-DNA-ends method. Each exon was amplified from genomic DNA of NOD and C57BL/6J strains by PCR and the products were directly sequenced. Mutation analysis of Hnf3beta revealed a homozygous point mutation (G in C57BL/6J -> A in NOD) in the coding sequence of exon 3. This base substitution was silent but could create a splice acceptor site which would truncate the mature protein. In addition, we found 3 single nucleotide substitutions in the 5 non-coding exon L1 and a 3-base deletion -0.2kb from the start codon. These observations are compatible with the notion that DNA sequence variations in left-right axis determining genes may be associated with strain-dependent susceptibility to teratogenic effects of maternal diabetes. Furthermore, it is intriguing to note that Hnf3beta belongs to and interacts with Hnf family proteins whose mutations are associated with diabetes (MODY) in human. Therefore, mutations in Hnf3 beta could account for both situs abnormalities in the fetuses and diabetes of the dam of the NOD strain.

Program Nr: 2608 from the 1999 ASHG Annual Meeting

INVESTIGATING THE HISTAMINE 1 AND HISTAMINE 2 RECEPTOR GENES AS CANDIDATES FOR SCHIZOPHRENIA AND CLOZAPINE DRUG RESPONSE. *D.T. Mancama, J. Munro, M.J. Arranz, A. Makoff, R. Kerwin.* Psychological Medicine, Institute of Psychiatry, London, England.

There is growing evidence to suggest the involvement of histaminergic pathways in the pathophysiology of schizophrenia. The efficacy of several antipsychotic compounds is thought to include their action at histamine receptors, while overactive histaminergic activity may significantly contribute to the deficit symptoms associated with the disorder. We have selected and investigated the histamine 1 (H1) and histamine 2 (H2) receptor genes as candidates for involvement in schizophrenia and patient response to clozapine treatment. The postulated promoter and complete coding regions of the two receptor genes were screened for polymorphisms using a combination of single strand conformation polymorphism (SSCP) analysis and automated sequencing. A total of sixteen previously unpublished polymorphisms were identified, of which five were H1 receptor coding polymorphisms (Lys19Asp, Asp349Glu, 1068-A/G, Phe358D and Leu449Ser) and one an H2 receptor coding polymorphism (543-G/A). Five H1 receptor promoter polymorphisms (-17-C/T, -974-C/A, -1023-G/A, -1204-G/C, -1640-G/A) and five H2 receptor promoter polymorphisms (-294-A/G, -478-T/C, -592-A/G, -1018-G/A, -1077-G/A) were identified. Association studies using these polymorphisms revealed a marginal increase (c^2=3.94, p=0.047) in the distribution of the H1 Ser449 allele in our control sample (n=118), compared with the group of schizophrenics (n=302), though no difference was observed when the polymorphism was examined for clozapine response. None of the other H1 and H2 receptor polymorphisms were found to be associated either with schizophrenia nor with clozapine response. These results suggest that genetic variance in the H1 and H2 receptor promoter and coding regions does not significantly influence the susceptibility of individuals to schizophrenia, nor does it appear to affect response to treatment with the atypical antipsychotic clozapine.

Program Nr: 2609 from the 1999 ASHG Annual Meeting

Sequence analysis of a-**synuclein gene in familial Parkinsons disease in Finland.** *A.J. Mannermaa[1], M.J. Hiltunen[1,2], J. Autere[2], P. Jäkälä[2], K. Majamaa[3], H. Soininen[2].* 1) Chromosome & DNA Laboratory, Kuopio Univ Hosp, Kuopio, Finland; 2) Department of Neurology, Kuopio Univ Hosp, Kuopio, Finland; 3) Department of Neurology, Oulu Univ Hosp, Oulu, Finland.

The molecular background of Parkinsons disease (PD) is by far not completely understood. Recently, mutations leading to amino-acid substitutions Ala30Pro and Ala53Thr in the gene encoding a-synuclein were shown to be associated with autosomal dominant form of PD. In order to assess the possible role of a-synuclein gene mutations among the Finnish familial PD patients, we have sequenced the coding and non-coding exons of the a-synuclein gene. Thirty-six unrelated patients with typical PD and at least one affected first-degree relative were recruited from the population of Eastern Finland and Northern Ostrobothnia. The coding and non-coding exons of the a-synuclein gene were PCR amplified from genomic DNA with primers and conditions previously described. Direct sequencing of the a-synuclein gene coding exons 3-7 from the familial PD patients did not reveal mutations when compared to previously published sequences. In addition, consensus sequences at the exon-intron splice junctions were found to be intact. Sequencing of the non-coding exons 1-2, however, revealed three novel alterations in the T10A7 sequence at the 5‘end of exon 2 including insertion of A (T10A8). Other two of these alterations encompassed simultaneous appearance of insertions and deletions: T12A5 and T11A6. Same alterations were also found from the 48 age-matched control subjects indicating that the changes are not causally related to PD. However, combining the T10A8, T12A5 and T11A6 alleles into one group revealed statistically significant increase in combined allele frequencies in PD patients (0.46) when compared to control subjects (0.30): Fischers exact p = 0.05, OR 1.96 (95% CI 1.04-3.69). In conclusion, our results indicate that mutations in the coding sequence of a-synuclein gene are not responsible for familial PD in Finnish population. However, we have found three novel polymorphisms in the non-coding exon 2, which appear to be associated with increased frequency in PD patients.

Program Nr: 2610 from the 1999 ASHG Annual Meeting

Exclusion of 5-HT1B and 5-HT1D serotonin receptor genes in migraine. *P. Marttila[1], M. Kallela[2], M. Wessman[3], J. Hartiala[1], M. Färkkilä[2], J. Kaprio[4], L. Peltonen[1], A. Palotie[5].* 1) Department of Human Genetics, UCLA, Los Angeles, CA; 2) Dept. of Neurology, University of Helsinki, Helsinki, Finland; 3) Dept. of Biosciences, University of Helsinki, Helsinki, Finland; 4) Dept. of Public Health, University of Turku, Turku, Finland; 5) Dept. of Pathology and Lab. Medicine, UCLA, Los Angeles, California, USA.

Migraine is a primary episodic headache disorder having a prevalence of 10 to 20% in the general population. It has a clear genetic component, with a multigene model being most likely. Previously, gene mutations underlying a rare subtype of migraine, familial hemiplegic migraine, have been demonstrated in a calcium channel gene. A selective agonist for 5-HT1B and 5-HT1D serotonin receptors, sumatriptan, is a drug for efficient treatment of migraine. Both receptors are expressed in the human cerebral cortex and are good candidate genes for migraine pathogenesis. Both genes are coded by a single exon and are located on chromosome 6q13 and 1p34.3-36.3 respectively. In order to study these genes in patients with migraine, we have collected 250 Finnish families with familial aggregation of migraine. We chose 21 phenotypically different migraine probands from families expressing strong inheritance. The probands included individuals having migraine with aura including basilar and hemiplegic migraine cases, and migraine without aura. In addition, individuals were stratified according to their responses to sumatriptan medication. The age of onset varied between 5 and 19 years. The coding regions of both genes were sequenced in both directions from the PCR-products of the genomic DNA using an ABI-377 sequencer. We found polymorphisms in both genes, but no alterations suggestive for mutations. Thus 5-HT1D and 5-HT1B genes can be excluded as major predisposing genes for migraine, at least in the Finnish migraine population.

Program Nr: 2611 from the 1999 ASHG Annual Meeting

A very large SCA7 CAG expansion is compatible with cell viability in somatic mosaicism. *T. Matsuura[1,2], M. Khajavi[1,2], R. de Silva[3], T. Ashizawa[1,2]*. 1) Neurology, Baylor College of Medicine, Houston, TX; 2) Neurology, VA Medical Centre, Houston, TX; 3) Neurology, Institute of Neurosciences, Southern General Hospital, Scotland, UK.

Spinocerebellar ataxia type 7 (SCA7) is an autosomal dominant disorder with progressive cerebellar ataxia, macular degeneration and variable other neurological deficits including pyramidal and extrapyramidal signs, dementia, hallucinosis and propioceptive sensory loss. The disease is caused by an expansion of a CAG repeat in the ataxin 7 gene on chromosome 3p12-13. Normal alleles range from 7 to 19 repats, while the expanded vary from 37 to 306 repeats. Intermediate alleles ranging from 28 to 35 repeats that are prone to furthur expand have also been described. Expanded alleles larger than 200 CAG repeats may cause the infantile form of the disease with cardiac anomaly, hypotonia and early death (Giunti et al. Am J Hum Genet 1999, Benton et al. Neurology 1998). In sperm of patients, the expanded allele frequently exceeds 150 repeats, and relative paucity of paternally transmitted cases have been attributed to embryonic lethality due to such larger alleles (Monckton et al. Am J Hum Genet 1998;supp63). We report a 67-year-old affected female who shows somatic mosaicism of the expanded CAG repeats. The CAG repeat sizes were determined by PCR analysis as previously described. The expanded repeats are heterogeneous in size, conforming a bimodal distribution with one peak around 45 repeats and the other in the range >350 repeats. The larger peak exceeds the largest allele reported to date in the infantile SCA7 cases and shows repeat size heterogeneity. Although the age at onset was 45 years, the phenotype is severe; she has severe ataxia, complete blindness, and severe dementia with hallucinosis, chorea, myoclonus, pyramidal signs and profound propioceptive sensory loss. Our case indicates that expanded CAG repeats are highly unstable in somatic tissues in SCA7 and can exceed the putative limit of the expansion for viabile fetal development when present as mosaic alleles. The presence of alleles with >350 repeats may have contributed to the rapid progression of the disease in spite of the late onset.

Program Nr: 2612 from the 1999 ASHG Annual Meeting

A Maternally Transmitted Huntington Disease CAG Repeat Contraction from the Affected Range to the "Mutable Normal" Range. *V.L. Matthias Hagen[1], M.J. Wick[2], C. Ludowese[3], M.A. Nance[3]*. 1) Dept Med, Div Gen & Metabolism, Univ Minnesota, Minneapolis, MN; 2) Dept Lab Med and Pathol, University of Minnesota, Minneapolis, MN; 3) Huntington Disease Clinic, Hennepin County Medical Center, Minneapolis, MN.

Meiotic instability of expanded trinucleotide repeats which are the causative mutation in the triplet repeat disorders is well documented. The CAG repeats on Huntington Disease (HD) chromosomes have been shown to undergo size change in approximately 70% of meiosis,occasionally showing large expansions in paternal transmission, and usually showing minor size changes of +/- 4 repeats when maternally inherited. We have recently performed predictive HD testing on an asymptomatic individual whose mother was previously tested in our laboratory. The mother, who had no family history of HD, was affected with personality changes and movement disorder in her early 40's; molecular HD testing showed two CAG repeats of 9 and 41. This result was consistent with the clinical diagnosis of HD. Molecular analysis (performed in triplicate) of peripheral blood from the asymptomatic son showed alleles of 16 and 35 CAG repeats, indicating that the maternal allele had undergone a contraction of 6 repeats. Although alleles of repeat size 35 have not been associated with the development of HD, counseling in this case was much more circumspect. Because the son was interested in starting a family, and because it has been reported that alleles of size 27-35 demonstrate instability in sperm, he subsequently submitted a semen specimen for molecular HD analysis; the majority of sperm carrying the larger allele were found to have a repeat of size 35, with a minority containing 32-36 repeats. To our knowledge, contraction of an allele across boundaries from the abnormal range to the mutable normal range has not been previously reported. Additionally, in only a few cases has the "meiotic behavior" of alleles in the mutable normal or reduced penetrance ranges been analyzed; such analyses may be useful in the genetic counseling setting. Unusual cases such as this demonstrate the need for cautious genetic counseling of predictive testing candidates.

Program Nr: 2613 from the 1999 ASHG Annual Meeting

Genetic relationship between hypertrophic cardiomyopathy and the onset of Friedreich's ataxia. *D.O. McDaniel, C.H. Gaymes, V.V. Vedanarayanan, D.S. Braden, S.H. Subramony.* University of Mississippi Medical Center, 2500 North State Street, Jackson, MS 39216.

Hypertrophic cardiomyopathy (HCM) is a primary feature of Friedreich's ataxia (FA) disease. Considerable information has been generated as to the possible role of (GAA)n expansion in the pathogenesis of FA. To evaluate the genetic relationship between HCM and FA we studied ten patients with typical FA, six with a mild form of ataxia and age of onset between 30-70, eight with HCM, and six non-FA/non-HCM individuals. The (GAA)n repeat expansion sizes unlike typical FA in late onset of FA were not correlated with the age at onset. Among the atypical patients except one, all were heterozygous for the FA gene carrying large fragments between 700-950 repeat sizes. The homozygous patient had an intermediate expansion of approximately 136 GAA repeats which was interrupted with a GAGGAA sequence. Seven out of eight HCM patients demonstrated a homozygous expanded allele with fragment sizes between 865-950 bp.

Homozygous Alleles	Majority of Typical	Minority of Atypical	All HCM
Heterozygous Alleles	Minority of Typical	Majority of Atypical	None

A sister (46y) and a brother (70y), from two separate atypical FA patients, carried the FA gene mutation without characteristics of FA. This makes the characterization of the FA disorder more complicated. Polymorphism of the transcription factor IID (TCFIID) gene was detected in association with FA/HCM. It allowed a better stratification and correlation with disease phenotype.

Screening of HCM patients for the presence of (GAA)n mutation as well as TCFIID gene polymorphism may allow early identification of disease onset. Whether polymorphism of TCFIID gene plays a role in cardiac hypertrophy warrants further investigation.

Program Nr: 2614 from the 1999 ASHG Annual Meeting

Genomic Characterisation and Molecular Genetic Investigations on PAX4, a Candidate Gene for Silver-Russell syndrome. *S. Mergenthaler[1], K. Eggermann[1], M.B. Ranke[2], K. Zerres[1], H.A. Wollmann[2], T. Eggermann[1]*. 1) Institute of Human Genetics, Technical University, Aachen, Germany; 2) University Childrens Hospital, Tuebingen, Germany.

Silver-Russell syndrome (SRS) describes a uniform malformation syndrome characterised by intrauterine and postnatal growth retardation, asymmetry of head and limbs, a small triangular face, and other less constant abnormalities. The majority of the so far described more than 400 cases occurred sporadically, but some familiar cases indicate a genetic reason for this disease. A subset of 10% of SRS patients show maternal Uniparental Disomy for the entire chromosome 7, thus indicating the involvement of at least one imprinted gene on this chromosome. Mutations in this gene or imprinting mutations might contribute to the SRS phenotype. PAX4 as a member of a highly conserved gene family contains two DNA-binding motifs, a paired domain, and a paired-type homeodomain, which may serve its function as a transcription factor. Several genes of this family are already associated with either inherited diseases (mutations in PAX3 cause Waardenburg syndrome, PAX6 mutations lead to aniridia). PAX4 is involved in regulating developmental processes concerning the fate of pancreatic island endocrine progenitor cells, as well as the maintainance of mature beta- and delta-cell-lines in the pancreas. Mice homozygously deficient for Pax4 show growth retardation, dehydration at birth and die within 3 days. Taking into account the function of this gene, its very restricted spatial and temprorary pattern of expression during embryogenesis and its localisation on 7q32, PAX4 was considered a strong candidate gene for Silver-Russell syndrome. There is no information about the imprinting status available so far. We isolated cosmids containing fragments of human PAX4 in order to establish the genomic structure. 41 SRS-patients were subsequently screened for sequence variants, but so far, two polymorphisms have been detected, whereas no SRS-specific mutation have been found in the coding region. Investigations on parent-of-origin-specific expression in adult humans as well as in fetal tissues are currently in progress.

Program Nr: 2615 from the 1999 ASHG Annual Meeting

The HOPA gene dodecamer duplication is not a significant etiological factor in autism. *R.C. Michaelis, S.A. Copeland-Yates, K. Sossey-Alaoui, C. Skinner, M.J. Friez, J.W. Longshore, R.J. Schroer, R.E. Stevenson.* JC Self Research Inst, Greenwood Genetic Ctr, Greenwood, SC.

A recent study has suggested that a dodecamer duplication in exon 42 of the human opa-containing (HOPA) gene in Xq13 may occur in a significant portion of male patients with autism. We have determined the incidence of this duplication in 204 patients from the South Carolina Autism Project as well as control groups consisting of newborns and college students. The incidence of the duplication was not significantly different between any of our race- and sex-matched patient and control groups. In addition, there were several instances in which autism and the duplication did not cosegregate in a number of our families. Three female patients with autism inherited the duplication from nonautistic fathers. In addition, there was no systematic skewing of X inactivation in the female patients with the duplication, or in nonautistic mothers and sisters with the duplication. These findings suggest that the dodecamer duplication in the HOPA gene does not play a significant role in the etiology of autism.

Program Nr: 2616 from the 1999 ASHG Annual Meeting

Genetic factors and and high and low HDL-C level in Russians. *O.V. Miloserdova[1], P.A. Slominsky[1], V.A. Metelskaya[2], N.V. Perova[2], S.A. Limborska[1].* 1) Dept Human Molec Genetics, Inst Molecular Genetics, Moscow, Russia; 2) National Research Centre for reventive Medicine, Moscow, Russia.

We studied a possible correlation between genetic polymorphism of major apolipoprotein and lipid transport genes and total cholesterol and HDL cholesterol level in Russia population. During this work 300 male subjects (age 40-59) was screening for HDL cholesterol level and two samples of patients - with high (more than 50 mg/dl) and low (below 40 mg\dl) - was studied further according to "case-control" principle. For genetic study we analysed different kinds of DNA polymorphisms (point mutations, microsatellite and minisatellite repeats) in APOB, APOA4, APOC2, AHJC3, LHAT, CETP, LHAT, LPL genes. For biochemical study was used measurements of lipid level (total cholesterol, HDL, VLDL and LDL cholesterol) and cholesterol efflux in cell culture. Moreover, genetic and biochemical data was analysed in respect of their physical data (age, blood pressure, obesity, CHD status). However we can't find any significant influence of genetic factors to HDL cholesterol status. In Russians man sample clear differences between HDL-C attributed to non-genetic factors. Aalcohol consumption (especially strong drinks) may be one of this epigenetic factors.

Program Nr: 2617 from the 1999 ASHG Annual Meeting

Molecular characterization of a set of Portuguese patients with Friedreich ataxia. *C. Miranda[1,2], C. Barbot[3], M. Pinto[2], M.C. Moreira[2], P. Mendonça[2], J. Poirier[1], C. Ferreira[4], J. Barros[4], P. Cabral[6], J. Ferro[6], I. Silveira[2], M. Pandolfo[1], P. Coutinho[1,5], J. Sequeiros[2]*. 1) Hôpital Notre-Dame, CHUM, Montréal, Québec,Canada; 2) UnIGENe, IBMC, Univ. Porto, Porto; 3) Hosp. Maria Pia, Porto; 4) Hosp. Geral Santo António, Porto, Portugal; 5) Hosp. São Sebastião, Feira, Portugal; 6) Serv. Neurol., Hosp. Sta Maria, Lisboa, Portugal.

Friedreich ataxia (FRDA) is an autosomal recessive disorder and the most common hereditary ataxia. More than 95% of patients are homozygous for a (GAA)n expansion in intron 1 of the frataxin gene. The remaining 5% are compound heterozygotes for an expansion and a point mutation. We studied the first set of 34 Portuguese patients (28 families), who had a clinical diagnosis of FRDA. Most of these were ascertained during a systematic, population-based, survey of hereditary ataxias and spastic paraplegias, being conducted in Portugal since 1993. The geographic distribution of cases seems uniform. A (GAA)n expansion was found in 28 (82%) patients (22 families), 27 (21 families) of whom were homozygous. The mean number of GAAs was 795±151 (GAA1 allele) and 936±122 (GAA2 allele), which are within reported ranges. A few cases showed meiotic instability and the expanded allele was of the same approximate size or contracted in father-to-child transmissions, while mother-to-child transmissions had contractions or further expansions. Interestingly, one obligate heterozygote (carrying an expansion with approximately 900 GAAs), who fathered an affected child (923/1090 GAAs) had a pure cerebellar ataxia with onset at age 45. We screened exons 1 to 5a by SSCP for possible compound heterozygosity but found no point mutations; we also excluded CAG expansions in all known genes for dominant ataxia (SCA1-3, 6-8, DRPLA). This could either be a manifesting heterozygote for FRDA (which has never been described), a phenocopy, or the result of an unknown mutation, e.g. in yet another gene for dominant ataxia. We cannot exclude, however, a mutation that escaped SSCP analysis or lies outside the coding region. The gene will be sequenced to answer this question.

Program Nr: 2618 from the 1999 ASHG Annual Meeting

Towards the isolation of differentially expressed mRNAs from the FMR1 knockout mouse. *J. Morales, D.L. Nelson.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Fragile X Syndrome is the most common cause of inherited mental retardation. The majority of cases are caused by the expansion and methylation of a CGG repeat in the 5' UTR of the FMR1 gene resulting in the silencing of the gene. The FMR1 protein is expressed in a variety of tissues with high levels in the hippocampus, cerebellum and testis. The FMR1 KO mouse exhibits a phenotype similar to that of humans. Analysis of the FMRP sequence revealed the existence of several functional RNA binding domains. It has been reported that FMRP is capable of binding RNA in vitro suggesting that RNA binding and regulation may be its primary function. Thus the identification of RNAs capable of interacting with FMRP is essential to the understanding of the pathway in which it works.

The isolation of RNAs that are affected in the absence of FMRP has been the primary focus of this project. Two different approaches have been undertaken in order to compare the RNA population of the knockout mouse to that of the wild type litter mate. A PCR based cDNA subtraction scheme was employed to analyze differences in whole brain, testis and hippocampus. A total of 28 clones were selected for further study. Of these, 8 had been reported previously in the database and 20 were unknown. RT-PCR and Northern blots were performed to confirm the results of the subtraction. None of the clones however, showed an observable difference between wildtype and knockout cells. In order to clarify our observations and refine our hypothesis, a cDNA hybridization approach has been initiated. Genome Systems cDNA arrays have been hybridized with cDNAs generated from hippocampus of knockout and wild type mice. Our preliminary data shows that 4 clones (neuroleukin and 3 unknown) are >30 fold higher in the knockout whereas 3 clones (asialoglycoprotein receptor and 2 unknown) are >20 fold higher in the wild type. A number of clones that display subtle differences in RNA levels are also being analyzed. RT-PCR and Northern blots are currently being performed to verify our results. The cDNA arrays will also be utilized to look at differences in the RNA population of testis and cerebellum.

Program Nr: 2619 from the 1999 ASHG Annual Meeting

Genetic analysis of Candidate genes in Nonsyndromic Cleft Lip with or without Cleft Palate Families. *L. Moreno[1], M. Arcos-Burgos[2], M. Marazita[3], K. Neal[1], B.S. Maher[3], C. Valencia[4], I. Fonseca[2], A.C. Lidral[1]*. 1) Orthodontics, Ohio State University, Columbus, OH; 2) Department of Biology, University of Antioquia, Medellin, Colombia, SA; 3) Cleft Palate-Craniofacial Center and Dept of Human Genetics, University of Pittsburgh; 4) College of Dentistry, University of Antioquia, Medellin, Colombia, SA.

Nonsyndromic cleft lip with or without cleft palate (CL/P) is a common, genetically complex, birth defect. Previous studies using candidate gene strategies to identify the genetic basis for Cl/P have revealed significant results for TGFA, TGFB3, and MSX1. In addition, translocations in the regions of 19q13 and 6p24 are associated with CL/P phenotypes and evidence from linkage and linkage disequilibrium studies support this association. However, studies of these candidate genes and loci have been contradictory, suggesting that heterogeneity between study populations may exist. The purpose of this study is to extend the evaluation of these candidate genes in multiplex nonsyndromic CL/P families from Central Ohio and Medellin, Colombia, SA. Twelve Ohio and 35 Colombian families were analyzed using parametric (dominant and recessive models were used in Linkage and GENEHUNTER) and nonparametric (GENEHUNTERnpl and SimIBD) linkage approaches. In addition, heterogeneity was analyzed using GENEHUNTER. Preliminary analysis of TGFA and TGFB3 revealed no evidence for linkage with TGFB3. However, SimIBD analysis showed suggestive linkage to the TGFA marker D2S443 (p=0.077), indicating that TGFA may play a role in the etiology of CL/P in these populations. Efforts are ongoing to genotype more markers for these and additional candidate genes to determine whether they have a role in CL/P in these populations. In addition, heterogeneity is being evaluated within these families and populations.

Program Nr: 2620 from the 1999 ASHG Annual Meeting

Linkage Disequilibrium Mapping In Reading Disability. *D.W. Morris[1], D. Turic[1], L. Robinson[1], M. Duke[1], V. Webb[1], M. Easton[1], S. Fernando[1], K. Pound[1], J. Stephenson[2], P. McGuffin[3], M.J. Owen[1], M.C. O'Donovan[1], J. Williams[1]*. 1) Department of Psychological Medicine, University of Wales College of Medicine, Heath Park, Cardiff, UK, CF14 4XN; 2) Psychology Department, University of Southampton, Southampton, UK, S017 1BJ; 3) SGDP Research Center, Institute of Psychiatry, London, SE5 8AF.

Developmental dyslexia/reading disability is a common condition with established heritable components. Replicated linkage analyses have highlighted two chromosomal regions which show suggestive evidence of susceptibility genes. We have collected a sample of over 100 unrelated probands and their parents for family based linkage disequilibrium mapping. Participants were collected from the population of South Wales (UK). Probands (aged 7 - 17 years) were defined as having a normal IQ (85 or above) with a general reading age at least 2.5 years below age-related norms. Linkage disequilibrium studies using polymorphic microsatellite markers were carried out on the 2 chromosomal regions of putative linkage. Evidence for allelic association was observed in both regions for markers in both regions (chromosome 6p21; p=0.01, chromosome 15q21; p=0.0015). These results were further supported by haplotype analyses using surrounding markers. Our data provide further support for susceptibility genes for dyslexia on chromosomes 6 and 15, and suggest more refined map positions of these loci. Replication and finer scale mapping is currently underway.

Program Nr: 2621 from the 1999 ASHG Annual Meeting

Further analysis of the association of tau with progressive supranuclear palsy. *H.R. Morris[1,2], M. Baker[2], A.J. Lees[3], M. Hutton[2], J. Hardy[2], N.W. Wood[1].* 1) Neurogenetics, Institute of Neurology, London, UK; 2) Neurogenetics Laboratory, Mayo Clinic, Jacksonville, Florida, USA; 3) National Hospital for Neurology, Queen Square, London UK.

Progressive supranuclear palsy (PSP) is a neurodegenerative condition characterised by the deposition of tau protein containing neurofibrillary tangles. The A0 allele of an intronic microsatellite marker of the tau gene is positively associated with the development of PSP. We have undertaken further analysis of six intragenic single nucleotide polymorphisms (SNPs) which span 100 kb at the tau locus, and five microsatellite markers in a 4.5 cM region around the tau gene. We have confirmed that the common variant at each intragenic SNP is associated with the development of PSP and that the SNPs are inherited together in unrelated Caucasian individuals as two major tau haplotypes. Analysis of the microsatellite marker allele distribution using the Likelihood Ratio Test shows that none of these close flanking markers are associated with the development of PSP ($LRT<1.2$, $p>0.15$). This refines the limits of the association of the immediate tau region with the development of PSP, and the extent of linkage disequilibrium around tau in the general population. It does not support the presence of a widely distributed pathogenic mutation ocurring on a common tau haplotype background, nor the involvement of genes other than the most likely candidate, tau.

Program Nr: 2622 from the 1999 ASHG Annual Meeting

Frequent duplications of triplet interruptions within a seven generation SCA8 family. *M.L. Moseley, M.D. Koob, L.P.W. Ranum.* Depts of Genetics, Cell Biology and Development, Neurology, and Institute of Human Genetics, University of Minnesota, Minneapolis, MN.

We recently described a novel CTG expansion that causes a previously undescribed ataxia (SCA8). In contrast to other triplet repeat diseases, pathogenic CTG expansions can have hypermutable sequence interruptions. The SCA8 CTG repeat is preceded by a polymorphic but stable CTA tract, with the configuration $(CTA)_{3\text{-}17}(CTG)_n$. The CTG repeat tract is elongated on pathogenic alleles and nearly always changes in size when transmitted from one generation to the next. Sequence interruptions observed within expanded CTG tracts among 11 ataxia families include: CCG, CTA, CTC, CCA and CTT. These interruptions, clustered at the 5' end of the repeat tract, do not appear to affect penetrance as both interrupted and uninterrupted alleles are found in affected individuals.

We are studying a seven-generation ataxia family that has CCG triplet interruptions within the CTG tract. Although haplotype analysis confirms that the expanded alleles are from a common founder, the CCG interruptions were often duplicated resulting in six different allele configurations. The presence of uninterrupted CTG expansions in one branch of the family suggests that a least one transmission within the past seven generations resulted in either the addition or deletion of a CCG interruption. In two instances duplications of the CCG repeat occurred over a single generation: $(CTG)_5\mathbf{CCG}(CTG)_{101}$ changed to $(CTG)_5\mathbf{CCG}(CTG)_7\mathbf{CCG}(CTG)_{105}$, while $(CTG)_5\mathbf{(CCG)_3}(CTG)_{103}$ became $(CTG)_5\mathbf{(CCG)_4}(CTG)_{87}$. In other instances repeat duplications that occurred in particular family branches could be inferred. These frequent mutation events altered the CTG repeat configuration at least six times in 28 transmissions. The presence of interruptions within the pathogenic expansion and their extremely high mutation rate are not observed in other triplet diseases.

Program Nr: 2623 from the 1999 ASHG Annual Meeting

Human mitochondrial ribosomal protein gene L12: A candidate gene for Russell-Silver syndrome. *E.B. Mougey[1], B.A. Maguire[1], J. Liu[2], J.E. Sylvester[1], T.W. O'Brien[2].* 1) Cellular and Molecular Medicine, Nemours Children's Clinic, Jacksonville, FL; 2) University of Florida, Gainesville, FL.

Mammalian mitochondrial ribosomes are responsible for translation of 13 mitochondrially encoded mRNAs that code for components of the oxidative phosphorylation system. The goal of the Human Mitochondrial Ribosomal Protein Consortium is to clone, map and study human mitochondrial ribosomal protein genes (hMRPs), (see abstract, Sylvester, et al., this meeting). It is well known that defects in other mitochondrially encoded components of the mitochondrial translation system, i.e. tRNAs, and rRNAs lead to human disease. Based on these observations, we hypothesize that mutations in hMRPs will also lead to human disease. To test this hypothesis, candidate diseases will be identified from the expanding list of mapped human disorders by using hMRP map location and genomic sequence generated by the consortium. The first hMRP gene that we are focusing on is the human homologue of bacterial L7/L12 (hMRP L12). hMRP L12 is critical for the function of several elongation factors and as such mutations in hMRP L12 should not be well tolerated. hMRP L12 has been mapped to 17q25 by FISH (Marty et al., Genomics 1;41(3):453-7, 1997; J. Liu, B. Barnoski and T. OBrien) and Ramirez-Duenas, et al., 41:51-53, 1992, and Midro, et al., Clin.Genet. 44:53-55, 1993, have described Russell-Silver patients with 17q25 translocations t(17;20) (q25;q13) and t(1;17) (q31;q25), respectively. The two main clinical features of Russell-Silver Syndrome are lateral-asymmetry and low birth weight dwarfism, i.e. retarded and abnormal development, both characteristics are consistent with reduced mitochondrial function. We present a strategy to identify hMRP L12 mutations in Russell-Silver patients based on PCR amplification of the entire hMRP L12 genomic region coupled with sequencing, and RT/PCR analysis of hMRP L12 mRNA coupled with sequencing. The strategy presented will be useful for the analysis of all mapped hMRP genes that are potential factors in human pathology.

Program Nr: 2624 from the 1999 ASHG Annual Meeting

Adult ADHD: association with the dopamine D4 receptor gene. *P. Muglia[1], U. Jain[2], V.S. Basile[1], J.L. Kennedy[1]*. 1) Neurogenetics Section,; 2) Adult ADHD Clinic, Department of Psychiatry, Centre for Addiction and Mental Health, University of Toronto, Toronto, Ontario, Canada.

The Attention deficit hyperactivity disorder (ADHD) is the most common child psychiatric disorder characterized by the combination of developmentally inappropriate attention, hyperactivity, and impulsivity. One third of the ADHD children continue to suffer from the disorder in adult life. A higher genetic loading for adult is suggested by findings of a higher relative risk in adults vs. childhood phenotypes (19 vs. 5, respectively), as ascertained by family studies. This increases the statistical power of genetic studies examining adult ADHD. Evidence indicates the dopamine system as primary candidate in the pathophysiology of ADHD and the dopamine D4 receptor gene (DRD4) represents a promising candidate. The third exon of DRD4 contains a 48-bp tandem repeat that can occur 1 to 10 times in the population. Each of these tandem repeats code for a 16 amino acid sequence that constitute the intracytoplasmic loop of the receptor. In vitro studies have shown that the 7-repeat allele of DRD4 has a small but significant blunted transmission of the signal if compared to the others alleles. Following our positive association of the 7-repeat allele in ADHD in children, various groups have replicated the result in independent samples. We genotyped the VNTR polymorphism of DRD4 in 33 adult ADHD and in 33 controls. Genotype analysis in the case control sample demonstrates that the 7-repeat allele is significantly more common in adult ADHD than in controls ($c2 = 7.16$, df=2, p=0.027). In an allelic analysis comparing the 7, 4 and the other repeat alleles, we also found significant results ($c2 = 6.80$, df=2, p=0.03). These results even if in a small sample confirm the significant higher presence of the 7 allele in ADHD children also in the adult subjects. The genotyping in a separate sample of trios is in progress.

Program Nr: 2625 from the 1999 ASHG Annual Meeting

Characterization of DNA methylation patterns in the 5' region of necdin, an imprinted gene in the Prader-Willi Syndrome region. *M.L. Munn, R. Wevrick.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Prader-Willi Syndrome (PWS) is a neurobehavioural disorder which affects about 1/15000 people. Patients exhibit severe hypotonia and failure to thrive in infancy followed by obesity and developmental delay. PWS patients usually have either deletions in their paternal chromosome 15 (~70%) or maternal uniparental disomy for chromosome 15 (~30%). Since the phenotype is dependent on parent of origin, genomic imprinting is implicated in this disorder. *NDN*, which encodes necdin, a protein involved in terminal differentiation of neurons, is one of four imprinted genes found in the PWS critical region. Methylation of CpG dinucleotides is one proposed mechanism for imprinting of specific genes. One site of maternal allele-specific methylation has already been detected by methylation-sensitive restriction digest analysis of EagI sites in the human and mouse necdin genes. In order to understand how the primary imprinting mark is established, we are characterizing in detail the CpG methylation patterns in the 5' region of *Ndn* (the mouse homologue of *NDN*) using the bisulfite-sequencing method in different adult tissues and early developmental stages. We can recognize allele-specific differences in DNA methylation using tissues from F1 crosses between different mouse species that exhibit DNA polymorphisms in this region. We are currently using mouse brain (expressing), liver (non-expressing) and heart (non-expressing) adult tissues. Our initial results include analysis of 39 contiguous CpG dinucleotides. They suggest that the maternal allele is more methylated than the paternal allele in brain, but in liver, both alleles are relatively unmethylated. We have collected preimplantation embryos from 2 cell, 4 cell, 8 cell and blastocysts and are also analyzing embryonic stem cells, sperm and oocytes. Preliminary results from the developmental analysis suggest the presence of an oocyte-specific methylation pattern which may serve as a gametic imprint for the *Ndn* gene. These experiments will provide the first insight into how genes are turned on or off in an allele-specific manner.

Program Nr: 2626 from the 1999 ASHG Annual Meeting

No association of the G-protein b**3 subunit C825T polymorphism with essential hypertension in an African Caribbean population.** *P.B. Munroe[1], D. Jadhav[1], M. Sandhu[1], J. Knight[1], A.J.L. Clark[2], M.J. Caulfield[1]*. 1) Clinical Pharmacology, St. Bartholomew's Hospital, London, United Kingdom; 2) Chemical Endocrinology, St. Bartholomew's Hospital, London, United Kingdom.

Essential hypertension and its complications, coronary heart disease, stroke and renal failure are leading causes of morbidity and mortality in westernised societies. The cellular sodium-hydrogen exchanger (NHE-1) is reported as having increased activity in up to 50% of hypertensive individuals, and recent data suggests a polymorphism, C825T, in the G-protein b3 subunit (GNB3) might account for this increased NHE-1 activity via enhanced cellular signal transduction. Studies of the C825T polymorphism have also revealed an association with essential hypertension in Caucasian individuals. A case-control study involving 221 hypertensive and 91normotensive African Caribbean individuals from St. Vincent and the Grenadines was performed to test for association between the C825T variant and essential hypertension. Analysis of the polymorphism was performed with the polymerase chain reaction and restriction digestion using *BseDI*. No association was found between the C825T polymorphism and essential hypertension ($c2 = 1.091$, 2df, $p = 0.58$), however, the frequency of the T allele was exceptionally high in this population (0.75 as compared to 0.30 in Caucasians).These results generate the hypothesis that GNB3/NHE-1 activity may be increased in this African Caribbean population and thus functional studies are warranted in this ethnic group.

Program Nr: 2627 from the 1999 ASHG Annual Meeting

A PNA-clamping based method of detection of point mutations in mtDNA. *D.G. Murdock, N. Christacos, S. Melov, D.C. Wallace.* Ctr Molec Med, Emory Univ, Atlanta, GA.

Inherited mitochondrial DNA (mtDNA) mutations have been shown to cause a variety of degenerative diseases, and the accumulation of somatic mtDNA mutations have been implicated in aging. Detection of mutations in mtDNA is complicated by the fact that each cell contains hundreds to thousands of mtDNAs, and a mutant cell can contain any proportion of mutant or wild type molecules, a condition known as heteroplasmy. As a result, it is often important to be able to detect low proportions of mutant mtDNAs in maternal relatives at risk for a disease or in the tissues of aging individuals. To develop a reliable procedure for detecting such mutations with low heteroplasmy, we have applied the peptide nucleic acid (PNA) clamping PCR technique to two pathogenic point mutations: the tRNA-Leu np3243 mutation causing mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes (MELAS), and the tRNA-Lys np8344 mutation causing myoclonic epilepsy and ragged red muscle fibers (MERRF). We have shown that the PNAs can selectively block amplification of the wild type molecule, leaving the mutant molecules available for amplification, and that the reaction can be multiplexed to identify more than one mutation per reaction. This method is extremely sensitive, being capable of detecting mutations at the level of 0.1% of total molecules, without false positives in the absence of mutant molecules. With this highly sensitive and specific assay, it will now be possible to evaluate the levels of somatic mtDNA point mutations in aging tissue.

Program Nr: 2628 from the 1999 ASHG Annual Meeting

Ethanol Responsive Genes Contributing To Alcoholism Identified by cDNA Expression Arrays. *B.C. Murphy, T. Chiu, P. McDonald, S.M. Singh.* Molecular Genetics Unit, Western Science Centre, University of Western Ontario, London, Ontario, Canada N6A 5B7.

Genetic strains of mice with extreme voluntary alcohol consumption (VAC) and sensitivity remain an invaluable model for the identification of genes involved in the complex etiology of alcohol preference leading to alcoholism. Ethanol has a direct effect on gene expression that is gene and strain/genotype specific. Variable expression of strain specific ethanol responsive (SSER) genes associated with VAC represent a logical approach to the identification of genes contributing to alcoholism.

Sequencing of many genes have prompted the development of the novel but untested expression array technology. We used Clontech's mouse cDNA expression array, containing 588 known genes. We labeled cDNA representing brain and liver of two strains (C57BL/6J with high and BALB/c with low VAC) that were ethanol fed using isocaloric liquid diet with matched controls. Expression differences between control and experimental animals were visually apparent and confirmed by computer analysis. In the liver, fifteen C57BL/6J and seven BALB/c genes were upregulated while none of the genes in either strain were downregulated in response to ethanol. Upregulation of six of these genes was observed in both strains. A number of these have been confirmed by semi-quantitative RT-PCR. Unlike the liver, brain specific upregulation of genes was confined only to the C57BL/6J strain. The single common gene upregulated in the two tissues was identified as glutathione S-tranferase. A number of other genes identified in this research on expression arrays are compatible with their known function. Others still under characterization may provide genes of importance in the complex etiology of alcohol preference. These results support the value of expression arrays in the identification of important genes in most complex etiologies.

Supported by Medical Research Council and the Ontario Mental Health Foundation.

Program Nr: 2629 from the 1999 ASHG Annual Meeting

Identification of QBP1, a synthetic peptide that preferentially binds expanded polyglutamine domain by phage display technique. *Y. Nagai[1,3], T.J. Tucker[1,3], D.J. Kenan[4,5], B.S. Henderson[4], J.D. Keene[4], W.J. Strittmatter[1,2,3], J.R. Burke[1,3]*. 1) Medicine (Neurology); 2) Neurobiology; 3) Deane Laboratory; 4) Microbiology; 5) Pathology, Duke University Medical Center, Durham, NC.

Expansion of polyglutamine domain is responsible for eight inherited neurodegenerative diseases, including Huntingtons disease, dentatorubral pallidoluysian atrophy (DRPLA), spinobulbar muscular atrophy (SBMA), and spinocerebellar ataxias (SCA1,2,3,6,7). The length of the polyglutamine domain is critical to pathogenesis and determines age of disease onset and disease severity. The mechanism by which expanded polyglutamine domain causes neurodegeneration remains unclear, but may be due to altered conformation leading to pathogenic protein-protein interactions. Molecules that selectively bind expanded polyglutamine domains may inhibit such pathogenic protein-protein interactions, and may be useful as a therapeutic tool. To identify a peptide that preferentially binds expanded polyglutamine domain, we screened a combinatorial M13 phage display library for binding to 19 or 62 glutamines (Q19 or Q62)-glutathione-S-transferase (GST) fusion proteins. We identified a peptide, named QBP1 (Glutamine Binding Peptide 1), which preferentially binds Q62-GST fusion proteins as compared to Q19-GST. Co-expression of Q81-yellow fluorescent protein (YFP) and QBP1-cyan fluorescent protein (CFP) fusion proteins in transfected COS-7 cells demonstrated co-localization of QBP1-CFP into the Q81-YFP aggregates. Our observations suggest that QBP1 fusion protein can be incorporated into polyglutamine aggregate and may be useful for developing potential therapies.

Program Nr: 2630 from the 1999 ASHG Annual Meeting

Investigation of TCF19 as a candidate gene for psoriasis susceptibility. *R.P. Nair[1], N.V. Chia[1], S. Jenisch[2], P. Stuart[1], J. Epperson[1], T. Henseler[3], E. Westphal[2], J.L. Arndt[1], E. Christophers[3], J.J. Voorhees[1], J.T. Elder[1,4]*. 1) Dept Dermatology, Univ Michigan, Ann Arbor, MI; 2) Dept Immunology, Univ Kiel, Germany; 3) Dept Dermatology, Univ Kiel, Germany; 4) Ann Arbor Veterans Affairs Hospital, Ann Arbor, MI.

Genome-wide searches for psoriasis susceptibility genes identified candidate regions on chromosomes 1q, 4q, 6p, 16q, 17q and 20p. The chromosome 6 locus (PSORS1, 6p21.3) encompasses HLA Class I and II genes long known to be associated with psoriasis, and linkage has been now been replicated in several family studies. Association analysis using the transmission / disequilibrium test (TDT) narrowed the susceptibility region to a ~300 kb interval in the centromeric HLA Class I region containing the HLA-B and -C genes. However, HLA haplotypes in this interval are in stronger linkage disequilibrium than are their component alleles, suggesting that the causative gene is probably not HLA-B or HLA-C. Transcription factor gene TCF19 (SC1) maps to this interval and is therefore a candidate for psoriasis susceptibility. We investigated polymorphisms in the exons of TCF19 in 4 heterozygous psoriasis patients carrying the two most common HLA susceptibility haplotypes (B57-Cw6 and B13-Cw6). One nondiseased B7-Cw7 homozygote served as a control, because this common haplotype has not been associated with psoriasis in Caucasians. Unlike the HLA-B and HLA-C genes centromerically and the corneodesmosin gene telomerically, TCF19 did not appear to be polymorphic. In the seven chromosomes examined we found no variations when compared to the published cDNA sequence (Genbank ID U25826), other than two single base insertions present in all chromosomes examined (3989insG and 4162insA). These variations are in agreement with the recently published genomic sequence of the region (Genbank IDs AC004195 and AC006047). These insertions would alter the predicted protein sequence and shorten it by 15 amino acids. Based on these results, we conclude that TCF19 is unlikely to be involved in psoriasis. Moreover, our results indicate that the distribution of allelic polymorphism is not uniform across centromeric HLA Class I.

Program Nr: 2631 from the 1999 ASHG Annual Meeting

The expression of genes important in endochondral ossification in human osteoarthritic tissue. *W.G Newman[1], K.L Chapman[1], M.C Hillarby[2], A.J Freemont[2], M.E Grant[1], R.P Boot-Handford[1], G.A Wallis[1].* 1) Wellcome Trust Centre for Cell Matrix Research, University of Manchester, Manchester,M13 9PT, UK; 2) Department of Pathological Sciences, University of Manchester, Manchester M13 9PT, UK.

Osteoarthritis (OA) is a common, complex disorder, characterised by cartilage loss and new bone formation at synovial joints. Recent work suggests that the process which forms the bony skeleton, endochondral ossification (EO), is reactivated in the development of OA. The new bone growth is related to disease progression and may be the initiating event in OA pathogenesis. We hypothesised that genes that are differentially expressed by chondrocytes during EO may have a role in the initiation and progression of OA.

To test this theory, an RT-PCR subtractive hybridisation was performed to create a cDNA pool enriched for proliferative chondrocyte cDNAs. The cDNA pool was validated and used to screen a foetal bovine chondrocyte lZap cDNA library. Six genes were identified which encode alpha enolase, heavy chain ferritin subunit, annexin V, matrix Gla protein, nexin and a vitamin D responsive transcript. The differential expression of these genes in the bovine growth plate has been confirmed by northern blot analysis and immunohistochemistry. Preliminary results suggest that the genes differentially expressed by the proliferative chondrocytes are up-regulated in OA tissue compared to normal human articular cartilage and as such may provide important clues regarding the pathogenesis of this disease.

Program Nr: 2632 from the 1999 ASHG Annual Meeting

Instability of FMR1 alleles with 40-60 CGG repeats. *S.L. Nolin, G.E. Houck, Jr., A.D. Gargano, S.Y. Li, A. Glicksman, W.T. Brown.* Institute for Basic Research, Staten Island, NY.

The stability of intermediate fragile X alleles with 40-60 CGG repeats is uncertain. To assess the frequency of instability, we have analyzed 92 transmissions in 60 families with no known history of fragile X. In families with repeats between 40-44, no unstable transmissions were observed in 32 meioses. No instabilities were observed among 16 meioses in 10 families with repeats from 45-49. One additional family, referred to us because of an instability, exhibited an increase of two repeats from 45 to 47 in three of five daughters. In the 50-54 repeat range, 3 of 25 (12%) meiotic events were unstable. Two of the three, however, were contractions and only one was an expansion. In the 55-59 repeat range, 5 of 20 (25%) meioses expanded by a few repeats, and 15 (75%) inherited the allele without change. These data suggest that instabilities in the 40-49 range are infrequent and that the risk of expansion to the full mutation in one transmission is negligible. Alleles in the 50-54 range have some propensity for expansion, but the risk for expansion to the full mutation in one transmission is low. Alleles >55 are likely to carry higher risks for expansion.

For 14 males with repeats 50, AGG interruptions were analyzed by sequencing to compare the length of pure CGG repeats with repeat instability. No unstable transmissions were observed in six families with <40 pure CGGs. In 3 males from families with unstable transmissions, 41, 42, and 49 pure CGGs tracts were observed at the 3' end. Five other families with 40-49 pure CGGs failed to exhibit repeat instability. These results indicate that the presence of pure CGG tracts >40 does not always confer instability on alleles in this size category and that additional factors are likely to influence instability. ’

.

Program Nr: 2633 from the 1999 ASHG Annual Meeting

Amino acids flanking polyglutamine stretches influence the competence of aggregate formation. *K. Nozaki, O. Onodera, S. Tsuji.* Dept. of Neurology, Brain Research Institute, Niigata University, Niigata, Japan.

Background: Expanded polyglutamine stretches have been shown to form aggregates and to be toxic to cells. Interestingly, however, the threshold of the size of expanded CAG repeats vary among the diseases caused by CAG repeat expansions. We hypothesized that amino acids flanking the polyglutamine stretches substantially influence the competence of aggregate formation of the mutant proteins, and eventually the clinical presentations in diseases caused by expansions of CAG repeats.

Method: Partial cDNA fragments containing various lengths of CAG repeats, and the flanking fragments (24-bp upstream fragment and 27-bp downstream fragment) for SCA2, HD, DRPLA, and MJD/SCA3 were cloned into pEGFPN1 to allow expression of polyglutamine stretches fused with GFP. These plasmids were transfected into COS-7 cells, and the frequencies of cells with aggregates were determined for each construct 72 hours after transfection.

Results: In the COS cells transfected with the SCA2 and DRPLA cDNA fragments, aggregate formation rate increases in a CAG repeat length-dependent manner with threshold between 34 and 36 repeats (ataxin-2; 6.5±1.6%®20.1±4.4%, DRPLAP; 7.5±3.7%®32.5±6.1%). When the rate of aggregate formation were compared among ataxin-2, huntingtin, DRPLAP and ataxin-3 containing the same size of CAG repeats (56 repeats), ataxin-2 (66.5±4.4%) and huntingtin (60.7±4.4%) showed significantly higher aggregate formation rate than DRPLAP (39.1±6.1%) and ataxin-3 (30.3±5.3%). These results are in good agreement with the fact that the thresholds of expanded CAG repeats in DRPLA and MJD patients are much larger than those in HD and SCA2 patients.

Conclusion: These results indicate that amino acids flanking the CAG repeats substantially influence the competence of aggregate formation.

Program Nr: 2634 from the 1999 ASHG Annual Meeting

Nuclear Localization of Truncated Atrophin-1, The DRPLA Gene Product, Increases Cellular Toxicity. *F.C. Nucifora[1], W.J. Herring[2], M.F. Peters[1], J.D. Wood[1], R.L. Margolis[1], V.L. Dawson[2], T.M. Dawson[2], C.A. Ross[1].* 1) Division of Neurobiology, Dept. of Psychiatry, Johns Hopkins School of Medicine, Baltimore, MD; 2) Dept. of Neurology, Johns Hopkins School of Medicine, Baltimore, MD.

Dentatorubral and pallidoluysian atrophy (DRPLA) is a neurodegenerative disorder similar to Huntingtons disease, with chorea, incoordination, ataxia, and dementia caused by an expansion of a CAG repeat encoding polyglutamine in the atrophin-1 gene. Identification of an N-terminal fragment of atrophin-1 in patients and transgenic mice containing 65 glutamine repeats suggests that truncation plays a role in the disease process. In transient cell transfection experiments using N2a cells, full length atrophin-1 with 26 or 65 glutamine repeats shows granular nuclear and cytoplasmic staining with no increase in toxicity caused by the expanded repeat. Atrophin-1 contains a putative bipartite nuclear localization signal (RKKEAPGPREELRSRGR) near the N-terminus (a.a. 16) and a putative nuclear export signal (LARLQMLNV) near the C-terminus (a.a. 1033). Constructs lacking the putative NES (a.a. 1-917, At-N917), show an increase in diffuse nuclear labeling and an increased toxicity (36.7%) for this construct with 65 repeats compared to this construct with 26 repeats (19.4%). Mutating the NLS (NNKEAPGPREELNSRGN) in At-N917-26Q or At-N917-65Q shifted atrophin-1 to the cytoplasm and eliminated the enhanced toxicity of 65 repeats. When the putative NES was mutated (AARAQMANV) full length atrophin-1 showed mostly diffuse nuclear staining and the expanded repeat now caused cell toxicity comparable to that of the truncation (36.5%). These data indicate that endogenous cellular targeting signals are functional, that the effect of truncation is to delete the NES, and that nuclear localization is directly related to cell toxicity . They are also consistent with the idea that proteolytic processing is relevant for toxicity. This work was supported by the HDSA, NS16375, and NS38377.

Program Nr: 2635 from the 1999 ASHG Annual Meeting

Stability of GAA•TTC triplet repeats in transgenic mice. *K. Ohshima, J. Poirier, M. Pandolfo.* CHUM, Campus Notre-Dame, Montreal, PQ, Canada.

Meiotic and mitotic instabilities of GAA•TTC triplet repeats are characteristic of Friedreich ataxia in which about 100 to more than 1,000 GAA•TTC triplets are found in the first intron of the target frataxin gene. We generated transgenic mice carrying about 250 GAA•TTC triplets. The repeats were cloned in both orientations within the intron of a reporter gene in a pSPL3-derived construct whose expression is controlled by the SV40 promoter. The DNA constructs were injected into the oocyte pronuclei of fertilized C57BL6/C3H female mice. Pups were evaluated for the presence of the transgene by Southern blot and PCR analyses on DNA extracted from tail blood samples. Seven transgenic lines were obtained for the construct in which TTC strand is on the transcript. We determined the size of repeats in the founders and their progenies (F1 and F2 generations) by PCR and Southern blot analyses. Most lines harbor multiple copies of the transgene, in some of which the GAA•TTC repeat underwent size changes (mostly contractions) at the time of insertion into the mouse genome. However, the repeats subsequently remained stable during meiotic and mitotic transmissions with no detectable increases or decreases in size regardless of orientation . We conclude that GAA•TTC triplet repeats containing up to 250 triplets are stably transmitted in the mouse at least in the context of the DNA construct we used to generate transgenic animals. In human, repeats of similar length contained in the first intron of the frataxin gene show moderate meiotic instability.

Program Nr: 2636 from the 1999 ASHG Annual Meeting

Interleukin-4 receptor alpha chain polymorphism Gln551Arg is associated with adult atopic dermatitis in Japan.
N. Oiso, K. Fukai, M. Ishii. Dermatology, Osaka City Univ, Osaka, Japan.

Localization of a locus for atopy to chromosome 16p12-p11 and reported associations of Ile50Val and Gln551Arg polymorphisms in IL4R gene with atopy prompted us to sequence the gene in 27 adult atopic dermatitis (AD) and 29 non-atopic (non-AD) subjects. All six IL4R missense polymorphisms and a silent L389L (CTG>CTT) polymorphism were clearly detected by sequencing. There were no statistically significant differences in codon 50 genotypes between AD and non-AD. The most significant association was found for the codon 551 polymorphism (p=0.010). Six of 27 atopic dermatitis patients were heterozygous for the Arg551 allele, but this allele did not occur in the 28 control subjects. The disease severity among the six Arg551 heterozygous AD subjects was variable; two had a mild phenotype and four had a severe phenotype. Ser411Leu and Ser761Pro polymorphisms were not detected in this study. One of 26 atopic subjects and three of 28 normal subjects were heterozygous for the Ala375 allele, which is not statistically significant. All of the four individuals who were heterozygous for Ala375 were heterozygous for both Arg406 and Leu389Leu (CTG>CTT), suggesting that these three polymorphisms probably occur in the same haplotype. However, this haplotype had no association with the development of AD.Very recently, Noguchi et al studied Glu551Arg polymorphism of IL4R gene in Japanese asthmatics, and found no association with atopy. The frequency of the Arg551 allele in their study was 0.16 in atopic subjects versus 0.13 in non-atopic parents. In our study, the frequency of the Arg551 allele was 0.11 in AD versus 0.00 in non-AD. The higher allele frequency of Arg551 allele in the non-atopic group in Noguchis report may reflect relatively low penetrance of this allele in the development of asthma among non-atopic parents. The reason for the low allele frequency of Arg551 in the present study may be that we excluded subjects as controls if they had a family history of any atopic diseases, and therefore we were able to exclude non-penetrant cases. In conclusion, the IL4R gene should be considered a strong candidate gene for AD.

Program Nr: 2637 from the 1999 ASHG Annual Meeting

Analysis of cell toxicity on cultured cells mediated by the a**1A-voltage-dependent calcium channel gene with CAG repeat expansion (SCA6 gene).** *K. Owada[1,3], K. Ishikawa[1,3], H. Saegusa[2,3], T. Tanabe[2,3], H. Mizusawa[1,3].* 1) Neurology, Tokyo Medical & Dental Univ., Tokyo, Tokyo, Japan; 2) Pharmacology, Tokyo Medical & Dental Univ., Tokyo, Tokyo, Japan; 3) CREST, Japan Science and Technology Corporation, Saitama, Japan.

Spinocerebellar ataxia type 6 (SCA6) is a late-onset neurodegenerative disorder caused by expansion of trinucleotide (CAG) repeat in the 3' region of the a1A-voltage-dependent calcium channel gene (CACNA1A). Neuropathology of SCA6 show predominant neuronal loss of the Purkinje cell in the cerebellum with formation of cytoplasmic aggregation of the a1A-calcium channel protein (Ishikawa, et al. Hum. Mol. Genet. 1999). However, the pathogenic mechanism by which mutated CACNA1A leads to cell death is poorly understood. To clarify the pathophysiology of SCA6, we analyzed the cell toxicity mediated by the expansion of the CAG repeat in CACNA1A in cultured cell system. The full-length CACNA1A with normal-length (13 CAG repeat unit) or expanded (28 repeat unit) repeats were fused with green fluorescent protein (GFP) cDNA, and were transiently expressed in human embryonic kidney (HEK)-293 cells and PC12 cells. While the fusion protein with normal-length polyglutamine was expressed diffusely in the cytoplasm, the fusion protein with expanded polyglutamine accumulated densely in the perinuclear cytoplasm in most occasions. In addition, a higher number of cells transfected with full-length CACNA1A with expanded CAG repeat underwent cell death with positive TUNEL staining, while cells transfected with CACNA1A with normal length CAG repeat appeared normal. Moreover, expanded polyglutamine in a portion of CACNA1A did not induce cell death. The present data provide evidence that the full-length a1A-calcium channel protein with expanded polyglutamine could be toxic to cells.

Program Nr: 2638 from the 1999 ASHG Annual Meeting

Screening and detection of variants in the Endothelin B Receptor Gene (EDNRB) : A candidate for asthma. *S.D. Pandit[1], S. Cheng[1], J. Dupuis[1], P. Van Eerdewegh[1,2], T. Keith[1].* 1) Human Genetics, Genome Therapeutics Corporation, Waltham, MA; 2) Department of Psychiatry, Harvard Medical School, Boston, MA.

Several studies have localized a putative candidate gene for asthma in the 13q14-q22 region. Among the known genes and ESTs that map in the candidate region, the endothelin B receptor gene (EDNRB) is particularly interesting because of its possible involvement in the pathophysiology of asthma. Endothelins (ET 1, 2 and 3) and their receptors, endothelin receptor type A and type B are highly expressed in human lung. Endothelins cause contraction of airway smooth muscle and this effect is predominantly mediated through the endothelin B receptor. Accordingly we analyzed the EDNRB for mutations using single stranded confirmation polymorphism (SSCP) analysis followed by sequencing of variants. The genomic structure of EDNRB gene has been elucidated previously (Arai, H., (1993), JBC, 268: 3463-3470). A total of ten primer pairs were utilized to cover the seven exons and an additional eight primer pairs were utilized to cover the promoter region. Eight out of the ten primer pairs covering the exons were redesigned to amplify smaller products (<250 bp) more amenable for SSCP analysis. Initially, we screened 40 unrelated asthmatics and 40 unrelated CEPH individuals for variants. Subsequently we identified and screened 51 unrelated asthmatic individuals from our collection of families that showed sharing by descent in affected for the 13q14-q22 chromosomal region. We have identified a total of eight variants in the EDNRB gene and confirmed the nucleotide changes by sequencing. Three of the variants (novel) were in the promoter region and five (2 novel) were in the coding region. Among the five variants detected in the coding region, three lead to amino acid substitutions of which one was novel. Statistical analyses were performed and no significant association of any to the asthma phenotype was observed (all p-values > 0.22). The current sample size could detect differences of 22% or more in allele frequencies between the asthmatic and non-asthmatic groups with 80% power using a two-sided test with type 1 error of 5%.

Program Nr: 2639 from the 1999 ASHG Annual Meeting

A common disease haplotype segregating in spinocerebellar ataxia 2 (SCA2) pedigrees of diverse ethnic origin.

J.T. Pang[1], R. Allotey[1], N.H. Wadia[2], H. Sasaki[3], L. Bindoff[4], S. Chamberlain[1]. 1) Molecular Genetics, Imperial College of Science, Technology and Medicine, London, UK; 2) Dept of Neurology, Jaslok Hospital and Research Centre, Bombay, India; 3) Dept of Neurology, Hokkaido University School of Medicine, Sapporo, Japan; 4) Dept of Neurology, Middlesborough General Hospital, UK.

The autosomal dominant cerebellar ataxias (ADCAs) are a clinically heterogeneous group of neurodegenerative disorders. Genetic heterogeneity has been demonstrated and six of the disease genes have now been cloned - spinocerebellar ataxia 1 (SCA1), SCA2, Machado Joseph disease/SCA3, SCA6, SCA7 and SCA8. The identification of a CAG trinucleotide repeat expansion, located within the coding sequence of the ataxin-2 gene, as the mutation underlying SCA2 has facilitated direct investigation of pedigrees previously excluded from linkage analysis due to insufficient size or pedigree structure. With the advent of markers known to lie in close physical proximity to SCA2, it is now feasible to undertake a comparative study of the disease haplotypes segregating in pedigrees of diverse geographical and ethnic origin. We have previously described the identification of the ancestral disease haplotype segregating in the Cuban founder population used to assign the disease locus to chromosome 12q23-24.1. Using microsatellite loci within and flanking the SCA2 gene [D12S1328 - (0.03) - D12S1332 - (0.00) - D12S1672 - (0.00) - D12S1333 - (0.01) - D12S1329], haplotype analysis has been undertaken in key affected individuals from 7 Indian, 16 Cuban, one English and 3 Japanese families. Our results demonstrate the segregation of the identical core haplotype in 23 of these pedigrees at the loci D12S1672 and D12S1333 located 20kb proximal and 200kb distal to the triplet repeat motif, respectively. To establish the significance of association between the disease and alleles at the polymorphic loci segregating in these families, unrelated individuals derived from the respective ethnic populations were also genotyped. Interpretation of our data is suggestive that for these SCA2 pedigrees at least, the mutation has arisen on a single ancestral or predisposing chromosome.

Program Nr: 2640 from the 1999 ASHG Annual Meeting

Aging and frequency of replication/ transcription errors in poly(A)/(T) runs of human genes. *A. Paoloni-Giacobino[1], C. Rossier[1], V. Lambert[2], S.E. Antonarakis[1].* 1) Division of Medical Genetics, Geneva University Medical School, Geneva, Switzerland; 2) Department of Medecine, Geneva University Hospital, Switzerland.

The goal of this study was to estimate the error rate of the complex machinery of nuclear gene expression and its possible age-related increase. Mutant transcripts and therefore aberrant proteins may be associated with aging and errors could occur at nucleotide runs such as poly(A)s or poly(T)s. Toward this goal we compared the occurrence of polymerase slippage errors during replication and transcription in A or T runs in both DNA and RNA from young (18 y.o.) and old (80 y.o.) healthy individuals. We selected to analyze the (A)/(T) runs of 3 human genes: a stretch of 8 (A)s in TPRD, 10 (A)s in TGFBR2 (within the coding region of these two genes), and 13 (T)s in the 3'-UTR of ATRX. Total RNA and genomic DNA from blood were isolated from each individual. The error rate in DNA molecules was determined by sequencing 100 cloned PCR fragments containing the nucleotide run. The error rate in RNA molecules was determined by sequencing 100 cloned RT-PCR fragments (primers were choosen in different exons so that contamination with DNA amplification was avoided). The error rates observed in the different stretches were always higher in the RNA than in DNA for each of the genes studied. The error rate in replication and/or transcription was associated with the length of the stretches of poly(A)/(T) runs: e.g. the errors were 5%, 22% and 58% in the RNAs of the 8(A), 10(A) and 13(T) repeats, respectively, in the "old" samples. Moreover, the observed error rate was higher in old than in young individuals: e.g. in 13(T) the differences were 10% for DNA (28% vs 38%) and 5% in RNA (53% vs 58%). To exclude that the observed errors were due to Taq polymerase, we analysed 100 clones obtained from PCR on a plasmid containing the stretch of 13(T) and observed only 1 error. The preliminary conclusion from these data is that aberrant proteins are always produced due to the replication/transcription errors and that their rate of production increases with age.

Program Nr: 2641 from the 1999 ASHG Annual Meeting

Parkinson's disease and monoamine oxidases A and B: Association with MAO-B Alleles. *A. Parsian[1,2], B. Racette[2], Z.H. Zhang[1], M. Rundle[2], J.S. Perlmutter[2].* 1) Dept Psychiatry, Washington Univ Medical Sch, St Louis, MO; 2) Dept Neurology, Washington Univ Medical Sch, St Louis, MO.

Idiopathic Parkinson's disease (PD) is an age dependent, neurodegenerative disorder and is predominantly a sporadic disease. Only 20-30% of patients have a positive family history for PD with complex mode of inheritance. Monoamine oxidases A and B (MAO-A and B)are involved in the serotonin and dopamine metabolism. The neurotoxin MPTP requires activation by MAO-B to be toxic to dopaminergic cells and causes parkinsonian symptoms. The inhibition of MAO-B with drugs such as selegiline blocks MPTP induced neuronal degeneration in primates and reduces the rate of PD progression in humans. There have been reports of inconclusive association between PD and an A/G transition in intron 13 of the MAO-B gene (Kurth et al., 1993; Ho et al., 1995; Costa et al., 1997) in Caucasians. Recently, Mellick et al., (1999) reported a highly significant association between a large allele of the dinucleotide repeat in the intron 2 of MAO-B and PD ($p<0.00005$) in an Australian sample. To determine the role of MAO-A and B in the development of PD, we have screened a well characterized sample of 89 patients with, 168 patients without a positive family history (at least one first degree relative with definite PD), and 95 matched controls with dinucleotide repeat markers in both genes. Comparison of the PD groups with normal controls for the MAO-B allele frequencies was positive (PD with history $p=0.012$, PD without history $p=0.019$). The frequency of the large alleles (1 and 2) in PD group with a positive family history was highly significantly different than controls ($p=0.0033$). However, comparison of the PD groups with and without a positive family history to controls for the MAO-A gene polymorphism was negative ($p=0.089$ and $p=0.282$, respectively). Our data indicate that MAO-B may play a role in the susceptibility to familial form of the PD.

