Juvenile Myoclonic Epilepsy (JME) is associated with SNPs and a microsatellite marker (GT-repeats) in the gene BRD2. An evolutionarily conserved, alternatively spliced exon (2a) is located in the same intron (Intron 2) as the associated microsatellite. We have proposed that the sequences of the intronic region between exons 2 and 3 may influence the splicing of the alternative exon 2a and hence, JME susceptibility. A four-basepair polymorphism, GTAA, allowed us to test if the intronic region sequence influences splicing. The GTAA polymorphism is found upstream from the GT-repeat region. We created two constructs of Exon2-Intron2-Exon3 of BRD2 from a human DNA sample, one with the GTAA-containing allele and one without. The microsatellite allele in both constructs was identical. We transfected mammalian expression constructs into 293T cells and examined splice products. Northern blot analysis of total RNA demonstrated differences in splicing of the two alleles. While products included both normally spliced (Exon2-Exon3) and alternatively spliced products (Exon2-Exon2A-Exon3), we also saw partially spliced products in greater proportions from the allele with the GTAA polymorphism than from the allele without. Complementary DNA sequencing showed that a portion of Intron2 was in the partially spliced product. This partially spliced product may reflect aberrant or inefficient splicing as a function of intronic length or structure. We propose that the presence or absence of this GTAA polymorphism and length of the microsatellite, may affect the function of BRD2 and play a role in the development of JME.

CCRaVAT - Case/Control Rare Variant Analysis Tool. *R. W. Lawrence, A. P. Morris, M. I. McCarthy, E. Zeggini, WTCCC* WTCHG, Oxford University, UK.

With the recent plethora of common variants found to be associated with complex diseases there is a realization that rare-variants may contribute a large part to their genetic content. This is true for type 2 diabetes (T2D) which has numerous associated genes but a relatively small cumulative lambda-s of 1.07. The available sample sizes, although sufficient for well-powered studies on common variants, do not provide sufficient power for single-point analysis of rare variants when effect sizes are small to moderate. We have developed rare variant analysis software which allows the analysis of low MAF SNPs by pooling rare variants within defined regions and treating them as a single super locus. Gene regions are defined as sequence 50kb either side of the transcriptional start/stop sites. For each region a 2x2 contingency table is constructed containing: (1) number of cases carrying at least one rare variant; (2) number of cases not carrying a rare variant; versus (3) number of controls carrying at least one rare variant; (4) number of controls not carrying a rare variant. Differences in frequency between rare variant carrying cases and controls are tested using Pearson's chi-squared test (or Fisher's exact test where required). Using this method we calculated P-values for all genes across the genome in the Wellcome Trust Case Control Consortium (WTCCC) type 2 diabetes (T2D) dataset. We found six gene regions in which rare variants of MAF0.01 were associated with T2D with $P10^{-4}$. The three strongest signals observed were: BMP2K (chr4, $p=2.9x10^{-6}$, two rare variants carried by 28/1821 cases and 9/2922 controls); LOC391845 (chr5, $p=3.7x10^{-6}$, six rare variants, carried by 26/1903 cases and 7/2913 controls) and CPN1 (chr10, $p=4.7x10^{-5}$, two rare variants, carried by 14/1921 cases and 1/2932 controls). Of the regions showing greatest significance there was a clear tendency for cases to have a higher proportion of rare variants compared to controls (5 of 6 regions with $P10^{-4}$ had higher proportions of rare variants in cases, binomial test p=0.11). We are following up regions that appear to be significantly different in rare variant content between T2D cases and controls.

Evaluation of gene expression patterns associated with genomic instability in colon cancer. *C. B. Wiese, B. Lomenick, T. A. Carver, M. J. Kovach* Biological & Environmental Sci, Univ. of Tennessee-Chattanooga, Chattanooga, TN.

Genomic instability is a molecular feature common to many cancers. Two types of genomic alterations associated with cancer are variability in microsatellites and global changes in DNA methylation status. The purpose of this study is to evaluate whether genes in the molecular pathways of cancer are subject to gene regulation by microsatellite repeat variability. We propose that microsatellite repeat elements represent a normal, but as yet uncharacterized mechanism of gene regulation in which polymorphisms in microsatellites function to control the local chromatin structure and mRNA secondary structure. We predict that microsatellite variants generate alternate secondary structures important in the recruitment of transcriptional proteins that directly influence the rate of transcription, as well as affect transcript stability. We also predict a relationship between the DNA structure induced by microsatellite variability and the methylation status of CpG islands, presenting an indirect mechanism by which genomic instability influence transcription. To examine the effect of microsatellite variability on gene expression, DNA from 14 colon cancer cell lines was characterized for 22 microsatellite elements in 7 genes associated with colorectal cancer. Preliminary evaluation indicates that microsatellites near the 5 and 3 ends of the transcripts exhibit a higher degree of variability; regions known to influence mRNA abundance. Secondly, the methylation status of CpG islands within these genes was analyzed by combined bisulfite restriction analysis (COBRA). Methylation varied depending on the functional nature of the gene. For example, the angiogenesis inhibitor *THBS1* is primarily unmethylated (mean: 8.6% methylation) except for four RER+ cell lines. Cell line LS411N shows 98% methylation and the other three cell lines show 15% methylation. However, *STK11* shows partial methylation for all the cell lines with a mean of 91.5% methylation for the cancer cell lines and 81% methylation for the normal colon control. The increase in methylation suggests that transcription of this tumor suppressor gene is repressed in these cancer cell lines.

Analysis of genetic origins of canine MEN 2-like phenotypes. *A. A. Kovinich Smith[1], C. Gibson[2], J. Keating[2], J. Alroy[2], A. S. Tischler[3], L. M. Mulligan[1]* 1) Dept Pathology and Molecular Medicine, Queen's Univ, Kingston, ON, Canada; 2) Dept Biomedical Sciences, Tufts Cumming School of Vet Medicine, Grafton, MA, USA; 3) Dept Pathology, Tufts Univ, Boston, MA, USA.

The proto-oncogene *RET* encodes a receptor tyrosine kinase expressed in neural crest-derived cell types. Germline mutations in the human *RET* gene are responsible for multiple endocrine neoplasia type 2 (MEN 2). MEN 2 is an inherited cancer syndrome characterized by medullary thyroid carcinoma (MTC), and may also be associated with pheochromocytoma (PC) and other less common tumor and developmental phenotypes. Phenotypes similar to that of MEN 2 have been documented in species other than humans; however, corresponding similarity between genotypes has yet to be confirmed. We performed an *in silico* alignment of *RET* sequences from available species to identify areas of similarity in the kinase. Comparisons of *RET* sequences between human and animal species suggest strong evolutionary conservation and make these RET-orthologs likely candidates for involvement in the development of MEN 2-like phenotypes in other species. We identified a dog expressing MEN 2-like phenotypes including both MTC and PC upon post-mortem autopsy. To determine if *Ret* was involved in the development of these phenotypes, we analyzed the genomic DNA sequences corresponding to human *RET* exons 10-16 in this animal, since greater than 99% of all MEN2-*RET* mutations are found within these exons. Western blotting was used to confirm Ret expression in adrenal tumor tissue from this animal. No sequence variants were detected in tumor material from either MTC or PC, suggesting that the dog does not share the genetic etiology commonly causing human MEN 2 phenotypes. Our data suggest that, despite the evolutionary conservation and the involvement of RET in the development of MEN 2 in humans, the *Ret* proto-oncogene may not play a role in the development of similar phenotypes in other species.

Molecular analysis of translocation breakpoints in a novel t(1;9) in a patient with isolated cardiac defect. *S. Saitta, K. Pickering, A. Gotter, A. Hacker, M. Nimmakayalu, E. Goldmuntz, B. Emanuel* Childrens Hospital of Philadelphia, Philadelphia, PA.

Chromosomal rearrangements such as deletions, duplications, and translocations play a critical role in gene discovery. In particular, de novo balanced translocations that might interrupt a gene or its regulatory elements, have been especially helpful in understanding the etiology for many disorders. We studied a non-syndromic male child with isolated tetralogy of Fallot, a commonly encountered conotruncal cardiac defect. The patient was found to have an apparently balanced de novo translocation, t(1;9) (q32;q23.3). DNA from the patient was analyzed by high resolution SNP-based oligonucleotide array analysis (500K), and no evidence of pathologic copy number changes were detected either near the putative breakpoints, or in other regions of the genome. Following G-banding, the breakpoints were further mapped by FISH using BACs and fosmids from specific regions, and localized by breakpoint-spanning probes. To further narrow the regions, a cocktail of multiple PCR probes was also labeled and used for FISH. Finally, a series of primers were developed for long-range PCR to amplify across the putative junction. The amplified product, found only in the patient, shows end sequences that localize to chromosome 1, while the other end of the product shows sequence from chromosome 9 by BLAST analysis. While the breakpoint does not directly interrupt the coding sequence of a specific gene, its proximity to two developmental genes may result in their dysregulation. Ongoing sequence analysis of these genes, completed in 40 patients with isolated tetralogy of Fallot, has identified polymorphic variants, though potential pathologic variants have not yet been identified. Further molecular and structural analysis of the sequences involved in this novel translocation breakpoint and assessment of the genes are underway. Overall, the utilization of newer sequenced-based tools and techniques have helped to localize the breakpoints of this de novo balanced translocation and identify potential new regions of the genome involved in the etiology of cardiac defects.

Common polymorphisms in candidate genes influence breast cancer phenotype and prognosis. *D. Eccles[1,3], W. Tapper[2], V. Hammond[2,3], S. Gerty[3], P. Simmonds[3], A. Collins[2]* 1) AcUGeM, WCGS, Southampton Univ Hosp Trust, Southampton, United Kingdom SO16 5YA; 2) Bioinformatics GroupUniversity of Southampton, Duthie Building , SUHT SO16 6YD; 3) Cancer Sciences DIvision, Somers Cancer Research Building, Southampton University Hospitals, SO16 6YD.

Introduction: Genome wide association studies (GWAS) confirm the existence of common genetic variants that affect breast cancer risk(1,2) and there is evidence from these studies that common genetic variants may influence tumour phenotype. Breast cancer prognosis is linked to tumour characteristics and stage. In addition data from population registries suggest that prognosis may have a heritable component(3). We investigated SNPs in 30 candidate genes that might plausibly influence breast cancer phenotype and prognosis. Methods: We genotyped blood DNA from 1001 young onset (40 years at diagnosis) symptomatic breast cancer cases from the POSH study(4). 206 tagging SNPs were typed reporting on 30 candidate genes. We used the Cochrane Armitage Trend to test association of SNPs comparing phenotypic extremes and Kaplan Meier survival analysis and Cox proportional hazards to assess the effect of each genotype on survival. Results: SNPs in FGFR2 and TNRC9 were significantly more frequent in ER +ve compared with ER -ve breast cancer (ptrend = 0.000003) and (ptrend = 0.0014) whereas ATM SNPs were associated with ER -ve disease (ptrend = 0.0000985). The rs2228480 synonymous SNP in ESR1 was associated with significantly earlier distant relapse which appeared to be mainly due to an effect on tumour grade (p0.01), there was no association of ESR1 SNPs with ER status of breast tumours. SNPs in TNRC9 and MMP7 were associated with a poor outcome that was independent of all known clinical prognostic indices. Conclusions: These novel findings will need to be replicated in further studies but suggest inherited genetic variants may be either modulating the host response to malignant cell growth or predisposing to certain types of somatic mutation that drive malignant cell proliferation. 1. Detailed behavior, language and neurological analysis of interstitial duplication 15q11.2-q12 autism patients. *L. T. Reiter[1], V. Brewer[2], J. T. Jabbour[3], J. Cleary[4]* 1) Dept Neurology, Univ Tenn HSC, Memphis, TN; 2) Dept Pediatrics, Univ Tenn HSC, Memphis, TN; 3) Memphis Neurology Practice, Memphis, TN; 4) Audiology & Speech-Lang Pathology, Univ Memphis, Memphis, TN.

Autism has proven a difficult disorder to evaluate both clinically and at the molecular level due to both a high degree of genetic heterogeneity and the influence of unknown environmental factors that may further alter phenotypes in these patients. This underlying genetic variation means that any given set of individuals with idiopathic autism analyzed clinically for detailed phenotypic variations in EEG, seizure status, MRI, serotonin levels or behavioral analysis may represent a combination of underlying molecular defects that may or may not be relevant to the next group of subjects examined. To better understand the minimal phenotypic elements of autism we chose to examine individuals with one of the simplest genotypes containing the fewest number of genes that consistently results in an autism phenotype. Individuals with interstitial duplications of chromosomal region 15q11.2-q12 present with autistic features and are one of the most common genomic lesion detected in autism. Using a battery of neuropsychological, language, neurological and genetic tests we examined 5 pediatric cases of 15q interstitial duplication. The most outstanding feature of these subjects is they appear to be mildly affected with one individual even scoring outside of the autism spectrum by ADOS and ADI evaluation. Although only one patient had a history of seizures, 3 out of 5 showed mildly abnormal brainwave activity by EEG. This activity appears to be sub-clinical and may dissipate with age. We also found a trend indicating that the verbal IQ may be equivalent or slightly higher than performance IQ, but the ability for these individuals to use language adaptively in daily life was limited. In general, these individuals also scored high for daily living skills on the Vineland test. In summary, this is the first step in defining features unique to duplication 15q autism patients which may illuminate genotype to phenotype correlations in autism.

The epigenetics of X-linked gene expression in monozygotic twins discordant for primary biliary cirrhosis. *M. Martin[1], A. Lleo[2,3], C. Selmi[2,3], JM. LaSalle[1]* 1) Medical Microbiology and Immunology, UC Davis School of Medicine, Davis, CA, USA; 2) Rheumatology, Allergy and Clinical Immunology, UC Davis School of Medicine, Davis, CA, USA; 3) Internal Medicine and Liver Unit, San Paolo School of Medicine, U of Milan, Milan, Italy.

Primary biliary cirrhosis (PBC) is a female dominant autoimmune chronic cholestatic liver disease with an expected genetic component to its etiology due to concordance in most monozygotic (MZ) twin sets. Previously we proposed an X-linked epigenetic component to explain the female prevalence of PBC. While most genes on the inactive X chromosome are silenced by promoter methylation, previous studies have shown that approximately 10% of X-linked genes exhibit variable patterns of inactivation in individual females. This study was designed to test the hypothesis that susceptibility to PBC arises from epigenetic modifications to an X-linked gene with variable silencing. Samples were from a unique cohort of MZ twin sets discordant and concordant (n=4 and n=1, respectively) for PBC. Expression levels of the 125 variably X inactivated genes was determined by RT-PCR analysis and two genes (*CLIC2* and *PIN4*) were identified and showed to be consistently down regulated in the affected twin of each pair. For promoter methylation analysis, DNA samples were bisulfite converted followed by PCR amplification, cloning and sequencing to determine methylation patterns and levels for each pair of discordant and concordant twins. Neither *CLIC2* or *PIN4* had promoter CpG islands and both showed partial methylation of CpG sties within 300 bp of the first exon. Promoter methylation of *CLIC2* showed no significant difference between samples, while *PIN4* methylation showed a positive correlation with expression in all samples. Interestingly, a discordant twin pair heterozygous for a genetic polymorphism that creates two additional CpG sites showed the best correlation between promoter methylation and expression of *PIN4*. These results suggest that expression of *PIN4* is down-regulated in affected versus unaffected PBC twins by a combination of genetic and epigenetic factors.

Admixture mapping identifies a putative chromosomal region for diabetic nephropathy (DN) in Mexican-Americans (MA). *M. F. Seldin[1], C. Tian[1], M. V. Pahl[2], K. Chen[1], H. Abboud[3], S. B. Nicholas[4], E. Ipp[5], N. Arar[3], F. Thameem[3], J. Tayek[5], S. Snyder[5], R. Kosoy[1], D. G. Ballinger[6], S. G. Adler[5], Family Investigation of Nephropathy and Diabetes (FIND)* 1) UC, Davis, Davis, CA; 2) UC Irvine, Irvine, CA; 3) UT San Antonio, San Antonio, TX; 4) UCLA, Los Angeles, CA; 5) Harbor-UCLA, Los Angeles CA; 6) Perlegen Sciences Inc., Mountain View, CA.

Epidemiological evidence suggests that there are differences in the prevalence of DN dependent on continental ancestry. MAs are disproportionately affected by DN, yet few genetic studies have been performed to identify the genetic contributions to DN in this population. Utilizing MA FIND participants with type 2 diabetes (T2DM) and DN as cases and geographically matched controls with T2DM without DN, a genome-wide admixture mapping scan was performed. All DN cases met criteria for nephropathy (0.3 mg albumin/24h, or random ACR 0.3 g/g) in subjects with T2DM. Non-DN controls were defined as subjects with DM duration >10 yrs, no first degree relative with known ESRD or CKD, and ACR <0.3 g/g. 664 cases and 490 controls also met quality control filters including >95% complete genotypes, <10% African admixture and database matching gender assignment. Admixture mapping was performed using the ADMIXMAP algorithms and applied a panel of 4300 European/Amerindian ancestry informative markers (AIMs) to estimate ancestry along each chromosome (parental population ancestry estimated using European and multiple Amerindian group genotypes). In an analysis including the gender, recruitment site, and diabetes duration as covariates, the maximum ancestry linkage peak was observed at rs721941 on chromosome 2 (2q37.1, 229.9 MB) and was linked to Amerindian ancestry (SCORE test = 4.3, nominal p value = 1.7e-5). Additional peaks, which also linked with Amerindian ancestry, were observed for regions of chromosome 1 (rs1564720, SCORE test = 3.13 and chromosome 14 (rs4267246, SCORE test 3.0). Only the chromosome 2 peak was significant by permutation testing (p <0.05 genome-wide). These findings have the potential to identify genes that predispose MAs to DN and to discern novel therapeutic targets.

Evidence for BMI mediated association of PREX1 SNPs with type 2 diabetes. *J. Lewis, N. Palmer, J. Ellington, J. Divers, C. Langefeld, B. Freedman, D. Bowden* Wake Forest University School of Medicine, Winston-Salem, NC.

In a dense SNP map analysis of the 20q12-13.13 type 2 diabetes mellitus (T2DM)-linked region on chromosome 20 we observed suggestive evidence of association with T2DM for SNPs near the phosphatidylinositol 3, 4, 5-triphosphate-dependent RAC exchanger 1 (*PREX1*) gene. To better understand this region (316 kb), we genotyped 31 additional SNPs in a cohort consisting of 300 diabetic patients enriched for end-stage renal disease (ESRD) and 310 healthy controls making a total of 59 SNPs genotyped across *PREX1*. Of these SNPs, 12 were significantly associated with T2DM with additive P-values ranging from 0.001 to 0.031. Six of these associations were replicated in a sample of 469 non ESRD diabetes cases and 442 controls (additive P-value range of 0.017-0.042). The combined analysis consisting of 769 cases and 752 controls resulted in the same 6 SNPs associated with T2DM in addition to 3 other SNPs leading to generally stronger evidence of association (additive P-value range of 0.001-0.041). To better understand the relationship between these SNPs, adiposity, and T2DM, we repeated the association test accounting for body mass index (BMI) resulting in only 2 SNPs remaining marginally associated with T2DM (additive P-value range of 0.030-0.044). Subsequently, we tested whether these SNPs were associated with BMI itself. In this analysis 10 SNPs were significantly associated with BMI with evidence of association comparable to that observed with T2DM (additive P=0.001-0.029). The test for association between BMI and these SNPs stratified by T2DM status identified 13 SNPs that were significantly associated with BMI solely in the case stratum with additive P-value ranging from 0.002 to 0.041 suggesting that BMI may mediate the effect of these SNPs on T2DM. A formal mediation analysis revealed that the effects of 6 SNPs are significantly mediated by BMI (30-40% mediated effect). These results suggest that SNPs near the *PREX1* gene may contribute to diabetes susceptibility, which is mediated through effects of adiposity in European Americans.

Methods and Discoveries Drawn from Twenty Genome-Wide Copy Number Variation Association Studies. *C. Lambert, J. Grover, I. Lake, G. Linse, G. Rudy* Golden Helix, Inc, Bozeman, MT.

With over a dozen ongoing collaborations with leading research organizations and access to a wealth of whole genome copy number variation (CNV) studies across multiple platforms, we have come across a number of challenges regarding data quality and analysis. To address these challenges we developed a number of methodologies in pre-processing data, including scaling quantile normalization and virtual array generation to thousands of samples for the calculation of log2 ratios against a reference population, detecting and correcting for batch effects and population stratification, optimal segmentation employing both single sample and multi-sample algorithms to detect CNVs, and whole genome CNV association analysis. We present methods and results using the various Wellcome Trust case/control studies (~2000 cases, ~1500 common controls) on Rheumatoid Arthritis, Bipolar Disorder, Coronary Artery Disease, Crohns Disease, Hypertension, Type I Diabetes, and Type II Diabetes.

One of the most persistent and challenging issues has been batch effect correction. With high genotyping call rates mostly unaffected by plate effects, the vast majority of research groups have either insufficiently randomized cases and controls on plates, or borrowed controls from other experiments. Unfortunately, CNV studies are very sensitive to batch effects. We have employed PCA-based approaches to mitigate the enormous confounding of CNV association studies by batch effects and population stratification. Further, in looking at over 20 different studies, we have seen particular regions of chromosome 7 and 14 persistently associated across a vast majority of diseases, regardless of genotyping platform. We have also found perhaps 30-40% of CNV associations are confirmed by past studies, whereas the remaining 60-70% represent novel findings. Corroborated CNV associations of note in the Wellcome Trust studies are regions in or near CHL1, PPP1R12B, SLC8A1, SMAD6 in Coronary Artery Disease, CHL1 in Bipolar Disorder, BTNL2 in Rheumatoid Arthritis, PTPRD in Hypertension, and GGTL4 in Type I Diabetes.

Evolution pathway of the oriental ALDH2 variant. *H. Li, J. R. Kidd, K. K. Kidd* Department of Genetics, School of Medicine, Yale University, New Haven, CT06520-8005, USA.

Mitochondrial aldehyde dehydrogenase gene (*ALDH2*) is one of the most studied human genes with thousands of relevant research reports. The East Asia specific allele *ALDH2*487Lys* produces an ALDH2 enzyme defective in oxidizing aldehyde into acetic acid; one effect is protection against alcoholism and other relevant disorders. Significant questions in human evolution studies are how and why this oriental ALDH2 variant arose and became frequent. We typed 41 SNPs and one STRP around the region of *ALDH2* in 45 world populations. Most of the polymorphisms showed high F_{st} values indicating high variation among the geographic regions. Some variants occur only in East Asia or the Americas, including the allele at rs671 defining *ALDH2*487Lys*. A long range haplotype network including all the typed polymorphisms drawn by the NETWORK program illustrates the diversification routes of *ALDH2*. The three-site haplotypes of rs10849970-rs671-rs10849971 best describe the evolutionary steps of the oriental *ALDH2* variant. The ancestral haplotype GGA occurs everywhere. The first mutational step to AGA appeared in sub-Saharan Africa. The second step to AGG started in Ethiopia and increased its frequency across Eurasia to East Asia. AGG subsequently evolved into two derived haplotypes, the oriental haplotype AAG and the American haplotype GGG. The long range haplotype test failed to detect any significant selection signals as high linkage disequilibrium was found in the region of *ALDH2*. Disease association studies of the *ALDH2*487His* allele reported protective effects for some diseases and increased susceptibility for others. Other variants in the region may be involved because of the very high LD. However, our analyses suggest that AGG without the derived allele of rs671 has been weakly selected for rather than AAG. The ALDH2 variants may have played very important roles in the demographic history of Asia.

A multifactor dimensionality reduction (MDR) approach for detecting epistasis in the presence of genetic heterogeneity. *R. Urbanowicz, P. Andrews, J. Moore* Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Genetic epidemiology is confronted with a technology-induced explosion of information and the realization that the majority of common diseases are likely the result of multiple interacting factors. Genetic heterogeneity is an additional phenomenon that is expected to significantly increase the complexity of genetic architecture. Genetic heterogeneity refers to the existence of multiple genetic pathways that yield the same phenotypic outcome. The goal of the present study was to develop a computational method that is capable of detecting epistasis in the presence of genetic heterogeneity. To accomplish this goal we developed a modified version of the Multifactor Dimensionality Reduction method and software that was developed specifically to detect nonlinear gene-gene interactions in the absence of independent effects. The MDR approach uses a constructive induction algorithm to combine two or more polymorphisms in a way that captures interaction effects. Here, we introduce a data-driven constructive induction (DCI) MDR algorithm that systematically develops gene-gene interaction models in different partitions of the data. To evaluate this approach we designed a simulation study with cases and controls generated using a wide variety of different epistasis models with heritabilities ranging from 0.025 to 0.4 and sample sizes ranging from 400 to 3200. We combined data from different model in differing proportions (1:1, 1:2, 1:4) to simulate epistasis in the presence of genetic heterogeneity. While the power to detect both underlying epistatic models varies according to these dataset parameters, permutation testing indicates that DCI MDR can significantly improve power to accurately identify the two independent underlying epistasis models. This study represent a first step toward the development of computational algorithms that address multiple sources of complexity in the genetic architecture of human diseases.

Targeted exome sequencing of the NF1 (Neurofibromatosis Type 1) gene: sequence capture and enrichment (SCE) by a high-density oligonucleotide microarray followed by next generation sequencing (NGS). *L. Chou*[1], *R. Mao*[1,2] 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, UT.

The recent introduction of instruments capable of generating millions of DNA sequence reads in a single run is rapidly changing the view of genetics. These instruments include: GS FLX (Roche 454), genome analyzer II (Illumina), SOLiD (ABI), and more. While implementation of these NGS instruments in a diagnostic laboratory remains in the future, the goal of the current study was to determine the feasibility of using SCE for specific genomic regions of interest by an oligonucleotide microarray followed by a NGS for targeted re-sequencing. In this pilot study, we selected *NF1* (17q11.2) as the target using 2 full-gene sequenced samples. With the existing pseudogenes, consisting of 58 exons and harboring complex genomic structures such as repetitive and Alu sequences, development of a comprehensive sequencing assay for the *NF1* is a challenge. After genomic DNA fragmentation, functional *NF1* sequences were captured and enriched by hybridizing to a custom-designed oligonucleotide microarray (385,000 features). The unbound fragments were removed through washing and the captured fragments were eluted and amplified to add specific tags for the following GS FLX sequencing. The initial call results showed 100% concordance between the SCE-NGS approach *vs*. the sequenced data. One sample possesses an insertion (an Alu repetitive element) close to exon 6 and the other sample possesses a single nucleotide deletion in exon 1. The percentage of captured and enriched pseudogene fragments was also analyzed by alignment against the reference sequence. In conclusions, the SCE-NGS approach provides advantages over the Sanger sequencing, such as avoiding initial PCR and pseudogene amplification to improve sequencing specificity, and sequencing multiple large regions of interest (including exons and introns) simultaneously. However, SCE-NGS does require high quantity and quality genomic DNA for initial fragmentation and hybridization processes that may not be suitable for certain sample types.

Genetic Basis of DYT6 Dystonia. *T. Fuchs[1], R. Saunders-Pullman[2,3], D. Raymond[2], P. de Carvalho Aguiar[4,5], A. Brashear[6], S. B. Bressman[2,3], L. J. Ozelius[1]* 1) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Neurology, Beth Israel Medical Center, New York, NY; 3) Department of Neurology, Albert Einstein College of Medicine, Bronx, NY; 4) Instituto Israelita de Ensino e Pesquisa Albert Einstein, Hospital Israelita Albert Einstein, São Paulo-SP, Brazil; 5) Department of Neurology and Neurosurgery-Universidade Federal de São Paulo, São Paulo-SP, Brazil; 6) Department of Neurology, Wake Forest University School of Medicine, Winston-Salem, NC.

Dystonia is a movement disorder characterized by twisting movements and abnormal postures. The molecular pathophysiology of dystonia is not well understood, in part due to limited knowledge of the genetic basis of the disorder. At least 15 different types of dystonia can be distinguished genetically, most of which are inherited in an autosomal dominant (AD) manner with reduced penetrance. Six types, DYT1, 2, 4, 6, 7 and 13, comprise primary forms, where dystonia is the only neurologic feature. The genetic basis for only one of these, DYT1, responsible for most cases of early onset generalized dystonia, has been identified and is caused by a heterozygous three basepair in-frame deletion in the TOR1A gene. DYT6 is a primary torsion dystonia that is dominantly inherited with reduced penetrance of about 60 percent. It has been mapped to a 23cM region spanning the centromere between markers D8S2317 and D8S232 in three Amish-Mennonite families who share a disease haplotype across this region. We report here the identification of the gene causing Primary Torsion Dystonia of mixed type (DYT6). We found a founder Insertion/Deletion mutation underlying DYT6 in the Amish-Mennonite population. Furthermore, we detected several different mutations in this gene in populations of distinct ethnic origins. The discovery of the genetic basis for DYT6 affords a window into understanding the other dystonia subtypes. It furthermore provides a venue for investigation leading to deciphering the pathophysiology and devising novel treatments for this poorly understood and disabling disease.

Mitochondrial DNA content in various tissues of patients with mtDNA depletion syndrome. *L. Tang, D. Dimmock, L. Wong* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The mitochondrial DNA depletion syndromes (MDDS) are autosomal recessive disorders characterized by a tissue specific reduction in cellular mitochondrial DNA (mtDNA) content. However, with at least 9 genes reported to result in mitochondrial DNA depletion (ECGF-1, POLG, DGOUK, Tk2, SUCLA2, MPV17, SUCLAG1, RRM2B, and TWINKLE), mutation based testing is expensive. It would be of great value if a simple method can be used to screen for mtDNA depletion before sequencing analysis of the genes. The purpose of this study is to evaluate the potential usage of real-time quantitative polymerase chain reaction (RT qPCR) in the measurement of the mtDNA content in various tissues and to determine the relevant tissues to be used for the diagnosis of mtDNA depletion syndrome. In this study we analyzed 370 blood, 343 muscle, and 29 liver specimens to establish reference ranges for mtDNA content. The mtDNA content is increased by age in muscle but not in blood or liver samples. We also evaluated the mtDNA content in different tissues from affected patients with proven mutations in POLG, DGOUK, MPV17, and TK2 genes responsible for mtDNA depletion. As a screening test mtDNA content in blood appears to be specific but not very sensitive. Conversely, severe mtDNA depletion can be easily detected in the affected tissues such as muscle of patients with TK2, and liver of patients with MPV17, DGUOK, and POLG mutations, and could provide the basis for a rapid and accurate test.

Evidential Analysis of Genome-Wide Association Studies: Sample Size and Multiple Testing Implications. *L. J. Strug[1,2], S. E. Hodge[3,4], T. Chiang[1]* 1) Child Health Eval Sci, Hosp for Sick Children; 2) Pub Health Sci, University of Toronto, Toronto, Canada; 3) Biostat, Columbia University; 4) NYSPI, New York, NY.

Genome-wide association studies (GWAS) grapple with methodology choice for measuring strength of evidence, choosing sample size, and adjusting for multiple testing (MT). We present the evidential paradigm (EP) for GWAS analysis, which uses likelihood ratios (LRs) to measure strength of evidence (as opposed to a p-value or Bayes factor), and provides informative graphical displays for drawing inferences. We derive EP GWAS methodology (cf. Strug, Hodge 2006a,b) to (1) estimate sample size; (2) adjust for MT; and (3) provide graphical displays for analysis. (1) *Sample Size* Choose sample size to control the probability of weak association signals (W) rather than Type I error (M). Via simulation we show, for LR32 representing strong evidence, that to detect an OR1.5 at one locus with n=200 cases and n=200 controls results in W=0.134 and M=0.005. For n=300 cases and controls, W=0.039 and M=0.004. Both M and W decrease as n gets large; moreover, when W is small, M is *very* small. (2) *Multiple Testing* With M small at one locus, the Family Wise Error Rate (FWER) may still be large with N SNPs analyzed. The EP decouples error probabilities (W, M) from evidence measures and MT adjustments are performed on error rates (i.e. FWER) rather than requiring larger LRs. We present three approaches to FWER control, (a) one for a single stage design, (b) one for two-stage (replication) designs, and (c) one working with the "x-FWER," i.e., the probability of making at least x errors in N SNP tests. Method (c) chooses smaller n than (a) or (b), and (b) has smaller bounds on the FWER but higher W. (3) *Application to Cystic Fibrosis Dataset* We show GWAS plots of likelihood intervals for SNPs by base pair position. Those with LRs<32 are greyed-out, highlighting important regions. *Conclusion* EP and Frequentist likelihood-based methodologies generally provide similar results on a given set of data. However, incorporating the planning and MT adjustment approaches of the EP may identify important signals that would be interpreted as weak with Frequentist analysis.