Program Nr: 2642 from the 1999 ASHG Annual Meeting

Exploring mutant huntingtin's conformational properties *in vivo*. *F. Persichetti[1], F. Trettel[1], V. Wheeler[1], C. Huang[1], S. Namura[2], L. Hirt[2], M. Timmers[3], M. Moskowitz[2], J. Gusella[1], M. MacDonald[1]*. 1) Molecular Neurogenetics Unit, Massachusetts General Hospital, Charlestown, MA; 2) Departments of Neurosurgery and Neurology, Massachusetts General Hospital, Charlestown, MA; 3) Laboratory for Physiological Chemistry, Utrecht University, Utrecht, The Netherlands.

Huntington's disease (HD) is caused by an expanded CAG repeat that lengthens a glutamine tract in huntingtin (htt)protein. A conformational change conferred by elongated glutamine may trigger the progressive neurological phenotype. Amino-terminal htt aggregates found in HD post-mortem brain may be causative in the disease, or may be the end products of a toxic process operating in the context of the full-length protein, possibly via interaction with normal or abnormal protein partners. We have examined the physical properties of mutant htt aggregates formed in cell culture from either truncated or full length proteins. Complexes derived from the truncated amino-terminal protein frequently present a conformational change that eliminate the reactivity with the glutamine specific mAb 1F8, coincident with the production of insoluble material. By contrast, complexes formed by the full-length protein retain their reactivity to 1F8 and do not generate insoluble aggregates. It is possible that the soluble full-length complexes foster non-covalent interactions with other proteins that could play an important role in HD pathogenesis. Interaction of an htt amino-terminal fragment with caspase *in vitro*has suggested glutamine-dependent cleavage, with apoptotic consequences. Therefore, we have also examined accurately expressed mutant htt in *Hdh*CAG knock-in mouse brain and have failed to find evidence of stable htt fragments or apoptosis. By contrast *Hdh*knock-in brain, in an *in vivo*apoptotic model (focal ischemia), accumulates a stable carboxy-terminal htt fragment, concomitant with apoptotic neuronal cell death. Differential cleavage of mutant and normal htt may suggest an altered conformational property of the mutant protein. Our inability to detect htt cleavage products in *Hdh*CAG knock-in brain suggests, therefore, that mutant htt triggers a subtle rather than an 'acute' pathogenic process, consistent with HD's late age at onset.

Program Nr: 2643 from the 1999 ASHG Annual Meeting

Analysis of the 4-1BB Gene in the NOD Mouse: A Positional Candidate for the *Idd9* Locus. *M.S. Phillips[1], P.A. Lyons[2], N. Armitage[2], P.J. Hey[1], L.S. Wicker[3], L.B. Peterson[4], M.L. Metzker[1], C.T. Caskey[1], J.A. Todd[2], J.W. Hess[1]*. 1) Dept. of Human Genetics, Merck Research Laboratories, West Point, PA; 2) Dept. of Medical Genetics, Cambridge Institute of Medical Research, WellcomeTrust/MRC Building, Addenbrokes's Hospital, Cambridge, UK; 3) Dept. of Autoimmue Disease Research, Merck Research Laboratories, Rahway, NJ; 4) Dept. of Pharmacology, Merck Research Laboratories, Rahway, NJ.

The nonobese diabetic (NOD) mouse is an animal model for human type 1 diabetes or autoimmune insulin-dependent diabetes mellitus. The NOD mouse also serves as a model for studying complex polygenic diseases. Currently, 16 loci that contribute to the development of type 1 diabetes in the NOD mouse have been mapped by linkage analysis. To fine map these loci, we used the strategy of congenic mapping by breeding a diabetes resistant mouse strain, C57BL/10, onto an NOD background. Using this approach, we localized the *Idd9* locus to a 2.1-cM interval on chromosome 4 containing several members of the TNF receptor superfamily, including the 4-1BB gene (CD137 or TNFRSF9).

The 4-1BB gene represents a good positional candidate for the *Idd9* locus since it is involved in the activation of T-lymphocytes. Using both cDNA and genomic sequencing, the 4-1BB gene was analyzed in six different mouse strains to determine polymorphic differences. Several polymorphic changes between NOD and B10 were identified, including two amino acid changes.

Program Nr: 2644 from the 1999 ASHG Annual Meeting

Hypomethylation of an expanded *FMR1* allele is not associated with a global DNA methylation defect. *B.W. Popovich[1], R.W. Burman[1], P.A. Yates[2], L.D. Green[1], P.B. Jacky[3], M.S. Turker[1,2]*. 1) Dept of Molecular and Medical Genetics, Oregon Health Sciences University, Portland, OR; 2) Center for Research on Occupational and Environmental Toxicology, Oregon Health Sciences University, Portland, OR; 3) Cytogenetics Laboratory, Kaiser Permanente NW, Clackamas, OR.

The fragile X syndrome is a mental retardation disorder caused by expansion of a CGG trinucleotide repeat in the 5' UTR of the *FMR1* gene. The vast majority of full mutations are heavily methylated throughout the expanded CGG repeat and the surrounding CpG island. Hypermethylation of promoter elements is associated with transcriptional silencing of the *FMR1* gene. The resulting decrease or absence of FMR1 protein (FMRP) is believed sufficient to cause the fragile X syndrome phenotype. The relation between repeat expansion and hypermethyaltion is not well understood, nor is it absolute as demonstrated by the identification of non-retarded males who carry full mutations that lack methylation at some sites in the promoter and produce some FMRP. To better characterize the methylation pattern in a hypomethylated full mutation carrier, we have evaluated methylation at numerous sites in the *FMR1* CpG island including those located within the CGG repeat. We find that the expanded CGG repeat and 1 kb or surrounding DNA are free of methylation in this full mutation male.

Methylation of the CGG repeats has been hypothesized to occur when the repeat is expanded sufficiently to resemble a potentially transposable repetitive element. To better understand the basis of the *FMR1* methylation deficiency in the full mutation male, we have assessed methylation levels at selected linked and unlinked repetitive element loci. We find normal methylation levels at *Alu* elements flanking the CGG repeat and at other repetitive element loci. This result demonstrates that the lack of methylation in the CGG repeat region is not associated with a global defect in methylation of highly reiterated DNA sequences. We also report that *de novo* methylation of the expanded CGG repeat region does not occur when it is moved via microcell mediated chromosome transfer into a *de novo* methylation competent mouse cell line.

Program Nr: 2645 from the 1999 ASHG Annual Meeting

Identification of a premature ovarian failure candidate gene. *R.L. Prueitt[1], J.L. Ross[2], A.R. Zinn[1].* 1) McDermott Center & Department of Internal Medicine, UT Southwestern Medical School, Dallas, TX; 2) Department of Pediatrics, Thomas Jefferson Univ, Philadelphia, PA.

Premature ovarian failure (POF) is defined as cessation of menses (amenorrhea) associated with elevated serum gonadotropins occurring in women before the age of 40. Roles for the environment, autoimmunity, and X chromosome abnormalities in the etiology of POF have been described. A region of the X chromosome from Xq13 to Xq26 is critical for normal ovarian development. Women with balanced translocations involving this region of the X chromosome often exhibit POF. Currently, neither the basis for the large critical region nor the mechanism(s) by which these translocations cause POF is known. It has been proposed that many different genes that are essential for normal ovarian function are present in this region.

We have collected cell lines from 14 patients with balanced Xq;autosome translocations. Nine of these translocations were associated with POF. To date, we have mapped eight Xq breakpoints to the limits of resolution of the X chromosome physical map using somatic cell hybrids. One breakpoint within Xq25 in a subject with 2° amenorrhea interrupts the gene encoding aminopeptidase P, *XPNPEP2*. Aminopeptidase P hydrolyzes N-terminal X-Pro bonds that are present in various hormones, growth factors, and cytokines. Soluble and insoluble forms of the protein have been isolated from brain, serum, platelets, leukocytes, kidney, and lung. So far the only known biological substrate is the vasodilator bradykinin, but because of the nature of its other potential substates, aminopeptidase P may have a hormone-processing or immunologic function which could define its role in POF.

Another candidate POF gene within the critical region, *diaphanous* has been previously reported to be disrupted by a balanced translocation in a woman with 2° amenorrhea. We conclude that *XPNPEP2* is also a candidate POF gene, supporting the theory that the critical region contains multiple genes required for normal ovarian development and function.

Program Nr: 2646 from the 1999 ASHG Annual Meeting

Mechanisms of CTG-repeat induced changes in gene expression. *G. Raca, E. Siyanova, S. Mirkin.* University of Illinois, Chicago.

Myotonic Dystrophy is the most common neuromuscular disease affecting adults. The molecular change responsible for the disease is an expansion of the normally polymorphic CTG repeat in the 3' UTR of the DM protein kinase gene. It is not yet known how the amplified repeat induces the complex and polymorphic phenotype of Myotonic Dystrophy. At least three different mechanisms were proposed: a) altered expression of the gene containing the repeat (DMPK) b) decreased expression of the downstream gene (DMAHP/SIX5) and c) effects mediated at the RNA level, possibly caused by the CUG-containing RNA structure. To explore the mechanisms through which long CTG repeats can interfere with gene function, we cloned CTG/CAG repeats of different lengths at various positions relative to the luciferase gene and analysed their effects on reporter gene expression upon transient transfection into the human colon carcinoma SW480 cells. We found that these repeats caused a significant decrease in luciferase activity only when positioned in the 5'UTR of the gene. The effects were much stronger with CTG in the transcribed strand (orientation dependence) and for longer repeats (length dependence). RNase protection studies showed no difference between the control and different constructs in the amount of luciferase RNA, demonstrating that a transcription block was not responsible for the observed decrease in gene activity. However, in vitro translation using reticulocite lysates demonstrated that CTG repeats located in the 5' UTR reduce protein levels relative to the control. In fact, the same type of orientation and length dependence was observed with CTG repeats in both the in vivo expression assay and in the in vitro translation experiments. We suggest that the formation of RNA hairpins by CUG repeats can explain our data. Such hairpins could block scanning through the 5' UTR by a small ribosomal subunit. While the formation of RNA hairpins by CUG repeats in vitro has been described before, the results of our expression studies suggest, for the first time, that such structures can also exist in vivo.

.

Program Nr: 2647 from the 1999 ASHG Annual Meeting

MULTIPLE SCLEROSIS AND RETINITIS PIGMENTOSA SEGREGATE IN A LARGE WELSH KINDRED.

R. Raha-Chowdhury[1], S.K. Raha[2], J. Trowsdale[1], J.R. Gruen[3]. 1) Pathology, University of Cambridge, Cambridge, Cambridge, UK; 2) Princes of Wales Hospital, Bridgent, South Wales, UK; 3) 3Yale Child Health Research Center Yale University School of Medicine, 464 Congress Avenue, P.O. Box 208081,New Haven, CT.

Multiple Sclerosis (MS) is the most common neurological disorder among young adults and affects around 85,000 people in UK. This is an autoimmune disorder which usually causes demyelination in genetically susceptible individuals. By genome wide screening several groups found that MS has association with several chromosomes (1p, 6p/q, 7p, 14q, 17p/q, 19q, x cen). The strongest association was found with the Major Histocompatibility Complex (MHC Ch6p21.3) especially HLA class II, DR15 haplotype. In our ongoing study the association of multiple sclerosis with the MHC, we are studying a family from South Wales where MS and Retinitis Pigmentosa (RP) were found to be segregated in four generations. Retinitis Pigmentosa (RP) is a progressive hereditary disorder of the retina of which various forms of have already been described. An autosomal dominant form of RP has been localised to Ch17q11.2 and an X linked RP (RPLX) was found at Ch Xp21.2 locus. In this kindred a male patient age, 45 suffered from a progressive type of MS, his mother also suffer from reminent-relapsing (RR) type MS and RP, grandmother was blind due to RP, maternal cousin and his Nephew suffer from progressive type of MS. The mode of inheritence of these disorders in this family has yet to be elucidated, but appears to be either autosomal dominant or X linked. We have found association with the myelin protein on Ch6, together with an association at Ch17q11.

Program Nr: 2648 from the 1999 ASHG Annual Meeting

Massive CTG expansions and deletions may reduce penetrance of spinocerebellar ataxia type 8. *L.P.W. Ranum[1], M.L. Moseley[1], M.F. Leppert[2], G. van den Engh[3], A.R. La Spada[3], M.D. Koob[1], J.W. Day[1].* 1) Genetics Cell Biol & Devel, Inst Hum Genet and Neurology, Univ Minnesota, Minneapolis, MN; 2) Hum Genet, Univ Utah, Salt Lake City, UT; 3) Univ Wash Med Ctr, Seattle, WA.

We recently isolated an untranslated CTG expansion that causes a novel ataxia (SCA8). Unlike other triplet diseases, SCA8 may have a window of pathogenic alleles (~110-250 repeats) with shorter and larger repeat tracts not resulting in disease. In our largest family (z=6.8), affecteds have 107-127 CTG repeats while repeats <100 are not associated with disease. Among 11 families, affecteds have up to 250 repeats. Although expanded alleles are transmitted from males or females, 26/30 affecteds inherited maternally transmitted expansions. This maternal penetrance bias is consistent with paternal contractions resulting in alleles shorter than the pathogenic threshold, and maternal expansions yielding alleles within the pathogenic range. In some cases, maternal transmissions result in very large repeats (250-800 CTGs). In two families, unaffected men (73 and 79 yrs) with 260 and 300 CTG repeats transmitted shorter pathogenic alleles to four affected offspring. In addition, out of 1200 control chromosomes, one allele of 800 repeats was found in a CEPH grandmother. Medical histories indicate that neither this woman nor her son (54 yrs, 800 repeats), are affected by ataxia. These observations indicate that very large alleles (>250 repeats) may not be pathogenic, possibly because they are not expressed or because of altered RNA processing or stability. In this CEPH family, four children inherited the expanded allele from their father, but in each case, the alleles underwent massive deletions (~700 repeats) resulting in 85, 93, 116 and 118 repeats. To further investigate the instability of very large alleles, we performed Southern analysis on sperm DNA from men with 500 and 800 repeats. In both cases, nearly all of the expanded alleles underwent massive deletions into narrow size ranges (~80 and ~110 CTGs) typically at or below the pathogenic threshold. Massive paternal deletions and maternal expansions may minimize moderately sized pathogenic alleles and play a role in the reduced penetrance of SCA8.

Program Nr: 2649 from the 1999 ASHG Annual Meeting

A new Digestion Pattern in Patients with Myoclonic Epilepsy and Ragged-Red Fiber Disease (MERRF) depending on the Ethnic Origin of the Individuals. *C. Rodas[1], J.C. Prieto[1], G. Keyeux[1], E. Espinosa[2], J.E. Bernal[1], A. Rotig[3], A. Munnich[3].* 1) Inst Genetica Humana, Univ Javeriana, Bogota, DC, Colombia; 2) Hospital Militar Central, Bogota; 3) U Genet Enfants Malades, Hopital Necker, Paris.

Myoclonic Epilepsy and Ragged-Red Fiber Disease, MERRF, is a maternally inherited disease characterized by progressive myoclonic epilepsy, a mitochondrial myopathy with RRFs, and a slowly progressive dementia. Approximately 80 to 90 percent of MERRF cases are caused by a heteroplasmic G to A point mutation at nt 8344. Additional cases have been attributed to a heteroplasmic T to C transition mutation at nt 8356 in the tRNALys gene. We analyzed mtDNA from 10 healthy control and 22 patients with probable MERRF disease for the mutations 8344 and 8356, using mutation-specific restriction endonuclease digestions (BglI and XbaI). Results: For position 8344: in 20 samples we obtained a band corresponding to the expected 187bp size, in 11 samples a band of 178bp and in one sample a band of 205bp. For position 8356: in one affected patient we obtained a three-band pattern, corresponding to the expected 88bp, 69 bp and 27bp cleavage products of the XbaI constitutive and mutation sites; 19 samples with two bands of 96bp and 88bp corresponding to the normal expected fragments without mutation; 11 samples with two bands of 96bp and 79bp, and one subjects with two bands of 106bp and 96bp. A 9-bp deletion between the COII and tRNALys genes, due to the lack of one of the two adjacent copies of a 9-bp sequence (5`CCCCCTCTA 3), has been described in some populations. The PCR primers used in our study for screening mutations 8344 and 8356 amplify sequences from the COII gene, the intergenic region and the tRNA Lys gene. We therefore reamplified the DNAs yielding unusual restriction patterns with the 9bp-region specific primers, and show that the PCR generates fragments with different sizes depending on the number of copies of the 9bp-sequence. Thus, in the analysis of the mutations in patients from different ethnic origins with MERRF, it is important to considerate the polymorphism in the intergenic region which may lead to erroneous interpretations.

Program Nr: 2650 from the 1999 ASHG Annual Meeting

The Turner syndrome-associated neurocognitive phenotype maps to distal Xp. *J.L. Ross[1], H. Kushner[2], A. Zinn[3].* 1) Pediatrics, Thomas Jefferson Univ, Philadelphia, PA; 2) Biomedical Computer Research Institute, Phila., PA; 3) University of Texas Southwestern Medical School, Dallas, TX.

Turner syndrome (monosomy X, TS) is associated with a characteristic neurocognitive profile including impaired visual-spatial/perceptual abilities in children and adults. We propose that this visual-spatial/perceptual deficit is genetically determined on the basis of haploinsufficiency of specific X chromosome gene/genes that escape X inactivation. We utilized a molecular approach and genotype/phenotype correlations to identify critical regions of the X chromosome for neurocognitive aspects of TS. The study population included 33 females with partial monosomy for Xp (ages 7-40 years). Deletions were mapped by FISH with a panel of Xp markers and, in some cases, by loss of heterozygosity of polymorphic markers. We previously identified, through discriminant function analysis, a composite formula for the TS-associated neurocognitive phenotype that optimally distinguished TS children and adults from female age-, Verbal IQ-, and SES-matched controls (Z-scores from 6 visual-spatial/perceptual tasks). Statistical criteria with optimal sensitivity and specificity were chosen for labeling an individual as having the TS-associated neurocognitive phenotype, and 11/33 partial deletion subjects met the specific phenotype criteria. Seven of these 33 subjects had terminal Xp delations distal to Xp22.3. Their mean spatial cognitive score was significantly lower than that of 448 controls (-5.9 +/- 3.9 versus 0.2 +/- 4.9, $P<0.001$) and was similar to the mean score of 208 TS children and adults (-7.1 +/- 4.9). All 7 terminal Xp deletion subjects has scores below the mean for the normal controls ($P<0.02$). One other subject with an interstitial deletion of Xp22.13-Xp22.32, who was not missing all of Xp22.33, had a normal spatial cognitive score (=0.03). In summary, females missing only the distal third of the short arm of the X chromosome manifested the characteristic TS-associated neurocognitive profile. We conclude that the TS neurocognitive phenoype maps to mid- or distal Xp22.3 in children and adults with partial monosomy Xp. Future studies will define the interval more precisely.

Program Nr: 2651 from the 1999 ASHG Annual Meeting

Molecular Characterization of Multiple Mitochondrial DNA Deletions of Ten Individuals. *C.A. Rupar[1,3,4], C. Regan[1,2]*. 1) Biochemical Genetics Laboratory, CPRI; 2) Dept Zoology; 3) Dept Biochemistry; 4) Dept Paediatrics, University of Western Ontario, London, Canada.

Large-scale deletions of the human mitochondrial genome are linked to a number of neuromuscular disorders associated with deficiencies of cellular energy production. Single site deletions are most often associated with classical mitochondrial myopathies such as Kearns-Sayre syndrome, whereas multiple site deletions are associated with an increasing variety of disorders and occur as part of the normal aging process. Multiple deletions were characterized in the mitochondrial genomes of ten individuals, aged twenty-two to seventy-seven, with a variety of neuromuscular symptoms. Most individuals presented with at least one of ptosis, proximal limb weakness or progressive external ophthalmoplegia and one or more additional neurological symptoms. Long-distance PCR, across a 10.4 kb region in which most mitochondrial deletions have been reported to occur, yielded multiple shorter amplicons from muscle DNA. Amplification using leukocyte DNA available from three individuals yielded only the normal 10.4 kb fragment. Fragments amplified across deletions were cloned and sequenced to determine deletion breakpoints. In thirty-three of fifty deletions detected in the ten individuals the 3' breakpoint was observed between nucleotide 16047 and nucleotide 16075. This lies in the control region of human mitochondrial DNA and indicates a potential protected region of the mitochondrial genome. Both direct repeats of 5-10 bp and small overlaps of 1-8 bp were frequently observed around breakpoints. In thirty-one of fifty deletions at least one of the direct repeats occurred within 10 bp of the breakpoint. Overlaps were seen in twenty-two of fifty deletions. These features are consistent with the emerging evidence that recombination and repair mechanisms are responsible for the generation of mitochondrial DNA deletions.

Program Nr: 2652 from the 1999 ASHG Annual Meeting

Reactivation of imprinted genes in Prader-Willi syndrome. *S. Saitoh, T. Wada.* Dept. Pediatrics, Hokkaido Univ., Sapporo, Japan.

Genomic imprinting results from a parent-of-origin specific gene modification, with monoallelic expression of imprinted genes. DNA methylation is associated with this inactivation process. However, the mechanism of imprinted gene inactivation is not fully understood. Chromosome 15q11-q13 harbors several imprinted loci involved in Prader-Willi syndrome (PWS). *SNURF-SNRPN* is an imprinted locus in 15q11-q13, and the imprinted status is stably maintained in somatic tissues and cell lines. The promoter region of *SNURF-SNRPN* is completely methylated on the inactivated maternally-derived allele, and unmethylated on the active paternally-derived allele. *In vitro* experiments showing that methylation eliminates promoter activity suggest methylation plays an important role in inactivation of *SNURF-SNRPN* . To better understand the role of methylation in regulation of imprinted genes, we treated lymphoblastoid cell lines from five PWS patients with a paternal deletion or maternal uniparental disomy, thus carrying only maternal alleles of 15q11-q13, with a demethylating agent, 5-aza-dC. Expression of two imprinted genes in 15q11-q13, *SNURF-SNRPN* and *IPW*, which were normally inactivated, was demonstrated by RT-PCR after 5-aza-dC treatment. This expression was shown to be associated with demethylation of the CpG island of *SNURF-SNRPN* . These results indicate that suppression of some imprinted genes in 15q11-q13 is maintained by DNA methylation.

Furthermore, gene inactivation by DNA methylation has recently been demonstrated to be carried out through interaction with a deacetylation complex. We treated PWS cell lines with trichostatin A (TSA), an inhibitor of deacetylation. After TSA treatment, expression of *SNURF-SNRPN* and *IPW* was demonstrated by RT-PCR. However, the CpG island of *SNURF-SNRPN* remained hypermethylated based on data using methylation-sensitive restriction exzymes. These results further support the idea that DNA methylation-mediated inactivation of imprinted genes requires recruitment of a deacetylation complex. The findings also have possible implications for the potential of pharmaceutical treatment of imprinting related-disorders.

Program Nr: 2653 from the 1999 ASHG Annual Meeting

Rat Models of Autoimmune Diseases: The Genetic Dissection of Complex Traits. *J. Salstrom[1], T. Furuya[1], G.W. Cannon[2], E.F. Remmers[1], M.M. Griffiths[2], R.L. Wilder[1].* 1) Arthritis & Rheumatism Branch, NIAMS / NIH, Bethesda, MD; 2) Research Service Veterans Affairs Medical Center and Department of Medicine/Rheumatology, University of Utah, Salt Lake City, Utah.

Because genetic heterogeneity, phenotypic heterogeneity, and environmental noise complicate the study of complex traits in humans, inbred rat strains in controlled laboratory environments are being used extensively to aid in the dissection of many multifactorial traits such as autoimmune diseases. The BB(DR) rat is a particularly good model for autoimmune diseases because, although it is resistant to spontaneous autoimmune insulin-dependent diabetes mellitus (Iddm), many autoimmune diseases such as Iddm, thyroiditis, and collagen-induced arthritis (CIA), a model of rheumatoid arthritis (RA), can be induced by environmental perturbation. To identify loci that regulate autoimmune diseases, we crossed the BB(DR) rat with the CIA resistant BN/SsN (BN) rat and conducted a genome-wide scan for quantitative trait loci (QTL) that regulated CIA severity and autoantibody production in the F2 population. We then compared the locations of these loci with the locations of loci known to regulate other autoimmune diseases. Seven genomic regions were found to regulate arthritis severity, and three were found to regulate autoantibody production. Several of these overlapped with homologous loci that regulate experimental autoimmune encephalomyelitis (EAE) in rats, insulin-dependent diabetes (Idd) in mice, as well as RA and multiple sclerosis (MS) in humans. However, only two severity QTL and two autoantibody QTL overlapped with the seven QTL (five severity and two autoantibody) found to regulate arthritis severity and autoantibody production in a similar analysis of DA (highly susceptible to CIA) X BN F2 progeny. These data support the view that polygenic autoimmune diseases share numerous genetic risk factors, but also illustrate that many unique profiles of regulatory loci can be identified for a single disease. Study of autoimmune diseases in inbred rat strains provides a powerful complementary approach to the dissection of related complex traits in outbred populations.

Program Nr: 2654 from the 1999 ASHG Annual Meeting

Increased Apoptosis of Huntingtons Disease Lymphoblasts Associated with Repeat Length-Dependent Mitochondrial Depolarization. *A. Sawa[1], G.W. Wiegand[2], J. Cooper[3], R.L. Margolis[3], A.H. Sharp[3], J.T. Greenamyre[4], C.A. Ross[1,3], S.H. Snyder[1,3].* 1) Dept Neuroscience, Johns Hopkins Univ, Baltimore, MD; 2) National Cancer Institute, Frederick, MD; 3) Department of Psychiatry, Johns Hopkins Univ, Baltimore, MD; 4) Department of Neurology, Emory Univ, Atlanta, GA.

Huntingtons disease (HD) is a genetically dominant condition caused by expanded CAG repeats coding for glutamine in the HD gene product huntingtin (htt). Though HD symptoms reflect preferential neuronal death in specific brain regions, htt is expressed in almost all tissues of the body, so that one might anticipate abnormalities outside the brain. We now report that lymphoblasts derived from HD patients display increased stress-induced apoptotic cell death. HD lymphoblasts also manifest a marked increase in mitochondrial depolarization correlated with increased glutamine repeats. Apoptotic cell death is often associated with activation of caspase-3. Following STS treatment, caspase-3 activity is markedly greater in HD cells compared with control subjects. Caspase-9 is also more activated in HD, however, no difference is found in caspase-8 after Fas addition between HD and controls. These results suggest that specific subsets of caspases are activated by abnormal htt. We tested drugs for effects on the increased apoptotic death of HD cells. CsA and z-VAD-fmk significantly reduce STS elicited cell death. To assess specificity, we also examined lymphoblasts of SCA-1 patients, which do not differ from controls regarding caspase-3 activation and mitochondrial depolarization.

Program Nr: 2655 from the 1999 ASHG Annual Meeting

A genome-wide scan for quantitative trait loci for lipid levels: The Framingham Study. *A.M. Shearman[1], J.M. Ordovas[2], L.A. Cupples[3], E.J. Schaefer[2], M.D. Harmon[3], O. Joost[3], A.L. DeStefano[3], D. Keen[1], P.W.F. Wilson[4], D.E. Housman[1], R.H. Myers[3].* 1) Center for Cancer Research, Massachusetts Institute of Technology, Cambridge, MA 02139; 2) Lipid Metabolism Laboratory, USDA Human Nutrition Research Center on Ageing at Tufts University, Boston, MA 02111; 3) Boston University School of Public Health and School of Medicine, Boston, Massachusetts 02118; 4) National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA 01701.

There is a significant association between cardiovascular disease and plasma lipid and lipoprotein levels. These traits show high genetic heritabilities as well as significant environmental effects. A genome-wide scan for plasma total cholesterol (TC) level, triglyceride (TG) level, triglyceride/HDL-cholesterol (TG/HDL-C) ratio and total cholesterol/HDL-cholesterol (TC/HDL-C) ratio was carried out in 237 families of the Framingham Study. The families included 1167 individuals that were genotyped. Multipoint lod scores were calculated for the four quantitative traits, using the variance component methods of the SOLAR program. There were 21 regions with multipoint lod scores greater than 1, on chromosomes 1, 3, 4, 5 (2 peaks), 7, 8, 11, 13 (3 peaks), 14, 15, 16, 17, 18, 20, 21. The maximum multipoint lod score for TC was 1.9 on chromosome 8 (at 100 cM), for logTG was 1.8 on chromosome 14 (at 126 cM), for TC/HDL-C was 2.4 on chromosome 13 (at 91 cM) and for TG/HDL-C the maximum lod scores were 2.0 on chromosome 7 (at 147 cM) and 2.8 on chromosome 20 (at 48 cM). These results suggest regions worthy of further exploration.

Program Nr: 2656 from the 1999 ASHG Annual Meeting

Lack of age-associated LFA-1 upregulation in lymphocyte from Down syndrome patients. *C.C. Shieh, R.F. Lee, S.J. Lin.* Pediatrics and Immunology, National Cheng Kung University, Tainan, Tainan, Taiwan.

Immunodeficiency in Down syndrome patients contributes to their susceptibility to infections. Excessive lymphocyte adhesiveness caused by overexpression of lymphocyte adhesion molecule-1 (LFA-1, CD11a CD18), of which the beta chain (CD18) is encoded in chromosome 21, was believed to cause abnormal immune development and responses. In order to understand the relationship between LFA-1 expression and immune development in DS, we analyzed the LFA-1 expression in lymphocytes from DS with CD11a and CD18 cell surface staining and flow cytometry. DS patients less than two years of age expressed higher level of LFA-1 when compared with age-matched controls ((MFI,mean±SEM) 242.1±36.4 vs. 128±20.6, $p<0.05$). The differences in LFA-1 expression were much less significant in older DS patients when compared with age matched children (2-6 year-old (yo) group: 205.8±15.2 vs. 194.8±40.5; 6-15 yo group: 265.8±33.0 vs. 287.5±89.9). Although older children (2-6 and 6-15 yo groups) without DS tend to increase their expression of lymphocyte LFA-1 when compared with young children (0-2 yo) ($p<0.05$), DS patients showed no age associated increase in lymphocyte LFA-1 expression. We further investigated whether abnormality in CD4 and CD8 subpopulations accounts for this LFA-1 expression pattern. Two-color analysis with CD4/CD8 and LFA-1 in patients over 2 yo showed that percentages of CD4+ lymphocytes were comparable in DS patients and controls, while percentages of CD8+ lymphocytes were higher in DS patients (39.3±3.2 vs. 29.2±3.2, $p<0.05$). Expression of LFA-1 on both CD4+ and CD8+ lymphocytes were higher in DS patients (CD4+: 1070±95.1 vs. 869.4±59.8; CD8+: 1936±217.5 vs. 1272±195.7). The observations that DS patients had higher percentage of CD8+ lymphocytes and that CD8+ cells tended to have higher expression of LFA-1 integrin suggest that change in CD4/CD8 ratio is not among the explanations that DS patients fail to upregulate their LFA-1 expression with ages. A generalized pathological process like early senescence of the immune system or incapability in converting to memory phenotye of lymphocytes may underlie this unique expression pattern of LFA-1 integrin in DS patients.

Program Nr: 2657 from the 1999 ASHG Annual Meeting

Molecular analysis of the untranslated $(CTG)_n$ trinucleotide repeat that causes SCA8. *I. Silveira[1], I. Alonso[1], P. Mendonça[1], M. Costa[2], L. Jardim[3], C. Barbot[1], J. Barros[4], P. Coutinho[5], J. Sequeiros[1]*. 1) UnIGENe, IBMC- Univ. Porto, Porto, Portugal; 2) Serv. Neurologia, Hosp. Pedro Hispano, Matosinhos; 3) Serv. Genética Médica, Hosp. Clínicas Porto Alegre, Brazil; 4) Serv. Neurologia, HGSA, Porto, Portugal; 5) Serv. Neurologia, Hosp. S.Sebastião, Feira, Portugal.

The autosomal dominant spinocerebellar ataxias (SCAs) are a group of late onset neurodegenerative disorders for which 10 loci have been mapped (SCA1,2,MJD,4,5,6,7,8,10 and DRPLA). The pathological proteins show an expanded polyglutamine tract in SCA1, SCA2, MJD, SCA6, SCA7, and DRPLA; a glycine-to-arginine substitution has also been shown in SCA6. Recently, an untranslated composite $(CTA)_n(CTG)_n$ expansion on chromosome 13q was found to cause a novel form named SCA8. In order to identify the molecular basis of neurodegeneration in our ataxia patients, we have assessed the size of this $(CTG)_n$ in our ataxia families. We studied 78 unrelated individuals belonging to 26 dominant families, nine apparently recessive kindreds and 43 isolated cases previously excluded for SCA1, SCA2, MJD/SCA3, SCA6, SCA7 and DRPLA; 63 families were of Portuguese origin, while 15 kindreds where from Brazil. Molecular analysis was performed by PCR amplification of the CTG repeat, and allele sizes were estimated by comparing migration relative to an M13 sequencing ladder. Two affected individuals from two families (3%) had an allele in the expanded range (over 107 CTA/CTG repeats); three other patients, representing three different families (4%) presented potentially pathogenic alleles (97 to 105 CTA/CTG repeats). The size of the normal alleles ranged from 18 to 36 CTA/CTG units. In one family the (unaffected) father, who had alleles with 82 and 170 repeats, transmitted an allele with 105 CTA/CTG units to his daughter, who has congenital ataxia. We are now sequencing expanded alleles, and determining the allele sizes of a control Portuguese population (2000 chromosomes). The SCA8 CTA/CTG repeat expansion may thus be responsible for a significant number of our SCA families.

Program Nr: 2658 from the 1999 ASHG Annual Meeting

Molecular analysis of a large panel of Dutch ataxia patients. *R.J. Sinke, C.M. Diepstraten, P.F. Ippel, J.K. Ploos van Amstel.* Dept Medical Genetics, Univ Medical Center Utrecht, Utrecht, Netherlands.

The hereditary ataxias are a heterogeneous group of progressive neurodegenerative disorders of which a reliable clinical classification is hampered by the great overlap of phenotypic features and the great variability found both within and between families. Also, the inheritance pattern is not always clear and a great genetic heterogeneity is observed. To date nine different loci have been identified in the etiology of autosomal dominantly inherited spinocerebellar ataxias (SCA) and one locus responsible for the autosomal recessively inherited Friedreichs ataxia (FRDA). In the corresponding genes the causative mutations are almost exclusively trinucleotide repeat expansions. For the SCA6 gene also point mutations have occasionally been detected in ataxia families. Here, we present our six years experience regarding the molecular analysis of the trinucleotide repeat expansions in SCA and FRDA genes. This provides insight in the incidence and relative frequency of the different mutations in our patient group. Our present panel consists of 388 Dutch families with familial or isolated ataxias. It comprises true autosomal dominant cerebellar ataxia families, families with unexplained, often sporadic, ataxias and Friedreichs ataxia families. Sequential analysis of the different trinucleotide repeats, viz.CAG (SCA1,2,3,6,and 7 genes), GAA (FRDA) and CTG (SCA8 gene), allowed the detection of SCA1 mutations in 2 %, SCA2 mutations in 2 %, SCA3 mutations in 9 %, SCA6 mutations in 7 %, SCA7 mutations in 4 %, and FRDA mutations in 4 % of all probands. The SCA8 locus is currently under investigation. In conclusion, we were able to identify the genetic defect in 28 % of the probands, with the SCA3 and SCA6 mutations being the most frequent ones in the Dutch population.

Program Nr: 2659 from the 1999 ASHG Annual Meeting

Twin Zygosity and Schizophrenia. *C.L. Smith[1], G. Nguyen[1], J. Bouchard[1], C. Foulon[1], L. Keith[2].* 1) Ctr Advanced Biotechnology, Depts. of Biomedical Eng, Biology and Pharmacology, Boston Univ, Boston, MA; 2) Dept. Ob. and Gyn., and Center for Study of Multiple Births, Northwester Univeristy.

Targeted genomic differential display was used to quantitate the level of genome similarity in twins presented to us as monozygotic and either discordant or concordant for Schizophrenia. Although this was a small sample size (10 pairs), two and possible three groups could be distinguished at the DNA level. One group has a DNA similarity level similar to that seen in sibling pairs, suggesting that this group was dizygotic rather than monozygotic. At the other extreme was a group that had a DNA similarity level greater than that of sibling pairs, suggesting that this group was monozygotic. An intermediate group was also distinguished. The intermediate group were, possibly, blood stem cell chimerics. All of the twin pairs concordant for Schizophrenia were in the group we classified as monozygotic whereas all the twins discordant for Schizophrenia were in the group classified as dizygotic. In contrast to earlier studies, the results suggests that Schizophrenia is clearly a predominantly genetic disease with high penetrance. These results bring into questions a large body of research of that depended on accurate twin zygosity determinations for measuring heritability and penetrance of disease.

Program Nr: 2660 from the 1999 ASHG Annual Meeting

Mutation analysis of myelin oligodendrocyte glycoprotein in dyslexic siblings. *S.D. Smith[1], P.M. Kelley[2], J. Askew[2].* 1) Center for Human Molecular Genetics, Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE; 2) Boys Town National Research Hospital, Omaha, NE.

Linkage analyses by our group and two others have localized a gene influencing specific reading disability (dyslexia) to an approximately 2 cM region of 6p21.3 (Gayan et al., 1999; Fisher et al., 1999; Grigorenko et al., 1997) . The myelin oligodendrocyte glycoprotein (MOG; MIM#159465) gene which maps to this region was selected as a candidate. MOG is a membrane protein, a member of the immunoglobin superfamily, that is found on the outermost lamellae of mature myelin. Although the exact function of this gene is unknown, its presence in the CNS and the hypothesized relationship between dyslexia and temporal processing rate (Livingtson et al, 1991), as well as a suggested relationship with intelligence by association analysis (Plomin et al., 1994) and a controversial relationship between dyslexia and immune disorders, made it a candidate for dyslexia. Analysis of the coding exons and adjacent splice sites in a subset of 22 dyslexic children from 10 sibships found a missense mutation in exon 3 in two of the sibships. This change from the published sequence occurred in 86 of 96 random controls, making it considerably less frequent in this small sample of dyslexics. We are examining the segregation of this SNP in our overall population of 150 sib pairs to determine if it is in disequilibrium with the reading disability locus.

Program Nr: 2661 from the 1999 ASHG Annual Meeting

Targeted genome screen of panic disorder and anxiety proneness using homology to murine QTL regions. *J.W. Smoller[1], J.S. Acierno[2], J.F. Rosenbaum[1], M.H. Pollack[1], J. Biederman[1], C. White[1], L. Helbling[2], J.F. Gusella[2], S.A. Slaugenhaupt[2]*. 1) Dept Psychiatry,; 2) Molecular Neurogenetics Unit, Massachusetts General Hosp, Boston, MA.

Family and twin studies have indicated that genes influence the susceptibility to panic and phobic anxiety disorders but the location of the genes involved remains unknown. Animal models can simplify gene mapping efforts by overcoming problems that complicate human pedigree studies including genetic heterogeneity and high phenocopy rates. Synteny homology between rodent and human genomes can be exploited to map human genes underlying complex traits. We used regions identified from QTL-mapping of anxiety phenotypes in mice to guide a linkage analysis of a large multiplex pedigree (103 members, 73 genotyped) segregating panic disorder/agoraphobia. Two phenotypes were studied: panic disorder/agoraphobia and a phenotype ("D-type") designed to capture early-onset susceptibility to anxiety disorders. A total of 103 markers across 10 chromosomal regions were typed. Parametric lod acore analysis was performed using parameters derived from a segregation analysis of panic disorder. In simulations, the maximum expected lod scores = 4.68 for panic disorder and 6.04 for D-type. One lod score > 2.0 was detected: lod = 2.4 at a locus on chr 10 under a reduced penetrance dominant model for the anxiety-proneness (D-type) phenotype. This finding was not supported in a nonparametric NPL analysis. Nonparametric analysis revealed interesting regions on chr 12 for panic disorder (NPL = 3.82, p =.009) and chr 1 for D-type (NPL = 1.99, p =.04). We are currently performing follow-up studies by typing additional markers in these regions. This study illustrates the potential utility of using murine models of anxiety phenotypes to map loci that may influence human anxiety disorders.

Program Nr: 2662 from the 1999 ASHG Annual Meeting

Sib-TDT analysis of human TGF-b1 gene SNPs in female twins: Evidence for linkage and association with blood pressure at the codon 263 polymorphism. *H. Snieder[1], RW. Keen[1], H. Molloy[2], F. Gibson[2], MC. Chiano[2], AJ. MacGregor[1], TD. Spector[1]*. 1) Twin Research Unit, St.Thomas' Hospital, London, UK; 2) Gemini Research Ltd., Cambridge, UK.

Recent evidence suggests that human transfoming growth factor b1 (TGF-b1) is a potential candidate gene for hypertension. This study's aim was to investigate the association between blood pressure and 6 SNPs within the TGF-b1 gene in a large population based sample of female twins. A sib-transmission disequilibrium test (S-TDT) for quantitative traits was used to control for spurious association due to population stratification and/or admixture. Full clinical data was available on 1,598 dizygotic (DZ) female Caucasian twins (799 pairs), mean age 47.3 (SD: 11.4) yrs. Systolic (SBP) and diastolic (DBP) blood pressure was measured twice (OMRON HEM713C). SNPs within the TGF-b1 gene were identified using either ABI TAQMAN or a PCR-based RFLP. Association analysis and the S-TDT were performed using structural equation modelling with the statistical software Mx. In total, 6 polymorphisms were assessed: 2 promoter SNPs (-800, -509), 3 exon SNPs (codon10, codon25, codon263), and 1 intronic SNP (Intron 5). Allele frequencies were: 0.08 (-800), 0.31 (-509), 0.38 (codon10), 0.07 (codon25), 0.03 (codon263) and 0.25 (Intron5). The codon263 showed a significant association with both SBP (p=0.022) and DBP (p=0.013), with higher values in heterozygote carriers (n=54) of the C®T substitution (carriers: 129.4/81.7, non-carriers: 123.4/77.7). Homozygote carriers were absent in our sample. The size of the codon263 polymorphism effect on blood pressure only slightly reduced after adjusting for age and use of antihypertensive medication. Results for the S-TDT confirmed the observed associations (before adjustment: p=.007 and p=.058; after adjustment for antihypertensive medication: p=0.006 and p=0.029 for SBP and DBP respectively), making it unlikely that above results are due to population stratification and/or admixture. This study has shown linkage in the presence of association between the TGF-b 263 polymorphism and blood pressure levels with carriers showing a 6 and 4 mmHG increase in SBP and DBP respectively.

Program Nr: 2663 from the 1999 ASHG Annual Meeting

The role of the 5-HT2A receptor gene in psychosis. *M.S. Sodhi[1], K.J. Aitchison[2], R.W. Kerwin[2], P. Sham[2].* 1) Molecular Neuropathology, Dept Psychiatry, Oxford University, England; 2) Dept Psychological Medicine, Inst of Psychiatry London.

Dysfunction of the 5-HT2A receptor has been implicated in the aetiology and treatment of psychosis by evidence from pharmacological, anatomical and genetic investigations. Many of the genetic association studies published have been conducted on small samples and have produced conflicting data. In this investigation we have combined several independent case control association studies of the 5-HT2A T102C polymorphism by meta-analysis to increase statistical power and to reach more reliable conclusions.

Firstly we failed to replicate the significant association found in a Japanese sample between the 5-HT2A T102C polymorphism and affective disorder[1]in British patients with unipolar disorder and controls(n=118, c^2=0.51, ns). Meta-analysis of the two studies detected increased frequency of the 5-HT2A C102 allele in patients (c^2=4.04, 1df, p=0.04). By contrast, no association was found with bipolar disorder after meta-analysis of 5 published studies (c^2=1.90, ns).

Case control association studies of this marker in schizophrenia have been numerous and have produced some evidence of association[2]. However meta-analysis including all 20 studies performed to date shows no association, although when white Caucasian samples were considered separately (n=12), an excess of the 5-HT2A C102 allele was observed in patients (c^2=7.08, 1df, p=0.007).

In conclusion, allelic variation of the 5-HT2A receptor gene is associated with schizophrenia in white Caucasians and with unipolar disorder, although not with bipolar disorder. The function of this silent genetic change remains to be elucidated and it is possible that another mutation in linkage disequilibrium with it is responsible for the effects observed.

Variant Alzheimer's Disease with Spastic Paraparesis: Clinical Characterization. *M. Somer[1], A. Verkkoniemi[2], H. Kalimo[3], L. Myllykangas[2,4], R. Crook[4], J. Hardy[4], J.O. Rinne[3], M. Viitanen[5], M. Haltia[2].* 1) Department of Medical Genetics, The Family Federation of Finland, Helsinki, Finland; 2) Departments of Pathology and Clinical Neurosciences, Helsinki University Central Hospital, Helsinki, Finland; 3) Departments of Pathology and Neurology, Turku University Hospital, Turku, Finland; 4) Neurogenetics Laboratory, Mayo Clinic Jacksonville, Jacksonville, FL; 5) Division of Geriatric Medicine, Karolinska Institutet, Huddinge Hospital, Huddinge, Sweden.

We have identified a Finnish family with 23 members in four generations affected with presenile dementia and spastic paraparesis. This variant Alzheimer's disease is due to deletion of exon 9 of the presenilin 1 gene. Neuropathological analysis shows cortical "cotton wool" plaques immunoreactive for the b amyloid peptide but lacking congophilic cores. The mean age at onset (±SD) is 50.9±5.2 years (range 40 to 61 years). All patients have memory impairment with deficits in immediate and delayed recall together with other cognitive deficits. Dementia appears simultaneously with or is preceded by walking difficulty due to spasticity of the lower extremities. However, minority of patients have dementia without spastic paraparesis. Clumsiness of hands and dysarthria suggesting cerebellar involvement is common. MRI of head reveals temporal and hippocampal atrophy, and PET shows bilateral temporo-parietal hypometabolism. Spastic paraparesis and/or brisk tendon reflexes of lower extremities combined with dementia should alert the clinician to consider this variant Alzheimer's disease.

Program Nr: 2665 from the 1999 ASHG Annual Meeting

Imprinting study of Prader-Willi syndrome with methylation-specific PCR (MSPCR). *M. Song, L. Li, J. Fu, X. Li, G. Lu.* Human Reproductive Engineering Laboratory, Hunan Medical University, Hunan, Changsha, P.R.China.

OBJECTIVE: Methylation-specific PCR (MSPCR) assay for genomic imprinting study was established and a case of a 14-year-old boy with typical symptoms associated with the Prader-Willi syndrome (PWS) was detected by this method, and confirmed by Southern blot methylation analysis. METHODS: The 5' CpG island of the SNRPN gene, candidate gene for PWS, is methylated and unmethylated on the maternally and paternally inherited chromosome 15, respectively. MSPCR is based on sodium bisulfite treatment of DNA, which converts unmethylated, but not methylated cytosine residues to uracil, and PCR primers specific for the maternal and the paternal allele. Methylation analysis by Southern blot was used to validate the MSPCR result. High-resolution banding (HRB) chromosome analysis was used to rule out deletion of 15q11-q13. RESULTS: Bisulfite-modified DNA from this patient amplified only with methylated allele-specific primer pair, showing maternal imprinting. This MSPCR result was confirmed by Southern blot methylation analysis. MSPCR and PW71B methylation studies showed an abnormal pattern consistent with the diagnosis of PWS. High-resolution banding analysis failed to reveal any deletion of 15q11-q13. CONCLUSIONS: It is known that methylation-specific PCR can detect all presently testable causes of PWS in an efficient first step for stepwise diagnostic testing. We proved here again that MSPCR is an effective and reliable method for the detection of methylation in genetic disorders of imprinting compared with time-consuming Southern blot methylation analysis.

Program Nr: 2666 from the 1999 ASHG Annual Meeting

Cardiovascular disease genetic risk assessment with a multilocus assay. *C. Stranieri[1], G. Malerba[1], E. Trabetti[1], D. Girelli[2], O. Olivieri[2], R. Corrocher[2], G. Gandini[3], S. Cheng[4], M. Grow[4], H. Erlich[4], P.F. Pignatti[1]*. 1) Section of Biol. and Genet., DMIBG, Univ. Verona, Italy; 2) Dpt. of Exp. and Clin. Med., Univ. Verona, Italy; 3) Blood Center, Hospital of Verona, Italy; 4) Dpt. of Human Genetic, Roche Molecular System, Alameda, CA, USA.

Several genes may be implicated in cardiovascular disease (CVD) risk, together with environmental factors. A multilocus genotyping assay was set up including 15 genes (68 alleles) related to various aspects of cardiovascular physiology: lipid metabolism (ApoE, ApoB, ApoCIII, CETP, LPL, PON), hypertension (ACE, ATIIR, AGT), homocysteine metabolism (CBS, MTHFR), thrombosis (Factor V, Fibrinogen, GPIIIa), and leukocyte adhesion (ELAM), (Cheng et al, Clin. Chem. Lab. Med. 1998; 36:561-66). A series of Italian patients presenting with coronary artery occlusion (CAD+, n=487) or not (CAD- mainly affected by valvular heart disease, n=261) detected by coronarography performed in the same clinic, were selected (Blood 1998; 91:4158-63). Also, blood donors from the same town (Verona, n=108) or a town located 100 Km away (Ferrara, n=138) were selected, persons whose grandparents were all born in the same region. Allele and genotype frequencies were determined in all persons for all polymorphisms in each cohort. No significant difference was obtained between blood donor groups. A significant difference was obtained for ApoCIII T(-455)C genotype distribution between CAD+ and CAD- patients (T/T: 0.37 v. 0.46; T/C: 0.44 v. 0.45; C/C: 0.19 v. 0.09, respectively. P=0.001). A significant difference was obtained in the frequency of the ATIIR A1166C polymorphism genotypes between CAD+ and blood donors in males (A/A: 0.54 v. 0.4; A/C: 0.4 v. 0.5; C/C: 0.06 v. 0.1 respectively. P=0.004) and for the CETP I405V between CAD- and blood donors in females (I/I: 0.39 v. 0.6; I/V: 0.58 v. 0.3; V/V: 0.03 v. 0.1 respectively. P=0.003). No other difference was obtained in any other comparison performed. The data indicate a possible correlation between the ApoCIII gene mutation and coronary atherosclerosis. Further analysis will be performed with the use of other clinical and laboratory data which have been collected.

Program Nr: 2667 from the 1999 ASHG Annual Meeting

Polymorphism of NACP-Rep 1 in patients with Parkinson's disease. *E.K. Tan[1], T. Matsuura[1, 2], S. Nagamitsu[1, 2], M. Khajavi[1, 2], J. Jankovic[1], T. Ashizawa[1, 2].* 1) Neurology, Baylor College of Medicine, Houston, TX; 2) Neurology Service, VA Medical Center, Houston, TX.

Background: Missense mutations in the alpha-synuclein gene has been identified in certain autosomal dominant Parkinson's disease (PD) families. Recently, Kruger et al have demonstrated that a polymorphism in the promoter region (NACP-REP 1) of this gene is associated with susceptibility to sporadic PD in German population (Ann Neurol 1999;45:611-7). Such an association has not been studied in American families.

Objective: To determine if there is an association between polymorphism of NACP-Rep 1 and susceptibility to PD in American patients.

Methods: This study includes 104 patients diagnosed to have idiopathic PD (58 gave positive family history of the disease) using standardized clinical criteria and 125 controls without the disease. The allele status in the promoter region of the gene was determined by a PCR-based method. Four different alleles were identified; 259bp, 261bp, 263bp and 265bp (novel allele).

Results: The allele frequencies of PD patients and controls were; 259bp (0.22 vs 0.33, $p<0.007$), 261bp (0.70 vs 0.56, $p<0.005$), 263bp (0.08 vs 0.10) and 265 (0.005 vs 0.004) respectively. Genotype frequencies of PD and controls were; 259/259bp (0.01 vs 0.10, $p<0.002$), 259/261bp (0.37 vs 0.35), 261/261bp (0.44 vs 0.33), 259/263bp (0.06 vs 0.09), 261/263bp (0.12 vs 0.11), 261/265bp (0.01 vs 0), 259/265 (0 vs 0.01) respectively. There were no differences in the allele distribution in PD patients with and without a family history of the disease.

Conclusions: There are significant differences in the allele distribution between PD patients and controls. Allele of 261bp is associated with increased PD susceptibility, whereas the 259bp is associated with decreased PD susceptibility. This contrasts with the findings in the German sporadic PD population where 263bp was associated with increased susceptibility. Thus these results questions the significance of the contribution of this polymorphism to NACP-Rep 1 gene function in susceptibility of PD.

Program Nr: 2668 from the 1999 ASHG Annual Meeting

The role of RNA CUG triplet repeats in Myotonic Dystrophy. *L.T. Timchenko[1], X. Lu[1], A-S. Lia-Baldini[1], Z-J. Cai[1], J. Chiu[1], N.A. Timchenko[2].* 1) Dept Cardiology/Medicine, Baylor Col Medicine, Houston, TX 77030; 2) Dept of Pathology and Huffington Center, Baylor Col Medicine, Houston, TX 77030.

Myotonic dystrophy (DM) is a neuromuscular disease characterized by multiple defects including myotonia, skeletal muscle weakness, brain dysfunction, and cardiac and endocrine abnormalities. Mutation responsible for DM is an unstable CTG trinucleotide repeat located in the 3' untranslated region of the myotonin protein kinase (DMPK) gene. We proposed that trinucleotide repeats in DMPK gene act at the RNA level sequestering specific RNA-binding proteins. In agreement with this hypothesis, a CUG-binding protein, CUGBP1, has been isolated. Immunoanalysis and library screening identified additional RNA binding proteins that can bind to CUG repeats: ETR-3 and apoptosis-related protein. Cardiac specific protein, ETR-3, binds to CUG repeats similar to CUGBP1. Binding affinity of the apoptosis-related protein is under investigations. Analysis of CUGBP1 expression showed that this protein is affected in DM disease and in cultured cells by expression of RNA CUG repeats. Northern analyses suggest that different members of CUG-binding proteins might function in a tissue specific manner. While CUGBP1 is expressed in all tissues with the highest levels in skeletal muscle and heart, ETR-3 mRNA is abundant in heart tissue. The apoptosis-related protein has been detected in the brain and heart. Tissue-specific expression of CUG-binding proteins suggests that they might have different functions in RNA processing regulating different RNA targets. Our data show that CUGBP1 is involved in the regulation of both translation and splicing of cardiac and liver-specific RNAs. Thus, these results demonstrate the existence of a family of RNA binding proteins that might be affected by expansion of CUG repeats in DM. Functional analysis of members of the CUG-binding proteins family and identification of their native RNA targets would help to elucidate molecular basis for DM pathogenesis.

Program Nr: 2669 from the 1999 ASHG Annual Meeting

RNA binding proteins involved in Myotonic Dystrophy. *G. Tiscornia, M. Mahadevan.* Dept Medical Genetics, Univ Wisconsin Madison, Madison, WI.

Myotonic Dystrophy is a complex, multisystemic inherited neuromuscular disorder. The DM mutation is a CTG expansion in the 3' untranslated region of the DMPK gene. The mechanism by which this mutation causes disease is unclear. It has been suggested that altered cellular RNA metabolism caused by the mutant DMPK mRNA contributes to DM pathophysiology. The mutant DMPK transcript forms nuclear aggregates of RNA in patient cells. We have undertaken a search for RNA-binding proteins interacting with the DMPK 3'UTR RNA. Radiolabeled RNA probes consisting of the normal or mutant DMPK 3'UTR were used to perform UV crosslinking assays in HeLa, C2C12 and fibroblast protein extracts. We have identified several RNA protein interactions which are specific for the DMPK 3'UTR RNA, as indicated by competition assays using excess amounts of unlabeled homologous or heterologous RNAs. By using radiolabeled RNAs composed of various segments of the 3'UTR, we initially mapped the binding sites of the interacting proteins to a 500 nucleotide region spanning from (but not including) the CUG repeats to the DMPK polyadenilation site. Use of smaller riboprobes within this sequence has led to the identification of two regions of 70 and 100 nucleotides respectively that account for the binding activity of the interacting proteins. We are currently working on identifying the proteins involved in the interaction and investigating what role they play in transcript metabolism and DM pathophysiology. We have determined that the interactions are unaffected by expansions of 130 CUG repeats, that there are no differences in binding activity of protein extracts from normal vs. DM cell lines and that a reporter construct spliced to a DMPK 3'UTR lacking the binding sites does not result in significant changes in reporter activity. Nontheless, a cell culture model developed in our lab has established that sequences downtsream of the repeats play a role in cell fusion of mouse myoblasts, suggesting a possible role for the RNA-binding proteins we have detected in that phenotype.

Program Nr: 2670 from the 1999 ASHG Annual Meeting

Dendritic spine maturation is delayed in cultured hippocampal neurons of the Fmr1 knockout mouse. *E.R Torre, S.T. Warren.* Howard Hughes Medical Institute and Departments of Biochemistry, Genetics and Pediatrics. Emory University School of Medicine. Atlanta, Georgia 30322.

Fragile X syndrome is a frequent cause of inherited mental retardation and is due to the absence of the Fmr1 protein, FMRP. The cognitive deficit in patients has been associated with an apparent compromise of synaptic structure found in postmortem cortices and characterized by long, thin, and tortuous spines. However, other forms of mental retardation have also been shown to exhibit these features. Therefore it remains unclear if the observation of abnormal spine morphology in fragile X syndrome is a direct consequence of FMRP loss or a general result of cognitive deficits which limit adaptation and interaction. To directly answer this question, we analyzed the development of dendritic spines of cultured primary neurons derived from the Fmr1 knockout mouse. Hippocampal brain cells from E16 wild type (WT) or Fmr1 knockout (KO) mice were plated on glass coverslips and cultured for 14, 21, and 35 days. Neuronal morphology was assessed by staining with the lipophilic dye, DiI, and dendritic spines were identified by colocalization with the presynaptic marker synaptophysin. By day 14, neurons were profusely innervated and dendritic spines were easily visualized in both WT and KO neurons. The mean length of dendritic spines for KO neurons was 2.41 ± 0.3mm (1462 spines from 16 cells) as compared to 1.6 ± 0.1mm (2417 spines from 23 cells) for the WT neurons. Further analysis reveals that the increase in length of KO spines reflects a decrease in the number of spines within the normal range size for that age (1 to 2mm) and a two-fold increase in the frequency of spines ranging between 2 and 4mm. Differences between the KO and WT spines are most manifest at 20 days in culture and almost disappear by day 35. Synaptic contacts transform long, thin filopodias into short, mature spines with stubby and mushroom shapes. Hence, these data suggest: a) the loss of FMRP influences synaptic plasticity and, in particular, delays synapse maturation; b) since cultured neurons presumably grow under identical environmental conditions, the spine differences are directly due to the loss of FMRP.

Program Nr: 2671 from the 1999 ASHG Annual Meeting

The use of cDNA-representational difference analysis (cDNA-RDA) to characterize expression differences between Proteus Syndrome paired tissue samples. *S.J. Vacha[1], S.H. Shin[1], P.S. Meltzer[3], M.M. Cohen, Jr.[2], L.G. Biesecker[1]*. 1) Genetic Disease Res Branch, NHGRI, NIH, Bethesda, MD; 2) Dalhousie University, Halifax, Nova Scotia, Canada; 3) Cancer Genetics Branch, NHGRI, NIH,Bethesda, MD.

Proteus syndrome (PS) is a rare, sporadic disorder characterized by the progressive overgrowth of various regions of the body. The range and severity of features, including hyperostoses, connective tissue nevi, macrodactyly, hemangiomas, and tumor predisposition, is highly variable between patients. It is hypothesized that this disorder is due to a postzygotic somatic mutation that is lethal in a non-mosaic state. To date, there are no molecular data for PS regarding the gene, type of mutation, or chromosomal location. Preliminary genomic experiments (comparative genomic hybridization, microsatellite analysis, representational difference analysis) comparing normal vs. abnormal tissues from within affected individuals did not detect aberrations. For this reason, cDNA-RDA was performed to characterize gene expression differences between paired fibroblasts of two affected patients. A positive control was successful in enriching for 3' Gli3 cDNA in a comparison between full-length Gli3-transfected 293 cells and truncated Gli3-transfected 293 cells. From each RDA difference product, 500 enriched clones were sequenced and further confirmed by colony blot array as well as Southern and Northern blot analysis. To characterize these clones we have employed an arraying approach that validates or rejects clones that are generated by this procedure. First, we array a large sample of clones from one RDA and then probe that array with a clone pool from the complementary experiment (where tester and driver were reversed) or with the same experiment performed on tissues from other Proteus patients. The second array approach is to use RNA from affected and unaffected cell lines to screen a 10K expression array and use these clones to probe the above noted arrays. These procedures should greatly facilitate the analysis of large numbers of cDNA clones in this and other disorders.

Program Nr: 2672 from the 1999 ASHG Annual Meeting

Role of Polymorphisms in Parathyroid Hormone Receptor 1, Transforming Growth Factor Beta 1 and Estrogen Receptor in the Genetics of Osteoporosis. *A.M. Valdes[1], M. Bouzyk[1], E. O'Brien[1], D. Gale[1], S. Panchal[1], M. Barnes[1], S. Ralston[2], D. Reid[2], A. Rut[1], N. Spurr[1].* 1) Smithkline Beecham Pharmaceuticals Harlow, UK; 2) Dept Medicine and Therapeutics, University of Aberdeen, UK.

Osteoporosis is characterized by a reduction in bone mass affecting one in three postmenopausal women. We describe the effects of three genes along the bone remodeling pathway in bone mineral density (BMD) and rate of bone loss. We tested two microsatellite markers near estrogen receptor (ESR1; 6q25) D6S440 and D6S441, a non-coding SNP located in exon 7 of the PTH receptor 1 (PTHR1; 3p22-p21.1), and a SNP located in intron 5 of the transforming growth beta factor 1 gene (TGFB1; 19q13). Estrogen influences bone growth and metabolism; TGFB1 regulates osteoblast and osteoclast activity and modulates bone matrix synthesis; PTH is a major regulator of extracellular calcium homeostasis. The cohort studied consisted of 554 healthy Scottish women (age range 51-57, mean =54.2) Genotypes were tested for association with baseline spine and hip BMD and rate of change measured as percent of BMD loss (or gain) per year. The latter was stratified by use of hormone replacement therapy (HRT). The average time span between BMD measures was 6.7 years. The genotype at the two markers flanking ESR1 accounted for 3.8% of variance in hip BMD ($p< 0.03$) and 6.7% of spine BMD ($p< 0.002$). Significant effects of genotypes on spine ($p<0.002$) and hip ($p<0.01$) rate of change were also found. TGFB1 affected BMD at both hip ($p<0.02$) and spine ($p<0.05$) and accounted for less than 1% of the variance. Individuals carrying genotype TT at PTHR1 not treated with HRT had a greater loss of spine BMD than CT or CC individuals ($p< 0.03$), whereas individuals on HRT had the same rate of change. The interaction effect with HRT response was statistically significant ($p<0.03$). PTHR1 genotype explained only 2% of the variance of spine rate of change. ESR1 and TGFB1 together account for up to 10.2% of the variance in spine BMD and 8.5% of the hip BMD. Some of this appears to come from the gene-gene interaction between ESR1 and TGFB1 ($p<0.05$). We discuss the role of these genes in susceptibility to osteoporosis in the normal population.

Program Nr: 2673 from the 1999 ASHG Annual Meeting

Using Late-Onset Alzheimer's Disease (LOAD) as a Model to Study the Application of Single Nucleotide Polymorphisms (SNPs) for Complex Disease Association Studies: Genotyping and Analysis of 65 SNPs in a 4-Megabase Region Surrounding Apolipoprotein E (APOE). *J.M. Vance[1], E.R. Martin[1], J.R. Gilbert[1], A.R. Rogala[1], A. Afshari[2], B.D. Slotterbeck[1], J.M. Grubber[1], A.M. Saunders[1], J. Riley[3], I. Purvis[3], D.E. Schmechel[1], P.M. Conneally[4], E.H. Lai[2], M.A. Pericak-Vance[1], A.D. Roses[2]*. 1) Center for Human Genetics, Duke University Medical Center, Durham, NC, USA; 2) Glaxo Wellcome, Inc., Research Triangle Park, NC, USA; 3) Glaxo Wellcome, Inc., London, UK; 4) Dept Medical Genetics, Indiana University Medical Center, Indianapolis, IN, USA.

Considerable discussion has occurred in recent years concerning the use of SNPs and association to find loci contributing to common, complex genetic disorders. However, little actual data is available to investigate this approach. APOE is a proven susceptibility gene for LOAD. Thus, it presents an excellent model to actually test and develop methodology for genotyping and data analysis, as well as many of the proposed assumptions affecting this model. In addition, it can be used to help predict some of the parameters likely to be needed in this gene mapping approach. We have previously studied 10 SNPs surrounding the APOE locus and found that the region of disequilbrium for LOAD and APOE was relatively small, but detectable. Thus, to further map this region and develop data for investigation of methodology for SNP data analysis and SNP genotyping, we have genotyped 65 additional SNPs surrounding APOE. 877 individuals consisting of LOAD patients and age-matched controls were genotyped using Taqman® methodology. Samples include both case controls as well as LOAD families, allowing sibling-based allelic association techniques to be applied as well. Genotyping was performed using quality control measures (samples duplicated in a blinded fashion) to provide estimates of the accuracy of the handling and genotyping methods. Association studies, maps and genotyping results will be presented.

Program Nr: 2674 from the 1999 ASHG Annual Meeting

Transmission on a fragile X full mutation through a normal transmitting male. *K.A. Ventura[1], L.M. Fraer[1], E.E. Smith[1], A.E. Merrill[2], K.J. Treat[2], Z. Wang[2], B.A. Allitto[2], J.M. DeMarchi[2], W.A. Hogge[1]*. 1) Dept Genetics, Magee Womens Hosp, Pittsburgh, PA; 2) Genzyme Genetics, Framingham, MA.