Fast and flexible simulation of DNA sequence data. *G. K. Chen[1], P. Marjoram[1], J. D. Wall[2]* 1) Department of Preventive Medicine, Keck School of Medicine, USC, Los Angeles, CA; 2) Inst Human Genetics, Univ California, San Francisco, San Francisco, CA.

Simulation of genomic sequences under the coalescent with recombination has conventionally been impractical for regions beyond tens of megabases. Here, we present an algorithm, implemented in the program MACS, that can efficiently simulate haplotypes under any arbitrary model of population history. We present several metrics comparing the performance of MACS against several available simulation programs. Practical usage of MACS is demonstrated through a comparison of measures of linkage disequilibrium between generated program output and real genotype data from populations considered to be structured.

DNA methylation profiling in placentae of growth restricted fetuses and controls using CpG Island (CGI) microarrays. *J. Ferreira[1,2], S. Choufani[1], D. Grafodatskaya[1], C. Shuman[3], S. Keating[5], D. Chitayat[3,4], J. Kingdom[4], R. Weksberg[1,2,3]* 1) Gen & Genomics Prog, Hosp Sick Children, Toronto, ON, Can; 2) Inst Medical Sciences, Univ of Toronto, ON, Can; 3) Div Clinical and Metabolic Genetics, Hosp Sick Children, Toronto, ON, Can; 4) MFM Division, Dep Obstetrics & Gynecology, Mt Sinai Hosp, Toronto, ON, Can; 5) Dep Pathology, Mt Sinai Hosp, Toronto, ON, Can.

The purpose of this work is to validate the use of microarray technology for the detection of altered methylation profiles in fetal growth restriction (FGR) placentae in comparison with controls. DNA was extracted from placentae of 8 FGR cases and 8 controls and control blood samples. Fractioned genomic DNA and a methylated enriched fraction obtained through immunoprecipitation with an antibody to the methylated cytosine (MeDip) was co-hybridized to Agilent 244K CGI microarrays. To validate the technique we tested for reproducibility and the capability to detect known methylation differences. Pyrosequencing of bisulphite converted genomic DNA was used to validate the differences found between cases and controls after analysis of the array data. Reproducibility was confirmed by verification that 1) Correlation among placental samples and among blood samples was higher than 90%; lower correlations were found between different tissues. 2) UCSC genome browser analysis of the microarray data demonstrated the expected higher methylation levels for female versus male X chromosomes; further, known methylation differences were detected in blood versus placenta in H19 promoter and IGF2DMR2. This difference was used to model the analysis of the array data from FGR and control samples using the Partek Genomics Suite. One of the first differences found between FGR and controls has already been confirmed by pyrosequencing. Our preliminary results have shown that our methodology is reliable and can be used to compare the methylation status of CGIs between FGR and control DNA samples.

Rapid identification of mutations in the CPT1A gene using SURVEYOR nuclease. *A. B. Santani[1], T. Tischler[1], S. Narayan[1], M. Bennett[1], S. Olpin[2], C. A. Stolle[1]* 1) Dept Pathology & Lab Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Sheffields Childrens Hospital, UK.

Carnitine palmitoyltransferase 1A (CPT1A) deficiency is a rare autosomal recessive disorder of mitochondrial long-chain fatty acid oxidation. CPT1 is located in the outer mitochondrial membrane and facilitates the transport of long chain fatty acids in to the mitochondria for oxidation. Mutations in the CPT1A gene (hepatic isoform) result in reduced activity of CPT I, which prevents the entry of fatty acids in to the mitochondria for energy production. CPT1A deficiency usually presents in a previously normal child as hepatic encephalopathy, precipitated by fasting or gastrointestinal illness. Typical symptoms include hypoketotic hypoglycemia and sudden onset of liver failure. CPT1A deficiency, although commonly seen in Alaskan and Hutterite populations, is quite rare in the general population with fewer than 50 cases reported worldwide. Even fewer cases have been characterized at the molecular genetics level. In this study, we developed an assay to screen for point mutations in the CPT1A gene using SURVEYOR nuclease and the Transgenomic WAVE system. Using this approach, we screened five patients with enzymatically confirmed CPT1 deficiency. Seven different mutations were identified. Of these seven variants, mutations in two residues have been previously reported. The remaining five were novel mutations that included three nonsense mutations, one splice site mutation and a 1469 bp deletion encompassing exon 12 of the CPT1A gene. All five patients were successfully genotyped using this assay, in that, these patients were either homozygotes or compound heterozygotes for mutations in the CPT1A gene i.e., a 100% detection rate in enzymatically confirmed CPT1A deficient patients. The SURVEYOR nuclease assay is a highly sensitive technique for rapid detection of mutations at a lower cost compared to direct sequencing. Use of genetic testing for early identification of CPT1A in patients and at risk family members improves diagnostic certainty and reduces morbidity since early recognition of clinical manifestations will allow timely intervention and improved outcome.

Functional impact of the expression of the transcription repressor ETV6 in humanized mice models of leukemia.

J. Larose[1], M. Bossolasco[1], S. Langlois[1], F. Fontaine[1], S. Desjardins[1], N. Heveker[1,3], E. Haddad[1,4], D. Sinnett[1,2,3] 1) Hematology-Oncology Dept, Research center CHU Sainte-Justine, Montreal, Qc, Canada; 2) Pediatric Dept, University of Montreal, Montreal, Qc, Canada; 3) Biochemistry Dept, University of Montreal, Montreal, Qc, Canada; 4) Microbiology and immunology Dept, University of Montreal, Qc, Canada.

Deletions at chromosome 12p12-13 are observed in 26 to 47% of childhood pre-B acute lymphoblastic leukemia (ALL) cases suggesting the presence of a tumour suppressor gene (TSG). Accumulating genetic and functional evidence points to ETV6 as being the most probable TSG targeted by the deletions. ETV6 is a ubiquitously expressed transcription factor of the ETS family with very few known targets. To better understand the contribution of ETV6 to leukemia, we have developed humanized mouse models of leukemia. This was achieved by injecting pre-B ALL cell lines Nalm-6 (ETV6+) and REH (ETV6-) in very immunodeficient mice NOD/SCID/c^{null}. In both models, we were able to recapitulate the human leukemia features but with different organ dissemination patterns: Nalm6 cells were found mainly in circulation (peripheral blood and spleen) whereas REH cells were found in bone marrow. To determine to which extend ETV6 status was responsible for differences in colonization capabilities, we genetically modified using lentiviral constructs both cell lines by restoring (overexpression) or silencing (shRNA) ETV6 expression. The modulation of ETV6 expression had a substantial impact on the dissemination pattern suggesting a role in either homing or migration processes. Both *in vitro* and *in vivo* studies indicate that ETV6 contributes to cellular migration. This work identify ETV6 as a key player in leukemia cells migration and provide an *in vivo* model for further studies on the role of ETV6 in human leukemogenesis.

Using Adaptive Numerical Integration for Multidimensional Genetic Problems. *S. Seok[1], Y. Huang[1], M. Evans[2], V. Vieland[1]* 1) Battelle Center for Mathematical Medecine, The Research Institute at Nationwide Childrens Hospital, Columbus, OH; 2) Dept. of Statistics, University of Toronto, Toronto, Canada.

Various statistical methods in genetics require numerical integration (NI). While MCMC is frequently used for this purpose, MCMC is not feasible in some settings. For example, the PPL framework requires integration of multidimensional likelihoods lacking closed form solutions, and for which the design of suitable Gibbs or Metropolis-Hastings samplers does not seem possible. We have therefore developed an alternative approach to NI for this problem which may be useful in other contexts as well. This approach is based on an integration algorithm known as DCUHRE. DCUHRE is a sub-region adaptive algorithm using an embedded family of fully symmetric multiple quadrature rules. These rules have the property that they integrate polynomials, up to a certain degree based on the number of points in the rule, exactly over hypercubes. More significantly, DCUHRE adapts to the integrand by iteratively subdividing the domain of integration into subregions based upon error estimates of the integral approximations in current subregions. This results in evaluating the integrand more frequently at points where significant contributions to the integral occur. Further DCUHRE records meaningful error estimates. We have implemented a version of DCUHRE specifically adapted to genetic likelihoods in the PPL software package Kelvin. This includes, for instance, ordering constraints on penetrances via variable transformation to treat the penetrance region as a hypercube. We have performed extensive comparisons against a brute force fixed-grid approach to NI as an available method to approximate these integrals with arbitrarily high precision. We show that our algorithm is highly accurate and efficient when applied to genome-wide gene mapping studies. In particular, it requires less than 0.01% of the brute force calculations for corresponding accuracy. In practical terms, this allows us to complete in 60 hours a genome-wide linkage or linkage disequilbrium scan that previously could have taken 7 years using the brute force approach.

Identification and functional characterization of sequence variation in the Zellweger spectrum of peroxisome biogenesis disorders. *W. Yik[1], S. Steinberg[2], K. Ramaswamy[1], A. Moser[2], H. Moser[2], J. Hacia[1]* 1) Dept Biochem & Molecular Biol, Inst Genetic Medicine, Los Angeles, CA; 2) 2Peroxisomal Diseases Laboratory Kennedy Krieger Institute Baltimore, MD, USA.

Peroxisome biogenesis disorders (PBD) are a heterogeneous group of autosomal recessive neurodegenerative disorders affecting multiple organ systems. Approximately 80% of PBD patients are classified in the Zellweger syndrome spectrum (PBD-ZSS). We conducted sequencing assays to survey the mutational spectrum in the coding regions and adjacent splice junction of five PEX genes (PEX1, PEX6, PEX10, PEX12, and PEX26) critical for normal peroxisome assembly in a cohort of 58 PBD-ZSS patients. We identified 69 unique sequence variants, including 18 novel mutations predicted to disrupt protein function and 2 novel silent variants. For two patients where two different PEX genes contained missense alleles affecting conserved amino acids, we conducted cell fusion complementation analyses to assign the identity of the disease-causing gene. By combining genotype from these 58 individuals with an additional 33 other PBD-ZSS patients, we found that mutations in the PEX1 (59.3%), PEX6 (9.9%), PEX10 (3.3%), PEX12 (7.7%), and PEX26 (5.5%) genes account for 85.7% of PBD-ZSS patients. Overall, we provide empirical data to estimate the relative fraction of disease-causing alleles that occur in the coding and splice junction sequences of these five PEX genes as well as identifying instances where mutations are found in multiple PEX genes. This is beneficial for efforts aimed at establishing rapid, sensitive, and cost-effective clinical diagnostics for PBD-ZSS patients.

Frequency distribution and selection in 4 pigmentation genes in Europe. *M. P. Donnelly, W. C. Speed, J. R. Kidd, A. J. Pakstis, K. K. Kidd* Dept Genetics, Yale Univ Sch Med.

Pigmentation is one of the more obvious forms of variation in humans, particularly in Europeans where one sees more within group variation in hair and eye pigmentation than in the rest of the world. We studied 4 genes (SLC24A5, SLC45A2, OCA2 and MC1R) that are believed to contribute to the pigment phenotypes in Europeans. SLC24A5 has a single functional variant that leads to lighter skin pigmentation. Data on 83 populations worldwide (including 55 from our lab) show the variant (at rs1426654) has almost reached fixation in Europe, Southwest Asia, and North Africa, has moderate to high frequencies (.2-.9) throughout Central Asia, and has frequencies of .1-.3 in East and South Africa. The variant is essentially absent elsewhere. SLC45A2 also has a single functional variant (at rs16891982) associated with light skin pigmentation in Europe. Data on 84 populations worldwide show the light skin allele is nearly fixed in Northern Europe but has lower frequencies in Southern Europe, the Middle East and Northern Africa. In Central Asia the frequency of the SLC45A2 variant declines more quickly than the SLC24A5 variant. It is absent in both East and South Africa. In OCA2 we typed 4 SNPs (rs4778138, rs4778241, rs7495174, rs12913832) with a haplotype associated with blue eyes in Europeans. This haplotype shows a Southeastern to Northwestern pattern in Europe with frequencies of .25 (.05 homozygous) in the Adygei to .85 (.75 homozygous) in the Danes. In MC1R we typed 5 SNPs (rs3212345, rs3212357, rs3212363, C_25958294_10, rs7191944) that cover the entire MC1R gene and found a predominantly European haplotype that ranges in frequency from .35 to .65 in Europe, reaching its highest levels in Southwest Asia and Northwestern Europe. Extended Haplotype Heterozygosity (EHH) and normalized Haplosimilarity (nHS) show evidence of selection at SLC24A5 in not only our European and Southwest Asian populations but also our East African populations. Neither SLC45A2 or OCA2 showed evidence of selection in either test. MC1R did not show evidence of selection for our European specific haplotype but we did see some evidence both upstream and downstream in our nHS test in Europe.

Identifying Recurrent DNA Copy Number Aberrations in Lung Cancer by Correlation Matrix Diagonal Segmentation. *Q. Zhang[1], L. Ding[2], A. Kraja[1], I. Borecki[1], M. A. Province[1]* 1) Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO; 2) Genome Center, Washington University School of Medicine, St. Louis, MO.

As a phenomenon of DNA amplification or deletion taking place at the same chromosomal region across multiple cancer patients, recurrent copy number aberration (RCNA) may play an important role in molecular mechanism of oncogenesis and provide useful information for the diagnosis and treatment of cancers. Most existing approaches of RCNA analysis require data discretization for individual samples, which may reduce statistical power and suffer computational burden. We have developed a novel approach, Correlation Matrix Diagonal Segmentation (CMDS), which directly uses raw copy number data to identify RCNAs with no need of discretization for individual samples. CMDS significantly reduces computational time, and therefore provides an efficient tool for genome-wide and large-population-based analysis. Simulation shows that CMDS can achieve higher statistical power compared with typical discretization-based approaches. Applying CMDS to the Affymetrix Human Mapping 250K Sty SNP Array data of matched tumor and normal tissue samples from 357 lung cancer (adenocarcinoma) patients in the Tumor Sequencing Project (TSP), we identify multiple RCNA regions on chromosomes 1,5,6,7,8,9,11,12,14,17,19 and 22. We investigate the distribution of these RCNAs among individual samples and identify five regions (5q35, 7p12, 11q13, 12p12, 12q15) showing significant differences of amplification frequencies between ever-smoking and never-smoking patients. Multiple tumor-related genes (EGFR, KRAS, CCND1, MDM1 and MDM2, etc.) are located within these regions. Of particular interest are the nuclear phosphoproteins MDM1 and MDM2, which bind to and inhibit trans-activation by tumor protein TP53. The stronger amplifications of the two genes in never-smoking patients are validated using qPCR data from an independent cohort of 121 patients. MDM2 is also validated at the RNA expression level by the data from the Affymetrix HGU133 arrays of 75 patients.

Functional variants in *TGFB1* are associated with increased airway responsiveness and disease exacerbations in children with asthma. *S. Sharma[1,2], B. A. Raby[1,2,3], M. Soto-Quirós[4], L. Avila[4], A. J. Murphy[1,5], B. Klanderman[1], J. Sylvia[1], S. T. Weiss[1,2,3], J. C. Celedón[1,2,3]* 1) Dept Respiratory Epidemiology, Channing Laboratory, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine, Center for Genomic Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA, United States; 4) Division of Pediatric Pulmonology, Hospital Nacional de Niños, San José, Costa Rica; 5) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Rationale: There has been no association study of TGFB1 and airway responsiveness or disease exacerbations in asthmatics. **Objectives**: To test for association between single nucleotide polymorphisms (SNPs) in TGFB1 and asthma severity in childhood. **Methods**: We tested for association between 9 SNPs in TGFB1 and asthma and indicators of severity (airway responsiveness and exacerbations) in two cohorts: 416 Costa Rican parent-child trios, and 465 families of white children in the Childhood Asthma Management Program (CAMP). We also tested for interaction between these SNPs and dust mite allergen on asthma severity. The analysis was conducted with the family-based association test statistic under a dominant genetic model. **Results**: The A allele of the promoter SNP rs2241712 was associated with increased airways responsiveness in Costa Rica (P=0.0006) and CAMP (P=0.01), and the C allele of a functional SNP (rs1800469) was associated with increased airways responsiveness in both cohorts (P 0.02). There was an interaction between the C allele of SNP rs1800471 and dust mite allergen exposure on airways responsiveness (P=0.03 in both cohorts). The T allele of a coding SNP in TGFB1 (rs1982073) was associated with a reduced risk of asthma hospitalizations (P=0.01 in both samples). There was also an interaction between the A allele of SNP rs2241712 and dust mite allergen on asthma-related hospitalizations in both cohorts. **Conclusions**: SNPs in TGFB1 may influence airway responsiveness and disease exacerbations in children with asthma. Dust mite allergen exposure may modify the effect of TGFB1 SNPs on airways responsiveness and hospitalizations in children with asthma.

Regulation of the master transcription factor RUNX2 by the nuclear. *P. Fonseca[1], T. Yang[1,2], T. Bertin[1], B. Dawson[1,2], Y. Chen[1], G. Zhou[3], B. Lee[1,2]* 1) Baylor Col Medicine, Houston, TX; 2) HHMI; 3) Case Western Reserve University.

RUNX2 is a member of the RUNT family of transcription factors that is essential for osteoblast formation and chondrocyte maturation. Loss-of-function mutations result in cleidocranial dysplasia (CCD). RIP (RUNX2-Interacting Protein) was isolated in a yeast 2-hybrid screen of a human osteosarcoma cDNA library. Two families with rearrangements involving the upstream region of the gene have a CCD phenotype with upregulation of RIP. RIP down-regulated the transactivation by RUNX2 in a dose-dependent manner in 10T1/2 and ROS17/2 cells. It localizes to the inner nuclear membrane. Its major components are lamins, which have an important role in nuclear organization and transcriptional regulation. Mutations in lamin and associated proteins result in laminopathies, including mandibuloacral dysplasia (MAD) that partially phenocopies CCD. RUNX2 function can be regulated at different levels, but its subnuclear localization is crucial. We hypothesize that the skeletal defects observed in laminopathies are due to the disruption of lamin interactions with key transcriptional regulator RUNX2. Knockdown of Rip in ROS17/2 cells up-regulates Runx2, Alp and Ocn while silencing Lmna down-regulates both Runx2, Osx and downstream targets. Lamin interacts with RIP through the tail domain, which is mutated in MAD patients. Lamin versions carrying MAD mutations have altered binding properties but show similar nuclear localization. RUNX2 partially co-localizes at the nuclear rim in ROS17/2 cells and mouse calvarial osteoblasts. Lamin is required for terminal differentiation of C2C12 cells into osteoblasts. To evaluate the in vivo consequences of RIP gain-of-function, we generated transgenic mice over-expressing RIP in the osteoblast. Multiple lines exhibited severe osteopenia and mineralization defects. Bone formation and mineral apposition rates were markedly reduced. We also observed a higher number of adipocytes in the bone marrow. Altogether, these are signs of a premature ageing bone. These data link RUNX2 function, the novel RIP protein, and lamin in a transcriptional regulatory complex and suggest a new mechanism for regulating skeletogenesis at the nuclear lamina.

The CHD7 protein, mutated in CHARGE syndrome, binds to enhancers marked with mono- and di-methylated H3K4. *M. P. Schnetz, C. F. Bartels, D. Balasubramanian, R. Balaji, T. LaFramboise, P. C. Scacheri* Genetics, Case Western Reserve University, Cleveland, OH.

CHARGE syndrome is characterized by multiple birth defects including coloboma of the eye, heart defects, choanal atresia, growth retardation, genital and ear abnormalities. De novo mutations in the gene encoding chromodomain helicase DNA-binding protein 7 cause most cases of CHARGE syndrome, but little is known about the function of the protein. To investigate the potential role of CHD7 in transcription and CHARGE syndrome, we mapped the distribution of the CHD7 protein on chromatin using the approach of ChIP on tiled microarrays (ChIP-chip). These studies were performed in human colorectal carcinoma cells, human neuroblastoma cells, and mouse embryonic stem (ES) cells before and after differentiation into neural precursor cells. The results indicate that CHD7 localizes to discrete locations along chromatin that are specific to each cell type. The CHD7 sites demonstrate several features of gene enhancers. First, most of CHD7 binding occurs >2 kb from 5' ends of genes, which is consistent with the location of enhancers relative to their target genes. Second, most of the CHD7 sites are contained within DNase hypersensitive sites that are known to harbor regulatory elements such as enhancers. Third, genes located within the vicinity of the CHD7 sites are expressed at relatively high levels. Fourth, a significant number of the CHD7 sites overlap with enhancers that were independently identified by ChIP-chip and computationally based methods. We also determined that the cell-specific binding of CHD7 correlates with a subset of histone H3 mono- and di-methylated at lysine 4 (H3K4me1/2). The CHD7 sites change concomitantly with H3K4me1/2 during ES cell differentiation, suggesting that H3K4me1/2 is part of the epigenetic signature that defines lineage-specific recruitment of CHD7 to enhancers. These findings suggest that CHD7 influences the rate of transcription by binding to gene enhancers, raising the possibility that the congenital anomalies in CHARGE syndrome are due to alterations in transcription of tissue-specific genes normally regulated by CHD7 during development.

Ancestry Informative Marker Sets for Determining Continental Origin: Validation and extension using Human Genome Diversity Panels. *R. Nassir[1], R. Kosoy[1], C. Tian[1], P. A. White[2], L. M. Butler[1], G. Silva[3], R. Kittles[4], M. E. Alarcon-Riquelme[5], P. K. Gregersen[6], J. W. Belmont[7], F. M. De La Vega[2], M. F. Seldin[1]* 1) Rowe Program Gen, Univ California, Davis, Davis, CA; 2) Applied Biosystems, Foster City, CA; 3) Obras Sociales del Hermano Pedro, Antigua, Guatemala; 4) Univ Chicago, Chicago IL; 5) Uppsala Univ, Uppsala, Sweden; 6) North Shore-LIJ Res Inst, Manhasset, NY; 7) Baylor College Medicine, Houston, TX.

To provide a resource for assessing continental ancestry in a wide variety of human genetic studies we identified, validated and characterized a set of 128 ancestry informative markers (AIMs). The markers were chosen for informativeness, genome-wide distribution, and genotype reproducibility on two platforms (TaqMan and Illumina arrays). Initial studies examined genotyping data from 825 subjects with diverse ancestry, including European, East Asian, Amerindian, West African, South Asian, Mexican, and Puerto Rican. A comprehensive set of 128 AIMs and subsets as small as 24 AIMs were shown to be useful for ascertaining the origin of subjects from particular continents, and to correct for population stratification in admixed population sample sets. Additional analyses using Human Diversity Panel Genotypes have confirmed the ability of the 128 AIMs to distinguish diverse population groups including those not represented in our previous data sets. These included populations from Oceana, and multiple additional South Asian, East Asian, Sub-Saharan African, Amerindian and European populations. In addition to being able to effectively identify Oceanic groups, these AIMs provide some population substructure information, for example, distinguishing Middle Eastern from Northern European population groups and Pygmi from other Sub-Saharan African population groups. Our findings provide general guidelines for the application of specific AIM subsets as a resource for wide application in subject set selection and in association testing. We conclude that investigators can use TaqMan assays for the selected AIMs as a simple and cost efficient tool to control for large differences in continental ancestry when conducting association tests in ethnically diverse populations.

A hotspot splice site mutation in LEPRE1 affects splice form, responsible for prolyl 3-hydroxylation of type I collagen, and causes recessive osteogenesis imperfecta. *P. J. Coucke[1], A. Willaert[1], S. Symoens[1], K. Gevaert[2,3], H. Kayserili[4], A. Megarbane[5], F. Malfait[1], A. De Paepe[1]* 1) Dept Med Genet, Univ Hosp Ghent, Ghent, Belgium; 2) Dept of Bioch, Ghent Univ, Belgium; 3) Dept of Medical Protein Res, VIB-Ghent, Belgium; 4) Div of Medical Genet, Instanbul Univ, Turkey; 5) Unit of Med Genet, University St-Joseph, Lebanon.

Recently, it has been shown that recessive forms of Osteogenesis Imperfecta (OI) can be caused by the absence of 3-hydroxylation of Pro986 in the 1(I)-collagen chain, resulting from defects in prolyl 3-hydroxylase 1 (P3H1) or cartilage-associated protein (CRTAP). Together with cyclophilin B (CyPB), P3H1 and CRTAP are constituents of the prolyl 3-hydroxylation complex. We screened LEPRE1 (encoding P3H1), CRTAP and PPIB (encoding CyPB) in a European/Middle Eastern cohort of lethal/severe OI-like patients without a type I collagen mutation. While no mutations were found in CRTAP and PPIB, 4 novel homozygous and compound heterozygous mutations were identified in LEPRE1 in 4 probands. Surviving probands showed a severe short stature, a relatively round face, white sclerae and rhizomelia with long hypermobile hands. Radiographs revealed progressively increasing severe matrix disorganisation with bulbous metaphyses. Interestingly, a hotspot splice site mutation was identified in two of four probands. As confirmed by RT-PCR, the latter mutation converts a suboptimal into an optimal donor splice site in intron 14, resulting in a full switch in donor splice site utilization. Consequently, this mutation affects only one of the three LEPRE1 mRNA splice forms, detected in this study. The affected splice form encodes a 736 amino acid protein. While western blotting and immunocytochemical analysis of fibroblast cultures showed absence of P3H1 protein in patients compared to controls, mass spectrometry and SDS-urea-PAGE data indicated respectively a severe reduction of 1(I)Pro986 3-hydroxylation and a resulting overmodification of type I (pro)collagen chains in the patients. These analyses showed that the 3-hydroxylation function of P3H1 is restricted to a single protein splice form, comprising 736 amino acids.

The association of lobular breast cancer with germline mutations of *CDH1* . *K. Schrader[1,2], S. Masciari[3], N. Boyd[2], J. Senz[1], P. Kaurah[2], M. B. Terry[4], E. John[4], I. L. Andrulis[4], J. Knight[4], F. P. O'Malley[4], M. Daly[4], P. Bender[4], M. C. Southey[4,5], J. L. Hopper[4,5], J. Garber[3], D. G. Huntsman[1,2], kConFab* 1) Department of Pathology and Laboratory Medicine, UBC, Vancouver, BC; 2) Hereditary Cancer Program, BCCA, Vancouver, BC; 3) Department of Medical Oncology, DFCI, Boston, MA; 4) Breast Cancer Family Registry (B-CFR); 5) University of Melbourne, Melbourne, Vic.

Background: *CDH1* encodes the cell-cell adhesion molecule, E-cadherin, for which loss of expression facilitates the infiltrative and metastatic potential of cancers. Germline mutations in *CDH1* are associated with hereditary diffuse gastric cancer (HDGC), and in this setting female carriers have been estimated to have a 39-50% risk of lobular breast cancer (LBC) by age 80 years.

Aim: To determine the frequency of *CDH1* germline mutations in individuals with early-onset LBC or those with LBC and a family history of multiple breast cancers but no gastric cancers.

Methods: Germline DNA analysis of *CDH1* in women with LBC, for whom germline *BRCA1* and *BRCA2* mutations have been excluded, who have been (1) diagnosed before the age of 45 years or (2) diagnosed at any age and have a family history of breast cancer.

Results: Analysis of 194 LBC cases has thus far revealed two novel missense mutations predicted to affect protein function. Functional assays to assess their pathogenicity along with germline analyses of the remaining 200 cases are currently underway. Several unreported silent changes have also been identified and will be measured in a case-control sample to assess whether they are associated with LBC risk.

Conclusion: Germline *CDH1* mutations may cause a small proportion of familial and early onset LBC.

Multi-study fine mapping of a chronic obstructive pulmonary disease susceptibility locus on chromosome 2q. *C. P. Hersh[1], S. G. Pillai[2], G. Zhu[2], D. A. Lomas[3], I. C. G. N. Investigators[4], P. Bakke[5], A. Gulsvik[5], D. L. DeMeo[1], A. A. Litonjua[1], J. J. Reilly[1], E. K. Silverman[1]* 1) Brigham and Women's Hospital, Boston, MA; 2) GlaxoSmithKline, Research Triangle Park, NC; 3) Cambridge Institute for Medical Research, Cambridge, UK; 4) International COPD Genetics Network; 5) University of Bergen, Norway.

Background: Two independent family-based studies of chronic obstructive pulmonary disease (COPD) have identified linkage for COPD-related traits to chromosome 2q. We hypothesized that merging results of high-resolution SNP mapping in four separate populations would lead to the identification of COPD susceptibility genes.

Methods: Within the chromosome 2q linkage region, 2843 SNPs were genotyped in 1839 individuals from 603 families from the International COPD Genetics Network (ICGN) and in 806 COPD cases and 779 controls from Norway. 2484 SNPs were genotyped in 309 patients with severe COPD from the National Emphysema Treatment Trial (NETT) and 330 community controls. 149 SNPs were genotyped in 949 individuals from 127 families in the Boston Early-Onset COPD Study. Family-based and case-control genetic association tests were performed, as appropriate for each study population.

Results: Merging the results of the two case-control analyses, 15 of the 790 overlapping SNPs had a combined p0.01. Five of these 15 SNPs were associated with COPD-related traits in the ICGN families. The association with one of these five SNPs, located in the gene XRCC5, was replicated in the Boston Early-Onset COPD Study families, with a combined $p = 2 \times 10^{-5}$ across the four studies. Genotype imputation was used to confirm the association with XRCC5.

Conclusions: By combining data from COPD genetic association studies conducted in four independent patient samples, we have identified XRCC5, an ATP-dependent DNA helicase required for immunoglobulin V(D)J rearrangement, as a potential COPD susceptibility gene.

A new case of keratin 14 functional knockout causing recessive EBS. *A. Décha[1], M. Titeux[1], L. Tonasso[1], C. Prost-Squarcioni[2], V. Pendaries[1], G. Albérola[1], J. E. Mejía[1], A. Hovnanian[1,3]* 1) U563, Inserm, Toulouse, France; 2) 2EA3410, Histology Laboratory, University of Paris XIII, Bobigny, France; 3) Purpan Hospital, Departement of Medical Genetics, Toulouse.

Epidermolysis bullosa simplex (EBS) is a group of inherited skin disorders characterized by intra-epidermal blistering upon mild trauma. Most cases are caused by dominant missense mutations in either the *KRT5* or *KRT14* genes encoding keratins 5 and 14, respectively. Only 5% of EBS cases are inherited recessively. We describe a 30-year-old patient with recessive EBS Köbner, born to first-cousin parents. He presented with generalized skin blistering, often hemorrhagic and more prominent on the hands and feet, associated with hyperkeratosis and the absence of dermatoglyphs. Mucosal involvement was observed as blisters on the tongue and an anal fissure. He had a hoarse voice since birth and developed bilateral hypoacousia since age 10. Electron microscopy of the skin revealed a cleavage within the cytoplasm of basal keratinocytes, and the absence of keratin filaments. Keratin 5 immunostaining in skin sections was normal, while keratin 14 was absent and keratin 15 slightly reduced. *KRT14* sequencing on leukocyte DNA showed a homozygous 1-bp deletion (c.827delC) in exon 4 resulting in a frameshift and a premature termination codon (p.Pro276LeufsX4). Western-blot analyses demonstrated the complete lack of keratin 14, while keratin 5 was normally expressed. Quantitative RT-PCR analysis on keratinocyte primocultures confirmed nonsense-mediated *KRT14* mRNA decay while the *KRT5* and *KRT15* mRNA levels were normal. Confocal microscopy demonstrated the presence of keratin 5/keratin 15 heteropolymers in both normal and EBS cultured keratinocytes, suggesting that keratin 15 could partially compensate for the loss of keratin 14, as previously described in keratin 14 knock-out mice and in patients affected with recessive EBS. The parents and the offspring of the patient, who are heterozygous carriers, will be carefully examined for clinical features reminiscent of Naegeli-Franceschetti-Jadassohn syndrome (NFJS), a dominant disorder proposed to arise through keratin 14 haploinsufficiency.

Association between LOXL1 polymorphisms and early-onset primary open-angle glaucoma using ordered subset case-control association analysis (OSACC). *K. Crooks[1], X. Qin[1], Y. Liu[1], J. Gibson[1], K. Hutchins[1], P. Challa[2], R. Allingham[1,2], M. Hauser[1,2], S. Schmidt[1]* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Department of Ophthalmology, Duke University Eye Center, Duke University Medical Center, Durham, NC.

Glaucoma is a complex genetic disorder and a leading cause of blindness for which there is no cure. One useful tool that may ultimately lead to novel therapeutic approaches is the identification of DNA sequence variants that modulate glaucoma risk. Recently, it has been reported that polymorphisms in the lysyl oxidase-like 1 (LOXL1) gene are associated with pseudoexfoliation glaucoma (XFG) in several distinct populations. Our group found no association between 14 tagging SNPs in LOXL1 and the most common form of glaucoma, primary open angle glaucoma (POAG), using 280 cases and 224 controls. However, since POAG is a genetically heterogeneous disease, we applied a novel algorithm for ordered subset case-control association analysis, using age at diagnosis as the clinical covariate. We found that three intronic LOXL1 SNPs showed a significantly stronger association with POAG risk in the subset of cases diagnosed at or before 55 years of age (n=100; permutation test p-values 0.02-0.04). Interestingly, for each of these SNPs, the allele that confers an increased risk of XFG (OR 2.0-2.3 per allele, additive model) is protective for early-onset POAG (OR 0.61-0.63 per allele). For example, allele G at rs4337252 has a frequency of 68.4%, 50.7% and 38.1% in XFG cases, normal controls and early-onset POAG cases, respectively (p=0.001 for XFG; p=0.005 for early-onset POAG). Our results extend the potential role of LOXL1 variants in modulating glaucoma susceptibility, although the alleles that confer risk for XFG appear to be protective for early-onset POAG. Given this observation, we hypothesize that a different biological mechanism than the non-synonymous coding changes implicated in XFG explains the decreased risk of POAG tagged by these intronic sequence variants of currently unknown function. Our data confirm that age-at-diagnosis is an important clinical variable for dissecting the genetic heterogeneity of POAG.

A demogenetic analysis of the LDLR-W66G mutation in the Saguenay-Lac-Saint-Jean (Quebec, Canada) population. *M. Tremblay[1], A. Achkar[1], D. Gaudet[2], D. Brisson[2]* 1) BALSAC Project, Univ Quebec, Chicoutimi, PQ, Canada; 2) Montreal University Community Genomic Medicine Center, Chicoutimi, Qc, Canada.

Familial hypercholesterolemia (FH) is the most prevalent monogenic disorder worldwide. FH is characterized by high plasma concentrations of low-density lipoprotein (LDL)-cholesterol and apolipoprotein B, tendinous xanthomas and an increased risk of premature coronary artery disease. Most often FH is caused by mutations in the LDL receptor (LDLR) gene. FH affects approximately 1 per 350 individuals among Caucasians, but the prevalence is significantly higher in some populations. In the Saguenay-Lac-St-Jean (SLSJ) region (Quebec, Canada), the prevalence of FH is 1:83 and almost 90% of all cases are the consequence of two LDLR gene mutations: a >15 kb deletion in the promoter and exon 1 and a missense mutation (W66G) in exon 3. This study aimed to identify the demogenetic factors that can explain the frequency and the distribution of the LDLR-W66G mutation within the SLSJ population. Analysis was performed on a sample of extended genealogies from 64 FH subjects carrying the LDLR-W66G mutation and 64 non-FH controls. The genealogies were reconstructed using data from the BALSAC population register. Number and occurrences of ancestors, mean genealogical depth, origins and genetic contribution of founders, and kinship coefficients between subjects and controls were measured using the S-Plus based GENLIB software package. Results show that on average, the genealogies have a depth of 10 generations, with some branches reaching up to 16 generations. These genealogies contain more than 300000 occurrences of ancestors, with an average of 16 (controls) to 20 (subjects) occurrences per ancestor. Kinship coefficients are significantly higher among subjects, where they reach a mean value of 0.009 at the 12th generation. Results also indicate that the founders who contributed most to the subjects gene pool came from France some 350 years ago. **Funding**: Supported by the ECOGENE-21 project (CIHR TEAM grant # CTP-82941) and by the Social Sciences and Humanities Research Council of Canada (grant # 410-2006-1414).

Preimplantation Genetic Diagnosis (PGD) for Metaphyseal Chondrodysplasia, Schmid Type [COL10A1, TYR628TER]and Aneuploidy. *E. Pomerantseva, I. Barsky, T. Sharapova, S. Rechitsky, Y. Verlinsky* Reproductive Genetics Institute, Chicago, IL.

Schmid metaphyseal chondrodysplasia (SMC) is a dominantly inherited disorder of the osseous skeleton, characterized by a short stature, coxa vara and a waddling gait. SMC is determined by mutations in the type X collagen gene, COL10A1, which is a short chain collagen expressed in hypertrophic chondrocytes during bone growth. Nonsense mutation (Y628X) in COL10A1 gene was identified in a sporadic case of Schmid metaphyseal hondrodysplasia (McIntosh et al. 1995). We performed PGD for a patient with such a *de novo* mutation, using nested and hemi-nested multiplex PCR protocol for the mutation and tightly linked short tandem repeats (STRs). Normal and mutant haplotypes were established by single sperm analysis, and the mutation analysis was performed simultaneously with aneuploidy testing as described earlier (Rechitsky et al. 2006). The final protocol included D6S1603, D6S401, 6S454, D6S1706, D6S304 markers along with mutation, and aneuploidy markers for 13, 18, 21, X and Y chromosomes. Mutation was studied by restriction endonuclease digestion and electrophoresis, while polymorphic markers were analyzed by fluorescent fragment analysis. Single blastomeres from 9 embryos were tested, of which 4 were found to be unaffected and normal for chromosomes 13, 18, 21, X and Y, two inherited paternal mutation and another two were found aneuploid. As no data were obtained for one of the embryos, a blastocyst biopsy was performed for this embryo on day 5, showing the normal genotype. Two out of five normal embryos were transferred, resulting in singleton pregnancy and delivery of a healthy mutation free child.

Dissecting the genetic architecture of type 1 diabetes via genome-wide association of 16,783 individuals. *J. C. Barrett[1], B. Akolkar[2], P. Concannon[3], H. A. Erlich[4], C. Julier[5], G. Morahan[6], J. Nerup[7], C. Nierras[8], F. Pociot[9], J. A. Todd[1], N. M. Walker[1], J. D. Cooper[1], D. J. Smyth[1], H. Schuilenburg[1], V. Plagnol[1], J. Allen[1], S. S. Rich[10], D. G. Clayton[1], The Type 1 Diabetes Genetics Consortium* 1) CIMR, Cambridge, UK; 2) NIDDK, NIH; 3) CPHG, University of Virginia; 4) Roche Molecular Systems; 5) Institut Pasteur, Paris, France; 6) WAIMR, Perth, Australia; 7) Steno Diabetes Center, Denmark; 8) Juvenile Diabetes Research Fund; 9) Steno Diabetes Center, Denmark; 10) Wake Forest University School of Medicine.

Identification of loci that contribute to risk of Type 1 Diabetes (T1D),has accelerated in the last few years with the advent of genome-wide association studies (GWAS). To date, nine non-HLA loci have been established; however, these loci do not fully explain the genetic risk of T1D. Therefore, the T1DGC has undertaken a new GWAS with the intent of jointly analyzing newly generated and pre-existing data to obtain maximum power to detect new T1D risk loci. The combined study comprises a meta-analysis of three distinct scans: 1963 cases/3326 controls (Wellcome Trust Case Control Consortium, Affymetrix 500K), 1785 cases/1727 controls (GoKinD and NIMH, Affymetrix 500K), which have been analysed previously, and new data from 3983 cases/3999 controls (T1DGC, Illumina HumanHap 550K). We have used a subset of 1500 controls genotyped on both platforms to impute genotypes in each sample for SNPs on the other platform. The combined dataset, which features 7731 cases and 9052 controls with imputation or direct genotype data at nearly 850,000 SNPs, is the largest ever assembled for a binary disease trait. The initial meta-analysis overwhelmingly confirms (p 10^{-9}) all nine previously confirmed non-HLA associations (as well as the MHC) and provides intriguing evidence of association at a number of other candidate loci. In addition, the meta-analysis reveals 14 previously unsuspected loci with p 10^{-7}, 27 with p 10^{-6}, and over 100 with p 10^{-5}. These results, as well as replication genotyping for the top tier of hits in an independent and similarly sized panel will be presented.

Joint maximum likelihood estimation of relatedness and allele frequencies. *A. Anderson* Dept Mathematics, Western Washington Univ, Bellingham, WA.

We present a method for estimating relatedness parameters (e.g. probabilities of sharing 0, 1, or 2 alleles IBD, kinship coefficients, etc.) and allele frequencies from a set of individuals with unknown pedigree. Our approach is iterative: We begin with intial guesses for the allele frequencies, then alternate between using these allele frequencies to find maximum likelihood estimates for the relatedness parameters and using our estimated kinship coefficients to update our allele frequency estimates. The method is tested on family data from the CEPH database and found to work fairly well.

Selecting SNPs to Correctly Predict Ethnicity. *J. N. Sampson[1], K. K. Kidd[2], J. R. Kidd[2], H. Zhao[1]* 1) Dept of Biostatistics, Yale University, New Haven, CT; 2) Dept. of Genetics, Yale University School of Medicine, New Haven, CT.

Because allele frequencies at many SNPs differ across populations, genotyping appropriate SNPs can offer insight into an individual's ancestry or ethnicity. For many forensic applications, it would be desirable to select a small group of highly informative SNPs, such that by genotyping only those SNPs, we could accurately predict the ethnicity for nearly any person. With this goal in mind, we preselected a group of 249 candidate SNPs, most already identified to have high Fst values in a small number of populations (e.g. HapMap), and then genotyped these candidate SNPs in approximately 2500 subjects from more than 40 populations. Here, we will discuss our novel method of selecting a small subgroup of these SNPs that can accurately distinguish populations. Specifically, we use a greedy algorithm to find subsets of SNPs that minimize the prediction error rate (Err), or the probability of assigning a future person to an incorrect ethnicity. In general, SNP selection procedures have needed to avoid estimating Err because of the large number of SNPs and the computational time required by traditional estimation methods such as cross-validation and bootstrapping. Because of some unique characteristics of our problem, we show that there is actually a simple calculation which can produce accurate estimates of the prediction error rate, allowing us to search through 1000's of SNPs relatively quickly. In addition to minimizing Err, our proposed method can also incorporate a penalty matrix so SNPs will be chosen to minimize a weighted error rate, emphasizing errors where the true and predicted ethnicities are highly dissimilar. The method also offers a means to weight populations by their prevalence in a region and estimate the true Err after selecting the SNPs. Overall, we demonstrate that a relatively small number of SNPs can accurately predict ethnicity.

Excess of X-chromosome copy number changes by microarray in women with skewed X-inactivation. *D. Warburton[1], V. Jobanputra[1], J. Kline[1,2], B. Levin[1], A. Kinney[1], O. Nahum[1], C.-Y. Yu[1], B. Levy[1]* 1) Columbia University, New York, NY; 2) N.Y. State Psychiatric Insititute, New York,NY.

Women with highly skewed X-chromosome inactivation (HSXI), defined as 85% skewing in favor of one allele, were detected during a study of the relationship between skewing and trisomic conceptions. Skewing in blood was measured by a standard HUMARA assay: for all women with HSXI we also measured the skewing in samples of left and right buccal mucosa. All women with HSXI had normal G-banded karyotypes. Because X-chromosome rearrangements are known to lead to HSXI, we looked for submicroscopic copy number changes on the X chromosome (using the Affymetrix 6.0 microarray) on 23 cases with HSXI detected in a blood sample. In 10 of the 23 women we identified at least one copy number change on the X chromosome (one deletion, 15 duplications) that showed no overlap with known variable regions. In comparison, using the same 6.0 array, only 3 of 50 women from the HapMap sample showed non-variant X chromosome changes (2 women with a duplication and one woman with 6 deletions). The proportion of women with copy number changes was significantly higher ($p<0.001$) among women with HSXI than among controls. Among the 23 women with HSXI, only 3 showed HSXI in blood and both buccal samples. Microarray analysis revealed that one of these women had a 3.3 Mb deletion in Xp22.2 containing 29 genes, including 9 identified with X-linked recessive disease (e.g., FACNB, NHS, PHKA2 and PDHA1). There was also a gene-rich duplication just proximal to the deletion. We did not identify X microaberrations in the other two women. A unique duplication in Xq13.3 was seen in 8 women with HSXI: this region contains no genes but is enriched in L1 sequences and is 4 Mb upstream of XIST. Three women had a duplication in Xp11.3 that contains a Ubiquitin gene cluster. Another woman had a duplication in Xp22.3 that includes most of the SHOX gene. None of these microduplications was identified in the 50 controls. We are currently confirming these preliminary results by analyzing additional cases with HSXI and concurrent controls from the same sample, as well as verifying the microarray findings by FISH.

SNP PGD Microarray Analysis from a Single Embryonic Cell. *W. G. Kearns[1], R. Pen[1], A. Benner[1], A. Kittai[1], E. Widra[2], R. Leach[1]* 1) Shady Grove Center for Preimplantation Genetics, Rockville, MD; 2) Shady Grove Fertility , Rockville, MD.

Objective: To amplify DNA from a single cell and to perform SNP PGD microarray analyses. We will determine total aneuploidy, identify structural chromosome aberrations and identify disease risks and copy number variations (CNVs) by a genome-wide scan. We will also determine what embryo implanted and what partner provided the extra chromosome using genotype data. **Methods:** DNA amplification was performed using a modified whole genome amplification (WGA) protocol on 398 single cells (112 WBCs, 252 human blastomeres from 37 embryos and 34 known cell lines). We used invariant DNA genomic loci to ensure the entire genome was amplified and TaqMan PCR to ensure heterozygous allele amplification. The Illumina HumanHap370 microarray was employed to determine chromosome aberrations and genotype data for ~370K SNPs. Data was analyzed with deCODE genetics Disease Miner Professional and Illumina BeadStudio software. **Results:** Our single cell analyses showed a consistent genomic coverage >90%. Our heterozygous allele detection rate >90% with a microarray detection rate and genotype call rate > 90%. We determined a complete molecular karyotype from all 252 blastomeres from 37 embryos (>5800 individual chromosomes) and all 34 cell lines (>780 individual chromosomes). Unbalanced structural chromosome aberrations were identified from all 9 cytogenetically abnormal cell lines. Genotype information was also obtained for ~370K SNPs for each cell analyzed. These genome wide scans identified disease risks from embryos for type-2 diabetes, prostate cancer, glaucoma, certain cardiovascular conditions and estrogen responsive breast cancer as well as single gene mutations. A high-resolution copy-number profile also identified CNVs throughout the genome. Using parental, embryonic and fetal genotypic data, we are also determining which partner provided the extra chromosome in aneuploid embryos and which embryo implanted. **Conclusions:** We successfully obtained complex genetic information from single embryonic cells for PGD microarray analyses. These PGD analyses can be completed for a fresh embryo transfer.

Genome-wide association study identifies FLNB and SBF2 as two novel genes underlying stature variation. *S. F. Lei[1,2], L. J. Tan[2], X. G. Liu[1,3], L. Wang[1,3], H. Yan[1,3], J. F. Liu[1], Y. Z. Liu[1], D. H. Xiong[4], J. Li[1], T. L. Yang[3], X. D. Chen[2], Y. Guo[3], F. Y. Deng[1,2], Y. P. Zhang[1,3], T. B. Jin[1,3], C. J. Papasian[1], B. M. Drees[1], J. J. Hamilton[1], R. R. Recker[4], H. W. Deng[1,2,3,4]* 1) School of Medicine, University of Missouri - Kansas City, USA 2. 3. 4; 2) College of Life Sciences, Hunan Normal University, China; 3) School of Life Science and Technology, Xi'an Jiaotong University, China; 4) Osteoporosis Research Center, Creighton University, USA.

Human stature is a highly heritable complex trait. To identify specific genes underlying human stature, a genome-wide association study was performed in 1000 unrelated homogeneous Caucasian subjects using Affymetrix arrays interrogating ~500,000 SNPs genomewide. A group of seven contiguous markers in the region of the SBF2 gene (Set-binding factor 2) are consistently associated with stature, significantly so at the genome-wide level after FDR (false discovery rate) correction (FDR q=0.034-0.042). Three SNPs in another SNP group in the Filamin B (FLNB) gene were also consistently associated with stature, significantly so with FDR q=0.042-0.048. Strong linkage disequilibrium exists among these SNPs, and two haplotype blocks were constructed in each SNP group. The haplotypes in these blocks are significantly associated with stature (e.g., point-wise testing p values are as low as 5.2×10-7). In follow-up independent replication studies, rs9834312 in the FLNB gene was consistently significantly (p=0.008), and rs10734652 in the SBF2 gene was marginally significantly, (p=0.07) associated with stature in 1,306 unrelated Caucasian subjects. In Chinese subjects, significant replication association signals were detected between rs9834312 and stature in 619 unrelated northern Chinese subjects (p=0.017), as well as between rs10734652 and stature in 2,953 unrelated southern Chinese subjects (p=0.048). These results, together with the known functional relevance of the SBF2 and FLNB genes to skeletal linear growth and bone formation, support the conclusion that FLNB and SBF2 are two novel genes underlying stature variation.

Comparison of Molecular Genetic and Anthropometric Study in a Cohort of Czech Osteogenesis Imperfecta Patients. *I. Mazura[1], I. Mařík[2], D. Zemková[3], F. Nutsu-Mazurová[4], O. Hudáková[2], P. Novosad[4], J. Zvárová[1]* 1) Dept.of Biomedical Informatics, Institute of Computer Science, Prague, Pod vodárenskou věží 2, 182 07, Prague 8, Czech Republic; 2) Ambulant Centre for Defects of Locomotor Apparatus, Olšanská 7, Prague 3, PC-130 00, Czech Republic; 3) Pediatr. Dept, University Hospital Motol, Charles University Prague, V úvalu 85, Prague 5, PC-152 00, Czech Republic; 4) Mediekos Labor Ltd, Antonínova 4464,PC-760 01, Zlín, Czech Republic.

Objectives. Aims of the study were analyse several important exons of COL1A1 gene in the group of Czech patients with diagnosis of osteogenesis imperfecta and compare the severity and progress of skeletal changes of OI types with proved molecular genetic defects. Osteogenesis imperfecta (OI) is an autosomal dominant or recessive connective tissue disease characterized by extremly high bone fragility (brittle bone disease). The incidence of this disease is approximately 1:10-50 000 newborns. Heterogenous syndrome of OI with variable phenotypic expression is defined by clinical findings . Much attention should be paid to the occurrence of mutations in the structural parts of the gene COL1A1 and COL1A2 as well as to the occurrence of single nucleotide polymorphisms in areas that are not translated into the structure of the resulting collagen protein. 52 patients with diagnosis OI type I -IV were included to this study. Patients were classified into 7 types of the OI Anthropometric parameters were useful in differential diagnostics among OI types (especially between type I and IV). We have found several molecular genetics changes e.g. nucleotide substitutions in the exon 31-36 and 39-40 of COL1A1 gene. At present we are able almost precisely characterized types of OI according to radio-clinical and anthropometric examinations but we are unable to correlate genotype and phenotype of OI patients. Acknowledgements. These results were supported by grant no. 1M06014 of Ministry of Education, Youth and Sport, Czech Republic. The research was supported by grant no.:00064203/6407 of Ministry of Health, too.

Modifying dendritic cells induces tolerance to coagulation factor VIII. *M. Seiler[1,2], V. Cerullo[1], G. Sule[1], V. Mane[1], C. Clarke[1], J. Sims[1], J. Rodgers[2, 3], B. Lee[1,2,4]* 1) Molecular and Human Genetics , Baylor College of Medicine, Houston, TX; 2) Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, TX; 3) Immunology Baylor College of Medicine, Baylor College of Medicine, Houston, TX; 4) The Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX.

Hemophilia A is a blood coagulation disorder due to deficiency in Factor VIII (FVIII). About 1 in 5000 males are affected by this. Current therapy includes frequent infusions of FVIII protein. However about one third of the patients develop inhibitory antibodies to recombinant protein as a consequence of the repeated protein infusions. Genetic modification of dendritic cells (DC) is already a powerful strategy to induce immune responses to tumor antigens in autologous cell therapies. DCs induce tolerance as well as immunity, but clinical application of tolerance-inducing DC has not been developed for protein or gene therapy. Our in vitro studies show, transducing DC by helper-dependent adenovirus to express the immune suppressive cytokines TGF- and IL-10 renders them tolerogenic by, inducing T cell apoptosis, and increasing the frequency of antigen-specific regulatory T cells. Adoptive transfer of FVIII-loaded, tolerogenic DC to FVIII knock-out mice prior to gene transfer and protein treatment induced suppression of the anti-FVIII immune response, and prolonged FVIII activity. This report demonstrates that autologous cell therapy for antigen-targeted immune suppression may be developed to facilitate long-term therapy. These findings may extend to other protein and gene therapies, and potentially autoimmune diseases and solid organ transplantation.

18q12.1 Interstitial Microduplication in Mother and Child: A Case Report. *R. Veith[1], A. Swanson[2], A. Denny[2], S. Leuthner[2], A. Mitchell[3], D. Bick[2]* 1) Children's Hospital of Wisconsin; 2) Medical College of Wisconsin; 3) GeneDx.

We report a male neonate with cleft lip and palate, frontal bossing, hypertelorism, omphalocele, micrognathia, double aortic arch, diaphragmatic hernia, broad thumbs/toes. The mothers features include uterine malformation, micrognathia, hypertelorism and omphalocele. The patient and the mother share a very similar facial appearance. No other individuals in this pedigree demonstrate the phenotype. Utilizing oligonucleotide array CGH analysis we identified a genomic microduplication in the neonate and his mother comprising three genes that encode calcium-dependent glycoproteins, DSC1, DSC2 and DSC3 that are members of the desmocollin subfamily of the cadherin superfamily. This microduplication has not been observed in approximately 2200 samples using the same oligonucleotide array CGH. The duplicated segment is approximately 2 Mb and involves a contiguous region of single copy gain at 23 probe locations between the flanking positions 25185867 and 27152802 in 18q12.1. Quantitative PCR analysis using a probe in intron 11 of the DSC2 gene within the duplicated region demonstrated three gene copies in the affected child and his mother, while the paternal DNA specimen showed a normal result. Thus, the duplicated interval is maternally derived. There are two previous reports of heterozygous mutations in the DSC2 gene: one associated with familial arrhythmogenic right ventricular dysplasia/cardiomyopapthy; [1,2] the other of an apparent de novo duplication of 18q12 in 10 year old male with severe mental retardation and minor dysmorphology, seizure disorder and syndactyly. [3] Reports of larger duplications of 18q12-22 also have included cognitive deficits, seizures and dysmorphic features. [4,5] Given the similarity between the proband and his mother we believe that the 2 Mb duplication of 18q12.1 is likely responsible for their phenotype and thus represents a new microduplication syndrome. Identification of a novel cataract gene, *TDRD7*, and its role in P body-mediated post-transcriptional regulation in the lens. *S. A. Lachke[1], F. S. Alkuraya[1], I. Saadi[1], R. Cavallesco[1], A. C. Tsai[2], A. V. Drack[2], R. L. Maas[1]* 1) Division of Genetics, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 2) Human Medical Genetics Program, University of Colorado-Denver, Aurora, CO.

We have identified a novel cataract gene, *TDRD7*, in a juvenile cataract patient who carries the balanced paracentric inversion 46, XY, inv(9)(q22.33q34.11). To rapidly identify the gene involved, we used a microarray gene expression database for mouse lens development and predicted *TDRD7* as the most probable candidate among 50 genes within a 5 Mb interval around the q22.33 breakpoint. Southern blot confirmed the direct disruption of *TDRD7* in intron 2, while qRT-PCR demonstrated *TDRD7* haploinsufficiency. Furthermore, *TDRD7* knockdown in chick lenses resulted in cataract formation recapitulating the patient phenotype. Interestingly, the Tdrd7 protein localizes to cytoplasmic foci that resemble Processing or P bodies in lens fiber cells. P bodies represent a newly discovered organelle that regulates mRNA turnover in eukaryotic cells by sequestering mRNA and processing it for either storage or decay. P bodies contain RNA binding proteins and components of the microRNA machinery. Tdrd7 co-immunoprecipitates with a P body marker GW182 and its overexpression results in large P bodies confirming a role in lens P body formation. We hypothesized that *TDRD7* haploinsufficiency alters the RNA-binding specificity of lens P bodies, resulting in misregulation of lens transcripts. Consistent with this model, *Tdrd7*-knockdown in lens cells specifically leads to aberrant transcript levels of *Foxe3* and *Prox1*, two genes with key roles in lens development. We propose a model wherein *TDRD7* controls fiber cell differentiation by post-transcriptional regulation of these lens-expressed genes.

In conclusion, we describe a novel cataract gene, *TDRD7*, and a new molecular regulatory mechanism for the etiology of cataract. Our work represents the first evidence that perturbation of a tissue specific P body component results in a specific human disease. Importantly, it also suggests the possibility that tissue-specific P body components may provide a mechanism to regulate transcriptional specificity during organogenesis.

Renin-Angiotensin System Genes and Renal Function in the Multi-Ethnic Study of Atherosclerosis. *C. Y. Campbell[1], X. Guo[2], B. Fang[2], J. H. Young[1], C. A. Peralta[3], J. Coresh[1], H. J. Kramer[4], M. G. Shlipak[3], B. M. Psaty[5], S. S. Rich[6], J. I. Rotter[2], W. S. Post[1]* 1) Johns Hopkins University, Baltimore, MD; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) University of California at San Francisco, San Francisco, CA; 4) Loyola University, Maywood, IL; 5) University of Washington, Seattle, WA; 6) University of Virginia, Charlottesville, VA.

Background: Single nucleotide polymorphisms (SNPs) in angiotensin-converting enzyme (ACE), angiotensinogen (AGT), angiotensin II type 1 receptor (AGTR1), and angiotensin II type 2 receptor (AGTR2) genes may contribute to renal function variation in the general population. Methods: 2847 participants without known cardiovascular disease in the Multi-Ethnic Study of Atherosclerosis (MESA) from 4 racial/ethnic groups (African-American, Chinese, White, and Hispanic) were genotyped. Single SNP and haplotype analyses were performed to determine the associations between genotypes and renal function, including urine albumin excretion (UAE), estimated glomerular filtration rate (eGFR) using serum creatinine and eGFR using Cystatin C. Multivariate regression analyses were used adjusting for age and gender, stratified by racial/ethnic group. Results/Discussion: 14/24 ACE, 6/10 AGT, 9/15 AGTR1, and 5/6 AGTR2 SNPs were associated with renal phenotypes ($p<0.05$ after permutation testing). 3 AGT, 3 AGTR1, and 1 AGTR2 SNPs were associated with the same phenotype in multiple racial/ethnic groups, suggesting internal replication. 2 ACE, 3 AGT, and 3 AGTR1 SNPs were associated with multiple phenotypes in the same racial/ethnic group. The AGT M235T polymorphism was associated with eGFR and UAE in African Americans (observed $p=0.02$ for continuous eGFR, $p=0.02$ for dichotomous eGFR, $p=0.004$ for continuous log UAE, $p=0.001$ for dichotomous UAE) and with dichotomous UAE in Chinese ($p=0.04$). This SNP has been shown previously to be associated with diabetic and hypertensive nephropathy. In general, haplotype data were consistent with associations identified by the single SNP analyses. These data suggest that renin-angiotensin system genes influence renal function in multiple racial/ethnic groups.

Mutation Screening of FBN1 Gene in Patients with Ascending Aortic Dilatation. *J. Šímová[1], I. Mazura[1,2], P. Čapek[2], J. Dudra[3], J. Lindner[4], J. Zvárová[1]* 1) Dept.of Biomedical Informatics, Institute of Computer Science, Prague, Prague 8, Pod vodárenskou věží 2, 182 07, Czech Republic; 2) Department of Anthropology and Human Genetics, Faculty of Science, Charles University in Prague, Viničná 7, Prague 2, 128 44 , Czech Republic; 3) Emergency Medical Service, City of Prague, Czech Republic; 4) Department of Cardiovascular Surgery, 1st Medical Faculty, Charles University, Prague, U nemocnice 2, Prague 2, Czech Republic.

Mutations in the FBN1 gene are known causes of Marfan Syndrome (MFS) and related disorders. Correlation between the genotype and the cardiovascular phenotype has not yet been estabilished. About 10 % of patients operated for aortic valve disease suffer simultaneously from ascending aortic dilatation (AAD). Cause and progression of the aortic valve disorder is considered to be the contributory factor for dilatation of primarily changed aortic wall of ascendant aorta. Our cohort contains 28 patients with ascending aortic dilatation (ranging from 35 to 76 years of age). In our study we suggest that variation in the genes encoding proteins constituting aortic wall and regulating the turnover of the extracellular matrix (e.g. FBN1, TGFBR1 and TGFBR2) are likely to influence properties of elastic fibres. We performed mutation screening of the gene for fibrillin-1 FBN1 gene. Screening involved exon 4 and exons 24-30 with their relevant intron/exon boundaries. Our gene scanning method was based on post-pcr analysis of high resolution melting curves and DNA sequrncing. We detected variation in intronic part situated close to exon 27, this variation was identified as insertion of guanine between nucleotide 37 682 and 37 683 of query sequence. We classified this mutation as IVS27 37682_37683insC. This is an initial study and although a causative link has not been shown, these data are very important for further research of the role of fibrillin-1 in relation to cardiovascular risk associated with aortic dilatation. These findings would have potential implication for risk stratification and therapeutic targeting not only for patients with existing disease but also for general population. This study was supported by grant 1M06014 of the Ministry of Education CR.

Toward a Molecular Definition of Heterochromatin. *J. A. Rosenfeld[1,2], Z. Xuan[1], R. DeSalle[3], M. Q. Zhang[1]* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) New York University, New York, NY; 3) American Museum of Natural History, New York, NY.

Heterochromatic regions of the genome have traditionally been defined by staining patterns or the hybridization of florescent probes. These techniques are, by definition, high-level and cannot achieve base-pair level resolution. We have utilized high-throughput Solexa sequencing data to make determinations at an individual nucleosome level in the human genome. This histone modification of H3K9me3 has been found to highly correlate with constitutively heterochromatic regions. Therefore, we obtained ChIP-seq data for H3K9me3 and mapped it across the entire genome. In order to account for the repetitive nature of heterochromatin, we have implemented a procedure for utilizing Solexa reads that map to multiple locations in the genome. A true-positive set of satellite regions was used as a control to calibrate the level of methylation needed to determine a region as ChIP-positive. We next determined the base composition preferences of the ChIP-positive regions and investigated the presence of any significant sequence motifs. This also included a determination of significant motifs at the boundaries of positive regions that may be barrier elements. Finally, we investigated the localization of H3K9me3 within the bodies of active genes.

Consumer experiences with and attitudes toward direct-to-consumer personal genome testing. *C. M. Diaz[1], T. Wang[2], S. G. Hilsenbeck[2], A. L. McGuire[1]* 1) Center for Medical Ethics & Health Policy, Baylor College of Medicine, Houston, TX; 2) Dan L. Duncan Cancer Center, Division of Biostatistics, Baylor College of Medicine, Houston, TX.

PURPOSE: This study assesses consumers experiences with and attitudes toward personal genome testing (PGT), with a focus on expectations related to the clinical integration of PGT results. METHODS: A survey of 1,087 online social networking users was conducted in April 2008 to assess (1) use and interest in PGT; (2) attitudes toward PGT companies and test results; and (3) expectations for the clinical integration of PGT. Descriptive statistics were calculated to summarize respondents characteristics and responses. RESULTS: 6% of respondents have used PGT, 64% would use PGT, and 30% would not use PGT. Of those who would use PGT, 74% would use it to gain knowledge about diseases they or their family might have. Of those who would not use PGT, 53% do not think the information would be useful and 21% have doubts regarding the reliability of PGT. 55% of all respondents think PGT will increase an individuals control over their own health and 58% think PGT will stimulate discussion about personal health within families. Of those who indicate an interest in PGT, 54% would consider testing their child, 67% would consider testing their spouse, and 43% would consider testing other family members. Those who would test their child are most likely to do so to find out if the child has a predisposition to disease. 78% of those who would consider PGT would ask their physician for help interpreting test results and 61% of all respondents believe that physicians have a professional obligation to help individuals interpret PGT results. CONCLUSION: Although PGT services are new, individuals in this sample express much interest in using these services, primarily for purposes related to their medical care. Respondents who would use PGT would seek help interpreting results from their physician and believe that physicians have a professional obligation to provide assistance. Physicians should therefore be prepared for patient demands for information, counsel, confirmatory diagnosis, preventive care, and treatment.