The Fragile X premutation has been thought to be unstable during female, but not male, transmission. We report a family in which a Fragile X full mutation was inherited through an unaffected male with a premutation. The female proband presented at 12 weeks gestation because of mental retardation in a sister and three maternal cousins (two boys and one girl). The cousins had been evaluated previously at another institution, and chromosome analyses were normal. Chromosome studies and Fragile X DNA analysis were performed on the proband and her sister. The proband was found to be 46,XX and negative for Fragile X with 20 and 38 CGG repeats. Her sister was found to be 46,XX with a full mutation (38 and 600 repeats) for Fragile X syndrome. Testing was performed on other maternal family members: the proband's mother and maternal aunt were found to be full mutation (abnormal methylation) carriers, with 20 and 300, and 30 and 267 repeat alleles, respectively; an uncle had 20 repeats; the grandmother had 20 and 30 repeats. Therefore, the premutation did not originate from the grandmother as expected. Fragile X DNA analysis of the grandfather, however, showed normal methylation, and a repeat size of 59, with a faint but reproducible smear from 59 to greater than 200 repeats detected by PCR. The PCR result and the inheritance pattern suggest instability of the 59-repeat allele and/or possible germline mosaicism for a full mutation. Since this family study indicates a transmitting male passed on a full mutation to at least two daughters, counseling of families with suspected Fragile X syndrome on the paternal side should be undertaken with caution.

Program Nr: 2675 from the 1999 ASHG Annual Meeting

Identification of genes at translocation breakpoints on chromosome 7q31 in autistic individuals. *J.B. Vincent[1], J.A. Herbrick[1], H.M.D. Gurling[2], S.W. Scherer[1],* .. 1) Department of Genetics, The Hospital for Sick Children, Torornto, ON, Canada; 2) Molecular Psychiatry Laboratory, Windeyer Institute of Medical Sciences, University College London Medical School, London, UK.

Autism is a severe and debilitating childhood-onset developmental disorder, characterized by impaired communication and social interaction coupled with preoccupations, repetitive behaviours, circumscribed interests and activities. The prevalence of typical autism has been estimated to be between 0.77 and 5.6 per 10,000, while a broader phenotype of autism spectrum disorders have a population prevalence of 5 in 1000. A strong genetic component is believed to be involved. The mode of genetic transmission for autism is unclear, however a complex, non-Mendelian inheritance pattern is suggested. Results from the first genome-wide scan for linkage to autism have recently been published. Regions on six chromosomes (4, 7, 10, 16, 19 and 22) were identified with multipoint maximum LOD scores (MLS) >1, with a most significant MLS of 3.55 on 7q. Initial results from autism genome scans by several other groups also implicate the 7q region. Linkage results for a severe speech and language disorder have also implicated a locus (SPCH1) on the same region of 7q. We have identified a number of autism patients and individuals with developmental or language delay with translocations or deletions involving 7q31. We have localised the breakpoint for one autism patient with a translocation t(7;13)(q31.2;q21) to a BAC clone within the critical region for linkage for autism, and a transcript which spans the breakpoint has been cloned. The function of this novel gene is unknown but characterisation is currently underway. A mutation search in this gene is underway in autistic individuals from multiplex families which share haplotypes around this gene.

Program Nr: 2676 from the 1999 ASHG Annual Meeting

Abnormalities in fibrillin-1-containing microfibrils in fibroblast cultures from patients with scleroderma. *D.D. WALLIS[1], F.K. TAN[1], C. KIELTY[2], F.C. ARNETT[1], D.M. MILEWICZ[1]*. 1) INT MED UNIV OF TX MS HOUSTON, HOUSTON, TX; 2) UNIV OF MANCHESTER UK.

Fibrosis of skin and viscera that is the hallmark of scleroderma (SSc) is produced by activated fibroblasts. The *Tsk* mouse model of SSc results from a fbn1 mutation which encodes fibrillin-1, a major component of microfibrils (MF) in the extracellular matrix (ECM). Evidence that *FBN1* alterations contributes to human SSc comes from studies of Choctaws, where a *FBN1* haplotype is associated with SSc. Mutations in *FBN1* cause Marfan syndrome (MFS) in a dominant negative pathogenesis where the mutant fibrillin-1 (fib-1) disrupts MF formation. Therefore, studies were undertaken using established methods to determine if there was abnormal fib-1 function or MF structure in skin fibroblasts explanted from 12 SSc patients (including 2 Choctaws and 2 siblings). Pulse-chase studies indicated diminished amounts of fib-1 in the ECM in 6 of 12 SSc strains compared to controls (n=14). Five strains had no recognizable MF by rotary shadow electron microscopy (R-EM) and 7 had diminished MF. Immunoblotting of high molecular weight ECM fractions from 2 Choctaw SSc fibroblast strains with antibodies for fib-1 and type VI collagen confirmed the lack of intact fib-1-containing MF; the amount of type VI collagen MF was similar to control cells. Immunofluorescence of cultures (12 SSc, 3MFS, 5 controls) demonstrated that the control and SSc fibroblasts displayed a prominent meshwork of fib-1 MF. MFS fibroblasts showed diminished MF, consistent with a dominant negative effect of the mutant fib-1 on MF formation. Four unaffected relatives of a SSc patient were biopsied and 2 of these cultures showed diminished fib-1 in the ECM with pulse-chase analysis. These results indicate that SSc fibroblasts can assemble MF in contrast to MFS fibroblasts. The diminished amounts of fib-1-MF found in the ECM of SSc cultures by metabolic labeling or R-EM implies that the assembled MF are abnormal and degrade with biochemical manipulation. Models are proposed to link the observed MF instability to the activated fibroblasts. Furthermore, the instability of the MF may be genetically determined based on the family studies.

Program Nr: 2677 from the 1999 ASHG Annual Meeting

Identification of a recombination hotspot on chromosome 15q11-13 in children with autism. *C.H. Wang[1,3,4], E. Villaca-Norat[1], M.B. Miller[2], B.D. Papendick[1], D.K. Gavrilov[3], R.E. Hillman[4], J.H. Miles[4].* 1) Neurology; 2) Psychology; 3) Biochemistry; 4) Child Health, Univ Missouri, Columbia, MO.

Autism is a complex genetic disorder characterized by repetitive stereotypic behaviors and impaired communication and social interaction. Recent cytogenetic and molecular studies indicate that DNA rearrangements within the chromosome 15q11-13 region may contribute to the pathogenesis of autism. We characterized the genomic arrangement of this region in 126 autism families using eleven microsatellite markers spanning about 3.0 Mb interval. Samples from four autism probands were trisomic for several 15q alleles. Karyotype analysis revealed supernumerary isodicentric 15q13-pter in 4 probands. One included a supernumerary derivative 15 chromosome from a balanced maternal 4/15 translocation. Of the 122 remaining families 31 were informative for haplotype analysis in this region yielding 60 informative meioses in transmissions to affected offspring. In six (10%) of these meioses, crossovers were observed between markers D15S986 and D15S1234 (an interval of less than 200 Kb). Four of these crossovers occurred on maternal chromosomes and two on the paternal chromosome. Of 179 meioses in control families, 1 (0.6%) demonstrated meiotic recombination within this interval. This region of frequent autism- associated recombination is distinctly different from the meiotic breakpoints observed in the control groups which were located more telomerically. We propose that meiotic recombination in chromosome 15q11-13 may result in genomic rearrangement and contribute to the pathogenetic etiology in children with autism.

Program Nr: 2678 from the 1999 ASHG Annual Meeting

Sulfonylurea Receptor Gene Polymorphism is Associated with Non-insulin Dependent Diabetes Mellitus(NIDDM) in Chinese Population. *H. Wang, L. Ji, X. Han.* Department of Endocrinology and Metablism, People's Hospital, Beijing Medical University, Beijing, P.R.China.

Non-insulin dependent diabetes mellitus(NIDDM) is a common polygenic disease, and deficiency in insulin secretion as well as in insulin utilization are involved in the pathogenesis of NIDDM. As a hypoglycemic drug, sulfonylurea has been widely used for the treatment of NIDDM. Sulfonylurea receptor gene was cloned in 1995 and its mutations were shown to be associated with familial persistent hyperinsulinemic hypoglycemia of infancy. In addition, polymorphisms in intron 24(-3t-3c) and exon 22 (T761T) of SUR gene were found strongly associated with NIDDM in Caucasians population , suggesting the SUR gene may contribute to genetic susceptibility of NIDDM. To study the role of SUR gene in the pathogenesis of NIDDM in Chinese population, we test the polymorphisms of the SUR gene in intron 24 and exon 22 by PCR-RFLP method in 86 NIDDM patients with at least two first degree diabetic relatives and 148 normal control subjects. The results show that the frequency of " -3 c "allele of intron 24 in NIDDM patients is significantly increased comparing with that in the control subjects (68.02% vs. 55.41% , P=0.007), and the frequency of the "-3c/-3c" genotype of intron 24 in the NIDDM group is also significantly higher than that in control group.(41.86% vs. 27.7%, P=0.013 ,OR=4. 39, CI: 1.52-12.66). The polymorphism of exon 22 described in the Caucasian population was not detected in this study. In conclusion, the association of the polymorphism of SUR gene with NIDDM in different races suggests that the SUR gene or nearby gene may play an important role in the genetic susceptibility of NIDDM.

Program Nr: 2679 from the 1999 ASHG Annual Meeting

Variable effects of the ApoCIII C-482T variant on insulin and triglyceride levels in different ethnic groups. *D.M. Waterworth[1], F.P. Cappuccio[2], D.G. Cook[2], P.D. Wicks[2], S.E. Humphries[1], P.J. Talmud[1]*. 1) Cardiovascular Genetics, RFUCLMS, London, UK; 2) St George's Hospital Medical School, London UK.

We have previously reported that the ApoCIII C-482T variant modulates insulin and glucose levels after an OGTT in young healthy white men (Circulation. 1999;99:1872-1877). In order to evaluate its effect in different ethnic backgrounds, this variant was investigated in a population-based cross-sectional study in South London which consisted of Whites (n=462), South Asians (n=442) and individuals of African origin (n=462). There was a considerable difference in T-482 allele frequency between the three groups: 0.25(CI 0.22-0.28) in Whites, 0.44(CI 0.41-0.47) in South Asians and 0.71(CI 0.68-0.74) in individuals of African origin. Significant associations with fasting insulin levels were observed in White males (p=0.03) and Black males (p=0.005), but not in South Asian males or any of the female groups. In whites, the group with the genotype CC-482 had the lowest mean insulin levels, while in blacks (the opposite association was observed) the TT-482 group had the lowest levels. No associations were observed with 2-hour post-load insulin in any of the groups. Relationships between C-482T and triglyceride were also investigated and a significant association was found only for white males (p=0.03). In order to clarify these relationships with insulin and triglyceride, linear regression models were constructed separately for each ethnic group and confirmed a relationship between insulin levels and C-482T in Whites (p=0.01) and Blacks (p=0.04) but gave no evidence in Asians (p=0.20). The significant relationship between C-482T genotype and triglyceride in Whites was confirmed (p=0.02) and there was also borderline significance observed for Asians (p=0.05), but there was no evidence in Blacks (p=0.88). This study illustrates the important influence of genetic background when investigating the effects of genetic variation on insulin sensitivity and lipids.

Program Nr: 2680 from the 1999 ASHG Annual Meeting

UBE3A Mutations in Angelman Syndrome: Types, Hotspots, and Origins. *H. Webber, J. Wagstaff.* Genetics Division, Children's Hospital, Boston, MA.

We have found mutations in the UBE3A ubiquitin-protein ligase gene in 28 sporadic or familial Angelman syndrome (AS) cases lacking 15q11-q13 deletions, chromosome 15 UPD, or imprinting defects. We and others (Fang et al., Hum. Mol.Genet. 1999, 8:129-135) have found a much higher frequency of mutations in familial cases (75-80%) than in sporadic cases (14-23%). Among 28 mutatations detected by SSCP, we have found 17 small insertions or deletions causing frameshifts, 3 mutations to stop codons, 3 single-amino-acid deletions or duplications, 2 splice site mutations, 2 missense mutations, and 1 mutation predicted to cause a 7-amino-acid deletion. We found multiple mutations at 2 sites: the same de novo 5-bp duplication in exon 16 was detected in 3 individuals, and 3 different single-amino-acid deletion or duplication mutations were found within an 8-bp region of exon 15. Among 14 mutations that could be traced to their origins, 9 apparently arose in the maternal germline; 2 arose in the paternal germline; 2 arose in females with somatic and germline mosaicism; and 1 arose in a mosaic male. The 2 missense mutations lead to nonconservative amino acid changes in the region of UBE3A required for E6-dependent association with p53. These missense mutations should prove useful in determining which UBE3A substrates are relevant to the pathogenesis of AS.

Program Nr: 2681 from the 1999 ASHG Annual Meeting

A comprehensive screen for genetic variation in the transforming growth factor b1 gene in multiple sclerosis.
B.G. Weinshenker, D. Hebrink, O. Kantarci, E. Atkinson, C.T. McMurray. Mayo Clinic/Mayo Foundation, Rochester, MN.

Background: Multiple sclerosis (MS) is a complex genetic disease. The course of MS is highly variable; the biological determinants of the variability are unknown. We evaluated transforming growth factor beta 1 (TGFb1) as a candidate gene for MS susceptibility and course. TGFb1 is a TH2 immunoregulatory cytokine that opposes the effects of pro-inflammatory TH1 cytokines. TGFb1 administration ameliorates and neutralizing antibodies to TGFb1 exacerbate experimental allergic encephalomyelitis, a model for MS. TGFb1 is encoded on chromosome 19q13, a region implicated in MS susceptibility by three independent whole genome scans. Methods: We scanned the promoter region and exons 1-7 and their splice junctions by dideoxyfingerprinting (ddF) or restriction endonuclease fingerprinting (REF). These mutation detection methods are hybrids of either sequencing (ddF) or multiple independent restriction digests (REF), combined with non-denaturing electrophoresis to detect single strand conformational polymorphism. We tested variants of sufficient frequency for association with disease susceptibility and severity. Patients were categorized for MS-related disability from 1 (most severe) to 10 (least severe) as previously described (Weinshenker et al. Neurology 1997; 49: 378-385). Controls were matched for age, gender and ethnicity in a ratio of 2:1. Results: We identified six sequence variants, including four in exons and one in the promoter region. Three missense variants were detected: exon 1(Gb_pr X05839) position 2005T®C (L10P) and 2050G®C (R25P); exon 5(Gb_prX05844) position 342 C®T (T263I). We evaluated variants at positions 2005 and 2050 of exon 1, and position -510 in the promoter region. There was no association of the three variants with disease susceptibility, but a trend was found for the -510 variant in the promoter region with disease severity (homozygotes 6.4 ± 1.3; heterozygotes 5.9 ± 1.9; wild type 5.5 ± 1.9; P=0.166). Conclusions: Variants in TGFb1 were not associated with MS susceptibility. A trend to association of a promoter region variant with disease severity was observed.

Program Nr: 2682 from the 1999 ASHG Annual Meeting

Obstetric cholestasis in a woman with no family history of progressive familial intrahepatic cholestasis caused by a novel mutation in the MDR3 gene. *C. Williamson[1,2], N. Weerasekera[1], P.H. Dixon[1], O. Donaldson[1], J. Chambers[1,3], E. Egginton[3], J. Weaver[3], C. Nelson-Piercy[4], M. de Swiet[2], E. Elias[3], D.G. Johnson[1], M.I. McCarthy[1].* 1) Dept. of Medicine, Imperial College, Hammersmith Hospital, London, UK; 2) Institute of Obstetrics and Gynaecology, Queen Charlotte's Hospital, London, UK; 3) Department of Gastroenterology, Birmingham University, Birmingham, UK; 4) Dept. of Obstetrics and Gynaecology, St Thomas' Hospital, London, UK.

Obstetric cholestasis (OC) is a disorder of pregnancy with serious consequences for the mother and fetus, and can cause unexplained third trimester stillbirth. Two pedigrees have been reported with OC in the mothers of children with a subtype of autosomal recessive progressive familial intrahepatic cholestasis (PFIC) with raised gamma glutamyl transpeptidase (GGT). In these pedigrees affected children have homozygous mutations in the multidrug resistance 3 (MDR3) gene, and heterozygote mothers have OC. We therefore investigated a woman with OC and raised GGT, and with no family history of PFIC, for MDR3 mutations. Using previously characterised intronic sequence, together with novel sequence generated from long-range PCR experiments, we designed 27 pairs of primers to amplify the coding exons of the MDR3 gene, together with the intron exon boundaries. DNA sequence analysis of the products revealed a C®A transversion in codon 546 in exon 14. This results in the substitution of the wild type alanine (GCC) with an asparagine (GAC). This DNA base change was confirmed and demonstrated to not be present in 100 normal chromosomes from a panel of parous controls using the restriction enzyme SexAI. Our analysis of the genomic sequence of MDR3 has also revealed a dinucleotide microsatellite polymorphism in intron 15 and a single nucleotide polymorphism in exon 16. These variants will be useful for further linkage and association studies of this gene. This is the first demonstration of a heterozygous missense mutation in the MDR3 gene in a patient with OC with no family history of PFIC. Our analysis indicates that MDR3 mutations may be responsible for OC in a subgroup of women with raised GGT.

Program Nr: 2683 from the 1999 ASHG Annual Meeting

Search for sequence variations in the NDUFA1 Gene of complex I deficient patients. *I. Wittig[1], P. Augstein[2], G.K. Brown[3], T. Fujii[4], A. Roetig[5], P. Rustin[5], P. Seibel[5], D. Thorburn[5], B. Wissinger[5], K. Tensing[5], A. Metspalu[5], E. Lamantea[5], M. Zeviani[5], Y. Goto[5], M. Wehnert[1]*. 1) Institute of Human Genetics, University of Greifswald, Greifswald, Germany; 2) Institute of Diabetes, Karlsburg, Germany; 3) Genetics Laboratory, Oxford, UK; 4) Department of Pediatrics, Shiga Medical Center for Children, Shiga, Japan; 5) Hospital des Enfants-Malades, Paris, France; 6)Research Group Neurobiology and Cell Biology, Dresden, Germany; 7)The Murdoch Institute, Melbourne, Australia; 8)Eye Clinic, Tuebingen, Germany; 9)Institute of Molecular and Cell Biology, Tartu, Estonia; 10)Institute of Neurology, Milano, Italy; 11)Nati.

The NDUFA1 gene is one of the human nuclear genes encoding a subunit of complex I of the respiratory chain that has been cloned and mapped to Xq24. The encoded 70 amino acids (MWFE peptide) predict a hydrophobic and a hydrophilic domain, which are putatively involved in anchoring and orientation of complex I at the inner mitochondrial membrane. MWFE is essential for an active complex I in mammals. The available sequence and mapping information was used to search for a human condition related to sequence variations in the NDUFA1 gene. We scanned for sequence variations in predominantly male patients with LHON (54) and other conditions of complex I deficiencies accompanied with neurodegenerative and / or neuromuscular symptoms including Leighs syndrome (137) from different countries. Under the 191 patients that have been studied by PCR, heteroduplex analysis and direct sequencing, no mutations in the exons (including exon/intron boundaries) and 367 bp of the promoter region have been found so far. Three single nucleotide polymorphisms (SNP), T/C nt at -189, C/G at nt -71 and T/G at nt 1454 were discovered and evaluated by restriction digestion of the PCR products in a German population (frequencies for the frequent alleles are 0.938, 0.512 and 0.963, respectively). As compared to the patient group no significant difference was observed. The polymorphisms seem to be neutral and not related to a disease phenotype caused by complex I deficiency, although population differences in allele frequencies have been found for all SNPs.

Program Nr: 2684 from the 1999 ASHG Annual Meeting

What else NPL linkage scores can tell us about complex diseases. *M. Wjst, T. Immervoll, S. Loesgen.* Institut fuer Epidemiologie, GSF Forsch Umwelt & Gesundh, Neuherberg Munich, Germany .

We report a reanalysis from a genome-wide scan for asthma and related traits in 97 families with at least 2 asthmatic children between age 6 and 18 recruited from several university hospitals in Germany and Sweden. All participants completed a detailed interview (Clin Exp All 1995; 18 Suppl: 482). Microsatellite typing was done in a high throughput laboratory with a panel of 351 markers evenly spaced over the genome with about 10 cM distance. For a multipoint linkage analysis a nonparametric IBD-based statistic was used as implemented in the software package Genehunter. Four identified regions suggestive for linkage to asthma were identified: chr. 2, 6, 9 and 12 (Genomics 1999; 58: 1-8).

For the current analysis NPL score at each region were set to missing if the PIC was less than 0.90 and coded as 1 or 0 for each subject if greater than 80% of the distribution. A logistic regression analysis then included clinical details as age of onset, attack rate, duration, severity and asthma trigger type. The locus on chr.2 seems to promote more an infection type asthma (odds ratio OR 1.4, NS) with longer attack durations (OR 2.0, NS) and less pollen induced asthma (OR 0.7, NS). The loci on chr. 6, 9, 12 are all in favour of pollen induced asthma with OR 4.6 (NS), OR 1.6 (NS) and OR 6.2 (NS) respectively. The patients with linkage at the chr.6 locus patients are less females (OR 0.3, P=0.08), have later disease onsets (OR 1.3, P=0.02) and longer attack duration (OR 2.5, P=0.02). The patients with the chr.12 locus have higher total IgE levels (OR 2.0, P=0.08 for log(IgE) increase). Despite a lack of power in the present study this approach seems to be useful to discriminate clinical subtypes of asthma.

Program Nr: 2685 from the 1999 ASHG Annual Meeting

Atrophin-1, the DRPLA gene product, interacts with a component of nuclear corepressor complexes, and associates with the nuclear matrix. *J.D. Wood[1], K. Duan[1], F.C. Nucifora, Jr.[1], J. Wang[2], Y. Kim[1], G. Schilling[1], J. Lui[2], C.A. Ross[1]*. 1) Division of Neurobiology, Dept. of Psychiatry, Johns Hopkins University, Baltimore, MD; 2) Hematology Branch, NHLBI, NIH, Bethesda, MD.

Dentato-rubral and pallido-luysian atrophy (DRPLA) is one of the family of autosomal dominant neurodegenerative disorders caused by the expansion of a polyglutamine tract. It has recently been shown that truncated fragments of atrophin-1, containing the expanded polyglutamine tract, accumulate in selective neuronal nuclei in a transgenic mouse model of DRPLA. Seemingly identical fragments were found in human DRPLA post-mortem brains, but not in control brains. These fragments may underlie the pathogenesis of DRPLA, and we have sought to identify the function of atrophin-1 in neuronal nuclei. Using the yeast two-hybrid system, we have found that the amino-terminus of atrophin-1 interacts with ETO - a brain-enriched protein which has recently been shown to associate with the N-CoR/mSin3A/HDAC transcriptional corepressor complex. Atrophin-1 and ETO colocalize in discrete nuclear structures when cotransfected into Neuro-2a cells. These structures stain for endogenous HDAC2 and are associated with the nuclear matrix. Furthermore, atrophin-1 and ETO cofractionate in nuclear matrix preparations from DRPLA transgenic mice. We have also found that atrophin-1 represses transcription of a reporter gene in cell transfection based assays. Taken together, these findings suggest that atrophin-1 is part of nuclear matrix-associated transcriptional corepressor complexes. We hypothesize that in DRPLA, the accumulation of truncated atrophin-1 fragments in the nuclear matrix causes neuronal dysfunction by interfering with transcriptional control mechanisms.

Program Nr: 2686 from the 1999 ASHG Annual Meeting

Evaluation of maternal genotypic effects in the etiology of nonsyndromic cleft lip and palate. *D.F. Wyszynski, T. Wu, M.H. Khoshnevisan, A.J. Miller-Chisholm, S.R. Diehl.* CEGB/NIDCR/NIH, Bethesda, MD.

Numerous investigators have searched for clues to understand the etiology of nonsyndromic cleft lip and palate (CL/P). Strong evidence of both genetic and teratogenic effects has been suggested. Recently, there has been an increasing interest in distinguishing maternal genetic effects from those due to the fetus. Animal models demonstrate that the effect of certain teratogens during pregnancy are strongly influenced by the mother's genotype. The purpose of our work was to investigate whether the maternal genotype plays an important role that can be distinguished from the fetal genotype in risk for CL/P. The transforming growth factor alpha Taq I SNP and periconceptional maternal cigarette smoking were used to test this hypothesis. Four statistical methods were used. The likelihood ratio test (LRT) distinguishes the effects of the mother's and child's genotype on risk for CL/P. The case-only and mother-only methods test for multiplicative interactions between genotype and exposure to an environmental factor. The case-only method focuses on the affected child's genotype as risk factor for CL/P. The mother-only method tests whether the mother's genotype interacts with her environmental exposure on risk for being the mother of a CL/P individual. Finally, a Fisher's exact test was performed to assess allele frequency differences between fathers and mothers of affected individuals. A total of 146 CL/P affected individuals, 90 mothers and 56 fathers were available for analysis. The case-only method provided an odds ratio (OR) = 1.43 (95% CI: 0.42-4.62), while the mother-only OR was 0.96 (0.21-4.05). The C2 SNP allele, previously shown to increase risk when occurring in the child, was less common in mothers (18%) versus fathers (30%) of CL/P affected children (p=0.158), suggesting a protective effect of this allele in the maternal genotype. This finding was also supported by an odds ratio of 0.35 (0.14-0.90) for this allele in the maternal genotype when analyzed using the LRT including multiplex sibships. These results suggest possible effects of both the maternal and child genotypes in risk of CL/P.

Program Nr: 2687 from the 1999 ASHG Annual Meeting

5,10-methylenetetrahydrofolate reductase gene polymorphism and HbA1c levels in patients with ischemic heart disease. *H. Yamagata[1], K. Kazutane[3], Y. Kanaoka[3], T. Fukuda[1], K. Obata[1], T. Miki[2], O. Yoshimura[4], I. Kondo[1]*. 1) Dept. of Hygiene, Ehime Univ. School of Med., Onsen-gun, Ehime,791-0295, Japan; 2) Dept. of Geriatric Medicine, Ehime Univ. School of Med., Ehime,791-0295, Japan; 3) Dept.of Cardiovascular Surgery, Iwakuni National Hosp., Yamaguchi, 740-8510, Japan; 4) Food and Nutrition Dept., St. Catherine Women's Junior Collage, Ehime 799-2431, Japan.

A common missense mutation (677C to T; Ala to Val) in the gene for 5,10-methylentetrahydrofolate reductase (MTHFR) is responsible for reduced enzyme activity and is associated with a modest increase in plasma homocysteine concentration. Association studies show that homozygosity for the Val allele of the MTHFR gene is an independent risk factor for atherosclerosis and thromboembolic disease. The findings, however, have not been consistent, indicative that the associations between MTHFR genotypes and diseases may be affected by additional genetic or non-genetic factors. We assessed the frequency of this common mutation in 306 patients with ischemic heart disease (IHD) and in 81 healthy controls. The frequency of the Val allele in patients with IHD did not differ significantly from that in the healthy controls (c2=1.31, df=1, P>0.25), whereas it was significantly increased in IHD patients with non-insulin-dependent diabetes mellitus (NIDDM) (0.509) as compared with IHD patients without NIDDM (0.373) (c2=6.64, df=1, P<0.010). Furthermore, patients with the Val/Val genotype were more frequent in NIDDM under poor blood-glucose control, HbA1c 7.1% groups (45.8%) than in patients with HbA1c <7.1% (13.2%); odds ratio was 7.58 (c2=12.5, df=1, P<0.0005). Our findings provide the first direct evidence that poor blood-glucose control in Val allele carriers of the MTHFR gene may be an important risk factor for IHD. cc.

Program Nr: 2688 from the 1999 ASHG Annual Meeting

Secretin gene structure, chromosome localization and mutation analysis on autism. *T. Yamagata[1], S. Aradhya[1], M. Mori[2], M.Y. Momoi[2], D.L. Nelson[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Jichi Medical School, Tochigi, Japan.

Secretin is a 27-amino acid gastrointestinal hormone. The main action of secretin is to stimulate the pancreas to produce pancreatic juice; however, a role for secretin in brain has been proposed. Recently, secretin was reported to improve some symptoms of autism in some patients. Therefore, we cloned human secretin gene, identified its position in the genome and analyzed the gene for mutations in autistic patients. We designed PCR primers from the sequence of pig secretin and amplified the secretin gene from human genomic DNA. Using this PCR product as a probe, we screened the RPCI-11 BAC library and isolated the clones carrying the secretin gene. The gene is composed of four exons. On the upstream site of the secretin gene, there is a VNTR that ranges from 11 to 14 repeats of a 30 or 31 bp sequence. The secretin gene was mapped between HRAS-1 and DRD4 on 11p15.5, distal to IGF2 - H19 imprinting region first by FISH and later using specific markers in the BAC contig. The promoter region of the secretin gene is not methylated in blood cells. Twenty-five Japanese autism patients were screened by heteroduplex analysis for mutations in the secretin gene. Two patients were found to carry nucleotide substitutions. One mutation was G to C change on the E-box of the promoter and the other was C to T change in exon 3 that altered an amino acid from Pro to Leu. Each patient was heterozygous for their mutation. We screened these mutations in 58 Japanese and 50 Caucasian controls. The mutation in the promoter region was found in two Japanese and none of the Caucasian samples. It is likely to be a Japanese-specific polymorphism. The mutation in exon 3 was not found in the control samples. Family studies revealed that both the normal mother and the unaffected sister of the proband carried this mutation. Although this mutation may lead to autism in this patient, its contribution might involve reduced penetrance or possibly a sex bias. Our results suggest a possible relationship between secretin gene mutations and autism, however, further analyses are required.

Program Nr: 2689 from the 1999 ASHG Annual Meeting

A gene-wide scan for mutations in the *ALOX5AP* gene; an association study between a polymorphism in the promoter region and asthma. *C.N. Yandava*[1, 2], *A. Pillari*[1, 2], *J.M. Drazen*[1, 2]. 1) Pulmonary & Critical Care Med, Brigham & Women's Hosp, Boston, MA; 2) Harvard Medical School.

The human arachidonate 5-lipoxygenase (5-LO) activating protein (ALOX5AP), which was referred as 5-LO activating protein (FLAP) is a highly hydrophobic integral membrane protein and is localized in the nuclear envelope of certain cells. ALOX5AP binds to arachidonic acid in the presence of Ca^{2+} and present it to 5-LO. 5-LO oxidizes arachidonic acid, which results in the biosynthesis of leukotrienes. Leukotrienes are involved in a variety of biological responses including inflammation and bronchoconstriction in asthma. The organization of *ALOX5AP* gene is known and it consists 5 small exons. In order to find association between asthma and *ALOX5AP*, we scanned all 5 exons, 5' UTR and 3' UTR regions for mutations by single strand conformation polymorphism analysis (SSCP). Variations were observed in the promoter region of the gene. The amplified PCR products of common and variant samples were sequenced directly on an automated ABI prism 377 sequencer. The observed change corresponds to a mutation form G to A at -337 nucleotide position from the translation initiation site (G-377A). This change results in the loss of the restriction site *Bss*SI. This base change is close to an AP-2 site in the promoter. 200 Caucasian controls and 150 asthmatic patients were genotyped for this mutation by restriction fragment length polymorphism analysis (RFLA). The allele frequencies for the common allele are 0.96 and 0.96 in the controls and asthmatics respectively. There are no differences between normal and asthmatic Caucasian populations.

Program Nr: 2690 from the 1999 ASHG Annual Meeting

Protective effect of CCR5 32 base pairs deletion in Crohn's Disease. *H. Zouali[1,2], M. Chamaillard[1,2], JF. Colombel & EPIMAD[2], J. Belaiche & the GETAID[2], JP. Cezard & the EPGWGPIBD[2], C. Tysk[2], S. Almer[2], M. Gasull[2], V. Binder[2], S. Lesage[1,2], J. Macry[2], G. Thomas[1,2], JP. Hugot[1,2]*. 1) Fondation Jean Dausset, Paris, France; 2) European Concerted Action on the Genetics of Inflammatory Bowel Diseases.

Background : During the inflammation in Inflammatory Bowel Diseases (IBD), the chemokines are increased in the intestinal tissue. The effect of chemokines is mediated by a number of receptors including CCR5. The CCR5 gene is located on chromosome 3 in the genetic region suspected to contain a gene involved in IBD susceptibility. The CCR5 32 base pair deletion (CCR5-D32) which generates a premature protein, has been recently associated with IBD.

Aim of the study : To determine whether CCR5-D32 might form a susceptibility allele for IBD.

Patients and methods : A total of 395 IBD families with at least one affected child were genotyped for CCR5-D32. Out of these families, 247 had only Crohn's Disease (CD) patients, 56 were pure Ulcerative Colitis disease (UC) patients, and 92 mixed families had CD's and UC's patients. The DNA samples of IBD family members were typed by PCR followed by electrophoresis on agarose gel. Genotyping data were analyzed using a transmission disequilibrium test (TDT-like from the Analyse package).

Results : The CCR5-D32 allele was less often transmitted to CD's patients than expected by chance (44 transmitted alleles versus 66 untransmitted ; p = 0.036). No transmission disequilibrium was observed for UC's patients (18 versus 19 ; p = 0,869) or healthy relatives (59 versus 61 ; p = 0,855).

Conclusion : The defective CCR5D32 allele may have a protective effect for CD. Similar results have been reported in both patients infected with HIV and in patients with Rheumatoid Arthritis. Since the RANTES chemokine is overexpressed in CD granulomas, we can postulate that the normal expression of chemokines and their receptors may be necessary to develop an inflammation in IBD patients.

Program Nr: 2691 from the 1999 ASHG Annual Meeting

Etiologic diversity for deafness on the island of Providencia - Colombia. *M.C. Lattig[1], R. Morell[4], T.B. Friedman[4], G. Tamayo[2], J.I. Uribe[3], J.E. Bernal[1], S.L. Plaza[1], M.L. Tamayo[1]*. 1) Instituto de Genetica Humana, Universidad Javeriana. Bogota, Colombia; 2) Fundacion Oftalmologica Nacional, Bogota, Colombia; 3) Hospital San Ignacio - Universidad Javeriana. Bogota, Colombia; 4) National Institute on Deafness and Other Communication Disorders (NIDCD), NIH, Rockville, MD. USA.

Providencia is an island located in the Caribbean Ocean, northwest of Colombia. The island's population is diverse, consisting of individuals from Holland, England, France, Spain and Africans. An unusually high frequency of hearing loss was found on this island (5.0 in 1,000 individuals). Non-syndromic autosomal recessive deafness accounts for 47% (8/17) of the deaf population of Providencia. Waardenburg Syndrome accounts for 29% of the hearing impaired (5/17) with the remaining 24% (4/17) isolated cases of deafness. The 30delG mutation of GJB2, (connexin 26) is responsible for the deafness observed in the 8 individuals with autosomal recessive non-syndromic hearing loss. The isolated individuals with nonsyndromic deafness do not have this mutation. The five cases of deafness associated with Waardenburg Syndrome (WS) show clear autosomal dominant inheritance. They did not carry the 30delG mutation and also appear not to have a mutation in either PAX3 or MITF. The present study reports an isolated and endogamous community with at least two etiologies for deafness.

Program Nr: 2692 from the 1999 ASHG Annual Meeting

PROP1 gene mutation analysis in patients with idiopathic hypogonadotropic hypogonadism. *L.C. Layman[1], J.D. Cogan[2], J. Carneal[2], K.L. Layman[1], D.V. Yu[1], S. Kale[1], J.A. Phillips III[2].* 1) Section of Reproductive Endocrinology & Infertility, Dept OB/GYN, Univ Chicago, Chicago, IL; 2) Division of Genetics, Vanderbilt University, Nashville, TN.

PROP1 gene mutations have been identified in patients with combined pituitary deficiency, who present with short stature, hypothyroidism, and delayed puberty. These patients have deficient levels of growth hormone, thyroid stimulating hormone (TSH), prolactin, luteinizing hormone (LH), and follicle stimulating hormone (FSH). Patients with idiopathic hypogonadotropic hypogonadism (IHH) have delayed puberty with low serum gonadotropin levels, but normal growth hormone, TSH, and prolactin levels. We hypothesized that some PROP1 gene mutations might only result in gonadotropin deficiency, sparing other pituitary hormones. Fifty IHH patients and 30 controls were studied using gene screening techniques. DNA from each patient was amplified by the polymerase chain reaction (PCR) for each of the three exons and splice junctions of the PROP1 gene. PCR products were then subjected to dideoxyfingerprinting and/or denaturing gradient gel electrophoresis (using GC-clamped fragments). Several variant fragments were identified in the IHH patients, but not in controls. Two IHH patients were heterozygous for a silent Pro to Pro change (exon 2 G174A) not seen in any of the 30 controls, and one IHH patient was heterozygous for a 1 bp deletion within intron 1 (IVS 1 delG1031). Although no definitive PROP1 gene mutations have been identified to date, additional variant fragments are currently being characterized. Even if some variants are ultimately demonstrated to represent mutations, PROP1 gene mutations are an uncommon cause of isolated IHH in humans.

Program Nr: 2693 from the 1999 ASHG Annual Meeting

Fragile X syndrome carrier females with full mutations inherited from a normal transmitting male. *L.P. Lazarou[1], S. Warburton[2], C.E. Roberts[1], V.H. Lindley[2], S. Bartlett[1], H.E. Hughes[1], L. Meredith[1], D. Ravine[1]*. 1) Institute of Medical Genetics, University Hospital of Wales, Cardiff, United Kingdom; 2) West Midland Regional Genetics Service, Birmingham,UK.

We report findings in a family having males affected with Fragile X syndrome and a normal transmitting male who has five phenotypically normal daughters, four with one partner and one with another. Two daughters have been shown to have a premutation sized mutations. Two other daughters have fully methylated expansions that were classified as full mutations. One of these daughters with a full mutation smear associated with cytogenetically visible fragile sites in 12% of cells has a Fragile X syndrome affected son. The other with fragile sites in 22% of cells has a fully methylated expansion of approximately 196 repeats. The mother of the full mutation carrying females, tested normal at the FMR1 gene locus. This observation indicates that normal transmitting males for Fragile X syndrome can on rare occasions have offspring with fully methylated expanded alleles.

Program Nr: 2694 from the 1999 ASHG Annual Meeting

Sarcospan-deficient mice maintain sarcolemmal expression of other components of the dystrophin-glycoprotein complex. *C.S. Lebakken[1], D.P. Venzke[1], R.F. Hrstka[2], J.A. Faulkner[3], R.A. Williamson[2], K.P. Campbell[1]*. 1) Departments of Physiology & Biophysics and Neurology, HHMI, University of Iowa College of Medicine, Iowa City, IA; 2) Department of Obstetrics and Gynecology, University of Iowa College of Medicine, Iowa City, IA; 3) Institute of Gerontology, University of Michigan, Ann Arbor, MI.

Sarcospan is a 25-kDa integral membrane component of the dystrophin-glycoprotein complex (DGC). It is unique among the components of the DGC in that it contains four transmembrane domains and intracellular C- and N-terminal domains. Proteins with such topology are known to facilitate protein-protein interactions at the plasma membrane. Sarcospan has recently been shown to be a component of the sarcoglycan sub-complex within both the skeletal and smooth muscle DGC. Stable expression of sarcospan at the sarcolemma is exquisitely dependent upon expression of the sarcoglycan sub-complex as has been shown in mice deficient for a-sarcoglycan and in the BIO 14.6 hamster, animal models for limb-girdle muscular dystrophies. To explore the function of sarcospan we have characterized its expression in embryonic and adult mouse tissues and have developed sarcospan-deficient mice by disruption of the murine sarcospan gene through targeted homologous recombination. Northern blot analysis indicates that sarcospan transcript is first detected between embryonic days 11 and 15, likely coinciding with secondary myogenesis. In embryonic and adult murine tissue, sarcospan protein expression is limited to skeletal, cardiac, and smooth muscle tissues. Surprisingly, sarcospan-deficient mice maintain expression of the other components of the dystrophin-glycoprotein complex at the sarcolemma including the sarcoglycans and a- and b-dystroglycan. No gross histological abnormalities of muscle from the mice have been found, and serum creatine kinase levels are not elevated. Detailed biochemical analysis of the DGC from these mice is currently being perfomed, as well as physiological tests to study their muscle function. To date, there have been no human mutations found within sarcospan that cause a muscular dystrophy which is consistent with this phenotype.

Program Nr: 2695 from the 1999 ASHG Annual Meeting

***NPHS1* Mutations in Non-Finnish CNF Populations.** *H.J. Lee, O. Gribouval, C. Antignac.* INSERM U423, Hopital Necker, PARIS, France.

Congenital nephrotic syndrome of the Finnish type (CNF) is an autosomal recessive disorder caused by mutations in the nephrin gene, *NPHS1*. *NPHS1* consists of 29 exons spanning 26kb of the chromosomal region 19q13.1. Although CNF exists predominately in Finland as a part of the Finnish disease heritage, many cases have been observed elsewhere. Linkage studies of the CNF locus in non-Finnish families correlate with patterns of disease inheritance, and a number of mutations have already been characterized in individuals of non-Finnish origins (*Am. J. Hum. Genet.* 64:51-61, 1999).

In this study, we screened 15 patients of European and North African origins for mutations in all 29 exons of NPHS1 by single strand conformation polymorphism analysis (SSCP) and direct sequencing. We detected a total of 16 mutations in 11 of the patients screened, 6 of the families being consanguineous. Seven of these mutations have been previously described, and 8 are novel. Of the novel mutations, 4 are micro-deletions. Three of these deletions cause frameshifts, leading to truncated proteins. The 4 point mutations lead to the following single amino acid substitutions: R379W, S398P, R460E, P519S. The first of these mutations was found in two patients.

Furthermore, we searched in a GA repeat sequence of the putative promoter region for a (GA) deletion previously suspected of being responsible for the disease (*Am. J. Hum. Genet.* 64:51-61, 1999). A number of $(GA)_n$ deletions (n=1 or 2) were found in a population of healthy individuals unassociated with CNF. The allele frequency (0.04) is far above that which would be expected if a deletion of one or more GA pairs indeed leads to the disease. Therefore, the difference in length of the GA repeat seems to be a polymorphism. We are in the process of screening 18 new non-Finnish patients for mutations in *NPHS1*, permitting additional prenatal diagnoses and the verification of the absence of any genetic heterogeneity. Further characterization of mutations may also allow the identification of functionally important domains of nephrin.

Program Nr: 2696 from the 1999 ASHG Annual Meeting

Novel and prevalent mutations of the LDL receptor gene in Korean patients with familial hypercholesterolemia.

S.-T. Lee[1], J.-H. Kim[1], H.-K. Choi[1], H. Lee[1], H.-Y. Park[2], J.-H. Kim[3], J.-W. Kim[4], H.J. Kim[5]. 1) Dept. of Biochemistry, Yonsei Univ., Seoul, Korea; 2) Yonsei Cardiovascular Research Institute, Yonsei Univ., Seoul, Korea; 3) Dept. of Clinical Pathology, Yonsei Univ., Seoul, Korea; 4) Dept. of Clinical Pathology, Sungkyunkwan Univ., Seoul, Korea; 5) Dept. of Medical Genetics, Ajou Univ., Suwon, Korea.

Familial hypercholesterolemia (FH) is an autosomal dominant genetic disorder caused by mutations in the LDL receptor gene. Although approximately 300 different mutations of the LDL receptor gene have been identified in the FH patients of various races, molecular defects in the Korean patients with FH have little been characterized. To examine kinds and prevalence of point mutations of the LDL receptor gene in the Korean FH patients, we have amplified each of the 18 exons including adjacent intron sequences of the LDL receptor gene by PCR and screened for the presence of mutations by SSCP and heteroduplex analyses. The specific mutations were identified by DNA sequencing of the aberrant exons. Three substitution mutations (E119K, E207K, and P664L), a novel deletion mutation (DM510-I521), a novel insertion mutation (D548insCTAG), and a splicing junction mutation (IVS13-1G®A) were found in the 10 Korean FH patients. Some of these mutations were recurrent in the unrelated patients; DM510-I521 (3 cases), E207K (2 cases), and P664L (2 cases). By RT-PCR of the fibroblast mRNA from the patient with the novel D548insCTAG mutation in which 4 nucleotides, CTAG, were duplicated at the 3' end of the exon 11, we found that the transcript from the mutant locus was not properly spliced and thus would lead to a non-functional truncated polypeptide. This study demonstrates the presence of the novel and prevalent mutations of the LDL receptor gene in the Korean FH patients and also makes it possible to do prognosis and prenatal diagnosis in Korean families at high risk of FH. [Supported by MOST of Korea (MM-1-1)].

Program Nr: 2697 from the 1999 ASHG Annual Meeting

Pseudoxanthoma elasticum maps to an 820 kb region of the p13.1 region of chromosome 16. *O. Le Saux[1], Z. Urban[1], H.H.H. Göring[2], K. Csiszar[1], F.M. Pope[3], A. Richard[3], I. Pasquali-Ronquetti[4], L. Bercovitch[4], M.G. Lebwohl[4], M. Breuning[5], P. van der Berg[5], L. Kornet[5], N. Doggett[4], J. Ott[2], P.T.V.M. Paulus[5], A.A.B. Bergen[5], C.D. Boyd[1]*. 1) Pacific. Biomedical. Research. Center, University of Hawaii, Honolulu, HI; 2) Department of genetics and Development, Columbia University, New York, NY; 3) Institute of Medical genetic, University Hospital of Wales, Cardiff, The United Kingdom; 4) The PXE Consortium and PXE International Inc., Sharon MA; 5) The Netherlands Ophthalmic Research Institute, Amsterdam, The Netherlands.

We have performed linkage analysis on 21 families with Pseudoxanthoma elasticum (PXE) using 10 polymorphic markers located on chromosome 16p13.1. The gene(s) responsible for the PXE phenotype was localized to an 8 cM region of 16p13.1 between markers D16S500 and D16S3041 with a maximum lod score of 8.1 at a recombination fraction of 0.04 for marker D16S3017. The lack of any locus heterogeneity suggests that the major predisposing allele is located in this region. Haplotype studies of a total of 36 PXE families identified several recombinations that further confined the PXE gene(s) to a region between markers D16S3060 and D16S79. This PXE locus was identified within a single YAC clone and several overlapping BAC recombinants. From sequence analysis of the BAC recombinants, it is clear that the distance between markers D16S3060 and D16S79 is about 820 kb and contains a total of 10 genes including 4 pseudogenes. We predict that mutations in one (or more) of the expressed genes in the locus will be responsible for the PXE phenotype in these families.

Program Nr: 2698 from the 1999 ASHG Annual Meeting

Production and characterization of tau transgenic mice. *J. Lewis[1], N. Mehta[1], E. McGowan[1], P. Davies[2], M. Hutton[1]*. 1) Neurogenetics, Mayo Clinc, Jacksonville, FL; 2) Pathology, Albert Einstein College of Medicine, Bronx, NY.

The microtubule associated protein tau, which promotes microtubule assemble and stabilization, has been implicated in various neurodegenerative diseases such as frontotemporal dementia and Alzheimer's disease. Six different isoforms of tau are produced by alternative splicing of exons 2, 3, and 10. In order to explore the role of wild-type and mutant tau isoforms in the neurodegenerative process, we have created multiple lines of tau transgenic mice expressing one of four different tau cDNAs (wild-type 3 repeat, wild-type 4 repeat, V337M 3 repeat, and P301L 4 repeat). The tau cDNAs driven by the mouse prion promoter (moPrP) were individually injected into fertilized eggs (C57BL/DBA2/SW) to yield founder lines. Western analysis using a human exon 1 (E1) specific antibody demonstrated ubiquitous human tau expression in the forebrains of tau transgenic mice. Based on Western analysis with an antibody that recognized human and murine tau isoforms, we have demonstrated a range of expression from endogenous to 10 fold overexpression of human tau when compared to murine tau. In situ hybridization showed the highest levels of expression in the hippocampus, cortex, striatum, and the thalamus. Aging studies of the tau mice as well as tau mice bred to the APP transgenic (Tg2576) mice are currently underway.

Program Nr: 2699 from the 1999 ASHG Annual Meeting

Mutation analysis of the human muscle LIM protein in patients of familial dilated cardiomyopathy. *D. Li, O. Gonzalez, M.A. Quinones, W.A. Zoghbi, R. Hill, L.L. Bachinski, R. Roberts.* Dept. of Medicine/cardiology, Baylor College of Medicine, Houston, TX.

Dilated cardiomyopathy (DCM) is the most common form of primary myocardial disease. Clinically, it is characterized by ventricular dilatation, systolic dysfunction, sudden death, and heart failure. About 50% of DCM is idiopathic, of which at least 20% is familial. Progress in unraveling the genetic causes of idiopathic DCM has been slow compared to that of hypertrophic cardiomyopathy. Using the candidate gene approach, the mutations of cardiac actin and desmin were shown to be responsible for a small portion of familial cases of idiopathic DCM. These emerging evidences support the hypothesis that DCM is a disease of myocardial force transmission, mainly caused by molecular disturbance of cytoskeletal proteins. The striated muscle-specific LIM -only protein (MLP) is a positive regulator of myogenic differentiation. It is highly expressed in the cardiac myocytes during development and in the adult. Recent evidence suggest that MLP may act as a scaffold protein to promote protein assembly along the actin-based cytoskeleton. Interestingly, MLP-knockout mice exhibited the structural and functional abnormality very similar to dilated cardiomyopathy in humans. To determine whether a molecular defect of MLP induces dilated cardiomyopathy in humans, 43 DCM index cases underwent clinical evaluation and DNA analysis. Diagnostic criteria, detected by echocardiography, consisted of ventricular dimension of >2.7 cm/m2 with an ejection fraction <50% in the absence of other potential causes. The exons of the MLP gene were amplified from the genomic DNA of patients by PCR ,and were sequenced in both sense and antisense directions on ABI 310 genetic analyzer. No mutation was found in this group of patients while a previously non-reported silent G/A sequence variation was detected in exon 3 at nucleotide 381 (U72899). Sequence of eighty normal control individuals did not show difference in the frequence of this sequence variation when compare with the DCM patients. Thus, we suggest that MLP defects, if they occur, are not a common cause of familial DCM.

Program Nr: 2700 from the 1999 ASHG Annual Meeting

Intranuclear huntingtin with expanded polyglutamine alters gene expression and cellular function in PC12 cells.
S-H. Li, A.L. Cheng, H. Li, X-J. Li. Department of Genetics, Emory University, Atlanta, GA.

Expanded polyglutamine tracts cause huntingtin and other proteins to accumulate and aggregate in neuronal nuclei. Whether the intranuclear aggregation or localization of a polyglutamine protein initiates cellular pathology remains controversial. We established stably transfected PC12 cells that express the N-terminal fragment of huntingtin containing 20 (20Q) or 150 (150Q) glutamine residues. The 150Q protein is predominantly present in the nuclei, whereas the 20Q protein is distributed throughout the cytoplasm. Electron microscopic examination confirmed that most of the 150Q protein is diffuse in the nucleus with very few microscopic aggregates observed. Compared to parental PC12 cells and cells expressing 20Q, cells expressing 150Q display abnormal morphology, lack normal neurite development, die more rapidly, and are more susceptible to apoptotic stimulation. The extent of these cellular defects in 150Q cells is correlated with the expression level of the 150Q protein. Differential display PCR and expression studies show that cells expressing 150Q have altered expression of multiple genes, including those that are important for neurite outgrowth. Our study suggests that mutant huntingtin in the nucleus is able to induce multiple cellular defects by interfering with gene expression even in the absence of aggregation.

Program Nr: 2701 from the 1999 ASHG Annual Meeting

The role of MSX1 in the Etiology of Congenital Hypdontia. *A.C. Lidral, B. Reising.* Sect Orthodontics, Postle Hall, Ohio State Univ, Columbus, OH.

The homeobox containing genes play a critical role in cell differentiation during the earliest stages of embryogenesis. Expression of the non-clustered homeobox gene MSX1 has been strongly implicated as vital to the normal development of various craniofacial structures. Msx1 homozygous deficient mice display cleft palate, disruption of dental and alveolar development and other craniofacial abnormalities. Previously, an Arg31Pro missense homeodomain mutation in a family with autosomal dominant agenesis of second premolars and third molars has been described. Congenital hypodontia occurs in 2-10% of the population, excluding missing third molars. The biology of dental development involves reciprical epithelial-mesynchymal interactions and thus serves as a model for the development of other organs which also have these interactions. We hypothesize that MSX1 mutations are present in some instances of congenital hypodontia of the permanent human dentition. To test this hypothesis, DNA samples were obtained from the buccal mucosa cells of 92 individuals (82 nuclear families) demonstrating congenital agenesis of at least one permanent tooth with the exception of third molars. A mutation screen of the MSX1 coding region was performed by SSCA of overlapping amplified segments. In this study population only 9% had hypodontia involving 5 or more teeth, while the majority (77%) had hypodontia of only 1 or 2 teeth. A T620A mutation resulting in a Met61Lys substitution, which is in the N-terminal region upstream from of the homeobox, was identified in two siblings from a family with 16 members affected with severe hypodontia segregating in an autosomal dominant manner. This mutation was not found in 80 normal chromosomes. This new mutation, which occurs in a region involved in protein-protein interactions, confirms that MSX1 mutations result in severe congenital hypodontia. The lack of mutations in individuals missing only 1 or 2 teeth suggests that MSX1 is not involved in the etiology of simple hypodontia, but rather it is important for the development of multiple teeth. In addition, the teeth that did develop in these individuals were generally normal, suggesting that MSX1 does not have a major role in determining tooth size and morphology.

Program Nr: 2702 from the 1999 ASHG Annual Meeting

Deletion of Col2A1 IVS7 5donor splice site in Stickler syndrome with SEMD: An expansion of Type II Collagenopathy phenotypic spectrum. *T. Lin[1], F.L. Lacbawan[2], J. Davis[2], M. Muenke[2], L.C. Wong[1], C.A. Francomano[2]*. 1) Inst Molec/Human Genetics, Georgetown Univ Medical Ctr, Washington, DC; 2) National Human Genome Research Institute, NIH, Bethesda MD.

Type II collagenopathy presents in a spectrum of chondrodysplasias with variable severity. In decreasing severity it includes achondrogenesis type 2, hypochondrogenesis, spondyloepimetaphyseal congenita, spondyloepimetaphyseal (SEMD), Kniest dysplasia, and Stickler syndrome. Col2A1 mutations in Stickler syndrome patients are predominantly missense, nonsense and frameshift mutations. However, in the original Stickler syndrome kindred, A to G transition at the -2 3' acceptor splice site of IVS17 eliminates 16bp because a cryptic splice site is utilized. Except for the missense mutation, these changes result in premature termination of translation.

We describe here a 6 yo boy with midface hypoplasia, high myopia, retinal detachment, bilateral SNHL, micrognathia, cleft palate, hyperextensible joints, and joint pains consistent with Stickler syndrome. In addition, he had platyspondyly, abnormal acetabulum, epiphyseal hypoplasia, remarkable metaphyseal flaring with decreased US/LS ratio, prominent clavicle, pectus carinatum, flexion contractures, decreased cervical mobility and kyphosis, and mild developmental delay. With TTGE and sequencing, we found a 4 bp deletion (GTAA) at the +1®+4 5' donor splice site of Col2A1 IVS7 in his leukocyte genomic DNA. The deletion brings a GTAT consensus sequence at the splice junction. Conceivably, this may eventuate in a splicing error or exon skipping. RT-PCR of polyA+ RNA is being done to demonstrate the outcome of the deletion.

The overlapping clinical features of SEMD and Stickler syndrome in this patient extends the phenotypic spectrum of Type II Collagenopathy.

Program Nr: 2703 from the 1999 ASHG Annual Meeting

HNBCoi: A novel Na^+/HCO_3^- cotransporter in the 5q region linked to ovarian dysgenesis and sensorineural deafness (Perrault Syndrome). *L. Lipovich[1], J.M. Opitz[3], J. Morrow[2], M.K. Lee[2], R. Person[2], M.-C. King[2], E.D. Lynch[2]*. 1) Dept. of Molecular Biotechnology, Univ. of Washington, Seattle, WA; 2) Div. of Medical Genetics, Univ. of Washington, Seattle, WA; 3) Primary Children's Medical Center, Salt Lake City, UT.

Perrault Syndrome is characterized primarily by sensorineural autosomal recessive deafness in both males and females, which occurs along with ovarian dysgenesis in the deaf females (Pallister PD, Opitz JM; Am J Med Genet 1979; 4:239-46). Genome-wide linkage analysis of a single large family with the ABI Prism Linkage Mapping Set, Version 2, revealed a region of likely linkage along 5q. The analysis excluded DFNA1 and DFNA15 as candidate loci. Linkage in this region was also found in two smaller, unrelated Perrault Syndrome families. The combined LOD score from these three families was +3.57 at seven markers spanning approximately 3 cM. A search for known genes, transcript identification, and exon prediction were conducted on all publicly available sequences from the region using SeqHelp (Lee MK, et al; Genome Res 1998; 8:306-12). This analysis indicated the presence of a novel Na^+/HCO_3^- cotransporter in the region, which we termed HNBCoi. Due to the relevance of ion channel mutations to inherited deafness, HNBCoi is currently being analyzed as a Perrault Syndrome candidate gene. SeqHelp analysis and sequencing of IMAGE clones corresponding to HNBCoi enabled us to identify 1036 nt of contiguous cDNA sequence, partially determine the genomic structure of HNBCoi, and sequence portions of the gene in the three affected families. To localize the 5' end of the gene, RACE and cDNA library screening are being conducted. LD-PCR has been used to amplify previously unknown genomic sequence containing the 3' end of the gene. Northern blot analysis yielded 4.3-kb and 6.0-kb transcripts at high levels in the kidney, with no expression in the heart, brain, placenta, lung, liver, skeletal muscle, or pancreas. We successfully detected an HNBCoi transcript in ovarian mRNA by RT-PCR, with sequence identical to that of the IMAGE clones. Ovarian expression of HNBCoi is interesting in the light of ovarian dysgenesis in Perrault Syndrome.

Program Nr: 2704 from the 1999 ASHG Annual Meeting

Aminoterminal end of the single CLD gene transcript is posttranslationally cleaved both in normal and inflammatory colon epithelium. *H. Lohi[1], S. Haila[1], P. Hoglund[1], P. Puolakkainen[2], J. Kere[3].* 1) Dept. of Medical Genetics, Haartman Institute, Helsinki, Finland; 2) Dept. of Surgery, Helsinki Univ. Central Hospital, Helsinki, Finland; 3) Finnish Genome Center, University of Helsinki, Helsinki, Finland.

Congenital chloride diarrhea (CLD) is a recessively inherited disorder of intestinal electrolyte absorption involving Cl-/HCO3- exchange. In CLD patients, watery stools containing an excess of chloride begin before birth, leading to polyhydramnios and often premature birth. Neonates develop dehydration and electrolyte disturbancies. The CLD gene encodes a Na+ independent anion exchanger expressed mainly in the apical surface of the colonic epithelium. We have studied the expression and processing of the CLD protein and mRNA in normal and inflammatory colon tissues. We produced rabbit polyclonal antibodies against different regions of the CLD protein. We found that about 10 kDa, corresponding to approximately the first two coding exons of the aminoterminal end of the CLD protein is posttranslationally cleaved, leading to the functional size of the protein of about 75 kDa. The aminoterminal antibody recognizes only the larger about 85 kDa proform of the CLD protein both in normal and inflammatory colon epithelium in Western analysis. Carboxyterminal antibodies recognize both the pro- and functional forms of the protein, suggestive for the aminoterminal cleavage. Futhermore, a single transcript for the gene in Northern analysis and in 5 RACE experiments suggest posttranslational cleavage of the protein rather than differentially spliced forms of the gene. There are no differences in the expression or processing of the CLD protein in inflammatory colon cells compared to normal colon. So far we have found three disease-causing point mutations in addition to three frameshift mutations in the aminoterminal region of the CLD gene. The three inframe mutations suggest that the aminoterminus is necessary for the proper processing or function of the protein. Ongoing studies try to resolve the functional roles of the amino- and carboxyterminus and effects of the mutations for processing and targeting in different cell lines.

Program Nr: 2705 from the 1999 ASHG Annual Meeting

A physical and transcriptional map of the SPG9 locus on 10q23.3-q24.2. *C. Lo Nigro[1], R. Cusano[1], M. Scaranari[1], V. Brescia Morra[2], G. De Michele[2], R. Ravazzolo[1,3], M. Seri[1].* 1) Lab. Molecular Genetics, Gaslini Institute, Genoa, Italy; 2) Dept. Neurological Science, Federico II University, Naples, Italy; 3) Dept. Oncology, Biology and Genetics, University of Genoa, Italy.

We have recently identified the SPG9 locus (OMIM:601162) on chromosome 10q23.3-q24.2, in a 12 cM interval between markers D10S564-D10S603. Using a genomewide approach in a large Italian family, we mapped this rare form of autosomal dominant spastic paraparesis complicated by amyotrophy, bilateral cataracts, gastroesophageal reflux with persistent vomiting. In order to identify the gene responsible for the disease, we constructed a contig of 19 YACs and we positioned 16 markers, which were used in the linkage analysis performed on the original pedigree. Based on these physical data, the estimated size of the critical region is about 6-7 Mb. GeneMap 99 reports 173 ESTs in the D10S564-D10S603 interval, which could represent candidate genes because of their location and function or expression. A bioinformatic approach, based on BLASTN and BLASTX, allowed us to cluster those ESTs belonging to the same transcript and to reduce to 118 the number of single transcripts. We are constructing a transcriptional map of the SPG9 locus, positioning by PCR the ESTs on the YACs contig. Firstly, we are selecting transcripts which: - are specifically expressed in brain; - contain a trinucleotide repeat, as suggested by the presence of the anticipation phenomenon in the original pedigree; - encode for mitochondrial proteins, since recently a nuclear-encoded mitochondrial metalloprotease has been demonstrated to be involved in a recessive form of spastic paraplegia in 16q24.3. In particular, we positioned within the critical region the COX15 gene, which is a constituent of the inner mitochondrial membrane and may be involved in the assembly of the Cytochrome-c oxidase (COX) protein backbone. COX15 cDNA analysis on RNA extracted from cultured fibroblast cells of an affected member of the original family is in progress. Histologic, histoenzymatic and ultrastructural studies of a muscle biopsy sample from the same patient is going on to test the possible mitochondrial involvement in the pathogenesis of the disease.

Program Nr: 2706 from the 1999 ASHG Annual Meeting

A candidate gene approach in Xcen-Xq21 toward the cloning of the FG syndrome gene (FGS1). *A.M. Lossi[1], L. Villard[1], L. Colleaux[1], S. Briault[2], C. Moraine[2], C. Schwartz[3], M. Fontes[1].* 1) INSERM U491, Faculté de Médecine La Timone, 27 Bd. Jean Moulin 13385 Marseille, France; 2) Dpt. de Génétique, INSERM U316, CHU Bretonneau, 37044 Tours, France; 3) Greenwood Genetic Center, Greenwood SC, USA.

FG syndrome (MIM 305450) is an X-linked mental retardation syndrome characterized by severe mental retardation, macrocephaly, facial dysmorphism and anomalies of the development of the distal part of the digestive tract, often resulting in anteposed or imperforated anus. Linkage studies have demonstrated that a gene (FGS1) responsible for the disease in 80% of the FG syndrome families is located in the Xq12-Xq21 region of the human X chromosome (with a Zmax=3.39 at theta=0 for DXS441 in a study based on 10 families). In a first step, we tested the potential involvment of the XNP gene which is located in the linkage interval (and close to the marker giving the maximal value of Z) and is responsible for a mental retardation syndrome associated with developmental anomalies (ATR-X and Juberg-Marsidi syndromes). We have analyzed the XNP genomic region and transcript from two FG patients, members of families linked to the region, and have found no abnormality. This result probably rules out the involvment of the XNP gene in the etiology of the FG syndrome. Since the available families are small, the linkage interval in which the causative gene is located remains large. This is the reason why we have undertaken a systematic candidate gene approach in this region of the human X chromosome to identify the FG syndrome gene. In a second step, we are thus currently using a detailed transcriptional map of Xcen-Xq21 to apply a systematic candidate gene approach. Data will be presented based on the analysis of ten different candidate genes.

Program Nr: 2707 from the 1999 ASHG Annual Meeting

ISOLATION OF THE PROMOTER REGION OF THE WD GENE AND CHARACTERIZATION OF THE MOST FREQUENT MUTATION IN THE SARDINIAN POPULATION. *G. Loudianos[1,2], V. Dessi[2], M. Lovicu[3], A. Angius[4], A. Figus[5], F. Lilliu[1,2], S. De Virgiliis[2], V. Deidda[2], P. Moi[1,2], M. Pirastu[4], A. Cao[1,2,3]*. 1) Ospedale Regionale per Le Microcitemie, ASL 8, Cagliari; 2) ICBEE- Università di Cagliari; 3) IRTAM CNR-Cagliari; 4) IGM CNR-Alghero; 5) IMI, Università di Cagliari.

As reported in our previous studies, despite an extensive characterization of the coding and splicing regions of the Wilson disease (WD) gene we had before failed to define the disease-causing mutation of the most common haplotype in the Sardinian population, which accounts for 60.5 % of the WD chromosomes. In order to extend our mutation analysis to the 5' UTR and to the promoter region, we have obtained and analysed 1,228 bp of novel 5 sequences. This DNA region was predicted by NIX analysis to contain two promoters oriented in a divergent, head to head fashion. The promoter immediately 5 to the WD gene contained a GC-rich island, a CAAT and a TATA consensus sequences as well as potential binding sites for transcription factors and metal responsive elements, all features suggestive of an housekeeping and metal regulated gene as it was expected for the WD gene. Comparative sequence analysis of this putative WD promoter region has led to the discovery of a 15nt deletion at -427 bp from the translation start site in all the 92 Sardinian chromosomes carrying the most common WD haplotype. Functional studies with a luciferase reporter gene demonstrated a 75% reduction in the transcriptional activity of the mutated promoter sequence compared to the normal control. These data clearly indicate that the fragment we have analysed contains the whole WD promoter and that the 15nt deletion is the disease-causing mutation associated with the common Sardinian WD haplotype. The addition of this novel common mutation brings the rate of the characterized WD mutations in Sardinian chromosomes to 92%. Thus the high frequency of the WD in Sardinians and the almost complete coverage of the mutations by DNA analysis make now feasible and convenient a newborn screening program that should allow early diagnosis and prevention of the Wilson disease progression at a preclinical stage.