Cancer resistance in Down syndrome: trisomy increases survival in a sarcoma mouse model in an Ets2-independent manner. *A. Yang, R. H. Reeves* Physiology Dept., Johns Hopkins University School of Medicine, baltimore, MD.

Epidemiological studies indicate that individuals with Down syndrome (DS) get fewer solid tumors compared to the euploid population. This finding has been documented in the Ts65Dn mouse model of DS, where trisomy was found to repress adenomas in the ApcMin mouse model (T. Sussan et al., Nature 451:73, 2008). Dosage of the Ets2 gene plays a critical role in tumor repression in this model. To determine whether Ts65Dn represses multiple kinds of tumors as reported for DS, we used the NPcis tumor model. These mice lack one copy of a segment containing the Nf1 and Trp53 genes and develop a high frequency of lymphoma, sarcoma and astrocytoma due to LOH. Ts65Dn mice and a strain containing a null allele of Ets2 were crossed with NPcis mice and survival curves were plotted for four genotype groups of offspring (NPcis; Ets2+/-, NPcis; Ts65Dn, NPcis; and Ts65Dn, Ets2+/-, NPcis). As in studies with ApcMin, we found that trisomy significantly extends survival pf NPcis mice by 25%, as predicted by the repression of many types of cancer in humans with DS. In contrast to the previous study, in which increased expression of Ets2 was shown to be critical in tumor repression in the ApcMin adenoma model, the presence of one, two or three copies of Ets2 did not play a significant role in tumor repression in the NPcis model. This indicates that additional dosage sensitive genes in this trisomic region contribute to reduced cancer incidence in the Down syndrome population.

Identification of the ADIPOQ Gene Promoter and Intron 1 Variants Associated with Insulin Resistance: the NHLBI Family Heart Study. *P. An[1], M. F. Feitosa[1], J. S. Pankow[2], R. H. Myers[3], D. K. Arnett[4], P. N. Hopkins[5], J. E. Hixson[6], K. E. North[7], L. Wagenknecht[8], I. B. Borecki[1], M. A. Province[1]* 1) St Louis, MO; 2) Minneapolis, MN; 3) Boston, MA; 4) Birmingham, AL; 5) Salt Lake City, UT; 6) Houston, TX; 7) Chapel Hill, NC; 8) Winston-Salem, NC.

The ADIPOQ gene on chromosome 3q27.3 encodes adiponectin which is produced by adipocytes and recognized as a key determinant of insulin resistance (IR). Precisely which variants in ADIPOQ confer risk of diabetes and associated traits is currently unclear. We performed association tests using 809 unrelated Caucasian subjects in the NHLBI Family Heart Study (FHS). IR was estimated using homeostasis model assessment and corrected for the effects of age, gender and field center. Subjects with diabetes or taken diabetes medications were excluded from this analysis. A total of 14 SNPs in the ADIPOQ gene were genotyped in the FHS genome-wide association study, and 47 additional SNPs in ADIPOQ were imputed using Bayesian imputation-based association mapping (BIMBAM) software and HapMap data. Association tests were carried out using SAS GLM procedure under the additive model. Significant marginal associations after Bonferroni correction included variants in the promoter (rs12637534, p=0.01, 9 kb upstream from the previously reported rs17300539 and rs266729 region; and rs16861194, p=0.03, 35 bp upstream from the previously reported region). The variants rs16861194, rs17300539 and rs266729 belonged to one haplotype block but were not in LD with rs12637534. Significant associations for IR were also found at the intron 1 (near exon 1) region (rs16861205, p=0.0098) and the intron 1 (near exon 2) region (rs9877202, p=0.01). These intronic regions were in LD but did not belong to one haplotype block. Major alleles of all these SNPs were consistently associated with lower IR. Taken together, using a total of 61 genotyped or imputed SNPs covering the ADIPOQ gene, we identified two regions in the promoter and two regions in the intron 1 influencing insulin resistance in a large non-diabetic population.

DNA Copy Number Analysis, Using SNP-Based Mapping Arrays, Reveals Numerous Genomic Imbalances in Malignant Mesothelioma Cells. *M. Cheung[1], J. Pei[1], Y. Pei[1], J. Fang[1], S. C. Jhanwar[3], H. I. Pass[2], J. R. Testa[1]* 1) Human Genetics Program, Fox Chase Cancer Center, Philadelphia, PA; 2) Dept of Cardiothoracic Surgery, Division of Thoracic Surgery, New York University School of Medicine, New York, NY 10016; 3) Dept of Pathology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

Malignant mesothelioma (MM) is a highly aggressive malignancy that arises from the serosal lining of the pleural, peritoneal, and pericardial cavities and is primarily caused by exposure to asbestos fibers. MMs are characterized by complex chromosomal alterations. To precisely identify recurrent genomic imbalances in this disease, we performed high resolution DNA copy number analysis on a series of 22 human MM cell lines. Chromosomal losses accounted for the majority of genomic imbalances. All cell lines showed homozygous or hemizygous deletions of 9p21.3, centered at the CDKN2A/ARF and CDKN2B loci. Other commonly underrepresented segments included 1p36.2-36.3, 1p22.1-22.3, 3p22.1-p21.31, 11q23.2-23.3, 13q12.2-13.2, 14q32.2, 15q15.1, 16p13.2, and 18q12.3, each observed in 52%-82% of cell lines. Loss of all or significant portions of chromosomes 22 and 4 were observed in 78% and 53% of MM cell lines, respectively, with peak levels of loss at 4q13.1, 4q34.1 and 22q12.1-12.2 in 82%-90% of the cell lines. Gain of 17q23.2 (55%) was also common. Genes located at these affected regions were analyzed by RT-PCR and genomic real time PCR to verify their status in MM cell lines. Two genes were studied further to confirm their role as tumor suppressors: Oncostatin M (OSM) and Promyelocytic Leukemia Zinc Finger (PLZF). Transfection of OSM expression constructs into MM cells or addition of recombinant OSM to the media led to a reduction in growth that correlated with decreased cyclin levels and subsequent G1 cell cycle arrest. Similarly, reintroduction of the PLZF gene into MM cells resulted in diminished cell growth. Collectively, these findings illustrate the utility of SNP-based mapping arrays for high-resolution analysis of genomic imbalances in MM and for the identification of several novel loci that may be associated with the pathogenesis of MM.

Clinical Assessment of Sequence Variants in the ClinSeq Large Scale Medical Sequencing Project. *C. Turner[1], P. Cherukuri[1], F. Facio[1], J. Teer[1], R. Cannon[2], R. Shamburek[2], J. Mullikin[1], E. Green[1], L. Biesecker[1], NISC Comparative Sequencing Program* 1) National Human Genome Research Institute, Bethesda, MD; 2) National Heart Lung and Blood Institute, Bethesda, MD.

Individualized genomic medicine promises to revolutionize the practice of medicine, though the interpretation of the vast amounts of data will be challenging. As part of the ClinSeq large scale medical sequencing project, we have sequenced 142 genes in 201 participants. A subset of three genes (LDLR, APOB and PCSK9) associated with Familial Hypercholesterolemia (FH) was used as a model for assessing pathogenicity of variants. There were 72 amplicons sequenced across these genes for the 201 participants that provided 18.1 Mbps of sequence. Comparison of these data to reference sequence identified 17 unique variants in LDLR, 62 in APOB and ten in PCSK9. To identify variants causing high-penetrance phenotypes we stratified variants as likely to be pathogenic, unlikely to be pathogenic, or uncertain. Likely pathogenic variants were nonsense, frameshift, splice (GT/AG), and those reported as causative. Unlikely pathogenic variants were common (MAF >2%) and synonymous. Uncertain variants were rare missense variants. One LDLR variant, p.Y188X, has been reported as causative for FH. Nine LDLR variants were synonymous, as were 20 in APOB and three in PCSK9. For the remaining nonsynonymous variants, we developed a position-specific amino acid substitution score reflecting the change and the conservation. Of the missense variants, six in LDLR, 19 in APOB and four in PCSK9 were not found in dbSNP. The literature suggests the p.P685L LDLR variant and the p.R3527Q APOB variant are causative. No causative variants were found in PCSK9. Analysis of the clinical data for the patients with mutations causing FH revealed markedly elevated LDL and severe atherosclerosis. These FH-causing variants were confirmed in a CLIA laboratory, and the results were returned to the participants and diagnosis and treatment for their families was instituted. These bioinformatic methods are being automated to analyze the variants in the other genes that will be sequenced in this project.

Large-scale assessment of genomic methylation in pre-implantation blastocysts. *S. Brown[1], G. Brown[2], K. Wright[1], L. Brown[1]* 1) Dept OB/GYN, Univ Vermont, Burlington, VT; 2) Columbus Regional Hospital, Columbus, IN.

A variety of evidence in both mice and humans suggests that super-ovulation and in-vitro embryo culture is associated with altered genomic methylation in resulting embryos. The data supporting this idea are largely derived from studies in which the methylation state of a small number of individual genomic loci are queried through the use of bisulfite conversion. Generally, specific loci with well-characterized methylation status (usually imprinted loci) are abnormally hypomethylated in manipulated embryos as compared with normal.

We hypothesized that if embryo manipulation results in abnormal methylation of specific loci, then the effects are likely to be generalized and present throughout the genome. In order to test this, our laboratory has developed a method for methylation-sensitive amplification of very small DNA quantities such as can be recovered from pre-implantation blastocysts. We have used this method in conjunction with micro-array analysis to comparatively assess methylation of a large number of loci in samples of trophoblast and lymphocyte derived DNA, and we present data that demonstrate the general validity of the method through bisulfite conversion analysis of specific loci.

In order to test whether super-ovulation and embryo culture results in widespread abnormal methylation, we have used our method to compare methylation of DNA from genetically identical E3.5 mouse embryos that were either the product of super-ovulation and in-vitro culture or were the product of normal mating and gestation. We have succeeded in amplifying DNA from 12 E3.5 embryos (7 experimental and 5 control), and, we present qualitative data (based agarose gel analysis of amplified products) showing evidence of widespread relative hypomethylation in the experimental group. In the next phase of this project, we will use microarray analysis to determine the degree of methylation difference between control and experimental embryos. We believe that our analysis will lead a better understanding of the effects of super-ovulation and embryo manipulation on genomic methylation.

Analysis of the Methyltetrahydrofolate reductase and Glutathione S-transferase omega-1 genes as modifiers of the cerebral response to ischemia. *L. Peddareddygari[1], A. V. Dutra[1], M. Levenstien[2], S. Sen[3], R. P. Grewal[1]* 1) New Jersey Neuroscience Institute at JFK Medical Center, 65 James Street, Edison, NJ 08818; 2) Program in Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, NY 10065; 3) UNC Hospital Stroke Center 7003A Neuroscience Hospital, CB# 7025, Chapel Hill, NC 27599.

Stroke is the third leading cause of death and the most common cause of disability in North America. There is increasing evidence of the role of genes as independent risk factors in the development of stroke. However, there have been few investigations of the potential role of genes in the response of the brain to ischemia. Cerebral ischemia involves a complex cascade of reactions in brain tissue and ultimately, in non-lacunar stroke, the volume of infracted tissue is influenced by many factors including vascular distribution, collateral supply and the mechanism of stroke (cardioembolic versus large artery atherosclerosis). The volume of a stroke is important because, in general, it correlates with resultant disability. We hypothesize that polymorphisms in the genes encoding those proteins involved in these reactions could act as modifiers of the response of cerebral tissue to ischemic injury and influence infarct size. We studied the effect of two genes, Methyltetrahydrofolate reductase (MTHFR) and Glutathione S-transferase omega-1 (GSTO1). The selection of these two genes is based upon biological plausibility as key participants in oxidative mechanisms in the cerebral response to ischemia. We analyzed the C677T polymorphism (in the MTHFR gene) and the C419A polymorphism (in the GSTO1 gene) in 134 patients with non lacunar ischemic stroke in whom the mean stroke volume was 71.37 cm3 (S.D 90.1 cm3). To detect the effect of the MTHFR C677T and GSTO-1 C419A polymorphisms on stroke volume, ANOVA and generalized linear model analysis was performed. We found no significant influence of the MTHFR (p=0.72) or GSTO-1 (p=0.58) polymorphisms on the stroke volume. Our study does not support a major gene affect of either of these genes as a modifier of the response of the brain to ischemia.

Detecting BRCA2 Protein Truncation in Breast Tissue Biopsies to Identify Hereditary Cancer. *J. Holt[1,3], R. Lieberman[1], C. Snyder[2], V. J. Clark[3], H. Lynch[2]* 1) University of Colorado Health Sciences Center, Aurora, CO; 2) Creighton University, Omaha, NE; 3) Tissue Genetics Inc, Aurora, CO.

Mutations in the BRCA2 gene are dominantly inherited, but cancer occurs when the wildtype allele mutates, resulting in LOH (loss of heterozygosity) within the cancer. Identifying breast cancer patients with hereditary BRCA mutations will enable appropriate treatment and screening, while non-carrier family members can follow general population screening guidelines. Because most disease-associated BRCA2 mutations are truncating mutations, a test for truncated BRCA2 proteins should identify most BRCA2 hereditary cancers. We have developed a test to identify truncated BRCA2 proteins in breast cancer tissue biopsies by direct immunohistochemistry, without amplification or genetic manipulations. N-terminal and C-terminal antibodies are used to visualize protein truncation by demonstrating that the beginning of the protein is present but the end (terminus) is absent. A quantitative C-terminal immunostaining score (a C/N terminal truncation ratio) correctly classified 20/21 breast cancers from BRCA2 mutation carriers and 57/58 sporadic breast cancers. This is a sensitivity of 95% and specificity of 98% for the test. Due to the presence of C-terminal BRCA2 protein and atypical clinical features of the misclassifed cancer in a BRCA2 mutation carrier, we performed DNA sequence analysis on this cancer. The results showed continued presence of the BRCA2 wildtype allele in the cancer, indicating that this is a sporadic cancer which occurred in a mutation carrier. Our immunohistochemistry based test (which takes only 4 hours) appears to identify BRCA2 hereditary cancer with high accuracy. The test also appears to diagnose the biochemical loss of BRCA2 protein in cancers (BRCA2 mutant genotype) which will usually but not always agree with the presence of a germline BRCA2 mutation detected by DNA sequencing of blood samples. This rapid but accurate tissue test can diagnose hereditary BRCA2 breast cancer at the time of biopsy, allowing medical oncologists to implement targeted therapies or timely prophylactic surgery without the usual four-week wait for DNA sequencing results.

Branchio-Oculo-Facial syndrome caused by a mutation in the TFAP2A gene. *R. Klatt[1], D. Chitayat[1], W. Reardon[2], J. Milunsky[3]* 1) Div Clinical Genetics, Hosp Sick Children, Toronto, ON, Canada; 2) Our Lady's Hospital for Sick Children, Crumlin, Dublin, Ireland; 3) Center for Human Genetics, Boston University School of Medicine, Boston, Massachusetts, USA.

Branchio-Oculo-Facial (BOF) syndrome (MIM 113620) is a rare autosomal dominant condition characterized by hypertrophy of the lateral pillars of the philtrum which look like a poorly repaired cleft, a broad, asymmetric nose with a broad root and tip, lacrimal duct obstruction and a branchial sinus and/or linear skin lesion behind the ear. We report on a 11-year-old male with typical features of BOF syndrome. The antenatal history was negative for exposure to maternal illness or known teratogens. The family history was negative for recognizable genetic syndromes. The patient was born at term by spontaneous vaginal delivery and a birth weight of 3.5 kg. At birth, a bilateral cleft lip and hemangiomatous areas behind both auricles (left more prominently than right) were noted. Additional dysmorphisms noted were a short forehead, heavy eyebrows, broad nasal root and tip, bilateral scars of repaired cleft lip, thin upper lip with prominent lower lip, and low-set ears. The patient also had conductive hearing loss and myopia. CT scan of the petrous bone showed deficiency of the long process of the incus on the right and a bony plate overlying the oval window on the left. Development was normal. The patient had a normal male karyotype. DNA analysis of the TFAP2A gene revealed a mutation (R254W) within exon 4. TFAP2A missense mutations have been detected in four patients with BOF. The exon 4 mutation described is within the central basic DNA binding region. TFAP2A knockout mice demonstrate impairment in neural crest-derived facial structures. The TFAP2A gene is part of the AP-2 family of transcription factors that regulate gene expression during embryogenesis of the eye, face, body wall, limbs, and neural tube. Specifically, this gene has been shown to regulate the development of the facial prominences, limb buds, cranial closure, and development of the lens vesicle, abnormalities detected in patients with BOF syndrome.

Modeling SNP Genotype Data with Informative Missingness in Samples of Unrelated Individuals. *N. Liu* Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL.

Even with the advancement of modern technology, data with missing genotypes are still common in genetic studies. Besides the possibility of causing missing from equipment itself, such as any damage or loss of performance of some probes of the multi-plexed platforms used for genotyping, there are other situations where missing can also be induced, such as variation in DNA quality or molecular effects, experimental techniques (including genotype calling algorithms) used, and the conduct of studies can cause some individuals (e.g. cases versus controls in the case-control studies) and some sites to have more or less than their fair share of missing data. Although some statistical methods can handle missing data, they usually assume that genotypes are missing at random either explicitly or implicitly, that is, at a given marker, different genotypes and different alleles are missing with the same probability. In this study, we demonstrate that the violation of this assumption may lead to serious bias in allele frequency estimates, and association analysis based on this assumption can be biased. To address this limitation in the current methods, we propose a novel missing data model which can estimate allele frequency and missing rate without assumption about the missing data distribution. Analytically, we prove that the allele frequency and missing probability are identifiable under our model. Empirically, simulation studies illustrate that our proposed model can reduce the bias both for allele frequency estimates and association analysis due to incorrect assumption on the missing data mechanism. In addition, we evaluate the impact of departure from Hardy-Weinberg equilibrium on the model. Lastly, we illustrate the utilities of our method through its application to HapMap data and another real data.

A Case of Goltz Syndrome Presenting with a Vascular Type Amniotic Band Sequence Phenotype. *J. A. Defant[1], H. J. Stalker[1], C. A. Williams[1], N. Knutson[2], A. I. Dagli[1], R. T. Zori[1]* 1) University of Florida Division of Genetics and Metabolism Gainesville, FL; 2) University of Florida Division of Neonatology Gainesville, FL.

Goltz syndrome is a rare X-linked dominant genetic condition characterized by distinctive skin abnormalities and other birth defects affecting multiple systems including: craniofacial, skeletal, urinary, gastrointestinal, cardiovascular and central nervous systems. The clinical manifestations are extremely variable and the recent identification of the PORCN gene has helped define the clinical expression of this condition. We present a female African-American infant born with multiple congenital anomalies including: external ear dysplasia, bilateral cleft lip and palate, Tessier clefts (types 4 and 7), cleft sternum, bilateral microphthalmia, omphalocele, bladder exstrophy and genital anomalies. Limb anomalies included: ectrodactyly of the right hand and foot, small appendage in place of left thumb and right 3-5 toe syndactyly. No structural anomalies of the brain or heart were noted. Some of the anomalies resembled disruptions that might otherwise have been considered to be amniotic band effects. At birth, the infants skin had generalized scaling and areas of reddish hypopigmentation. Some of these areas appeared atrophic. At a few weeks of life, some of the atrophic areas were following the lines of Blaschko. Sequencing of the PORCN gene identified a heterozygous c.178G>A nucleotide change, previously reported as pathogenic, that confirmed a diagnosis of Goltz syndrome. To our knowledge, this is the most severe presentation of Goltz syndrome with a documented PORCN mutation. This case illustrates the wide range of pigmentary changes that can be seen in this condition and illustrates the severe extent to which malformations, some resembling vascular disruption events, can occur in the syndrome.

Detection of mosaic *RB1* mutations in families with retinoblastoma. *B. Piovesan[1], D. Rushlow[1], K. Zhang[1], N. L. Prigoda[1], M. N. Marchong[2], R. D. Clark[3], B. L. Gallie[1,2]* 1) Retinoblastoma Solutions, Toronto Western Hospital, Toronto, Ontario, Canada; 2) Division of Applied Molecular Oncology, Ontario Cancer Institute/Princess Margaret Hospital, University Health Network, Toronto, Ontario, Canada; 3) Division of Ophthalmology, Childrens Hospital Los Angeles, Los Angeles, CA, USA.

We fully analyzed the *RB1* gene in 1,020 retinoblastoma families and increased our mutation detection rate for bilaterally affected probands from 92.6% to 94.8% by including an allele-specific PCR (AS-PCR) assay, sensitive enough to reveal low-level mosaicism for any of eleven recurrent RB1 CGA>TGA nonsense mutations. For unilateral tumors we detected both oncogenic changes in 92.7% of sporadic unilateral tumors (357/385) and determined that 14.6%(52/357) of unilateral probands, with both tumor mutations identified, carried a tumor mutation in blood. Mosaicism was evident in 5.5% of bilateral probands, in 29% of unilateral probands with constitutional mutations and in one unaffected mother of a unilateral proband. Half of the mosaic mutations were identified only with the help of the AS-PCR test for the eleven recurrent mutations, which detects mosaic mutations at levels between 1% and 15%, not usually detectable by standard sequencing methodology. This suggests that a significant number of low-level mosaics with non-recurrent RB1 mutations remain unidentified by current technology. We show that the use of linkage analysis in a two-generation retinoblastoma family resulted in the erroneous conclusion that a child carried the parental mutation, because the founder parent was mosaic for the RB1 mutation. We also show that almost 10% of unaffected parents of sporadic constitutional probands carried heterozygous reduced penetrance mutations, but only 0.7%(one unaffected parent) showed mutational somatic mosaicism.

Congenital high airway obstruction and gastrointestinal atresia: A new syndrome? *R. J. Silver[1], S. Keating[2], S. Pantazi[3], P. Shannon[2], H. Sroka[1], D. Chitayat[1,4]* 1) Prenatal Diagnosis & Medical Genetics, Mount Sinai Hospital, Toronto, Canada; 2) Dept of Laboratory Medicine & Pathobiology, Mt Sinai Hospital, Toronto, Canada; 3) Dept of Diagnostic Imaging, Mt Sinai Hospital, Toronto, Canada; 4) Division of Clinical Genetics & Metabolics, Hospital for Sick Children, Toronto, Canada.

Congenital High Airway Obstruction Syndrome (CHAOS) is a rare condition that is usually lethal in fetuses. Characteristic fetal ultrasound findings secondary to the obstruction include enlarged echogenic lungs, dilated airways, flattened/inverted diaphragm, polyhydramnios, and ascites. Most cases are sporadic with unknown etiology, though cases with chromosome abnormalities as well as single gene disorders have been reported. Here we report on a case of CHAOS associated with multiple gastrointestinal atresias. The patient is a 27-yr-old G1 woman of Indian descent; her husband is of the same descent. Their family history is non-contributory and there is no history of consanguinity. Fetal ultrasound at 20.7 and 21.7 wks gestation showed ascites and large, hyperechoic lungs with inverted diaphragm (consistent with CHAOS), a dilated stomach and proximal duodenum (suggestive of duodenal atresia), and a two-vessel cord. Fetal MRI at 22.3 wks gestation showed findings consistent with CHAOS (laryngeal obstruction measuring 5mm, diaphragm inversion and lung hyperinflation, centrally compressed heart, dilated airways). Additionally, there were findings suggestive of duodenal atresia and possible anal atresia. The couple elected to terminate the pregnancy. Autopsy confirmed laryngeal atresia with expanded lungs, duodenal and anal atresias, and possible esophageal atresia. Other findings included a small spleen, heterotopic pancreas, midline liver, ascites, and two-vessel cord. The remainder of the anatomy, including the brain, was normal. Chromosome analysis revealed a normal male karyotype, and microarray analysis did not reveal microdeletions or duplications. The etiology remains unknown. This case represents a novel association of laryngeal atresia with multiple gastrointestinal atresias and may be a hitherto new syndrome.

HBA Mutations Detected by MLPA in -thalassemia Patients. *H. Onay[1], A. Ekmekci[1], E. Ataman[1], M. Akgul[1], A. Vahabi[1], Y. Aydinok[2], C. Vergin[3], F. Ozkinay[1,2]* 1) Dept Medical Genetics, Ege Univ, Izmir, Turkey; 2) Dept Pediatrics, Ege Univ, Izmir, Turkey; 3) Dr Behcet Uz Children Hospital, Izmir, Turkey.

Thalassemia syndromes are the most common monogenic disorders in humans and -thalassemia major is one of the most important public health problem in Turkey. Many genetic factors play roles in modifiying the disease severity such as mutations in the alpha globin gene (HBA), UGT1 gene (bilirubin metabolism) or HFE gene (iron metabolism). Deletions or duplications in HBA gene determine the cumulation of chain in -thalassemia major patients. The human alpha globin gene cluster is located on chromosome 16 and deletions or duplications are the most important mutations. Multiple ligation dependent probe amplification (MLPA) technique is a simple and rapid technique and used in many genetic disorders in which deletions and duplications are common. In this study we used a commercial MLPA kit for detecting alpha globin gene mutations. The kit contains 24 different probes in the HBA region. In this study we aimed to investigate the incidence of alpha globin gene mutations using MLPA technique in 19 -thalassemia major patients which were diagnosed in our department. Alpha globin gene deletions were detected in 2 out of 19 (10,5%) -thalassemia major patients. In one of the patients the deletion was located between the HBA2 gene and HBA1P gene. The deletion detected in the other patient was located between the HBA1 gene and HBA2 gene. This result suggests that alpha globin gene mutations in -thalassemia major patients are not rare. MLPA technique is suitable to investigate the mutations in this complex gene cluster.

Pre And Postnatal Features Of Edwards Syndrome Due To A Novel Partial Deletion/Duplication of Chromosome 18. *S. Kirmani, D. Babovic-Vuksanovic, C. Hutchens, G. Velagaleti* Mayo Clinic College Of Medicine, Rochester, MN.

Most cases of Edwards syndrome are due to full trisomy 18, with only 2% of cases having partial trisomy 18. We describe pre and postnatal findings in a case with a novel partial deletion/duplication of chromosome 18, with severe phenotypic features of Edwards Syndrome. A 26-year-old G2P1001 female underwent amniocentesis, since ultrasound at 24 weeks gestation showed a fetus that was small for gestational age, with a VSD and a single umbilical artery. Rocker-bottom feet and a hypoplastic cerebellum were seen on subsequent scans. Chromosome analysis revealed an abnormal karyotype: 46,XX,der(18)dup(18)(q21.3q11.2)del(q21.3). Subtelomere and locus specific FISH revealed dup(18)(18pter+,cen18+,MALT1++,BCL2-,18qter-). Both parents had a normal karyotype. The baby was born via induced vaginal delivery at 38 4/7 weeks gestation. Birth weight was 1.92 kg and length was 43 cm (both << 3 %ile). Apgars were 3, 5 and 6 at 1 5 and 10 minutes. Mechanical ventilation was initiated due to poor respiratory effort. On exam, she had hypertelorism, epicanthal folds and upslanting palpebral fissures. The nose was short with an upturned tip, the ears were small, low-set and overfolded, and a cleft palate was noted. Cardiac exam revealed a harsh grade 3/6 systolic murmur. She had a single umbilical artery, and genital exam revealed hypoplastic labia majora. Both hands were short with proximally implanted thumbs, cutaneous partial 2-3 syndactyly, tapering digits, and 5th finger clinodactyly. She had bilateral club feet and rocker-bottom deformity. Echocardiogram showed 2 large VSDs, and tricuspid valve dysplasia.. Respiratory support was withdrawn, and the baby died at 3 days of age. De novo partial deletion/duplication of 18q resulting in phenotypic features of Edwards Syndrome has not previously been described. Molecular mapping of the Edwards Syndrome phenotype has implicated 2 non-contiguous regions, 18q21.1-qter and 18q12.3-q22.1, with duplications of the latter region associated with a severe phenotype. Our results confirm these findings, and suggest that prognostic information can be given based on the region duplicated on 18q.

MUC5AC is a Candidate Gene for Familial Interstitial Pneumonia. *A. Wise[1], M. Speer[2], M. Steele[2], L. Burch[3], A. Herron[2], J. Loyd[4], K. Brown[1,5], J. Phillips III[4], S. Slifer[6], T. Sporn[2], P. McAdams[2], M. Schwarz[1,5], D. Schwartz[1]* 1) National Jewish Medical and Research Center, Denver, CO; 2) Duke University Medical Center, Durham, NC; 3) National Institute of Environmental Health Sciences, Research Triangle Park, NC; 4) Vanderbilt University School of Medicine, Nashville, TN; 5) University of Colorado Health Sciences Center, Denver, CO; 6) University of Miami, Miami, FL.

The Idiopathic Interstitial Pneumonias (IIPs) are complex conditions, with limited treatment options and unknown etiology. Previously, a whole genome screen of 82 families with FIP (the familial form of IIP), found linkage to the p-ter end of chromosome 11 with a LOD score of 3.3. Follow-up association testing revealed one SNP in particular, RS7944723 with a p-value=1 x 10-6 in familial cases versus controls and p-value=0.002 in sporadic cases versus controls. RS7944723 lies in the mucin gene MUC2, however, markers within MUC2 and MUC5AC exhibit strong LD and no markers were typed in MUC5AC (one of the predominant mucins expressed in the airways). Therefore, both MUC2 and MUC5AC were sequenced. Sequencing of both genes resulted in 34 significant SNPs with p-values < 0.05 in either familial or sporadic cases from MUC2 and MUC5AC. However, only in MUC5AC were 6 SNPs found that were significant in both familial and sporadic cases. Thus, further genotyping of a subset of 9 promising SNPs in MUC5AC was conducted using additional familial cases and spouse controls, along with an entirely separate replicate cohort of sporadic patients. All 9 of the SNPs tested to date have replicated the previous results, strongly implicating mutations in the mucin genes in both familial and sporadic IIP. Moreover, a strong association was found for a haplotype containing 4 SNPs in both familial and sporadic cases (p-value 0.002 and 0.001 respectively). While the SNP in MUC2 is intronic, all 3 MUC5AC SNPs produce amino acid changes. Thus, non-synonymous polymorphisms in MUC5AC are associated with both familial and sporadic cases of IIP.

Genetic variants associated with blood lipids levels in the U.S. population: Third National Health and Nutrition Examination Survey. *M. Chang[1], A. Yesupriya[1], RM. Ned[1], NF. Dowling[1], PW. Mueller[2]* 1) National Office of Public Health Genomics, CDC, Atlanta, GA; 2) National Center for Environmental Health, CDC, Atlanta, GA.

Identification of genetic variants related to blood lipid levels using a large, nationally representative population-based survey may allow for a better understanding of the genetic contribution to serum lipid levels in the major race/ethnic groups of the U.S. population. We examined the association of 22 polymorphisms in 13 candidate genes [including *ABCB1* (rs1045642), *ADH1C* (rs698, rs1693482), *ADRB2* (rs1042713, rs1042714), *ADRB3* (rs4994), *APOE* (rs7412, rs429358), *ITGB3* (rs5918), *MTHFR* (rs1801131, rs1801133, rs2066470), *MTRR* (rs1801394), *NOS3* (rs1799983, rs2070744), *SERPINE* (rs1799762), *PON1* (rs662, rs854560), *PPARG* (rs1801282), *TNF* (rs1800750, rs1800629, rs361525)] with serum high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LCL-C), total cholesterol (TC), and triglycerides (TG) in individuals aged 17 years and older (n=6,016) from the second phase (1991-1994) of the Third National Health and Nutrition Examination Survey (NHANES III). Univariate and multivariable linear regression analyses were used to test for genetic associations assuming an additive mode of inheritance for the three major race/ethnic groups in the U.S. (non-Hispanic white, non-Hispanic black, and Mexican-American). *APOE* (rs7412 and rs429358) was significantly associated ($p<0.05$) with LDL-C and STC levels in all three ethnic groups after adjustment for demographic, environmental, and behavioral factors (age, sex, education, alcohol intake, smoking status, physical activity, body mass index, dietary fat intake). In addition, variants in *ABCB1*, *ITGB3*, *MTHFR*, *NOS3*, *PON1*, and *TNF* were found to be associated with one or more blood lipid measures in at least one race/ethnicity group. This is the first study to describe genetic associations with blood lipid levels in a nationally-representative sample of the U.S. population. These results may provide some insight into the biological mechanisms underlying serum lipid and cholesterol concentrations.

Constitutional 11p15 imprinting center mutations, epimutations and uniparental disomy cause non-syndromic Wilms tumor. *R. H. Scott[1], J. Douglas[1], L. Baskcomb[1], N. Huxter[1], K. Barker[1], A. Craft[2], M. Gerrard[2], J. Kohler[2], G. Levitt[2], S. Picton[2], B. Pizer[2], M. Ronghe[2], D. Williams[2], J. Cook[3], P. Pujol[4], E. Maher[5], J. Birch[6], C. Stiller[7], K. Pritchard-Jones[2], N. Rahman[1], The Factors Associated with Childhood Tumours (FACT) Collaboration* 1) Section of Cancer Genetics, Institute of Cancer Research, Sutton, UK; 2) Childhood Cancer and Leukaemia Group (CCLG), UK; 3) Department of Clinical Genetics, Sheffield Children's Hospital, Sheffield, UK; 4) Service de Génétique Médicale, Centre Hospitalier Universitaire, Montpellier, France; 5) Department of Medical and Molecular Genetics, University of Birmingham, Birmingham, UK; 6) CRUK Paediatric and Familial Cancer Research Group, Royal Manchester Children's Hospital, Manchester, UK; 7) Childhood Cancer Research Group, University of Oxford, Oxford, UK.

Constitutional abnormalities at the imprinted 11p15 growth regulatory region cause syndromes characterised by disordered growth, some of which include a risk of Wilms tumor.We explored their possible contribution to non-syndromic Wilms tumor using methylation-specific MLPA. This identified constitutional 11p15 abnormalities in in genomic lymphocyte DNA from 13 of 437 individuals (3%) with sporadic Wilms tumor without features of growth disorders, including 12% of bilateral cases (P=0.001) and in one familial Wilms tumor pedigree. No abnormality was detected in 220 controls (P=0.006). Abnormalities identified included H19 DMR epimutations, uniparental disomy 11p15 and two novel H19 DMR imprinting center mutations (one microinsertion and one microdeletion).Our data identify microinsertion as a new class of imprinting center mutation and provide insights into mechanisms of imprinting disruption. In addition, they identify constitutional 11p15 defects as one of the commonest known causes of Wilms tumor and reveal clinically important epigenotype-phenotype associations. The impact on clinical management dictates that constitutional 11p15 analysis should be considered in all individuals with Wilms tumor.

COMPLEX CHROMOSOMAL REARRANGEMENT IS REVEALED BY CGH-A IN A GIRL WITH MULTIPLE CONGENITAL ANOMALIES. *M. Michelson[1,2], C. Vinkler[1,2], I. Linder[2,3], M. Yanoov-Sharav[1,2], T. Lerman-Sagie[2,3], D. Lev[1,2]* 1) Genetics Inst, Wolfson Medical Ctr, Holon, Israel; 2) Metabolic Neurogenetic Clinic,Wolfson Medical Ctr, Holon, Israel; 3) Pediatric Neurology Unit,Wolfson Medical Ctr, Holon, Israel.

Structural chromosomal aberrations are often associated with multiple congenital anomalies (MCA) and various syndromes. Cryptic microduplications and microdeletions undetected by routine karyotype analysis can be revealed by CGH-microarray and help both in diagnosis and proper genetic counseling. A 9 month old baby girl presented to our clinic with developmental delay,congenital heart defect(VSD), nephrolithiasis, cholelthiasis and dysmorphic features.She has hypertelorism,upslanting palpepbral fissures,arched eyebrows, epicantal folds and abnormal structure of her right external ear. During pregnancy single umbilical artery and hyperechogenic bowel were found by ultrasound examination. Amniocentesis was done and a normal 46,XX karyotype was found. She is the second child of an unrelated generally healthy couple. They have a healthy six year old girl and a history of a previous pregnancy which was terminated because of severe cleft lip and palate. Due to MCA CGH-microarray was performed on DNA from lymphocytes, using BAC clones. This analysis detected single copy gain of 12 BAC clones from the proximal region of the long arm of chromosome 13q12.11q12.12. A second abnormality was also detected and characterized by a single copy gain 4 BAC clones from the pericentromeric region of the short arm of chromosome 20 at 20p11.21. Fluorescence in situ hybridization (FISH) analysis using BAC clones from the 13q12.11 region and 20p11.21 identified two marker chromosomes. These marker chromosomes were seen in 28 of 30 cells examined (93%) and result in partial mosaic trisomy for proximal 13q and pericentromeric 20p. Neither parent carried a translocation or marker chromosome for either 13q or 20p. This case emphasizes the importance of further investigation in cases of multiple congenital anomalies in spite of normal karyotype in amniocytes or lymphocytes. Molecular cytogenetic analysis by CGH-microarray allowed both diagnosis and accurate counseling to this family.

Follow up of the genome-wide association study in celiac disease - identification of two novel shared immune loci.

A. Zhernakova[1], G. Trynka[2], J. Romanos[2], K. A. Hunt[3], A. Ryan[4], G. Turner[4], L. Franke[1,2], C. C. van Diemen[2], M. Bruinenberg[2], D. Barisani[5], R. McManus[4], D. A. van Heel[3], C. Wijmenga[1,2] 1) Dept Biomedical Gen, UMC Utrecht, The Netherlands; 2) Genetics Department, UMC Groningen, The Netherlands; 3) Barts and the London, School of Medicine and Dentistry, London, United Kingdom; 4) Department of Clinical Medicine, Institute of Molecular Medicine, Trinity College Dublin, Ireland; 5) Department of Experimental Medicine, University of Milano Bicocca, Italy.

Celiac disease is a common food intolerance, affecting 1% of Caucasians and caused by an abnormal immune reaction against gluten - a dietary protein present in wheat, barely and rye. Recently we performed a genome-wide association study (GWAS) in 767 celiac cases and 1422 controls, that was followed up by replication of the top-1020 associated SNPs in an extended cohort of >5000 celiac cases and controls from three populations. We identified 8 novel celiac genes, most of which are involved in immune response and a number of these are shared risk factors with other autoimmune and inflammatory disorders. Interestingly, from the 8 genes, only 3 were identified by SNPs ranking in the top 100 of p-values in the original GWAS, whereas 3 loci were presented by SNPs ranking below the top-800 in the original study. Therefore we decided to extend the GWAS replication further by genotyping an additional 650 SNPs in the replication cohort of 5000 celiac cases and controls. In a combined analysis of 7200 subjects (GWAS + replication cohorts), 13 novel non-HLA SNPs showed association with p(CMH)<10E-05. The top 12 SNPs were further typed in 545 Italian celiac cases and 593 controls. Combined analysis in >8300 subjects indicate association of 2 loci with pCMH of 1.3E-08 and 5.2E-07 respectively. Both associated loci are not unique for celiac, but confer also susceptibility to rheumatoid arthritis and type 1 diabetes (locus 1) and inflammatory bowel disease (locus 2). By extension of the GWAS-follow up in a large collection of samples, we have discovered two novel shared autoimmune loci. The extensive follow up of GWAS is a promising strategy for identification of novel genes in complex disorders.

***SMN1* allele frequencies in the major ethnic groups within North America.** *B. C. Hendrickson[1], C. Donohoe[1], V. Akmaev[1], E. Sugarman[1], P. Labrousse[1], L. Boguslavskiy[1], K. Flynn[1], E. M. Rohlfs[1], B. Allitto[1], C. Sears[2], T. Scholl[1]* 1) Genzyme Genetics, Westborough, MA; 2) Department of Hematology and Oncology, Childrens Hospital, Boston, MA.

Spinal Muscular Atrophy (SMA) is the most common inherited lethal disease of children. Various genetic deletions involving the loss of *SMN1* exon 7 are reported to account for 94% of mutant alleles that convey this recessive trait. Published literature places the carrier frequency for *SMN1* mutations between 1 in 25 and 1 in 50 in the general population. Although SMA is considered to be a pan-ethnic disease, carrier frequencies for specific ethnicities are unknown. To provide an accurate assessment of *SMN1* mutation carrier frequencies in African American, Ashkenazi Jewish, Asian, Caucasian, and Hispanic populations, more than 1000 anonymous specimens in each ethnic group were tested using a clinically validated, quantitative real-time PCR assay that measures exon 7 copy number.

Differences in the frequency of carriers with only 1 copy of *SMN1* were significant between several ethnic groups. The 1 copy genotype frequency in Caucasians was 1 in 37 (2.7%; 95%CI: 1.9%, 3.9%), 1 in 46 (2.2%; 95% CI: 1.5%, 3.3%; P=0.4762) in Ashkenazi Jews, 1 in 56 (1.8%; 95% CI: 1.1%, 2.8%; P=0.1393) in Asians, 1 in 91 (1.1%; 95% CI: 0.6%, 1.9%; P=0.0089) in African Americans, and 1 in 125 (0.8%; 95% CI: 0.4%, 1.5%; P=0.0007) in Hispanics (P value = significance of 1 copy genotype frequency difference from Caucasian). Also, differences in the frequency of genotypes with three or more *SMN1* copies were observed.

These data refine the knowledge of SMA by specifically assessing mutation carrier frequencies within the major ethnic groups within North America at a high level of accuracy afforded by large data sets. These results support recent recommendations by some researchers and family support groups for more widespread SMA carrier screening by expanding the information base available to clinicians and patients considering testing.

Brachydactyly Type D and Type E linked to chromosome 7p in an ethnic group from eastern Nepal. *K. D. Williams[1], J. Blangero[2], S. A. Czerwinski[1], C. R. Cottom[1], S. Lawrence[1], J. Subedi[3], B. Jha[4], T. Dyer[2], J. L. VandeBerg[2], S. Williams-Blangero[2], B. Towne[1]* 1) Wright State University Boonshoft School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) Miami University, Oxford, OH; 4) Tribhuvan University Institute of Medicine, Kathmandu, Nepal.

There is phenotypic overlap between Brachydactyly Type D (BDD) and Brachydactyly Type E (BDE) that suggests a possible common underlying etiology. BDD is characterized by a short, broad distal phalanx of the thumb, and BDE includes short 3rd, 4th, and/or 5th metacarpals and often the thumb. The Jirel ethnic group of eastern Nepal participates in various genetic epidemiological studies, including those of skeletal growth and development. As part of the Jiri Growth Study, a hand-wrist x-ray is taken annually for each child to assess skeletal maturation. Hand-wrist x-rays have also been taken for all adult relatives in order to study familial brachydactylies. For this study, a total of 2,308 individuals (1,381 children; 927 adults) in one large extended pedigree were examined for BDD and BDE. The prevalence of BDD and BDE in this sample is 3.94%. We used variance-components methods implemented in SOLAR (Almasy and Blangero, 1998) to conduct a genome-wide linkage scan for QTL influencing BDD- and/or BDE-affected status in a subsample of 1,722 individuals typed for ~400 STR markers. The additive genetic heritability was highly statistically significant in this sample (h^2 SE = 0.78 0.11, $p=2\times10^{-12}$). Significant linkage was found for BDD and/or BDE to markers on chromosome 7p at 40 cM between 7p21-7p14 (LOD score = 3.74). Possible positional candidate genes in the one-lod support interval include *TWIST1* and the *HOXA1-A13* cluster. Mutations of *TWIST1* and *HOXA13* have been implicated in other limb development disorders. This is the first study to report significant linkage results for BDD and BDE using a large extended pedigree, and the first to suggest that *TWIST1* and/or the *HOXA1-A13* cluster may contribute to these specific skeletal anomalies. Supported by NIH grants F32HD053206, R01HD40377, R01AI37091, R01AI44406, and R37MH59490.

Limitations on the predictive power of combining genetic markers. *M. Mosteller, L. Li, I. Grossman, M. R. Nelson*
Genetics, GlaxoSmithKline, Res Triangle Pk, NC.

Substantial research effort is being applied to the discovery of predictive genetic markers with the intent of estimating the probability that a patient will develop a disease or respond a particular way to a drug treatment. The increasing application of whole genome genotyping technologies has resulted in the identification of numerous individual genetic risk factors for diseases and clinical responses. These markers are statistically associated with disease status or treatment response, but may lack sufficient predictive power to be clinically useful. In these situations, we are interested in the opportunities for combining genetic markers to generate a prognostic test with useful predictive power. We have investigated the conditions under which the composite sensitivity and specificity (SE and SP, respectively) of combinations two independent markers will both exceed the sensitivities and specificities of the contributing markers (SE1, SE2 and SP1, SP2, respectively). When we classify marker genotypes as either high risk (+) or low risk (-), there are four possible two-marker combinations: ++, +-, -+, and --. If, for example, the -- combination were predictive of individuals at low risk and all other combinations were predictive of high risk, then it can be shown that while the sensitivity of the composite test may be as large as the sum of SE1 and SE2, its specificity will be no greater than the lesser of SP1 and SP2. Only under restricted conditions - conditions that depend on the presence of epistatic genetic effects and the relative frequencies of the high risk genotypes - can composite sensitivity and specificity be greater than those of the contributing markers. However, in most circumstances, the prospects for using combinations of multiple markers to substantially improve the predictive power of markers with moderate effects appear to be limited.

Comprehensive analysis of common SNPs at 22 circadian genes: associations with bipolar I disorder at NPAS2.
H. Mansour, M. Talkowski, J. Wood, K. Chowdari, L. McClain, K. Prasad, D. Montrose, A. Fagiolini, E. Friedman, M. Allen, C. Bowden, J. Calabrese, R. El-Mallakh, S. Faraone, M. Fossey, L. Gyulai, J. Loftis, P. Hauser, T. Ketter, V. Nimgaonkar Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Objective: Prior reports suggest association of key circadian genes with bipolar I disorder (BP1), schizophrenia (SZ) and schizoaffective disorder (SZA). Our objectives were: 1. to comprehensively test association at representative common polymorphisms of validated circadian genes; 2. to explore association with Morningness/Eveningness (M/E), a quantitative trait that reflects circadian phase and replicably distinguishes BP1 cases from controls. METHODS: We assayed 279 publicly available tag SNPs at 22 circadian genes in a sample of 523 patients with BP1, 532 patients with SZ/SA, and 477 screened adult controls. The composite scale (CS), a measure of M/E was completed by a subset of participants (n = 128 controls, n = 146 SZ patients). RESULTS: Gene-based tests, but not individual SNP analyses yielded significant associations between NPAS2 and BP1 (Bonferroni corrected $p = 0.02$). Similar trends were observed with SZ/SZA (corrected $p < 0.1$). Exploratory analyses suggested associations between CS scores and SNPs from 11 genes (n = 25 SNPs), with NPAS2 SNPs outnumbering the other genes (n = 9 SNPs). SNP rs13025524 at NPAS2 was nominally associated with BP1 and SZ/SZA. CONCLUSION: Several lines of evidence suggest that NPAS2 is associated with disorders in the BP1/SZ spectrum, as well as a quantitative trait related to these disorders. Replicate studies using sufficiently powered samples, as well as functional analyses are warranted. Additional authors: Lauren B. Marangell, David J. Miklowitz, Andrew A. Nierenberg, Jayendra Patel, Gary S. Sachs, Pamela Sklar, Jordan W. Smoller, Nan Laird, Matcheri Keshavan, Michael E. Thase, David Axelson, Boris Birmaher, David Lewis, Tim Monk, Ellen Frank, David J. Kupfer, Bernie Devlin.

Profound deficits in pancreatic islet function lead to hormone deficiency in a deletion mouse model of Prader-Willi syndrome (PWS). *M. Stefan[1,2], R. A. Simmons[3], S. Bertera[1,2], M. Trucco[1,2], F. Esni[1,2], P. Drain[2], R. D. Nicholls[1,2]* 1) Children's Hospital of Pittsburgh, Pittsburgh, PA; 2) University of Pittsburgh, Pittsburgh, PA; 3) University of Pennsylvania, Philadelphia, PA.

Type 2 diabetes is considered a frequent outcome of obesity in PWS. Nevertheless, several studies have shown that patients with PWS have increased insulin resistance and decreased insulin secretion relative to the degree of obesity. The mechanisms underlying these phenomena are unknown. Genetic defects in PWS lead to loss of function of multiple imprinted, paternally-expressed loci encoding proteins and small RNAs with most predicted to regulate other RNAs suggesting that multiple pathways could be affected in PWS. In a transgenic deletion mouse model of PWS (TgPWS) with neonatal failure to thrive we identified exceptionally low to undetectable levels of plasma insulin and glucagon in fetal and neonatal life. Circulating hormone deficiencies were associated with disrupted islet architecture, reduced and cell mass and decreased insulin, C-peptide and glucagon pancreatic content at postnatal (P) day 1. As circulating levels of pancreatic hormones were out of proportion to decreased and cell mass we used an Ins-C-Timer fluorescent reporter that changes color with time after insulin synthesis to monitor secretion from cells in TgPWS pancreas at P1. We found impaired insulin release which may explain the severe hypoinsulinemia in TgPWS mice. Analysis of pancreatic global gene expression by microarray and quantitative QRT-PCR, and expression studies using purified islets, showed that mRNAs encoding all islet hormones and many proteins involved in secretion/exocytosis are increased by 4-7.5 fold relative to islet cell mass in P1 TgPWS mice. This may represent an islet-specific compensatory response to deficient plasma hormone levels and/or a primary effect of a missing PWS gene. In conclusion, profound functional and developmental pancreatic islet deficits are found in a PWS mouse model. Elucidation of the basis for global islet hormone secretory abnormalities in the PWS mouse model may identify a new regulatory pathway of insulin and other hormone secretion.

Eight-year clinical outcomes of enzyme replacement therapy in 884 children with type 1 Gaucher Disease. *H. C. Andersson[1], P. Kaplan[2], K. Kacena[3], J. Yee[3]* 1) Hayward Genetics Ctr, Tulane Univ Medical Ctr, New Orleans, LA; 2) Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Genzyme Corporation, Cambridge, MA.

OBJECTIVE: To analyze the clinical responses to enzyme replacement therapy (ERT) in a large international cohort of children with type 1 Gaucher disease (GD1). METHODS: Anonymized data from 884 children in the Gaucher Registry were analyzed for the effect of long-term ERT on hematological and visceral manifestations, linear growth and skeletal disease. Data analysis used mixed effects models and Kaplan-Meier curves (bone pain and bone crises). Median ERT dose was 75u/kg/4wks. RESULTS: The median height Z-score for the study population was -1.4 at baseline and 34% of patients were less than normal 5%ile height. After 8y of treatment, the median height and percentiles approximated that of the normal population. Anemia was present in over 50% at baseline and resolved in all patients after 8y of treatment. Over 50% of patients had platelet counts below 100,000/cu mm at baseline but over 95% had platelets above this level after 8y of treatment. Liver and spleen volumes decreased over 8y of treatment. Mean bone density Z-score was -0.34 at baseline, and normalized within 6.6y of treatment. In patients reporting bone crisis before treatment (17%), no bone crises were reported after 2y of ERT. Few (2.5%) patients without bone crises pre-ERT at baseline had a crisis after the start of treatment. CONCLUSIONS: Within 8y of ERT most clinical parameters studied became normal or near normal. The data provide pediatricians a measure of expected response in GD1 patients for individual clinical parameters relative to baseline and offer the first long-term outcomes for a large worldwide pediatric cohort.

Differential Bias in Genotype Calls between Plates due to the Effect of a Small Number of Lower DNA Quality and/or Contaminated Samples. *A. Pluzhnikov[1], J. E. Below[1], A. Tikhomirov[1], A. Konkashbaev[1], S. Roe[1], D. Nicolae[1,2], N. J. Cox[1]* 1) Medicine/Genetic Medicine, Univ Chicago, Chicago, IL; 2) Statistics, Univ Chicago, Chicago, IL.

Quality control (QC) issues in genotype calling are becoming increasingly important in genome wide association studies. We examined the effect of a small number of samples that had lower than average DNA concentration, DNA fragmentation, contamination, or other quality issues not detected by standard QC, on genotype calling of other samples in the study using data from the Genetics of Kidneys in Diabetes (GoKinD) collection of more than 1600 unrelated probands with Type I diabetes. All samples were typed using the Affymetrix Genome-Wide Human SNP Array 5.0 platform, and genotypes were called by plate using the Birdseed v.2 algorithm to minimize the amount of missing data. We detected 8 problematic samples displaying unusual patterns of relatedness and high levels of heterozygosity and showed that, for a number of markers, these samples cluster together, thus altering the allele calls for other samples on the plate and leading to significant differential bias in allele frequencies between plates that eventually resulted in false-positive associations in the GoKinD data. We discuss ways to detect this kind of differential bias between plates, and to correct it depending on the availability of the raw intensity (.cel) files.

Skeletal features, cardiovascular involvement and outcomes of patients with TGFBR2 mutation and comparison with unaffected patients and patients with FBN1 mutation. *D. Attias, C. Stheneur, L. Faivre, MA. Delrue, H. Plauchu, S. Lyonnet, M. Rio, C. Francannet, M. Le Merrer, C. Boileau, G. Jondeau* APHP, Consultation multidisciplinaire Marfan, Hopital Bichat Claude Bernard, Paris, France.

TGFBR2 mutation is a rare event leading to still incompletely characterized phenotypes. We report clinical features and outcome of 94 patients with known TGFBR2 mutation, belonging to 26 different families. They were compared with a large group of 243 patients with FBN1 mutations matched for age and sex. Patients with TGFBR2 mutations were 28,3 16,1 y.o.; 49M/45F. Common skeletal in the TGFBR2 group were joint hypermobility (73.3 %), pectus anomaly (43 %) and highly arched palate (48.6 %. According to Ghent criteria, 86.1 % (62/72) of patients with TGFBR2 mutation showed less than 3 major skeletal criterion and 31.9 % patients (23/72) showed no major skeletal criterion. Mitral valve prolapse was present in 26% vs 45% in the group of patients with FBN1 mutation ($p<0.001$) and no surgery for mitral valve was performed. Maximal aortic diameter was observed at the level of the sinuses of Valsalva for all patients. However, the degree of dilatation was very variable from one patient to another : 27 % of patients with TGFBR2 mutation were without significant aortic dilation including 3 patients above 55 y.o. 27 patients died before or during the study period; the mean age of death was 36,314,6 years (range 9 to 67) with ascending aortic dissection and sudden death as leading cause. There was no difference in the occurrence of ascending aorta surgery (for aneurysm or dissection) between the two groups but patients with TGFBR2 mutation had to undergo this surgery younger (3113 years vs. 3912 years, $p = 0.01$). Conclusions TGFBR2 mutation is associated with mild skeletal features, less frequent and less diffuse than in patients with FBN1 mutation. There was no mitral valve prolapse leading to qurgery in the TGFBR2 group. Aortic involvement is more severe as a mean than in patients with FBN1 mutations. However it is very variable: moderate or no aortic dilatation was observed in some elderly patients carrying the mutation.

Massively parallel paired-end transcript sequencing of primary malignant glioblastoma. *M. J. Clark[1], N. Homer[2], Z. Chen[1], B. O'Connor[1], B. Merriman[1], S. Nelson[1]* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Computer Science, UCLA, Los Angeles, CA.

Glioblastoma multiforme (GBM) is the most deadly form of brain cancer, having a median survival time of less than a year. Abnormal transcripts resulting from aberrant splicing and translocation events are common features. With the advent of massively parallel paired-end sequencing, we are capable of visualizing these abnormal transcripts on a genome-wide basis, which can be performed in parallel with sequence mutation discovery. We have performed paired-end sequencing using the Solexa Genome Analyzer II on full-length cDNA prepared from eight primary GBMs from separate patients. Randomly sheared cDNA libraries with an average insert size of 200 bases were selected, and we attempted to sequence 50 bases from both ends. BFAST was used to align the reads to RefSeq and to the genome. This method is sensitive to detecting fusion transcripts, known alternative splicing events, and novel mRNA isoforms, but relies on reasonable expression level of the transcripts. Further, for more highly expressed genes, the aligned sequences can be searched for differences relative to the consensus sequence of the human genome. We show that homozygous mutations leading to premature stop codons in PTEN are detectable with this approach. Novel transcripts unique to glioblastomas are strong candidates as key role-players in tumorigenesis.

Meta-analysis of genetic association studies and adjustment for multiple testing when SNPs or traits are correlated. *K. N. Conneely[1], M. Boehnke[2]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

A recent wave of large-scale genetic association studies has led to a host of positive and promising genetic association results. In turn, validation of these results through testing in independent samples and the boost in statistical power from combining results across samples have led to an increased focus on meta-analysis. Prospective meta-analysis, in which several samples are genotyped and phenotyped with the intent to combine results, has become more feasible due to decreases in genotyping costs and the collection of increasingly large samples. This includes the popular and efficient two-stage analysis, in which the most significant SNPs or traits from an initial study are followed up in independent samples. Retrospective meta-analysis, which combines results from published studies, remains common as a method to summarize and clarify findings from previous studies which may lack precision and power due to small sample size.

Meta-analyses of genetic association studies based on multiple SNPs and traits are subject to the same multiple testing issues as single-sample studies, but it is often difficult to accurately adjust for the multiple tests. Procedures such as Bonferroni may control the type I error rate but will generally provide an overly harsh correction if SNPs or traits are correlated. Depending on study design, availability of individual-level data, and computational requirements, permutation testing may not be feasible in a meta-analysis framework. We present methods and software for adjusting for multiple correlated tests under several study designs commonly employed in meta-analyses of genetic association tests. Our methods are applicable to both prospective and retrospective meta-analyses, and the study designs include cases where the same SNPs are not genotyped in all studies due to missingness-at-random or two-stage design. Simulations show that these methods accurately control the rate of type I error and achieve improved power over multiple testing adjustments that do not account for correlation between SNPs or between traits.

Micro CT analysis of bone phenotypes: Thresholding for accurate density vs. trabecular geometry across different scan resolutions. *B. Dawson[2], T. Sibai[1], B. Lee[1,2]* 1) Dept. Mol & H Genetics, Baylor College Med, Houston, TX; 2) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX.

High resolution MicroCT scanning is primarily used for geometric and densitometric quantification of small animal bone tissues. The analysis of these samples requires a "thresholding" step that differentiates bone from background or lower density material not intended for analysis. Thresholding for density measurements and trabecular geometric estimation (BV/TV) is classically performed separately. Objective: To assess the optimum threshold that best reflects both density and trabeculal architecture simultaneously and to examine the mathematical relationship held between density and threshold. A phantom of known density of 1051 mg HA/ccm was scanned alongside a murine femur at four different resolutions (12, 16,20 and 30 m). The phantom was scanned at different resolutions by using a single fixed size sample holder but altering the softwares scan resolution in order to reduce position variability among scans. For each threshold increment of 10 of threshold values (150-300) commonly used for trabecula geometry estimation, the density of the standard phantom was assed using the machines configured trabecular bone analysis algorithm. The mouse femur was included alongside the phantom to help determine the accuracy of trabecular geometry at the threshold that best reflects the true density of phantom. Results: At higher resolution scans (12, 16, and 20 m), the density measurement across the range of thresholds is linear with best estimation of true density at thresholds of 182, 206, 226 respectively. The relationship between threshold and density at 30 m resolution was less linear especially at thresholds below 240. At the optimum density threshold, higher scan resolution tended to overestimate and lower resolutions tended underestimate trabecular geometry Conclusion: The optimum threshold for density estimation was inversely proportional to scan resolution .The density optimized threshold at 16 m resolution best represented trabecular architecture. These results should be considered when critically evaluating bone density data on animal models reported in the literature.

Mutation analysis of the GIGYF2 (PARK11) gene in 55 families with parkinsonism. *B. Schuele, L. C. Sterling, D. Tewari, K. K. Johansen, J. W. Langston* Parkinson's Institute, Sunnyvale, CA.

Objective: To determine the mutation frequency in the Grb10-Interacting GYF Protein 2 (GIGFY2) gene in cases with parkinsonism and family history. Background: A mutation frequency of 4.8% (12/249) in the GIGYF2 gene has been reported in patients with familial Parkinsons disease (PD) from France and Italy. Methods: PD cases with at least one affected relative were enrolled in the study. Cases and healthy controls were ascertained through the outpatient clinic at the Parkinsons Institute and signed IRB approved informed consent. All 28 coding exons including exon-intron boundaries were sequenced bi-directionally in 55 familial cases. Samples tested negative for the LRRK2 p.G2019S mutation. Detected sequence changes were genotyped using restriction enzyme digestion of the PCR products in controls and relatives. Results: We detected four novel sequence changes that were not present in 378 control alleles. Two changes (2/55, 3.6 %) were missense mutations (p.D349E and p.S1035C). One change was a 3-bp duplication c.3063_3065dupGCA and one was a synonymous variant (c.1983AG). In addition, we found a known synonymous variant (c.1716 GT), which was not present in the control population. The two amino acid substitutions, p.D349E and p.S1035C, were found at highly conserved regions of the protein, however, bioinformatic predictions of the pathogenicity using SIFT showed tolerable scores of 0.59 and 0.06, respectively. The carrier of the p.D349E change had LOPD (age at onset 78) showing a recessive mode of inheritance with two additional affected siblings. The patient with the p.S1035C change had a phenotype of EOPD (age at onset 27) with slow progression, and five affected relatives showing an dominant inheritance pattern with reduced penetrance. Conclusion: We detected a similar mutation frequency in our families from North America as was reported in families from France and Italy. To conclude that these variants are disease-causing, we are in the process of ascertaining DNA samples from additional family members to test if the variants segregate within the family. We will perform functional assays of the detected variants to determine pathogenicity.

Breakpoint location in 22q11 deletions determined by aCGH. *D. C. Bittel[1], S. Yu[1], H. Newkirk[1], N. Kibiryeva[1], A. Holt III[1], M. G. Butler[2], L. Cooley[1]* 1) Section of Medical Genetics, Children's Mercy Hospital, Kansas City, MO; 2) 6410 Hillside St. Shawnee, KS 66218.

A hemizygous deletion of chromosome 22q11 commonly results in conotruncal cardiac defects along with a variable group of other anomalies. Four distinct highly homologous blocks of low copy number repeats (LCRs) flank the deleted region. Mispairing of the LCRs during meiosis resulting in unequal meiotic exchange is hypothesized to be the mechanism causing the deletion. The proximal LCR is located on 22q11 from 17.037 to 17.083 Mb and the distal LCR is located from 19.835 Mb to 19.880. Although the breakpoints are known to localize to the LCRs, the position of the breakpoints have not been investigated in more than a few individuals. We used high resolution oligo-based array Comparative Genomic Hybridization (aCGH) to resolve the breakpoints in 20 subjects with 22q11 deletions. We also investigated copy number variation (CNV) in the rest of the genome. It appears that the 22q11 break can occur on either side of the LCR, although more commonly on the distal side of the first LCR. The proximal breakpoints in our subjects spanned the region from 16.932 Mb to 17.343 Mb. This region includes the genes PEX26, (peroxisome biogenesis factor 26); TUBA8, (tubulin, alpha 8) USP18, (ubiquitin specific protease 18); DGCR6, (DiGeorge syndrome critical region protein 6); PRODH, (proline dehydrogenase 1) along with several open reading frames that may encode proteins of unknown function. The distal breakpoints in our subjects spanned the region from 19.788 Mb to 20.136 Mb. This region includes the genes GGT2, (gamma-glutamyltransferase-like protein 2); HIC2, (hypermethylated in cancer 2) and multiple transcripts of unknown function. The genes in these two regions are variably hemizygous depending on the location of the breakpoint. These 20 subjects had 75 CNVs, 15 duplications and 60 deletions ranging in size from 1 Kb to 10 Mb. The variable presence or absence of genes at the breakpoints plus the variation in the genome due to CNVs likely contributes to the variable phenotype associated with DiGeorge/velocardiofacial syndrome.

Identification of a Single Gene Locus for Canine Squamous Cell Carcinoma of the Digit. *E. A. Ostrander[1], B. vonHoldt[2], E. Karlins[1], D. Mosher[1], J. Mulliken[1,3], H. Parker[1], R. K. Wayne[2], D. M. Karyadi[1]* 1) NHGRI, NIH, Bethesda, MD; 2) Dept of Biology, UCLA, Los Angeles, CA; 3) NISC, NIH, Bethesda, MD.