Program Nr: 2708 from the 1999 ASHG Annual Meeting

Toward the elucidation of the molecular mechanism of the genomic recombination leading to duplication/deletion rearrangement associated with Pelizaeus-Merzbacher disease. *J.R. Lupski[1], J. Takanashi[2], K. Murayama[3], T.D. Bird[4], K. Inoue[1]*. 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Pediatrics, Chiba University, Chiba, Japan; 3) Pediatrics, National Rehabilitation Center for Disabled Children, Tokyo, Japan; 4) Neurology, University of Washington, Seatle, WA.

Duplication of the genomic region containing the *PLP*gene is the major cause of the CNS dymyelinaing disorder, Pelizaeus-Merzbacher disease (PMD). Rarely, deletion of the *PLP*gene is also responsible for PMD. We investigated the hypothesis that unequal sister chromatic exchange in male meiosis is likely to be the common mechanism for the recombination of the duplicated genomic region, even though the breakpoints of the duplications are strikingly variable. Here we show further findings to clarify the molecular mechanism of the *PLP*dulication/deletion. In two families with different size duplications, we performed interphase FISH and haplotype analyses on maternal grandparents to determine that the duplications actually occurred in the male meiosis by the sister chromatic exchange. In one family with *PLP*deletion, submicroscopic interstitial translocation of the Xq22 to 19qter was identified in the patient's mother, which resulted in the *PLP*deletion in the patient. Sequencing analysis of the breakpoint showed that *Alu-Alu* recombination is the mechanism. Breakpoints of another *PLP*deletion family have been mapped in a different region with those of the *PLP*duplications, suggesting different genomic mechanism between duplication and deletion. These data indicate complex genomic structure and mechanism of the rearrangement leading to duplication/deletion of the *PLP*gene.

Program Nr: 2709 from the 1999 ASHG Annual Meeting

A splicing mutation in dysferlin produces limb-girdle muscular dystrophy with inflammation. *C.T Ly[1], H. Rosenmann[2], S. Rosenbaum[3], D. Soffer[2], W. Jiang[1], L.V.B. Anderson[4], Z. Argov[2], E.M. McNally[1]*. 1) Medicine, Univ of Chicago, Chicago, IL; 2) Neurology, Hadassah University Hospital; 3) Mol Biol and Genetic Engineering, Hadassah University Hospital, Jerusalem, Israel; 4) Neurology, Univ. of Newcastle, Newcastle on Tyne.

Mutations in dysferlin were recently described in patients with both the mild Miyoshi Myopathy and the more severe Limb-Girdle Muscular Dystrophy (LGMD) type 2B (Bashir et al., Liu et al., 1998). Despite striking phenotypic differences, the types of dysferlin mutations associated with Miyoshi Myopathy and LGMD type 2B do not differ significantly. To extend the phenotype associated with dysferlin mutations, we have identified a large inbred pedigree of Yemenite Jewish descent that exhibited limb-girdle muscular dystrophy. The phenotype in these patients includes progressive, proximal muscular weakness with markedly elevated serum creatine kinase levels. In contrast to Duchenne Muscular Dystrophy and sarcoglycan-mediated LGMDs, these LGMD 2B patients have normal development and muscle strength and function until the late second decade. Furthermore, muscle biopsies from two affected patients show an inflammatory pattern that is mainly perivascular but also intrfascicular. Linkage analysis revealed a locus at chromosome 2p16 (D2S292, Z = 3.35, q = 0). A novel mutation producing a G to A bp alteration was identified. This mutation is predicted to affect position 5 in the intron following aa 1686, (5711 bp) of the dysferlin cDNA sequence. We found this mutation alters an acceptor site resulting in cryptic splicing and no normal dysferlin mRNA synthesis. Dysferlin is a novel protein of unknown function. Sequence comparisons suggest that dysferlin may be important for membrane fusion in muscle. Thus, splice site mutations that disrupt dysferlin appear to cause a phenotype that may be consistent with a membrane fusion defect. The etiology of the inflammatory response remains unexplained.

Program Nr: 2710 from the 1999 ASHG Annual Meeting

Towards new mouse models for Duchenne Muscular Dystrophy. *R.G.H.J. Maatman[1], E.J. de Meijer[1], J.J. Heus[2], G.J.B. van Ommen[1], J.T. den Dunnen[1]*. 1) Dept Human and Clinical Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) Pharming Holding N.V., Leiden, Netherlands.

Duchenne Muscular Dystrophy (DMD) is caused by mutations in the 2.4 Mb dystrophin gene, affecting 1:3500 new born males worldwide. For DMD the mdx-mouse is the preferred model, but, for specific purposes the value of the mdx-mouse model is limited. We are currently generating a mouse model, using the Cre/loxP technology, carrying a deletion of the entire dystrophin gene and a "humanized" dystrophin mouse. Introduction of a loxP site in dystrophin's first and last exon by homologous recombination in mouse embryonic stem (ES) cells and subsequent Cre-recombinase introduction results in lines, lacking the entire dystrophin gene. The mdx0 mouse facilitates transgenic experiments directed at the elucidation of the function of individual dystrophin isoforms. In addition, it will allow to study gene therapy by providing a tool to evaluate the therapeutic potential of gene transfer protocols, especially regarding the immunogenic rejection of the expressed dystrophin. To generate a "humanized" dystrophin mouse a 2.6 Mb YAC containing the human dystrophin gene was constructed and transferred to ES cells, using spheroblast fusion. Two ES cell lines showed stable integration of the YAC without any detectable dystrophin gene rearrangements. Dystrophin expression was detected, using specific antibodies after MyoD induced in vitro differentiation. Both ES cell lines have been used to generate chimeric mice which are currently being crossed to obtain germline transmission. Analysis of one of the chimera by RT-PCR and Western blotting showed expression of the full-length human dystrophin gene in muscle tissue, proving the presence of all elements to direct tissue specific expression. Crossing these transgenic mice onto mdx0 mice lacking dystrophin will give a "humanized" dystrophin mouse, facilitating specialized studies e.g. testing protocols for gene therapy by modification of splicing in vivo.

Program Nr: 2711 from the 1999 ASHG Annual Meeting

The common CFTR deletion of Slavic descent, CFTRdele2,3(21kb), is associated with severe cystic fibrosis phenotype: a matched case control study in 30 Czech patients. *M. Macek Jr[1], T. Dörk[3], D. Zemkova[2], A. Krebsova[1], M. Koudova[1], I. Sakmaryova[1], M. Macek Sr.[1], V. Vavrova[2].* 1) Inst. Biol & Med. Genetics, 2nd Sch. Med & UH Motol, Prague, Czech Rep; 2) II. Dept. Pediatrics, Charles Univ., UH Motol-Prague, Czech Rep; 3) Inst. Hum. Genetics, MHH, Hannover, Germany.

The recently identified cystic fibrosis transmembrane conductance regulator (CFTR) gene deletion, CFTRdele2,3(21kb), spanning introns 1 to 3 (www.genet.sickkids. on.ca/cftr/) is one of the most common CFTR mutations in European populations with the current or historic Slavic presence (Dork et al. 1999)-Russia, Ukraine, Poland, Austria, Germany, Slovenia, Slovakia, Lithuania, Latvia and Macedonia in an decreasing order; range 0.9%-6.4% of all CF chromosomes. It was found in 40/628 (6.4%) of Czech CF chromosomes by using a rapid PCR-based assay. It is our 2nd most common CF allele that raised the total mutation detection rate to > 95%. In all cases it is associated with uncommon CF-linked "A" (Km19-XV2c) and STR intragenic "16-33-13" (IVS8CA-IVS17bTA-IVS17bCA) haplotypes. One patient was homozygote, 30 were compound heterozygote (CH) with DF508, while 8 cases were CH with other CF alleles (G551D, G542X, N1303K, 2143delT, R1162X, 1898+1G->A). In 30 CFTRdele2,3(21kb)/DF508 CH a matched case-control study (for sex, closest age and level of therapy) with DF508 homozygotes (DF508/DF508) was performed. Semi-longitudinal study was carried out versus a group of 151 DF508/DF508. This deletion is a severe CF allele, with all patients being PI, comparable to the DF508/DF508. However, meconium ileus (MI) and DIOS are more frequent (11/30; p=0.002), despite the comparable frequency of other GI complications. This implies that our patients were diagnosed earlier than DF508/DF508 (at 0.8+1.9 years; p=0.014), but do not have a less favorable survival than DF508/DF508. Our data indicate that patients with yet unidentified CF alleles, in particular suffering from MI or DIOS, should be screened for the CFTRdel21kb mutation. Screening for this deletion may also significantly improve prenatal and postnatal diagnosis of CF in families of Slavic origin in Canada and United States. Supported by IGA MZCR (2056-5, 2899-5, 3526-3, 4124-3); OK192.ö.

Program Nr: 2712 from the 1999 ASHG Annual Meeting

Mutational Analysis of the SMN-associated genes SmN and SIP1. *M.D. Mailman[1], K.Y. Alam[1], A.H.M. Burghes[2], T.W. Prior[1]*. 1) Department of Pathology, Ohio State Univ, Columbus, OH; 2) Department of Medical Biochemistry, Ohio State Univ, Columbus, OH.

Although we now have a highly sensitive and specific direct molecular test for 5q-SMA, the clinical diagnosis is not as straightforward. In our experience, we have found that approximately 50% of the cases sent to the molecular diagnostic lab do not have deletions of the SMN gene. These patients all share some clinical features of SMA, ranging from the more severe type I to the milder type III. Recent reports have shown that SMN interacts with SIP1 and with several of the snRNP Sm core proteins, including SmN. SIP1 colocalizes with SMN in nuclear bodies called gems and this complex is believed to be important for pre-mRNA splicing via its role in snRNA metabolism. It is possible that mutations in the proteins that interact with SMN and its biochemical pathway might produce a phenotype resembling SMA. Only the cDNA sequence of SIP1 and SmN have previously been published. Therefore, to screen patients for mutations in these genes, intron/exon borders had to be identified so that intronic primers could be used for exon screening. Intron/exon borders were identified using the vectorette PCR and long PCR techniques. Heteroduplex analysis was then used to screen individual exons for mutations. We show here that the SmN gene contains 7 exons. Thus far, we have screened 99.7% and 27% of the SmN and SIP1 coding sequences, respectively, for mutations. A rare polymorphism has been found in exon 5 of the SmN gene, however no mutations have yet been identified in 203 patients with clinical symptoms resembling SMA who are SMN-positive. Since SIP1 and SmN are among the first proteins that have been shown to directly associate with SMN, they are potential candidates for mutation analysis. However, mutations have not been identified. Therefore, we believe that mutations in these genes are not a predominant cause of an SMA-like phenotype.

Program Nr: 2713 from the 1999 ASHG Annual Meeting

A novel frameshift mutation in the ATP7B gene in Saudi Wilson disease patients. *R. Majumdar[1], M. Al Jumah[1], S. Al Rajeh[2], A. Awada[1], A. Al Zaben[1], A. Al Traif[1], M. Fraser[3], S. Al Uthaim[1], A. Snellen[1], M. Paterson[3].* 1) Division of Neurology, Dept of Medicine, King Fahad Natl Guard Hosp, Riyadh, Saudi Arabia; 2) Division of Neurology, King Saud University, Riyadh, Saudi Arabia; 3) Department of Biological and Medical Research, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

Wilson disease (WD) is an autosomal recessive disorder of copper metabolism culminating in liver, brain, and kidney damage. ATP7B, the gene mutated in WD, contains 21 exons and encodes a copper transporting ATPase. Numerous mutations, all of which are located in the first twenty exons have been reported among different ethnic groups. In this study, we have screened for mutations in the ATP7B gene in fifteen Saudi WD patients representing different tribes. In all patients, the entire gene coding sequence, in addition to the intron-exon boundaries, were screened for alterations by conventional mutation detection enhancement (MDE) heteroduplex analysis, followed by direct sequencing of the regions that showed heteroduplex formation. A novel homozygous mutation (4193delC) in exon 21, causing a frameshift leading to premature truncation of the protein, was detected in seven of fifteen patients. This mutation was not found in a total of 55 normal Saudi subjects (i.e. 110 chromosomes). To our knowledge, this is the first time a mutation has been detected in exon 21 of ATP7B (hydrophilic C-terminus of the open reading frame). The finding that all seven Saudi WD patients from different tribes have consistently shown the same mutation in exon 21 of the ATP7B gene, strongly suggests that 4193delC is a unique mutation for Saudis, especially that this mutation was not described in other ethnic groups. This finding may also provide insight into the function of the long stretch of the C-terminal hydrophilic domain on the ATP7B protein. (This work was supported by KACST Project AT 18-03, Saudi Arabia).

Program Nr: 2714 from the 1999 ASHG Annual Meeting

Novel *FGFR2* mutation associated with a partial Apert syndrome phenotype. *D.K. Manchester[1,2], J.K. Allen[1,2], M. Handler[3], F.V. Schaefer[4].* 1) Div Genetics Services, The Children's Hosp, Denver, CO; 2) University of Colorado Health Sciences Center, Denver, CO; 3) Rocky Mountain Pediatric Neurosurgery,P.C., Denver, CO; 4) H.A. Chapman Institute of Medical Genetics, Oklahoma City, OK.

Several distinct phenotypes with craniosynostosis - Crouzon, Apert, Pfeiffer and Jackson-Weiss syndromes - are associated with missense mutations in the human gene for Fibroblast Growth Factor Receptor 2 (FGFR2), a transmembrane tyrosine kinase receptor with three extracellular immunoglobulin(Ig)-like domains. The mechanisms responsible for these phenotypes are not understood. Missense mutations in the linker region between the second and third extracellular Ig domains of FGFR2 are associated with Apert syndrome (AS, acrocephalosyndactyly). We have ascertained a patient with a partial AS phenotype in whom we have detected a novel missense mutation outside the Ig-like loops of FGFR2. This female infant presented at birth with facial features (hypertelorism; high, broad, flat forehead; downslanting palpebral fissures; midface hypoplasia; depressed nasal bridge with beaked nose) and radiographic findings (bilateral coronal synostosis with expansion of the temporal regions; small cranial base; unilateral anomalies of the cochlea, middle ear ossicles and external canal; fusion of cervical vertebra, C5-C6) felt to be typical of AS. Hands, however, had no syndactyly. Fingers were tapering and there were unusual palmar creases but thumbs were normal. She developed hydrocephalus at 4 months. Molecular analysis of *FGFR2* performed by PCR amplification of exons 7 and 9 and DNA sequencing (ABI model 373) revealed her to be heterozygous for a C to T transition changing codon 355 from alanine to valine (ala355-to-val). Parents had normal examinations and neither carried the ala355-to-val variant. No point mutations in *FGFR1* and *3* were found in any of the three family members. Anderson *et al.* (1998, *Hum. Molec. Genet.* 7: 1475-1483) have presented evidence that missense mutations previously associated with AS affect FGFR2 dissociation kinetics *in vitro*. The apparent novel mutation found in this patient would also be expected to have limited impact on overall protein structure.

Program Nr: 2715 from the 1999 ASHG Annual Meeting

Emerin is associated with lamin A/C in one subset of kidney cell nuclei while lamin B1 is present in the emerin-negative nuclei. *S. Manilal, N.T. Man*, C.A. Sewry, G.E. Morris.* MRIC Biochemistry Group, N. E. Wales Institute, WREXHAM, UK.

The X-linked form of Emery-Dreifuss muscular dystrophy (EDMD) is caused by mutations in the nuclear membrane protein emerin, while mutations in lamin A/C of the nuclear lamina are responsible for most cases of autosomal dominant EDMD. The two forms have a similar phenotype, with cardiac and skeletal muscle affected, suggesting a functional relationship between the two proteins. Direct interaction between emerin and lamin A/C has not yet been demonstrated, but remains a strong possibility.

In an earlier study (Manilal et al, Hum. Mol. Genet. 8 (1999) 353), lamin B1 was virtually undetectable immunohistochemically in emerin-positive cardiomyocyte and skeletal muscle nuclei, but levels of this protein were high in nuclei without emerin. We now present evidence supporting an association of emerin with lamin A/C, but not lamin B1, in the pig kidney. Triple-labelling was performed using a rabbit antiserum against emerin, mouse monoclonal antibodies against lamins and a DAPI stain for nuclei. In kidney glomeruli, about half the nuclei stained for both emerin and lamin A/C, but not lamin B1, and the other half stained for lamin B1 only. Kidney tubule nuclei were emerin-negative and lamin B1-positive. Similar mutual exclusivity was observed in other tissues, such as spleen, heart and skeletal muscle, but not in all tissues. It is not yet clear whether absence of immunostaining is due to absence of the antigen or epitope masking by other nuclear proteins. However, EDMD carrier skin biopsies, in which 50% of cells are emerin null mutants, showed no variation in lamin immunostaining, which shows that emerin does not mask the lamin B1 epitope.

The results are consistent with functional interaction between emerin and A-type lamins. The absence of lamin B1 staining is not restricted to the affected tissues in EDMD.

We thank the British Heart Foundation for grant support (PG97142) and Yves Raymond (Montreal) for lamin mAbs..

Program Nr: 2716 from the 1999 ASHG Annual Meeting

Extrachromosomal Amplification of a *CFTR* YAC in a Cystic Fibrosis Airway Epithelial Cell Line. *M.K. Mansoura, K.A. Henning, E.A. Novotny, S.T. Compton, A.P. Chetty, M.A. Ashlock.* Genetics and Molecular Biology Branch, NIH/NHGRI, Bethesda, MD.

We attempted to correct the cystic fibrosis (CF) phenotype in CF airway epithelial cell lines by introducing the full-length 250 kb *CFTR* gene and 300 kb of 5' flanking DNA in a YAC containing a neo^R gene for selection in mammalian cells. Two restriction sites have been engineered into the 3' untranslated region (UTR) of the *CFTR* gene, allowing for the unique identification of YAC-derived *CFTR* DNA and RNA. Stable neo^R CFT1 (n=5)and IB3-1 (n=7) CF airway epithelial clones were derived by transfection of gel-purified YAC DNA. Southern blot analysis indicated that the 3' UTR of *CFTR* derived from the YAC was present at single copy in the IB3 clones. However, this region of the gene was amplified greater than 10-fold in the three CFT clones analyzed thusfar. This level of amplification was present after more than 20 passages in culture but diminished significantly, but not completely, when the cells were taken off selection. Fluorescent in-situ hybridization (FISH) analysis revealed a single site of integration in each of the IB3 clones. In striking constrast, the *CFTR* YAC was present in extrachromosomal elements in the 3 CFT clones. In addition to the somewhat heterogeneous size appearance of these signals, the number of signals varied from metaphase-to-metaphase (n=0 to >50) in these clones indicating that they were not mitotically stable. Pulsed-field gel electrophoresis of one of these CFT clones in the presence and absence of gamma irradiation indicated that the extrachromosomal elements were most likely circular and greater than 6 MB in length. Future experiments are designed to further identify (1) the content and stability of these extrachomosomal elements, and (2) the critical factors which led to their generation. Specifically, to address the latter, we have repeated the transfection experiment in the same two cell lines using a comparably-sized YAC which does not contain the *CFTR* gene. Neo^R clones from each cell line have been derived and are being expanded in culture for future analysis.

Program Nr: 2717 from the 1999 ASHG Annual Meeting

Genetic and transcritpion analysis in Rett syndrome. *E. Manzati[1,2], S. Bigoni[1], F. Gualandi[1], C. Scapoli[3], M. Guarna[4], G. Pini[5], M. Zappella[4], F. Muntoni[2], G. Hajek[4], E. Calzolari[1], A. Ferlini[1,2].* 1) Istituto di Genetica Medica, Universita' di Ferrara, Ferrara, Italy; 2) Neuromuscular Unit, Imperial College School of Medicine, Hammersmith Campus, London, UK; 3) Sezione di Biologia Evolutiva, Universita' di Ferrara, Ferrara, Italy; 4) Neuropsichiatria Infantile, Policlinico Le Scotte and Istituto di Istologia, Universita' di Siena, Siena, Italy; 5) Servizio di Neuropsichiatria Infantile, Azienda USL12, Viareggio, Italy.

Rett syndrome (RS), a severe progressive neurodegenerative disease, is predominantly sporadic but the existence of several families with recurrence of the disease reinforces the view that this pathology represents a genetic entity. The evidence that RS affects females only has also suggested an X-linked dominant inheritance and linkage analysis has recently mapped the RS locus to Xq28. In order to investigate the molecular defect of this disease we performed transcription analysis on an autoptic specimen from a RS brain cortex as well as on several normal adult and foetal cerebellum and brain tissues. We have studied the transcription pattern of the following four known genes, previously mapped to Xq28: interleukin 9 receptor gene (IL9R), host cell factor 1 gene (HCF1), melatonin-related receptor gene (GPR50), putative new subunit class (e) of the GABA-A neurotransmitter receptor gene (GABRE). Total RNA was extracted from frozen tissues, RT-PCR method was carried out using four pairs of oligonucleotides designed to amplify specific regions of the candidate genes transcripts. The RS brain cortex exhibited an identical transcription pattern to that found in the normal tissues. In order to confirm the Xq28 mapping, we collected DNA from a very large Italian pedigree with RS recurrence, already reported by our group. A preliminary segregation analysis showed as both the autosomal recessive and the X-linked model of inheritance are compatible with the pedigree configuration. We are studying this pedigree using several polymorphic markers mapped in Xq28. In addition we are exploring in this family a polymorphic (CAG)n repeat located in exon 9 of IL9R gene both for linkage analysis and for evaluating the possibility of a triplet repeat expansion mutation.

Program Nr: 2718 from the 1999 ASHG Annual Meeting

Mutation analysis of Krabbe Disease and Metachromatic Leukodystrophy in Portugal. *A.M.L. Marcao, O.M.O. Amaral, E.M. Pinto, M.C. Sa Miranda.* Genetic Neurobiology, IBMC- Univ.of Porto, Porto, Portugal.

The molecular characterisation of Portuguese MLD and KD patients was carried out in order to identify the molecular lesions underlying the biochemical deficits. In the case of MLD, the application of PCR-RFLP and PCR-SSCP analysis allowed a 100% rate of mutation identification; eight different mutations were identified. The I allele was found at a very high frequency (64%), whereas the A allele represented only 3,5% of the mutated MLD alleles. As expected, all the homozygotes for the I allele presented the late infantile form, making it much more frequent than the juvenile and adult forms. Two previously described missense mutations (I179S; D255H), here associated to adult and late infantile MLD were both found in heterozygosity with allele I. Two new missense mutations (C300F; P425T) were found to be associated to late infantile and juvenile forms and two novel microlesions (g.2408delC and g.1190-1191insC) were identified in two late infantile patients. The haplotypes previously proposed for I, A, I179S and D255H mutations were confirmed, suggesting the possible existence of common ancestors. With regard to KD, although all patients presented the infantile form, large molecular heterogeneity was found. In this case, the approach followed consisted on RT-PCR-SSCP analysis. In addition to the five mutations previously identified, in a collaborative study with Dr. Wenger, four other mutations and several polymorphic changes were found. Of the nine mutations identified four led to deletions, one was nonsense and four were missense mutations, three alleles remain undefined. It should be noted that only one of the deletions (del30-kb, ex11-17) and one of the missense mutations (T513M) are known to be common in North European KD patients, all other mutations seem to be private and appear in various polymorphic backgrounds. As described for patients with North European ancestry, mutations del30Kb and T513M appeared associated with polymorphisms 502T and 694A, respectively. The molecular findings here reported may provide useful information for the study of other populations, since different mutation profiles were found in Portuguese patients.

Program Nr: 2719 from the 1999 ASHG Annual Meeting

Mutation Screening in the CYP1B1 Gene of German Primary Congenital Glaucoma Patients. *C.Y. Mardin[1], M. Zenker[2], U. Mayer[1], G.O.H. Naumann[1], B. Rautenstrauss[2], K. Michels-Rautenstrauss[2].* 1) Department of Ophthalmology, FAU Erlangen-Nuremberg, Erlangen, bavaria, germany; 2) Institute of Human Genetics, Erlangen, Germany.

Autosomal recessive primary congenital open-angle glaucoma (buphthalmus) is caused by developmental defects of the trabecular meshwork and the anterior chamber of the eye. Two chromosomal locations on 2p21 (GLC3A) and 1p36 (GLC3B) are known to be associated with this condition. For GLC3A-linked families a series of mutations in the cytochrome P4501B1 (CYP1B1) gene were found to be the predominant cause of buphthalmus. One half of the known mutations, including 1 nonsense, 6 frameshifts and one large deletion are predicted to truncate the CYP1B1 open reading frame, whereas the other half are missense mutations in highly conserved positions. A mutation screening in buphthalmus patients by direct sequencing of exon 2 and 3 of the CYP1B1 gene revealed a novel mutation in exon 3. A newborn male with opaque corneae was detected to show on the forth day after birth intraocular pressures under general anaesthesia of 34/37 mmHg (R/L), Haab's lines, axial lengths of 20.6 mm and corneal diameters of 13.0x12.0 mm. No family history for glaucoma was known. The parents were consanguinous. The homozygous missense mutation Arg355Stop found, truncates the protein by 188 aminoacids including the functionally essential hem binding site. Furthermore we identified five of the six known polymorphisms. Thus our results confirm the crucial role of CYP1B1 in primary congenital glaucoma.

Program Nr: 2720 from the 1999 ASHG Annual Meeting

A null a**1(V) collagen allele in a family with type II Ehlers-Danlos Syndrome causes variation in type I collagen fibril diameter.** *J.C. Marini[1], P. Bouma[1], W.G. Cole[2], J.B. Sidbury[1]*. 1) Sect Connective Tissues Disord, HDB/NICHD/NIH, Bethesda, MD; 2) Division of Orthopaedics, The Hospital for Sick Children, Toronto, Ontario M5G1X8, Canada.

Splicing defects in the a1 and a2 chains of type V collagen have been identified in several families with EDS I-II. We studied a three generation family with EDS II. They show skin laxity, small joint hypermobility, easy bruising and occasional cigarette paper scars. RT-PCR amplification using primers in exons 9 and 28 of a1(V) cDNA yielded normal and larger products from the proband. Sequencing revealed a 100 bp insertion from the 3'end of intron 13 between exons 13 and 14. The genomic defect was identified as an A®G substitution at the -2 position of the acceptor site of exon 14. A cryptic acceptor site -100 bp within intron 13 is used as the new acceptor splice site. The insertion shifts the reading frame +1 and results in a stop codon within exon 17. To determine the level of mutant a1(V) mRNA, we did RNA protection assays and Northern slot blot with ASO. RPA of proband total RNA showed that the mutant a1(V) mRNA was 7-9% of the level of normal a1(V) mRNA. ASO blots yielded proband levels of normal a1(V) mRNA that were about half of the control. This suggests that the mutation causes a null allele with nonsense mediated decay. Proband fibroblasts secreted 65% the amount of a1(V) chain secreted by controls. Type V collagen incorporates into type I collagen fibrils in the ECM and regulates fibril diameter. Scanning electron micrographs of type I collagen fibrils in proband dermal biopsy showed variation in fibril diameter. Two to five percent of fibrils have a smaller diameter and occasional fibrils have a cauliflower configuration. These abnormalities are the same type seen in EDS patients with exon skipping defects, but at lower frequency. This case demonstrates that a reduction in the amount of normal a1(V) collagen is sufficient to cause symptoms of mild EDS II. Similar to the relationship seen for type I collagen defects and osteogenesis imperfecta, the null allele in this family appears to cause milder clinical features than seen in cases with structural alterations in type V collagen.

Program Nr: 2721 from the 1999 ASHG Annual Meeting

Molecular Characterization of Congenital Glaucoma in an Inbred Community: a step towards preventing glaucoma-related blindness. *S. Martin[1], J.E. Sutherland[3], A.V. Levin[2,3], E. Héon[1,2,3,4].* 1) Eye Research Institute of Canada; 2) University of Toronto, Department of Ophthalmology; 3) The Hospital for Sick Children, Department of Ophthalmology; 4) The Hospital for Sick Children Research Institute, Toronto, Canada.

Glaucoma constitutes a leading cause of irreversible blindness in Canada. Congenital glaucoma usually manifests during the first five years of life and is characterized by severe visual loss and autosomal recessive inheritance. Four congenital glaucoma loci have been identified on chromosome 1p36, 2p21, 6p25 and 4q25 respectively. A branch of a large inbred Amish community from Southwestern Ontario was affected with congenital glaucoma and studied to identify the glaucoma-related genetic defect. Members of a 4 generation family were examined and the attribution of the genotypes was done masked from the disease status. Linkage analysis was performed using the MLINK component of the LINKAGE package (v.5.1). Mutational analysis of the candidate gene was done by direct cycle sequencing, restriction enzyme digestion and fragment analysis. Evidence for linkage was found with markers in the 2p21 region with a maximum LOD score 3.34 with markers D2S1348 and D2S1346. Mutational analysis of the candidate gene CYP1B1 identified two different disease causing mutations in exon 3 not seen in a control population of 100 individuals. The congenital glaucoma phenotype for this large inbred Amish family appears to be due to mutations in CYP1B1 (2p21). The identification of these molecular defects will be used to identify carriers of the CYP1B1 mutation and those who are at high risk of developing glaucoma in that community. Other Amish communities should be assessed for these mutations. This will improve genetic counseling and early identification of glaucoma and hopefully minimize glaucoma-related visual loss

.

Program Nr: 2722 from the 1999 ASHG Annual Meeting

Mutation detection by TaqMan-allele specific amplification: application to molecular diagnosis of glycogen storage disease type Ia and medium-chain acyl-CoA dehydrogenase deficiency. *Y. Matsubara[1], K. Fujii[1,2], J. Akanuma[1], K. Takahashi[1], S. Kure[1], Y. Suzuki[1], P. Rinaldo[3], K. Narisawa[1]*. 1) Department of Medical Genetics; 2) Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester MN.

We have devised an allele-specific amplification method with a TaqMan fluorogenic probe (TaqMan-ASA) for the detection of point mutations. A target sequence containing a mutation site was PCR-amplified with two sets of allele-specific primers, one complementary to the wild-type sequence and the other complementary to the mutant sequence, in the presence of a TaqMan fluorogenic probe. The TaqMan probe, which hybridized to the template in between the two PCR primers, was labeled with a reporter dye at the 5'-end and a quenching dye at the 3'-end. During PCR with a matched primer set, Taq DNA polymerase synthesizes a new strand and cleaves the reporter dye, thus increasing the intensity of the fluorescence signal. The level of fluorescence was monitored on a fluorometer in real-time during PCR to determine the "threshold cycle" at which the fluorescence exceeds a baseline. A difference in the amplification efficiency between two separate PCR reactions was determined from the difference of "threshold" cycles, thus differentiating mutant and normal alleles. Since the method measured the efficiency of amplification rather than the presence or absence of end-point PCR products, false amplification of mismatched template did not interfere with the interpretation. Therefore it allowed greater flexibility in designing allele-specific primers and an ample technical margin for allelic discrimination. We applied the TaqMan-ASA method to detect a prevalent g727t mutation in Japanese patients with glycogen storage disease type Ia and a common a985g mutation in Caucasian patients with medium-chain acyl-CoA dehydrogenase deficiency. The method requires no post-PCR processing, can be automated and may be applicable to the DNA diagnosis of various genetic diseases.

Program Nr: 2723 from the 1999 ASHG Annual Meeting

Germline mosaicism of a partial *DCX* deletion causes lissencephaly in a son and subcortical band heterotopia in a daughter. *N. Matsumoto[1], S. Mewborn[1], J.A. Kuc[1], C. Schanen[2], B.F. Crandall[3], W.B. Dobyns[1], D.H. Ledbetter[1]*. 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Departments of Human Genetics and Pediatrics, UCLA School of Medicine, Los Angeles, CA; 3) Departments of Psychiatry and Biobehavioral Sciences and Pediatrics, UCLA School of Medicine, Los Angeles, CA.

Classical lissencephaly (LIS) and subcortical band heterotopia (SBH) are related malformations of neuronal migration. *LIS1* (*PAFAH1B1*) at 17p13.3 and *DCX* (*XLIS*) at Xq22.3-q23 are the two LIS and SBH-causative genes isolated to date, and cause different patterns of malformations (Pilz et al.; Hum Mol Genet;1998;7:2029-2037). *DCX* mutations have been found in sporadic LIS males, sporadic SBH females, and families with both SBH females and LIS males.

We evaluated a family with a LIS son and SBH daughter. The son had hypotonia and feeding problems at birth, seizures at 2 months, and a gastrostomy tube at 2 years. Cranial CT scan at age 1 week showed diffuse LIS and enlarged lateral ventricles. At 7 years, he had profound mental retardation and occasional seizures. The girl presented with developmental delay and seizures in the first year of life. Examination at 4 years showed normal head size, borderline hypertelorism, and mild mental retardation. Cranial MRI at 4 years showed bilateral SBH of medium width. The mother of the two children has normal intelligence and no history of seizures. No brain imaging was performed.

PCR analysis indicates that *DCX* exons 6 through 9 are deleted in the boy with LIS. Southern analysis demonstrates that three restriction fragments are deleted in the LIS male and that the same fragments show a 50% reduction in intensity in the SBH female. These three restriction fragments are present at the control level of intensity in the mother. These results are strongly suggestive of maternal germline mosaicism, although we cannot completely exclude the possibility of low level somatic mosaicism. We also studied X chromosome inactivation patterns in this family, and found no significant skewing in the peripheral blood of the SBH female.

Program Nr: 2724 from the 1999 ASHG Annual Meeting

Screening of autosomal dominant recurrent fever families for TNFR1 mutations. *M. McDermott[1], I. Aksentijevich[2], E. Aganna[1], L. Karenko[3], E.M. McDermott[4], A.I. Hoepelman[5], M. Phelan[1], A-M. Teppo[3], T. Pettersson[3], K.A. Quane[1], R.J. Powell[4], M.G. Molloy[1], B.W. Ogunkolade[1], E.J. Zweers[5], D.L. Kastner[2], G.A. Hitman[1].*
1) Medical Unit, Royal London Hosp, London, England; 2) ARB/NIAMS, NIH, Bethesda, MD, USA; 3) Depts. of Dermatology (LK, AR), and Int. Medicine (TP, AT), Helsinki University Hospital, Helsinki, Finland; 4) Clinical Immunology Unit, Queen's Medical Centre, Nottingham, UK; 5) Bronovo Ziekenhuis, The Hague, Holland.

We have recently described a range of missense coding mutations of tumor necrosis factor receptor 1 (TNFR1) in autosomal dominant TNFR-1 associated periodic syndromes or TRAPS (Cell 97:133). The majority of these mutations disrupt disulphide bonds in the extracellular domains. We have screened a further 3 families (Dutch, Finnish and Irish) with autosomal dominant recurrent fevers (ADRF) as well as 2 sporadic cases for TNFR1 mutations. Sequencing of TNFR1 in the proband daughter and father of the Dutch family revealed a G to C transversion producing an arginine to proline mutation at residue 92 (R92P). All members except the mother in this family were found to have half the normal levels of soluble TNFR1 in their sera. An RFLP assay confirmed a mutation in all family members except the mother. There are 2 unaffected carriers in the family and this non-cysteine mutation appears to be less penetrant than those involving cysteine residues. In the Northern Finns and Irish families we have sequenced the TNFR1 coding region but did not identify any mutations. These families are therefore either TRAPS negative or have mutations in the TNFR1 regulatory regions, which we are currently investigating. The Finnish family has features typical of TRAPS but, based on history, a diagnosis of familial cold urticaria is more likely in the Irish family. Finally the 2 sporadic cases whose symptoms responded to steroids were also mutation negative. These results indicate some degree of genetic heterogeneity in ADRF and it is possible that in isolated individuals where the disease phenotype is not transmitted a TRAPS-like condition may be polygenic or have arisen through non-genetic causes.

Program Nr: 2725 from the 1999 ASHG Annual Meeting

Novel and disease-related mutations in the HEXA gene in non-Jewish individuals. *M.J. McGinniss[1, 2], D.H. Brown[2], A. Fulwiler[1], M. Marten[1], M.M. Kaback[2].* 1) Molecular Genetics Lab, #5031, Children's Hosp, San Diego, CA; 2) Department of Pediatrics University of California, San Diego.

Tay-Sachs disease (TSD) is a neurodegenerative disease that is inherited in an autosomal recessive fashion. Mutations that abolish the activity of the Hex A enzyme encoded by the HEXA gene are associated with the more severe and usually lethal infantile form of TSD. Individuals in the California TSD carrier screening program that do not carry one of the four common disease-associated mutations or one of the two common pseudo-deficient alleles, but that are enzymatically defined as carriers, have been screened for the presence of novel mutations. To date more than 70 mutations have been associated with infantile TSD and we report here 5 novel mutations that appear to be disease-related. DNA samples from enzymatically defined carriers that were negative for both the disease-associated and the two pseudo-deficient mutations were analyzed by SSCP. DNA was amplified from all coding regions of the HEXA gene and electrophoretic variants evident from SSCP were sequenced revealing 5 novel and potentially deleterious mutations. All of these mutations were found in non-Jewish individuals of European or Hispanic ethnic origin and included: two single base pair deletions (1258delT, 1499delT), a nonsense mutation (Ser52Stop), and two missense mutations (His318Arg, Pro439Ser). All 5 mutations are almost certainly disease-related since three are evident in obligate carriers, one involves a frameshift with a stop codon downstream, and the remaining one involves a nonconservative amino acid change in an enzymatically-defined carrier. Identification of these novel mutations adds to the extensive mutational spectrum for the HEXA gene, and contributes to more accurate carrier identification, diagnosis and prognosis for TSD. In addition, these mutations are candidates for further studies of gene expression and to elucidate the structure function relationships of the heterodimeric Hex A (ab) isozyme. (Supported in part by a contract from the Genetic Disease Branch, Department of Health, State of California.).

Program Nr: 2726 from the 1999 ASHG Annual Meeting

Deletion of a branch-point consensus sequence in the LMX1B gene causes exon skipping in a family with nail patella syndrome. *I. McIntosh, J.D. Hamlington, M.V. Clough, J.A. Dunston.* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Nail patella syndrome (NPS) is a pleiotropic condition characterized by dysplasia of the nails, hypoplasia of the patellae, elbow dysplasia and progressive kidney disease. The syndrome is inherited in an autosomal dominant manner and has been shown to result from mutations in the LIM-homeodomain encoding LMX1B gene. The LMX1B transcription factor plays a role in defining the development of dorsal specific structures during limb development; its role in other organs is unclear. Analysis of over sixty LMX1B mutations in NPS families supports the hypothesis that the syndrome results from haploinsufficiency due to loss of function mutations. During the search for LMX1B mutations causing NPS, a 17bp deletion was identified upstream of the 3' splice consensus which removed a canonical branchpoint sequence within the first intron. This deletion was found to segregate with the NPS phenotype in 14 individuals in a single, large family, and was absent from 11 unaffected relatives. Analysis of RNA extracted from skin fibroblasts from an individual carrying the mutation revealed two distinct LMX1B transcripts: one of normal sequence, the other lacking exon 2. Mutations of branchpoint sequences have been shown previously to result in cryptic splicing and intron retention, as well as exon skipping. In this instance, it is hypothesized that the absence of a branchpoint sequence prevents stable binding of the U2 snRNP during spliceosome assembly presumably destabilizing the interactions of U2AF and U1 with the 3' and 5' splice sites. Since these factors are required for definition of the downstream exon (exon 2), the splicing machinery would join exon 1 to exon 3. Skipping of exon 2 disrupts the reading frame leading to premature termination within exon 3. Any polypeptide synthesized from this transcript would lack all functional domains and would be predicted to be non-functional. This is in agreement with the haploinsufficiency mechanism suggested previously.

Program Nr: 2727 from the 1999 ASHG Annual Meeting

Hypotrichosis of Marie Unna maps between D8S258 and D8S298: Exclusion of the hairless gene by FISH on combed DNA. *W.H.I. McLean[1], R. Ekong[2], C.M. Coleman[1], F.J.D. Smith[1], M.A.M. van Steensel[3], I. Kluijt[3], H.P. Stevens[3], A. Messenger[3], J. Uitto[4], C. Schurra[5], A. Bensimon[5], M.S. Povey[2], P.M. Steijlen[3].* 1) Epithelial Genetics Group, Human Genetics Unit, University of Dundee, Dundee, Scotland, UK; 2) MRC Human Biochemical Genetics Unit, London; 3) Depts Dermatology and Clinical Genetics, Nijmegen, Amsterdam, Sheffield and London; 4) Dept Dermatology, Jefferson Medical College, Philadephia; 5) Institut Pasteur, Paris.

Hypotrichosis of Marie Unna (MU) is an autosomal dominant form of alopecia without other ectodermal abnormality. Following genomewide linkage analysis using large Dutch and British kindreds, a maximum combined 2-point lod score of 13.42 at q = 0, was obtained using marker D8S560 on chromosome 8p. Informative recombinants placed the gene between D2S258 and D8S298. The human homologue of the murine hairless gene (*hr*), in which recessive loss-of-function mutations have been shown to cause congenital atrichia, had previously been mapped to this vicinity. Radiation hybrid mapping with the Stanford G3 panel placed this candidate gene 7 $cR_{10,000}$ from D8S298 but was unable to resolve the order of these markers. No mutations were identified in *hr* using strategies based on either cDNA or genomic DNA. However, there remained the possibility of there being unknown alternate exons or transcription initiation sites for the gene. BAC clones were obtained from the Research Genetics library, corresponding to D8S560, *hr* and D8S298. FISH analysis on combed total human genomic DNA using these BAC clones placed the *hr* clone at an estimated distance of 124-146 kb outside of the interval between D8S560 and D8S298, formally excluding the involvement of this gene in MU. The distance between the BAC clones corresponding to D8S560 and *hr* was determined to be 264-285 kb, with an overall mapped distance of 440-460 kb, representing an increase in the distance over which markers have been ordered on combed DNA. Currently, we are constructing a physical map of this locus to enable positional cloning of the MU gene, whose function may shed light on the molecular pathogenesis of alopecia in humans.

Program Nr: 2728 from the 1999 ASHG Annual Meeting

Mutation analysis of the *NF1* gene in 62 patients using an optimized protein truncation test (PTT), heteroduplex analysis (HA) and karyotyping allows to identify 93% of mutations. *L.M. Messiaen[1], T. Callens[1], G. Mortier[1], F. Speleman[1], D. Carton[2], M. Craen[2], J. Leroy[2], M. Abramowicz[3], F. Hayez[3], N. Van Regemorter[3], M. Bonduelle[4], A. De Paepe[1]*. 1) Dept Med Genetics, Univ Hosp Gent, Belgium; 2) Dept Pediatrics, Univ Hosp Gent, Belgium; 3) Service de Genetique, Hopital Erasme Brussels, Belgium; 4) Center Med Genetics, Vrije Universiteit Brussels, Belgium.

NF1 is characterised by neurofibromas, cafe-au-lait spots, freckling and Lisch nodules. Additional complications are often seen. Mutation analysis in the *NF1* gene has been difficult. Mutation detection rates largely depend on the efficiency of the techniques used as well as on the correct clinical diagnosis of the patients included.

We performed mutation analysis in 62 unrelated NF1 patients: 28 familial and 34 sporadic cases. Only patients fulfilling NIH diagnostic criteria were admitted. Clinical data were recorded using the NNFF International NF1 Genetic Analysis Consortium Submission Form. For all patients, we established an EBV lymphoblastoid cell line and extracted gDNA and total RNA. We analysed the complete coding region by an optimized PTT. Truncated fragments were characterised by cDNA and gDNA sequencing. If no truncated fragment was present, HA of all exons and a karyotype was performed. Thus we characterised 58 mutations (93%), including 35 novel ones. 51 mutations were found by PTT (82%), 6 by HA (10%) and 1 translocation t(14;17)(q32;q11.2) by karyotyping. 15 mutations occurred at CpG dinucleotides. 18 mutations resulted in splicing errors, only 4 of them involving the AG splice acceptor or GT donor nucleotides. Other splicing errors were caused by specific nonsense mutations, creation of novel intronic/exonic splice donor or acceptor sites, or mutations in less conserved regions of splice sites. By HA we identified 3 novel missense mutations and 3 recurrent in frame deletions of 3-6 nucleotides. All 4 patients in which the mutation remains unknown are sporadic and somatic mosaicism might underly their disorder. Deletion analysis by FISH and Southern blotting is in progress.

Program Nr: 2729 from the 1999 ASHG Annual Meeting

Mutations in chondrodysplasia punctata, X-linked dominant type (CDPX2). *A.B. Metzenberg[1], R. Kelley[2], D. Smith[1], K. Kopacz[3], R. Sutphen[4], L. Sheffield[5], G. Herman[3]*. 1) Biology, Cal State Northridge; 2) Kennedy Krieger Institute, Johns Hopkins University; 3) Children's Hospital, The Ohio State University; 4) All Children's Hospital, St. Petersburg, FL; 5) The Murdoch Institute, Australia.

Chondrodysplasia punctata comprises a group of heterogeneous disorders affecting skin and bone development. Abnormal cholesterol synthesis has recently been found in patients with the X-linked dominant form, CDPX2, and mutations in the implicated EBP gene (a putative isomerase gene) on Xp11.22-23 have been found in some individuals with CDPX2. Here we present a range of mutations in the EBP gene in 15 unrelated individuals with CDPX2, and note the prevalence of CDPX2-associated EBP mutations in Exon 2, and the existence of two potential mutational hotspots. Direct sequencing of the EBP gene from 15 of 16 unrelated individuals with a clinical diagnosis of CDPX2 revealed mutations in several exons. There were 12 patients with mutations in exon 2, including 5 nonsense mutations, 3 frameshifts resulting in early termination, 3 missense mutations, and one in-frame deletion. One missense mutation was found in Exon 3, one nonsense mutation in Exon 5, and none in one patient. One of the patients with a frameshift mutation in Exon 2 was a male, raising the possibility of a postzygotic mutation. We observed identical C->T transition mutations in a CG dinucleotide in Exon 2 in three individuals, supporting the notion of a mutational hotspot via deamination of a methyl C. Another CG->TG mutation was observed in Exon 2, which may identify a second mutational hotspot. There is no indication of a clear genotype-phenotype correlation for either the biochemical or physical abnormalities. Mutations in regulatory regions of the EBP gene or in other cholesterol biosynthetic genes have not been excluded in patients for whom no mutation was found. The CDPX2 phenotype resembles that of the bare patches mouse, which has mutations in the Xq28-syntenic Bpa gene that encodes a 3b-hydroxysteroid dehydrogenase, found in post-squalene cholesterol biosynthesis. However, no mutations have been found in the human Bpa gene thus far. bb.

Program Nr: 2730 from the 1999 ASHG Annual Meeting

Phenotype analysis in patients with a *JAGGED1* mutation. *M. Meunier-Rotival[1], C. Crosnier[1], C. Driancourt[1], N. Raynaud[1], O. Bernard[2], M. Hadchouel[1,2].* 1) INSERM U347, Kremlin-Bicetre, France; 2) Hopital de Bicetre, France.

The Alagille syndrome (MIM 118450, AGS) is an autosomal dominant disorder characterized by 5 main features: intrahepatic cholestasis, pulmonary artery stenosis, butterfly-like vertebrae, posterior embryotoxon and peculiar facies. Three of the 5 features allow the diagnosis of AGS. There are also minor features including other vascular or skeletal abnormalities, renal malformation or dysfunction, mental retardation and high-pitched voice. The AGS disease gene is *JAGGED1*. By SSCP and sequencing, mutations have been detected in 75 probands (65% of AGS patients tested). Only 19 (31%) among 62 of these cases are inherited, with no paternal or maternal bias. We studied the genotype/phenotype correlation within families.

The characteristics of 6 sibling pairs show the variability in the expressivity of the syndrome in terms of both number and severity of the features, whatever the mutation type. Similarly, a parent with a mild phenotype could have an affected child with a complete syndrome. The 7 families in which missense mutations were transmitted (of a total of 14 missense mutations corresponding to 19% of all mutations found in this work), were studied. The carrier parent had either no AGS feature (L79H, R184H), or subclinical features (R184G, W288C, C731S) or were patients with AGS (P129R, C284F). The presence of a mutation in *JAGGED1* allowed the discrimination between inherited cases of AGS, sporadic cases and cases which were erroneously presumed to be transmitted, due to familial data.

A missense mutation (C753R) in *JAGGED1* was found in an individual with an isolated paucity of intrahepatic bile ducts. Mutations in *JAGGED1* have previously been shown in patients presenting with tetralogy of Fallot. Therefore isolated hepatic defects could also be due to mutations in *JAGGED1*.

Program Nr: 2731 from the 1999 ASHG Annual Meeting

GLC1A-Locus: Mutation Screening in MYOC/TIGR and COX-2 of German POAG Patients. *K. Michels-Rautenstrauss[1], C.Y. Mardin[2], D. Schweitzer[1], S. Oezbey[1], U. Schloetzer-Schrehardt[2], G.O.H. Naumann[2], B. Rautenstrauss[1]*. 1) Inst Human Genetics, Friedrich-Alexander Univ, Erlangen, Bavaria, Germany; 2) Department of Ophthalmology, FAU Erlangen-Nuremberg, Bavaria, Germany.

Primary open-angle glaucoma (POAG) is a clinically and genetically heterogeneous disease. Juvenile open-angle glaucoma (JOAG) is an early-onset form and is linked to the GLC1A locus on chromosome 1q24.3-24.2. For several GLC1A-linked families and sporadic cases mutations were found in the trabecular-meshwork inducible glucocorticoid response (TIGR) gene, synonymous Myocilin (MYOC. A mutation screening in 530 German POAG patients resulted in 6 % being carriers of mutations in exon 3 of the MYOC gene. In JOAG families 3 missense mutations were found. A predominant mutation is the Gln368Stop, predicting a protein truncated by 136 aminoacids. Surprisingly this mutation was found not only in 5 POAG patients, but also in 1 patient with normal tension glaucoma and in several healthy individuals. Taken together this results suggests that MYOC may play a crucial role in some but not all cases of POAG and that other, additional pathological factors are implicated in POAG. As different groups reported GLC1A-linked families without mutations in the MYOC gene there still might be another yet unknown gene in the GLC1A locus involved in the pathogenesis of POAG. One candidate in our study is the Cyclooxygenase 2 (COX-2) gene, located in close vicinity to MYOC. Cyclooxygenase is a key enzyme in the biosynthesis of prostaglandins. Prostaglandins appear to play an important role in the regulation of intraocular pressure. COX-2 is a steroid-regulated enzyme. It was found in reduced amounts in eyes of patients suffering from POAG. A mutation screening in the COX-2 gene of 50 patients with POAG revealed two different mutations in intron 6. One of them, suggesting a potential activation of a cryptic branching site, is cosegregating with a Pro370Leu MYOC mutation in a JOAG family. The second intronic mutation in the splice acceptor site was found in a single case. These intronic mutations may lead to a decresead splicing efficiency and subsequently to a decreased amount of COX-2 enzyme.

Program Nr: 2732 from the 1999 ASHG Annual Meeting

Localization of the putative transcription factor FMR2 in the mammalian brain. *W.J. Miller, J.A. Skinner, K.E. Davies.* Department of Human Anatomy and Genetics, University of Oxford, Oxford, OX1 3QX, United Kingdom.

The cytogenetic expression of the folate sensitive fragile site, FRAXE, on Xq28 of the human X chromosome is associated with a mild form of mental handicap characterised by learning deficits, including speech delay, reading and writing problems. The chromosome fragility is caused by the expansion of a CCG trinucleotide repeat array in the 5' region of the FMR2 (fragile X mental retardation 2) gene. The FMR2 messenger RNA is highly expressed in the placenta and brain but is absent from adult heart, lung, kidney, pancreas and skeletal muscle. FMR2 encodes a large protein of 1311 amino acids and is a member of a gene family encoding proline-serine rich proteins which have properties of nuclear transcription factors. In order to characterise the function and expression of the FMR2 protein, two human fusion proteins N-terminal (A) and middle (B), have been expressed using the pET32a expression system (Novagen) in *E.coli* . These fusion proteins were used to raise polyclonal antibodies in rabbits. Both antibodies detect a band of approximately 141 kDa on western blots of total mouse brain extract which correspond to the size predicted from the open reading frame of FMR2. FMR2 antibodies have been used for immunofluorescence experiments on mouse brain cryosections. Preliminary results demonstrate that FMR2 protein is localised in the neocortex, Purkinje cells of the cerebellum and the granular cell layer of the hippocampus. FMR2 staining appears to co-localise with the nuclear stain DAPI which strengthens the hypothesis that it acts as a transcription factor. In addition there appears to be a sub-set of neurones that contain the FMR2 protein. To date very little is known about the function of FMR2. Since the FMR2 protein has now been shown for the first time localised to the mammalian hippocampus and other brain structures involved with cognitive function we can now begin to investigate the possible function of the FMR2 protein in learning and memory.

Program Nr: 2733 from the 1999 ASHG Annual Meeting

A three generation-family with anterior segment mesenchymal dysgenesis and mutation in a novel homeobox-containing gene, VSX1. *H.A. Mintz-Hittner[1], E.V. Semina[2], J.C. Murray[2,3]*. 1) Dept Ophthalmology, Univ Texas-Houston Medical Sch, Houston, TX; 2) Dept Pediatrics, Univ Iowa, Iowa City, IA; 3) Dept Biol Sciences, Univ Iowa, Iowa City, IA.

The propositus of a three-generation family with autosomal-dominant anterior segment mesenchymal dysgenesis was found to have Axenfeld anomaly, bilaterally. The left eye had congenital and progressive corneal opacity and glaucoma. The iris of the right eye had neither collarette nor crypts by slit lamp biomicroscopy. There were no iris vessels identified by indocyanine green angiography. The optic nerve had peripapillary thinning and remnants of the embryonic hyaloid vascular system on its surface. Thus, the embryonic hyaloid vascular system appear to be affected anteriorly and posteriorly. In addition to the ocular findings, the propositus had a broad flat nasal bridge, abnormal pinnae and hearing loss, bilaterally. Other affected family members had similar but less severe findings.DNA samples from affected individuals from this family were analyzed for mutations in PITX2, PITX3 and FKHL7 genes, previously shown to be responsible for similar human phenotypes, and also a novel ocular homeodomain- containing transcription factor gene, VSX1. Two missense mutations in the VSX1 gene were identified: one predicts an arginine-to-serine change (R131S) in the N-terminal region of the encoded protein and another an alanine-to-serine substitution (A256S) in the highly conserved CVC-domain of the protein, located immediately C-terminal to the homeodomain. Function of the CVC-domain is unknown, but its proximity to the homeodomain is consistent with its participation in DNA-binding. Both of the mutations appear to reside on the same chromosome and co-segregated with the phenotype in this three-generation family. The R131S variant was found in approximately one-half percent of controls, while the A256S mutation was not found in any of 400 control chromosomes. The protein encoded by the VSX1 gene is most highly homologous to the zebrafish vsx1, goldfish vsx2 and mouse chx10 proteins, previously shown to play an important role in ocular development in different species. The VSX1 gene was mapped to 20p11-q11.

Program Nr: 2734 from the 1999 ASHG Annual Meeting

Mutations in the gene for alpha-cardiac actin in familial hypertrophic cardiomyopathy. *J. Mogensen[1,3], H. Egeblad[1], I.C. Klausen[1], T.A. Kruse[2], N. Gregersen[3], P.S. Andersen[5], A. Perrot[4], O. Havndrup[5], M. Christiansen[5], H. Bundgaard[5], K.J. Osterziel[4], P. Bross[3], A.K. Pedersen[1], A.D. Borglum[2]*. 1) Department of Cardiology, Skejby University Hospital, Aarhus, Denmark; 2) Institute of Human Genetics, University of Aarhus, Denmark; 3) Reseach Unit for Molecular Medicine, Skejby University Hospital, Denmark; 4) Charite/Frantz-Volhart-Klinik, Berlin, Germany; 5) Department of Cardiology, Rigshospitalet, Denmark.

Background: Familial hypertrophic cardiomyopathy (FHC) is an autosomal dominantly inherited disease caused by mutations in genes encoding sarcomeric polypeptides. We have recently reported that the alpha-cardiac actin gene (ACTC) is the 8th FHC gene. An Ala295Ser mutation was localized in exon 5 close to two missense mutations described to cause the inherited form of idiopathic dilated cardiomyopathy (IDC). Thus ACTC is the first sarcomeric gene described in which mutations are responsible for two different cardiomyopathies. Purpose: In order to estimate the frequency of ACTC mutations in FHC we are currently screening 70 Danish FHC families and 150 German probands for ACTC mutations. Methods: Individuals were considered to have FHC if they had hypertrophy of the myocardium (>13mm), hypertrophy in the ECG or Q-waves/major ST-segment changes in at least 2 ECG leads. The genetic investigations included mutation analyses by direct sequencing or SSCP. Results: So far 40% of the patients have been analyzed and a Met305Leu mutation has been identified in exon 5 of a German proband having apical hypertrophy and bradyarrythmia. The Met305Leu mutation identified is localized close to a myosin binding site and within a short distance of the bound actin ATP. Both Ala295 and Met305 are situated on the same face of domain 3 of the actin molecule. Conclusion: On basis of analysis of 88 patients the frequency of ACTC mutations in FHC seems to be above 2%. The fact that the Met305Leu mutation as well as the Ala295Ser mutation are localized in proximity to myosin binding sites supports the hypothesis that ACTC mutations affecting sarcomere contraction lead to FHC while mutations affecting force transmission from the sarcomere to the surrounding syncytium lead to IDC.

Program Nr: 2735 from the 1999 ASHG Annual Meeting

Analysis of SMN binding partners using a yeast two-hybrid system. *P. Mohaghegh, L. Campbell, K. Hunter, K.E. Davies.* Dept. Human Anatomy & Genetics, Univ Oxford, Oxford, England.

Childhood onset Spinal Muscular Atrophy (SMA) is autosomal recessive disorder, which maps to 5q13. It is caused by mutations in the survival motor neuron (SMN) gene that is a ubiquitously expressed gene, which has been implicated in RNA processing. However, how the function of SMN relates to the specific motor neuron death remains unsolved.

We have used a yeast two-hybrid assay to look for binding partners of SMN in mouse brain. SMN has previously been shown via yeast-2-hybrid system to interact with SIP1 and Bcl-2 proteins using a HeLa cDNA library (Liu & Dreyfuss 1996) and a thymus cDNA library (Iwahashi et.al 1997) respectively.

We have isolated several novel binding partners as well as SMN and SIP1. Database searches with the new binding partners revealed one of these to be part of cytosolic transport factors. We have made several SMN deletion constructs and have established via yeast two-hybrid approach which domain of SMN interacts with this cytosolic protein complex. We furthermore have determined this interaction via co-immunoprecipitation and co-localisation experiments. The relevance of this to the disease pathology is currently being explored.

Program Nr: 2736 from the 1999 ASHG Annual Meeting

Infantile GM1-gangliosidosis: new mutations in the b**galactosidase gene identified in two patients with cardiomyopathy.** *A. Morrone[1], T. Bardelli[1], A. Caciotti[1], M.A. Donati[1], G. De Gregorio[1], A. d'Azzo[2], E. Zammarchi[1].*
1) Dept. Pediatrics, Univ Florence, Florence, Florence, Italy; 2) Dept. of Genetics, St. Jude Hospital, Memphis, USA.

Infantile GM1-gangliosidosis is a rare lysosomal storage disorder with autosomal recessive inheritance. The disease is caused by primary deficiency of acid b-Galactosidase and it is clinically characterised by early psychomotor delay, severe and progressive neurological involvement. Death usually occurs within two years. The human b-galactosidase (Hb-Gal) gene gives rise to two alternatively spliced mRNAs: a major transcript (Hb-Gal long) of 2,5 kb that encodes the classical lysosomal form of the enzyme, and a minor transcript (Hb-Gal short) of 2.0 kb encoding Elastin Binding Protein (EBP). Here we report the identification of three new b-galactosidase gene mutations in total RNA and DNA preparations of an Italian and an American patients affected by infantile GM1 gangliosidosis with cardiomyopathy. In the Italian patient an out-of-frame Hb-Gal transcript with 154 bp insertion in E10/E11 was detected in combination with the previously reported stop codon mutation W92X. The aberrant Hb-Gal transcript, has also been confirmed in his father's mRNA. These genetic lesions give rise to aberrant mRNAs with a complete lack of function of both the lysosomal protein and EBP. In the American patient,two new transitions,C252T and C1356T,have been identified that results in the aminoacid substitutions R68W and L436F. In addition to these mutations,the previously reported R201C substitution was also identified in this patient. The R68W has been confirmed in the father's genomic DNA. Both L436F and R201C have been identified in the mother and sister. The mutation R201C, mapping in a CpG island of a region encoding only for the lysosomal enzyme, correlates with juvenile GM1-gangliosidosis phenotype. Therefore the severe clinical manifestations must be attributed with R68W/L436F. These aminoacid changes are present in the Hb-Gal premRNA region common between Hb-Gal long and Hb-Gal short, consequently both proteins are affected by the mutations.

Program Nr: 2737 from the 1999 ASHG Annual Meeting

GENETIC STUDY OF A LARGE ADPKD AND PSYCHOSIS TUNISIAN FAMILY. *R. M'RAD[1], R. Zemni[1], F. Maazoul[1], F. El younsi[2], N. Smaoui[1], H. Ben Maiz[2], H. Chaabouni[1]*. 1) genetique, faculte de medecine de Tunis, Tunis, tunisia; 2) Service de nephrologie hopital Charles Nicolle.

Autosomal dominant polycystic kidney disease (ADPKD) is a genetically heterogeneous disorder. At least, two distinct forms of ADPKD are well defined. In ~86% of affected families, a gene defect localised to 16p13.3 was responsible for ADPKD while a second locus has been localised to 4q13.q23 as candidate gene for the disease in the remaining families. Here, we report a large ADPKD Tunisian family with 15 members; 12 (9 females, 3 males) of whom show clearly ultrasonografic scanning signs of ADPKD. 3 (2 females, 1 male) of the 12 shows signs of ADPKD associated with psychosis. To establish Linkage status in this family, we mainly used 3 highly polymorphic DNA markers, 3'HVR, KG8 and SM6 flanking PKD1 gene on 16p13.3 and 2 highly polymorphic DNA markers, 046 and 224, flanking the PKD2 gene. By means of molecular haplotypes identification, we show that this family is unlinked neither to PKD1 nor PKD2. Our data support a theory of more than 2 loci being responsible for ADPKD.

Program Nr: 2738 from the 1999 ASHG Annual Meeting

Molecular analysis and clinical characterization of nonsyndromic, autosomal recessive (DFNB) hearing loss. *A. Murgia[1], R. Polli[1], M. Martella[1], C. Vinanzi[1], E. Leonardi[1], E. Orzan[2].* 1) Dept Pediatrics, Univ Padua, Padua, Italy; 2) Service of Audiology, Univ Padua, Italy.

In industrialized countries approximately 1/1000 children is affected by preverbal hearing loss. In the majority of the cases this is a genetic, nonsyndromic, autosomal recessive condition (DFNB). It has been demonstrated that the single most common form of congenital preverbal nonsindromic deafness is due to mutations of the Cx26, GJB2 gene, which accounts for at least 50% of the cases (DFNB1), with a carrier frequency of about 1/30 in the mediterranean area. Nevertheless several other DFNB loci have been mapped and five of the corresponding disease-genes have been identified: MYO7A (DFNB2), MYO15 (DFNB3), PDS (DFNB4), OTOF (DFNB9), TECTA (DFNB21). With the aim of a clinical and molecular characterization of these forms of hearing loss, we have carefully selected, on the bases of a protocol that minimizes the possible inclusion of acquired deficits, a population of more than 200 individuals, aged between 3 and 35 years, affected by sensorineural, nonsindromic, autosomal recessive or sporadic hearing impairment. Molecular analysis of the Cx26 gene has allowed to identify mutations in 49% of our cases. The hearing loss in these latter individuals has been found to be of variable severity even within families, always preverbal, possibly not always congenital, and never progressive. No de-novo mutations have been found. The M34T Cx26 variant has not been found to act as a dominant mutation in three families of our series. The group of clinically selected subjects, who resulted negative for Cx26 mutations, represent now a particularly interesting population for the study of the role of other DFNB genes. We are characterizing, by PCR SSCP/CSGE analysis and direct sequencing, the exons of myosin 7A, myosin 15, pendrin, otoferlin and alpha-tectorin, that have been found mutated in cases of autosomal recessive nonsyndromic deafness. This analysis may contribute important information for a better understanding of the molecular bases and the clinical characteristics of these heterogeneous conditions.

Program Nr: 2739 from the 1999 ASHG Annual Meeting

Lysinuric protein intolerance (LPI) gene SLC7A7: Fine mapping and spectrum of mutations. *J. Mykkanen[1], D. Torrents[2], M. Pineda[2], A. Zorzano[2], V. Nunes[3], M.E. Yoldi[4], K. Huoponen[1], A. Reinikainen[1], O. Simell[1], M.-L. Savontaus[1], M. Palacín[2], P. Aula[5].* 1) Dept Medical Genetics, Univ Turku, Turku, Finland; 2) Dept Biochemistry and Molecular Biology, Univ Barcelona, Spain; 3) Dept Molecular Genetics (IRO), Hospital Duran i Raynalds, Barcelona, Spain; 4) Dept Neuropediatry, Hospital Virgen del camino, Pamplona, Spain; 5) Dept Medical Genetics, Univ Helsinki, Finland.

Lysinuric protein intolerance (LPI; MIM 222700) is an autosomal recessively inherited metabolic disorder characterised by basolateral plasma membrane transport defect of cationic amino acids presenting growth failure, hepatosplenomegaly, osteoporosis, postprandial hyperammonemia and aversion to dietary protein. We have previously identified a human cDNA, encoding y^+LAT-1 (y^+L Amino Acid Transporter-1), as the LPI gene SLC7A7. y^+LAT-1 co-expresses and induces y^+L transport activity with the surface antigen 4F2hc in *Xenopus* oocytes. In Finland LPI is more prevalent (incidence 1:60000) than in other parts of the world and all the Finnish patients studied share the same founder mutation.