Squamous cell carcinoma (SCC) of the digit is a highly breed-specific skin cancer with increased risk found in large black dogs, including the standard poodle, giant schnauzer, briard and Gordon setter. This cancer is more aggressive than most SCCs with 80% of cases involving bone lysis and 5-13% recurring in multiple toes. When invasive, metastasis to the lung or lymph nodes ultimately leads to death. Using the canine-specific Affymetrix chip, containing 127,000 single nucleotide polymorphisms (SNPs), we conducted a whole genome association study for SCC of the digit using 31 standard poodle cases and 34 controls. SNPs were removed from the analysis if greater than 10% of the data was missing, there were more then 60% heterozygous calls, or minor allele frequency was less than 1%. The final SNP set consisted of 45,078 SNPs. Using the single-locus chi-squared test of significance, we calculated the allelic association of each SNP with the disease phenotype. The top 6 most significant SNPs were all at the same genomic locus (P_{raw}=5.62x10^{-5}-1.20x10^{-7}). Chromosome-wide permutations (n=100,000) were performed to test for significance yielding a chromosome-wide empirical value of P=7.00x10^{-5} for the most significant SNP. Five other SNPs in this region were also significant (P_{emp}=0.0299-0.0010). No other genomic regions yielded peaks significant at the chromosome-wide level. Initially, the distance spanned by the significant peak was 999.4 kb, and included four known and four predicted genes. After additional SNP genotyping and sequencing haplotype analysis, utilizing over 325 markers, resolved the region to 812.2 kb with 3 crossovers on each side. A reduced region, defined by 1 crossover, spans 515.7 kb, and contains only 1 complete gene plus 2 exons of a second gene. The complete gene is an excellent candidate and is a potential oncogene. The entire region is being scanned using a capture technology combined with Solexa sequencing to identify the causal variant. Identification of the mutation underlying this canine cancer is likely to inform human forms of SCC.

Inside the brain in Angelman Syndrome: Phenotypic characterization using advanced neuroimaging techniques.

S. U. Peters[1], C. A. Bacino[2], Z. Chu[3], R. Yallampalli[4], J. V. Hunter[3], E. A. Wilde[4] 1) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 2) Dept. Molecular & Human Genetics, Baylor Col Medicine, Houston, TX; 3) Dept. Radiology, Baylor Col Medicine, Houston, TX; 4) Dept. Physical Medicine & Rehab, Baylor Col Medicine, Houston, TX.

Angelman syndrome (AS) is a neurogenetic disorder that is characterized by severe mental retardation, lack of speech, ataxia, seizures, and frequent outbursts of laughter. We utilized quantitative magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI) techniques to examine the neuroanatomical correlates and white matter alterations that contribute to the phenotype in AS. Here we present preliminary findings of five deletion positive patients with AS and five age and gender matched controls. Results of DTI studies reveal significant differences between AS patients and controls for white matter pathways involving the frontal, temporal, parietal, and limbic areas. Patients with AS exhibited lower fractional anisotropy values and higher apparent diffusion coefficient and radial diffusivity values in these regions. Significant correlations were noted between cognitive, language, motor, and memory skills and impairment in frontal regions. Abnormalities in temporal pathways were associated with fine motor and expressive language deficits. Abnormalities in limbic pathways were correlated with deficits in socialization and play skills. Results of quantitative MRI indicate that after controlling for total intracranial volume, AS patients have reduced white matter volumes in the cerebellum and cerebrum. Reduced volumes were also noted for the hippocampus, caudate, and putamen relative to controls. Reduction in volume in the cerebellum, caudate, and putamen was significantly correlated with gross motor abilities while impairments in play and social skills were significantly correlated with amygdala volume. These findings demonstrate that AS patients exhibit microstructural changes in white matter fiber tracts that affect the development, wiring, and targeting of axons that link affected brain regions. They also exhibit reduced volume in brain regions that directly contribute to the phenotype observed.

What's in an aging clinic? Family concerns and medical issues in Cornelia de Lange syndrome. *A. D. Kline[1], J. Peracchio[2], M. Simonson[3], A. Kimball[1]* 1) Harvey Inst Human Gen, Greater Baltimore Medical Ctr, Baltimore, MD; 2) Cornelia de Lange Syndrome Foundation, Avon, CT; 3) Johns Hopkins Univ/National Human Genome Research Inst, NIH Genetic Counseling Graduate Program, Bethesda, MD.

Multidisciplinary clinics for the assessment of aging are rarely found for specific genetic syndromes. We have held such a clinic for older individuals with Cornelia de Lange syndrome (CdLS) for seven years. A total of 59 patients have been seen with an equal male to female ratio, and age range from 11 to 50 years, with 36% over 21 years. Of these, 47% are severely involved, 19% moderately and 34% mildly. Parent(s) accompanied 98% of the patients, and 22% brought siblings, with 42% from outside our mid-Atlantic region. Seventy-five percent live with the family and 3% have died. The diagnosis of CdLS was questioned in three additional patients. Regarding family concerns, the greatest have been behavioral, especially in the moderately affected group, and then gastrointestinal (GI), although lower than expected for the high incidence of GI involvement. Other concerns have included nutrition and weight, regardless of age or severity, dental, particularly in the most severe group, orthopedic issues in those under 21 years, and reproductive health issues in females. Medical findings and evidence for premature aging from this clinic have been previously reported [Kline et al., AJMG 145C:248-60, 2007]. Recommendations were GI-related in 68% of patients, behavioral in 53%, with medication adjustments in 31%, and related to diet and exercise in 34%. Preventative diagnostic work-up was recommended in 36%. Other recommendations included hormonal testing, dental work, and audiology evaluation. State funding, work-related issues after schooling, and other social needs were also raised. Clearly, there is a need for additional regional clinics, as well as specific diagnostic studies recommended on all diagnosed patients. A major component of aging is the existing concerns by siblings related both to future care of the affected individual and recurrence. Assessment of the genetics of healthy aging is a recent public health initiative and similar clinics could elucidate some important findings.

Rai1 overexpression in specific brain regions is enough to induce phenotypes observed in PTLS mouse model. *J. Molina, P. Carmona-Mora, J. Young, K. Walz* Centro de Estudios Científicos, Valdivia, Valdivia, Chile.

Retinoic acid induced 1 gene (RAI1) is a dosage-sensitive gene located within the human chromosome 17p11.2 region. Mutations in RAI1 have been associated with Smith-Magenis syndrome (SMS; MIM182290). Duplication of 17p11.2 chromosome region, results in the Potocki-Lupski syndrome (PTLS; MIM610883) characterized by mental retardation, growth delay, reduced body weight, anxiety, hyperactivity and autistic behaviors. The objective of this work is to study when and where overexpression of Rai1 is causative of the PTLS phenotype. For this purpose we generated mice that bear an inducible wild-type Rai1 allele in a wild type genetic background. We tagged a wild type copy of Rai1 cDNA with HA and subcloned it downstream of a bidirectional tetracycline-responsive promoter (EGFP-pBI-Rai1-HA) to generate transgenic mice that bear an extra copy of Rai1. We crossed the Rai1 transgenic mice with those expressing tTA under CamKII or Eno2 promoter regulation. In these EGFP-Pbi-Rai1-HA; Eno (or CamKII)-tTA transgenic mice, expression of the Rai1 transgene can be initiated in a spatial promoter-dependent manner at different stages of development. Brain sections analysis of double transgenic mice, EGFP-Pbi-Rai1-HA, CamK2-tTA or EGFP-Pbi-Rai1-HA, Eno-tTA showed the expected EGFP And Rai1-HA pattern. In a first and rapid screening in order to see if the overexpression of Rai1 in different brain regions was enough to trigger a phenotype present in PTLS mouse model (Dp(11)17/+) we weighted the double transgenic mice from the first to the sixth month of life. Dp(11)17/+ mice are significantly underweight when compared to their wild type littermates. Interestingly enough we found that mice overexpressing Rai1 in different brain regions are significantly slimmer that their wild types littermates. Moreover, in Dp(11)17/+ mice the differences of weight are due to a decrease in adipose tissue when compared to wild type littermates a similar phenotype was found when we analyze these double transgenic mice. These results indicate that overexpression of Rai1 in specific brain regions is enough to trigger some of the phenotypes observed in PTLS mouse model.

Keratitis-ichthyosis-deafness (KID) syndrome: a connexin 26 gap junction disorder. *G. Oswald[1,5], K. Puttgen[2,5], B. Cohen[2,5], T. Wakefield[3,5], G. Raymond[4,5,6], J. Hoover-Fong[1,5]* 1) McKusick-Nathans Institute of Genetic Medicine; 2) Dept of Pediatric Dermatology; 3) Dept of Pediatric Otolaryngology; 4) Dept of Pediatric Neurology; 5) Johns Hopkins Univ, Baltimore, MD; 6) Kennedy-Krieger Institute, Baltimore, MD.

KID syndrome (MIM 148210) is a rare, congenital AD form of ectodermal dysplasia characterized by Keratitis, Ichthyosis and Sensorineural Deafness. It is caused by heterozygous mutations in gap junction beta 2 (GJB2) encoding connexin 26 (*Cx26*). Mutations in GJB2 also cause AD and AR nonsyndromic hearing loss, DFNA3 and DFNB1 respectively, and other AD keratoses with/out SNHL (e.g. hystrix-like ichthyosis-deafness, palmoplantar keratoderma, Vohwinkel syndrome).

A 10-month old Caucasian male was admitted for severe failure to thrive after foster care placement. Limited medical information revealed ectodermal dysplasia diagnosed at 2 months of age and failed hearing screens. Current findings include diffuse ichthyotic skin, photophobia, dystrophic nails, sparse eyebrows, eyelashes and hair, plagiocephaly, epidermal cyst and hypertonia; he could tear and sweat. Audiogram confirmed deafness and KID syndrome was proposed.

Molecular analysis of Cx26 revealed a heterozygous GA transition at codon 50 causing substitution of aspartic acid with asparagine, the most common mutation reported to cause KID syndrome. Most cases represent sporadic dominant mutations, though gonadal mosaicism or decreased penetrance has been suggested. Other complications of KID syndrome include inflammatory nodules, squamous cell carcinoma, epidermal cysts and corneal vascularization abnormalities.

Skin improved with aggressive lubrication and topical steroids, though abscesses of the neck and head have occurred. Photophobia has resolved and vigilant ophthalmologic followup is ongoing plus evaluation for cochlear implants. Early nutritional and psychosocial deficits likely contributed to poor weight gain and plagiocephly and are likely not part of KID disease spectrum.

TGF- and BMP- Signaling Pathways have Antagonistic Effects during Chondrogenesis. *B. Keller[1], T. Bertin[1], Y. Chen[1], E. Munivez[1], B. Dawson[2], P. Hermanns[3], B. Zabel[3], B. Lee[1,2]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Baylor Col Medicine, Houston, TX; 3) Centre for Pediatrics and Adolescent Medicine, University Hospital of Freiburg, Germany.

TGF/BMP signaling is essential for the development of the majority of embryonic and extraembryonic tissues. Ligands of these pathways are involved in the development of cartilage and bone at multiple stages. *Smad1* and *Smad5* are mediators of the BMP signals and both are expressed in the growth plate. TGF signaling has been shown to exhibit diverse effects both *in vitro* and *in vivo*. To compare the role of these signaling pathways in the growth plate, we generated mouse models of loss of BMP vs. TGF signaling function. To down regulate BMP signaling in vivo, we generated chondrocyte-specific deletions of *Smad1* on either a wild type and *Smad5+/-* background. Conditional deletion of *Smad1* in proliferating chondrocytes results in a slight shortening of the growth plate, while an additional *Smad5+/-* deletion leads to a more severe phenotype with shorter prehypertrophic and hypertrophic zones and a decreased proliferation rate. *Ihh* expression is down-regulated. Morphologically, the conditional *Smad1* deletion with and without *Smad5+/-* background leads to craniofacial alternations characterized by agenesis of the nasal septum. To down regulate TGF signaling in chondrocytes, we generated transgenic mice over-expressing a dominant negative form of the TGF receptor I (TRI). These mice are smaller but show histologically an elongated growth plate with enhanced *Ihh* expression, an increased proliferation rate and disturbed production of the extracellular matrix. Morphologically, they also exhibited a craniofacial phenotype: smaller skull with a prominent mandible. Hence, during endochondral ossification, BMP and TGF signaling have antagonistic effects on cell proliferation and differentiation. While disruption of BMP signaling leads to a shortening of the growth plate with fewer proliferating cells, impairment of TGF signaling results in an increased proliferation rate and thus a longer prehypertrophic and hypertrophic zone.

SNPs associated with normal variation in adult human height are not associated with osteoarthritis susceptibility.

K. Chapman[1], E. Zeggini[1], A. Gonzalez[4], N. W. Rayner[1], E. Suchiman[2], M. Kloppenburg[2], J. Rodriquez-Lopez[4], M. N. Weedon[5], T. M. Frayling[5], P. E. Slagboom[2], J. Loughlin[3], I. Meulenbelt[2] 1) WTCHG, Oxford, UK; 2) Leiden, The Netherlands; 3) Newcastle upon Tyne, UK; 4) Santiago, Spain; 5) Exeter, UK.

Osteoarthritis (OA) is a late-onset complex disease. A compelling genetic association with OA of a functional SNP (rs143383) in the 5' UTR of the *GDF5* gene has been observed in Asian and European cohorts. Intriguingly, this SNP is also significantly associated with normal variation in human height, opening up the possibility that there are common mechanistic pathways between these two polygenic traits. A large number of additional loci that influence human height have recently been reported. Our aim was to assess whether these SNPs were also associated with risk for primary OA. We genotyped 25 SNPs, previously associated with normal variation in human height, in a total of 4901 case-control samples. These were ascertained from 3 European cohorts in Spain (810 cases, 294 controls), the UK (1854 cases, 833 controls) and the Netherlands (191 sib-pairs from the GARP study, 728 controls). Association with overall OA was examined in the 3 populations individually and by meta-analysis using a fixed-effect model. Two SNPs were associated with OA in the Spanish cohort; rs16896068 within *LCORL* (OR 1.42, 95% CI 1.10-1.82), p=0.006 and rs1390401 within *ZNF678* (OR 1.64, 95% CI 1.23-2.18), p=0.0009. However, they were not replicated in the GARP (p=0.06 and p=0.48 respectively) or UK (p=0.71 and p=0.78 respectively) cohorts. Meta-analysis provided no evidence for significant association with the lowest p-value for rs9289476 within *ANAPC13* (combined OR 0.9, 95% CI 0.82-0.99), p=0.04. This was also the strongest signal in the UK sample (p=0.07). In conclusion, we do not find robust evidence for association to overall OA of any of the 25 SNPs genotyped. Within the power limits of our study we will further explore stratified associations to specific OA subtypes and/or gender. Our study indicates that, if human height and OA have a shared genetic component, the effect sizes of common variants affecting both traits are likely to be small.

Evidence of Genetic Epistasis and Sex-Gene Interactions in Susceptibility to Hypertension. *P. A. Shih[1], J. H. Moore[2], B. K. Rana[1], M. Mahata[1], S. Mahata[1], D. T. O'Connor[1]* 1) Department of Medicine, University of California, San Diego, San Diego, CA; 2) Computational Genetics Laboratory, Dartmouth Medical School, Lebanon, NH.

Hypertension is a multi-factorial disease. Here we applied case-control associations to explore high-order gene-gene and gene-sex interactions among 82 polymorphisms (SNPs) in three biological pathways known to affect hypertension risk. A cross-sectional study was analyzed using 679 hypertensive cases (352 male/327 female, mean SBP=154/DBP=99) and 704 normotensive controls (305 male/399 female, mean SBP=108/DBP=56) from a large, community-based sample. TuRF was used to filter 82 SNPs and to select a subset of 10 contributors most likely to interact. Epistatic interactions were probed using Multifactor Dimensionality Reduction (MDR). Association tests were conducted using Fisher's exact test and ANOVA. In vitro study of IL6 on *CHGA* promoter activity was conducted by luciferase assay. Of four candidate SNPs contributing to epistatic effects, *CHGA (3UTR)* , *IL6*, and *COMT* revealed individual associations with BP status ($p < 0.005$). Gene-sex interaction effect on risk was observed initially in MDR, while further association tests showed differential SNP-DBP associations for *CHGA (3UTR)* , *IL6* , and *COMT* polymorphisms, when analyzing men and women separately. *CHGA (3UTR)* was associated with DBP in men ($p = 0.004$) but not in women, while *COMT* was associated with DBP in women ($p = 0.0002$) but not in men. *IL6* was associated with DBP both in men and women. Multivariate ANOVA further showed evidence of epistasis on risk for 6 sets of interactions. Luciferase analysis revealed increased transcription of *CHGA* promoter upon stimulation by IL6. This study revealed association of not only individual SNPs with risk of hypertension, but also sex-gene and gene-gene interactions contributing to risk. Epistasis between inflammatory and adrenergic pathways was further confirmed in an in vitro assay, suggesting a potential novel mechanism for hypertension risk.

Mutation spectra in *PITPNM3* known as a cause of autosomal dominant cone rod dystrophy (CORD5). *L. Kohn[1], S. Haraldsson[1], S. Kohl[2], C. F. Inglehearn[3], O. Sandgren[4], I. Golovleva[1]* 1) Medical Biosciences/Medical and Clinical Genetics, Umeå University, Sweden; 2) Centre for Ophthalmology, Institute for Ophthalmic Research, Molecular Genetics Laboratory, Tübingen, Germany; 3) Section of Ophthalmology and Neuroscience, Leeds Institute of Molecular Medicine, St. Jamess University Hospital, Leeds, United Kingdom; 4) Clinical Biosciences/Ophthalmology, Umeå University, Sweden.

Autosomal dominant cone dystrophy (CORD5) is a rare disease predominantly affecting the cone photoreceptor cells. The main clinical symptoms are impaired visual acuity, sensitivity for light and defective colour vision. The disease locus was initially mapped to chromosome 17p13 and later on narrowed down from 27 cM to 14.3 cM exploring material from two Swedish families (Balciuniene et al, 1995; Köhn et al, 2007). Sequencing of a candidate gene, phosphatidylinositol transfer membrane-associated protein (*PITPNM3*) revealed a missense mutation, Q626H. *PITPNM3* known as a human homolog of the *Drosophila* retinal degeneration B (*rdgB*) gene is needed for transport of phospholipids, renewal of photoreceptors membrane and provides the ERG response to light. The plausible mutation causing CORD5 is located in the C-terminal region interacting with a member of nonreceptor protein tyrosine kinases, PYK2. Through collaboration with research groups in Germany and UK we have ascertained DNA from cone and cone-rod dystrophy patients for further screening of *PITPNM3* to establish the global impact of this gene in retinal diseases. Mutation screening of *PITPNM3* was performed by dHPLC (WAVE, Transgenomic) followed by DNA-sequencing. 111 samples were analysed in total. Several potential pathogenic mutations located in both coding and intronic sequences were found in the trial. Matched control populations are currently screened to elucidate whether or not these sequence variations are true mutations. In conclusion, the findings of additional mutations to Q626H in PITPNM3 will provide stronger evidence for novel pathways and a potential important role of PITPNM3 in mammalian phototransduction and molecular pathogenesis of retinal degenerations.

Comprehensive analysis of 40 kb in the 19p13 region points to a novel risk variant predisposing to celiac disease.

G. Trynka[1], A. Zhernakova[2], J. Romanos[2], L. Franke[1,2], K. A. Hunt[3], G. Turner[4], A. Ryan[4], D. Barisani[5], R. McManus[4], D. A. van Heel[3], C. Wijmenga[1,2] 1) Genetics Dept. UMC Groningen, The Netherlands; 2) Complex Genetics, UMC Utrecht, The Netherlands; 3) Barts and the London, School of Medicine and Dentistry, UK; 4) Dept. Clinical Medicine, Institute of Molecular Medicine, Trinity College Dublin, Ireland; 5) Dept. Experimental Medicine, University of Milano Bicocca, Italy.

Myosin IXB (MYO9B, 19p13) is one of the first non-HLA genes to be associated to celiac diseases (CD), an autoimmune disorder characterized by inflammation of the small intestine in response to gluten. MYO9B variants have also been shown to predispose to other traits (ulcerative colitis, type 1 diabetes and dermatitis herpetiformis), suggesting that it is a general risk factor in autoimmune disorders. In this study we have selected 20 individuals for sequence analysis of the entire associated region of MYO9B (30-kb LD block) and the two downstream genes, USE1 (6.6kb) and OCEL1 (4kb), which are in strong LD with the associated block (D>0.8). We have identified 165 sequence variants, of which 34 were novel. We further genotyped 67 of these SNPs in extended case-control cohorts in 3 populations from the Netherlands, Ireland and the UK (total of 1682 cases, 3258 controls). In the combined analysis we observed the strongest association for rs388484 (p=1.2E-4). This variant is located in the first intron of the USE1 gene, the hematopoietic stem/progenitor cells protein that also plays a role in the vesicle transport. We are now typing an Italian cohort to further validate this finding and are performing haplotype analysis to narrow down the association. In addition, we will include imputed genotypes from the previously performed genome-wide association study. Conclusions: By sequencing and further fine-mapping of the MYO9B associated block in multiple CD cohorts, we have replicated the association to the 19p13 block and may have located the true signal to the USE1 gene. Our study proves that deep sequencing of the associated locus with further replication of all variants from the region is a good strategy for fine-mapping.

Allopregnanolone in cyclodextrin significantly effects hepatic disease in feline Niemann-Pick type C. *C. Vite[1], W. Ding[1], C. Bryan[1], P. O'Donnell[1], M. Haskins[1], T. van Winkle[1], S. Walkley[2], S. Mellon[3], M. Vanier[4]* 1) School of Veterinary Medicine, University of PA; 2) Albert Einstein College of Medicine, Yeshiva University; 3) University of California, San Francisco; 4) INSERM Unit 820, Lyon-Laennec Medical School, Lyon, France.

Subcutaneous injections of 25 mg/kg of the neurosteroid allopregnanolone in hydroxypropyl-beta-cyclodextrin (Allo/HPBCD) were given to two cohorts of ages of cats with a mutation in NPC1 (C955S) and with clinical signs of Niemann-Pick type C (NP-C) disease: six cats were treated at 1, 3, 7, 14, and 21 days of age (Allo/HPBCD-Early) and six cats were treated weekly from 3 to 11 weeks of age (Allo/HPBCD-Late). Allo/HPBCD-Early cats showed no measurable benefit compared to untreated cats. In contrast, Allo/HPBCD-Late cats were significantly different ($p<0.05$) from untreated cats by the following measures: weighed more from 5 weeks of age until death, less serum alanine aminotransferse and aspartate aminotransferase activities, greater serum albumin, less serum cholesterol, and less serum and CSF chitotriosidase activity. In liver tissue, cholesterol, sphingomyelin and free sphingosine concentrations were also significantly less. Allo/HPBCD-Late cats were NOT significantly different from untreated cats by any measure of neurological dysfunction. Why was Allo/HPBCD ineffective at treating neurological disease in the cat when it effectively treated the npc1-/- mouse? Several possibilities exist: 1) Allopregnanolone may not cross the blood brain barrier sufficiently in the cat. 2) Allopregnanolone may not activate pregnane X receptor-dependent pathways as they do in the mouse. 3) Allopregnanolone may require in utero administration in the cat in order to mimic its effects at P7 in the mouse. 4) Finally, the failure of Allo/HPBCD to treat neurological disease in feline NP-C disease may be due to the inability of adequate levels of HPBCD to reach the brain by crossing an intact blood-brain barrier. Based on data in the mouse, we hypothesize that increasing CNS concentrations of HPBCD will improve the storage in the brains of cats and that improvement in neurological disease will be seen.

Amniotic Band Syndrome. A case report with bilateral choanal atresia. *A. Del Toro-Valero[1,2], N. Davalos-Rodriguez[1,3], G. Hernandez-Zaragoza[1], S. Barrios-Guyot[3], V. Vargas[3], A. L. Plascencia-Rocha[3], A. Estrada-De la Fuente[3], R. E'Vega-Hernandez[1,2], M. G. Lopez-Cardona[1,3]* 1) Instituto de Genetica Humana, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Becario CONACYT; 3) Hospital Regional Dr. Valentin Gomez Farias del ISSSTE, Jalisco, Mexico.

Del Toro-Valero Azucena1,2, Dávalos-Rodríguez Nory1,3, Herrnández-Zaragoza Guillermo2, Barrios-Guyot Selene3, Vargas Víctor3, Plascencia-Rocha Ana Lilia3, Estrada-De la Fuente Alejandro3, EVega-Hernández Ricardo1,2, López-Cardona María Guadalupe1,3. 1.-Instituto de Genética Humana, Universidad de Guadalajara. 2.-Becario CONACyT 3.-Hospital Regional Dr. Valentin Gomez Farias del ISSSTE,Jalisco,Mexico. Introduction: The Constricting Bands Syndrome (CBS) is a group of congenital malformations that include constricting bands and lymphadema, tumecaction and amputacion of fingers, arms and legs, facial asymmetry, encephalocele, anencephalia, pseudosyndactyly and microphtalmos. The prevalence rate is 7.7/10,000. Etiology is still unknown. It has been associated with preterm delivery, low birthweight and oligohydramnios. Exist two theories (endogenous and exogenous) proposed in the pathogenesis that can explain the most, but not all of the features. so exist a third theory called vascular, that can explain the intravisceral anomalies of the syndrome. Case report: Propositus is a male of 45 days old, product of III pregnancy of healthy and non-consanguineous parents. Throughout the pregnancy, the mother show frequent cough with sputum. The product was obtained by caesarean at 36 weeks in duration with 2800gr weight. Was present a few dark bands around their hands and feet, encephalocele, hydrocephaly, decrease in the size of the right ventricle, hypoplasia of the corpus callosum, absence of superior portion of parietal, frontal and occipital skull, facial asymmetry, bilateral choanal atresia, hypoplasia of the right ocular globe, distal tumefaction of limbs, absence of some phalanges and amputation of some fingers. Discussion: The purpose of this report is to present the case of a patient diagnosed with CBS which also present bilateral choanal atresia, not described above, that can be consequence of the syndrome.

Overexpression of Trpc6 in mouse podocytes causes kidney disease. *CP. Canales[1], P. Krall[1,2], K. Walz[1]* 1) Centro de Estudios Científicos, Valdivia, Chile; 2) Universidad Austral de Chile, Valdivia, Chile.

The TRPC6 channel (Transient receptor potential channel 6) is a member of the TRPC family that presents six transmembrane domains. It is activated by Di-acilglicerol (DAG) and is related with the calcium transport towards the cytoplasm through a pore located between the transmembrane domains 5 and 6. Since 2005, mutations in the TRPC6 gene have been associated to patients with Focal and Segmental Glomerulosclerosis (FSGS), pathology with dominant autosomic inheritance. In kidney, TRPC6 is enriched in the collecting ducts and the podocyte foot processes, where it co-localizes with podocin and nephrin. In 2006, it has been demonstrated that elevated levels of wild-type TRPC6 protein, in a transient in vivo over expression model, lead to podocyte dysfunction evidenced by the appearance of proteinuria. Taken together, these data suggest that TRPC6 play a key role in the pathogenesis of FSGS. With the hypothesis that the over expression of wild-type TRPC6 seems to be sufficient to cause proteinuria in healthy mice, our goal was the generation of a transgenic mouse that over express the wild type form of Trpc6 in the podocytes and its subsequent phenotypic characterization. We have generated a construct with the full length Trpc6 cDNA and we have added a hemaglutinin (HA) tag. This construct was subcloned into an expression vector, downstream of the human podocin promoter (pNPHS2) to direct expression to the podocytes. After in vitro studies, the construct was microinjected to generate transgenic mice. Three independent lines with different copy number integration and expression levels of the transgene were analyzed. Phenotypic characterization of the lines showed a significant increased proteinuria in 40-50% of the mice, with different onset ages that ranked between 5-10 months of age and abnormal urine protein pattern by SDS-PAGE analysis. Abnormal glomerular morphology was also observed by H&E staining. Finally, a podocyte specific marker has been detected in 24h urines samples of transgenic proteinuric mice. We can conclude that overexpression of Trpc6 in a podocyte specific manner gives a kidney disease that may be related to podocytes loss.

Expanding the Clinical and Molecular Spectrum of Timothy Syndrome. *T. A. Maher[1], G. Zhou[1], J. M. Milunsky[1,2]*
1) Center for Human Genetics; 2) Departments of Pediatrics, Genetics and Genomics, BUSM, Boston, MA.

Timothy syndrome (TS; MIM 601005)is a multi-system disorder characterized by lethal arrhythmias (prolonged QTc), cutaneous syndactyly of the fingers and toes (2/3), congenital heart defects, facial dysmorphism, hypotonia, seizures, autistic spectrum disorder (ASD), and mental retardation (MR). This rare disorder has been reported to result from an identical, *de novo* missense mutation (G406R) in the alternately spliced exon 8A of the *CACNA1C* gene. One additional mutation (G402S) has also been reported in exon 8 of the gene and typically results in a longer QTc without syndactyly. Expression studies have shown that the G406R mutation produces maintained inward calcium currents by causing nearly complete loss of voltage-dependent channel inactivation. We report a 3½ year old Hispanic male who meets the cardinal diagnostic features of TS including a prolonged QTc (up to .546), characteristic facies, hypotonia, bilateral 2/3 toe syndactyly, congenital heart disease (VSD and PDA), seizures, MR, and ASD. No MRI data has been reported on individuals diagnosed with TS. MRI of our patient revealed diffuse pachygyria and microcephaly. Sequencing of exon 8/8A of the *CACNA1C* gene was normal. However, full sequencing of the gene revealed a *de novo* missense mutation (G419R) in exon 9. G419R was not found in 300 normal controls or in the SNP database, and was predicted to be not tolerated by SIFT. G419R is in the same functional linker domain as the major mutation (G406R) known to cause this syndrome. Several genes that result in neuronal migration disorders (*Lis1* and *DCX*) when mutated, function through calcium dependent signaling. This may offer a clue to the underlying pathophysiology behind the pachygyria seen in our TS patient. We report for the first time a novel missense mutation not involving Exon 8/8A of the *CACNA1C* gene that leads to TS. We also expand the clinical phenotype to include pachygyria that may explain the MR, seizure disorder, and ASD in TS patients. Further neuroimaging studies are recommended in other TS patients. An EKG should be considered in patients with pachygyria and 2/3 toe syndactyly to evaluate for a prolonged QTc.

Clinical Molecular Genetic Testing for Primary Ciliary Dyskinesia. *M. Zariwala, K. Chao, M. Langley, M. Leigh, J. Booker, M. Knowles, K. Weck* Dept Path/Lab Medicine, Medicine, pediatrics, UNC School of Medicine, Chapel Hill, NC.

Primary ciliary dyskinesia (PCD) is a rare, autosomal recessive disorder due to impaired mucociliary clearance associated with abnormal ciliary structure and function. It is associated with oto-sinu-pulmonary disease, male infertility, and in some cases situs inversus, termed Kartagener syndrome. Diagnosis of PCD relies upon clinical phenotype, ultrastructural studies of cilia, nasal nitric oxide levels, and ciliary beat frequency. Current diagnostic methods are challenging and cumbersome. Development of a molecular genetic test panel was predicted to aid with diagnosis in some patients. Mutations in two ciliary outer dynein arm genes (*DNAI1* and *DNAH5*) have been noted in ~38% of well characterized PCD patients. Clinical molecular genetic testing using sequence analysis of selected exons with mutation clusters is available at the UNC Molecular Genetics Laboratory. Sequencing of the complete coding region of *DNAI1* is also performed for patients with one mutation identified. Since May 2007, 41 patients have been referred for PCD genetic testing and mutations are found in four on at least one allele. Patient #3372 had Cri-cu-chat syndrome, and features of PCD with a monoallelic deletion of chromosome 5p, which includes *DNAH5*. We detected a known *DNAH5* mutation [F476SfsX26] on the other allele, thus confirming the diagnosis of PCD. One patient (#1896) had a known founder mutation [IVS1+2_3insT] and a novel missense variant [R124C] in *DNAI1*. R124C was also found in another unrelated PCD patient (#1456) and was not detected in 196 control chromosomes. This patient had a splice mutation on the other allele and both these variations were also present in an affected sibling. A PCD patient (#1457) had 2 novel variants of unknown significance [I567T+F451N] in trans in *DNAI1*; both these residues are evolutionarily conserved and not present in 180 control chromosomes. In patient #2361, known *DNAH5* mutation [I1855NfsX6] was found on one allele. We recommend enrollment in a research protocol to identify additional mutations for patients in whom one or no mutations are identified. This abstract was funded in part by NIH/ORD CETT, MRG, RO1 HL071798 and U54 154 RR019480.

Age at diagnosis among individuals with hereditary and non-hereditary retinoblastoma. *S. Gilinsky, R. D. Clark, A. L. Murphree* Division of Ophthamology, Retinoblastoma Program, Children's Hospital Los Angeles, Los Angeles, CA.

Retinoblastoma (Rb), a malignant childhood tumor of the eye, affects approximately 1/15,000-1/20,000 live births in developed countries. This childhood eye cancer can affect one eye (unilateral) or both eyes (bilateral). All individuals with bilateral Rb and approximately 15% of individuals with unilateral Rb have a cancer-predisposing germline mutation in the *RB1* gene. The reported mean age of diagnosis of individuals with unilateral Rb is 24 months, and the mean age of diagnosis in bilateral Rb has been reported to be 12 months. We report the genetic status and age of diagnosis of 178 unilateral (n=143) and bilateral (n=35) Rb patients referred for genetic counseling. The average age of diagnosis among bilateral cases was 9 months, and among unilateral cases was 18 months. Seventeen of 102 sporadic unilateral Rb cases were positive for a germline mutation (16.7%). Of the 17 sporadic unilateral germline cases, 5 were mosaic, and 4 had cytogenetic deletions of 13q14. The median age of diagnosis among all unilateral germline mutation carriers (n=17) was 18 months. The median age of diagnosis among all unilateral non-carriers (n=85) was also 18 months. These data suggest that the *RB1* germline mutation status of the patient is not associated with the age at diagnosis in cases of unilateral Rb. This highlights the point that a child who presents with later onset unilateral Rb cannot be assumed to be a sporadic case. All individuals with sporadic unilateral Rb should be offered genetic testing regardless of age of onset. The discovery of a germline mutation in an individual with unilateral Rb could have implications for the patients risk for secondary cancers as well as for family members and future offspring of the patient. We hypothesize that bilateral retinoblastoma may be diagnosed earlier because of the higher likelihood of detecting an abnormality present in two eyes, rather than in unilateral Rb where only one eye is affected.

Molecular pathogenesis of Wolfram Syndrome different in different causal genes. *S. Amr, R. Shiang* Dept Human Genetics, Virginia Commonwealth Univ, Richmond, VA.

Wolfram Syndrome (WFS) is a debilitating autosomal recessive neurodegenerative disorder characterized by juvenile onset insulin dependent diabetes mellitus (DM) and optic atrophy (OA) as well as a number of neurological and endocrine complications that result in early death. Previous research has mapped Wolfram syndrome to chromosome 4p16.1 and the disease has been attributed to mutations the WFS1 gene affecting the WFS1 protein (wolframin), an ER membrane glycoprotein that plays an important role in intracellular Ca2+ homeostasis. Several studies of WFS1 mutant or knockdown cells revealed increased levels of the unfolded protein response (UPR) markers, increased apoptosis, and decreased proliferation. Furthermore, other research shows an upregulation of WFS1 upon activation of UPR elements. An additional locus for WFS on chromosome 4q22-24 was identified by linkage studies of 4 Jordanian Bedouin families with 16 affected individuals. We were able to identify the responsible gene in the critical region as CISD2, a gene encoding an ER intermembrane small protein (named ERIS) with a conserved iron-sulfur binding CDGSH domain. Using the pSUPER RNAi system (oligoengine) to knockdown CISD2, WFS in-vitro models were created in two cell lines; rat pancreatic insulinoma cells (INS1) and mouse neuroblastoma cells (N1E-115). Effective knockdown was measured by semi-quantitative RT-PCR and Real-Time PCR. Spliced XBP-1, a marker of the UPR, was not upregulated in CISD2 knockdown N1E-115 cells and CISD2 mutant lymphoblastoid cells taken from a WFS affected individual. Another marker, phosphorylated-eIF2, also did not show upregulation in the affected lymphoblastoid cells. CISD2 expression in wildtype cells treated with the ER stressor thapsigargin did not change compared with untreated controls. These data suggest that, unlike WFS1, CISD2 does not play a role in the UPR and mutant CISD2 results in WFS in a manner different than that in mutant WFS1. Possible alternatives to disease development, including changes in apoptosis and proliferation, are currently being studied in CISD2 knockdown cells.

CYP17, CYP1B1, CYP1A1 AND COMT POLYMORPHISMS AND THE SPONTANEOUS GENOMIC LESIONS IN BREAST CANCER WOMEN. *R. A. Santos[1], M. B. Mayorano[1], A. C. Teixeira[1], J. M. Andrade[1], H. H. A. Carrara[1], C. S. Takahashi[2]* 1) Faculty of Medicine, , Ribeirão Preto, São Paulo, Brazil; 2) Faculty of Philosophy Sciences and Letters of Ribeirão Preto, São Paulo, Brazil.

Breast cancer (BC) is the second most frequent form of cancer in worldwide and the most common malignant disease among women. Risk factors for BC include early age of menarche and late menopause, hormonal therapies, exposure to environmental pollutants, smoking and alcohol habits; however, increased or prolonged estrogen exposure is the most important risk factor. Estrogen biosynthesis and metabolism requires enzymatic pathways regulated by different genes with some polymorphisms described in association with BC. Estrogens increase the formation of DNA adducts, 8-oxo-dG and breaks on DNA molecule. Here we investigated the levels of DNA damage on untreated BC patients, the possible association of estrogen metabolizing genes CYP17, CYP1B1, CYP1A1 and COMT polymorphisms on BC risk and its influence on the spontaneous levels of DNA damage. DNA damage was detected by Micronucleus test and Comet Assay using peripheral blood lymphocytes from 45 diagnosed BC women and 85 healthy women. Micronucleus frequencies and DNA damage detected by Comet Assay were significantly higher in BC group than in controls. Polymorphism study was conduced in 131 healthy control and 104 BC women using PCR-RFLP. Polymorphisms in CYP17, CYP1B1, CYP1A1 and COMT were not different between patients and controls and CYP17 and CYP1A1 had no effect on basal DNA damage in both groups; the Leu allele in CYP1B1 was significantly associated with the higher levels of DNA damage in control group and did not affect DNA damage in BC group. Otherwise, in the control group individuals carrying the Met allele of COMT exhibited lower levels of DNA damage when compared to homozygous wild type, but in BC group the polymorphic homozygous individuals (Met/Met) presented higher levels of DNA lesions than their counterparts carrying the wild type allele. The present results suggest that BC women present an important genomic instability and estrogens metabolizing polymorphisms may modify the levels of DNA damage in healthy and in BC.

Influence of ethnicity on the OCA phenotype. *P.-W. Chiang[1], A.C-H Tsai[1], C. Clericuzio[2], E. B. Spector[1]* 1) Dept Pediatrics, UCD School of Medicine, Aurora, CO; 2) Pediatrics-Division of Dysmorphology, University of New Mexico School of Medicine.

The spectrum of pigmentation in humans is highly diverse. Pigmentation disorders, such as oculocutaneous albinism (OCA), are characterized by hypopigmentation of eyes, skin and hair and have been traditionally considered to be autosomal recessive disorders. The potential influence of genetic background (ethnicity) on the OCA phenotype and/or mechanism has not been addressed. More than 50% of Caucasian OCA1 and OCA2 patients have only one identifiable mutation. Almost every African American (Black) OCA patient has two identifiable mutations. A common allele in the Black population cannot explain the discrepancy. The Hispanic population, which carries a mixture of Caucasian, Native American and Black alleles, has rarely been studied. Our studies of 2 Hispanic families with OCA provide evidence that genetic background is essential in the determination of OCA phenotype and mutation mechanism. The first large Hispanic family studied carried the common Sub-Saharan African 2.7-kb deletion of OCA. The skin color of family members who carried the deletion (haplo-insufficient) was lighter compared with non-carrier family members, indicating that the effect of an OCA2 mutation on skin color is not strictly recessive. In a second Hispanic family two siblings were diagnosed as having OCA1B. They demonstrated variable expression of the OCA phenotype, even though they carried the same two OCA1 mutations. Molecularly, these two patients have autosomal recessive ocular albinism (AROA). Similar to Caucasian AROA patients, our patients carry one severe OCA1 mutation (G47D) and the hypomorphic R402Q allele. Unlike the reported Caucasian AROA patients, our patients are clearly hypopigmented. We hypothesize that the clinical spectrum of OCA depends upon pigmentation threshold. In individuals with darker complexion, two severe mutations are usually required to produce a visible phenotype. In individuals with lighter complexion, OCA can have a broader spectrum depending upon the presence of two mutations or the presence of one mutation plus a hypomorphic or ethnic specific allele.

Exploring genome-wide association and expression quantitative trait loci of cystatin C. *E. O. Kistner[1], D. L. Nicolae[2,3], A. Pluzhnikov[2], A. Tikhomirov[2], J. E. Below[4], A. Konkashbaev[2], C. Roe[2], M. E. Dolan[5], N. J. Cox[2,4]* 1) Dept Health Studies, Univ Chicago, Chicago, IL; 2) Section of Genetic Medicine, Dept. of Medicine, Univ Chicago, Chicago, IL; 3) Dept. of Statistics, Univ Chicago, Chicago, IL; 4) Dept. of Human Genetics, Univ Chicago, Chicago, IL; 5) Section of Hemotology/Oncology, Dept. of Medicine, Univ Chicago, Chicago, IL.

Serum cystatin C has been identified as a predictor of glomerular filtration rate in healthy individuals and those suffering from chronic kidney disease. Cystatin levels have also been shown to associate with cardiovascular endpoints, including hypertension and myocardial infarction. In order to identify risk variants in either chronic kidney disease or cardiovascular disease pathways, a genome-wide association study of serum cystatin C was conducted using the Genetics of Kidneys in Diabetes (GoKinD) cohort. This sample consisted of 1825 probands with type I diabetes, ascertained such that half the cohort suffered from diabetic nephropathy. The Affymetrix 5.0 SNP platform was used and tests of linear association between the inverse of serum cystatin C and additive genetic effects were conducted. The most significant association was found on chromosome 20 where the CST3, CST4, and CST9 genes are located (p=6.09E-07). Using the 90 human lymphoblastoid cell lines (LCLs) from the HapMap CEU population, expression quantitative trait loci (eQTLs) of the cystatin genes were explored. Single nucleotide polymorphisms (SNPs) predicting cystatin expression levels in LCLs were discovered using the publicly available SNP and CNV Annotations Network (SCAN) database serving Affymetrix Exon Array data. Cystatin eQTLs were found in regions on chromosome 2 that also show significant association with serum cystatin levels in type I diabetics (p<.0001). The protein kinase C (PRKCE) and Rap guanine nucleotide exchange factor (RAPGEF4) coding regions are implicated both as predictors of cystatin expression in LCLs and cystatin levels in the GoKinD cohort. The KEGG pathway database shows PRKCE inhibits the insulin signaling pathway. Further work is necessary to determine the mechanisms through which PRKCE and RAPGEF4 influence cystatin levels.

Congenital joint dislocations and chondrodysplasia caused by carbohydrate sulfotransferase 3 (CHST3) deficiency. *A. Superti-Furga[1], P. Hermanns[1], A. Megarbane[2], R. Mendoza-Londono[3], B. Afroze[4], A. Perez-Aytes[5], A. Rossi[6], L. Bonafé[7], L. Boccone[8], G. Nishimura[9], S. Hollander[1], J. Spranger[1], B. Zabel[1,10], S. Unger[1,10]* 1) Ctr Pediatrics, Univ of Freiburg, Freiburg, Germany; 2) Genet Medicale, Univ St. Joseph, Beyrouth, Lebanon; 3) Clin and Biochem Genetics, Hosp for Sick Children, Toronto, Canada; 4) Dept of Pediatrics, Aga Khan Univ Hospital, Karachi, Pakistan; 5) Hospital Infantil La Fe, Valencia, Spain; 6) Dept. of Biochemistry, Univ of Pavia, Pavia, Italy; 7) Molecular Pediatrics, Univ of Lausanne, Lausanne, Switzerland; 8) Clinical Genetics, Univ of Cagliari, Cagliari, Italy; 9) Dept. of Radiology, Tokyo Metropolitan Kiyose Children's Hosp, Tokyo; 10) Inst of Human Genetics, Univ of Freiburg, Freiburg, Germany.

We recently reported CHST3 gene mutations in children diagnosed with recessive Larsen syndrome and Humero-Spinal Dysostosis (Hermanns et al, AJHG 82:1368-74, 2008). We now report CHST3 mutations in four additional patients who had been diagnosed with Larsen syndrome (1 case), SED with luxations (1 case), and chondrodysplasia with luxations, "Megarbane type" (two cases; AJMG 130A:107-109, 2004, and AJMG 143A:1782-1787, 2007). The clinical features in our group of ten patients are homogeneous and include dislocation of the knees and/or hips at birth, clubfoot, elbow joint dysplasia with subluxation and limited extension, short stature, and kyphoscoliosis developing in late childhood. The recessive CHST3 mutations comprise missense, nonsense, and splicing mutations; pathogenicity of missense mutations was confirmed by the observation of impaired 6-O-sulfation of chondroitin sulfate proteoglycans in fibroblasts of three patients. CHST3 mutations had first been observed in an Omani kindred with a spondyloepiphyseal dysplasia variant (SED Omani type). Our results show that congenital luxations of knees, hips, and elbows are common and important diagnostic criteria for CHST3 deficiency, and that the condition is more common than hitherto believed and includes disorders variably diagnosed as recessive Larsen syndrome, Humero-Spinal Dysostosis, chondrodysplasia with luxations (Megarbane type), SED Omani type, and unspecified SED forms.

The Investigation of Risk Factors Associated with Nondisjunction of Chromosome 21 in Sperm and an Examination of the Excess of Males among Individuals with Down Syndrome. *T. Oliver[1], A. Bhise[1], E. Feingold[2], S. Tinker[1], N. Masse[1], S. Sherman[1]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Previous studies on relatively small samples of paternally-derived cases of live births with trisomy 21 have shown that: 1) advanced paternal age is not a risk factor for nondisjunction (NDJ) of chromosome 21, 2) absence of recombination, but not location of recombination, is associated with paternal NDJ and 3) an excess of males compared to females are born with paternally-derived trisomy 21. Some studies have suggested that the excess of males with paternally-derived trisomy 21 may explain the male excess observed among live births with trisomy 21 in general. We have studied 129 cases of trisomy 21 due to paternal nondisjunction to examine these three factors: paternal age, recombination and the male:female sex ratio. We genotyped STRs along 21q to identify the origin of the error and the location of recombination along the nondisjoined chromosome. We found among meiotically-derived paternal errors, 32% occurred in meiosis I (MI) and 68% in meiosis II (MII). We confirmed the lack of a paternal age association with either type of error (mean paternal age for MI errors, MII errors, and controls: 32.2 6.3, 30.6 6.5, 31.3 6.6, respectively). However, contrary to previous studies including our own, we did not find an association with recombination patterns among MI or MII cases of paternal NDJ. We found an increased male:female sex ratio among both paternal (1.28, 95%;CI: 0.68-1.91) and maternal (1.16, 95%;CI: 1.02-1.33) meiotic cases of trisomy 21. While the sex ratio in paternal cases is not statistically significant, taken together these findings suggest that the excess of males among live births with trisomy 21 may be due to selection against female fetuses with trisomy 21. The results from this study have enabled us to understand the risk factors associated with nondisjunction of chromosome 21 in sperm, in addition, they have provided insight on the origin of the excess of males observed among all cases of trisomy 21.

Distribution and prevalence of Lisch nodules in adults with NF1. *D. Stewart[1], S. Boley[2], J. Sloan[1]* 1) NHGRI/NIH, Bethesda, MD; 2) Vassar College, Poughkeepsie, NY.

The presence of 2 or more Lisch nodules (LN) is a diagnostic criterion for neurofibromatosis type 1 (NF1). No prospective, quantitative study has been performed on the distribution of LN in adults. Methods. Digital slit-lamp photographs of both eyes were obtained in 80 individuals enrolled in a natural history study of NF1. All patients met consensus criteria for the diagnosis of NF1, except 4 patients with missense mutations in NF1. LN were identified computationally and manually and LN characteristics (coordinates, area, diameter, distance to pupil center) were determined using ImageJ software. Eye color was determined by consensus from 3 observers. Results. Among post-pubertal individuals in our population, 93.6% had LN. Although the prevalence of LN increased with age, younger patients did not necessarily have fewer LN than older patients. Individuals with brown irides had a median of 2.0 LN while those with blue or green irides had a median of 16.3 LN. There were more LN in the inferior aspect than in the superior aspect of the iris ($p<0.0001$). There were more LN in the supranasal quadrant than the supratemporal quadrant ($p = 0.04$). In 4/7 sib pairs we observed a discordant number of LN. There were no significant differences in LN burden between the right and left eye. LN were not observed in any of the individuals with a missense mutation in NF1. Discussion. Our data supports the hypothesis that ultraviolet (UV) light exposure is needed for the development of Lisch nodules: 1) LN are most commonly located in the inferior portion of the iris, the region associated with the highest UV exposure, 2) the unequal distribution of LN across the superior portion of the iris (supranasal > supratemporal) is consistent with albedo (reflected sunlight) focusing by the cornea, 3) brown eyes have significantly fewer LN than blue eyes. In our dataset, 4.8% of adults lacked LN, a percentage observed in other studies. LN burden does not correlate with age. We hypothesize that haplo-insufficiency of NF1 and UV light are necessary but not sufficient for the development of LN. Variation in LN burden may be influenced by environmental factors and/or modifier genes.

Investigation on Mitochondrial tRNA genes of Iranian Multiple Sclerosis Patients. *S. EtemadAhari[1,2], M. Houshmand[1], M. Moin[3], M. Shafa Shariat Panahi[1], S. Kasraie[2]* 1) Dept Molecular Medical Genetic,National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 2) Sciences & Research Campus, Azad University, Tehran, Iran; 3) Immunology, Asthma & Allergy Research Institute, Tehran, Iran.

As with chromosomal DNA, the mitochondrial DNA (mtDNA) can contain mutations that are highly pathogenic .In fact, many diseases of the central nervous system are known to be caused by mutations in mtDNA. Dysfunction of the mitochondrial Respiratory Chain (RC) has been shown in patients with neurological disease including Alzheimers disease (AD), Parkinsons disease (PD) and Multiple sclerosis (MS). MS is a demyelinating disease of central nervous system characterized by morphological hallmarks of inflammation, demyelination and axonal loss. Considering this importance, we decided to investigate several highly mutative parts of mtDNA for point mutations as MT-LTI (tRNALeucine1(UUA/G)), MT-NDI (NADH Dehydrogenase subunit 1), MT-COII (Cytochrome c oxidase subunit II), MT-TK (tRNALysine), MT-ATP8 (ATP synthase subunit F0 8) and MT-ATP6 (ATP synthase subunit F0 6) in 20 IranianMSpatients and 80 age-matched control subjects by PCR and automated DNA sequencing to evaluate any probable point mutations. Our results revealed that 15 (75%) out of 20 MS patients had point mutations. Some of point mutations were newly found in this study. This study suggested that point mutation occurred inmtDNA might be involved in pathogenesis of MS.

Genetic and Immunologic Characterization of Gingiva in Systemic Hyalinosis. *T. C. Hart[1], R. Muralidharan[1], D. Pallos[2], S. I. Jang[1], S. K. Lee[1], P. S. Hart[3]* 1) NIDCR, NIH, Bethesda, MD; 2) University of Taubate, Sao Paulo, Brazil; 3) NHGRI, NIH, Bethesda, MD.

ANTXR2 mutations are etiologic for systemic hyalinosis (SH), clinically characterized by subcutaneous skin lesions, gingival hypertrophy, joint contractures and osteoporosis. Hyaline deposits of the dermis and other organs are pathognomonic. To understand gingival enlargement, which is seen in all SH cases, we identified ANTXR2 mutations in cases from 4 families. ANTXR2 isoform expression was determined with TaqMan assays. Immunohistochemical assays for 17 proteins associated with extracellular matrix, cell proliferation, apoptosis and vasculature development were performed in gingiva from SH cases and controls. Results: All SH cases were homozygous for a c.1074delT mutation, disrupting the cystolic domain. While ANTXR2 transcript levels were lower in SH, isoform expression profiles were similar in control (%) and SH [%] gingiva: ANTXR2-489 (84%),[90%]; ANTXR2-488 (15%), [10%]; ANTXR2-322 (<< 1%), [<<1%]. Immunolohistochemical assays revealed enlargement of SH gingiva occurred in the connective tissue, with decreased collagen and decreased fibroblast cell numbers ($p < 0.05$). Increased numbers of abnormal vascular vessels were seen, associated with amorphously hyalinized stromal tissue. Increased ANTXR2 expression was seen in hypertrophic SH gingival epithelium, connective tissue, and in the vasculature. Vasculature associated increased expression of extracellular matrix proteins, proliferative markers and apoptotic markers were noted. These findings suggest disruption of the ANTRX2 cystolic domain results in increased accumulation on the cell surface in SH tissue, particularly the vasculature. Immunohistochemical findings indicate abnormal proliferation and cellular apoptosis, resulting in defective vascular development in SH gingival enlargement. Finally, our findings indicate that SH associated gingival enlargement, characterized by decreased collagen, decreased fibroblasts and abnormal vasculature is distinct from gingival enlargement in more common forms of gingival fibromatosis, which demonstrate increased fibroblast numbers, increased collagen and normal vasculature.

Population genetics analysis of ALMS1 in humans reveals a surprisingly complex evolutionary history. *L. B. Scheinfeldt[1], S. Biswas[1], J. Madeoy[1], C. F. Connelly[1], E. E. Schadt[2], J. M. Akey[1]* 1) Dept Genome Sci, Univ Washington, Seattle, WA; 2) Rosetta Inpharmatics, LLC, a Wholly Owned Subsidiary of Merck and Co., Inc., Seattle, WA.

Mutations in the human gene ALMS1 result in Alström Syndrome, which presents with early childhood obesity and insulin resistance leading to Type 2 diabetes. Previous genome-wide scans for selection in the HapMap data suggest that ALMS1 was a target of recent positive selection. Through a detailed population genetics analysis of ALMS1 DNA sequence, haplotype, and SNP allele frequency variation in geographically diverse populations, we find that the signature of selection at ALMS1 is considerably more complex than what would be expected for an idealized model of a selective sweep acting on a newly arisen advantageous mutation. Specifically, we observed three highly divergent and globally dispersed ancient haplotypes (TMRCA ~ 1-3 mya), two of which carry a set of seven derived non-synonymous SNP alleles that are nearly fixed in Asian populations. Our data suggest that the interaction of human demographic history and positive selection on standing variation in Eurasian populations no later than 20 kya ago parsimoniously explains the spectrum of extant ALMS1 variation. Furthermore, our re-analysis of genome-wide SNP and gene expression datasets in humans and mice demonstrates that common inter-individual variation at ALMS1 is associated with metabolic phenotypes related to insulin resistance. These results provide new insights into the evolutionary history of ALMS1 in humans and suggest that selective events identified in genome-wide scans may be more complex than currently appreciated.

Statistical approaches for integrating gene-disease evidence into the medical care of individuals. *B. Mellen Snively*
Department of Biostatistical Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

In this era of ongoing genetic discoveries and widely available genetic tests, challenges exist for clinical translation to keep pace. For many genes and diseases, insufficient gene-disease information is available and ready for integration into clinical research and practice. The methods developed here aim to facilitate the appropriate use of genetic testing by 1) developing a flexible statistical framework that encompasses and enhances current tools for interpreting medical test outcomes in individuals, and 2) applying this framework to inform study designs to facilitate collection of gene-disease evidence applicable to interpreting genetic test outcomes. First, we developed and compared a set of competing estimators of the individual-specific likelihood ratio, LR=Pr(Observed test outcome|Phenotype present)/Pr(Observed test outcome|Phenotype absent); in diagnostic settings, LR is multiplied by a pre-test odds of disease to calculate the post-test odds and probability of disease. Then we simulated data to investigate study designs across allele frequencies, sample sizes, genetic models (general, additive, dominant, recessive) and LR thresholds. Applying the methods to TA-repeats of the *UGT1A1* promoter in colorectal cancer patients entering treatment with irinotecan (MIM 191740; N=250 in Toffoli et al., J Clin Oncol 2006), we observed similar LRs among estimators but not models. Under the general model, a novel profile LR for modifying the odds of an adverse drug reaction was 3.41, 1.33, and 0.421, and for a positive tumor response was 2.53, 0.938, and 0.889, respectively, given genotypes 7/7, 6/7, and 6/6 (generalizations to more complex tests are in progress). Differences among estimators were pronounced with smaller sample sizes, and size affected the probability of obtaining a LR of at least some threshold magnitude. In conclusion, our work provides study design tools specifically for the collection of gene-disease evidence applicable to interpreting genetic test outcomes in individuals. Furthermore, our work demonstrates the importance of close scrutiny of gene-disease measures with implications for genetic testing in clinical research and practice.

Expanding the Clinical Spectrum of Microgastria-Limb Reduction Complex. *S. Goobie[4], A. Koifman[1,2,4], S. Blaser[5], S. Keating[3], P. Shannon[3], S. Viero[3], L. Fishman[4], D. Chitayat[1,2,4]* 1) Prental Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, ON, Canada; 2) Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, ON, Canada; 3) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada; 4) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 5) Department of Radiology, Hospital for Sick Children, Toronto, ON, Canada.

Microgastria-limb reduction defect is associated with (usually) upper limb defects including radial abnormalities, absent digits, generalized limb hypoplasia or amelia. Asplenia and splenogonadal fusion, as well as a variety of other abnormalities, have been reported. Microgastria can also be associated with VATER association. Although no specific etiology has been detected, it is obvious that this is an etiologically heterogeneous condition and in most cases sporadic. To the best of our knowledge, 15 cases with this condition have been reported in the English literature. Al-Gazali et al., (1999) reported two brothers from a consanguineous Sudanese family with features of the condition associated with hydrocephalus and agenesis of the corpus callosum, suggestive of an autosomal recessive mode of inheritance. We report 5 cases with this condition, and provide detailed clinical and autopsy findings which expand our knowledge about this rare condition. All of our cases presented with microgastria (5/5) and limb abnormality (ranging from lateral placement of the thumb to amelia). Renal abnormalities were uniformly present. All five cases had brain abnormalities and their karyotypes were normal. One case is a set of monozygotic twins who presented with the same abnormalities. Microarray analysis on the twin was normal thus excluding submicroscopic deletion or duplication detectable by the Signature Genomic chip. This supports the possibility that in some cases the condition is a single gene disorder with an autosomal recessive (or dominant) mode of inheritance.

Sixth female case of Myhre Syndrome. *M. Lopez-Cardona[1,4], A. Del Toro-Valero[1,2], G. Hernandez-Zaragoza[1], R. E'Vega-Hernandez[1,2], A. Feria-Velazco[3], J. C. Ledezma-Rodriguez[4], A. Bolaños-Muñoz[4], A. Macias-Anton[4], N. Davalos-Rodriguez[1,4]* 1) Instituto de Genetica Humana, Universidad de Guadalajara, Jalisco, Jalisco, Mexico; 2) Becario Conacyt; 3) Centro Universitario de Ciencias Biologías y Agropecuarias. Universidad de Guadalajara; 4) Hospital Regional Dr. Valentin Gomez Farias, ISSSTE, Jalisco, Mexico.

Lopez-Cardona MG1,4, Del Toro-Valero A1,2, Hernandez-Zaragoza1, EVega-Hernandez1,2, Feria-Velazco3, Ledezma-Rodriguez JC4, Bolaños-Muñoz A4, Macias-Anton A4, Davalos-Rodriguez N1,4. 1.- Instituto de Genética Humana. Universidad de Guadalajara 2.-Becario CONACYT 3.-Centro Universitario de Ciencias Biologías y Agropecuarias. Universidad de Guadalajara 4.- Hospital Dr. Valentín Gómez Farias, ISSSTE, Jalisco, México. Introduction: Myhre Syndrome (MS), a unknown rare heritance disease,characterized by short stature, mental retardation, low birth weight, facial dysmorphism, heart anomalies, early-onset mixed deafness, muscle hypertrophy and decreased joint mobility. Up to date 11 males cases and 5 females cases have been published. Objective: We describe the 6th female case and compare the clinical and radiological findings between all the patients. Case Report: The proposita a 26 year-old. In early infancy evidenced delay development and autoagression. At physical examination show short stature, microcephaly, mental retardation, maxillary hypoplasia, short palpebral fissures, short neck, bilateral thenar-hypothenar hypoplasia in hands, cutaneus syndactyly and brachydactyly and middle finger clinodactyly in the left hand, bilateral brachydactyly and syndactyly in 2nd and 3th toes. Radiological studies showed thick calvarium, broad ribs, hypoplastic iliac wings and hallux valgus. Discussion: The clinical and radiological characteristics present in the proposita suggested a diagnosis of MS, but she present new radiological characteristics. Even though, she isnt show deafness and microcephaly, and actually she wasnt muscular built.

Meta-Analysis of Genome-Wide Association Studies on Multiple Genotyping Platforms. *N. Zaitlen[1], B. Han[2], H. Kang[2], E. Eskin[3]* 1) Dept Bionformatics, Univ California, San Diego, La Jolla, CA; 2) Dept Computer Science, Univ California, San Diego, La Jolla, CA; 3) Dept Computer Science, Univ California, Los Angeles, Los Angeles, CA.

Genome-Wide association studies have successfully identified many novel loci associated with a variety complex human diseases. These associations have been of moderate to weak effect and therefore required the collection of large number of individuals. Recent analysis methods have leveraged the HapMap to improve the power of these studies by imputing genotypes of SNPs not contained on the genotyping platform. These imputation methods have also promised simple meta-analysis of association studies using different SNP sets, such as those on the Illumina and Affymetrix platforms. Meta-analysis would serve not only as means of validation and replication, but also improve the power of existing studies by vastly increasing the number of available individuals in a study. In this work, we show that straightforward meta-analysis of imputed genotypes causes significant inflation of p-values. We examine this problem in detail, determine which studies are most susceptible, and present two methods for addressing this problem. The first approach is permutation based requires complete access to the genotype data of both studies, and is computationally expensive. However, due to the sensitive nature of these data, we develop a second meta-analysis method which only requires the estimated genotype frequencies in the case and control populations. We show that the meta-analysis p-value inflation problem is due to heterogeneous errors of imputation across studies. We present a novel method for estimating the between study variance of imputed genotypes and use this variance to adjust the imputation based p-values during meta-analysis. We examine the severity of the problem and performance of our meta-analysis technique over simulation studies based on the Welcome Trust Case Control Consortium data. We show that our methods correct the distribution of p-values and improve the overall power of the studies.

Anthropological Insights from a Novel Visualization and Clustering Tool for HLA Haplotypes and Populations.

L. Gragert[1], V. Kumar[2], M. Steinbach[2], W. Klitz[3], M. Maiers[1], M. Ferdandez-Vina[4], S. Israel[5], C. Brautbar[5] 1) Bioinformatics, National Marrow Donor Program, Minneapolis, MN; 2) Computer Science, University of Minnesota, Minneapolis, MN; 3) Public Health, University of California, Berkeley, CA; 4) MD Anderson Cancer Center, Houston, TX; 5) Hadassah Medical Center, Jerusalem, Israel.

The HLA system has among the highest signal-to-noise ratios for population clustering in human genetics resulting from selection and demographic effects. We have applied methods inspired by gene expression array profile clustering to visualize and cluster HLA haplotype frequencies across human populations. The method first clusters haplotypes based on their frequency patterns in each population. The resulting haplotype clusters each contain a set of haplotypes that have a similar frequency pattern that is private to a subset of populations with the most recent common ancestry. A secondary clustering step independently creates a neighbor-joining tree of the populations to show their relatedness. The final matrix rearranges the haplotypes and populations to maximize block density and give clear human-interpretable signals. We applied this technique to Jewish populations from 32 countries and were able to make several important inferences about cryptic population history and migratory patterns. We also found that the haplotypes that clustered together were often recombinants or mutations of each other, so the common origin of many HLA haplotypes could be inferred. If datasets from multiple admixed and ancestral source populations are used, the composition of admixed populations and the source of their haplotypes can be determined. We conclude that this tool reveals information on both haplotype and population origins from large and complex datasets, giving the user rapid interpretation of HLA data for anthropological studies.

Phelan-McDermid syndrome in a patient with del(22)(q13.31q13.33) and an intact *SHANK3* gene. *F. M. Mikhail, R. D. Burnside, M. Descartes, A. J. Carroll* Department of Genetics, University of Alabama at Birmingham, Birmingham, AL.