In order to perform fine mapping of SLC7A7 gene, a PAC library was screened. PACs found were hybridised on DNA fibers together with y^+LAT-1 cDNA and a control PAC with known insert size. Distance measurement of 21 fibers showed SLC7A7 gene to be located 250 kb distal from T-cell receptor a/d intragenic microsatellite TCRA. The non-Finnish patients with Caucasian and Arabic ethnic background were screened for mutations at cDNA and/or genomic DNA level using RT-PCR of full y^+LAT-1 ORF, genomic PCR amplification of exons and automated sequencing. The genomic mutations found comprise nonsense, missense and splice site mutations, small deletions and a tandem duplication. A homozygous nonsense mutation 1012 G®A was found to be common in 4 LPI patients of Arabic ethnic background. The missense mutation 447 G®T found in Estonian and Latvian LPI patients changes fully conserved amino acid in this protein family of 4F2hc subunits reducing totally the transport activity of dibasic amino acids arginine and leucine when injected into *Xenopus* oocytes.

Program Nr: 2740 from the 1999 ASHG Annual Meeting

Homomeric channels of P932L mutations in muscle chloride channel gene (hClC-1) is associated with a severe myotonic myopathy. *S. Nagamitsu[1,2], T. Matsuura[1,2], M. Khajavi[1,2], R. Armstrong[1], C. Gooch[1], T. Ashizawa[1,2].* 1) Department of Neurology, Baylor College of Medicine, Houston, TX; 2) Neurology service Veterans Affairs Medical Center, Houston, TX.

Chloride channelopathies (dominant myotonia congenita, Becker myotonia) are nonprogressive, nondystrophic skeletal muscle disorder caused by a variety of mutations in the gene encoding the muscle chloride channel (hClC-1). So far over forty mutations have been identified in hCLC-1 gene. One-third of the identified mutations are nonsense mutations or frameshift mutations. These mutations result in a truncation of the predicted protein product. In diseases caused by nonsense or frameshift mutations, the mutant mRNA may be selectively degraded, thus, the organism is supposed to be protected from deleterious truncated protein. The two members of the family showed a unique myotonic myopathy with early development of proximal muscle hypertrophy, late onset of generalized progressive muscle weakness and predominantly distal atrophy with joint contracture. Clinically, the unique phenotype of this myotonic disorder clearly distinguishes this familys diseases from other myotonic disorders. We identified two novel mutations comprising a compound heterozygous state in this family : (1) a base (G) insertion in exon 7 generating early stop codon (fs289X) in the putative transmembrane domain D5, and (2) a C-to-T substitution in exon 23 resulting in a missense mutation (P932L). RT-PCR analyses of total RNA were extracted from one patient's affected muscle showed the expression of only P932L mutant mRNA. The fs289X mutant mRNA was undetectable, suggesting that it is degraded rapidly after transcription.

We propose a hypothesis that fs289X is a null mutation, rendering the patients with the compound heterozygous genotype of fs289X/P932L to exclusively express P932L homomeric channels that cause the severe phenotype.

Program Nr: 2741 from the 1999 ASHG Annual Meeting

A donor splice site mutation in intron 4 of the fibrinogen alpha-chain gene (*FGA*) is the common defect in congenital afibrinogenemia. *M. Neerman-Arbez[1], P. de Moerloose[2], A. Honsberger[1], C. Rossier[1], E.G.D. Tuddenham[3], S.E. Antonarakis[1], M.A. Morris[1]*. 1) Division of Medical Genetics, University Medical Centre and University Hospital, Geneva, Switzerland; 2) Division of Angiology and Hemostasis,University Hospital, Geneva, Switzerland; 3) Haemostasis Research Group, MRC Clinical Services Centre, Imperial College School of Medicine, London, U.K.

Congenital afibrinogenemia is a rare, autosomal recessive disorder characterised by the complete absence of detectable fibrinogen. We previously identified the first causative mutations in a non-consanguineous Swiss family; the four affected male individuals have homozygous deletions of approximately 11 kb of the fibrinogen alpha (*FGA*) gene on 4q28-4q31. Haplotype data imply that these deletions occurred separately, on distinct ancestral chromosomes, suggesting that the *FGA* region of the fibrinogen cluster may be susceptible to deletion by a common mechanism. The deletion junctions were initially mapped to the unsequenced *FGA-FGB* intergenic region by PCR and Southern blot analysis. We subsequently cloned this region following long-range PCR, and sequenced the deletion junctions of all three mutated chromosomes. We found that all the deletion junctions were identical, and probably resulted from non-homologous recombination involving two 7 bp direct repeats, AACTTTT, situated in *FGA* intron 1 and in the *FGA-FGB* intergenic sequence. We collected 13 additional unrelated patients with congenital afibrinogenemia from France, U.K. and Belgium in order to identify the causative mutations in affected individuals, and to determine the prevalence of the 11kb *FGA* deletion by sequence analysis and Southern blotting. No further patients were found to be carriers of the deletion. A second mutation, however, in the invariant GT dinucleotide (GT>TT) at the donor splice site of *FGA* intron 4, accounted for 12 out of 20 mutant alleles (60%).Two frameshift mutations were also found in compound heterozygosity in one further affected individual. Interestingly, all are early truncating mutations in *FGA* although mutations in all three fibrinogen genes, *FGG*, *FGA* and *FGB* are predicted to cause congenital afibrinogenemia.

Program Nr: 2742 from the 1999 ASHG Annual Meeting

Usher type IIa: Spectrum of Mutations in Danish and Norwegian Patients. *O. Nilssen[1], B. Dreyer[1], T. Rosenberg[2], M.D. Weston[3], W.J. Kimberling[3], L. Tranebjærg[1].* 1) Dept Med Genetics, Univ Hospital, Tromsø, Norway; 2) National Eye Clinic for Visually Impaired, Hellerup, Denmark; 3) Dept of Genetics, Boystown National Research Hospital, Omaha, NE.

Usher syndrome type II (MIM 276901/276905) is an autosomal recessive disorder characterized by hearing impairment from childhood and progressive retinitis pigmentosa from the late teens. Mutations in *USH2A*, located on 1q41 were recently shown to be responsible for Usher type IIa. The *USH2A* gene encodes a protein of 1546 amino acids that contains laminin type epidermal growth factor (LE)- and fibronectin type III like motifs. However, the exact function of USH2A is not known.

We have investigated the molecular pathology of Usher type II by screening the *USH2A* gene for mutations in a panel of 31 unrelated patients from Denmark and Norway. Mutations were detected by PCR-based exon amplification and direct, automated DNA sequencing.

Besides from the frequent 2299delG mutation, which accounted for 48% of the disease alleles, a heterogeneous spectrum of mutations was identified. Sixteen novel, putative disease-causing mutations were detected, of which 12 were private and 4 occurred in more than one family. The disease-causing mutations were scattered throughout the gene and included 7 missense mutations, 6 nonsense mutations, 2 small deletions and 1 small insertion. In addition, 6 polymorphic sites were identified.

All missense mutations resulted in major alterations in the properties of the corresponding amino acid side chains. Four missense mutations affected the N-terminal domain whereas 3 missense mutations affected the laminin type epidermal growth factor like (LE) domain of the USH2A protein. The structural consequences of the LE mutations are discussed in relation to the 3-dimensional structure of LE-domains.

Program Nr: 2743 from the 1999 ASHG Annual Meeting

Spectrum of minor lesion NF1 gene mutations in 521 unrelated German neurofibromatosis type 1 patients*NF1*.

P. Nurnberg[1], R. Fahsold[2], D. Kaufmann[3], C. Mischung[1], C. Gille[1], C. Ehlers[2], M. Abdel-Nour[1], H. Peters[1], A. Buske[1], S. Tinschert[1], S. Hoffmeyer[4]. 1) Inst Medical Genetics, Charite University Hosp, Berlin, Germany; 2) Inst Medical Genetics, Dresden, Germany; 3) Department of Human Genetics, University Hosp, Ulm, Germany; 4) Epidauros AG, Bernried, Germany.

In excess of 500 unrelated neurofibromatosis type 1 patients have been screened for mutations in the NF1 gene. For each patient the whole coding sequence and all splice sites were studied for aberrations either by the protein truncation test (PTT), temperature gradient gel electrophoresis (TGGE) of genomic PCR products, or mostly by direct genomic sequencing (DGS) of all individual exons. A total of 301 sequence variants including 278 bona fide pathogenic mutations were identified. As many as 216 of the genuine mutations, among them 179 different ones, can be considered novel when referring to the most recent review in the field (Upadhyaya and Cooper, 1998). Mutation detection efficiencies of the different screening methods were very similar to each other, 47.1 % for the PTT, 53.7 % for TGGE, and 54.9 % for DGS. Some 224 mutations (80.2 %) yielded directly or indirectly premature termination codons. These mutations showed a very even distribution over the whole gene from exon 1 to exon 47. Of all sequence variants determined in our study, less than 20 % represent C to T or G to A transitions within a CpG dinucleotide and only six different mutations do also occur in NF1 pseudogenes with five of them being typical C to T transitions in a CpG. Thus, neither frequent deamination of 5-methylcytosines nor interchromosomal gene conversion may account for the high mutation rate of the NF1 gene. As opposed to the truncating mutations, the 28 (10.1 %) missense or single amino acid deletion mutations identified clustered in two distinct regions, the GRD and an upstream gene segment forming a so-called cysteine/serine-rich domain. Coincidence of mutated amino acids and those conserved between human and Drosophila strongly suggests significant functional relevance of this region.*DrosophilaNF1*.

Program Nr: 2744 from the 1999 ASHG Annual Meeting

Genetic heterogeneity in hereditary and autonomic sensory neuropathy type 4 (HSAN4). *C. Oddoux[1], J. Wang[1], C.M. Clayton[1], M. Hilz[1], R. Cilio[2], E. Bertini[2], C. Mayaan[3], A. Blumenfeld[3], F. Axelrod[1], H.. Ostrer[1].* 1) New York University Medical Center, New York, NY; 2) Ospedale Bambino Gesu, Rome, Italy; 3) Hadassah Hospital, Jerusalem, Israel.

HSAN4 is an autosomal recessive disorder characterized by insensitivity to pain and anhydrosis, and is usually associated with self mutilation, mental retardation, and absence of histamine-induced axon flare. Previously, mutations in the tyrosine kinase domain (Trk) of the high affinity nerve growth factor receptor (NTRK1) have been observed in individuals with HSAN4 (Indo, et al., 1996 Nat Genet 13:485). To determine whether mutations in other regions of the NTRK1 gene or other genes in the NGF signal transduction pathway cause HSAN4, we studied 8 families with affected children; three from northern Italy, three from southern Italy, one Greek and one Bedouin. With the exception of the northern Italian families all were consanguineous. Haplotypes of the NTRK1 flanking and intragenic markers D1S2624, D1S506, and D1S116, demonstrated the absence of a founder mutation among the Italian patients and were compatible with linkage to NTRK1 for all of the families. Direct sequence analysis of the NTRK1 gene revealed that two individuals had homozygous mutations within the Trk domain, one of which was a complex allele with two sequence changes. Another patient with a particularly mild phenotype (some residual pain sensation and sweating, no self mutilation, and normal intelligence) had two different mutations distal to the Trk domain in exon 17, suggesting incomplete impairment of signal transduction. This study suggests that most cases of HSAN4 are caused by mutations in NTRK1 and is the first to demonstrate that mutations outside the Trk domain can give rise to either comparable or milder disease.

Program Nr: 2745 from the 1999 ASHG Annual Meeting

Molecular analysis of Greig cephalopolysyndactyly syndrome shows a high frequency of deletions. *I.M. Olivos-Glander[1], J. Blancato[2], J. Meck[3], L.G. Biesecker[1]*. 1) Genetic Disease Research, NIH/NHGRI, Bethesda, MD; 2) Institute of Molecular Human Genetics, Georgetown University, Washington, D.C; 3) Department of Obstetrics and Gynecology, Georgetown University, Washington, D.C.

We have ascertained a cohort of 23 families with one or more persons affected by Greig cephalopolysyndactyly syndrome (GCPS). Diagnostic criteria include preaxial polysyndactyly of the feet with either macrocephaly or hypertelorism. These families consist of 19 sporadic cases and four familial cases. We are developing a diagnostic protocol to systematically assess the wide range of genetic alterations that are capable of generating this phenotype. The protocol begins with high resolution karyotyping with attention directed to 7p13, the locus of the Gli3 gene that is known to be haploinsufficient in many GCPS patients. Next, to assess for submicroscopic deletions, we use both microsatellite analysis and FISH analysis using cosmids and BACs. Biallelic cDNA expression assays will be performed next to select patients for sequencing or Southern analysis. Patients who express both alleles will be sequenced and those who do not will be analyzed by a series of Southern analyses for this large (~290 kb) gene.

We have so far identified that at least 7 of the 23 affected probands have gene deletions either by microsatellite analysis, Giemsa banding or FISH analysis. Future work will include determining the extent of the deletions in those patients identified with a deletion and performing the biallelic expression assay in those who are not deleted in GCPS. The high frequency of deletions in GCPS patients precludes sequencing as a logical first step and we conclude that an integrated diagnostic scheme would be useful in this disorder.

Program Nr: 2746 from the 1999 ASHG Annual Meeting

Towards mouse models for Parkinson's disease: humanizing the a-**synuclein locus.** *B.M. Orrison, D.E. Cabin, S. Gispert, A. Chen, L. Garrett, R.L. Nussbaum.* Genetic Disease Research Br, NHGRI/NIH, Bethesda, MD.

Mutations in the a-synuclein gene (*SNCA*), which encodes a major component of Lewy bodies, were the first to be associated with familial forms of Parkinson's disease. The mouse homolog was mapped to mouse chromosome 6 (MMU6) at 26.8 cM on the Jackson Laboratory BSS backcross panel. This establishes a new region of shared synteny between MMU6 and human chromosome 4, to which *SNCA* was previously mapped. No possible candidate neurological phenotypes map to that region of MMU6. As the first step in developing animal models for the disease, the a-synuclein locus has been knocked out in the mouse by replacing the second and third coding exons with the neomycin resistance gene. Mice homozygous for the deletion produce no a-synuclein detectable by protein blotting, are viable, and have no obvious phenotypes. Matched +/+ and -/- pairs are being bred for behavioral testing, and mutant animals are being aged to determine if any phenotypes may develop late in life. The -/- animals are also being bred to transgenic mice carrying both the human wild type and A53T mutant versions of a-synuclein. The wild type human gene is carried on a PAC and is under the control of its endogenous promoter; the A53T mutant transgenic animals carry a cDNA construct driven by the prion promoter. The PAC transgenic animals carry about 25 copies of the transgene, and the A53T mutant cDNA is present at more than 10 copies. Currently intercrosses of animals carrying both transgenes on a +/- a-synuclein background are in progress. Animals that carry both these transgenes on the mouse null background will mimic the situation seen in a familial form of Parkinson's disease.

Program Nr: 2747 from the 1999 ASHG Annual Meeting

Multiorgan autonomic dysfunction in mice lacking the b2 and the b4 subunits of neuronal nicotinic acetylcholine receptors. *A. Orr-Urtreger[1], W. Xu[2], F. Nigro[3], S.E. Gelber[5], C.B. Sutcliff[2], L. Goldberg[2], R.A. Lewis[4], D. Armstrong[4], C-N. Ou[3], J.W. Patrick[3], L.W. Role[5], M. De Biasi[3], A.L. Beaudet[2].* 1) Genetics Inst, Tel-Aviv Sourasky Medical Ctr, Tel Aviv, Israel; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; 3) Division of Neuroscience, and; 4) Departments of Ophthalmology and Pathology, Baylor College of Medicine, Houston, Texas; 5) Department of Anatomy and Cell Biology and Center for Neurobiology and Behavior, Columbia University, New York, NY.

We have generated mice with null mutations in the b2 and the b4 subunits of the neuronal nicotinic acetylcholine receptor (nAChRs) genes and created double null mice (b2-/-b4-/-) by mating. The b2-/- and the b4-/- single mutant mice grow to adult life with no visible phenotypic abnormalities. The b2-/-b4-/- mutants survive to birth but have impaired growth and increased perinatal mortality. They also present enlarged bladders with dribbling urination and develop urinary infection and bladder stones. The ocular pupils are widely dilated and do not contract in response to light. Histological studies revealed no significant abnormalities of brain and peripheral tissues except for hyperplasia in the bladder mucosa of the b4-/- and the b2-/-b4-/- mutants. Bladder strips from b2-/-b4-/- mice did not respond to nicotine but contracted when stimulated with a muscarinic agonist or electric field stimulation. Bladder strips from b4 mutants did not respond to nicotine despite the absence of major bladder dysfunction in vivo. Acetylcholine-activated whole-cell currents were absent in superior cervical ganglion neurons from b2-/-b4-/- mice and reduced in neurons from b4-/- mice. Our previous results with the a3-/- mutant mice ant the current data suggest that the a3 and the b4 subunits are the major components in autonomic nAChRs. The phenotype of the b2-/-b4-/- and a3 mice resembles the autosomal recessive megacystis-microcolon-hypoperistalsis syndrome in humans.

Program Nr: 2748 from the 1999 ASHG Annual Meeting

Methylation Studies in Facioscapulohumeral Muscular Dystrophy. *M.J. Osborn, D.N. Cooper, M. Upadhyaya.* Institute of Medical Genetics, Uni Wales College of Medicine, Cardiff, U.K.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant neuromuscular disorder characterized by progressive weakness of the facial, shoulder and upper arm muscles. The disorder has been mapped to 4q35 and is associated with the deletion of integral copies of a D4Z4 repeat. Although the D4Z4 repeat contains homeobox-like sequences, no transcript from this locus has been identified. It has been proposed that the underlying disease mechanism in FSHD is by deletion-mediated position effect variegation (PEV). Thus D4Z4 deletions could place the proximally located FSHD gene closer to the heterochromatinizing influence of the 4q35 telomere. Assuming hypermethylation to be one consequence of heterochromatinization, establishing the methylation status of the 4q35 region in both FSHD and in control subjects might further define the chromosomal region affected by PEV. We have attempted to assess the methylation status of the 4q35 region in both FSHD patients and matched control individuals by means of methylation-sensitive restriction enzymes and bisulphite-modified genomic sequencing. Preliminary examination of the D4Z4 locus with methylation-sensitive enzymes revealed increased methylation of FspI and EagI sites within the 3.3kb repeat, whereas, by contrast, the SacII sites were to a large extent unmethylated. Analysis of the D4F104S1 region demonstrated a proximal HpaII site that exhibited 50% methylation which could be due to either the 4q or 10q homologue being methylated. Our preliminary results suggest that FSHD muscle DNA may be less methylated than normal muscle. Bisulphite sequencing of the promoter sequence of the FRG1 gene in normal and FSHD blood and muscle DNA failed to provide any evidence of methylation. We are currently investigating the methylation status of the sequences in the first D4Z4 repeat specific to 4q35 to determine if there is a difference between FSHD and normal samples or between the homologous chromosome 4 and 10 repeat loci.

Program Nr: 2749 from the 1999 ASHG Annual Meeting

Molecular cloning of the breakpoint junction in a family with nephronophthisis type 1. *E. Otto, R. Betz, C. Rensing, S. Schaetzle, T. Vetsi, T. Kuntzen, A. Imm, F. Hildebrandt.* Univ Childrens Hospital, Freiburg, Germany.

Juvenile nephronophthisis (NPH1) is an autosomal recessive kidney disorder, characterized by disrupted tubular basement membranes, cysts, and tubulo-interstitial nephropathy. The disease leads to end-stage renal failure at an average age of 13 years. The defective gene for NPH1 was identified as *NPHP1* by positional cloning at 2q13, however, its function is still unknown. Approximately 80% of all patients exhibited a 250 kb genomic deletion in the *NPHP1* region. In this study, we identified the proximal and distal deletion breakpoints in a family (F12) that bears a shorter 200 kb deletion. PCR deletion analysis revealed that this family has a unique proximal breakpoint within intron 2 of the *NPHP1* gene. By Southern blot restriction mapping we detected a 40 kb EcoRI junction fragment besides the normal 14 kb fragment. For breakpoint fine mapping, the entire 20.8 kb intron 2 and a 30 kb EcoRI fragment from the distal breakpoint region were sequenced using PAC clones. Across breakpoint PCR was carried out and yielded a 1,800 bp fragment which was sequenced directly. The proximal breakpoint was localized 360 bp downstream of the 5' end of a LINE 1 element of 6 kb. Besides this repetitive element, sequence analysis of the breakpoint genomic regions yielded no candidate sequence responsible for a deletion mechanism. The characterization of further breakpoint regions will be helpful to identify NPH1-patients with heterozygous deletions and may offer insights into deletion pathomechanisms.

Program Nr: 2750 from the 1999 ASHG Annual Meeting

Functional Analysis of *C.elegans* and *S.pombe* orthologues of the human Survival Motor Neuron (SMN) protein.

N. Owen[1], I. Miguel-Aliaga[1], E. Culetto[2], D.S. Walker[3], H.A. Baylis[3], D.B. Sattelle[2], K.E. Davies[1]. 1) Dept of Anatomy and Genetics, University Oxford, Oxford, UK; 2) Babraham Institute, LMS, Department of Zoology, University of Cambridge, UK; 3) Department of Zoology, University of Cambridge, UK.

Childhood onset Spinal Muscular Atrophy (SMA) is characterised by the loss of lower motor neurones and proximal muscle weakness. All three types of SMA result from defects of the gene for the Survival Motor Neurone (SMN) protein.

We have isolated and characterised SMN orthologues from both *Caenorhabditis elegans* (CeSMN) and *Schizosaccharomyces pombe* (*smn1+*). Both orthologues show a high degree of conversation with the human SMN at the amino acid level, particarlly in regions of the human protein with known function: at the 5` binding SIP1 and at the 3` binding the Sm proteins and including the YG box.

Utilising translational GFP tagged fusion proteins we have analysed cellular localisations of both orthologues and have observed phenotypes in both for over expression of the proteins. Using dsRNA interference we have reduced the CeSMN protein level, resulting in a spectrum of severe phenotypes including lethality. Similarly in *S.pombe* we have created targeted knockouts leading to lethality.

In *S.pombe* we have analysed missense mutations in specific amino acids of the protein that are absolutely conserved between yeast and man. The residues chosen are known to be SMA causing mutations seen in Type I patients. Over expression of the mutations in smn1 demonstrate a dominant negative effect on growth phenotype and a change in subcellular localisation of the protein, observed through GFP tagging. We have also created and analysed a new mutation in the yeast *smn1* gene to determine the phenotype and localisation of the protein. Analysis of human and mouse identical mutations and effects on SMN binding partners will be presented.

Program Nr: 2751 from the 1999 ASHG Annual Meeting

MEFV Mutation Analysis in Turkish Familial Mediterranean Fever Families. *T.H. Ozcelik[1,2], E. Erken[3], B. Cevher[2], G. Tuncman[2], L. Mesci[2], H. Ozer[3], R. Gunesacar[3], M. Ozturk[1,2].* 1) Dept Molecular Biol & Genetics, and; 2) BilGen, Bilkent University, Ankara Turkey; 3) Dept of Internal Medicine Cukurova University School of Medicine, Adana, Turkey.

Familial Mediterranean fever (MEFV) is an autosomal recessive disorder that frequently affects Turkish, North African Jewish, Arab, and Armenian populations. It is characterized by episodic attacks of inflammation in the peritoneum, synovium or pleura accompanied by fever, and skin rash. The FMF gene (MEFV) on chromosome 16 was identified recently. In addition the disorder was shown to be genetically heterogenous through linkage analysis in two Turkish families with clinical features of FMF. In order to determine the spectrum of MEFV gene mutations we collected blood samples from 42 unrelated Turkish FMF families predominantly from the Southern and Southeastern regions of the country. We screened the probands for four missense mutations in exon 10 by PCR amplification of genomic DNA and automated DNA sequencing. Distribution of the mutations in 84 independent FMF alleles is as follows: M680I (14), M694V (34), V694I (3), and V726A (13). Both FMF mutations were identified in 28 patients (66.6%), only one mutation was identified in eight patients (19%), and no mutation was found in six patients (14%). Based on these findings mutations in 76% of the carrier chromosomes were identified. However 85-93% of MEFV mutations were identified in other populations. The relatively low number of mutations in our study group may be due to genetic heterogeneity in FMF. In fact none of the families were selected through linkage analysis. In addition other MEFV mutations can be expected especially in the group of patients with only one mutation. We are now screening for E148Q mutation in the groups of patients with no mutation and only one mutation. We will further perform linkage analysis in mutation negative families. These results indicate that DNA-based diagnosis of FMF in the Turkish population may be helpful. However, determination of MEFV carrier frequency based on the above mentioned mutations appears to be early.

Program Nr: 2752 from the 1999 ASHG Annual Meeting

Connexin 26 mutations in Greek patients with prelingual deafness. *A. Pampanos[1], M. Grigoriadou[1], J. Economides[2], T. Iliadis[3], N. Voyiatzis[3], P. Neou[4], N. Apostolopoulos[4], T. Antoniadi[5], J. Petmezakis[5], V. Christophidou-Anastasiadou[5], K. Grønskov[5], K. Brøndum-Nielsen[5], J. Gyftodimou[1], A. Skevas[5], M.B. Petersen[1].* 1) Dept of Genetics, Inst Child Health, Athens, Greece; 2) "Aghia Sophia" Children's Hosp, Athens, Greece; 3) Aristotle Univ Thessaloniki, Thessaloniki, Greece; 4) "P. and A. Kyriakou" Children's Hosp, Athens, Greece; 5) Cx26 Consortium.

Mutations in the gene encoding the gap-junction protein connexin 26 (Cx26) on chromosome 13q11 have been shown as a major contributor to prelingual, sensorineural, non-syndromic recessive deafness in Caucasian populations. One specific mutation, a deletion of G in a sequence of six Gs (35delG), has accounted for the majority of the mutations detected in the Cx26 gene and is one of the most frequent disease mutations identified so far with highest carrier frequency in Southern European populations. We have previously detected a carrier frequency of the 35delG mutation of 3.5% in Greek people. In a collaboration with the major referral centers for prelingual deafness in Greece and Cyprus, patients were examined by an extensive questionnaire to exclude syndromic forms and environmental causes of deafness, and by allelle-specific PCR for the 35delG mutation. The 35delG mutation was detected in 33% of the alleles in 30 cases (27 sporadic, 3 familial): 9 homozygotes and 2 heterozygotes. Individuals non-homozygous for the 35delG mutation are further analysed by DGGE and dideoxy fingerprinting techniques and sequencing. Due to the marked preference of deaf persons for a deaf spouse, vertical transmission of deafness due to homozygosity of the 35delG mutation was observed in one family, not resembling the typical recessive pattern of inheritance. We conclude that all individuals with prelingual, sensorineural, non-syndromic deafness should be tested for the 35delG mutation, irrespective of pedigree pattern.

Program Nr: 2753 from the 1999 ASHG Annual Meeting

Estimate on the frequency of Connexin 26 mutations in the deaf population in the USA. *A. Pandya[1], R. Morell[3], K. Oelrich[2], K.S Arnos[2], X.J. Xia[1], X.Z. Liu[1], J. English[1], S.H. Blanton[1,4], A. Griffith[3], T. Friedman[3], W.E. Nance[1].* 1) Virginia Commomwealth University,Richmond, VA; 2) Gallaudet University, Washington D.C; 3) NIDCD, Rockville,MD; 4) University of Virginia, Charlottesville, VA.

Prelingual hearing loss affects 1:1000 children, at least half of which is genetic in etiology. The GJB2 gene encoding gap junction protein 2, also called Connexin 26 is one of a growing number of genes found to have mutations which can cause hearing loss. One particular mutation 35delG accounts for up to 50-80% of recessive deafness in the French, Spanish and Italian populations. A different mutation, 167delT, has a high prevalence in the Ashkenazi Jewish population with a carrier frequency of about 4%. At least 40 other GJB2 alleles associated with hearing loss have been reported. However, there is marked phenotypic variability in the degree of hearing impairment as well as progression. This, coupled with the relative ease of testing for mutations at this locus has raised important ethical and social issues. In order to address these issues and to estimate the frequency of different mutations at the GJB2 locus in the US population we have begun to ascertain deaf probands from both multiplex and simplex families through a national survey conducted by the Research Institute at Gallaudet University. Molecular analysis was performed by direct sequencing of the coding region for GJB2 locus. So far, we have observed six previously described and one new mutation. The new mutation is an Arg32Cys substitution in the first transmembrane domain in a compound heterozygote with congenital deafness. Connexin deafness accounted for 25% of the 92 US probands and at least 77% of the mutant alleles were 35delG. Audiometric data is available on 47 of these probands. Identification of the mutational spectrum at this locus will allow a careful genotype-phenotype correlation and provide more accurate estimates of the frequencies of various GJB2 alleles . This will enable provision of accurate diagnosis, prognosis and, counseling for language and speech as well as for future recurrence risk.

Program Nr: 2754 from the 1999 ASHG Annual Meeting

Screening of mutations in the Caveolin-3 gene in Brazilian limb-girdle muscular dystrophy patients. *F.de Paula[1], M. Vainzof[1,2], E.E. McNally[3], L.M. Kunkel[4], M. Zatz[1].* 1) Centro de Estudos do Genoma Humano, IB-USP, Sao Paulo, Brazil; 2) Dept. of Neurology, FMUSP; 3) Section of Cardiology, University of Chicago, Chicago, USA; 4) Division of Genetics and the Howard Hughes Medical Insitute, Childrens Hospital, Boston, USA.

Limb-girdle muscular dystrophy (LGMD) is a clinically and heterogeneous group of myopathies characterized by proximal muscular weakness and a variable clinical course. Eight autosomal recessive (AR) and 4 autosomal dominant (AD) forms have already been identified. Caveolin-3 (CAV3) is localized to the sarcolemma where it forms a complex with dystrophin and its associated glycoproteins. Mutations in the CAV3 gene, mapped at 3p25, with a reduction of more than 95% in the protein expression (Minetti et al.,1998), cause AD LGMD 1C. It has also been suggested that mutations in CAV3 might also cause AR LGMD (McNally et al., 1998).We have analyzed (through SSCP and sequencing of abnormal fragments) a total of 74 Brazilian LGMD patients for mutation in the CAV3 gene: 7 with AR , 53 isolated cases (22 women and 31 men) and 14 familial cases (6 with confirmed AD inheritance). Muscle protein analysis done in 49 patients excluded dystrophinopathies (in 49), sarcoglicanopathies (in 42) and calpainopathies (in 25). One female (previously reported) had a C71W change in one allele. Other missense mutations, in one of the alleles were detected in 3 isolated cases: G55S (in two males with mild course) and R125H (in a female with mild course). Analysis of the C71W change in 100 normal controls detected 1 case in heterozigous state and G55S in 2 cases (2%) also in heterozigozity. The R125H mutation was not found in 200 normal chromosomes but was present in 2 apparently unaffected sibs of the proband. IF analysis for caveolin-3 in muscle biopsies from patients with mutations G55S and R125H showed a strong positive sarcolemal pattern, suggesting no protein reduction. The possibility that these mutations in the CAV3 gene are interacting with other genes resulting in an abnormal phenotype cannot be ruled out. However, the present study suggests that the mutations in CAV3 gene, causing LGMD 1C, is rare in our population.

Program Nr: 2755 from the 1999 ASHG Annual Meeting

High carrier frequency of the hemochromatosis C282Y allele in factor V Leiden-positive patients. *J.E. Paulus-Thomas, J.E. Hudson, M. Matzinger.* MCP Hahnemann University, Pittsburgh, PA.

A significant association was found between heterozygosity for factor V Leiden mutation (R506Q) and the common hereditary hemochromatosis mutation (C282Y) in unselected patients referred for hypercoaguable testing (Xie et al, 1998). The frequency of C282Y carriers was 18.7% in factor V Leiden-positive cases compared to 3% in factor V-negative patients and 6% in control populations. A subsequent study of patients diagnosed with venous thromboembolism did not reveal an increased prevalence of the C282Y allele in factor V Leiden heterozygotes. Our investigation analyzed coinheritance of the C282Y and R506Q alleles in patients who were referred for factor V Leiden mutation analysis in comparison to unrelated Caucasian controls. Genomic DNA extracted from peripheral blood specimens was tested by PCR in combination with restriction digestion. In 50 patients who were referred for DNA testing and found to be factor V Leiden heterozygotes, 26% were also carriers of the C282Y allele and 74% were negative for C282Y. Two individuals homozygous for factor V Leiden mutation also possessed one copy of C282Y. In the random Caucasian group, only 6.4% were C282Y carriers and none of these individuals were homozygous C282Y. Our results support a significant association between R506Q and C282Y heterozygosity in patients referred for DNA testing and presumably at risk for hypercoagulation. Additional studies are required to identify the subgroup of these patients in which this association is highest and to unravel the biological relationship of these two alleles.

Program Nr: 2756 from the 1999 ASHG Annual Meeting

***APOE* haplotype segregating with Late-Onset Familial Alzheimer's Disease for 200 years.** *J. Perez-Tur[1], R. Crook[1], J. Hardy[1], D.S. Borgaonkar[1, 2]*. 1) Mayo Clinic Jacksonville. Jacksonville, FL; 2) Christiana Care Health System. Wilmington, DE.

Several genetic risk factors have been proposed to modulate the appearance of late-onset Alzheimer's disease (LOAD). Among these, only *APOE* is widely accepted to influence the risk for the disease. Moreover, recent evidence shows that genetic variability at this locus modifies the risk for the disease conferred by this isoform. We have previously described a large American pedigree affected by LOAD with a suggestive role for the e4 allele of *APOE*. Now, we present more detailed studies of this locus on chromosome 19. We genotyped the following microsatellite markers D19S178, APOC II, D19S908 and D19S918 and performed a parametric analysis of the data. In the modeling of the disease we took into account the influence of the e4 allele, that all definitely affected individuals were women and the existence of two consanguineous marriages in the pedigree. The maximum two-point LOD score observed in this pedigree was of 1.0 for marker D19S918 at q=0.0. This is in good agreement with the power calculations performed using the same parameters as in the linkage analysis. A haplotype was observed segregating with the disease but was also present in some clinically unaffected individuals. We sequenced the coding region of the gene looking for additional variation that could explain the apparently high risk conferred by possession of this haplotype in this family. In addition, we have determined the genotypes at the polymorphic sites -491, -427, -291 and E4P. No differences were observed between affected and unaffected individuals with regard to these polymorphisms. No new coding polymorphisms were observed. Finally, we also investigated the influence of other AD loci, *APP*, *PS1* and *PS2*, in this family but found no evidence of cosegregation of genotypes at any of these loci with the disease. Work supported by the Crystal Trust, the Rieffel Memorial Fund and the Mayo Foundation.

Program Nr: 2757 from the 1999 ASHG Annual Meeting

Mutational screening by DGGE in French PKD1 families. *R.A. PERRICHOT[1, 2], B. MERCIER[1], P. SIMON[3], B. WHEBE[4], J. CLEDES[2], C. FEREC[1]*. 1) Genetic laboratory, ETSBO - CHU, BREST, FRANCE; 2) Nephrology department, CHU, Brest - FRANCE; 3) Nephrology department, CH, Saint Brieuc - FRANCE; 4) Nephrology department, CH, Quimper - FRANCE.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most commonly inherited renal disorders. Mutations in at least three different genes can lead to ADPKD. PKD1, the major locus, mapped to chromosome 16p13-3, accounts for approximately 85% of ADPKD cases. We screened 146 French unrelated patients for PKD1 mutations analysis by denaturating gradient gel electrophoresis (DGGE) approach. In the first step of the study, we have successfully identified novel mutations in the non duplicated region of the gene. The same approach has been used to analyse part of the duplicated area from exon 15 to 33 after a step of long range PCR followed by nested PCR for the analyse of each exon. This strategy allowed us to identify novel mutations that we report here. This is the first study using the DGGE approach for PKD1 mutation screening. From our data and others published in the literature the correlation of genotype-phenotype is not evident; variability of mutation and DNA variants exists widespread along the gene. In order to understand the molecular mechanisms underlying ADPKD we must screen for additional mutations along the entire PKD1 gene.

Program Nr: 2758 from the 1999 ASHG Annual Meeting

The SOX10 transcription factor: evaluation as a candidate gene for central and peripheral demyelination. *V. Pingault[1], N. Bondurand[1], C. Le Caignec[1], S. Tardieu[2], The European Network on Brain Dysmyelinating Diseases[3], N. Lemort[1], O. Dubourg[2], E. Le Guern[2], O. Boespflug-Tanguy[4], M. Goossens[1]*. 1) INSERM U468 et Laboratoire de Biochimie et Genetique Moleculaire, AP-HP, Hopital Henri Mondor, Creteil, France; 2) INSERM U289, Hopital de la Pitie-Salpetriere, Paris, France; 3) The European Network on Brain Dysmyelinating Diseases; 4) INSERM U384, Faculte de Medecine, Clermont-Ferrand, France.

Several *SOX* genes have already been shown to be transcription factors involved in the decision of important cell fates during development. The *Sox10* gene was first cloned from rat glial cells and shown to be expressed in neural crest cells during early development and in neural crest derivatives, including melanocytes and peripheral nervous system. In the central nervous system, the *Sox10* expression pattern suggests an expression in oligodendrocytes. The SOX10 factor acts as an autonomous transcription factor in humans, but also modulates the activity of others transcription factors involved in Schwann cells development, such as TST1/OCT6/SCIP, PAX3, Krox20/EGR2. We previously showed that heterozygous *SOX10* loss of function mutations result in Waardenburg-Hirschsprung disease, a condition characterized by enteric nervous system defect, hypopigmentation and deafness. Recently, another mutation was reported in a patient showing a central and peripheral demyelinating disease associated with Waardenburg-Hirschsprung syndrome. All these data suggest that *SOX10* could be a candidate gene for demyelinating disease. Here we report the results of mutation screening in 60 patients with Charcot-Marie-Tooth disease type 1, and in 87 patients expressing demyeliniting or hypomyelinating leukodystrophies (including a few patients with an associated peripheral neuropathy, spinal motor involvment, deafness or hypopigmentated areas of the skin).

Program Nr: 2759 from the 1999 ASHG Annual Meeting

Molecular basis of CD 36 deficiency in the African Bantu population. *S. pissard[1], K. Lee[2], F. Niels[1], R. Narwa[1], P. Bierling[2], B. Godeau[4], M. Goossens[1], F. Galacteros[3]*. 1) lab of Biochemistry and Genetics, Hop Henri Mondor, Creteil, France; 2) Transfusion Medicine Unit, Hop Henri Mondor, Creteil, France; 3) Centre de la Drepanocytose,Hop Henri Mondor, Creteil, France; 4) Internal Medicine Unit, hop Henri Mondor, Creteil.

CD 36 is a cell-surface glycoprotein (472 aa, 88 KD) expressed on a large set of cells including hematopoietic cells and "derivates" (platelets, monocytes, reticulocytes and young red cells), epithelial cells, adipocytes. The deficiency can be complicate by isoimmunization against platelets which results in transfusion refractoriness, post-transfusion purpura or neonate thrombocytopenia. About 5 to 10% of Asians lack platelet CD 36. This deficiency is very rare in the Caucasian population (less than 1%) and concerns 5 to 10 % of the whole African population . In a survey of the African population from sub-Saharan African countries, this frequency was found to be in the range of 10 to 20%. This unexpected high frequency is probably related to the role that CD 36 plays in the adhesion of malaria parasitized erythrocytes on epithelial cells. We have searched for the mutation responsible for CD 36 deficiency in 17 platelet-, CD36 - patients from this population using an RNA-based detection method (NIRCA). We did not find the P90S mutation described in the Japanese population, but we observed two recurrent mutations : 446 AA->G (exon4) in 10 patients and IVS 5, +2 T->C in 3 other patients. These two mutations lead to a frameshift and therefore inactivate the gene. We analysed the polymorphic microsatellite marker that lies in the 3rd intron of the CD 36 gene in the CD 36 - patients and in African Bantu newborns (control population). In the CD 36 - patients, the 46 AA->G mutation is always associated with the 196 allele, while the IVS 5, +2 TC mutation is associated with the 184 allele. The 196 allele seems to be significantly more frequent in CD 36- patients than in control population (27% to 11% $p<0.05$. since it is a rare allele, 184 do not show significant difference between CD 36- and control population (9 to 6%, ns). This could be an indication of founding mutations in Cd 36 deficiency in African Bantu population.

Program Nr: 2760 from the 1999 ASHG Annual Meeting

Functional analysis of a novel rhoGAP gene in Xp22.3. *S. Prakash[1], R. Paylor[1], B. Xu[1], H. Zoghbi[1,2].* 1) Baylor College Medicine; 2) Howard Hughes Medical Institute, Houston, TX.

Microphthalmia with Linear Skin defects (MLS) is an X-linked dominant, male lethal syndrome characterized by microphthalmia, aplastic skin and agenesis of the corpus callosum, and is caused by the deletion of a 500 Kb critical region in Xp22.3. We cloned a novel rho GTPase-activating protein (rhoGAP) gene named *ARHGAP6* from the MLS region. *ARHGAP6* contains 14 exons encoding a 975 amino acid protein with three putative SH3-binding domains. Exons 2-14 are deleted in all MLS patients. This led us to hypothesize that *ARHGAP6* may be responsible for some of the phenotypic features of MLS. RhoGAPs are regulators of cell migration and morphology through interactions with the actin cytoskeleton and another rhoGAP gene was recently implicated in nonsyndromic mental retardation. Two approaches were pursued to determine the role of *ARHGAP6* in the pathogenesis of MLS: gene targeting of the rhoGAP domain in embryonic stem cells and *in vitro* expression studies. Surprisingly, loss of the rhoGAP activity of *Arhgap6* does not cause any detectable phenotypic or behavioral abnormalities in the mutant animals. However, transient transfection studies suggest that the rhoGAP domain may be dispensible for some functions of the protein. Transfected HeLa and COS7 cells expressing ARHGAP6 retract from the growth surface and extend thin, branching processes resembling filopodia. ARHGAP6 associates with actin filaments through an N-terminal domain and mediates the redistribution of F-actin from focal adhesions into the growing processes. Mutation of a conserved arginine residue in the rhoGAP domain inhibits loss of stress fibers but has little effect on process outgrowth. These results suggest that ARHGAP6 has two independent functions as a GAP with specificity for rhoA and as a cytoskeletal protein that promotes actin polymerization or remodeling. The N-terminus of ARHGAP6, which remains intact in the mutant animals, may be essential for its in vivo activity. Therefore a second targeting vector was integrated into the first exon of *Arhgap6* to delete the entire coding region using cre-*lox*P recombination. Germline transmission the floxed *Arhgap6* allele is in progress.

Program Nr: 2761 from the 1999 ASHG Annual Meeting

Non-radioactive Dideoxy Fingerprinting for Mutation Analysis of BRCA1 and BRCA2. *S. Preisler-Adams, B. Dworniczak, J. Wansch, J. Horst.* Universitaet Muenster, Humangenetik, Muenster, NRW, Germany.

Mutations in the breast cancer susceptibility genes BRCA1 and BRCA2 account for a substantial proportion of familial breast and ovarian cancer syndromes. Both genes are comprised of more than 20 exons and contain a large internal exon, which has to be subdivided for mutation analysis. Due to the multitude of PCR formats there is a demand for an appropriate prescreening method before performing direct sequence analysis. Thus, dideoxy fingerprinting (DDF), a hybrid between dideoxy sequencing and single strand conformation analysis (SSCA), has been applied to test whether it meets the respective requirements. A ladder of bands is generated by performing only one of the four standard dideoxy sequencing reactions and resolving the products by electrophoresis on a nondenaturing polyacrylamide gel. Performing radioactive dideoxy fingerprinting according to the published procedures a high sensitivity could be obtained. In order to avoid the use of radioactivity we tested a nonradioactive approach using Cy5 labeled sequencing primers and an automated sequencer (A.L.F.express, Pharmacia). All reactions were performed following a standardized protocol using M13 primers and ddG as termination nucleotide. The required temperature control of the polyacrylamide gel was achieved by bypassing the heater and external cooling. Using the nonradioactive DDF we were able to identify all known common BRCA1 and BRCA2 polymorphisms in heterozygous state as well as in both homozygous forms. Furthermore all tested BRCA1 and BRCA2 mutations - including six point mutations - were also detectable with nonradioactive DDF.

Program Nr: 2762 from the 1999 ASHG Annual Meeting

Development of a Sensitive and Efficient Testing Strategy for Mutations in the APC Gene Associated with Familial Adenomatous Polyposis. *T.L Price-Troska, G. Chong, K. Snow.* Molecular Genetics Laboratory, Mayo Medical Center, Rochester, MN.

Familial Adenomatous Polyposis (FAP) is a dominantly inherited autosomal disorder characterized by multiple adenomatous polyps of the colon and a high probability of developing colorectal cancer an early age. The APC gene, which contains mutations associated with FAP, contains almost 9kb of coding sequence. Mutations in FAP are distributed throughout the gene, meaning that mutation detection can be very labor intensive. Our laboratory has developed an efficient and sensitive testing strategy for detecting mutations in the APC gene. The APC gene is divided into 5 segments. Segment 1 (exons 1-14) is analyzed by single-stranded conformation polymorphism (SSCP) and conformation sensitive gel electrophoresis (CSGE) methods using multiplexed PCR products, and by the protein truncation test (PTT). Segments 2 to 5 (which are overlapping regions of exon 15) are analyzed by the PTT using DNA as the starting material. Sequencing is used to characterize alterations detected by the above methods. In screening 35 unrelated patients that had a diagnosis of classical FAP, the overall mutation detection rate was 89%. Of interest, 55% of these mutations were in exons 1-14, which is significantly higher than previously reported detection rates for that segment. This difference is probably due to the inefficient detection of mutations in segment 1 by the PTT method. In our study of cases where RNA was available, testing of segment 1 using RT-PCR and PTT detected only 5 of 10 mutations detected by CSGE and/or SSCP, and all mutations detected by the PTT of segment 1 were detected by CSGE and/or SSCP. To maximize efficiency of testing in the clinical laboratory, we divide testing into two tiers. The first tier includes PTT analysis for segments 2 and 3, and CSGE analysis for segment 1. If no alterations are observed after the first tier, testing is continued. The second tier includes SSCP and PTT for segment 1, 4 and 5. To date, we have identified 38 different nonsense or frameshift mutations, and 26 of these have not been previously reported.

Program Nr: 2763 from the 1999 ASHG Annual Meeting

Molecular Analysis of the Duchenne Muscular Dystrophy Gene in Colombian Individuals. *J.C. Prieto[1,5], G. Keyeux[1], F. Leturcq[2], C. Duran[1], C. Rodas[1], S. Bautista[1], D. Recan[2], L.M. Camacho[3], E. Espinosa[4], J.E. Bernal[1], M.L. Tamayo[1], M. Cediel[4], P. Garavito[1], J.C. Kaplan[2]*. 1) Inst de Genetica Humana, Univ Javeriana, Bogota, Cundinamarca, Colombia; 2) Inst Cochin de Genetique Moleculaire, Paris; 3) Clinica Marly,Bogota; 4) Inst Roosevelt,Bogota; 5) Hospital la Victoria.

Duchenne muscular dystrophy (DMD) is the most common and severe neuromuscular disease in man and has an X-linked recessive mode of inheritance. Approximately 60% of DMD/BMD mutations are major deletions and 10% represent duplications. The deletions are nonrandomly distributed, one extending over the first 20 exons and the second near the middle of the gene around exons 45 to 53. In this pilot study in Colombia, a total of 38 patients were diagnosed using standard clinical diagnostic criteria. Deletion testing was performed by multiplex PCR, using 17 primer sets. STR loci (5`DYS II, 3`DYS MSA, 44, 45, 49 and 50) were analised determined in 50 X-chromosome haplotypes from unrelated individuals and the frequencies of observed alleles, % Heterozygosity and PIC were determined. Five families with DMD or BMD patientes were referred by carrier detection for segregation analysis of highly polymorphic STR loci. Of the 38 patients,14 (38%) had deletions located in the two mutational hot spots, 11 of them (79% of deletions) in the distal hot-spot, and 3(21%) in the proximal hot spot. The frequency of deletions found in this study is lower than described in the Caucasian population and similar to Asiatic and Spanish populations. Preliminary results suggest a high proportion of small mutations in our country or other dystrophin-complex diseases. Five of the families studied were informative because the carrier mothers were heterozygous for some the markers. In one family, the affected boy suffered a detectable de novo deletion of the intron 49 marker. This boy is affected by a deletion including adjacent exons. The frequencies of all observed alleles, % Heterozygosity and PIC were estimated and compared in several ethnic groups. Results derived from this study are useful for carrier detection and genetic counseling in DMD/BMD.

Program Nr: 2764 from the 1999 ASHG Annual Meeting

Identification of a carboxy-terminal nuclear localization signal in dyskerin. *M. Qatanani, V. Gharibyan, H. Youssoufian.* Dept. Molecular and Human Genetics, Baylor College of Medicine , Houston, TX.

The X-linked form of the bone marrow failure syndrome Dyskeratosis congenita is caused by mutations in dyskerin, a 514 amino acid protein that is presumed to play a role in ribosome biogenesis. There are at least two potential nuclear localization signals in dyskerin. Here we report that dyskerin tagged with the human immunoglobulin IgG1 epitope localizes to the nuclei of transfected HeLa and COS-1 cells. Placement of a carboxy-terminal domain consisting of amino acids 467-475 and encoding KKEKKKSKK at the carboxy-terminus of FANCC, a 558 amino acid cytoplasmic protein deficient in Fanconi anemia complementation group C, showed that this motif is both necessary and sufficient to mediate nuclear entry. This is the first report of the subcellular localization of dyskerin. The location of a nuclear localization signal at the carboxy terminus suggests that otherwise stable or active truncated mutants will remain inactive by failing to reach the nucleus, a mechanism similar to mutations in the Werner syndrome helicase.

Program Nr: 2765 from the 1999 ASHG Annual Meeting

Increased glycogen load accelerates the course of the disease in the acid alpha-glucosidase knockout mice. *N. Raben, K. Nagaraju, E. Lee, P. Plotz.* Arthritis and Rheumatism Branch, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD.

We have previously reported generation of a knockout mouse model of Glycogen Storage Disease Type II (GSDII), a recessively inherited deficiency of acid alpha-glucosidase (GAA), which in its most severe form results in abnormal intra-lysosomal accumulation of glycogen in multiple organs, cardiomyopathy and death in infancy (Pompe disease). The animals lacking GAA activity (GAA-/-) developed generalized glycogen storage and showed obvious clinical signs of muscle weakness by 8-9 months of age. The knockouts have been followed now for up to 20 months. In this time the mice developed a severe progressive muscle-wasting disorder remarkably similar to that in human infantile GSDII: massive glycogen accumulation in skeletal muscle, diaphragm, heart, and brain, cardiomyopathy, hypotonia, severe motor disability, and profound muscle wasting with striking spine hunching. The relatively slow progression of clinical signs in mice suggests that the process of structural muscle damage resulting from the accumulation of lysosomal glycogen is absolute, and not relative to the life span. In order to develop a model with an earlier onset of the disease, the knockouts were bred to transgenic mice that overexpress the human GlutI glucose transporter in skeletal muscle (Marshall et al, JBC, 1993). The elevated glucose transporter activity in transgenic mice was associated with a significant increase in glycogen concentration in skeletal muscle, but phenotypically the mice remained normal. The transgenic mice on a GAA knockout background (GlutI/GAA-/-) developed the first obvious clinical signs of muscle weakness and wasting significantly earlier than the knockouts - by 4-5 months of age. By 9-12 months of age, however, the strains become clinically indistinguishable. In contrast to the knockouts, in which the females were more affected then males, the time course and the severity of the disease in GlutI/GAA-/- were similar in females and males.

Program Nr: 2766 from the 1999 ASHG Annual Meeting

The R3531C mutation in the APOB gene does not segregate with hypercholesterolemia in a large family. *J-P. Rabès[1,2], M. Varret[1], M. Devillers[1], L. Villéger[1], P. Aegerter[3], M. Krempf[4], C. Junien[1,2], C. Boileau[1]*. 1) INSERM U383, Paris; 2) Service de Biochimie et de Génétique Moléculaire, Hôpital A. Paré, Boulogne; 3) Service de Biostatistique, Hôpital A. Paré, Boulogne; 4) Service de Nutrition, Hôpital Hôtel-Dieu, Nantes (FRANCE).

Familial Hypercholesterolemia (FH) and Familial ligand-Defective apolipoprotein B-100 (FDB) are dominantly inherited disorders leading to impaired low density lipoprotein (LDL) receptor/apolipoprotein B-100 (apo B-100) interaction, plasma LDL elevation and hypercholesterolemia (HC). Numerous mutations in the LDL receptor gene (LDLR) lead to FH. Conversely, only 3 mutations in the apo B gene (APOB) have been associated with FDB, the R3531C substitution being one of them. We previously identified the first French APOB-R3531C proband, a 40 yo woman with very high cholesterol, in a group of type IIa dyslipoproteinemic families. We report herein the finding of the same mutation with an identical APOB haplotype in her unaffected husband. Further investigation of the family at large revealed 8 other carriers of the mutation but also, the absence of cosegregation with HC. Six of the 10 subjects heterozygous for the R3531C mutation had total plasma cholesterol lower than the 97.5th percentile for their age and sex, and plasma cholesterol was not significantly higher in carriers compared to family members lacking the mutation, questioning the deleterious nature of this substitution. Two family members with similar high cholesterol were not carriers of the R3531C mutation, suggesting the implication of another major gene. Segregation analysis of polymorphic markers of the LDLR gene revealed statistically significant genetic linkage with HC and analysis of proband LDLR gene lead to the identification of a 664 proline to leucine defective mutation and its detection in all 6 hypercholesterolemic members of the family. Therefore, our results show that the family presents with FH and give evidence that the R3531C substitution in the APOB gene is not an allelic variant leading to FDB. Furthermore, a two-way analysis of variance shows no significant interaction between APOB-R3531C genotype and LDLR-P664L mutation on cholesterol.

Program Nr: 2767 from the 1999 ASHG Annual Meeting

Mutational screening of the cationic trypsinogen gene in a large cohort of patients with sporadic chronic pancreatitis reveals novel DNA variants. *O. Raguenes[1], P. Deprez[2], Ch. Verellen[3], A. Andriulli[4], I. Quere[1], J.M. Chen[1], C. Ferec[1]*. 1) Centre de Biogenetique, Universite, Hopital, ETSBO, Brest, France; 2) Service de Gastroenterologie, Clinique Universitaire Saint Luc, Belgium; 3) Centre de Genetique Humaine, Unite de Genetique Medicale, Universite Catholique de Louvain, Bruxelles, Belgium; 4) Laboratorio Di Ricerca, Istituto Di Ricovero E Cura A Carattere Scientifico, San Giovanni Rotondo, Italy.

Two missense mutations of the cationic trypsinogen gene have been associated with hereditary pancreatitis (HP). To explore whether the cationic trypsinogen could play a role in the sporadic disease, we performed mutational analysis of the gene in 312 patients with sporadic chronic pancreatitis using denaturing gradient gel electrophoresis and detected novel DNA variants, all of which were absent in 400 control chromosomes. 1) In contrast to the single G>A transition resulting in an R122H (R117H in chymotrypsin numbering system) mutation identified in HP, a **GC**>**AT** 2-bp substitutions resulting also in an R122H was detected in 1 patient. This novel variant seems to arise as a gene conversion event: presences of **AT** at the corresponding positions of two other trypsinogen genes and a *Chi*-like sequence in the 3' proximity of the mutation. This finding also raises practical concerns: an R122H mutation, if arose as a gene conversion event, will be missed by the widely used PCR-*Afl* III digestion method (single G>A transition creates a novel restriction enzyme recognition site for *Afl* III—A¯CRYGT) and thus cause misleading interpretation. 2)A C>T transition resulting in an A16V detected in 2 patients. Since residue 16 is the signal peptide cleavage site, A16V may have an effect on the intracellular transport of the mutated protein. 3) Other single nucleotide substitutions detected once in different individuals: except for G>A (E79K), C>G (P36R), G>A (G83E) and G>T (K92N) all resulted in a nonconservative amino acid substitution at a well conservated residue. Furthermore, that no frameshift, nonsense and splicing mutations were detected is consistent with a "gain-of-function" dominant disease. Our results indicated that genetic testing is warranted in sporadic pancreatitis.

Program Nr: 2768 from the 1999 ASHG Annual Meeting

Developmentally regulated expression of AIRE during human leukocyte differentiation. *C. Ramsey[1], J. Kaukonen[2], A. Palotie[3], L. Peltonen[1,4].* 1) Department of Human Genetics, UCLA School of Medicine, Los Angeles, CA; 2) Department of Clinical Chemistry, University of Helsinki, Finland; 3) Department of Pathology, UCLA School of Medicine, Los Angleles, CA; 4) Department of Human Molecular Genetics, National Public Health Institute, Helsinki, Finland.

Autoimmune PolyEndocrinopathy-Candidiasis-Ectodermal Dystrophy (APECED) is a rare autosomal recessive disease enriched in Finnish, Iranian Jewish, and Sardinian populations. The APECED gene was previously identified and assigned to chromosome 21q22.3 by positional cloning. The causative gene, AIRE, is 2.25 kb long and northern blots show expression in thymus, pancreas and adrenal cortex. The predicted primary protein sequence of AIRE contains a proline rich region, two PHD-type zinc finger motifs, a nuclear localization signal and a newly identified SAND domain. To investigate the mechanism of autoimmunity with respect to AIRE, we monitored its expression in both peripheral blood cells and thymocytes. We examined the expression of AIRE mRNA in enriched populations of CD34+ peripheral leukocytes, B-cells, T-cells, monocytes, granulocytes, and thymocytes by RT-PCR. The AIRE mRNA is detected in peripheral CD34+ cells and T-cells. To characterize the expression of AIRE during T-cell maturation, we examined established human T-cell lines which were arrested at distinct stages of thymocyte maturation (in the order ARR-> MOLT-> CEM->Hut78), as well as one mature T-cell line, Jurkat, and compared the expression of AIRE in these cell lines with normal peripheral T-cells. Positive RT-PCR product was detected only with Hut78 cells; no product was observed from the other T-cell lines. These data are consistent with the previously reported expression of AIRE in mature medullary thymocytes, but not in immature cortical thymocytes. Interestingly, mature Jurkat cells did not express detectable level of AIRE mRNA, unlike normal peripheral T-cells. Thus, our data suggests that the AIRE mRNA is expressed in early hematopoietic development in pluripotent CD34+ cell leukocytes; AIRE expression is down regulated during T-cell maturation in the thymus, and then increases again in mature thymocytes and peripheral T-cells.

Program Nr: 2769 from the 1999 ASHG Annual Meeting

Members of a novel gene family on Xp22.3 are deleted in patients with X-linked non-specific mental retardation.

G.A. Rappold[1], M. Fukami[1], S. Kirsch[1], S. Schiller[1], S. Merker[1], B. Franco[2], A. Richter[3], W. Ansorge[3], K. Muroya[4], T. Ogata[4], B. Niesler[1]. 1) Institute of Human Genetics, University of Heidelberg, Im Neuenheimer Feld 328, 69120 Heidelberg, Germany; 2) Telethon Institute of Genetics and Medicine, Via Orgettina 58, Milan, 20132 Italy; 3) European Molecular Biology Laboratory, Meyerhofstrasse 1, 69012 Heidelberg, Germany; 4) Department of Pediatrics, Keio University, 35 Shinanomachi, Shinjyukuku, 160 Tokyo, Japan.

Genotype-phenotype correlations in male patients with a partial nullisomy of the X chromosome have suggested the existence of at least one locus involved in X-linked non-specific mental retardation (MRX) on Xp22.3. Previous deletion mapping has defined that the critical region for this gene resides between markers DXS1060 and DXS1139, a region encompassing roughly 1.5 Mbp of DNA. Analysing the DNA of sixteen males with Xp deletion, we have narrowed down this MRX critical region to an interval of about 15 kb. Through exon amplification and the sequencing of two different cosmids which cover this region, a gene, VCX-A (Variably charged, X chromosome mRNA on CRI-S232A), was isolated. VCX-A consists of three exons. Due to a variable number of tandem repeats in exon III, the size of the predicted protein varies between 186 to 226 amino acids. VCX-A belongs to a gene family which contains at least four paralogs on Xp22.3 (VCX-A, B, B1 and C), and one on the Yq11.2 (VCY). Known motifs or domains were not detected in the gene sequence, and the function of VCX remains unknown at the present time. We found that all individuals with normal intelligence either have VCX-A or VCX-B or both, while all cases with MR lack both VCX-A and B, suggesting that one intact copy of either VCX-A or VCX-B is sufficient to maintain normal mental development.

Program Nr: 2770 from the 1999 ASHG Annual Meeting

Duplication of Chr. 17p13 in a patient affected with peripheral neuropathy, mental retardation and cranial dysmorphy. *B.W. Rautenstrauss[1], L. Brecevicz[1], D. Schweitzer[1], W. Voss[2], E. Gebhart[1]*. 1) Institute of Human Genetics, FAU Erlangen-Nuremberg, Erlangen, Bavaria, Germany; 2) Sozialpaediatrisches Zentrum, Janusz-Krozak-Allee 8, 30173 Hannover.

Charcot-Marie-Tooth disease type 1 A (CMT1A) is the most frequent form of autosomal dominantly inherited peripheral neuropathies. Typical clinical signs are reduced nerve conduction velocity, pes cavus deformity, gait disturbances and on sural nerve biopsy signs of de- and remyelination. Rarely patients show additional features like mental retardation. Most frequently a 1.5-Mb duplication in Chr. 17p11.2 including the PMP-22 gene is observed as cause of CMT1A. For some cases with additional mental retardation a partial or full duplication of the Smith-Magenis region was observed. The patient reported here has typical symptoms of a CMT disease like reduced NCV, on sural nerve biopsy signs of de- and remyelination and a pes cavus deformation. Additionally this patient is of short stature, has a cranial dysmorphy and is mentally retarded, at age of 7 years he did never learn to speak. Peripheral blood was used for the inital test on a CMT1A duplication in order to clarify the peripheral neuropathy, but this could be excluded by means of EcoRI/SacI Southern hybridisation (probe pLR7.8) and two color interphase fluorescence in situ hybridisation (FISH) with probes c132G8 (PMP-22) and cRCNeu. Point mutation screening in PMP-22, MPZ, Cx32 and EGR2 is ongoing. Duplication or deletion of the Smith Magenis region was excluded by two color FISH (fli-probe) as well as for the Miller-Dieker region. Finally by comparative genomic hybridisation (CGH) an extended duplication in chr. 17p13 was identified. This type of duplication in combination with a similar complex phenotype was described only once up to now in the Human Cytogenetics Database indicating the possibility of a contigous gene syndrome.

Program Nr: 2771 from the 1999 ASHG Annual Meeting

Mutation identified in crystallin gene in a family with zonular pulverulent cataract. *Z. Ren[1], A. Li[1], B.S. Shastry[2], T. Padma[3], R. Ayyagari[4], M.H. Scott[1], M.I. Kaiser-Kupfer[1], J.F. Hejtmancik[1].* 1) National Eye Institute, National Institutes of Health, Bethesda, MD; 2) Eye Research Institute, Oakland University, Rochester, MI 48309-4480; 3) Department of Genetics, Osmania University, Hyderabad,India; 4) Department of Ophthalmology, University of Michigan, Ann Arbor, MI.

Autosomal dominant zonular pulverulent cataracts were described in 48 members of an American family of European extraction over seven generations by Scott et al., Ophthalmology, 1994. We have mapped this locus to a 19 cM interval including the gamma-crystallin gene cluster on chromosome 2q33-q35. Sequencing and allele-specific oligonucliotide analysis of the pseudo gamma E-crystallin promoter region from individuals in the pedigree suggested that activation of the pseudo gamma E-crystallin gene with synthesis of an unstable crystallin is unlikely to be the cause of the cataract formation. In order to further investigate the cause of these cataracts and the underlying genetic mechanism, other gamma-crystallin genes were studied. Genomic DNA samples from affected family members and controls were analyzed by PCR with exon specific primers for the gamma C- and gamma D-crystallin genes, the most highly expressed human gamma-crystallins, and subsequently sequenced. The gamma D-crystallin gene showed no abnormalities, but a five base pair duplication within exon 2 of gamma-C crystallin was found in affected individuals and absent from unaffected individuals. The mutation disrupts the reading frame of the gamma C-crystallin coding sequence and is predicted to result in synthesis of an unstable gamma C-crystallin with the first Greek key motif followed by 52 random amino acids. This finding suggests that association of mutant beta gamma-crystallins into oligomers is not necessary to cause cataracts and may give us new insights into the genetic mechanism of cataract formation.

Program Nr: 2772 from the 1999 ASHG Annual Meeting

Novel mutations in a-**mannosidosis.** *H.M.F. Riise[1], T. Berg[2], H. Klenow[3], G. Evjen[4], E. Breines[3], O.K. Tollersrud[4], O. Nilssen[3]*. 1) Department of Human Genetics, UCLA, Los Angeles, CA, USA; 2) Department of Chemical Pathology, Womens and Childrens Hospital, Adelaide, Australia; 3) Department of Medical Genetics, University Hospital of Tromsø, Tromsø, Norway; 4) Department of Medical Biochemistry, University of Tromsø, Tromsø, Norway.

Lysosomal a-mannosidase (EC 3.2.1.24) is an exoglycosidase involved in the ordered degradation of N-linked oligosaccharides. Lack of LAMAN activity leads to the lysosomal storage disorder a-mannosidosis (MIM 248500), an autosomal recessive disorder described in man, cattle and cat. Affected individuals accumulate partially degraded oligosaccharides in the lysosomes, and typical symptoms in man are mental retardation, hearing loss, recurrent infections and various skeletal changes. Recently, we reported 23 disease causing mutations and six single nucleotide polymorphisms in the LAMAN gene of 42 unrelated a-mannosidosis patients mainly of European origin. In this work, 24 additional patients were analyzed by screening for known mutations as well as by automated DNA sequencing of the 24 LAMAN exons and exon-intron borders. Sixteen novel mutations; five missense, three nonsense, three splice site and five small insertions/deletions, were identified. In total, the 39 mutations were detected on 103 of the 132 alleles (78%). Most of the mutations were private or occurred in two or three families, except for one missense mutation, R750W, that was detected on 31 alleles (23.5%) in patients from 11 different countries. Haplotype analysis using four intragenic SNPs revealed that the 750W allele existed on three different haplotype backgrounds. The majority of the alleles (17 out of 20) shared the same haplotype, indicating that the 750W mutation probably spread by founder effects. The two other associated haplotypes could have emerged from the ancestral haplotype by single recombination events or, alternatively, resulted from recurrent mutations.

Program Nr: 2773 from the 1999 ASHG Annual Meeting

Darier Disease - Novel Mutations and a silent Polymorphism in ATP2A2. *F. Ringpfeil[1], A. Raus[1], J.J. Uitto[1], J.J. DiGiovanna[2,3], S.J. Bale[2], G. Richard[1]*. 1) Dept Derm, Jefferson Univ, Philadelphia, PA; 2) Gen Stud Section, NIAMS, NIH, Bethesda, MD; 3) Dept Derm, Brown Univ, Providence, RI.

Darier disease (DD) is a progressive, autosomal dominant genodermatosis with variable, but often debilitating skin manifestations. It may be associated with a range of neurological problems. Acantholysis of the epidermis is a histological hallmark suggesting impaired functionality of desmosomes. Recently, Sakuntabhai et al. (Nat Genet 21: 271-7, 1999) identified mutations in ATP2A2 in individuals with DD. ATP2A2 is a slow-twitched calcium pump that is widely expressed and controls cytosolic calcium levels. Thus it may confer a direct effect on the established calcium-dependant assembly of desmosomes. We screened the coding sequence of ATP2A2 in over 20 European and American families using conformation sensitive gel electrophoresis, and direct automated sequencing. To date, we identified 11 distinct mutations. We detected 7 missense mutations, 1 nonsense mutation, and small 3 in-frame deletions, all of which are novel with the exception of K683E. In addition, a silent polymorphism (nt.2172 G to A) with an allele frequency of 13.2% was found in exon 15. In accordance with previous reports, most pathogenic mutations are private. Our mutations are dispersed over different exons and are predicted to affect the upstream stalk, the transduction, phosphorylation, and ATP-binding sites, as well as the transmembrane and hinge domains. Two different missense mutations affect codon K683 changing this residue to arginine or glutamic acid in the corresponding hinge domain. Interestingly, K683E has been reported twice so far (Ruiz-Perez et al., abstract, JID in press), implying that this residue is critical for the function of the protein. To establish genotype-phenotype correlation, we compared molecular data with phenotypic features, such as severity and type of disease, occurrence of mucosal involvement, superinfections, or association with mental disorders. In our cohort, mutations in families with severe disease afflict the cytoplasmic transduction and phosphorylation domains, and the transmembrane regions, respectively. However, data are still too limited to draw further conclusions.

Program Nr: 2774 from the 1999 ASHG Annual Meeting

Protein expression of *COCH*, the DFNA9 sensorineural deafness gene, in human fetal cochlea and vestibule. *N.G. Robertson[1,2], J.S. Lin[1,2], C. Lee[1,2,3], H.L. Rehm[1,2,3], A. Shahsafaei[1], J.C. Aster[1,3], C.C. Morton[1,2,3]*. 1) Dept Pathology; 2) Dept Ob/Gyn, Brigham & Women's Hosp; 3) Harvard Medical School, Boston, MA.

The human *COCH* gene was shown previously to have four different missense mutations in American and European families with DFNA9, an autosomal dominant sensorineural hearing loss with vestibular dysfunction. To understand the functional role of *COCH*, we have developed a polyclonal antibody against the human Coch protein. The Coch peptide used as the immunogen consists of the Coch N-terminal factor C-like domain (Coch-FC peptide), which is mutated in DFNA9 patients. The von Willebrand type A-like domains present in *COCH* were omitted from the peptide to avoid possible cross-reactivity with other secreted proteins containing vWFA domains, such as collagens expressed in the cochlea.

The Coch-FC peptide expressed with an N-terminal histidine tag was purified over a Ni2+ column and used to immunize chickens. Antibodies isolated from immune eggs recognized the Coch-FC peptide and *in vitro* translated full-length Coch protein (~60 kD) on Western blots, whereas pre-immune serum did not react.

Using the a-Coch antibody, we performed immunohistochemistry on paraffin sections from 18-week-old human fetal cochlear and vestibular organs. High levels of staining were detected in the extracellular matrix of the spiral limbus, the area adjacent to collagen fibrils of the spiral ligament, the osseous spiral lamina along the fibers of the cochlear nerve, the spiral ganglion, and the epithelium and stroma of the saccular macula. This localization parallels the previously shown pattern of *Coch* mRNA expression in the chicken inner ear and matches the sites with characteristic acidophilic deposits observed in the cochlear and vestibular sections of individuals with DFNA9. The a-Coch antibody is a valuable biological tool to assess whether the mutant Coch protein is contained within the acidophilic deposits seen in DFNA9 and to investigate further the mechanism underlying this histopathology.

Program Nr: 2775 from the 1999 ASHG Annual Meeting

ARE A4336G POINT MUTATIONS AND mtDNA REARRANGEMENTS INVOLVED IN ALZHEIMERS DISEASE AETIOLOGY? *B. Rodriguez-Santiago[1], M. Gomez Zaera[1], J. Casademont[2], V. Nunes[1]*. 1) Med. and Mol. Genetics Center-IRO, Avia.Castelldefels km 2'7,08907 Hosp. Llobregat, Barcelona, Spain; 2) Muscular Research Unit, Department of Internal Medicine, Hospital Clnic, University of Barcelona, Villaroel 170, 08036 Barcelona, Spain.

Alzheimers disease (AD) is associated with defects in mitochondrial function. AD has a complex aetiology, and it is widely considered that genetic factors, acting independently or in concert with other genetic and/or environmental factors, modify the risk of developing the disease. There is controversy about the role of the mitochondrial tRNA (Gln) sequence variant (A4336G transition). This mutation was reported to occur with increased frequency in individuals with AD (Egensperger et al, Hutchin and Cortopassi, i.e.) but other groups reported no association (Wragg et al) or it being a polymorphism variant (Leroy et al). We have examined the mtDNA A4336G transition in necropsy samples of cerebellum, hipocampus and cortex from 7 confirmed cases of AD and from 9 age-matched controls without clinical or histological evidence of neurodegenerative disease. The mtDNA (A4336G) mutation was present in all necropsy regions from 2 AD cases and in another AD case the three regions analyzed showed an abnormal digestion pattern. All control samples showed a normal pattern. This mutation was also analyzed in blood samples from 6 AD patients and 8 age-matched controls: neither the AD nor the control samples harbored the mutation. We have also examined the presence of large mtDNA rearrangements in the brain necropsy samples by long PCR and southern-blot analysis. There was no difference between AD and controls. Our data supports the involvement of the A4336G mutation in Alzheimers disease.

Program Nr: 2776 from the 1999 ASHG Annual Meeting

Deletion of a novel Zinc finger gene in Smith-Magenis Syndrome. *F. Romero-Pastrana[1], A.M. Brown[1,2], C.E. Schwartz[1], A.K. Srivastava[1]*. 1) Center for Molecular Studies, J. C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Present address: Div. of Endocrinology, Med. Univ. of South Carolina, Charleston, SC.

Smith-Magenis syndrome (SMS) is a clinically distinctive mental retardation syndrome associated with a complex and heterogeneous phenotype. The features include developmental and growth delay, brachycephaly, flat midface, short broad hands, syndactyly, and characteristic behavioral problems. Ear abnormalities, sleep disorder, conductive hearing loss, and moderate to sever myopia are also seen among SMS patients. The complex phenotype is associated with variable hemizygous deletions and duplications in chromosomal band 17p11.2. A repeated gene cluster, SMS-REP, has been identified, which flanks the genomic region commonly deleted in SMS patients. (Chen et al., 17, 154-163, 1997).

We have isolated most of the SMS critical region (D17S58-D17S445) in YAC clones and have analyzed a series of SMS patients to facilitate the cloning of the gene(s) involved in SMS. In a search for local transcripts, we have identified three novel zinc finger genes (ZNFa, ZNFb and ZNFc) from the SMS region. The transcripts corresponding to two of these zinc finger genes, ZNFa and ZNFb, have been assembled and characterized. Both genes consist of multiple exons and encode novel ZNF proteins containing 10-14 C2H2-type finger motifs. We have verified the deletion of at least one zinc finger gene, ZNFa, in several SMS patients. ZNFa is found to be expressed differentially in human fetal and adult tissues, with relative abundance much in fetal and adult brain. Deletion of one or all the ZNFs in this cluster can now be tested as contributory to the multiple anomalies observed in SMS patients.

Program Nr: 2777 from the 1999 ASHG Annual Meeting

Novel missense mutations in the DKC1 gene in patients with dyskeratosis congenita. *K. Rostamiani[1], N. Heiss[2], A. Poustka[2], A.B. Metzenberg[1]*. 1) Biology, Cal State Northridge, Northridge, CA; 2) Dept. of Molecular Genome Analysis, Deutsches Krebsforschungszentrum, Heidelberg, Germany.

Dyskeratosis congenita (DKC) is a rare, lethal inherited syndrome characterized by abnormal skin pigmentation, nail dystrophy, and mucosal leukoplakia. Progressive pancytopenia and bone marrow failure are the most common causes of death, and patients also have an increased risk for infections and have an increased incidence of malignancy. The X-linked form of the disease (MIM 305000) has been shown to be caused mainly by mutations in the DKC1 gene, which lies 40 kb centromeric to the MPP1 gene in Xq28. The product of DKC1 is predicted to be a 514-amino-acid protein, called dyskerin. Dyskerin is highly conserved through evolution, from bacteria to humans, and is believed to be a nucleolar protein which functions in rRNA biogenesis.

DNA was extracted from peripheral blood from each of nine unrelated male patients with DKC. Each of the 15 exons and flanking intron/exon boundaries of the DKC1 gene were amplified by PCR, and sequenced revealing one previously observed mutation, as well as unique missense mutations in three patients, including one at a potential mutational hotspot. Two of the mutations, ntC206T (T49M) in Exon 3 and the new ntG1025A (R322Q) in Exon 10, are C to T transitions in CG dinucleotides, which are common hotspots for such mutations. The T49M mutation has been previously reported, as have recurring CG->TG mutations in two other exons of the DKC1 gene. The other two novel missense mutations are ntC1009T (L317K) in Exon 10, and ntC1210T (P384S) in Exon 11. Five of the patients had wild-type DKC1 sequences, including one with an affected brother. In the absence of informative linkage analysis in the families of these affected males, it is not possible to predict whether it is likely that they have mutations in the promoter regions, introns or 3'-UTRs of the DKC1 gene, or whether they have mutations in another X-linked or even an autosomal locus. Further studies are essential for improving the usefulness of molecular testing in DKC for clinicians and families.

Program Nr: 2778 from the 1999 ASHG Annual Meeting

Human EST screening provides 96 new nuclear candidate genes for mitochondrial disorders. *A. Rotig, C. Mugnier, P. Rustin, A. Munnich.* INSERM U393, Hopital Necker, Paris, France.

Mitochondrial disorders represent an increasing group of metabolic diseases. Mutations in mitochondrial as well as nuclear genes encoding respiratory chain proteins have been recently described. Interestingly, mutations in genes encoding proteins involved in respiratory chain assembly, mitochondrial proteins traffic or mitochondrial iron metabolism have been shown to lead to mitochondrial disorders as well. Yet, only few genes encoding proteins involved in respiratory chain assembly, protein trafficking, and mtDNA maintenance have been identified in human. However, several hundred of those nuclear genes have been described in yeast. These yeast nuclear genes constitute an invaluable tool for characterization of human genes possibly responsible of mitochondrial disorders. In order to identity the human counterparts of these genes, we developed a systematic "cyber-screening" approach combining different yeast protein databases and the Genbank dbEST database. Using 312 yeast protein sequences as templates, we screened the human dbEST using the BLAST similarity searching program and identified more than 140 groups of human EST likely to represent orthologs of yeast genes with a significant P value ($p<10^{-5}$). This collection of human genes possibly involved in mitochondrial turnover will help identifying nuclear genes responsible of mitochondrial disorders.

Program Nr: 2779 from the 1999 ASHG Annual Meeting

Characterization of the murine homolog of the Treacher Collins Syndrome gene product, treacle. *S. Rujirabanjerd[1], S.T. Winokur[2], R. Shiang[1]*. 1) Virginia Commonwealth University, Richmond, VA; 2) University of California, Irvine, CA.

Treacher Collins Syndrome (TCOF1) is an autosomal dominant disorder of craniofacial development. Although the gene has been cloned, the functional and biochemical properties of the protein, treacle, are still unknown. Treacle is thought to be a member of a class of nucleolar phosphoproteins from its predicted protein sequence. The murine homologue of the TCOF1 gene has also been identified. The murine treacle is 1320 amino acids in length with a predicted molecular weight of 133 kDa. It also contains several potential sites for CKII (casein kinaseII) phosphorylation. Both the human and mouse proteins have been previously shown to localize to the nucleolus. To determine whether murine treacle is phosphorylated, we performed *in vitro* dephosphorylation experiments with non-specific calf intestine alkaline phosphatase (CIAP) using cell lysates from mouse P19 cells, an embryonic carcinoma cell line. The results were visualized using anti-treacle antibodies after electroblotting. The untreated protein was found to be 205 kDa while the protein treated with CIAP was 190 kDa. The smaller protein was not observed when phosphatase inhibitors were added. We concluded that the murine treacle is highly phosphorylated. The molecular weight of both forms of treacle is larger than its predicted molecular weight. This may be caused by aberrant migration of the protein on the gel or other post-translational modification of the protein. To further determine if the 190 kDa product is a true unmodified product of the murine treacle, *in vitro* transcription/translation was performed using a rabbit reticulocyte lysate system and the protein was labeled by ^{35}S-methionine. The result of this experiment confirms that the 190 kDa protein is the unphosphorylated and unmodified form of treacle. Since the predicted protein sequences contain several sites for CKII phosphorylation, experiments to determine whether CKII mediates phosphorylation were performed. The unphosphorylated form of treacle was incubated with CKII *in vitro*. The results show that treacle can be phosphorylated by CKII. This work confirms that treacle is a member of a nucleolar phosphoprotein family.

Program Nr: 2780 from the 1999 ASHG Annual Meeting

The PHEX locus-specific mutation database: A centralized location and search tool for mutations causing X-linked hypophosphatemia. *Y. Sabbagh[1], A.O. Jones[1], P. Nowacki[3], H.S. Tenenhouse[1,2]*. 1) Dept Biology; 2) Dept Pediatrics and Human Genetics, McGill University, Montreal Children's Hospital Research Institute, Montreal, PQ, Canada; 3) Centre for Genome Research, McGill University, Montreal General Hospital Research Institute, Montreal, PQ, Canada.

X-linked hypophosphatemia (XLH) (OMIM 307800) is a dominant disorder of phosphate homeostasis associated with growth retardation, rachitic and osteomalacic bone disease, hypophosphatemia, and renal defects in the reabsorption of filtered Pi and the metabolism of vitamin D. The gene responsible for XLH was identified by an International Consortium by positional cloning, and was designated *PHEX* (formerly *PEX*) to depict a Phosphate regulating gene with homology to Endopeptidases on the X chromosome. Approximately 86 mutations in the *PHEX* gene have been reported in XLH patients. However, with time more mutations will be identified, and a novel way to access this information is through a database search tool. PHEXdb (http://data.mch.mcgill.ca/phexdb) is a relational database on presently published mutations in the *PHEX* gene. This site is dedicated to the collection and distribution of information on all PHEX mutations in one location that is easily accessible to the scientific community. PHEXdb will allow online access where users will be able to search the database by mutation, which includes mutation name, mutation type, and codon name; by phenotype, which includes inheritance, X-linked or sporadic, clinical and biochemical phenotype; and by authors who published or submitted mutations. Also PHEXdb provides a submission form that will allow newly identified mutations in the *PHEX* gene to be added to the database, thereby centralizing the information in one location. The PHEXdb homepage also includes links to information pages, including publications relevant to PHEX, XLH and mouse homologues (Hyp and Gy).

Program Nr: 2781 from the 1999 ASHG Annual Meeting

Mutational analyses and comparison of clinical phenotypes of six families with autosomal recessive juvenile parkinsonism (AR-JP). *M. Saito[1,2], M. Maruyama[2], T. Ikeuchi[2], H. Kondo[3], T. Yuasa[4], A. Ishikawa[5], S. Tsuji[2].* 1) Department of Neurology, National West Niigata Central Hospital, Niigata 950-2085, Japan; 2) Department of Neurology, Brain Research Institute, Niigata University, Niigata 951-8585, Japan; 3) Department of Neurology, Niigata National Hospital, Kashiwazaki 945-8585, Japan; 4) Department of Neurology, National Center of Neurologyand Psychiatry, Kohnodai Hospital, Ichikawa 272-8516, Japan; 5) Department of Neurology, Nishi-Ojiya National Hospital, Ojiya 947-0041, Japan.

Purpose; Recently, the causative gene for AR-JP was mapped on chromosome 6q, and a novel gene 'parkin' was identified. This study is aimed to analyze the genotype-phenotype correlations of six families with AR-JP. Methods; Six unrelated Japanese families (Pedigrees 455, 549, 552, 554, 992 and 1535) with AR-JP were investigated in this study. Blood samples were taken with informed consent from the family members. Exon deletions were detected by PCR amplification of individual 12 exons of the parkin gene, and were confirmed by genomic Southern blot hybridization analysis using a 1.4kb parkin cDNA fragment. To accurately determine the deleted exons in two alleles, gene dosage analysis of individual exons of parkin gene were performed using ABI Prism 7700 Sequence Detection System. Point mutations were identified by direct nucleotide sequence analysis of the RT-PCR products using total RNA extracted from the lymphoblastoid cell lines. Results; Deletions of exons 2-4 (Ped 549), exon 4 (Ped 455 and Ped 1535) and exons 6-7 (Ped 992) were identified. Gene dosage analysis revealed that affected individuals of Ped 455 was compound heterozygotes for one allele missing exon 2 and the other allele missing exons 2-4. Nonsense and missense mutations were identified in Ped 552 and Ped 554, respectively. The clinical features and the severity were similar among the affected individuals in the six pedigrees irrespective of the genotypes. Although the age at onset varies considerably among the affected individuals in the six pedigrees, we could not detect any correlations between the age at onset and the genotypes, suggesting involvement of other genetic or environmental factors in the age at onset.

Program Nr: 2782 from the 1999 ASHG Annual Meeting

A novel point mutation of tyrosinase gene causes atypical oculocutaneus albinism in Syrian hamster. *A. Sakamoto[1, 2], M. Abe[2], T. Masaki[1]*. 1) Div Biotech, Dept Biosci, Natl Cardiovasc Ctr, Osaka, Japan; 2) PRESTO, JST, Saitama, Japan.

BIO14.6 Syrian hamster, a representative animal model for hereditary cardiomyopathy, accompanies oculocutaneus albinism (OCA) with unique profile. At birth, BIO14.6 hamster has red eye-appearance with no melanin deposit in retinal pigment epithelium (RPE) but, as it grows, its eye-appearance becomes dark brown with gradual pigment accumulation in RPE.

We failed to identify any exons responsible for OCA in the genomic interval deleted in BIO14.6 hamster, which spans about 30 kb and includes the two first exons of delta-sarcoglycan (Sakamoto et al. FEBS Lett. 447:124-8. 1999). Thus we searched for genetic mutation of tyrosinase, a key enzyme for melanin production. The open reading frame of normal Golden hamster cDNA for tyrosinase, isolated from the whole eye cDNA library, comprised 1,590 nucleotides and was assumed to encode a type I single transmembrane polypeptide consisting of 530 amino acid residues with calculated molecular mass of 60,436. The amino acid identities of tyrosinases between hamster and human or hamster and mouse were 85.7 % or 90.1 %, respectively. RNA blot analysis detected tyrosinase transcript in the eye of BIO14.6 hamster, which was equal in size and amount to that of Golden hamster. Cloning and sequencing of BIO14.6 hamster cDNA for tyrosinase revealed single nucleotide change of T785C, which caused amino acid change of Leu262Pro. Leucine at this corresponding position of tyrosinases is conserved among human, mouse and chick, and this mutation has never been reported in OCA of any species. We established several pedigrees between Golden and BIO14.6 hamsters, where only F2 with homozygotic allele of (C/C) manifested OCA phenotype. We generated Hela cell lines stably expressing tyrosinase of Golden or BIO14.6 hamsters. Various enzymatic characteristics of BIO14.6 hamster tyrosinase are now being determined.

These data not only suggest that Leu262Pro mutation of tyrosinase causes atypical OCA in Syrian hamster but also indicate that BIO14.6 hamster also serves as a useful animal model for studying the effect of gradual pigmentation in RPE on visual function.

Program Nr: 2783 from the 1999 ASHG Annual Meeting

A CRX mutation in a Finnish family with dominant cone-rod retinal dystrophy. *E.M. Sankila[1,3], T.H. Joensuu[1,2], R.H. Hamalainen[1,2], N. Raitanen[1,2], J. Ignatius[4], B. Gormand[1,2].* 1) Department of Medical Genetics, Univ Helsinki, Helsinki, Finland; 2) Department of Molecular Genetics, The Folkhalsan Institute of Genetics, Helsinki, Finland; 3) Department of Ophthalmology, Helsinki University Hospital, Helsinki, Finland; 4) Department of Neurophysiology, Jorvi Hospital, Espoo, Finland.

Cone-rod retinal dystrophy (CRD) is a progressive retinal degeneration clinically characterized by early loss of colour vision and visual acuity followed by nyctalopia and loss of peripheral vision. Autosomal dominant, recessive and X-linked inheritance have been described. Recently, an autosomal dominant CRD locus was assigned to chromosome 19q13 by linkage and subsequently, mutations in a photoreceptor-specific homeobox gene (CRX) were found in CRD patients. CRX has also been implicated in Leber's congenital amaurosis and retinitis pigmentosa. We have studied a Finnish CRD family with 21 affected family members in six generations. CRD in this family is characterized by a relatively early age of onset (2-6 years), early loss of blue-green colour vision and progressive visual failure. Typically, macular pigmentation, bull's eye lesion and later changes resembling retinitis pigmentosa are seen in ophthalmoscopy. The assignment of a CRD locus in 19q13 prompted our clinical follow-up studies and linkage analyses of the Finnish CRD family. Blood samples were collected from 14 affected and 10 unaffected consenting family members. Linkage analyses with chromosome 19 markers revealed positive lod scores with two markers flanking the CRX locus, namely D19S178 and D19S246 (theta 0.1, zmax 2.12 for both loci). The sequence analysis of the CRX gene in the patients revealed a G to A transition resulting in a Glu80Lys substitution. Previously, a Glu to Ala change at this first position of the recognition helix has been reported in a dominant CRD family.

Program Nr: 2784 from the 1999 ASHG Annual Meeting

Transmission of an *AZFc* deleted Y chromosome from a non-mosaic male to his three infertile sons. *N. Saut[1], P. Terriou[2], A. Navarro[1,3], C. Guillemain[4], N. Levy[1,3], M.J. Mitchell[1]*. 1) INSERM U.491, Faculte de medecine, Marseille, FRANCE; 2) Institut de Medecine de la Reproduction, Marseille, FRANCE; 3) Laboratoire de Genetique Moleculaire, Hopital de la Timone, Marseille, FRANCE; 4) Biologie de la Reproduction, Hopital de la Conception, Marseille, FRANCE.

Several studies have found that the *AZFc* interval of the human Y chromosome is deleted in between 3-20% of males with an idiopathic infertility associated with a severely reduced sperm count. These large deletions of the distal Yq euchromatin remove members of several testis-specific multi-copy gene families, such as *DAZ*, which therefore represent candidate azoospermia genes. We have analysed a cohort of 160 azoospermic or oligospermic patients (sperm concentration <20 x 10^6/ml) with a panel of 24 markers using the polymerase chain reaction (PCR). We identified 9 *AZFc* deletions in patients with <5 x 10^6 sperm/ml (9%; n=102). No deletions were detected in patients with 5-20 x 10^6 sperm/ml. Southern analysis revealed that all 9 *AZFc* deletions removed the entire *DAZ* gene cluster. FSH levels were elevated in all cases. Interestingly, three of the patients with *AZFc* deletions are brothers (2 oligospermic/azoospermic, 1 azoospermic), suggesting that the deleted Y chromosome was transmitted by their father. The father's DNA was tested exactly as for his sons, by PCR and Southern, and at this level of resolution he and his sons were determined to possess an identically deleted Y chromosome. No evidence of mosaicism was seen in the father by PCR with 13 *AZFc* markers on DNA from blood lymphocytes. The father was 26 years old at the birth of his first son and 29 years old at the birth of his third son. This, therefore, shows that efficient spermatogenesis can be sustained over a period of 3 years in a male with a Y chromosome bearing a large *AZFc* deletion which removes all copies of the candidate azoospermia gene *DAZ* (*Deleted in azoospermia*). Molecular characterisation of this exceptional family is continuing with the aim of defining the precise extent of the deleted interval in the father and his sons.

Program Nr: 2785 from the 1999 ASHG Annual Meeting

A stem-loop mutation in intron 18 of the RB1 gene leads to aberrant splicing. *H. Scheffer[1], P. van der Vlies[1], M. Burton[1], E. Verlind[1], E. Leter[2], C.H.C.M. Buys[1].* 1) Dept Medical Genetics, State Univ Groningen, Groningen, Netherlands; 2) Dept Clinical Genetics, Free Univ Hospital Amsterdam, Amsterdam, Netherlands.

In 74 out of 92 familial and/or bilateral retinoblastoma patients we have identified the causative germ line mutation in the RB1 gene. In 26% of the mutations identified the splicing of the RB1 primary transcript is disturbed by changing the splice acceptor site or the splice donor site sequences. In a sporadic patient a T to C transition at nucleotide position +11 from the exon 18 to intron 18 junction was identified. The unaffected parents were not available for analysis. This intronic mutation was not detected in any other DNA sample we studied. It restores a perfect inverted repeat sequence of the exon 18 splice donor site, and thus leads to stabilization of a stem-loop with this splice site at the primary transcript level. Its use as a splicing signal will at least partially be abolished. An altered ratio of normally versus aberrantly spliced transcripts has been detected in this patient.

Program Nr: 2786 from the 1999 ASHG Annual Meeting

Characterization of retinoic acid-sensitive developmental genes using an induction gene trap approach. *M. Schlicker[1], O. Batista[1], K. Recker[1], A. Voigt[1], W. Wurst[2], I. Hansmann[1]*. 1) Martin-Luther-Universitaet, Humangenetik und Med. Biologie, Halle/Saale, Germany; 2) GSF-Forschungszentrum fuer Umwelt und Gesundheit, Molekulare Neurologie, Neuherberg, Germany.

In man and mammals prenatal exposure to retinoic acid (RA) and/or retinoids (RX) results in characteristic congenital anomalies. Incidence and pattern of the malformations apparently depends on dose and stage of exposure. Yet, the respective molecular mechanisms as well as the genes involved are more or less unknown. RA/RX signalling is mediated by intracellular RA/RX binding proteins and nuclear receptors that activate target genes containing RA-binding elements (RAREs). Based on a retinoic acid-induced gene trap approach (Forrester et al., 1996) we set up a strategy to identify RA/RX downstream genes relevant for mouse and human development. By RACE-PCR of trapped ES clones we identified two novel genes that are expressed in early brain and heart. A 1 kb cDNA fragment of the 1st gene (EScD-1) identifies a brain-specific 15 kb transcript in new born mice. The 2nd gene (EScD-2), represented so far by a 400 bp cDNA-fragment is expressed in fetal brain (2.5 kb) and heart (1.4 kb). The expression of both transcripts has been identified prenatally from day 8 p.c. onwards at least to birth. The heart-specific transcript of 1.4 kb is expressed also in adult heart. Both cDNA sequences, EScD-1 and EScD-2 have been completely sequenced and and show single open reading frames. Searches for human homology revealed that parts of EScD-2 are represented within a human cosmid and cDNA both mapping to chromosome 16p13.3. Breakpoints within that chromosome segment are known to be associated with cardiac anomalies. Using EscD-2 cDNA as a probe we isolated a human BAC clone to verify the localization of the respective gene in 16p13.3. The corresponding FISH analysis and a detailed analysis of the expression patterns of EScD-1 and EScD-2 as well as the cloning of the respective human genes is in progress. These data as well as the study of the mouse gene trap phenotypes will give information about the involvement of the two genes in specific human disorders of brain and/or heart. (Supported by DAAD and DFG).

Program Nr: 2787 from the 1999 ASHG Annual Meeting

The cardiac pacemaker channel gene, HCN-2, is not linked with congenital sinus node dysfunction and AV-conduction block. *E. Schulze-Bahr[1,2], E. Morhofer[2], M. Borggrefe[1,2], P. Vogt[3], S. Kotthoff[3], H. Funke[2], G. Breithardt[1,2]*. 1) Dep. of Cardiology, Hospital of the Univ. Muenster, Muenster, Germany; 2) Institute for Arteriosclerosis Research at the Univ. Muenster; 3) Dep. of Pediatric Cardiology, Hospital of the Univ. Muenster.

Sinus node dysfunction is the major indication for pacemaker implantation. The underlying cause remains in 40-60% ("idiopathic") when there is no evidence for organic heart disease. Recently, the HCN-2 gene encoding the fast-activating component of the cardiac pacemaker current I(f)has been cloned and localized on chromosome 19p13.3. We identified one large (n=33 family members) and one small (n=4) German descendent with congenital sinus node dysfunction binodal disease and, thus performed linkage analysis with microsatellite markers at chr. 19p13.3. Using markers D19S216-D19S413-D19S604-D19S209, encompassing the HCN-2 locus, we did not find an haplotype co-segregating with the disease. We continued in studying further 15 candidate gene loci, primarily including ion channel gene loci in which the mutated genes are linked to distinct arrhythmias and hypothesized that mutations in these genes may cause allelic disorders including sinus node dysfunction. When investigating the LQT1-6 locus, the Kir locus, the NF-kappa as well as loci for dilatated cardiomyopathy we have not found linkage yet. Taken together, we have exluded the gene encoding the fast component of the pacemaker current from candidacy in congenital sinus node dysfunction. For further investigations, we now collect additional individuals or families with congenital sinus node dysfunction and/or AV-conduction block and perform genome-wide linkage analyses to identify the disease gene by combined linkage with SNP and microsatellite markers.

Program Nr: 2788 from the 1999 ASHG Annual Meeting

Functional analysis of the *PDS* gene product explains phenotypic variation in patients with Pendred syndrome and nonsyndromic hearing loss (DFNB4). *D.A. Scott[1,2], R. Wang[3], T.M. Kreman[3], J.M. McDonald[4], J.R. Marietta[4], R.J.H. Smith[4], L.P. Karniski[3,5], V.C. Sheffield[1,2].* 1) Howard Hughes Medical Institute; 2) Dept. Pediatrics; 3) Dept. Internal Medicine; 4) Dept. of Otolaryngology-Head and Neck Surgery, University of Iowa Hospitals and Clinics, and; 5) Iowa City Veterans Affairs, Iowa City, IA.

Mutations in the *PDS* gene are responsible for Pendred syndrome (early onset hearing loss and goiter), as well as autosomal recessive nonsyndromic hearing loss (ARNSHL) at the DFNB4 locus on chromosome 7q31. The *PDS* gene encodes a transmembrane protein, known as pendrin, which was hypothesized to transport sulfate. However, we have demonstrated, in both *Xenopus* oocytes and Sf9 cells, that pendrin does not transport sulfate but is a transporter of iodide and chloride. To determine if *PDS* mutations which result in Pendred syndrome are functionally distinct from those causing ARNSHL, we analyzed the transport properties of oocytes injected with modified *PDS* cRNA containing one of three common Pendred syndrome mutations, L236P, T416P, and E384G, and the I490L and G497S variants which are each homozygous in an inbred Indian family with ARNSHL. All of the Pendred syndrome mutations caused complete loss of pendrin iodide and chloride transport; oocytes injected with I490L cRNA showed near wild-type levels of ion transport (simple polymorphism); and oocytes injected with G497S cRNA showed residual activity compared to water injected controls and Pendred syndrome mutations. To identify additional *PDS* mutations associated with ARNSHL, we screened 20 individuals with apparent nonsyndromic hearing loss and dilated vestibular aqueducts (DVA), a common radiological finding in hearing loss. This screen revealed three individuals (15%) who carried one or more *PDS* mutations: V653A/+, L236P/V480D, T416P/+. Functional analysis of the V653A and V480D alleles revealed residual *PDS* activity. These data indicate that *PDS* mutations can be identified in a significant percentage individuals with nonsyndromic hearing loss and DVA and that residual pendrin function may postpone or eliminate the onset of goiter in *PDS*-related nonsyndromic hearing loss.

Program Nr: 2789 from the 1999 ASHG Annual Meeting

Structure of the SLC7A7 gene and mutational analysis of patients affected by lysinuric protein intolerance. *G. Sebastio[1], M.T. Bassi[2], M.P. Sperandeo[1], M. Riboni[2], G. Parenti[1], A. Buoninconti[1], M. Manzoni[2], B. Incerti[1], M. Di Rocco[3], P. Strisciuglio[3], I. Dianzani[3], R. Parini[3], A. Adami[3], C. Dionisi Vici[3], M. Candito[3], F. Endo[3], A. Pepe[1], A. Ballabio[2,4], G. Andria[1], G. Borsani[2]*. 1) Dept Pediatrics, Federico II Univ, Naples, Italy; 2) Telethon Institute of Genetics and Medicine, TIGEM-HSR, Milan, Italy; 3) LPI Collaborative Group; 4) Universita' Vita e Salute, San Raffaele, Milan, Italy.

Lysinuric protein intolerance (LPI; MIM 222700) is a rare autosomal recessive defect of cationic amino acid transport at the basolateral membrane of enterocytes and renal tubuli. We previously reported the isolation of SLC7A7, the gene mutated in LPI, and found mutations in four Italian pedigrees and Finnish patients (Nature Genet 21: 297-301, 1999). Here we report the genomic structure of the gene and the results of the mutational analysis in additional Italian, Tunisian and Japanese patients. The SLC7A7 gene consists of 10 exons; sequences of all the exon-intron boundaries are reported here. Twenty-five out of the 26 independent mutant alleles were characterized and 9 novel mutations were detected, including: 3 missense mutations, 242A to C (M1L), 390T to A (M50K) and 1399C to A (S386R); a nonsense mutation 967G to A (W242X); 2 splice mutations IVS3+1G to A and IVS6+1G to T; a single base insertion, 786insT; two 4-bp deletions, 455delCTCT and 1425delTTCT. Noteworthy, 242A to C causes the change of Met1 to Leu, a rare mutational event previously found in a few inherited conditions. We failed to establish a genotype/phenotype correlation. Actually, both intrafamilial and interfamilial phenotypic variability were observed in homozygotes for the same mutation. A strong mutational heterogeneity was observed in Italian patients (9 different mutations for 23 independent alleles), though they originate mainly from two restricted geographical areas. This recalls the so called 'Reunion paradox', that is the occurrence of different mutations for rare diseases in genetic isolates. The DNA based tests are now easily accessible for molecular diagnosis, genetic counseling and prenatal diagnosis of LPI.

Program Nr: 2790 from the 1999 ASHG Annual Meeting

Spectrum and frequency of PITX2/RIEG mutations in patients with Rieger syndrome and related ocular anomalies. *E.V. Semina[1], C. Funkhauser[1], P. Bitoun[2], W.L.M. Alward[3], S. Daack-Hirsh[1], B. Amendt[4], B. Ludwig[1], J.C. Murray[1,5]*. 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) Pediatrie Genetique, Hpital Jean Verdier, 93143 Bondy, FRANCE; 3) Dept Ophthalmology, Univ Iowa, Iowa City, IA; 4) Dept Phisyology, Univ Iowa, Iowa City, IA; 5) Dept Biol Sciences, Univ Iowa, Iowa City, IA.

Rieger syndrome (RIEG) is an autosomal dominant heterogeneous disorder with complete penetrance but variable expressivity, mainly characterized by craniofacial dysmorphism, malformations in the anterior chamber of the eye predisposing to glaucoma, dental and umbilical anomalies. We have previously identified a homeodomain- containing transcription factor gene PITX2 responsible for 4q25-linked cases of Rieger syndrome. The Pitx2 gene has also been shown to play a crucial role in determination of left/right patterning of visceral organs in vertebrates. Three different isoforms of PITX2 gene have been reported. The complete genomic sequence of the RIEG1/PITX2 gene was obtained and genomic structure of all of the isoforms was determined and used to design primers for PCR-based mutation search. We have now evaluated 30 individuals with RIEG and 98 with isolated anterior segment anomalies for mutations in PITX2 gene. Six additional mutations have been identified, four of which represent novel alterations of the gene. A total of 37% of Rieger syndrome patients and 1% of patients with isolated ocular anomalies were found to have PITX2 mutations in our sample. A composite of our and published findings shows that almost all mutations affect the homeobox region which encodes a homeodomain with a major role in target recognition and protein binding. Most of the alterations are unique with two repetitive mutations. We found no visible correlation between the location or type of mutation and clinical features of Rieger syndrome. Although there were no clear difference in the clinical picture between RIEG patients with PITX2 mutations and others, they tend to more frequently demonstrate gut malformations including omphalocele and Meckel's diverticulum. A search for mutations in additional patients with Rieger syndrome and related anomalies is in progress.

Program Nr: 2791 from the 1999 ASHG Annual Meeting

Molecular genetic analysis of 40 patients with glycogen storage disease type Ia: 100% mutation detection rate and 5 novel mutations. *H.H Seydewitz[1], D. Matern[2]*. 1) Children's Hospital, Albert-Ludwigs-University, Freiburg, Germany; 2) Division of Medical Genetics, Department of Pediatrics, Duke University Medical Center, Durham, NC.

BACKGROUND: The catalytic subunit of microsomal glucose-6-phosphatase (G-6-Pase; EC 3.1.3.9) plays a pivotal role in glycogenolysis and gluconeogenesis catalyzing the last step of both metabolic pathways. Its deficiency leads to glycogen storage disease type Ia (GSD Ia; MIM 232200), which is characterized by hepatomegaly, hypoglycemia, lactic acidemia, hyperuricemia, hyperlipidemia and short stature. The demonstration of a reduced G-6-Pase activity measured in a fresh liver biopsy specimen is still considered the gold standard for verification of the clinical diagnosis of this autosomal recessive disorder. In 1993, the gene (G6PC) spanning 12.5 kb on chromosome 17 and consisting of 5 exons coding for the enzyme was cloned (Lei et al. Science 1993;262:580-3) and mutations were identified. We report the successful molecular genetic analysis of G6PC in 40 patients with GSD Ia. METHODS: DNA was isolated from EDTA-blood, and all 5 exons and the promoter region of G6PC were screened for mutations by SSCP analysis following PCR amplification. Mutations found by SSCP analysis were further characterized by DNA sequencing. In the event of normal SSCP band-patterns, all exons and the promoter region were sequenced. RESULTS: The diagnosis could be verified in all patients. 5 novel mutations, Q20R, W50X, G81R, W156L, and G188D were detected. No true common mutation was identified, with the mutations R83C, Q347X, and G188R occurring in our study population with the highest frequencies of 29%, 15%, and 14% respectively. CONCLUSION: GSD Ia is a genetically heterogenous disease. This study underscores that molecular genetic analysis is a reliable and convenient alternative to the enzyme assay in a fresh liver biopsy specimen to diagnose GSD Ia.

Program Nr: 2792 from the 1999 ASHG Annual Meeting

SOD1 mutation screening in sporadic ALS patients from Russia. *M.I. Shadrina[1], G.N. Levitsky[2], Y.A. Kondratyeva[1], P.A. Slominsky[1], V.I. Skvortsova[2], S.A. Limborska[1]*. 1) Dept Human Genetics, Inst of Molecular Genetics, Moscow, Russia; 2) Dept of Neurology, Moscow Medical University, Moscow, Russia.

Amyotrophic lateral sclerosis (ALS) is degenerative disorder of motor neurons in cortex, brainstem and spinal cord. 10 percent of ALS is familial which inherited as an autosomal dominant trait. It was found, that mutations in gene for Cu/Zn-binding superoxide dismutase (SOD1), in the region 21q22.1-q22.2, accounting for some familial cases of ALS. Mutation in the SOD1 gene can also be responsible for sporadic cases.We observed 15 patients (7 females and 8 males) within age range 29-73 years with idiopathic motor neuron disease and 23 consanguine patient's relatives. 12 patients to had amyotrophic lateral sclerosis, 3 patients had progressive bulbar palsy. We carried out a mutation screening by single stranded conformation polymorphism analysis and direct sequencing of five exons of the SOD 1 gene in these patients. In total, we found mutations in 2 of 15 patients. So, SOD1 gene mutations are infrequent in sporadic ALS patients from Russia. In this patients we identified an aspartic acid to alanine substitution in codon 90 (D90A). One patient is homozygous for the D90A mutation, whereas another patient is heterozygous for this one.

Program Nr: 2793 from the 1999 ASHG Annual Meeting

Novel Mutations and An Update Summary of Mutations in the Glycogen Debranching Enzyme Gene. *W.-L. Shaiu, D.R. Lamson, Y.-T. Chen.* Molecular Genetics, Duke University Medical Center, Durham, NC 27710.

Genetic defects of glycogen debranching enzyme AGL cause glycogen storage disease type III (GSD-III), an autosomal recessive disorder. This multifunctional enzyme has both 1,4-a-D-glucan:1,4-a-D-glucan 4-a-D-glycosyltransferase and amylo-1,6-glucosidase activities, deficiencies of which result in abnormal accumulation of glycogen. Overall loss of AGL activity results in GSD-IIIa, and tissue-specific retention of AGL activity in muscle results in GSD-IIIb. Lack of only glucosidase or transferase activity results in GSD-IIIc or IIId, respectively. We previously described mutations in the coding region of the enzyme that are specifically associated with North African Jewish GSD-IIIa patients (4455delT), or are only found in GSD-IIIb patients (17delAG and Q6X). Here we report the identification in GSD-IIIa patients of a novel class of mutations affecting several 3' and 5' splice sites in the AGL gene. Thus, four individuals were identified with A to G transitions at position -12 upstream of the 3' splice site of intron 32 (IVS 32 A^{-12} ® G) that resulted in insertion of 11 bp intronic sequence between exons 32 and 33. Three of these individuals are heterozygotes and one is the homozygous offspring of non-consanguineous parents. The same mutation has been reported before, although it was associated with a presumed GSD-IIIb patient (Okubo *et al*., Hum Genet 102: 1-5, 1998). Furthermore, we identified a donor splice site mutation at intron 21 (IVS 21 G^{-1} ® A) which caused exon 21 skipping in the mRNA. Other new mutations located in the coding region that resulted in frameshifts and premature terminations also were characterized. Although GSD-IIIa has high genetic heterogeneity, our studies reveal that the molecular defects of GSD-IIIa are clustered disproportionately along the 3' end of the gene, where the putative glycogen binding domains are postulated to reside.

Program Nr: 2794 from the 1999 ASHG Annual Meeting

Common Mutation in Transglutaminase 1 in Lamellar Ichthyosis. *Y.O. Shevchenko, J.G. Compton, J.R. Toro, J.J. DiGiovanna, S.J. Bale.* Genetic Studies Section, NIAMS/NIH, Bethesda, MD.

Lamellar ichthyosis (LI, OMIM#242300) is a severe autosomal recessive skin disorder with an estimated prevalence of 1 in 200,000. LI is characterized by platelike scaling over the entire body, often with a typical presentation at birth of a collodion-like membrane encasing the neonate. Other features of LI include palmar and plantar hyperkeratosis, ectropion, eclabium, and scarring alopecia. Our laboratory established that the disease is caused by mutations in transglutaminase 1 (TGM1), which is located at 14q11 (Russell et al., 1995). The TGM1 gene spans 14 kb and is distributed on 15 exons, whereas the corresponding mRNA is only 2.7 kb in length. Mutations are distributed throughout the TGM1 coding sequence. We have developed an efficient screen for mutations in TGM1 cDNA based on RT-PCR, which can be easily utilized in a clinical laboratory setting. Our analyses revealed a common mutation (29% of US families in our data set) involving loss of the intron 5 splice site acceptor and leading to alternative splicing of the message, which results in full or partial loss of enzyme activity. We have found families in which the splice site mutation was homozygous in affected individuals, as well as families where the patients were compound heterozygotes for the splice site mutation and another TGM1 mutation. A mutation at this same site has been reported to account for the majority of Norwegian LI patients (Pigg et al., 1998). Results of marker typing and haplotype analysis around the TGM1 locus suggested the existence of a founder effect for the mutation. The conserved region spans an interval between markers D14S581 and D14S1032, which are separated by approximately 1.5 cM. Using our set of families that derive from a mix of ethnic and racial backgrounds but have no known Norwegian ancestors, we have traced the founder chromosome to the region of Westfalia in Germany.

Program Nr: 2795 from the 1999 ASHG Annual Meeting

A second family with familial encephalopathy with neuroserpin inclusion bodies (FENIB). *A.E. Shrimpton[1], R.L. Davis[1], P.D. Holohan[1], M.S. Yerby[2].* 1) SUNY Health Sci Ctr, Syracuse, NY; 2) University of Washington School of Medicine, Seattle, WA.

We have previously described a point mutation, S49P, in the neuroserpin gene (PI12), in a large family with familial encephalopathy with neuroserpin inclusion bodies (FENIB). We have called this mutation PI12 Syracuse. A maximum lod score of 3.40 at zero recombination is obtained between PI12 Syracuse and FENIB. The S49P mutation occurs at the homologous serine that leads to a-1 antitrypsin polymerization when substituted by phenylalanine (S53F) as seen in a-1 antitrypsin Siiyama, which leads to inclusion body formation in the liver. A different mutation, S52R, which we have called, PI12 Portland, has been detected in a second family with neuroserpin inclusion bodies (Collins-bodies). The disease in this family, progressive dementia and epilepsy also has an autosomal dominant mode of inheritance but with an earlier onset ages (ages 19 and 30) than that seen in the original family (ages 45 to 55). Affected individuals presented with seizures and a progressive deterioration of personality and memory. The 20 year or so earlier onset associated with PI12 Portland is in keeping with the predicted greater severity of the S52R from modeling of the serpin template. PI12 Syracuse and PI12 Portland are the first examples of neurodegenerative disease resulting from a mutation in a serpin gene. The mutations lead to polymerization of neuroserpin in neurons, which being long-lived non-dividing cells are particularly susceptible to the accumulation of polymerized neuroserpin.

Program Nr: 2796 from the 1999 ASHG Annual Meeting

Mutation analysis in Stargardt disease: Direct sequencing and Southern analysis of *ABCR*. *N.F. Shroyer, R.A. Lewis, J.R. Lupski.* Baylor College of Medicine.

Stargardt disease (STGD) is an autosomal recessive, juvenile onset macular dystrophy which affects 1:10,000 individuals. The STGD locus was mapped to a 2 cM region on chromosome 1p with no evidence for genetic heterogeneity observed in families segregating recessive STGD. The gene causing STGD is a rod photoreceptor specific ATP-binding cassette transporter, *ABCR*. The *ABCR* gene consists of 50 exons encoding an 8 kb, retina-specific transcript. We recently reported a screen for mutations in 150 unrelated STGD patients with heteroduplex and SSCP analysis, that yielded a mutation detection of 57% (173/302 disease chromosomes; *Am J Hum Genet* (1999) 64:422-434). Other investigations using similar methods have yielded mutation detections of 19% (82/430 disease chromosomes), 31% (41/132 disease chromosomes), 32% (35/110 disease chromosomes) 6:291-295) and 62.5% (50/80 disease chromosomes). Thus, many mutations underlying recessive STGD are unidentified by these screening methods. To investigate the frequency of coding region alterations in STGD patients, we initiated direct sequencing of the 50 exons of *ABCR* in 24 unrelated STGD probands. Thus far, we have identified mutations in 25/34 (74%) disease chromosomes in which sequencing is 94% complete. This higher mutation detection rate suggests that some coding region mutations are not detectable by heteroduplex or SSCP analysis and that mutation detection efficiency with these methods ranges from 26% to 84%. To identify the remaining ~25% of STGD-associated *ABCR* mutations, we have initiated a screen for DNA rearrangements with Southern blot analysis. We have selected a cohort of 97 STGD patients in which a PCR-based mutation screen failed to identify one or both mutant alleles. DNA from each patient is then analyzed with six probes encompassing eight to ten exons each; dosage of each band is compared to a standard probe (*osteoprotegerin*, chromosome 8q24). Our data suggest that heteroduplex and SSCP analysis is not sufficient to identify all *ABCR* mutations, and further suggests that some *ABCR* mutations do not result from coding region point mutations.

Program Nr: 2797 from the 1999 ASHG Annual Meeting

Five novel germline gene variants in the RET proto-oncogene identified in MEN type 2 (MEN2) patients. *K. Snow[1], M. Wick[2], R. Mao[1].* 1) Molecular Genetics Lab, Mayo Clinic, Rochester, MN; 2) Department of Laboratory Medicine and Pathology, University of Minnesota, MN.

In 95% of MEN2A patients and in 85% of familial medullary thyroid carcinoma (FMTC) cases, germline mutations occur at one of five cysteine residues in the extracellular domain of the RET proto-oncogene (at codons 609, 611, 618, 620, and 634). Using DNA sequencing to identify mutations within exons 10 and 11, we have identified novel DNA alterations in the RET proto-oncogene in 6 unrelated cases. Case 1 is a 35 year-old male with elevated calcitonin and a history of unilateral pheochromocytoma that was resected; DNA testing showed an alteration at codon 666: AAG>GAG (K666E). Case 2, which is unrelated to case 1, had the same codon 666 alteration. In case 2, testing of multiple family members demonstrated that the alteration segregated with MTC and C-cell hyperplasia. Case 3 is a male with bilateral pheochromocytoma whose maternal maternal great-grandfather was also reported to have had pheochromocytoma; DNA testing identified two alterations: codon 631 GAC>GTC (D631V) and codon 665 CAC>CAG (H665Q). The same alterations were detected in the unaffected mother and unaffected maternal grandmother of case 3. Case 4 is a 37 year-old female with MTC and a family history of thyroid cancer; alterations at codon 634 (TGC>TAC; C634Y) and at codon 631 (GAC>GAA; D631E) were detected. Case 5 is a 68 year-old male with metastatic MTC and no family history of MEN2 or MTC; DNA testing found the alteration 1955-11 G>A in intron 9. Case 6 is a presymptomatic male with a family history of MTC; alterations at codon 618 (TGC>AGC; C618S) and at codon 623 (GAA>AAA; E623K) were detected. Testing of family members of case 6 showed that C618S and E623K were on different chromosomes and that carriers of the E623K alone did not have any clinical manifestations of MEN2 or FMTC. When novel DNA alterations are found, family studies may be helpful in determining clinical significance of findings. However, additional case reports, animal models, and/or functional studies are needed to be certain of the clinical significance of novel variants.

Program Nr: 2798 from the 1999 ASHG Annual Meeting

Characterization of TCOF1 mutations in Brazilian patients affected with Treacher Collins syndrome. *A. Splendore, E.O. Silva, L.G. Alonso, D. Brunoni, N. Alonso, A. Richieri-Costa, D. Cavalcanti, G. Carakushansky, M. Zatz, M.R. Passos-Bueno.* Depto. de Biologia, Univ. de São Paulo, São Paulo, SP, Brazil.

Treacher Collins syndrome (TCS) is a well-characterized autossomal dominant disorder affecting craniofacial development. The estimated incidence is 1/50,000 live births, with 60% of the cases resulting from fresh mutations. Great phenotypic variability is observed within and between families. The gene associated with the syndrome, TCOF1, mapped to chromosome 5q32, was cloned in 1997. In order to characterize TCOF1 mutations in 24 (14 sporadic and 10 familial) unrelated Brazilian patients with a clinical diagnosis of TCS, we screened the 25 coding exons of the gene by SSCP. The exons displaying a mobility shift were sequenced and tested in a 100-chromosome control sample. Thirty-five different mobility shifts were detected by SSCP. Eighteen of these were polymorphisms, including 14 previously undescribed ones. Of the 17 rare alterations that were not detected in the control sample, 11 were new pathogenic alterations, including 7 deletions and 4 insertions, all causing a frameshift. Two other previously described pathogenic mutations were also found: a splice-site alteration and a 5-bp deletion in exon 24. Interestingly, this deletion was found in a much higher proportion among our patients (5/24) as compared with other studies. The 6 remaining rare alterations were silent or intronic, and two of them were also found in unaffected relatives, suggesting that they are not the main cause of the syndrome. Furthermore, 4 patients presented one of these alterations in addition to a pathogenic mutation. The combination of such rare alterations or some of the polymorphisms with a frameshift mutation could be causing the marked phenotypic variability observed in TCS patients The effectiveness of SSCP in detecting the causative mutation in TCS patients is 75%. The 25% (6/24) undetected mutations could be due to lack of sensitivity of SSCP analysis or the presence of mutations in other regions of the gene, as in the promoter or introns. Alternatively, we cannot rule out a heterogeneous nature for TCS.

Program Nr: 2799 from the 1999 ASHG Annual Meeting

Hemochromatosis mutations C282Y and H63D in "cis" phase. *E.L. Spriggs[1,2], P.E. Harris[3], L.G. Best[1,2].* 1) Dept of Clinical Chemistry, Health Sciences Centre, Winnipeg, Manitoba, Canada; 2) Dept of Human Genetics, Univ of Manitoba, Winnipeg, Canada; 3) Faculty of Medicine, Univ of Manitoba, Winnipeg, Canada.

Homozygosity for the C282Y mutation of the HFE gene is a highly significant risk factor for the development of hereditary hemochromatosis (HH) and 83-100% of patients with HH have this genotype. Compound heterozygotes (C282Y/H63D) account for 2-5% of HH patients, and the clinical significance of the H63D mutation in the homozygous state is uncertain. Among 6053 individuals genotyped for these two mutations in 13 studies, no instances of either homozygous C282Y or H63D individuals who also carry the alternate mutation have been reported.

Genotyping was carried out on a 76 year old, Irish/Belgian female with a elevated serum ferritin of 493 ug/L (normal 40-330). She has one sister with a ferritin level of 1056 ug/L, liver disease consistent with HH and bronze skin pigmentation. The affected sister's genotype is currently being determined.

The proband was tested by two PCR amplifications, and the products were digested with SnaBI for C282Y and Bcl I for H63D. Gel electrophoresis of digested products showed the patient to be homozygous for C282Y and heterozygous for H63D. Testing a second sample from the same patient yielded identical results. Concerns that a polymorphism may be interfering with primer binding were addressed by PCR with primers that outflank the original C282Y primers. Results were consistent with the initial genotype. Both the original and second C282Y PCR products were sequenced in both directions, confirming homozygosity for the expected G to A change at nucleotide 845. Sequencing of the H63D product revealed the anticpated heterozygous C to G change at nucleotide 187.

Implications of this finding are: 1) The compound heterozygous state is by far the most common, but not the universal phase for individuals found to be heterozygous for the two mutations. 2) C282Y and H63D in "cis" phase may account for some cases of questionable parentage.

Program Nr: 2800 from the 1999 ASHG Annual Meeting

Human Cytochrome P4501B1: Expression in E. coli and report of 21 new mutations in subjects with Primary Congenital Glaucoma. *I. Stoilov[1], I. Jansson[2], J. Schenkman[2], M. Sarfarazi[1]*. 1) Molecular Ophthalmic Genetics Laboratory, Surgical Research Center, Department of Surgery, and; 2) Department of Pharmacology University of Connecticut Health Center, Farmington, CT.

Molecular genetic studies have already established the existence of a hereditary form of primary congenital glaucoma (PCG) that is caused by mutations in the CYP1B1 gene. During an ongoing screening of PCG probands, we identified a total of 21 new DNA alterations: 16 misense mutations and 5 deletions/insertions. This brought about the number of mutations identified by us to 37 and provided evidence for an extensive allelic heterogeneity. These mutations were observed in 87% of familial and 27% of sporadic cases. The PCG associated with CYP1B1 mutations was inherited as an autosomal recessive trait with 100% penetrance and with both sexes being equally affected. Moreover, there was strong evidence that the sporadic cases were the result of marriages between two normal carriers of CYP1B1 mutations. In parallel to our ongoing mutation screening, the expression study of recombinant human CYP1B1 in E. coli has also been underway. The complete coding sequence of CYP1B1 has been amplified from retinal cDNA library and subcloned into pCWori+ expression vector. Degenerate PCR amplifications were used to create a series of modified expression constructs. The modifications were directed toward increasing the AT content at the 5'-end of the wild type sequence. The different constructs were introduced into DH5a competent cells. Hemoprotein expression was quantified by difference spectroscopy. An efficient construct serving as a template for In Vitro mutagenesis experiment was selected to introduce ten different CYP1B1 mutations in the wild type sequence. These are a series of missense mutations previously reported by us that affect key structural elements of either the hinge region or the conserved core structures of CYP1B1. This expression system is currently being used to produce both wild type and mutant forms of CYP1B1, which will serve as a tool for comparative functional analysis. Program Nr: 2801 from the 1999 ASHG Annual Meeting

Silent codon substitution in the VHL gene results in exon skipping and familial pheochromocytoma. *C.A. Stolle[1], V. Kasparcova[1], G.J. Tsongalis[2], S. Inzucchi[3].* 1) Dept Genetics, Univ Pennsylvania Sch Medicine, Philadelphia, PA; 2) Dept Pathology, Hartford Hospital, Hartford, CT; 3) Section of Endocrinology, Yale U School of Medicine, New Haven, CT.

Von Hippel-Lindau disease is an autosomal dominant cancer predisposition syndrome due to mutations in the VHL gene and characterized by hemangioblastoma, retinal angioma, clear cell renal carcinoma, pheochromocytoma, neuroendocrine tumors and cysts of the pancreas, endolymphatic sac tumors, and papillary cystadenomas of the epididymis and broad ligament. Pheochromocytomas occur in some VHL families as the predominant or only characteristic tumor. In 98% of cases of VHL with pheochromocytomas, the gene defect is a missense mutation, suggesting that an intact, but defective protein is necessary for development of adrenal tumors. We have followed a three generation family with pheochromocytoma but no other overt manifestations of VHL. DNA sequence analysis revealed a silent mutation in codon 138 (A to G nt 627) that segregated with the disease in this family and was not seen in over 100 normal alleles. To determine whether this mutation could alter splicing of the primary transcript, total RNA from the proband and an unaffected control was reverse transcribed and amplified with primers specific for VHL exons 1 and 3. Two bands corresponding to alternatively spliced transcripts characterized by inclusion (isoform I) or exclusion (isoform II) of exon 2 were present in both the proband and control samples. However, the percentage of isoform II was greater than 50% in the proband, but less than 20% in control samples. This mutation, although outside the consensus splice sites, apparently causes efficient skipping of exon 2, resulting in the in frame removal of 41 amino acids. The data support the observation that a defective, but not necessarily full-length protein predisposes to pheochromocytoma. Furthermore, the fact that a silent mutation in the VHL gene can cause disease suggests that functional assays may be needed to rule out the disease-causing potential of some apparently neutral polymorphisms.

Program Nr: 2802 from the 1999 ASHG Annual Meeting

Linkage and Candidate Gene Analysis of Two Pedigrees with Charcot-Marie-Tooth Neuropathy Type 1C. *V.A. Street[1], M.P. Keller[2], R.A. George[2], A.S. Golden[1], B.L. Tempel[1], T.D. Bird[3], P.F. Chance[2].* 1) Otolaryngology and Bloedel Hearing Research Center, University of Washington, Seattle, WA; 2) Pediatrics, Division of Genetics and Development, University of Washington, Seattle, WA; 3) Neurology, University of Washington School of Medicine and Veterans Administration Medical Center, Seattle, WA.

Charcot-Marie-Tooth (CMT) neuropathy is the most common inherited peripheral nervous system disorder affecting approximately 1 in 2000 individuals and characterized by degenerative changes in motor and sensory nerves. The hallmark of CMT Type I (CMT1) is reduced nerve conduction velocities (NCVs) (<40 meters/sec) and nerve biopsies that demonstrate hypertrophic demyelination. The present study includes two large five-generation CMT1C pedigrees (K1550 and K1551). Affected members have clinical findings and reduced NCVs consistent with CMT1. Male-to-male transmission is present confirming autosomal dominant inheritance. Previous linkage analysis with markers from the CMT1A region on chromosome 17p11-12 and CMT1B region on chromosome 1p21 excluded linkage. Furthermore, the DNA duplication commonly associated with CMT1A is not present. Sequence analysis for three genes known to play critical roles in the development of demyelinating neuropathies, the peripheral myelin protein (PMP-22), the myelin protein zero (MPZ), and the early growth response 2 gene (EGR2) also known as Krox-20, disclosed no abnormalities, confirming further genetic heterogeneity in CMT1 and indicating that the mutant gene in these CMT1C pedigrees represents a novel unmapped form of CMT1. To assign a chromosomal address, we are performing a 10 cM genome scan on both pedigrees.

Program Nr: 2803 from the 1999 ASHG Annual Meeting

Molecular heterogeneity of Carbonic Anhydrase II deficiency in Italy. *P. Strisciuglio[1], G. Bonapace[1], D. Concolino[1], G. Ruffa[2], A. Dammacco[3].* 1) Dept. of Pediatrics, University of Catanzaro, Italy, MD; 2) Dept. of Pediatrics, University of Genoa, Italy, MD; 3) Hospital "Giovanni XXIII" of Bari, Italy, MD.

Deficiency of Carbonic Anhydrase (CA II) results in a syndrome of osteopetrosis, renal tubular acidosis and cerebral calcification, that is inherited as an autosomal recessive disorder. Other features include mental retardation, frequent fractures, growth failure and dental malocclusion. The geographical distribution of this disease is striking, with more than half the known case observed in families from mediterranean area. In the last years, we have identified several families affected by CA II deficiency. All the families, except one, came from Southern Italy. We performed molecular analysis on the patients by SSCP and direct sequencing. Interestingly, the first family discovered turned to have the same missense mutation Hys107Tyr found in a homozygous belgian patient and in three american siblings of italian origin who were compound heterozygotes. Moreover, a single base pair deletion in exon 2 was identified in the family of Northern Italy and a splice junction mutation at the 5' of intron 6 was found in another family in whom we performed the first prenatal diagnosis. We extended the molecular analysis to two new families coming from Southern Italy. The patient of the first family turned to be homozygous for the missense mutation Hys107Tyr. The brothers of the second family were heterozygous for an insertion gt of two bases in exon 6, undescribed previously, and a polimorphism CTG-TTG with an unchanged aminoacid (Leu) at the same exon 6 was present. Studies are in progress to complete the characterization of this family. Our results show that our families are different from arabic patients accounting for 75% of reported cases of CA II deficiency in whom a splice junction mutation at the 5' of intron 2 is present. Also a frame shift mutation in exon 7 is the most common mutation in hispanic patients from the Caribbean Islands. In conclusion, our data underline the presence of a novel mutation in one of our families and suggest a molecular heterogeneity of CA II deficiency in Italy. A genotype-phenotype correlation in not possible at least for italian patient.

Program Nr: 2804 from the 1999 ASHG Annual Meeting

Cloning, characterization and mutation screening of the RP1 gene in autosomal dominant retinitis pigmentosa.

L.S. Sullivan[1], S.J. Bowne[1], J.R. Heckenlively[2], J. Zuo[3], K. Cheon[3], J. Treadaway[3], W.A. Hide[6], A. Gal[4], M. Denton[4], C.F. Inglehearn[5], S.P. Daiger[1]. 1) Human Genetics Ctr, The Univ. of Texas-Houston; 2) Jules Stein Eye Institute, UCLA; 3) St. Jude Children's Research Hospital, Memphis, TN; 4) Univ. Hospital Eppendorf, Hamburg, Germany; 5) Leeds University, Leeds, UK; 6) Univ. of the Western Cape, Belleville, South Africa.

We recently identified a novel retina-specific gene as the cause of the RP1 form of adRP. The RP1 gene codes for an unusually large protein (2,156 amino acids) with a relatively short region of sequence similarity to the doublecortin family of proteins. We have also identified another member of this gene family, apparently retina-specific, which maps to the p-arm of chromosome 8.

In mouse, the RP1 gene is expressed predominantly in photoreceptors and expression occurs primarily during postnatal development. We have mapped the mouse RP1 gene to mouse chromosome 1, near the centromere, using two different techniques. This localization excludes RP1 as the causative gene for the mouse retinal degeneration *Rd4*, previously thought to be the mouse model for RP1.

Mutation screening of RP1 in over 250 adRP patients shows that the frequency of RP1 mutations is at least 6% and potentially higher, since screening is not complete in all patients. All disease-causing mutations identified so far are nonsense or frameshift mutations, causing premature truncation of the protein. These mutations cluster in a region of the protein beyond the doublecortin domain. Two potential missense mutations have also been found in adRP patients but it is not yet clear if they are disease-causing. A number of highly polymorphic amino acid substitutions have been identified, indicating that the protein has numerous common isoforms. Comparison to the mouse protein sequence reveals both highly conserved and highly divergent domains, the former probably representing important functional domains.

Supported by NEI-NIH grant EY07142 and grants from the Foundation Fighting Blindness, the Hermann Eye Fund, the March of Dimes Found., the British RP Soc. and the Wellcome Trust.

Program Nr: 2805 from the 1999 ASHG Annual Meeting

Nonsense mutation of the actinin 3 gene is not associated with severity of dystrophinopathy. *R. Suminaga[1], Y. Takeshima[1], H. Wada[3], H. Nakamura[1], M. Matsuo[2].* 1) Pediatrics, Kobe Univ. School of Medicine, Kobe, Hyogo, Japan; 2) Division of Genetics, ICMR, Kobe Univ. School of Medicine, Kobe, Hyogo, Japan; 3) Sakura Ryoikuen Hospital, Sanda, Hyogo, Japan.

There is a wide variety of clinical severities among patients with Duchenne or Becker (DMD and BMD) muscular dystrophy especially in the wheelchair bound age. To explain this, some modifying factors are supposed to be present in addition to the mutations in the dystrophin gene. Recently, a common nonsense mutation causing alpha actinin 3 deficiency was reported. Considering that alpha actinin 3 is expressed specifically in type 2 muscle fibers and that the alpha actinins are a family of actin-binding and crosslinking proteins related to dystrophin, we supposed that nonsense mutations of the alpha actinin gene function as modifying factors for the clinical phenotype of DMD/BMD. Frequently detected in the ACTN3 gene is a C to T transversion at position 1747 in exon 16 which converts arginine (CGA) to a stop codon (TGA) thus creating a novel Ddel restriction site. We, therefore, analyzed the genotype of the ACTN3 gene in 150 Japanese DMD/BMD cases and 27 normal Japanese controls by PCR amplification of the genomic fragment between exons 15 and 16. This amplified fragment then subsequently underwent digestion using Ddel. Homozygosity for the stop codon was identified in 32 of 150 (21.3%) of the DMD/BMD patients and in 7 of the 27 (25.9%) Japanese controls. No significant statistical difference was found when these two values were compared. Of the 76 DMD cases, 12 (15.8%) were homozygous and 42 (55.3%) were heterozygous for the nonsense mutation and no significant difference was noted with regards the age when these DMD patients first started walking nor with regards the age when they became wheelchair bound. These results suggest that no association exists between the nonsense mutation of the alpha actinin gene and the clinical phenotype of DMD/BMD.

Program Nr: 2806 from the 1999 ASHG Annual Meeting

FMR1 mRNA expression levels in fragile X. *F. Tassone[1], RJ. Hagerman[2], AK. Taylor[3], JB. Mills[1], S. Wood[2], LW. Gane[2], PJ. Hagerman[1]*. 1) Biochemistry and Molecular Gen, UCHSC, Denver, CO; 2) 2 Child Development Unit, The Children's Hospital, Denver, CO; 3) 3 Kimball Genetics, Inc., Denver, CO.

Premutation carriers are generally believed to be clinically unaffected, their alleles unmethylated and associated with normal transcription and normal FMRP production. However, some individual carriers of the FMR1 premutation show a broad variety of psychopathological symptoms including learning disabilities, emotional problems and in some cases mental retardation. In order to establish whether the observed differences in phenotypic involvement among premutation individuals may be associated at molecular level with FMR1 gene dysfunction, we have investigated the FMR1 mRNA expression levels by quantitative fluorescence RT-PCR, and FMRP expression by immunocytochemistry in 40 premutation carriers (27 females and 13 males). Unexpectedly, we found that all male carriers (5) of a premutation above 110 CGGrepeats and presenting clinical features typical of fragile X syndrome, showed a substantial increase in the FMR1 mRNA. In addition, 3 of the male carriers showed a significant decrease of FMRP expression detected by immunocytochemistry. These data suggest that the fragile X phenotype does not always correlate with a decrease in FMR-1 mRNA and that the absence or deficit of FMRP expression does not arise only from decreased mRNA levels. Thus, other mechanisms may be involved in the regulation of the FMR-1 transcription. Results will be discussed.

Program Nr: 2807 from the 1999 ASHG Annual Meeting

Homologous and non-homologous recombinations at the glucocerebrosidase locus: Implications for Gaucher disease. *N. Tayebi, B. Stubblefield, D. Stone, M. Callahan, V. Madike, E. Sidransky.* DHHS/PHS, NSB/NIMH/NIH, Bethesda, MD.

The molecular diagnosis of Gaucher disease, the inherited deficiency of the lysosomal enzyme glucocerebrosidase (GC), is complicated by the presence of a 96% homologous pseudogene, which is located 16kb downstream of the functional gene. Metaxin, a convergently transcribed gene adjacent to the GC pseudogene, also has a highly homologous pseudogene downstream of the GC gene. Several patients with Gaucher disease have mutant alleles which have resulted from recombination between these two genes and their pseudogenes. Earlier studies of genotype-phenotype correlations revealed that Gaucher disease patients with diverse clinical manifestations can have the same point mutations. However, some of these point mutations, particularly L444P, originate from the pseudogene sequence and are often accompanied by other pseudogene sequence changes, suggesting the presence of recombination. We studied 398 alleles from 199 patients with Gaucher disease and identified 40 recombinant alleles (17 Type 1, 16 Type 2, and 7 Type 3). The sites and the possible mechanisms of crossover were determined using several methods. Southern blots of genomic DNA digested with the restriction enzymes SstII and SspI demonstrated major rearrangements. These included gene fusion with the deletion of the intergenic region in 13 alleles and a duplication in three alleles. Southern blots of HincII digested DNA, long template PCR, and direct sequencing identified 24 additional recombinant alleles. Sequencing identified eight different crossover sites and indicated the probable crossover site in many other alleles. In 75% of recombinant alleles, the crossover occurred within introns 8-11. Different mechanisms, including reciprocal and nonreciprocal recombination, intramolecular crossover, and chi structures appear to have occurred in different cases. One possible motif sequence, which could be a hot spot for crossover, was identified. Homozygosity for recombinant alleles appears to result in early lethality. Further studies of these recombinant alleles may provide insights into the etiology of the more atypical Gaucher phenotypes.

Program Nr: 2808 from the 1999 ASHG Annual Meeting

CTNS MUTATIONS IN AN ITALIAN POPULATION OF CYSTINOSIS PATIENTS. *R. Tenconi[1], S. Mason[1], M. Clementi[1], R. Dall'Amico[2], G. Zacchello[2], G. Ardissino[2], C. Pecoraro[2], A. Burlina[2], E. Zamorani[2], F. Ginevri[2], M. Pennesi[2], P. Sorino[2]*. 1) Dept Ped, Clinical Genetics, Univ Padova, Padova, Italy; 2) Italian Registry of Cystinosis.

Nephropatic Cystinosis (NC) is an autosomal recessive lysosomal storage disease (OMIM 219800) characterized by renal failure in pediatric age and other systemic complications. The cystinosis gene was mapped to chromosome 17p13 in 1995 and cloned in 1998. Two studies performed in European and American patients for a total of 178 subjects have found 33-44% of patients to be homozigous for a 65-Kb deletion encompassing a polymorphic marker (D17S829) located within the intron 3. Several mutations have been found in the remaining patients, while no mutations were identified in about 20% of subjects. We have studied 17 probands from the Italian Registry of NC and found 2/17 homozigous and 3/17 heterozygotes for the 65-kb deletion. The analysis by SSCP of the exon 7, where a recurrent nonsense mutation (G--A substitution) was found in European patients, did not identify any mutation in our patients. We present the mutational spectrum of CN in Italy.

Program Nr: 2809 from the 1999 ASHG Annual Meeting

Creation and characterization of transgenic mouse lines expressing Cre recombinase in skeletal muscle or neurons. *F. Tiziano, P. Miniou, T. Frugier, A. Dierich, M. Le Meur, J. Melki.* IGBMC. INSERM/CNRS/ULP, Illkirch, Strasbourg, France.

In order to elucidate the pathophysiology of spinal muscular atrophy (SMA), a conditional mutagenesis of the mouse SMN gene has been undertaken using the CRE-LoxP system. We inserted two loxP sites flanking SMN exon 7 (SMNF7) through homologous recombination in order to delete SMN exon 7, the most frequent mutation found in SMA. Since homozygous deletion of SMN exon 7 in all cell types results in early lethality of mouse embryos, our goal was to restrict the induced mutation to either skeletal muscle or neurons, the target cells in SMA. For this purpose, we generated transgenic mouse lines expressing Cre recombinase under the control of the human alpha-skeletal actin (HSA-Cre) or rat neuron specific enolase (NSE-Cre) promoters. To test the efficiency of Cre recombinase activity, HSA-Cre transgenic lines were crossed with LacZ reporter line (Akagi et al, 1997). Specific recombinase activity was demonstrated in heart and skeletal muscle, in a pattern similar to the expression of the endogenous alpha-skeletal actin gene, both in adult tissues and during development. To test Cre recombinase activity in NSE-Cre transgenic lines, transgenic mice were crossed with (SMNF7/+) mice, and double transgenic mice were selected. Cre mediated deletion of SMN exon 7 was quantified by both Southern blot and semi-quantitative PCR amplification analysis of genomic DNA extracted from various tissues. The extent of induced deletion was variable, ranging from very low percentage in heart or skeletal muscle, to 47% in spinal cord and 56% in brain. In these tissues, the intermediate values may reflect Cre recombinase activity restricted to certain cell types. In order to further characterize tissue-specificity of Cre recombinase expression, in situ hybridization using Cre riboprobe is currently performed. The reported transgenic lines can be used to target SMN exon 7 deletion to either skeletal muscle or neurons. Therefore, this approach may avoid embryonic lethality resulting from inactivation of the SMN gene and should allow to create an animal model of SMA.

Program Nr: 2810 from the 1999 ASHG Annual Meeting

Mendelian Cytogenetics Network. A resource for genotype-phenotype delineation in man. *N. Tommerup[1], M. Bugge[1], K. Brondum-Nielsen[2], U. Kristoffersson[3], P.K.A. Jensen[4], H.H. Ropers[5]*. 1) Dept. of Med. Genet., Univ. of Copenhagen, Denmark; 2) J.F. Kennedy Inst., Glostrup, Denmark; 3) Dept. of Clinical Genet., Univ. Hosp. of Lund, Sweden; 4) Dept. of Clinical Genet., Univ. Hosp. of Aarhus, Denmark; 5) Max-Planck-Inst. for Mol. Genet., Berlin (Dahlem), Germany.

One evident link between phenotype and genotype are disease-associated balanced chromosome rearrangements (DBCRs) that truncate/inactivate specific genes. We have established a network of cytogenetic laboratories, Mendelian Cytogenetics Network (MCN), for the systematic identification and mapping of DBCRs. This includes an online database MCNdb (http://mcndb.imbg.ku.dk) and a YAC panel for FISH mapping of the breakpoints (http://www.mpimg-berlin-dahlem.mpg.de/~cytogen/). To get an estimate of the potential of this approach, we surveyed the cytogenetic files in Denmark/Scania, with a population of ~7 million. The 8 labs involved have made ~70.000 postanatal cytogenetic tests since 1970. We identified 210 DBCRs, excl. Robertsonians and the common chr. 9 inversion. The frequency of DBCRs (0.3%) is two-three times more frequent than in the general population, suggesting that up to 2/3 of the cases may be causally related to the traits involved. Of the 210 cases identified, only 10% have been published previously. Several of the unpublished DBCRs immediately defined specific/promising breakpoints associated with Nail-patella, Prader-Willi, Rett and Schmidt syndromes, Crohns disease, VATER association, ataxia, and ulna-aplasia. The remaining DBCRs were associated with mental retardation, autism, dysmorphic features, and male and female infertility. The implications of the survey is apparent when we compare with the size of MCN: Altogether, the 292 participating cytogenetic laboratories have performed >2.5 million postnatal analyses, with an estimated ~7.500 DBCRs stored in the cytogenetic files, of which 2/3 (~5.000) might be causative mutations. In addition, an estimated ~450 novel cases should be added each year. Our data illustrate that DBCRs and MCN are resources for large scale establishment of phenotype-genotype relationships in man.

Program Nr: 2811 from the 1999 ASHG Annual Meeting

Mohr-Tranebjaerg Syndrome is an X-linked Recessive Disorder Characterized by Mitochondrial Dysfunction Associated with Neuronal Cell Death. *L.. Tranebjaerg[1], S. Lindal[1], S. Merchant[2], OC. Ingebretsen[1], B. Hamel[3], V. Fung[4], M. Hayes[4], C. Koehler[5], O. Nilssen[1], M. van Ghelue[1]*. 1) Dept Medical Genetics, Dept Pathol, Dept Clinical Chemistry University Hosp, Tromsoe, Norway; 2) Temporal Bone Registry, Massachusets Gen Hosp, Boston; 3) Dept Human Genet Univ Hosp Nijmegen,Netherlands; 4) Dept Neurol,Westmead Hosp, Westmead, Australia; 5) Biozentrum Basel Univ, Basel, Switzerland.

Mohr Tranebjaerg syndrome (MIM 304700) is clinically well characterized and shown to be due to frameshift /stop mutations in the DDP gene(Tranebjaerg L et al, J Med Genet 32; 257-263, 1995; Jin H et al, Nat Genet 14;177-180,1996).We present the updated spectrum of mutations in 7 families identified in Norway,USA,Spain,Denmark, Australia,and the Netherlands each having a private DDP mutation. Recently,a DDP homologue(TIM 8)in yeast was shown to be involved in mitochondrial membrane protein transport (Koehler C et al,PNAS; 99:2141-6,1999)which implies that human deafness-dystonia syndrome is likely to be a mitochondrial dysfunction associated with neurodegenerative disease. Restudy of patients from the original Norwegian family showed optic atrophy,loss of neurons in the basal ganglia, morphologically abnormal mitochondria in muscle EM analysis and reduced number of spiral ganglion cells at the analysis of temporal bone.The DDP protein was absent in cultured fibroblasts as determined by means of polyclonal antibodies.Our findings for the first time support mitochondrial dysfunction in human patients with deafness-optic atrophy-dystonia syndrome.The ATP production rate in fresh muscle biopsy specimens was slightly reduced.There are striking clinical and neuropathological similarities between this disorder and other entities caused by mutations in nuclear genes such as Friedreich ataxia, providing independently confirmatory evidence that gene mutations causing mitochondrial dysfunction have a predilection for compromizing the functions of regions of the central nervous system requiring high metabolic turn over,such as the auditory and visual pathways.Financial support is acknowledged from the Norwegian Research Council(grant no 114575/320).

Program Nr: 2812 from the 1999 ASHG Annual Meeting

Identification of a new COL2A1 mutation in a family with autosomal dominant Spondyloepimetaphyseal dysplasia (SEMD) Strudwick type. *C.J. Tysoe[1], J. Saunders[1], L. White[1], N. Hills[1], G. Evans[2], T. Cole[3], S. Chapman[4], A. Richards[5], S. Martin[5], M. Pope[1]*. 1) Institute of Medical Genetics, Uni Wales College of Medicine, Cardiff, U.K; 2) Robert Jones and Agnes Hunt Orthopaedic and District Hospital NHS Trust, Oswestry, Shropshire, SY10 7AG; 3) West Midlands Regional Clinical Genetics Service, Clinical Genetics Unit, Birmingham Womens Hospital, Edgbaston, Birmingham, B15 2TG; 4) Birmingham Childrens Hospital, Steelhouse Lane, Birmingham, B4 6NH; 5) MRC Connective Tissue Genetics Group, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge.

We have carried out mutation screening analysis of the COL2A1 gene in a three generation family with an autosomal dominant form of Spondyloepimetaphyseal dysplasia (SEMD) Strudwick type. SEMD is a specific member of a clinically heterogeneous group of skeletal disorders, characterised by defective growth and modelling of the spine and long bones. Common clinical features include disproportionate short stature, malformed vertebrae and abnormal epiphyses or metaphyses. The family exhibited specific phenotypic features including chest deformity, characteristic limb abnormalities, myopia and early-onset degenerative joint disease; specifically, the proband showed limb shortening, abnormal epiphyses and metaphyses with tilting of the left tibial epiphysis. Direct sequencing of PCR amplified genomic DNA showed a point mutation within exon 20 of the COL2A1 gene, causing a glycine to aspartic acid substitution at codon 261. Previous reports have identified five point mutations causative for SEMD (three in SEMD Strudwick patients and two in unclassified SEMD patients, who exhibited some characteristics of SEMD Strudwick type). All five point mutations resulted in the substitution of a glycine residue for an alternative amino acid. Here we report the finding of a sixth point mutation, also a glycine substitution, which provides additional information as to the mutational spectrum of this disorder, with a view to further defining the genotype/phenotype correlation for this specific skeletal defect.

Program Nr: 2813 from the 1999 ASHG Annual Meeting

Identification of sixteen new PHEX gene mutations in Finnish patients with X-linked hypophosphatemic rickets.

H. Tyynismaa[1,2], I. Kaitila[3], T. Alitalo[1,2,4]. 1) Dept. of Medical Genetics, University of Helsinki , Helsinki, Finland; 2) Dept. of Molecular Genetics, The Folkhalsan Institute of Genetics, Helsinki, Finland; 3) Dept. of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 4) Depts. of Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland.

X-linked dominant hypophosphatemic rickets (HYP) is the most common form of hereditary rickets. It is characterized by a defect in renal phosphate reabsorption and an abnormal 1,25-dihydroxyvitamin D metabolism. Affected patients have short stature, skeletal pain and deformities, and periapical abscesses. The defective gene, PHEX, has been cloned and over 80 mutations identified. Since several other disorders with similar defects in renal phosphate transport and bone mineralization have been described, we have carried out a mutational screening of the PHEX gene to confirm the diagnosis in the Finnish patients. All 22 exons were analysed by SSCP and the aberrantly migrating bands sequenced. Included in the study were 15 sporadic patients and 5 familial cases. We identified 18 mutations, of which 16 were novel. Two families were segregating the same nonsense mutation in exon1. This mutation has been reported in three independent studies previously, and therefore, it presents a mutational hotspot rather than a Finnish founder mutation. Mutations were found in 100% of the familial cases and 94% of the sporadic patients. No apparent genotype-phenotype correlations could be observed. X-inactivation status of the female patients was normal.

Program Nr: 2814 from the 1999 ASHG Annual Meeting

Unusual disease mechanism in a new mutation FSHD family. *M. Upadhyaya[1], T. Haaf[2], M. Osborn[1], P. Thompson[1], S. van der Maarell[3], M. Rogers[1], D. Cooper[1]*. 1) Dept Medical Genetics, Univ Wales, Cardiff, Wales,UK; 2) Max-Planck-Institute,Berlin,Germany; 3) MGC Dept of Human Genetics,Leiden,Netherlands.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant muscular disorder. The disease locus has been mapped to 4q35 but the FSHD gene has not yet been isolated. FSHD is causally related to the presence of a shorter than normal EcoRI/BlnI fragment detected with probe p13E-11. This fragment size is <35 kb in FSHD patients. We have recently studied a sporadic FSHD family in whom the male proband exhibited symptoms at age 10 and was wheel-chair bound by age 33. Restriction analysis of DNA from this family following EcoRI and BlnI double digestion and electrophoresis, demonstrated that a 48kb EcoR1/Bln1 fragment was the only band present in the affected child, while both his parents possessed larger (>50kb) DNA fragments. Pulsed field gel electrophoresis analysis with EcoRI/BlnI,demonstrated that the mother was apparently homozygous for a 100kb fragment, whereas the father had two separate fragments of 60kb and 70kb. The affected child had inherited a 60kb paternal fragment but not a 100kb maternal allele. The apparent homozygosity for the 100kb EcoR1/Bln1 fragment in the mother may be explicable in terms of hemizygosity for a chromosome 4 with the affected child inheriting this deleted (null) allele. Further genotype analysis excluded non-paternity or sample mix-up. Analysis with chromosome 4 and 10 telomeric YAC clones indicated that this family is not deleted for the subtelomeric region whilst chromosome-specific painting probes for chromosomes 4 and 10 did not detect any gross rearrangements. FISH studies with a 4.1 kb KpnI-NaeI probe(which encompasses p13E-11 and lacks most of the D4Z4 sequence) suggests a partial deletion in one of the son's chromosome 4 homologue. We are currently defining the size of this deletion.The signal with chromosome 10 was similar in all three members of this family. Sequence analysis of entire FRG1 transcript did not identify any mutations. Thus despite extensive molecular and cytogenetic analysis, the underlying FSHD disease mechanism in this family remains uncertain.

Program Nr: 2815 from the 1999 ASHG Annual Meeting

Partial a-**sarcoglycan (**a-**SG) deficiency associated with the retention of the SG complex in a LGMD2D family.** *M. Vainzof[1,2], E.S. Moreira[1], M. Canovas[1], O.T. Suzuki[1], R.C.M. Pavanello[1], M.R. Passos-Bueno[1], M. Zatz[1].* 1) Dept Neurology, FMUSP; 2) Dept. of Biology, IBUSP, Sao Paulo, Brazil.

Mutations in four genes at 17q, 4q, 13q and 5q, which encodes a-SG, b-SG, g-SG and d-SG are responsible for sarcoglycanopathies, a subgroup of Limb-Girdle muscular dystrophies (LGMD2C-2F). The sarcoglycan proteins are known to be tightly associated with each other and a common immunohistochemical finding in sarcoglycan deficient patients is the loss or a significant reduction of all SG proteins at the sarcolemma, demonstrating that a primary defect in one of the associated glycoproteins results in secondary deficiency of the others components. Here we are describing a Brazilian family, in which the proband showed normal dystrophin and a partial deficiency of a-SG protein but retention of b-, g-, and d-SG in the sarcolemma of muscle fibers. The clinical course of the 3 affected brothers is variable. The oldest, currently 27 years old, was wheelchair bound at age 18. The second showed the first signs at age 11, weakness in upper limbs at age 19 and is still walking at age 23. The youngest, aged 16, reported onset at age 9 with toe walking and frequent falls and is still ambulant. DNA analysis detected a novel mutation in the a-SG gene, a G724T transversion in exon 6, a region close to the transmembrane domain of the protein that probably does not alter the domain of interaction among a-SG and the other SG proteins within the DGC complex. In a recent study on the proportion of SGpathies in the Brazilian population we verified that 23 among 115 LGMD patients showed a deficiency of a-SG, as well as a deficiency of the whole SG complex. However, in 12 other patients, a partial deficiency of only a-SG was detected and a SGpathy was excluded. The present observation suggests that these 12 patients, which represent about 10% of our LGMD patients, might have been misdiagnosed. This result highlight the importance of better investigating patients with a partial or isolated deficiency of any one of the SG proteins. Supported by FAPESP, PRONEX, CNPq, FFM.

Program Nr: 2816 from the 1999 ASHG Annual Meeting

Novel mutations in the BIG-H3 gene associated with an atypical granular corneal dystrophy and lattice corneal dystrophy type IIIA.*BIG-H3*. *S. Valleix[1], P. Dighiero[2], S. Drunat[1], F. D'Hermis[2], J.M. Legeais[2], G. Renard[2], G. Grateau[1], M. Delpech[1]*. 1) Genetique Moleculaire Humaine, Faculte de Medecine, Cochin, Paris, France; 2) Department of Ophthalmology, Hotel-Dieu Hospital, Paris, France.

The BIG-H3 gene, encoding kerato-epithelin, has been previously shown to be the disease gene for, at least, six distinct autosomal dominant corneal dystrophies. A clinical, histological, ultrastructural and molecular analysis of three unrelated French families was performed to determine the mutational status of the BIG-H3 gene. Two of these families were affected with a lattice corneal dystrophy closely resembling type IIIA, while the other one was affected with an atypical corneal dystrophy of granular type. Exons of the BIG-H3 gene were amplified by polymerase chain reaction and analyzed by a direct sequencing method. We identified, in all patients from the two families affected with the lattice dystrophy, a heterozygous single base-pair transition from G to A of the first nucleotide of codon 546 (GCC/ACC) predicting the replacement of alanine by threonine (A546T). This novel A546T mutation identified in these French patients with lattice dystrophy type IIIA differs from that reported in Japanese patients (P501T). Molecular data from patients affected with the unusual form of granular corneal dystrophy revealed a molecular defect never reported as yet. All patients (nine individuals across three generations) were found to be heterozygous for two mutations, the R124L mutation and a novel mutation predicting the deletion of two amino acid residues, threonine (T) and glutamic acid (E), at codons 125-126. These two mutations were both transmitted on the same chromosome in all nine patients with complete penetrance. This molecular defect is intriguing since the presence of R124L mutation alone is responsible for the superficial variant of granular dystrophy, while its association with deletion of codons 125 and 126 produces significant phenotypic variations of granular corneal dystrophy.

Program Nr: 2817 from the 1999 ASHG Annual Meeting

The COCH P51S mutation, a frequent cause of cochleovestibular dysfunction in Belgium and The Netherlands, is present on a common chromosomal haplotype. *G. Van Camp[1], E. Fransen[1], M. Verstreken[1], W.I.M. Verhagen[2], S. Bom[3], C. Cremers[3], F. Cremers[4].* 1) Dept Medical Genetics, Univ Antwerp - UIA, Antwerp, Belgium; 2) Department of Neurology, Canisius-Wilhelmina Hospital, Nijmegen, The Netherlands; 3) ENT Department, University Hospital Nijmegen, The Netherlands; 4) Department of Human Genetics, University Hospital Nijmegen, The Netherlands.

Among the loci for autosomal dominant hearing impairment, the DFNA9 locus on chromosome 14 is the only one involving vestibular problems in addition to non-syndromic deafness. Affected family members typically suffer from progressive hearing loss associated with progressive vestibular problems, such as instability in the dark and vertigo. The gene responsible for DFNA9 is the COCH gene, probably encoding an inner ear specific extracellular matrix protein. A missense mutation, changing a highly conserved Proline into a Serine (P51S), has recently been found in several families in Belgium and the Netherlands. In this study, we have analyzed additional patients and families with cochleo-vestibular dysfunction for the P51S mutation, and determined the haplotype of these families for a number of closely linked markers. In total, we have now identified 10 independent families with the P51S mutation, all living in Belgium and The Netherlands. The haplotype analysis showed a significant amount of allele sharing for all families, indicating that the P51S mutation originates from a common ancestor.

Program Nr: 2818 from the 1999 ASHG Annual Meeting

Skewed X-chromosome inactivation in two manifesting carriers of choroideremia. *J.A.J.M. van den Hurk[1], T.J.R. van de Pol[1], M.A. van Driel[1], L.I. van den Born[2], M. Seeliger[3], B. Wissinger[3], H.-H. Ropers[1,4], F.P.M. Cremers[1].* 1) Department of Human Genetics, University Hospital Nijmegen, Nijmegen, The Netherlands; 2) Institute of Ophthalmology, Erasmus University, Rotterdam, The Netherlands; 3) Universitäts-Augenklinik, Eberhard-Karls-Universität, Tübingen, Germany; 4) Max Planck Institute for Molecular Genetics, Berlin, Germany.

Choroideremia (CHM)is an X-linked recessive eye disorder that is characterized by progressive degeneration of the choroid, retinal pigment epithelium (RPE), and retina. Affected males develop night-blindness in their teenage years, followed by progressive constriction of visual fields and, eventually, complete blindness. Female carriers generally show no serious visual impairment, but they have patchy pigmentation and degeneration of the RPE. There are occasional reports of female carriers who are fully affected by choroideremia. Two of these symptomatic females were found to have X-autosome translocations that involve the *CHM/REP-1* gene.

DNA of two previously undescribed females with clinical signs of choroideremia was searched for *CHM/REP-1* gene mutations. In one female patient exon 1 of the *CHM/REP-1* gene was found to be deleted, the other had a nonsense mutation in *CHM/REP-1* exon 14 (Cys575Stop). In both patients no additional mutations could be detected.

Subsequently, the X-inactivation pattern in lymphocytes of the manifesting carriers was studied by PCR analysis of a polymorphic CAG repeat in the androgen receptor (ARA) gene. One of the females was found to be homozygous for the CAG repeat. X-chromosome inactivation in this patient was studied by Southern blot analysis using probe M27b (DXS255). In both manifesting carriers the normal X-chromosome was found to be inactive in the majority of cells.

In conclusion, the clinical manifestation of choroideremia in the two carrier females is likely to be the result of a *CHM/REP-1* gene mutation and skewed X-chromosome inactivation.

Program Nr: 2819 from the 1999 ASHG Annual Meeting

Niemann-Pick C disease: mutational spectrum in *NPC1* gene and genotype/ phenotype correlations. *M.T. Vanier[1], G. Millat[1], C. Marçais[1], M. Rafi[2], T. Yamamoto[3], J.A. Morris[4], P.G. Pentchev[4], E. Nanba[3], D.A. Wenger[2].* 1) INSERM U189, Lyon-Sud Medical School, Oullins, France; 2) Dpt Neurology, Jefferson Medical College, Philadelphia, PA, USA; 3) Gene Res. Center,Tottori University Medical School, Yonago, Japan; 4) DMNB, NINDS, NIH, Bethesda, MD, USA.

Niemann-Pick C (NPC) disease is a neurovisceral lysosomal lipid storage disorder resulting from mutations affecting the *NPC1* gene in 95% of the families. A recent study of 20 NPC1 patients led to the identification of 20 point mutations, 1bp and 163bp deletions, 1 approx. 500 bp insertion and a 14 bp duplication. The mutations were distributed throughout the gene, with 8 of them located before the region coding for the sterol sensing domain (SSD) (first 11 exons), 3 within that region, 13 in the last 10 exons. They were all private apart from one important exception, the T3182C transition, which leads to a I1061T substitution affecting a transmembrane domain. In a further study, I1061T was shown to be the most frequent mutation in NPC patients of Western European descent (including in USA and Canada)(40/290 mutant alleles) and from the study of 14 homozygous patients, to correlate with a classical juvenile phenotype. This mutation was demonstrated as highly prevalent in the described isolate of Hispanic NPC patients from the upper Rio Grande valley of the USA. Among the 7 additional alterations found in a homozygous state, three (S940X, 845delT, dup749-763) lead to a truncated protein while the Q775P mutation affects a SCAP conserved residue in the SSD. All 4 patients had shown a severe infantile neurological disease. A neurological adult-onset patient with mild variant biochemical alterations was found homozygous for a V950M substitution. Among 16 other mutations found in the heterozygous state, M631R and L724P affect the SSD while M1142T and T1205K, located in transmembrane domains, affect residues conserved in human *Patched*. Characterization of the impact at the cellular and biochemical level of mutations with well defined genotype/phenotype correlations should provide clues for better understanding the function of the NPC1 protein.

Program Nr: 2820 from the 1999 ASHG Annual Meeting

In vitro analysis of FTDP-17 missense mutations in 3 and 4 repeat tau in neuronal and non-neuronal stable cell lines. *M.A. van Slegtenhorst, N. Mehta, M. Hutton.* Neurogenetics, Mayo Clinic Jacksonville, Jacksonville, FL.

Mutations in tau have recently been found associated with Fronto-temporal Dementia with Parkinsonism linked to chromosome 17 (FTDP-17). The majority are missense mutations and exon 10 splice-site mutations that effect the ratio of Tau containing 3 and 4 microtubule binding domains. We have created stable lines in CHO and human neuroblastoma M17 cells overexpressing mutant and wild type Tau constructs. They express Tau with 3 or 4 microtubule binding domain repeats and a series of missense mutations (V337M, R406W and P301L).

Western blot analysis shows high expression levels in all lines tested. The CHO lines have been tested for the distribution of mitochondria and preliminary data suggest that there is clustering in all lines overexpressing tau. No qualitative effect on mitochondrial transport could be detected for the different mutations or between Tau with 3 or 4 microtubule binding domains. We are in the process of analyzing the stable lines for differences in free versus bound Tau and the relative cellular levels of Glu-tubulin and Tyr-tubulin.

In addition we have generated GFP-tau in lines with an inducible promotor (Tet-on) to study the effect of the different mutations on microtubule dynamics.

This study was supported by the Kendall Fellowship, Mayo Foundation.

Program Nr: 2821 from the 1999 ASHG Annual Meeting

Incidence of the major Nijmegen breakage syndrome (NBS) mutation 657del5 in Czech Republic, Poland and Ukraine. *R. Varon[1], E. Seemanova[2], K. Chrzanowska[3], D. Abramczuk[3], O. Hnateyko[4], K. Sperling[1], A. Reis[1,5]*. 1) Institute of Human Genetics, Humboldt University, Charite, Berlin, Germany; 2) Department of Medical Genetics, Charles University, Prague, Czech Republic; 3) Department of Medical Genetics, Children's Memorial Health Institute, Warsaw, Poland; 4) Scientific-Research Institute of Hereditory Pathology, Lvov, Ukraine; 5) Mikrosatellitenzentrum, Max-Delbrck Center, Berlin, Germany.

Nijmegen breakage syndrome (NBS) is an autosomal recessive chromosomal instability syndrome, characterised by microcephaly, bird-like face, growth retardation, radiosensitivity, immunodeficiency and high susceptibility to lymphoid malignancy. Most patients are of Slavic ancestry. Recently we cloned the NBS1 gene which codes for nibrin, a member of the RAD50 protein complex of DNA double-strand break repair and recombination. We identified a total of 7 truncating mutations in different NBS patients, the majority being homozygous for mutation 657del5 in exon 6. We found this mutation in 68 unrelated NBS patients. Based on epidemiological data it has been proposed that NBS heterozygotes also have an elevated incidence of malignancies. In order to determine the population incidence of NBS mutations we now undertook a study to estimate the frequency of the 657del5 mutation in the Czech Republic and Poland. We analysed 1713 randomly selected, anonymous Guthrie cards from new-borns, 645 from Czech Republic 568 from Poland and 500 from Ukraine. Using PCR-SSCP analysis followed by direct sequencing of positive samples we identified a total of 11 heterozygotes (5, 3 and 3, respectively), corresponding to an incidence of approx.1 in 156 in the three populations tested. If the elevated cancer risk for NBS heterozygotes is confirmed this high carrier frequency would mean, that this NBS mutation contributes considerably to the cancer load of both populations investigated. Other non-founder mutations in NBS1 could also contribute to the cancer frequency in other populations and confirm the hypothesis that nibrin acts as a tumour-suppressor. We now plan to asses the exact cancer risk for these individuals trough epidemiological studies.

Program Nr: 2822 from the 1999 ASHG Annual Meeting

The human LDL receptor gene (LDLR) database: Molecular analysis of 535 mutations. *M. Varret, J-P. Rabès, L. Villéger, C. Junien, C. Béroud, C. Boileau.* INSERM U383, Hopital Necker, 75015 Paris, France.

To date, 620 mutations have been identified in the LDLR gene, encoding the low-density lipoprotein receptor, in subjects with Familial Hypercholesterolemia. Although genotype/structure-function correlations have been substantially investigated, genotype/phenotype correlations have not been systematically explored. Thus, we have compiled a database containing standardized data for each LDLR gene mutation, and developed the software that provides sorting tools and allows optimized multicriteria research [http://www.umd.necker.fr]. The analysis of the 535 point mutations in our LDLR database gives the following information: [1] 61% of the mutations are missense, and 20% occur in CpG dinucleotides known to be mutational hot spots; [2] although widely distributed throughout the gene, there is an excess of mutations in exon 4 ($p<0.001$) encoding the 3 central ligand-binding repeats, exon 6 ($p<0.02$) encoding the last ligand-binding repeat, exon 7 ($p<0.05$) encoding the first EGF-like repeat, and exon 9 ($p<0.02$) encoding the NH2-end of the EGF-precursor-like domain; [3] there is a deficit of mutations in exon 13 ($p<0.01$) encoding the COOH-end of the EGF-precursor-like domain, exon 15 ($p<0.001$) encoding the O-linked-sugar domain, exon 16 ($p<0.01$) encoding the transmembrane domain, and exons 17-18 ($p<0.05$) encoding the cytoplasmic domain; [4] 48% of the small deletions occur between repeated sequences and can be explained by the slipped-mispairing model described by Krawczak et Cooper (Hum Genet 1991, 86:425); [5] 69% of the mutations in the ligand-binding domain affect conserved amino-acids for calcium cage formation involved in LDL binding; [6] the functional data we have for 210 (40%) mutations indicate that 33% and 29% of them are class 2B mutations (transport defective alleles) and class 1 mutations (null alleles) respectively; [7] finally, the investigation of genotype/phenotype correlations is difficult since the clinical data is usually incomplete in mutation reports. Direct access to the database through the web site should facilitate the input of high quality clinical information for each mutation and should overcome this shortage.

Program Nr: 2823 from the 1999 ASHG Annual Meeting

Further evidence for a chromosome 4p haplotype segregating with Parkinson's disease in an independent Italian kindred. *J.R. Vaughan[1], M. Farrer[2], G. De Michele[3], G. Volpe[3], J. Hardy[2], N.W. Wood[1]*. 1) University Department of Clinical Neurology, Institute of Neurology, Queen Square, London, WC1N 3BG, UK; 2) Mayo Clinic Jacksonville, Neurogenetics, 4500 San Pablo Road, Jacksonville, Florida 32224; 3) Dipartimento di Scienze Neurologiche, Universita Federico 11, Naples, Italy.

A chromosome 4p haplotype segregating with Parkinson's disease and postural tremor has been suggested as a new locus for Lewy body parkinsonism (4p15). The two branches of the kindred (Spellman-Muenter /Waters and Miller (Iowa kindred)) shared a haplotype spanning the interval from D4S1551 to D4S3350, a genetic distance of 10.7cM. The disorder is characterised by young age at onset, rapidly progressive dopa-responsive parkinsonism and dementia. We report an Italian family where the 4 affected individuals in 2 successive generations all share part of this haplotype for four adjacent markers, D4S2305, D4S2397, D4S1609 and D4S230 (same allele sizes in both families). They have a young onset age and moderately progressive dopa-responsive parkinsonism. Cognitive impairment was present in 2 out of the 4 affected individuals.One individual sharing the haplotype is not yet affected (aged 71) and is not said to have a postural tremor.Three recombinant haplotypes in the Italian family were observed. Assuming intermarker linkage equilibrium, the region of shared haplotype between the Iowa and Italian families spans 5.36cM and has a frequency of 1/374, but due to its small size the pedigree can generate only 1/3.5 odds for linkage. These data are supportive of evidence for linkage and may point to the same gene being involved in the development of the parkinsonian syndrome in both families, but more affected individuals will be needed or a common ancestor demonstrated between the two kindreds if this family is to be used conclusively to study 4p15. Several genes map to 4p15 including ubiquitin C-terminal hydrolase isozyme L1 (PGP9.5)which was negative in the Italian family. Positional cloning strategies will be used to find the causative gene at this locus but this kindred may represent an important link in narrowing down the 4p candidate region.

Program Nr: 2824 from the 1999 ASHG Annual Meeting

Characterization of the mouse Wolf Hirschhorn Syndrome Candidate gene 1. *A.J.M.H. Verkerk[1], J. Schimenti[2], D. Naf[2], E.W. Gutteling[1], R. Florijn[1], G.J.B. van Ommen[1], J.T. den Dunnen[1].* 1) Dept Human and Clinical Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands; 2) The Jackson Laboratory, Bar Harbor, Maine, USA.

The Wolf Hirschhorn syndrome (WHS) is a malformation syndrome associated with a hemizygous deletion of the distal short arm of chromosome 4 (4p16.3). Patients have specific facial characteristics, midline defects and are mentally retarded. Recently a candidate gene, WHSC1 (Wolf Hirschhorn Syndrome Candidate gene 1) has been identified which maps to the 165 kb critical region deleted in patients. The putative 152 kDa protein contains: two PWWP domains, an HMG box, a SET domain and a PHD-type zinc finger, pointing to a function in transcriptional regulation during development. The gene shows a complex expression involving differential splicing and polyadenylation in many embryonic and adult tissues. All WHS patients characterized to date have different deletions which extend far beyond the WHSC1 gene. To facilitate a functional analysis of the gene we are therefore generating mice with a deleted copy of the gene (knock-out) using loxP-technology, such that it facilitates the subsequent construction of more complex genetic rearrangements, e.g. a PWWP-deleted gene to study this domain, which is present in several other proteins. We are currently also characterizing ES-cell lines carrying X-ray induced deletions originating in the mouse Hd gene near the whsc1 locus. Several lines of mice bearing deletions that span the Hd-/Whsc1- interval have been generated and studied and exhibit strain-dependent heterozygous phenotypes consistent with WHS. These include growth retardation, eye colobomata, midline closure defects, asymmetric skulls, seizures, and embryonic/perinatal lethality. We have constructed a PAC map of the murine Whsc1-Hd locus using known genes and markers and use these PACs to analyze the deletions by metaphase-, interphase- and fiberFISH.

Program Nr: 2825 from the 1999 ASHG Annual Meeting

Evidence that revertant mosaicism in a Fanconi anemia group A patient is caused by mitotic gene conversion.

P.C. Verlander[1], O. Levran[1], S.D. Batish[1], J.E. Wagner[2], A.D. Auerbach[1]. 1) Lab. Human Gen. & Hematology, Rockefeller Univ, New York, NY; 2) Univ. of Minn. School of Medicine, Minneapolis, MN.

Fanconi anemia (FA) is an autosomal recessive disorder characterized by cellular hypersensivity to DNA crosslinking agents. While most FA patients are uniformly sensitive to crosslinkers, approximately one third of FA patients are somatic mosaics in regard to diepoxybutane (DEB) sensitivity of lymphocytes. We previously established that this mosaicism is not limited to lymphocytes by demonstrating the loss of the maternally inherited mutation (2815-2816ins19, exon 29) in individually plucked hematopoietic progenitors from a mildly affected 16 year old FA-A patient (IFAR #557/2). The patient is a compound heterozygote; the paternal mutation is a genomic deletion 3' to exon 34. The fibroblasts retained the 2815-2816ins19 mutation in genomic DNA, while the LCL had no evidence of this mutation. In order to demonstrate that loss of the mutation resulted in expression of a normal transcript, we examined cDNA prepared from fibroblasts and from the LCL. PCR amplification of a 1 kb fragment spanning the maternal allele (exons 23-30) generated two bands from fibroblast cDNA: a normal size fragment and a fragment with a 620 bp deletion involving exons 25-29; the breakpoint in exon 29 was 3' to the 2815-2816ins19 mutation. The LCL cDNA produced a single normal band, with no evidence for the maternal mutation. Examination of polymorphisms in genomic DNA from mother, father, and patient, and cDNA from both fibroblasts and revertant LCL from patient, establish that transcripts are produced from both *FANCA* alleles in the LCL. Heterozygosity for polymorphisms in exon 13, 14, 16 and 22 demonstrate that the loss of the maternal mutant allele is not simply a deletion of that allele, but reflects a reversion of the mutation. Loss of heterozygosity (LOH) in the patient for polymorphisms on the revertant maternal allele in exons 30 and 32 is evidence that this reverse mutation was the result of the nonreciprocal transfer of part of the paternal allele for the maternal, by mitotic gene conversion. Despite this natural gene therapy, the patients continues to exhibit progressive marrow failure.

Program Nr: 2826 from the 1999 ASHG Annual Meeting

Molecular genetic analysis of the glypican gene cluster on chromosome Xq26. *M. Veugelers, G. David.* Laboratory for Glycobiology and Developmental Genetics, Center for Human Genetics, Flemish Interuniversitary Institute for Biotechnology (VIB4), K.U.Leuven, Belgium.

The glypicans compose a family of glycosylphosphatidylinositol(GPI)-anchored heparan sulfate proteoglycans. Mutations in *dally*, a gene encoding a *Drosophila* glypican, disturb the pattern of cell division in the nervous system, while mutations in *GPC3*, the gene for human glypican-3, are associated with the Simpson-Golabi-Behmel overgrowth syndrome (SGBS). We have previously shown that some SGBS-patients also have deletions in *GPC4*, another glypican gene which lies adjacent to *GPC3* on Xq26. We have analysed by SSCP and DNA-sequencing the mutation status of *GPC3* and *GPC4* in a set of 17 SGBS-patients, 9 BWS-patients and 3 patients with other overgrowth syndromes (Perlman syndrome and other syndromes). So far, we have identified one patient with a deletion of the last two exons of *GPC3* and the entire *GPC4* gene. Two other patients with deletions of *GPC3* exons could be identified. Five patients showed point mutations in *GPC3*: different types of mutations were observed: frameshift-, nonsense-, missense- and splice-mutations. All identified mutations are predicted to lead to a complete loss of function of the glypican-3 protein. No mutations could be identified in non-SGBS patients. We have also identified three single nucleotide polymorphism (SNPs) in the *GPC4* gene, but except for the total gene deletion in one patient no evidence was found for the presence of pathological mutations in *GPC4* associated with SGBS. Our data indicate that point mutations in *GPC3* are sufficient to cause the Simpson-Golabi-Behmel syndrome.

Program Nr: 2827 from the 1999 ASHG Annual Meeting

RNA Profiling of Global Expression Changes in Progressive Myoclonus Epilepsy (EPM1). *K.I. Virtaneva[1,2], J. Palatini[1], A-E. Lehesjoki[2], A. de la Chapelle[1,2], R. Krahe[1,2].* 1) Div. Human Cancer Genetics, Comp. Cancer Ctr., Ohio State Univ., Columbus, Ohio; 2) Dept. of Molecular Genetics, Folkhälsan Inst. of Genetics, Univ. of Helsinki, Finland.

Progressive myoclonus epilepsy of Unverricht-Lundborg type (EPM1; OMIM 254800) is an autosomal recessive disorder characterized by stimulus-sensitive myoclonus, tonic-clonic seizures and a progressive course with a mean age of onset of 10 years. By positional cloning, cystatin B (*CSTB*) encoding a cysteine protease inhibitor was shown to underlie EPM1. In the majority of EPM1 patients a 12-mer minisatellite repeat expansion in the *CSTB* promoter was identified as the disease-causing mutation. Expansion of the GC-rich repeat disrupts the function of the *CSTB* promoter and causes transcriptional down-regulation, indicating CSTB loss-of-function as the molecular defect in EPM1. The pathophysiological mechanisms underlying EPM1 are currently unclear. We have performed global RNA profiling of expression changes in lymphoblastoid cell lines of two EPM1 patients and one EPM1 carrier with oligo-based GeneChip microarrays (Affymetrix) to simultaneously quantify 6,800 unique human genes. In the EPM1 patients homozygous for the expansion, CSTB mRNA levels were decreased 4.5-fold and 6.6-fold, respectively. The carrier father showed a decrease of -1.5-fold as predicted for a heterozygous individual. Interestingly, in the profiles of both patients CSTB showed the second most decreased transcript level. Thus, we suggest that CSTB could have been identified as the EPM1 gene by functional positional cloning using DNA microarrays. Of 6,800 genes assayed 1,300 genes were expressed. Thirty-six genes were concordantly dysregulated in both EPM1 patients. Of these 36 genes, 17 showed decreased and 19 increased expression. Several of the down-regulated genes are involved in signal transduction and neural biology. Moreover, one of the down-regulated genes constitutes a functional candidate for EPM1 pathogenesis.

Program Nr: 2828 from the 1999 ASHG Annual Meeting

Variant alleles in the CPT2 gene are associated with increased susceptibility to carnitine palmitoyltransferase II deficiency. *G.D. Vladutiu, D. Smail.* Pediatrics, State Univ.of NY at Buffalo,NY.

Adult-onset carnitine palmitoyltransferase II (CPT II) deficiency is a common lipid myopathy characterized by exercise intolerance and myoglobinuria. CPT II deficiency may be even more common due to increasing biochemical and molecular evidence for the existence of manifesting carriers for certain of the disease-causing mutations. The mutation status of patients can be predicted using the ratio of muscle CPT activity to citrate synthase (CPT:CS) as follows: 2 mutations (0.47-1.00), 1 mutation (1.71-2.69), no mutations (4.90-5.79). An increasing number of symptomatic individuals exist who have modest reductions in CPT enzyme activity ("gray zone" patients; CPT:CS = 2.70-3.00) and who are negative for 15 known mutations in the CPT2 gene. As a potential explanation for these partial reductions, we hypothesize that the known CPT2 gene polymorphisms, V368I and M647V, may play a causative role either independently or in association with pathogenic mutations. Using multiplex allele-specific amplification of genomic DNA, we examined the distribution of the polymorphisms in the general population and in suspected heterozygotes and "gray zone" patients. The frequencies of 368I and 647V were 0.43 and 0.11, respectively, in 50 control individuals. Both the I and V alleles occurred more frequently in 14 suspected heterozygotes (368I, 0.75 [p=0.003]; 647V, 0.43 [p=<0.0001]) and in 6 "gray zone" individuals (368I, 0.83 [p=0.02]; 647V, 0.58 [p=<0.0001]). Eight patients suspected of having 2 disease-causing mutations in CPT2 (CPT:CS <1.00) had the general population frequencies of the variants. Homozygosity for the and 368I and 647V alleles in the "gray zone" group was 2.4- and 9-fold higher, respectively, than in the general population. The IV haplotype has been expressed in vitro and shown to augment CPT enzyme deficiency when associated with certain mutations in the gene (Verderio et al. 1995). Variant haplotypes in different combinations may alter the tetrameric configuration of the enzyme protein thus altering its activity. The identification of detrimental haplotypes may make risk assessment feasible. In vitro expression studies are underway. Supported by the MDA.

Program Nr: 2829 from the 1999 ASHG Annual Meeting

Genetic analysis in Spanish cases of dominant cerebellar ataxia. *V. Volpini[1], J. Corral[1], I. Banchs[1], M. Pujana[1], M. Gratacos[1], X. Estivill[1], O. Combarros[2], D. Genis[3], J. Berciano[2].* 1) Molecular Genetics Department, Cancer Research Institute (IRO), Barcelona, Spain; 2) Neurology Service, Hosp Valdecillas, Santander, Spain; 3) Neurology Unit, Hosp J Trueta, Girona, Spain.

Autosomal dominant cerebellar ataxias (ADCA) are a clinically heterogeneous group of neurodegenerative disorders caused by unstable trinucleotide repeat expansions. Five spinocerebellar ataxia genes: SCA1, SCA2, SCA3, SCA6, SCA7 and the gene for DRPLA (dentato-rubro-palido-Luisian atrophy) have been cloned with the finding of an expansion of a CAG repeat which encodes a polyglutamine tract. The exception is SCA8, which consists of an exonic but untranslated CTG repeat. We present here the molecular analysis of 92 unrelated familial and 114 sporadic Spanish cases of spinocerebellar ataxia. For ADCA cases 15% were SCA2, 15% SCA3, 6% SCA1, 3% SCA7, 1% SCA6 and 1% DRPLA. About 58% of ADCA cases remained genetically unclassified. The expanded alleles ranged from 41 to 59 for SCA1, 67 to 77 for SCA3, 25 for SCA6, 38 to 113 for SCA7 and 63 for DRPLA. The highest CAG repeat variation in meiotic transmission of expanded alleles was detected in SCA7, being of +67 units in one paternal transmission and giving rise to a 113 CAG repeat allele in a patient who died at 3 years of age. Meiotic transmissions have also shown a tendency to more frequent paternal transmission of expanded alleles in SCA1 and SCA7. All SCA1 and SCA2 expanded alleles analyzed consisted of pure CAG repeats, whereas normal alleles were interrupted by 1-2 CAT trinucleotides in SCA1, except for three alleles of 6, 14 and 21 CAG repeats, and by 1-3 CAA trinucleotides in SCA2. No SCA and DRPLA mutations were detected in the 114 isolated cases of spinocerebellar ataxia. In order to complete the study, we are currently performing the CTG-SCA8 screening in our ataxia sample.

Program Nr: 2830 from the 1999 ASHG Annual Meeting

Clinical and genetic characterization of 9 Japanese patients with X-linked a-**thalassemia/mental retardation (ATR-X) syndrome.** *T. Wada[1], T. Kubota[2], Y. Fukushima[2], S. Saitoh[1]*. 1) Dept. of Pediatrics, Hokkaido Univ., Sapporo, Japan; 2) Dept. of Hygiene and Medical Genetics, Shinshu Univ., Nagano, Japan.

Mutations of the *ATRX* gene have been reported in patients with the X-linked a-thalassemia/mental retardation (ATR-X) syndrome (MIM 301040). *ATRX* is also involved in Juberg-Marsidi syndrome, Carpenter-Waziri syndrome, and mental retardation syndrome without a-thalassemia. To elucidate further the significance of mutations of *ATRX* in relation to clinical manifestations, we performed clinical and genetic examinations on a series of Japanese patients with ATR-X phenotypes. Nine male patients from 8 families, including one pair of sibs, were included in the study. All patients had typical clinical features for the syndrome with severe mental retardation. HbH inclusions were positive for 7 patients (including sibs), while negative for 2 patients. *ATRX* mutations were screened by RT-PCR followed by direct sequencing, using lymphoblastoid cell lines. Mutations were confirmed using genomic DNA, including that from 3 mothers. We detected 4 missense mutations (N179S, P190L, V1194I, R246C) in the zinc finger domains and 2 missense mutations (V1552C, Y1847C) in the helicase domains. R246C was found in 2 independent patients. No mutation was detected in one patient who was negative for HbH inclusions. Two mothers were carriers for the respective mutation, while one did not have the mutation suggesting a *de novo* origin of the mutation. All mutations except one (R246C) were novel ones. R246C was previously reported in 15 families and these patients demonstrated typical clinical features associated with a wide range of HbH inclusion (0.006-14 %). One patient with R246C was positive for HbH, but another was not, indicating phenotypic variability associated with an identical mutation. Although the presence of HbH or genital abnormalities were not identified constantly, characteristic facies and behavior were extremely similar in these Japanese patients with *ATRX* mutations. Therefore, severe mental retardation associated with characteristic facies and behavior in males, even without presence of HbH or genital abnormalities, should prompt diagnosis of the ATR-X syndrome.

Program Nr: 2831 from the 1999 ASHG Annual Meeting

DHCR7 mutation analysis in Smith-Lemli-Opitz syndrome. *M.R. Wallace[1], R. Trimpert[1], N. Nwokoro[3], P. Arn[2], C. Williams[1], L. Keppen[5], E. Elias[6], D. Abuelo[7], R. Kelley[4].* 1) Pediatrics/Genetics, Univ Florida, Gainesville/Jacksonville, FL; 2) Nemours Children's Clinic, Jacksonville, FL; 3) NIH--NICHD, Bethesda, MD; 4) Kennedy Krieger Institute, Johns Hopkins Uni., Baltimore, MD; 5) Univ South Dakota, Sioux Falls, SD; 6) Harvard Univ, Boston, MA; 7) Brown Univ, Providence, RI.

Smith-Lemli-Opitz syndrome (SLOS, also called RSH syndrome) is an autosomal recessive condition with a frequency in Caucasians of 1/20,000-40,000. It shows variable expressivity, ranging from severe birth defects leading to early death, to mild cases with little more than mental impairment. The underlying defect is a deficit of cholesterol and accumulation of 7-dehydrocholesterol (precursor), due to loss or impairment of the enzyme catalyzing the last step in cholesterol synthesis, 7-dehydrocholesterol reductase (DHCR7). The DHCR7 gene was cloned in 1998, and mutation studies in 19 patients were published. We are surveying for mutations in a panel of 19 additional unrelated patients, by screening for previously-published mutations, sequencing DHCR7 exons, and doing RNA-based analyses. The most common reported mutation, IVS8-1G>C, an intron error causing cryptic out-of-frame splicing, represents 12 of the alleles in our panel. There are three alleles each of the previously-reported T93M and R352W, and 2 patients with R242C and 2 with Y472H (neither previously published). Thus, these five alleles constitute 58% of the mutations. With the exception of the splicing error, all of the mutations to date are missense mutations (many affecting C-terminal amino acids), with no evidence of homozygosity in any patients. We are analyzing parent DNA in many cases, with no evidence for new mutation thus far. PCR-RFLP tests for many of the mutations have been developed, simplifying screening. We also report analysis of an unusual family with multiple affected first cousins, and another family in which there may be two mutations on one allele. Mutation data, cholesterol biochemistry, and clinical severity are being compared (including 5 other affected sibs), and preliminary work suggests we will find a strong correlation between genotype and phenotype.

Program Nr: 2832 from the 1999 ASHG Annual Meeting

Comparison of genotype and glaucoma treament outcome in patients with Axenfeld-Rieger malformations. *M.A. Walter[1], W.G. Pearce[1], E. Héon[2], I.M. MacDonald[1]*. 1) Ophthalmology, Rm. 832, Univ Alberta, Edmonton, AB, Canada; 2) Eye Research Institute of Canada, Univ. Toronto, Toronto, ON, Canada.

Axenfeld-Rieger (AR) malformations are autosomal dominantly inherited developmental disorders in which patients present with developmental anomalies in the formation of the anterior segment of the eye, leading to juvenile-onset glaucoma. Anomalies of the teeth, jaw and umbilicus are often also present. Very recent results have indicated that mutations of either the PITX2 or FKHL7 genes can underlie AR. We have therefore begun to correlate the specific gene mutation with the glaucoma management and outcomes for AR patients. A S82T missense mutation within the FKHL7 forkhead domain was found in the eight affected members of the "RM" family, a Q23X mutation of FKHL7 was found in the nine affected members of the "KA" family, and a R70H mutation of the PITX2 homeodomain was found in the six affected members of the "AD" family. Of these individuals, 5/8 (RM family), 1/9 (KA family), and 3/6 (AD family) developed increased intraocular pressure (IOP) and/or suffered glaucomatous field defects. These very preliminary data are consistent with the previous indication that about 50% of patients with AR malformations develop glaucoma. Importantly, this suggests that patients with mutations in either PITX2 or FKHL7 have a similar propensity to develop glaucoma. However, the increased IOP/glaucoma found in the RM family with the FKHL7 mutation responded well to medical treatment while that in the AD family with the PITX2 mutation was more difficult to treat, with one patient not responding to either medical or surgical treatments. Similar analyses of an expanded AR patient panel are currently underway. Comparisons of the treatment outcomes with the underlying genetic defect in additional AR patients could allow derivation of improved glaucoma treatment courses for AR patients.

Program Nr: 2833 from the 1999 ASHG Annual Meeting

Mutations in the human androgen receptor ligand-binding domain that impair function of the coactivator TIF2, are associated with defective spermatogenesis. *Q. Wang, E.L. Yong.* Obstetrics & Gynecology, National University of Singapore, Singapore.

The effects of androgen are mediated through the androgen receptor (AR), an X-linked member of the steroid/nuclear receptor family of nuclear transcription factors. The action of AR is tripartite, involving the AR, androgens and coactivators such as transcriptional intermediary factor 2 (TIF2). Androgens when bound to the ligand-binding domain (LBD) activate the AR, and TIF2 is necessary for full transcriptional activity. The AR LBD, based on the crystal structures of related steroid receptors, is likely to conform to a canonical fold consisting principally of 12 a-helices (H) in a three-layer sandwich. Mutations of the AR LBD commonly abrogate ligand-binding resulting in complete androgen-insensitivity (AIS), but amino-acid substitutions in the AR LBD have also been identified in patients who present solely with defective spermatogenesis. In our study, several mutations in the AR LBD were found in 5 unrelated patients with impaired spermatogenesis and infertility. They were located in three hot spots in the predicted interhelical regions between H3/H4, H11/H12 and in H7. Unexpectedly, these mutants (N727K, Q798E, M886V) although located in the AR LBD did not affect androgen binding, but yet reduced AR transactivation function by about 30-50% when measured with reporter genes coupled to synthetic, viral (MMTV) or human (PSA) androgen response elements. The transactivation defect of mutant ARs correlated with defective TIF2 function in cotransfection assays. Binding of chimeric mutant AR LBD fragments to the coactivator, TIF2, in the mammalian two-hybrid and GST-pull down assays, were reduced by about 50% compared to the wild type. Thus our LBD mutations reduce AR transactivation function through defective interactions with TIF2. Two AR mutations are located in the predicted interhelical regions H3/H4 (N727K) and H11/ H12 (M886V) which correspond to subdomains in other steroid receptors known to interact with coactivators, and may define a new disease paradigm in which defective coactivator function causes male infertility and defective spermatogenesis.

Program Nr: 2834 from the 1999 ASHG Annual Meeting

How do missense mutations cause disease phenotypes? A paradigm for mechanism - and for modulation. *P.J. Waters[1], M.A. Parniak[2], B.R. Akerman[1], C.R. Scriver[1].* 1) De Belle Laboratory, McGill University-Montreal Children's Hospital Research Inst., Montreal, PQ, Canada; 2) Lady Davis Institute, Montreal, PQ, Canada.

Missense mutations account for 48% of all disease-causing alleles (HGMDdb). Since very few are predicted to ablate directly an enzyme's catalytic site, how do most affect activity and cause disease? As an example we have analysed four missense mutations in the phenylalanine hydroxylase gene (*PAH*), each associated with disease (PKU) and each changing an amino acid distant from the active site.

Mechanism of effect: On expression in transfected human embryonal kidney cells, all four mutations caused reduced PAH enzyme activity in cell lysates (F39L 47%; K42I 30%; L48S 9%; I65T 18%). Immunoreactive PAH protein was similarly decreased; suggesting that these mutations act solely by reducing protein biostability. Study in two further expression systems (*E. coli* and *in vitro* transcription-translation) confirmed that these mutations did not affect specific catalytic activity, or kinetic properties, of the isolated PAH enzyme. Rather, they all caused altered folding/assembly of the enzyme and accelerated cellular proteolytic degradation of the resulting aberrant protein, explaining the reduced protein levels seen in the human cell system. These findings join other new work (Bross et al., Hum. Mutat., in press) to implicate such a mechanism as an emerging paradigm; whereby missense mutations in various genes cause disease phenotypes.

Modulation of severity: Subtle changes in our conditions for transfection and expression in human cells affected general growth and metabolic state of the cells; while the rank order of observed severity of the four mutations was unchanged, levels of PAH activity and protein (as % wild-type) were altered 2- to 3-fold by such manipulations. Thus altered cellular handling of mutant proteins, likely involving protease and chaperone systems, can significantly modulate phenotype in cultured cell systems. This points to similar modulation *in vivo* directly causing variability in phenotype for "single-gene diseases" between individuals with different background genotypes and environmental experience.

Program Nr: 2835 from the 1999 ASHG Annual Meeting

Mutation analysis of two candidate genes within the hereditary neuralgic amyotrophy locus on chromosome 17q25. *G.D.J. Watts[1], M.P. Keller[1], T.P Iismaa[2], P.F Chance[1]*. 1) Univ Washington, Seattle, WA 98195; 2) The Garvan Institute of Medical Research, St. Vincents Hospital, 384 Victoria Street, Sydney NSW 2010.

Hereditary neuralgic amyotrophy (HNA) is an autosomal dominant disorder characterized by episodes of brachial plexus neuropathy. Frequently associated with HNA are dysmorphic features, including hypotelorism, long nasal bridge and facial asymmetries. Linkage analysis has defined the HNA locus to lay between the markers D17S1603 and D17S802, corresponding to approximately 4.0cM. In this study we have screened two candidate genes, the human GALR2 galanin receptor and survivin gene both mapping to the HNA region, for mutations in affected individuals. The hGALR2 gene is a receptor sub-type for the neuropeptide galanin. The hGALR2 gene contains two exons, and encodes 387 amino acids. Survivin is encoded for by 142 amino acids and belongs to the inhibitor of apoptosis protein (IAP) family. These proteins suppress apoptotic cell death and are highly conserved between species. Sequence analysis of the hGALR2 exons showed no mutations in 5 unrelated probands. Sequence data from LCL cDNA for the survivin gene identified a polymorphism (A®C) at codon 129 in two non-related, affected and non-affected, individuals. This change leads to the Lys being changed to Gln, but is unlikely to be the mutation associated with HNA, since the mutation is present in a non-affected individual.

Program Nr: 2836 from the 1999 ASHG Annual Meeting

Haploinsufficiency for COL5A1 expression is a common molecular mechanism underlying the classical form of the Ehlers-Danlos Syndrome (EDS). *R.J. Wenstrup[1], J.B. Florer[1], F. Young[2], W.G. Cole[2]*. 1) Human Genetics, Pavillion Bldg, Children's Hosp Research Fndn, Cincinnati, OH; 2) The Research Institute, The Hospital for Sick Children, Toronto, Ontario, Canada.

The classical form of EDS (formerly types I and II) is characterized by fragile, hyperextensible skin, widened dermal scars, ligamentous laxity and autosomal dominant inheritance. Linkage of classical EDS to COL5A1 has been reported in several pedigrees; it has been estimated that as many as two-thirds of classical EDS pedigrees have causative mutations in COL5A1 or COL5A2, the genes encoding the proa1(V) and proa2(V) chains of type V collagen respectively. However, published series based on RT-PCR/SSCP screening methods have reported a comparatively low yield of mutations (10-15% of EDS cell strains). Because RT-PCR/SSCP does not detect mutations that diminish COL5A1 gene expression, we screened 53 probands with classical EDS for COL5A1 haploinsufficiency by detection of two genomic restriction length polymorphisms (RFLPs) in cDNA prepared from cultured dermal fibroblasts. For each cell strain, a 660 bp segment of genomic DNA or cDNA from the 3'UTR of COL5A1 was amplified by PCR and digested with BstU1 and DpnI. Thirty-two of 52 (61%) probands were heterozygous for one or both RFLPs; cDNA was available from 27 for RFLP analysis. Eight of 27 (30%) had only one COL5A1 allele represented in cDNA. Ribonuclease protection experiments indicated that all eight cell strains with apparent expression of only one COL5A1 allele had a reduced ratio of proa1(V):proa2(V) mRNAs compared to 12 control cell strains or to 15 EDS cell strains in which haploinsufficiency was excluded by RFLP analysis. Therefore mutations resulting in haploinsufficiency for proa1(V) chains were present in 30 percent of individual with classical EDS, which are detectable by analysis of expressed RFLPs in COL5A1 and quantitation of proa1(V):proa2(V) mRNA ratios by ribonuclease protection. These data also indicate that unmineralized connective tissues are highly sensitive to quantitative reduction of type V collagen expression.

Program Nr: 2837 from the 1999 ASHG Annual Meeting

A family with PROMM unlinked to the DM2 locus on chromosome 3q22. *T. Wieser[1], D. Boensch[2], K. Eger[1], W. Schulte-Mattler[1], S. Zierz[1]*. 1) Neurologische Klinik, Universität Halle, Halle/S, Germany; 2) Klinik für Neurologie, Universität Jena, Jena, Germany.

Proximal myotonic myopathy (PROMM) is a newly described, autosomal dominantly inherited multisystem disorder similar to myotonic dystrophy. PROMM is characterised by weakness of the legs, myotonia, cataracts, and slight elevation of liver enzymes. Since PROMM patients do not harbour the trinucleotide expansion on chromosome 19 causing Myotonic dystrophy (DM), PROMM is a genetically distinct disease. A recently mapped second locus for myotonic dystrophy (DM2) was thought to be an attractive candidate locus for PROMM, and this hypothesis was supported by reports of linkage to this locus in some PROMM families. We present a German pedigree with PROMM, large enough to formally show or exclude linkage to this locus. Nine markers were used spanning the 8 centimorgan interval comprising the DM2 locus. Lod scores below -2 excluded linkage to this locus. The genetics of the multisystemic myotonic dystrophies besides classical DM seem to be complex. Exclusion of the DM2 locus in our family is further evidence of genetic heterogeneity of PROMM and stresses the broad genetic variety in this small group of disorders, for which the acronym DOMMOPS (dominant myotonic myopathies) was recently introduced. The situation seems comparable to the situation in the dominant ataxias where the broad clinical spectrum underlies an even broader genetic variety.

Program Nr: 2838 from the 1999 ASHG Annual Meeting

Achondroplasia/hypochondroplasia intermediate phenotypes are also associated with the N540K substitution in the FGFR3 gene. *W.R. Wilcox[1], V. Fano[2], L. Chertkoff[2], G. Bonaventure[2], C. Barreiro[2], H. Kitoh[3], D. Kim[4], M. Eswara[5], S. Shelley[5], A. Grix[4], R.S. Lachman[1], H. Lejarraga[2].* 1) Div. Medical Genetics, Cedars-Sinai Med. Cntr., Los Angeles, CA, USA; 2) Depts. of Growth and Development and Genetics, Hosp. de Pediatria J.P. Garrahan, Buenos Aires, ARGENTINA; 3) Dept. Genet., Inst. Dev. Res., Aichi Prefect. Colony, JAPAN; 4) Kaiser-Permanente Hosp., Honolulu, HI and Sacramento, CA, USA; 5) Lucille Packard Childrens Hosp., Palo Alto, CA, USA.

Achondroplasia (ACH) is the most common form of short-limbed dwarfism in humans. In 99% of the cases, the disorder results from the same single amino acid substitution (G380R) in the transmembrane domain of the fibroblast growth factor receptor 3 (FGFR3) gene. Hypochondroplasia (HCH) is a condition similar to but milder than ACH, generally presenting after the second year of life. Approximately 2/3 of HCH patients are heterozygous for a N540K substitution in the intracellular domain of FGFR3 while some families are unlinked to FGFR3. We report 6 patients presenting between 22 weeks of gestation and 1 year of life with short-limbed dwarfism. The clinical and radiographic features range from typical ACH to a phenotype between ACH and HCH. Their growth has been between the 50^{th} and 95^{th} centile for ACH, and their head circumference between the 25^{th} and 50^{th} centile for ACH. An heterozygous N540K substitution in FGFR3 was identified in each case. We conclude that the spectrum of phenotypes for the G380R and N540K substitutions overlap, but the N540K substitution may imply a better prognosis.

Program Nr: 2839 from the 1999 ASHG Annual Meeting

Mutations in Ribosomal Protein S19 gene account for Diamond Blackfan anemia phenotype in 58 out of 216 affected families. *T.N Willig[1], N. Draptchinskaia[2], I. Dianzani[3], S. Ball[4], C. Niemeyer[5], U. Ramenghi[3], K. Orfali[4], P. Gustavsson[2], E. Garelli[3], A. Brusco[3], C. Tiemann[5], N. Dahl[2], N. Mohandas[1], G. Tchernia[1]*. 1) Lawrence Berkeley Laboratory, Berkeley, CA; 2) Unit of Clin. Genet., Dept. of Genet. and Pathol., Uppsala Univ. Child. Hosp., Uppsala, Sweden; 3) Dept of Ped. and Genet., Univ. of Torino, Torino, Italy; 4) DBA Study group, Div. of Haematol., Dept. of Cellular and Molecular Sci., St George's Hosp. Med. School, London, UK; 5) Universität-Kinderklinik, Freiburg, Germany.

Diamond Blackfan anemia (DBA) (OMIM: 205900) has recently been shown to be the first human disease caused by mutations in a gene encoding for a ribosomal protein (RPS19). In order to determine the prevalence of mutations in this gene in DBA, and to describe the molecular basis for the variable clinical phenotype, the genomic sequence of the six exons and the 5untranslated region of the RPS19 gene was directly assessed in DBA index cases from 216 families. Mutations affecting the coding sequence of RPS19 or splice sites were found in 48 cases (22.2 %), while mutations in non-coding regions were found in 10 patients (4.6%). Mutations included nonsense, missense, splice sites defects and frameshift mutations, as well as complete loss of a normal allele and disruption of the gene by chromosomal translocations. A hot spot for missense mutations was identified between codons 52 and 62 of the RPS19 gene, in a new sequence consensus motif W-[YFW]-[YF]-x-R-[AT]-A-[SA]-x-[AL]-R-[HRK]-[ILV]-Y, derived from the alignment of RPS19 amino-acid sequence of 22 species. No correlation between the nature of mutations and the different patterns of clinical expression, including age at presentation, presence of malformations and therapeutic outcome could be documented. Moreover, RPS19 mutations were also found in some first-degree relatives presenting only with isolated macrocytosis and/or high erythrocyte adenosine deaminase activity, but without documented erythroblastopenia. Our findings suggest that other genetic factors may modulate the expression of this gene to account for the variable phenotypic expression, and that haploinsufficiency is likely to play a key role in the pathophysiology of DBA.

Program Nr: 2840 from the 1999 ASHG Annual Meeting

CNGA3 mutations in cone photoreceptor disorders. *B. Wissinger[1], D. Gamer[1], H. Jaegle[1], S. Mayer[1], S. Andreasson[2], T. Rosenberg[2], B. Jurklies[3], E.C. Sener[4], S. Tatlipinar[4], N. Akarsu[4], D.B. Hanna[5], S.G. Jacobson[5], G. Rudolph[3], U. Kellner[3], E. Apfelstedt-Sylla[1], L.T. Sharpe[1], S. Kohl[1]*. 1) University Eye Hospital, Tuebingen, Germany; 2) University Eye Hospital, Lund, Sweden, National Eye Clinic, Kopenhagen, Denmark; 3) University Eye Hospitals Essen, Muenchen and Berlin, Germany; 4) Hacettepe University, Ankara, Turkey; 5) Scheie Eye Institute, Philadelphia, USA.

We have recently shown that mutations in the CNGA3 gene, encoding the cone cGMP gated channel cause rod monochromacy (RM), an autosomal recessive disorder characterized by the absence of color discrimination, photophobia and low visual acuity (Kohl et al., Nature Genet.19: 257-259). Here we present the results of a screening for CNGA3 mutations in patients with RM and other types of cone photoreceptor dystrophies, which enables us to establish a first comprehensive mutation spectrum of the CNGA3 gene. In total 27 missense mutations, 4 nonsense (stop and frameshift) mutations and 1 in-frame deletion, all of them excluded from 100 controls (= 200 chromosomes), were identified. Both mutant alleles could be identified in 28 families (= 56 mutant chromosomes) including 8 cases harbouring homozygous mutations and 20 cases showing compound heterozygosity. In 6 cases only a single heterozygous mutation could be found. 10 of the mutations were observed recurrently in different families. Recurrent mutations mostly share common haplotypes and one of them, Arg283Trp, has been exclusively found in Northern Europe. Mutations were only found in three of the seven coding exons of the CNGA3 gene and cluster in the S4 domain (5 mutations), the cGMP binding domain (9 mutations) and its preceeding linker region (8 mutations). At least in 5 patients with CNGA3 mutations residual cone photoreceptor function associated with better visual function and clear color discrimination abilities was found, indicating that mutations in the CNGA3 gene do not necessarily cause RM.
Supported by the DFG.

Program Nr: 2841 from the 1999 ASHG Annual Meeting

Placental tissue supporting females with X-linked incontinentia pigmenti does not show skewed X-inactivation.

H. Woffendin[1], T. Jakins[1], H. Stewart[2], D. Donnai[2], P. Lunt[3], M. Hamilton Ayres[4], S. Kenwrick[1]. 1) Cambridge Institute for Medical Research,Addenbrooke's Hospital, Cambridge, UK; 2) Regional Genetics Service, St Mary's Hospital, Manchester, UK; 3) Clinical Genetics Service, Bristol Children's Hospital, Bristol, UK; 4) Pediatrics, Teweksbury Hospital, Teweksbury, UK.

Familial incontinentia pigmenti (IP) is an X-linked dominant genodermatosis characterised by male lethality and abnormalities of the skin, hair, teeth, eyes nails and central nervous sytem in affected females. The disorder has been genetically linked to Xq28, a region containing many candidate genes. Examination of candidates is hampered by the fact that affected females exhibit severely skewed X-inactivation of blood and skin cells with early elimination of cells expressing the mutated X. In order to identify a tissue expressing the IP chromosome we have examined X-inactivation patterns in matched samples of cord blood and placenta from 2 affected IP cases using the human androgen receptor gene assay (HUMARA). Both cases were born of an affected mother with skewed X-inactivation and both went on to develop typical IP signs as neonates. Term placental tissue from both subjects showed random X-inactivation whereas cord blood exhibited partial (case 1) or complete (case 2) skewing. Thus, selection against peripheral blood cells in IP occurs at or before term and even cord blood is not a suitable source of RNA for gene analysis. That both X chromosomes were active in placental tissue was confirmed by RT-PCR analysis of X-linked, expressed polymorphisms. These results indicate either that the IP gene is not expressed in placenta or that the IP mutation is not detrimental in this context. Thus we have identified a tissue, placenta, that can be used for screening of candidate genes through direct sequencing of cDNA. We have already used this approach to examine the gene for MTCP-1, an Xq28 locus involved in the control of cell proliferation.

Program Nr: 2842 from the 1999 ASHG Annual Meeting

Differential toxic effects of transition metal ions in Friedreich's ataxia cells. *A. Wong[1], S. Danielson[1], J. Yang[1], F. Taroni[2,3], G. Cortopassi[1]*. 1) VM Molecular Biosciences, UC Davis, Davis, CA; 2) Laboratory of Cellular Pathology, Istituto Nazionale Neurologico "Carlo Besta", Milan, Italy; 3) Biochemistry and Genetics, Istituto Nazionale Neurologico "Carlo Besta", Milan, Italy.

Friedreich's ataxia (FRDA) is an autosomal recessive, neurodegenerative disease characterized by progressive gait and limb ataxia and cardiomyopathy. Expansions of an intronic GAA repeat inhibits transcription of a mitochondrial protein, frataxin. In studies using yeast lacking the frataxin homolog, there is an increase in mitochondrial iron concentration, respiration deficiency, and sensitivity to oxidative stress. These data support the hypothesis that FRDA is a disease of mitochondrial oxidative stress. We have now compared the sensitivity of FRDA and control lymphoblast cell lines to transition metal ions. Both control and FRDA cells exhibited equal sensitivity to ferrous ion, given as FeSO4. However, FRDA cells were more sensitive to ferric ion given as FeCl3 than control cells. Additionally, FRDA cells were more sensitive to Mn2+ compared to control cells. Neither FRDA nor control cells were sensitive to Co2+ (given as CoCl2) and Zn2+ (given as ZnCl2) up to 10 mM. FRDA and controls cells were equally sensitive to Cu2+. In summary we have observed that FRDA lymphoblasts are differentially sensitive to some forms of iron and to manganese, but not to other metal ions. This differential sensitivity may relate to the pathophysiological mechanism of FRDA.

Program Nr: 2843 from the 1999 ASHG Annual Meeting

Autosomal dominant cerebellar ataxia type III: no evidence for a large pathological CAG repeat expansion in the SCA 11 gene. *P.F. Worth[1], E. Dunne[2], A.H. Nemeth[2], N.W. Wood[1]*. 1) Department of Clinical Neurology, Institute of Neurology, Queen Square, London, WC1N 3BG, UK; 2) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, OX3 7BN, UK.

Autosomal dominant cerebellar ataxia type III is a relatively pure cerebellar syndrome, with no other major neurological signs. Moderate expansions in the CAG trinucleotide repeat sequence of the SCA 6 gene have been shown to account for around 50% of ADCA III families in our series. Two other loci, SCA 5 and SCA 10, have been identified by linkage analysis of separate ADCA III families. We recently reported linkage of the disease phenotype in a large British family with ADCA III to a fourth locus on chromosome 15q14-21.3 (SCA11). In common with SCA 6 expansion-positive families, this family displays a relatively benign, slowly progressive phenotype, and anticipation has not been observed. In order to investigate the possibility that a pathological expanded CAG trinucleotide repeat is the cause of the disease in this family, we performed the repeat expansion detection method (RED) using a CTG(10) oligonucleotide, on DNA samples from individuals in this family. The largest RED product obtained was 150bp (equivalent to 50 CAG repeats), but this was obtained in all of 10 affected and 7 unaffected members. It has previously been shown that polymorphic sequences on chromosomes 17 and 18 may contain large, presumably non-pathological, CAG repeats in normal individuals. These repeats may therefore confound RED analysis. Using PCR with specific primers to amplify these sequences, we have shown that these loci are not responsible for the 150bp RED products in this family. However, a pathological CAG repeat expansion of 50 or less CAG repeats, analagous to that of SCA 6, remains possible as the mutational mechanism in the SCA 11 gene in this family.

Program Nr: 2844 from the 1999 ASHG Annual Meeting

Connexin 26 (GJB2) gene mutation analysis for hereditary non-syndromic sensorineural deafness. *B.L. Wu[1], V. Lip[1], D. Wattana[1], G.F. Cox[1], M. Kenna[2], B.R. Korf[1]*. 1) Div Genetics; 2) Div ORL, Children's Hospital and Harvard Medical School, Boston, MA.

We describe a simple and sensitive DNA test to detect all mutations in the coding region of the connexin 26 gene, which can be used cost-effectively in clinical-based molecular diagnosis. This three-step sequencing-based assay involves: 1) single tube PCR amplification of the entire coding sequence of the gene from genomic DNA; 2) direct sequencing of the PCR product using two sets of overlapping primers, which will identify most mutations; and 3) direct sequencing of a nested PCR product to identify compound heterozygosity for two different deletions, which otherwise may be difficult to detect. Using this approach, we have unambiguously identified compound heterozygosity for 35delG/167delT in three unrelated deaf individuals. Because 35delG is the most common connexin 26 mutation in the general population and 167delT is the most common in the Ashkenazi Jewish population, compound heterozygosity for these mutations is expected to occur relatively frequently. We have found four new mutations, N206S, E114G , R127H and T26T, in individuals with hearing loss and have detected 14 known mutations present in homozygous, heterozygous, and compound heterozygous states in 18 of 52 unrelated families, including prenatal testing.

Program Nr: 2845 from the 1999 ASHG Annual Meeting

Mutation screening of candidate genes in Rett syndrome. *F. Xiang[1,2], S. Buervenich[1,3], P. Nicolao[4], M.E.S. Bailey[5], L. Edstrom[2], M. Anvret[1,2], Z. Zhang[1,2].* 1) Department of Molecular Medicine, Karolinska Hospital, Stockholm, Sweden; 2) Department of Clinical Neuroscience, Karolinska Institute/Hospital, Stockholm, Sweden; 3) Department of Neuroscience, Karolinska Institute, Stockholm, Sweden; 4) Department of Neurology and Psychiatry (second Neurological Clinic), University of Padova, Italy; 5) Division of Molecular Genetics, Institute of Biomedical and Life Science, University of Glasgow, Glasgow, U.K.

Rett syndrome (RTT) is a neurodevelopmental disorder which appears to affect females only. Its biological and genetic foundations remain unclear. The small numbers of familial cases and available pedigrees have hindered the use of linkage analysis. In this study, we have evaluated six candidate genes for Rett syndrome selected on clinical, pathological and genetic grounds:*UBE1* (Human ubiquitin-activating enzyme E1), *UBE2I* (ubiquitin conjugating enzyme E2I, homologous to yeast UBC9), *GdX* (ubiquitin-like protein), *SOX3* (SRY-related HMG-box gene 3), *GABRA3* (g-aminobutyric acid type A receptor a3 subunit) and *CDR2* (cerebellar degeneration-related autoantigen 2). No mutations were detected in the coding regions of these six genes from ten affected individuals and, therefore, alterations in the amino acid sequences of the encoded proteins can be excluded as having a causative role in Rett syndrome. Furthermore, we investigated the expression of three Rett candidate genes in Xq28 (*GdX, GABRA3* and *L1CAM* [L1 cell adhesion molecule]) by *in situ* hybridization. No gross differences in the mRNA levels of these three genes were observed in neurons of the frontal cortex between normal controls and Rett patients.

Program Nr: 2846 from the 1999 ASHG Annual Meeting

Emerin mutations in Emery-Ddreifuss muscular dystrophy in Israeli families. *Y. Yaron[1], Y. Nevo[2], S. Ahituv[1], C. Legum[1], H. Reznik-Wolf[1], S. Harel[2], R. Shomrat[1], A. Orr-Urtreger[1].* 1) Genetic Inst, Sourasky Medical Ctr, Tel Aviv, Israel; 2) Institute for Child Development and Pediatric Neurology Unit, Dana Children's hospital, Tel Aviv Sourasky Medical Center,Tel Aviv, Israel.

Emery-Dreifuss Muscular Dystrophy (EDMD) is an X linked recessive disorder characterized by progressive muscle wasting , debilitating contractures, and might be life threatening due to cardiomyopathy with arrythmias and atrial paralysis. During the past three years four Israeli families of both Jewish Ashkenazi and non-Ashkenazi origin (10 patients) were referred to our genetic institute with the clinical diagnosis of EDMD for molecular analysis, genetic counseling and pre-natal diagnosis. Direct sequencing analysis was performed in order to detect mutations in the emerin gene which is located on Xq28. Four different mutations were detected: two in exon 2 (333delT and 412 insA) and one in exon 6 (1675-1678delTCCG) that was previously described. All three mutations result in a frame-shift and a stop codon after 30, 4 and 39 amino acids respectively. The fourth mutation was detected in exon-intron 5 splice junction (IVS5+1G>A), causing a splice site mutation. The three novel mutations that were detected reinforce the concept of preponderance of unique mutations in EDMD. Based on our sample and published data, it seems that exon 2 tend to be mutation prone. Two families underwent prenatal diagnosis in four different pregnancies. In two cases, the families chose to terminate the pregnancy of an affected fetus. Direct sequencing is the method of choice for new mutation detection in EDMD and for carrier detection and prenatal diagnosis.

Program Nr: 2847 from the 1999 ASHG Annual Meeting

Generation and analysis of myocilin transgenic mice. *L. Ying[1], J.H. Fingert[3], E.M. Stone[3], V.C. Sheffield[1, 2]*. 1) Howard Hughes Medical Institute, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics, Univ Iowa, Iowa City, IA; 3) Dept Ophthalmology, Univ Iowa, Iowa City, IA.

We have previously determined that mutations in the gene coding for myocilin (MYOC) cause the vast majority of cases of autosomal dominant juvenile-onset primary open angle glaucoma (JOAG), as well as some cases of adult-onset primary open angle glaucoma (POAG) (1). MYOC is expressed in many ocular and non-ocular tissues. The GLN368STOP mutation of MYOC produces a late-onset form of POAG and is the most common known mutation. In order to better understand the pathophysiology of POAG, we developed MYOC transgenic mice containing either the normal human or GLN368STOP variant in an attempt to develop an animal model for primary open angle glaucoma. The normal human MYOC and mutant variant sequences were ligated into the BamHI site of a vector which contains the beta-actin promoter, intron I sequence and a poly-A site. All constructs were sequenced to demonstrate proper orientation and the presence of the desired sequence (normal and mutant). Plasmid DNA was linearized and used to produce transgenic mice on a C57BL/6 x SJL F2 background by DNA microinjection of fertilized embryos. Potential transgenic mice were screened by PCR and southern blot using genomic DNA isolated from tail clippings. A number of founders were identified for both the normal and GLN368STOP mutation. Expression analysis of F1 mice shows that MYOC mRNA is expressed in eyes, brain, heart, kidney, lung, liver, spleen and skeleton muscle. The mRNA transcribed from the GLN368STOP transgene is the same size as the message produced by the normal MYOC gene. Protein analysis using antibodies specific to MYOC and histological evaluation of mature mice are in progress. The expression studies suggest that these transgenic mice will be suitable for further investigation of the role of MYOC in elevating ocular pressure and optic nerve damage.

Stone, E.M. et al (1997) Science 275:668-670.

Program Nr: 2848 from the 1999 ASHG Annual Meeting

Sarcoglycan-sarcospan complex interacts with syntrophins/a**-dystrobrevin as well as the dystroglycan complex.**

M. Yoshida[1], H. Hama[1], M. Sakurai[1], M. Imamura[1], Y. Mizuno[1], K. Araishi[1], T. Sasaoka[1], E. Wakabayashi[1], S. Noguchi[1,2], E. Ozawa[1]. 1) Dept Cell Biol, Natl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan; 2) PRESTO, JST, Saitama, Japan.

The sarcoglycan (SG) complex composed of four dystrophin-associated proteins (DAPs) termed a- to d-SGs is a subcomplex of dystrophin-DAP complex present on sarcolemma. The SG complex is known to be essential for skeletal muscle survival, since a loss or a remarkable reduction of the SG complex due to a mutation of any one of the SG genes causes a group of diseases termed sarcoglycanopathy, which is a Duchenne-like muscular dystrophy inherited with an autosomal recessive mode. Nevertheless, the higher order structures surrounding SG complex in dystrophin-DAP complex, which are the basis for understanding the function of SG complex, had been ill-defined. In order to understand these structures, we explored the methods to prepare the SG complex holding interactions with remainders of dystrophin-DAP complex and discovered the methods by which three kinds of DAP complexes containing the SG complex are prepared. The complexes are 1) the SG-sarcospan (SPN) complex, 2) the SG-SPN-syntrophins/a-dystrobrevin complex and 3) the SG-SPN-dystroglycan complex. Based on these results, we conclude that the SG complex is associated with SPN and that this SG-SPN complex interacts with both syntrophins/a-dystrobrevin and the dystroglycan complex. Since the presence of SG complex is fundamental in these connections, its loss or great reduction would make serious effects on muscles, which causes sarcoglycanopathy.

Program Nr: 2849 from the 1999 ASHG Annual Meeting

Intrafamilial variability of myocardial hypertrophy and modifying factors in familial hypertrophic cardiomyopathy (FHC). *B. Yu[1,3], R.W. Jeremy[2,3], D.R. Richmond[2,3], R.J. Trent[1,3].* 1) Dept Molecular & Clinical Genetics, Royal Prince Alfred Hosp; 2) Dept Cardiology, Royal Prince Alfred Hosp; 3) Dept of Medicine, University of Sydney, Australia.

FHC is an autosomal dominant disease caused by >120 family-specific mutations in at least 7 genes coding for sarcomere proteins. Clinically it is characterised by left ventricular hypertrophy (LVH). To identify modifying factors, the severity of LVH was analysed in relationship to potential modifiers in 40 mutation carriers from two FHC pedigrees. In family W, eight individuals carried an Arg453Cys mutation in the cardiac b-myosin heavy chain gene. Complete penetrance was observed. The proband had mild LVH and died of heart failure aged 53. Her 9 year-old granddaughter had massive LVH and started to develop cardiac insufficiency aged 12. The proband's daughter with the same mutation was asymptomatic in her 30s with minimal LVH. In four generations of family S there is a Gln966X mutation in the cardiac myosin binding protein-C gene. Only 14 of 32 mutation carriers had cardiac hypertrophy. A range of potential modifying factors were explored. These included: age, gender and several candidate genes. Intrafamilial variations in family W could not be accounted by age, sex and environmental factors such as exercise. However, the severity of LVH in family S was significantly correlated with age ($r=0.76$, $p<0.001$). The expression of LVH in two families was not due to an over-representation of the D allele in the angiotensin-I converting enzyme gene. According to the affected pedigree member analysis, there was no significant association between the myotonin gene and those with clinically detectable LVH in both families. However, significant allele-sharing was detected between the androgen receptor gene and clinically affected mutation carriers in family S ($p=0.003$). This association was supported by multipoint linkage analysis using Genehunter (NPL scores>2.1, $p=0.021$). The association remained significant when the clinically affected individuals in family W were added. Our results indicate that although FHC is a monogenic disease, the development of LVH can be influenced by multiple factors.

Program Nr: 2850 from the 1999 ASHG Annual Meeting

Disruption of mouse kynurenine aminotransferase II gene, a possible factor in the pathophysiology of Huntington's disease. *P. Yu[1], A. Chen[1], R. Schwarcz[2], D. Tagle[1]*. 1) NIH/NHGRI, Bethesda, MD; 2) Maryland Psychiatric Research Center,University of Maryland School of Medicine, Baltimore.

Decreased levels of the endogenous neuroprotectant kynurenic acid (KYNA) have been observed in the brain of Huntington Disease (HD) patients and may contribute to neuronal loss in this disorder. This reduction may be caused by a dysfunction of kynurenine aminotransferase II (*Kat-2*), the major enzyme responsible for the synthesis of KYNA in the brain. Towards understanding the role of *mKat-2* in kynurenine pathway and HD, we disrupted *mKat-2* gene in the mouse. To date, we have obtained a total of 30 *mKat-2*$^{+/+}$, 62 *mKat-2*$^{+/-}$ and 36 *mKat-2*$^{-/-}$ F_2 mice from 6 founder lines with the gender and genotypes reflecting the expected Mendelian frequency. There are no detectable *mKat-2* protein and mRNA in the homozygous knock out mice by Western and Northern blot analysis. Homozygous *mKat-2*$^{-/-}$ mice were phenotypically indistinguishable from their littermates at birth. However, at 40 days of age a noticeable forelimb clasping posture can be elicited in less than a minute upon tail suspension of *mKat-2*$^{-/-}$ mice but not in littermate controls. By 50 days of age, nullizygous mice have progressed to display clasping responses involving all four limb upon tail suspension, similar to the earlier stage phenotype of HD mice model developed in our laboratory (Nature Genet 1998; 20:198-202). The pathological evaluation of brain sections from *mKat-2*$^{-/-}$ mice including hematoxylin and eosin (H & E) stain, glial fibrillary acidic protein (GFAP), and Nissl are currently underway. KYNA-deficient mice would be useful in determining the link between kynurenine pathway metabolism and HD pathogenesis. In addition it may provide relevant information regarding the role of kynurenines in excitatory amino acid (EAA)-related physiology and pathology.

Program Nr: 2851 from the 1999 ASHG Annual Meeting

Haplotype analysis of b-**thalassaemia mutations in Lebanon.** *L.F. Zahed[1], M. Qatanani[1], M. Nabulsi[2].* 1) Dept of Pathology and Laboratory Medicine, American Univ Beirut,Beirut, Lebanon; 2) Dept of Pediatrics, American University of Beirut, Beirut, Lebanon.

Studies on the molecular basis of b-thalassaemia in Lebanon have revealed the presence of 18 different mutations, reflecting the heterogeneity of the lebanese population, which is known to be a mosaic of individuals of different religious and ethnic origins. We have proceeded to study the haplotypes linked to these mutations, by analyzing seven restriction sites in the b-globin gene cluster. A total of 108 chromosomes were analyzed for the following sites: HindIIe, HindIIIGg, HindIIIAg, HindII5'yb, HindII3'yb, AvaIIb and HinfIb. Twelve different haplotypes were identified. While the linkage of many mutations to particular haplotypes was as previously reported for Mediterranean populations, some unusual linkages were observed, such as the linkage of an African haplotype to IVSI-110, the most frequent mutation in the Eastern Mediterranean. This linkage was exclusively found among individuals from a particular community. Many mutations were also found to be linked to different haplotypes: these include both common and rare mutations. Haplotype analysis in conjunction with b-thalassaemia mutations will allow us to retrace the origin of the different groups making up our population.

Program Nr: 2852 from the 1999 ASHG Annual Meeting

Evidence for genetic heterogeneity in Leydig cell hypoplasia. *J.C. Zenteno[1], P. Canto[2], S. Kofman-Alfaro[1], J.P. Mendez[2]*. 1) Genetics, Hospital General Mexico UNAM, Mexico City, Mexico; 2) Research Unit in Developmental Biology, CMN SXXI, IMSS, Mexico City, Mexico.

Leydig cell aplasia or hypoplasia is a rare form of male pseudohermaphroditism resulting from inadequate fetal testicular Leydig cell differentiation. Affected individuals presented a wide phenotypic spectrum ranging from complete female external genitalia to males with micropenis. Recessive mutations in the LH receptor gene have been identified as responsible of the condition. The majority are point mutations and have been located in exon 11 of the gene. We report the molecular characterization of the LH receptor gene in a familial case of Leydig cell hypoplasia where the presence of an already described polymorphism in exon 11 excludes that a mutation in this gene is responsible of the disorder in this particular family. A non-consanguineous Mexican family with 3 affected individuals was studied. The patients presented a female phenotype,primary amenorrhea, absence of secondary sexual characteristics, intraabdominal testes and an 46,XY karyotype. Testicular histology revealed seminiferous tubules lined by Sertoli cells and absence of mature interstitial Leydig cells. Genomic DNA was obtained from peripheral blood leukocytes of the three patients, their father and a healthy sister. PCR amplification and direct automated sequencing of the LH receptor gene were performed in all subjects. After sequencing the 11 exons of the gene, no deleterious mutations were detected in any patient. However, we identified a previously described silent polymorphism in exon 11: in patients 1 and 3 DNA sequencing revealed a C to T substitution at nucleotide 1065, being both patients homozygous GAT/GAT at codon 355. In contrast, patient 2 was homozygous GAC/GAC at this polymorphic site. These results exclude that Leydig cell hypoplasia in this family is due to a mutation in the LH receptor gene and provide evidence that defects in other loci may also result in failure of Leydig cell differentiation demonstrating for the first time, that Leydig cell hypoplasia is a genetically heterogeneous condition.

Program Nr: 2853 from the 1999 ASHG Annual Meeting

Functional Consequences of Chloride Channel Gene (*CLCN1*) Mutations Causing Myotonia Congenita. *J. Zhang[1,2], S. Bendahhou[4], L.J. Ptacek[1,2,3,4].* 1) Neuroscience Program, Univ Utah, Salt Lake City, UT; 2) Department of Neurology, Univ Utah, Salt Lake City, UT; 3) Department of Human Genetics, Univ Utah, Salt Lake City, UT; 4) Howard Hughes Medical Institute, Univ Utah, Salt Lake City, UT.

Myotonia congenita (MC) is a genetic muscle disease with two inherited forms: autosomal dominant (Thomsen's disease) and autosomal recessive (Becker's diseases). MC is associated with membrane hyperexcitability due to abnormalities in the skeletal muscle voltage-gated chloride channels (ClC-1). In skeletal muscle, ClC-1 channels contribute 80% of total resting transmembrane conductance and determine the membrane excitability. Mutations have been identified in ClC-1 gene (*CLCN1*) of MC patients. In order to understand the molecular basis of this inherited disease, and to prove the mutations are disease associated defects, it is important to determine the physiological consequences of uncharacterized mutations found in MC patients. We used a mammalian cell (HEK-293) expression system and whole-cell voltage clamp technique to functionally express and physiologically characterize five *CLCN1* mutations. Both I329T and R338Q mutant channels shifted the voltage dependence of open probability of ClC-1 channels to more positive potentials. In addition, the I329T mutant channels deactivated to a lesser extent than normal at negative potentials. V165G, F167L, and F413C mutant channels also shifted the voltage dependence of open probability, but only by +14 to +20 mV. The functional defects caused by these mutations could result in the reduced macroscopic chloride conductance in muscle membrane, which could impair the ability of the ClC-1 channels to maintain normal muscle excitability and cause myotonia congenita.

Program Nr: 2854 from the 1999 ASHG Annual Meeting

New Mutations in RPGR and RP2 and a New Locus for X-linked Retinitis Pigmentosa. *I. Zito[1], D.L. Thiselton[1], M. Gorin[2], A.C. Bird[1], S.S. Bhattacharya[1], A.J. Hardcastle[1].* 1) Depts. of Molecular Genetics and Clinical Ophthalmology, Institute of Ophthalmology, London, UK; 2) Dept. of Ophthalmology, School of Medicine, University of Pittsburgh, USA.

Purpose. To establish the spectrum of mutations in the RPGR and RP2 genes causing X-linked retinitis pigmentosa (XLRP), and define the number of distinct loci on the X-chromosome involved in retinal disease. **Methods.** A comprehensive screen for RPGR mutations was undertaken for all 19 exons by SSCP analysis, and RP2 mutations were detected by sequencing all 5 exons of this gene. Segregation of mutations with disease was demonstrated by SSCP analysis, sequencing or agarose gel electrophoresis. Haplotype analysis was performed with over 34 polymorphic markers spanning the entire X-chromosome. **Results.** A subset of 30 XLRP families, where disease segregates with the RP3 locus, were selected for RPGR mutation screening. 6 novel mutations in RPGR have been identified and this analysis includes the first reported mutations in exon 1. RPGR mutations therefore account for 20% of disease in families with an RP3 genotype. We also identified 8 families, from a total of 61, with mutations in the RP2 gene accounting for approximately 13% of familial XLRP. We have extensively haplotyped many XLRP families and here we report a new locus for XLRP (RP23) in a single family. Disease maps to a 14 cM region on the distal short arm of the X-chromosome (Xp22) between markers DXS1223 and DXS7161. **Conclusions.** These results describe mutations in 14 of our XLRP families. We have also identified a new locus for XLRP (RP23) adding to the level of heterogeneity for this disease. A large proportion (up to 70%) of XLRP remains unaccounted for by combined genetic mapping and gene mutation studies.

Program Nr: 2855 from the 1999 ASHG Annual Meeting

Screening for mutations of cardiac actin gene in dilated cardiomyopathy. *R. Zolty[1], G.L. Brodsky[1], P.A. Underhill[2], L.L. Cavalli-Sforza[2], M.R. Bristow[1], L. Mestroni[1].* 1) Molecular Genetics, CU-CVI, Aurora, CO; 2) Dept. of Genetics, Stanford University, Stanford,CA.

Idiopathic dilated cardiomyopathy (DC) is frequently inherited and genetically heterogeneous. Recently, mutations in exons 5 (Arg312His) and 6 (Glu361Gly) of the human cardiac actin gene (ACTC) have been found to segregate with the disease in 2 families with DC. In order to evaluate prevalence and characteristics of cardiac actin gene mutations in DC, 65 DC patients have been studied: 17 with sporadic DC and 48 with documented familial DC (belonging to 32 unrelated families); 2 patients with ischemic heart disease were used as controls. Genomic DNA was extracted from blood or explanted heart tissue using standard procedures. PCR products were generated from all 6 exons of the ACTC gene, allowing the inclusion of the exon/intron boundaries. The G-to-A transversion in codon 312 (Arg312His) of exon 5 introduces a unique Bcl1/Nde1 restriction site. Exon 5 amplimers generated from all patients were digested with Bcl1/Nde1. None of the exon 5 amplimers showed the presence of the expected restriction fragments. Mutation analysis of all 6 exons is currently being performed, using PCR amplification with allele-specific oligonucleotide primers for the A-to-G transversion in codon 361 of exon 6, and DHPLC and sequencing for novel mutations. Our preliminary results indicate that the Arg312His mutation in exon 5 is not responsible for the disease in a large population of familial DC patients and in a pilot group of sporadic DC cases, and is probably rare. The results of the fine mutational analysis of ACTC gene currently in progress will add important information about the relevance of this gene in the pathogenesis of DC.

Program Nr: 2856 from the 1999 ASHG Annual Meeting

Pulmonary hypertension (PHT) in type 1 Gaucher disease : Prevalence and impact of enzyme replacement therapy(ERT). *P.K. Mistry[1,2], H. Chung[1], S. Wallenstein[3], R.J. Desnick[1], M. Goldman[2]*. 1) Departments of Human Genetics,; 2) Medicine,; 3) Biomathematics, Mount Sinai School of Medicine, New York.

In Gaucher disease(GD), deficiency of lysosomal glucocerebrosidase leads to widespread accumulation of macrophages engorged with glucosylceramide-laden lysosomes. Although, the lungs represent a major site for deposition of pathological macrophages, overt pulmonary disease is rare, presenting as infiltrative/fibrotic lung involvement or PHT. Angiotensin converting enzyme (ACE) is secreted abundantly by Gaucher cells and it has been implicated in pathogenesis of primary PHT. We screened 103 patients with type 1 GD (19 untreated and 81 on ERT with Alglucerase and/or Imiglucerase for 6-105 months; age 12-82 yrs; 3 patients were excluded because of other underlying causes for PHT) for presence of PHT using doppler echocardiography to estimate physiologic tricuspid regurgitant gradient(TIG, with pressure >25 mm Hg defined as PHT). The GBA genotype of the patients was N370S/N370S in 42 patients, N370S/84gg in 24 and N370S/L444P in 14. The prevalence of PHT in untreated patients was 32% vs 18% among patients on ERT. On univariate analysis, age was significantly correlated with PHT(P=0.0012). Females were over-represented among patients with PHT(27% vs 12% TIG in females was 19.9 mm Hg vs 17.0 mm Hg, p=0.06). There was no relationship of PHT with GBA genotype, serum ACE levels, ACE polymorphisms or splenectomy status. ERT was associated with slight reduction of TIG (21 vs 16.5 mm Hg, p=0.04). On multivariate analysis, age emerged as the stongest risk factor for PHT in GD. The results indicate a hitherto unrecognized, high prevalence of sub-clinical PHT in type 1 GD, consistent with the lungs being a major site of Gaucher cell infiltration. Older age and female sex emerge as additional risk factors for development of PHT in GD. There is no association between PHT and ACE polymorphisms or serum ACE levels. ERT appears to preclude PHT, but further evaluation is required to assess its effect in reversing this complication compared to visceral and bone marrow disease.

.

Program Nr: 2857 from the 1999 ASHG Annual Meeting

The Repopulation Potential of Different Size Fractions of Hepatocytes in the Serial Transplantation Assay. *E. Montini[1], K. Overturf[3], M. Al-Dhalimy[1], M. Finegold[4], M. Grompe[1,2]*. 1) Dept. Mol.& Med. Gen., Oregon Health Sci. Univ., Portland, OR; 2) Dept. of Pediatrics, Oregon Health Sci. Univ., Portland, OR; 3) Wallace Tumor Inst.Comprehensive Cancer Center University of Alabama, Birmingham, AL; 4) Dept. Pathol., Texas Childrens Hospital, Houston, TX.

The mouse deficient for the enzyme fumarylacetoacetate hydrolase (FAH) is a model of the human disease hereditary tyrosinemia type I (HT1) and can be used to study basic aspects of liver repopulation by transplanted cells. Using serial transplantation we have previously shown that adult mouse liver contains cells capable of dividing > 100 times in vivo without loss of function. The question whether all hepatocytes or only a sub-population (stem cells) possessed this regenerative ability remained unanswered. In order to address this problem we used centrifugal elutriation to separate hepatocytes by cell density. Unexpectedly, small diploid hepatocytes (16 m) had lower repopulation capacity during the first round of transplantation when compared to both the medium-sized (21 m) and large cells (27 m). Our initial experiments did not explore the long-term repopulation potential of the different size fractions as determined by serial transplantation. Thus it still was possible that the small, diploid hepatocytes harbored the subpopulation capable of more than 100 doublings. We therefore performed 1:1 competitive repopulation between genetically marked 16 m cells and unfractionated hepatocytes in combination with serial transplantation. Analysis of DNA from livers of recipient repopulated in the second round of serial showed that the contribution from the small cells remained unchanged to round 1. Using a competition assay we also compared the repopulation capacity of hepatocytes that had undergone different degrees of prior *in vivo*expansion. Previous cell division neither reduced nor increased the repopulation capacity of transplanted liver cells. Our data indicate that the serially transplantable liver repopulating cells are the differentiated 21 m hepatocytes themselves.

Program Nr: 2858 from the 1999 ASHG Annual Meeting

***In vivo* modulation of the splicing pattern of CFTR exon 9 by cellular and viral splicing factors.** *M. Nissim-Rafinia[1], O. Chiba-Falek[1], E. Kerem[2], B. Kerem[1].* 1) Department of Genetics, The Hebrew university, Jerusalem, Israel; 2) Department of pediatrics and CF Clinic Shaare Zedek Medical Center Jerusalem Israel.

Disease variability among CF patients carrying the same splicing mutation is associated with variable levels of aberrantly spliced CFTR transcripts, suggesting a variability among individuals in the efficiency of exon recognition by trans-acting factors. Here we studied the effect of overexpression of cellular and viral splicing factors, known to promote exon inclusion or skipping, on the splicing pattern of CFTR exon 9. Transient transfection of minigenes carrying the IVS8-5T (p5T), IVS8-7T (p7T) and IVS8-9T (p9T) alleles, to NIH3T3 and COS-1 cells, resulted in their expression and alternative splicing. RT-PCR analysis showed that the efficiency of exon 9 recognition in the pT(n) minigenes was inversely correlated with the length of the pyrimidine tract, as in individuals carrying these alleles. The level of exon 9 skipped RNA transcribed from p5T in COS-1 and NIH cells was 22%±6% and 34%±6%, respectively. Cotransfection of p5T with E4-ORF3, led to a substantial promotion of exon inclusion, resulting in only 9%±3% skipped RNA. Cotransfection of p7T with E4-ORF3 also promoted exon inclusion. Cotransfection of p5T with E4-ORF6 had no effect. Next we studied the effect of the cellular splicing factors ASF/SF2 and hnRNP A1. Cotransfection of p5T with ASF/SF2 to COS-1 and NIH cells, promoted exon skipping to 36%±5% and 57%±3%, respectively. ASF/SF2 had no effect on p7T or p9T. Cotransfection of p5T with hnRNP A1 also promoted skipping to 44%±11% in COS-1 cells, and had no effect in NIH3T3 cells. Our study suggests that in vivo overexpression of cellular and viral factors can affect the splicing pattern of CFTR exon 9 pre-mRNA. Interestingly, the effect of the studied factors on the level of skipped RNA was higher in NIH3T3 than in COS-1.This might indicate that the mechanism of exon recognition is a complex network of genetic and environmental interactions, which might differ among organisms and in a tissue-specific manner. These results are important for understanding the basis of disease variability and for the development of therapies for patients carrying splicing mutations.

Program Nr: 2859 from the 1999 ASHG Annual Meeting

The use of antisense hammerhead ribozymes in an animal model of osteogenesis imperfecta. *J. Niu[1], M.W. Kilpatrick[1], R.J. Wenstrup[2], P. Tsipouras[1]*. 1) Pediatrics, UConn Health Center, Farmington, CT; 2) Human Genetics, Children's Hospital Research Foundation, Cincinatti, OH.

Nearly all forms of Osteogenesis Imperfecta (OI) are caused by mutations in the two genes for type I collagen (COL1A1 and COL1A2). There is considerable evidence that the more severe OI phenotypes are due to the mutant gene product exerting a dominant negative effect. That is, the phenotypic consequences of heterozygous mutations that alter the structure of type I collagen monomers are usually much greater than those which result from simple functional loss of an allelic product. Antisense hammerhead ribozymes are small catalytic RNA molecules that can be designed to cleave a target RNA molecule that contains a putative NUY cleavage site (where N is any base and Y any base except G). Hammerhead ribozyme technology designed to reduce or eliminate expression of a mutant collagen gene is therefore a potentially useful approach to patients with dominant-negative mutations. Hammerhead ribozymes were designed to specifically target a human COL1A1 minigene which is deleted for exons 6 through 46. Expression of this construct in transgenic mice and in the murine calvarial cell line MC3T3-E1 results in reproducible phenotypic and biochemical abnormalities. The ribozyme COL1A1RZ547, targeted to the junction between COL1A1 exons 5 and 47, specifically cleaved its target, the product of the COL1A1 minigene, in an efficient manner. The ribozyme did not cleave a control RNA which was not deleted for exons 6 through 46. Similarly, a control inactive ribozyme molecule cleaved neither the minigene RNA nor the normal control RNA. The COL1A1RZ547 ribozyme is being delivered to MC3T3-E1 cells that stably express the minigene. Delivery is by receptor-mediated endocytosis via the transferrin receptor. The ribozyme will be tested for cleavage efficacy and reversal of the well defined biochemical phenotype of the cells by northern and western blot analysis, pulse chase labelling of procollagens and measurement of several markers of cellular differentiation. In this way, the potential of this ribozyme to ameliorate phenotypic features of OI will be evaluated.

Program Nr: 2860 from the 1999 ASHG Annual Meeting

Cyclophosphamide Mediated Selection of Hematopoietic Stem Cells Corrected by Gene Therapy in a Model of Fanconi Anemia. *M. Noll[1], R.L. Bateman[1], A. D'Andrea[2], M. Grompe[1]*. 1) Dept. of Molecular & Medical Genetics, Oregon Health Sciences Univ., Portland, OR; 2) Dept. of Ped. Onc., Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA.

Fanconi's Anemia (FA) is an autosomal recessive disorder characterized by birth defects, increased incidence of malignancy and progressive bone marrow failure. Bone marrow transplantation is therapeutic and therefore FA is a candidate disease for hematopoietic gene therapy. The frequent finding of somatic mosaicism in blood of FA patients has raised the question, whether wild-type bone-marrow has a selective growth advantage. We have previously shown that mitomycin C (MMC) can be used to select for wild-type stem cells in transplanted FA group C knockout (FACKO) mice. Like MMC, cyclophosphamide (CPA) is a DNA damaging agent and produces interstrand DNA cross-links. However, in contrast to MMC, CPA is already used in human FA patients for preparation during bone marrow transplantation. Since the dose tolerated by human FA patients is known, CPA could potentially be used for enhancement of human FA gene therapy. Preliminary experiments determined that the LD50 of this compound in FACKO mutant mice was four-fold lower than for wild type mice (~ 140 mg/kg vs. 600 mg/kg). Therefore, FACKO mice were transplanted with 1 x 106 wild-type marrow cells without prior radioablation. Transplanted animals were then given a single dose of either 75-140 mg/kg of CPA. In contrast to untreated mice, CPA-treated mice showed significant percentage of wild-type DNA to peripheral blood. The wild-type contribution ranged from ~ 20% at the lower doses to >80% at the higher doses after 8 weeks. Serial transplantation showed that the selection occurred at the level of hematopoietic stem cells (HSCs). We next used a VSVG pseudotyped MMLV vector expressing the human FANCC cDNA to transduce FACKO mutant marrow cells. Similar to the results of obtained with transplanted wild-type cells, a single dose of CPA produced significant selection of retrovirally corrected HSCs. We conclude that cyclophosphamide could be used to enhance stem cell selection in gene therapy of Fanconi anemia.

Program Nr: 2861 from the 1999 ASHG Annual Meeting

Effects of dextromethorphan in autistic children with abnormal plasma amino acid profiles. J.A. Phillips III, R. Hamid and S. McGrew. Dept. of Pediatrics, Division of Medical Genetics, Vanderbilt University. School of Medicine, Nashville, TN. *J.A. Phillips III, R. Hamid, S. McGrew.* Dept Pediatrics/Genetics, Vanderbilt Univ Sch Medicine, Nashville, TN.

Autism is characterized by deficits in sociability, reciprocal communication, repetitive behavior and onset by 3 years of age. Most (75-80%) autistic individuals have primary autism in which no underlying cause is found. Previous studies have implicated derangements of neurotransmitters such as serotonin, norepinephrine and histamine in some cases of autism. In screening a series of consecutive autistic probands, we detected 5/36 (14%) who had elevated plasma levels of glutamine (Gln) or glycine (Gly) or both on repeated studies. Patient one was diagnosed as having autism at 2 10/12. His Gln (mean 884-normal 370-682) and Gly (mean 379-normal 120-315) levels were consistently elevated. Urine Gln and Gly, levels were 1410 (165-510), 5663 (569-1395) respectively. His CSF Gln was 708 (normal 356-680) while his Gly level was normal. His routine chemistry labs including his urine organic acid profile was normal. Patient two had persistent elevated Gly levels on multiple plasma amino acid profiles. These levels ranged from 324-439 (normal for age 120-315). These patients were empirically treated with dextromethorphan (DM) at 5 mg/kg/day (Delsym) divided BID. DM blocks the NMDA (N-methyl-D-aspartate) type receptor in the brain which has an accessary binding site for Gly. Both patient's special education and classroom teachers and speech and occupational therapists (blinded to treatment) reported significant improvement in their expressive and receptive language skills, attention span and focus; motor planning and socialization with peers. After withdrawal of DM regression in all improved areas was noted by all of these treatment blinded observers. These patients continue to respond to resumed, long term DM treatment. Our data suggest some autistic children have consistent elevations of Gln, Gly or both and they may respond clinically to DM. Further studies are needed to determine the cause of these biochemical findings and to quantitate the response of other subjects to DM or other NMDA inhibitors.

Program Nr: 2862 from the 1999 ASHG Annual Meeting

Adenoviral vectors modified for increased CFTR expression and persistence in human ciliated airway epithelia.

H. Romanczuk[1], J. Zabner[2], P. Berthelette[1], S. Wadsworth[1], R. Gregory[1]. 1) Genzyme Corp, 31 New York Ave, Framingham, MA; 2) University of Iowa College of Medicine, Iowa City, IA.

Cystic fibrosis (CF) is a genetic disease resulting from mutations in the chloride channel Cl^-) encoded by the cystic fibrosis transmembrane conductance regulator (CFTR) gene. The apical membrane of CF airway epithelia lacks functional CFTR, resulting in a loss of cAMP-mediated transepithelial Cl^- transport. Gene therapy for CF would require the delivery of a corrected CFTR gene to the airway in sufficient quantity to result in a measurable therapeutic index. Recombinant adenoviruses (Ad) are being designed as vectors for gene transfer to a wide variety of cells and tissues, including the respiratory epithelium of patients with CF. Currently, Ad-based gene transfer is limited in part by the low efficiency of viral entry into human airway cells. Achieving CFTR expression levels that can impart a corrective therapeutic index may thus rely on maximizing gene expression from DNA templates that gain entry into the cell. We have tested the ability of viral vectors altered in their CFTR cassettes to provide high and sustained levels of gene expression in the lungs of immunocompetent BALB/c mice and, *in vitro*, in ciliated human airway epithelia from CF donors. We show that incorporation of an intron upstream of the CFTR cDNA and an a-globin mRNA stability element (aSE) downstream of the transcription termination site each increased the level of CFTR gene expression, both *in vitro* and *in vivo*. A keratin 18 (K18) gene enhancer/promoter directed functional CFTR expression in human airway epithelia, at levels equal to that of the CMV promoter at day 3. Unlike the CMV promoter, whose activity declined over time, K18 provided functional and stable CFTR expression over the course of 30 days. These results suggest that correction of the CFTR defect in human airways should be attempted by using a tissue-specific enhancer and promoter combined with *cis*-acting elements that provide more efficient mRNA stability and translatability. Enhanced expression and persistence of CFTR may be important factors in allowing lower vector doses and longer intervals between readministration.

Program Nr: 2863 from the 1999 ASHG Annual Meeting

Towards a prevention of cardiomyopathy in Friedreich ataxia by idebenone. *P. Rustin, K. Chantrel-Groussard, J.C. von Kleist-retzow, A. Munnich, A. Rotig.* INSERM U-393, Hopital Necker Enfants Malades, Paris, France.

Friedreich Ataxia (FRDA) is a frequent cause of autosomal recessive spinocerebellar degeneration and hypertrophic cardiomyopathy, ascribed to mutations of the frataxin gene. We have reported a generalized deficiency of mitochondrial iron-sulfur proteins (ISPs) in endomyocardial biopsies of FRDA patients (Nat. Genet. 1997, 17:215-217). Reduced iron triggered similar damages to ISPs in human heart homogenates. Reduced idebenone efficiently protected mitochondrial ISPs from iron-induced injury in vitro. Further In vitro data indicate that both iron chelators and antioxidant drugs likely to reduce iron should be potentially harmful in FRDA. Based on these observations, three FRDA patients with hypertrophic cardiomyopathy were given idebenone orally (5 mg/kg/d). After 4-9 months, quantitative ultrasound evidence of drug efficiency was provided by the reduction of left ventricle hypertrophy in the three patients (mass index: -21, -30, -32%, respectively). These first results provided a basis for a subsequent long-term open trial started April 99 in France. Adults (32) and children (20) with proven FRDA are given idebenone (5 mg/kg/d) for 18 months. Primary criteria of efficiency include heart ultrasound and cerebellar syndrome scoring (WFN ataxia rating scale) each three months. In addition, an audiogram, an estimation of nystagmus and a Steward-Holmes test will be performed each 6 months, and an electromyogram after 1 year of treatment. Results of this open trial will hopefully confirm the preliminary data observed in the three FRDA patients.

Program Nr: 2865 from the 1999 ASHG Annual Meeting

Fabry Disease Bone Marrow Transplantation in a-**Galactosidase A Deficient Mice Reverses Substrate Accumulation, Except in the Kidney.** *C.M. Simonaro[1], R.E. Gordon[2], Y.A. Ioannou[1], R.J. Desnick[1]*. 1) Dept Human Genetics, Mount Sinai Sch Medicine, New York, NY; 2) Dept Pathology, Mount Sinai Sch Medicine, New York, NY.

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism resulting from the deficient activity of the lysosomal exoglycosidase, a-galactosidase A (a-Gal A). The enzyme defect leads to the pathologic accumulation of its major substrate, globotriaosylceramide (GL-3), particularly in blood vessels, heart, and kidney leading to early demise due to vascular occlusions, cardiac disease and renal failure. To investigate the effects of bone marrow transplantation (BMT), 18 newborn a-Gal A deficient mice generated by gene targeting (Wang et al., Am. J. Hum. Genet. 59:A208, 1996) were successfully transplanted with normal adult bone marrow following sublethal irradiation at 400 cGy. Engraftment was monitored by determining a-Gal A and GL-3 levels in peripheral leukocytes and plasma. Twelve of the BMT recipients (6 hemizygous males and 6 homozygous recessive females) remained engrafted up to 38 weeks post-BMT, and several had normal or near normal a-Gal A levels in plasma and leukocytes and activities in the spleen, heart, liver and kidney that were 88, 21, 20 and 8 percent of normal, respectively. The GL-3 concentrations in the plasma and liver decreased to normal, while the pathogenic glycoplipid was reduced by 75% in the spleen and 65% in the heart. Electron microscopy also revealed markedly reduced substrate accumulation in hepatic Kupffer cells, splenic macrophages, smooth muscle and vessels of the heart, and vascular endothelium. However, the GL-3 accumulation in the kidney, a major site of pathology in human Fabry disease, was not depleted by BMT. In particular, the substrate deposition in the podocytes of the glomeruli and the epithelium of the proximal and distal tubules remained unchanged ultrastructurally, and the renal GL-3 concentration was unchanged, if not slightly increased, post-BMT. These results indicate that BMT performed early in life may prevent many pathological and clinical manifestations in affected males, but may have limited, if any, effect on the renal disease.

Program Nr: 2866 from the 1999 ASHG Annual Meeting

Retroviral mediated transfer and expression of b-**hexosaminidase** a-**chain gene in human fibroblasts from B and B1 variant G_{M2}-Gangliosidosis.** *C.A.F. Teixeira[1], M. Sena-Esteves[3], X.O. Breakefield[3], M.C.S Miranda[1,2], M.G. Ribeiro[1,2].* 1) Genetic Neurobiology, I.B.M.C., Porto,Portugal; 2) Unidade de Enzimologia,Instituto de Genetica Medica,Porto,Portugal; 3) Molecular Neurogenetics Unit, Massachusetts General Hospital,Boston,USA.

The variants B and B1 of G_{M2}-Gangliosidosis are recessive fatal lysosomal disorders characterised by the accumulation of ganglioside G_{M2} particularly in the CNS due to b-hexosaminidase A (HexA) deficiency. The variant B1, a common disorder among Portuguese, is distinct from variant B in that the HexA (hetrodimer ab) is synthesized but the a-subunit is inactive. For these disorders no treatment is available and therefore gene therapy could represent a therapeutic approach, specially for variant B1 that is a late-onset disease. We have therefore studied the effectiveness of providing the human a-chain gene via a retroviral vector to HexA-deficient cultured human fibroblasts from B and B1 variant patients as a first step in evaluating the potential of gene therapy for these disorders.

The full-length human a-chain cDNA was subcloned into pBabe retroviral vector under the control of MoMLV LTR element and the recombinant retrovirus used to transfect the packaging cell line y-CRIP. The NIH3T3 cells infected with the recombinant retroviral particles overexpressed the a-chain resulting in the formation of HexS (homodimer aa). With the a-chain specific synthetic substrate 4MU-GlcNAcS, the activity was increased about 10-fold above the non-transduced cell level. The viral stocks which resulted in the highest activity in NIH3T3 cells were subsequently used to transduce cultured human fibroblasts from B and B1 variant patients. In transduced HexA-deficient cells a catalytically active HexA was produced. The enzymatic activity measured with 4MU-GlcNAcS increased about 30-fold above the level of non-transduced HexA-deficient fibroblasts, being within the range of values observed in non-transduced normal cells. Further studies are being undertaken in order to evaluate the value of retroviral-mediated gene transfer in correcting the HexA deficiency in cultured human cells.

Program Nr: 2867 from the 1999 ASHG Annual Meeting

Muscle is a major site for latent adeno-associated virus genomes. *Z. Tezak, E.P. Hoffman.* CNMC CRI III, Washington, DC.

Adeno-associated virus (AAV) is a human parvovirus of no known pathogenicity. Recombinant AAV can infect a large number of cell types, integrate into genomic DNA, and show persistent gene expression. As such, it is becoming an increasing focus for gene delivery in brain, skeletal muscle and liver. About 80% of humans are seropositive for AAV. However, the normal tissue tropism of wild-type AAV has not been well defined; this is of importance both with regards to the nature of this benign integrating DNA virus in humans, and with regards to interpreting gene therapy efforts centered on neuromuscular diseases. The goal of this study was to investigate whether skeletal muscle is a major target organ for wild type AAV. Previously published DNA studies have shown only uterine tissue to consistently and with high frequency test positive for AAV. To analyze whether AAV genomes are present in human muscle, we isolated DNA from 87 skeletal muscle biopsies, and tested for presence of AAV rep sequences by PCR. To ensure that we are not detecting contaminating recombinant AAV sequences, we designed the set of PCR primers recognizing these sequences. We detected wild type AAV DNA in 17% (8/48) of normal human muscle biopsies. Compared to published values for AAV DNA in blood (2/55 or 3.6%) and our own testing of lymphocytes (1/33 or 3%), there is statistically significantly (c^2 is 4.07) more AAV DNA found in normal muscle. We also identified AAV DNA in 10% (4/39) of Duchenne muscular dystrophy patients muscle biopsies. All together, we detected AAV genomes in 14% (12/87) of muscle biopsies tested. We found AAV sequences in biopsies of both genders, ranging in age from 0.5 to 43 years. Automated sequencing showed that AAV sequences were identical to AAV-2 DNA sequence. We subsequently isolated RNA from the same muscle biopsies and could not detect AAV transcripts by PCR. These findings suggest human muscle as a target for latent AAV infection. Our result is of particular interest given that we and others have shown that common helper viruses for AAV (HSV and adenovirus) show exceedingly poor infection of adult muscle. Thus, it appears that latent, integrated AAV genomes are present in tissues that may not be capable of producing viral particles.

In vivo analysis of photoreceptor degeneration in light-inducecd LACA mice and in vitro ribozyme cleavage of key mRNA targets involved in apoptotic mediated cell death. *In vivoIn vitro*. *G.P. Tuohy[1], P.F. Kenna[1], S.J. Martin[2], P. Humphries[1], G.J. Farrar[1]*. 1) Wellcome Ocular Genetics Unit, Smurfit Institute of Genetics, Trinity College Dublin, Dublin 2, Ireland; 2) Department of Biology, National University of Ireland, Maynooth, Kildare, Ireland.

Retinitis pigmentosa (RP) is a group of genetic degenerative diseases of the retina which afflicts approximately 1 in 4000 of the general population. The genetics of inherited retinopathies display all known mechanisms of inheritance and involve disruptions on nearly every human chromosome. Families exhibiting autosomal dominant, autosomal recessive, X-linked, maternal (mitochondrial) and digenic inheritance are well documented in the literature. Despite the diversity of genetic lesions which give rise to the progressive blindness found in RP patients many forms of the disease are believed to advance through a programme of apoptotic degeneration. An animal model of light-induced apoptotic death in the retina demonstrates a number of the classical markers of apoptosis including morphological changes, TUNEL labelling and DNA laddering. Several studies have demonstrated apoptotic degeneration in mouse models of RP in addition to studies showing activation of caspase 3, a key mediator of apoptotic cell death. Down regulation of caspase activity either by protein inhibition of caspase family members or by employing ribozymes directed against caspase family mRNA may slow or halt the destruction of photoreceptors. This study presents in vitro data of ribozymes directed to cleave caspase 3, 8, 9 and Apaf-1 mRNA targets. Interference with such cell death may in itself represent an effective therapy or may provide a window of opportunity to introduce a gene-based therapy aimed at correcting the primary genetic lesion. In so far as the retina may be representative of fully differentiated neuronal tissue such a strategy may prove beneficial in other diseases involving neurological degeneration.

The Pathobiology and Treatment of Mucopolysaccharidosis Type VI: Studies in the Cat and Rat Animal Models.

N.J. Vigna[1], J.J. Hopwood[3], M.E. Haskins[4], E.H. Schuchman[1,2], C.M. Simonaro[1]. 1) Human Genetics, Mount Sinai School of Medicine, New York, NY; 2) Institute for Gene Therapy and Molecular Medicine, Mount Sinai School of Medicine, New York, NY; 3) Department of Chemical Pathology, Womens and Childrens Hospital, North Adelaide, Australia; 4) University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA.

Mucopolysaccharidosis type VI (MPS VI) is the lysosomal storage disorder due to the deficient activity of arylsulfatase B (ASB) and the resultant accumulation of the glycosaminoglycan, dermatan sulfate. MPS VI is clinically manifested by severe bone and connective tissue deformities, short stature, degenerative joint disease, cardiopulmonary complications, hepatosplenomegaly, and corneal clouding. MPS VI also has been described in cats, rats, and dogs. We evaluated several approaches for the treatment of MPS VI in rats and cats, including hematopoietic stem cell (HSC) gene therapy, bone marrow transplantation (BMT), and/or enzyme replacement therapy (ERT). BMT and ERT in these animal models led to modest improvements in locomotor skills, improved histology in relevant tissues, including the heart, liver and trachea, and some modest reduction of long bone disfigurement. However, the major skeletal abnormalities which are characteristic of MPS disorders were not significantly improved by these approaches. We have also achieved long-term engraftment of retrovirally transduced HSCs in the MPS VI cats and rats without any myeloablative preconditioning, but this approach has been unsuccessful due to low levels of expression in the appropriate target sites, particularly cartilage and bone. Currently, we are evaluating BM stromal cell transplants as a source of progenitor cells for cartilage and bone and developing new forms of the enzyme which may be taken up more efficiently by these cell types. We are also continuing to investigate the pathobiology of these animal models to better understand the disease process and possible avenues of therapeutic intervention. Towards this end we have found widespread and progressive apoptosis in chondroctyes from MPS VI animals, but not age-matched controls.

Identical mutation in the dysferlin gene can cause either a limb girdle muscular dystrophy type 2B or a Miyoshi myopathy phenotype. *K. Wrogemann[1], E. Nylen[1], T. Weiler[1], R. Singal[1], C.R. Greenberg[1], I.A. Ivanova-Smolenskaya[3], V.S. Sukhorukov[3], R. Bashir[2], K. Bushby[2], S.N. Illarioshkin[3].* 1) University of Manitoba, Winnipeg, MB, Canada; 2) University of Newcastle upon Tyne, Newcastle upon Tyne, UK; 3) Russian Academy of Medical Sciences, Moscow, Russia.

Limb girdle muscular dystrophy Type 2B (LGMD2B) and Miyoshi myopathy (MM) are both caused by mutations of the recently identified dysferlin gene on chromosome 2p13. In a large Russian kindred, eight patients with the proximal LGMD2B phenotype, three with the distal MM phenotype and one preclinical case have been previously described to be homozygous for the same extended haplotype around the dysferlin locus (Brain 119:1895-1909, 1996). This suggested that identical mutations could lead to both phenotypes. We have screened the 55 exons of the dysferlin gene by SSCP/heteroduplex/sequencing analysis and found a dinucleotide change, TG to AT at nucleotide positions 573-574 in exon 3. This leads to a Val67Arg mutation in dysferlin. The mutation segregates as expected for a mutation causing an autosomal recessive disorder, and all patients are homozygous for this mutation. The mutation has not been previously reported in patients with MM or LGMD2B nor has it been seen in 120 control chromosomes. Similar observations have been made in a large Canadian aboriginal kindred with both LGMD2B and MM where patients with both phenotypes are homozygous for a Pro791Arg mutation (Human Molecular Genetics 8:871-877, 1999). Thus, we conclude that diverse dysferlin mutations can cause both LGMD2B and MM and that additional factors, such as modifier gene(s) must contribute to the development of the presenting clinical phenotype.

Program Nr: 2871 from the 1999 ASHG Annual Meeting

Molecular Cloning and Functional Characterization of a Translational Control Protein (TCP) that Binds to Coding Sequences of Acid b**-Glucosidase RNA and Other RNAs.** *Y-H. Xu, C. Busald, G.A. Grabowski.* Div Human Genetics, Children's Hosp Medical Ctr, Cincinnati, OH.

GCase is the enzyme deficient in Gaucher disease; a prototypical inherited metabolic error for enzyme and gene therapies. An 80 kDa cytoplasmic protein, termed TCP80, inhibited GCase mRNA translation in mammalian cells by binding to GCase RNA coding regions. The TCP80 cDNA was cloned from an expression library by screening with the GCase RNA coding region. The cDNA sequence was nearly identical to those for M-phase phosphoprotein (MPP4; 99%) and to an IL-2 enhancer binding protein (NF90; 96%). Expression of the carboxy terminal third of the protein, termed TCP30, showed TCP80 to be an RNA binding protein with specificity for 184 nt of GCase RNA coding sequence. This fragment was located near the 5' end of the GCase RNA. TCP30 diminished the translation inhibition of GCase RNA caused by cytoplasmic TCP80. TCP50, expressed from the NH2 - terminal two-thirds of TCP80, did not bind to GCase RNA nor inhibit its translation. Intact TCP80, heterologously expressed in insect cells, reconstituted in vitro translation inhibition of GCase. Time course analyses showed that TCP80 functions at the initiation phase of GCase mRNA translation, probably by inhibiting its binding to polysomes. These effects could be reconstituted in vivo by co-infection of TCP80 and GCase baculoviruses into Sf9 insect cells that do not constitutively express TCP. Seven additional RNAs were isolated by specific binding to TCP30. In vitro translation of several of these was inhibited by TCP80. These studies show that TCP80 has RNA binding (TCP30) and inhibitory (TCP50) domains that function to modulate translation of several mRNAs with implication for gene-based therapeutic approaches.