Deletion 22q13.3 syndrome (Phelan-McDermid syndrome) is a microdeletion syndrome resulting from loss at 22q13.3 by simple deletion, unbalanced translocation, ring chromosome formation, or other unbalanced structural changes. The *SHANK3* gene maps to 22q13.33 and codes for a structural protein that plays a critical role in connecting ion channels and receptors in the post-synaptic membrane to the cytoskeleton and to signal transduction pathways. Haploinsufficiency of *SHANK3* has been proposed to be the cause of the major neurological features associated with deletion 22q13.3 syndrome. Here we report a 38-month-old boy with history of developmental delay, mild dysmorphic features and delayed expressive speech. The patient manifests many clinical features of deletion 22q13.3 syndrome including normal/accelerated growth, large prominent dysplastic ears, pointed chin, large and fleshy hands with thin deep set fingernails, hypoplastic toenails, and slightly decreased tone. HRB chromosome analysis was normal. Targeted array CGH analysis using the PerkinElmer constitutional chip v3.0 demonstrated an interstitial 22q13.3 deletion, which was confirmed by FISH analysis using the *ARSA* (22q13.33) and the 22q subtelomere probes. The *ARSA* probe showed a significantly diminished signal size both on metaphase chromosomes and in interphase nuclei indicating that the distal breakpoint mapped within the *ARSA* probe, whereas the 22q subtelomere probe showed a normal hybridization pattern. Using the 32k tiling path BAC array CGH chip, we were able to precisely map the breakpoints of our patients interstitial deletion, which was estimated to be ~5.2 Mb in size and to spare the most telomeric 205 kb on 22q including the *SHANK3* gene. In conclusion, our patient provides evidence that haploinsufficiency of *SHANK3* might not be the only candidate responsible for the majority of features in the deletion 22q13.3 syndrome, and that other critical genes proximal to *SHANK3* could have a major causal role in the phenotype. Detailed description of our patients clinical features, cytogenetic findings, and comparison with previously reported 22q13.3 deletion patients will be presented.

Dentatorubral-pallidoluysian atrophy in a family of African American ancestry. *K. A. Mraz[1], H. H. Wetzel[2], G. E. Hoganson[2]* 1) Northwestern University, Graduate Program in Genetic Counseling, Chicago, IL; 2) University of Illinois-Chicago, Department of Pediatrics, Division of Pediatric Genetics, Chicago IL.

Dentatorubral-pallidoluysian atrophy (DRPLA) is a rare neurodegenerative disease caused by a trinucleotide expansion in atrophin-1 on chromosome 12. Phenotypically, DRPLA is most similar to Huntington disease and is characterized by ataxia, choreoathetotic movements, and dementia. DRPLA occurs primarily in Japan and is considered extremely rare elsewhere. One exception is a large African American family from North Carolina in which DRPLA was genetically confirmed in the early 1990s. This family consists of five affected generations who have resided in the Haw River area of North Carolina since the mid-1800s and as a result, this variant of DRPLA has been classified as Haw River Syndrome. We report here what is predicted to be an additional family of African American ancestry recently identified as having DRPLA. This newly identified family, who primarily reside in the Midwestern United States, shows at least three affected generations, many with DNA confirmation of the atrophin-1 expansion. While the possibility of a distant relationship to the Haw River family remains, our family did not report any known ancestors in North Carolina and thus is presumed to represent an additional kindred with an expansion in the atrophin-1 gene and a phenotype consistent with DRPLA, or Haw River syndrome.

A two-stage, family-based candidate gene association study of left-sided heart defects. *K. McBride[1], G. Zender[1], S. Fitzgerald-Butt[1], S. Fernbach[2], A. Menesses-Dias[2], J. Towbin[2], J. Belmont[2]* 1) Dept Mol & Human Gen, Res Inst Nationwide Child, Columbus, OH; 2) Dept Mol & Human Gen, Baylor Coll of Med, Houston, TX.

Left-sided heart defects, including congenital aortic valve stenosis (AVS), coarctation of the aorta (COA), and hypoplastic left heart syndrome (HLHS), are common and carry significant morbidity and mortality. We have previously demonstrated a strong genetic component in these defects. A two stage association study was performed on a group of candidate genes from developmental pathways and processes important in cardiogenesis, to identify susceptibility genes for this group of defects. *First stage:* 199 genes were selected, based on animal models demonstrating a cardiac phenotype. The individuals consisted of 138 White and 58 Hispanic affected case-parent trios. 1977 SNPs were genotyped using the Molecular Inversion Probe methodology. TdT analysis with FDR correction for multiple testing in the White trios resulted in a total of 45 different genes with a $q<0.20$. ERBB3, B4, and NRG1 in the ERB pathway had positive association; ERBB3 & B4 were also associated in the Hispanic trios. Resequencing of the ERB3 & B4 and NRG1 genes did not identify specific disease-causing mutations. *Second stage:* A total of 139 tag SNPs were selected in the 3 ERB pathway genes. Genotyping was performed with ABIs SNPlex assay in the original cohort, plus a second cohort of trios (total White trios n=344; AVS n=102, COA n=134, and HLHS n=98; and total Hispanic n=101). FBAT analysis with correction by permutation demonstrated replication of the association for ERBB4. A 3 SNP high-risk haplotype in the 3 region of intron 3 was over-transmitted in both cohorts of White subjects (separately and analyzed together), and independently among those with AVS, COA and HLHS. Analysis of the Hispanic trios also demonstrated over-transmission of the haplotype, but did not reach statistical significance. This study confirms the positive association of ERBB4 in two cohorts with left sided heart defects as a group and individually by specific defect.

Genome-wide epistasis analysis of multiple sclerosis susceptibility. *W. Bush, J. Haines, M. Ritchie, IMSGC* Ctr Human Genetics Research, Vanderbilt Univ, Nashville, TN.

Evaluating epistasis in genome-wide association studies (GWAS) is an important yet difficult challenge in human genetics, as most common diseases have complex underlying genetic architectures that likely include small independent effects and interactions between many genes. The combinatorial explosion to test interactions among GWAS dataset SNPs prevents an exhaustive search. Thus, filtering the SNPs to identify a favored subset is a necessity. To address this problem we applied a bioinformatics approach for generating and ranking biologically supported multi-locus models of multiple sclerosis (MS) susceptibility. This approach automatically accesses and indexes data sources implying interaction of molecules, data sources implying gene relationships to disease, and literature-based data sources. These sources are integrated using genomic convergence and an implication index that measures the number of data sources that support the model. We constructed a set of putative gene-gene interactions based on the Kyoto Encyclopedia of Genes and Genomes (KEGG), Reactome, the Database of Interacting Proteins (DIP), the Protein Families Database (PFAM), the Gene Ontology (GO), and Netpath. We also constructed a set of putative disease-associated genes, using the Genetic Association Database (GAD), previous linkage screens of MS families, three studies of MS gene expression, and other candidates from literature-based sources. Using these sets, we identified 16.9 million multi-locus models for evaluation using conditional logistic regression in 931 MS case/pseudo-control pairs from the International Multiple Sclerosis Genetics Consortium. We demonstrate a highly significant relationship ($p < 0.001$) between the increasing number of data sources supporting a multi-locus model and model significance. This result strongly implicates genetic interactions as a significant source of MS susceptibility. Several individual models were highly significant and did not include known MS risk genes. Our approach can be applied to any GWAS dataset for rapid exploration of epistasis and will help further our dissection of the genetic architecture of complex disease.

Smith-Lemli-Opitz syndrome and autism: Correlation of neurocognitive measures with plasma and CSF sterols.

F. D. Porter[1], S. E. Sparks[2], A. Aneja[3], H. Goodwin[1], L. E. Kratz[3], W. E. Kaufmann[3], E. Tierney[3] 1) NICHD, NIH, DHHS, Bethesda, MD; 2) CNMC, Washington, DC; 3) KKI, Baltimore, MD.

Smith-Lemli-Opitz syndrome (SLOS) is a recessive malformation syndrome with a specific behavioral phenotype that includes autistic findings in most patients. SLOS is an inborn error of cholesterol synthesis where mutations of *DHCR7* impair the reduction of 7-dehydrocholesterol (7DHC) to cholesterol. Thus SLOS patients have both a deficiency of cholesterol and an accumulation of 7DHC. The neurocognitive defects in SLOS are likely due to a combination of fixed neurodevelopmental defects and functional deficits due to the abnormal sterol biochemistry in the brain. Because therapeutic interventions can improve the sterol biochemistry, it is critical to establish the relationship between the neurocognitive defects and sterol levels. We hypothesized that the autistim features, adaptive behavior deficits, and IQ would correlate with sterol levels. To test this, we measured plasma and CSF sterol levels in 15 SLOS subjects for whom we had concurrent results of the ADOS, ADI-R, Mullen or Stanford-Binet and Vineland. Linear regression analyses of variables: CSF cholesterol/total sterol (C/TS) ratio: ADOS ($p<.04$); ADI-R present score (ADI)($p<.0001$); FSIQ ($p<.001$); Vineland Adaptive Behavior Composite (VABC) $p<.002$). CSF cholesterol: ADOS (Not significant (NS)); ADI ($p<.04$); FSIQ ($p<.03$); VABC (NS). Plasma Cholesterol: ADOS (NS); ADI (NS); FSIQ ($p<.001$); VABC ($p<.0004$) Plasma C/TS ratio: ADOS ($p<.04$); ADI ($p<.0004$); IQ ($p<.0001$; VABC ($p<.0003$). Subsequent anlaysis showed significant correlations between CSF 7DHC, but not cholesterol, and the social and non-verbal communication subdomains of the ADI. This data show that in SLOS the sterol abnormality correlated with increased autistic features, decreased IQ, and increased adaptive behavior deficits. Thus, the neurocognitive deficits in SLOS may be a functional consequence of the abnormal biochemistry in the brain, and potentially amendable to therapeutic interventions that improve the biochemical defect. These observations may have broader implications in that low cholesterol levels have been reported in non-syndromic autism.

High resolution reconstruction of HLA haplotypes in Native Americans. *W. Klitz[1], L. Gragert[2], M. Maiers[2], B. Tu[3], J. Ng[3], C. Hurley[3]* 1) Public Health, University of California, Berkeley, CA; 2) National Marrow Donor Program, Minneapolis, MN; 3) Georgetown University, Washington, DC.

It is not uncommon for a defined ethnic group to be the product of admixture between two or more parental populations occurring one or many generations in the past. Here we examine Mexican Americans--residents of the United States who have immigrated from Mexicoand reconstruct the HLA haplotype frequencies of their Native American ancestors. Mexican Americans are composed of a combination of ancestral Native American, European and African source populations, at estimated proportions of 44%, 48% and 8% respectively. Sequence based typing on HLA A, C, B and DRB1 was performed on each of 553 self-described Mexican Americans. A-B-DRB1 haplotypes frequencies were estimated. Existing European American and African American A-B-DRB1 high resolution haplotype frequency data was used to remove the Europe and African source haplotypes from the Mexican American data, leaving haplotype frequencies representing Native American founder A-B-DRB1 haplotypes HLA alleles and haplotypes previously characterized as native American were evident. Curiously, of the most frequent 40 A-B-DRB1 haplotypes, ten were present one or more times in the large sample of Europeans, many of these at similar or even higher frequencies. Closer examination of these cases showed that these instances are all likely present in the modern Spanish population at frequencies higher than in the more northerly origin European sample used. The high resolution data represent the best and probably most knowable sample of Native American HLA from the time of the European invasion 500 years ago.

***SHANK3* haploinsufficiency may be responsible for as much as 10% of cases of pervasive developmental disorder not otherwise specified (PDD-NOS).** *L. Boccuto[1,2], M. Lauri[2], C. D. Skinner[1], D. Buccella[2], J. S. Collins[1], M. Zollino[2], R. J. Schroer[1], G. Neri[2], R. E. Stevenson[1], F. Gurrieri[2], C. E. Schwartz[1,3]* 1) Greenwood Genetic Center, Greenwood, SC; 2) Istituto di Genetica medica, Universitá; Cattolica del Sacro Cuore, Rome, Itlay; 3) Department of Genetic and Biochemistry, Clemson University, Clemson, SC, USA.

Autism Spectrum Disorders (ASD) include three main conditions: autistic disorder, pervasive developmental disorder not otherwise specified (PDD-NOS), and Asperger syndrome. In recent years, many genes associated with ASD have been identified. Notably, some of these genes are involved in the neuroligin-neurexin interaction at the glutamate synapse: *NLGN3*, *NLGN4*, *NRXN1*, and *SHANK3*. We screened two cohorts of ASD patients - 131 patients from the South Carolina (SC) and 74 from Italy - for mutations in the *SHANK3* gene, a component of post-synaptic density. We found seven cases with *de novo* alterations: a c.1349C>T (p.P450L) transition in one SC patient with autistic disorder and two Italian patients with PDD-NOS, a c.3895delG (p.Glu1299fs) mutation in one Italian patient with PDD-NOS, three large intragenic deletions in three Italian patients with PDD-NOS. The overall mutation rate was 3.4%, three-fold higher than previously reported in autism patients. There were some significant differences in mutation rates by clinical phenotype. The mutation rate was 0.7% in cases with autistic disorder and 10.3% in cases with PDD-NOS. Thus, *SHANK3* mutations appear to be responsible for a significant number of PDD-NOS cases, with a lesser prevalence in patients with autistic disorder. We also noted some features - overgrowth at birth, tendency to obesity, and absent or delayed speech - shared by the patients carrying *SHANK3* mutations, are compatible with the diagnosis of 22q13 deletion syndrome, confirming a potential role of this gene in the neurological symptoms of 22q13 deletion syndrome. *SHANK3* is the first gene that exhibits evidence of a genotype/phenotype correlation in ASD. This suggests that a detailed clinical-neuropsychiatric evaluation may be an important tool for effective genetic screening of ASD patients.

Clinical Diagnostic *PORCN* Gene Sequencing for Focal Dermal Hypoplasia. *P. H. Fernandes[1,2], V. R. Sutton[1,2], P. A. Ward[1,2], C. M. Eng[1,2], I. B. Van den Veyver[2,3], P. Fang[1,2]* 1) Medical Genetics Laboratories; 2) Department of Molecular and Human Genetics; 3) Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX.

Focal dermal hypoplasia (FDH) or Goltz syndrome is an X-linked dominant disorder characterized by defective development of ecto-mesodermally-derived tissues. The gene responsible for FDH was recently identified as *PORCN*, which encodes an enzyme that enables membrane targeting and secretion of Wnt proteins. Approximately 80% of FDH-causing mutations in *PORCN* are single nucleotide substitutions, small deletions or small insertions, identifiable by sequence analysis of the *PORCN* coding region. Up to 20% of FDH patients have large genomic deletions that include *PORCN*. We implemented clinical diagnostic sequencing for *PORCN* mutation analysis in September 2007 and thus far have studied samples of 27 females and 5 males that were referred for a clinical diagnosis of FDH. Mutations that were either previously reported or predicted to be disease-associated were found in 15/32 samples (47%). These included 7 nonsense mutations, 5 previously reported missense mutations, 1 small deletion, 1 small insertion, and 1 splice site mutation. Two of these mutations were found in affected males and were mosaic, 13 were presumed heterozygous in females. Mutations were *de novo* in all 3 cases where parental studies were performed. One previously reported mutation, p.G60R, was identified 3 times in apparently unrelated families and appears to be recurrent. We also identified novel unclassified variants in 4 patients. One was a *de novo* missense p.H341Y change in a female patient, not seen in either parent. We also found a c.555+4A>G change that is predicted to disrupt the exon 5 splice donor site in two affected half-siblings. No mutation was identified by sequence analysis in 13 probands (40%). Further studies to evaluate large gene deletions are indicated in these patients. These results indicate that *PORCN* gene sequencing for a clinical diagnosis of FDH detects point mutations in up to 60% of cases.

ENZYME REPLACEMENT THERAPY FROM BIRTH IN MUCOPOLYSACCHARIDOSIS IVA MICE: EARLY TREATMENT LEADS TO REMISSION OF BONE LESIONS. *S. Tomatsu, A. Montaño, H. Oikawa, A. Ohashi, V. Chi Dung* Dept Pediatrics, St Louis Univ, St Louis, MO.

Mucopolysaccharidosis IVA (MPS IVA) is a lysosomal storage disorder characterized by severe systemic bone disease, resulting in short stature, bone deformities, and pulmonary compromise. Early treatment is vital to prevent long-term clinical pathology in lysosomal storage disorders. We used MPS IVA mice to assess the effects of long-term enzyme replacement therapy initiated at birth. Two recombinant human N-acetylgalactosamine-6-sulfate sulfatase (GALNS) produced in CHO cell lines were used: native GALNS and sulfatase-modifier-factor 1 (SUMF1) modified GALNS. MPS IVA mice received weekly intravenous injections of 250 units/g body weight of recombinant human GALNS until 14 wk of age. After doses of 250 units/g body weight were administered intravenously, each enzyme was primarily recovered in liver and spleen, with detectable activity in other tissues including bone and brain. MPS IVA mice treated from birth by 14 weekly intravenous injections of SUMF1-GALNS demonstrated almost no lysosomal storage in most tissues including heart valves, sinus lining cells in bone marrow, osteoblasts, osteocytes, and connective tissues surrounding the articles and ligaments. We obesrved reduction of the storage materials in chondrocytes. MPS IVA mice treated from birth kept the normal level of serum keratan sulfate. These data suggest that the enzyme which enters the cartilage before the cartilage cell layer becomes mature is able to protect against accumulation of storage material in MPS IVA mice. In conclusion, early treatment at birth leads to remission of bone pathology in MPS IVA mouse.

Reliable detection and detailed characterization by the Affymetrix SNP Array 6.0 of a wide variety of cytogenetic abnormalities in samples from the NIGMS Human Genetic Cell Repository. *J. Leonard[1], J. Veitch[2], N. Gerry[1], P. Bender[1], D. Coppock[1], N. Faravashi[2], M. Christman[1], J. Collins[2]* 1) Coriell Cell Repositories, Coriell Inst Medical Research, Camden, NJ; 2) AFFYMETRIX, INC., Santa Clara, CA.

The Affymetrix SNP Array 6.0 was used to define the chromosomal segments gained and lost in cultures in the Chromosomally Abnormal Collection of the NIGMS Repository. Cultures with known deletions or duplications, detected by other molecular analyses, and cultures from subjects with apparently balanced chromosomal rearrangments associated with abnormal phenotypes were also analyzed. Data were analyzed using both Affymetrix Genotyping TM Console Software and Partek Genomics Suite. To date, 380 unbalanced chromosomal abnormalities detected by G-band cytogenetic analysis were detected by the microarray. The band assignments of molecular breakpoints were compared with the cytogenetic calls using the UCSC Genome Browser. There was a high degree of consistency between the breakpoints involved in the abnormalities as called by the microarray and by the G-band analyses. In approximately 90% of the cases the breakpoints coincided or were in adjacent sub-bands. In addition thirty sub-microscopic deletion or duplication abnormalities previously determined by FISH or PCR were detected. In each case the segments detected were of the expected size and contained genes in the critical regions for the respective disorders: Williams Beuren, Wilms Tumor, Angelman, Prader-Willi,Charcot Marie Tooth A1, Miller-Dieker, Smith-Magenis, DiGeorge, Velocardiofacial, X-linked Ichthyosis, Duchenne Muscular Dystrophy, Pelizaeus-Merzbacher, and Azospermia. Samples from an additional forty-five subjects with phenotypic abnormalities and apparently balanced chromosomal abnormalities were also studied. Megabase sized deletions were found in the vicinity of the putative breakpoints in eight cases and five deletions were found at other sites. Evaluations of smaller changes are in progress.

The female Gaucher patient: recommendations for management of reproductive events. *P. Kaplan[1], A. Zimran[2], E. Morris[3], E. Mengel[4], N. Belmatoug[5], D. A. Hughes[6], V. Malinova[7], R. Heitner[8], E. Sobreira[9], M. Mrsić[10], S. Granovosky-Grisaru[2], S. vom Dahl[11]* 1) Ped/Metabolic, Childrens Hosp, Univ Pennsylvania, Philadelphia, PA; 2) Jerusalem, Israel; 3) Cambridge, UK; 4) Mainz, Germany; 5) Paris, France; 6) London, UK; 7) Prague, Czech Republic; 8) Johannesburg, South Africa; 9) Genzyme São Paulo, Brazil; 10) Zagreb, Croatia; 11) Cologne, Germany.

Background: Manifestations of type 1 Gaucher disease [GD] (bleeding, anemia, spleno-hepatomegaly & bone disease) may be relevant for female reproductive events. Aim: To advise on optimal management of females with GD based on data from women treated with alglucerase &/or imiglucerase (enzyme replacement [ERT]) or not treated. Methods: Clinicians experienced in GD reviewed peer-reviewed literature, a Canadian survey, an alglucerase-imiglucerase pharmacovigilance database & their own clinical data. Results: Menarche may be delayed in untreated girls with GD (average 14yrs untreated; 13.6yrs with ERT compared with 12-13yrs in general population). Menorrhagia is common & may worsen anemia. ERT can ameliorate menorrhagia alone (2 p=0.043) or with oral contraceptives (2 p=0.001). There is no evidence of decreased fertility. Literature on 356 untreated and 42 treated pregnancies and 338 untreated & 78 treated pregnancies in our patients show women can have successful pregnancies but in untreated GD symptoms may worsen and increased spontaneous abortions, pre & post partum hemorrhage, infection, and complications from splenomegaly may occur. Data show reduced risk with ERT of spontaneous abortion (2 p = 0.008), delivery complications (2 p <0.0005) & GD-related post partum complications (2 p = 0.014) compared with untreated. There is no evidence of adverse effects of ERT on the fetus or breast fed infants. Menopause data are lacking. Conclusions: ERT reduces menorrhagia & pregnancy complications in GD. Symptomatic patients needing ERT should achieve therapeutic goals before conception & have multidisciplinary care of pregnancy. ERT treated women may be advised to continue ERT in pregnancy & breast feeding. GD bone disease in menopause requires further study.

A Pyrosequencing assay to rapidly and quantitatively assess methylation at KvDMR1. *D. K. Bourque[1], L. Avila[1], M. S. Peñaherrera[1], D. E. McFadden[2], P. von Dadelszen[3], W. P. Robinson[1]* 1) Medical Genetics; 2) Pathology and Laboratory Medicine; 3) Obstetrics and Gynaecology, University of British Columbia, Canada.

KvDMR1 is the centromeric imprinting control region (ICR2) on chromosome 11p15.5 and is involved in the regulation of several genes, including *CDKN1C*. Methylation of this region is usually measured at a differentially methylated *NotI* restriction enzyme cutting site using Southern blotting. This differentially methylated region has previously been reported to be hypomethylated in some cases of Beckwith-Wiedemann syndrome (BWS). We have developed a Pyrosequencing assay to rapidly and quantitatively measure methylation at seven CpG sites in KvDMR1, including the BWS diagnostic *NotI* site. The assay is highly reproducible ($r=0.98$, $p<0.0001$) and was validated in several BWS cases, two of which showed reduced methylation (27% and 10%) as compared to blood controls (70%, N=11). Eight cases of Silver-Russell syndrome (a syndrome of growth deficiency) showed normal methylation. We also assessed KvDMR1 methylation in placentas from pregnancies affected with either fetal intrauterine growth restriction (IUGR) or preeclampsia (PET) because genes on 11p15.5 are known to be involved in fetal and placental growth and development. However, we found no significant difference in mean methylation level between the placental groups: control (N=22), 65.4%; IUGR (N=13), 64.8%; PET (N=17), 65.2%; PET+IUGR (N=21), 64.7%. Trophoblast and mesenchymal cells from one complete hydatidform mole (CHM) of androgenetic origin were also assessed with reduced methylation levels of 8% and 30%, respectively. This suggests that while the paternal allele is generally unmethylated, there may be some paternal methylation present in the mesenchymal cells, at least in this case. Placental samples from three cases of androgenetic chimerism (identified as placental mesenchymal dysplasia) also showed reduced methylation only in the samples identified as having significant levels of androgenetic cells. The rapidity and reproducibility of this Pyrosequencing assay should make it a useful tool in the timely diagnosis of KvDMR1 methylation errors in BWS and CHMs.

Pentraxin 3 genetic variation is associated with dizygotic twinning in The Gambia: linking innate immunity with super-fertility in a pleiotropic model. *G. Sirugo[1,2,3], D. R. Velez[4], K. K. Ryckman[4], C. Bisseye[1], H. Chapman[1], A. Worwui[1], M. Diatta[1], G. Morris[1], R. Agedbola[1], K. Odunsi[5], G. Page[6], S. M. Williams[4]* 1) Dept Human Genetics, Medical Res Council Labs, Banjul, Gambia, Gambia; 2) Medical Genetics Unit, Ospedale S. Pietro FBF, Rome, Italy; 3) Tor Vergata University, Rome, Italy; 4) Vanderbilt University, Nashville, TN; 5) Roswell Park Cancer Institute, Buffalo, NY; 6) University of Alabama, Birmingham, AL.

Dizygotic (DZ) twinning has a known genetic component and its frequency is particularly high in West Africans, up to 4% of live births in Nigerian Yoruba. However, no genes have so far been identified that would explain the peculiar frequency of the trait in sub-Saharan Africa. In The Gambia the frequency of DZ twinning is about 2% of live births, without epigenetic effects due to the use of fertility drugs or to consumption of food known to induce ovulation. Pentraxin 3 (PTX3), a soluble pattern recognition receptor which plays a functionally important role in both innate immunity and female fertility, is a candidate gene for DZ twinning in a tropical setting where prevalence of infectious diseases and twinning is high. In order to investigate the role of PTX3 in Gambian women with DZ twins we typed a set of five PTX3 intragenic SNPs in 113 sister pairs who had DZ twins (98 full sister and 15 half-sister pairs). Significant linkage between PTX3 and DZ twinning was found with markers rs1840680 and rs3845978 by ASP analysis (P=0.01 and P=0.0003 respectively). We also compared inferred haplotype frequencies in subjects with DZ twins to frequencies from 95, ethnically diverse Gambians: subjects with DZ twins were found to significantly differ from controls (P=0.003 for the 5 SNPs-extended haplotype spanning PTX3). Our results suggest that PTX3 variation affects DZ twinning in Gambians: selective pressure on PTX3 variants modulating immune responses to infectious agents could explain the high frequency of DZ twinning in West Africa.

Recurrent 15q13 microdeletion CNV: a susceptibility locus for autism, mental retardation, and psychiatric abnormalities. *S. Ben-Shachar[1], B. Lanpher[2], JR. German[1], M. Shinawi[1], CW. Cheung[1], JR. Lupski[1], AL. Beaudet[1], T. Sahoo[1]* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Vanderbilt University, Nashville, TN.

Deletions of chromosome 15q11.2q13 result in Angelman or Prader-Willi syndromes (AS and PWS). Recurrent deletions within 15q13, immediately distal to the AS/PWS critical region, are associated with a novel microdeletion syndrome whose clinical features include mental retardation, seizures, facial dysmorphisms, and mild digital abnormalities. The consistent size (~1.6 Mb) and clustering of breakpoints at low copy repeats (LCRs) suggest that the rearrangements are mediated by non-allelic homologous recombination (NAHR). We identified 14 individuals with microdeletions of 15q13 (11 children including a pair of siblings and 3 parents) by testing of over 12,000 clinical samples by array-CGH. The children had neurological and psychiatric phenotypes including mental retardation (10/11), autistic spectrum disorder (5/11), speech delay, aggressiveness, and other behavioral problems. The deletion was *de novo* in one family, inherited from an apparently normal mother in two families, and inherited from a father with cognitive impairment and bipolar disorder in a fourth family. Familial origin is presumed in two affected siblings with the same deletion and phenotype; thus the deletion was inherited in four of five families implying high heritability and possible incomplete penetrance. Interestingly, 7 of the 11 affected probands were not living with their biological parents, and most of the 11 biological parents unavailable for testing had a history of social, cognitive and psychiatric disabilities including bipolar disorder, depression, antisocial behavior, and schizophrenia. We hypothesize that additional some of these parents, including one parent of the affected sibs, harbor the deletion. These results reveal a major novel locus not only for a syndromic form of autism, but also a strong association with neuropsychiatric problems. Further analysis of the involved genomic interval and the genes contained therein may provide a better understanding of their role in these phenotypes.

Rapid and accurate genomewide p-value correction and power estimation with correlated markers. *B. Han[1], H. Kang[1], E. Eskin[2]* 1) Dept Computer Sci, Univ California, San Diego, La Jolla, CA; 2) Dept Computer Sci and Human Genetics, Univ California, Los Angeles, CA.

With the development of high-throughput genotyping technologies, current genetic association studies typically involve genotyping hundreds of thousands of markers. The large number of correlated markers bring to the forefront two variants of the multiple-hypothesis testing correction problem, p-value correction and per-marker threshold estimation. Permutation test, the gold standard, is computationally impractical for a large dataset. Several recent studies efficiently solve the problem by utilizing the multivariate normal distribution to simulate the null distribution of test statistic. These approaches straightforwardly scale to the whole genome by partitioning the region into blocks. However, by assuming independent blocks, the correlations between blocks are ignored which may lead to inaccuracies. Moreover, it is not possible to estimate the null distribution of p-values with previous methods, which requires repeated application of the method to each p-value. In this article we propose a novel method for multiple-hypothesis testing correction and power estimation called SLIDE which takes into account all correlations within a sliding window. Since SLIDE estimates the null distribution of p-values, every p-value of interest can be simultaneously corrected. Our simulations show that SLIDE is two orders of magnitude faster than the previous methods, and reduces the errors in the corrected p-values by 38% on average. We show that power estimation can also be solved by the multivariate normal distribution framework. SLIDE estimates genomewide power with the same accuracy as standard empirical simulations of power, and is faster up to two orders of magnitude. Connecting the two different problems, multiple-hypothesis testing correction and power estimation, provides useful insights that the per-marker threshold estimated from a reference dataset can approximate the true per-marker threshold. Our method is publicly available at **http://slide.cs.ucla.edu**.

Patterns of Genetic Variation at *TAS2R38*, a Bitter-Taste Receptor Gene, in Diverse African Populations. *M. Campbell[1], A. Ranciaro[1], A. Froment[2], D. Drayna[3], P. Breslin[4], S. Tishkoff[1,5]* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Muséum National d'Histoire Naturelle-Centre National de la Recherche Scientifique, Paris, France; 3) National Institute on Deafness and Other Communication Disorders, National Institutes of Health, Rockville, MD; 4) Monell Chemical Senses Center, Philadelphia, PA; 5) Department of Biology, University of Pennsylvania, Philadelphia, PA.

An important dietary adaptation in human populations is the ability to taste bitter compounds. A hypothesized selective advantage of bitter taste perception is that it helps individuals to avoid ingesting toxic substances in plants. Although studies have examined *TAS2R38*, a taste receptor gene associated with perception of the bitter substance PTC, in a number of geographic populations, little is known about patterns of variation at this locus in diverse populations from sub-Saharan Africa. In this study, we sequenced a 3.0 kb region encompassing the *TAS2R38* receptor locus in a number of culturally and linguistically diverse populations from Cameroon and Kenya. We also examined correlations between genotypic variation and bitter taste phenotypes (perception of PTC) in these populations. Our study shows that African populations have a higher degree of nucleotide and amino acid haplotype variability compared to previous studies of non-African populations. The presence of several amino acid haplotypes at high frequency across diverse African populations is also consistent with balancing selection. Furthermore, our sliding window analysis of Tajimas D values suggests that variants at the 5' and 3' ends of the coding region may be the targets of selection. Additionally, the diverse haplotypes present in Africans are correlated with a broader range of taste sensitivity than is typically observed outside of Africa, enabling us to assess the effect of particular amino acids on taste perception. Overall, this study provides further information regarding the genetic basis of taste perception in Africa and the role that genetic and phenotypic variability may play in adaptation to diverse diets.

Molecular and functional analysis of a novel MEK2 mutation in cardio-facio-cutaneous syndrome: Transmission through four generations. *K. A. Rauen[1], A. L. Estep[1], S. J. Bale[2], W. E. Tidyman[1], Y. Lacassie[3]* 1) Department of Pediatrics, UC San Francisco, CA; 2) GeneDx, Gaithersburg, MD; 3) Department of Pediatrics, LSUHSC and Childrens Hospital New Orleans, LA.

Cardio-facio-cutaneous (CFC) syndrome is a rare MCA disorder in which individuals have characteristic dysmorphic features, cardiac defects, ectodermal anomalies and delay. CFC is caused by alteration of activity through the Ras/mitogen-activated protein kinase (MAPK) pathway due to heterozygous de novo mutations in protein kinases B-Raf, MEK1 or MEK2; the majority occur in BRAF, whereas mutations in MEK1 or MEK2 comprise about 27%. We report a 7 mo male with a clinical diagnosis of CFC. Bidirectional sequence analysis of MEK2 revealed a novel c.383C>A transition in exon 3 resulting in a nonsynonymous missense substitution p.P128Q. Upon further evaluation, other family members including the probands mother and half-sib displayed phenotypic features of CFC. Genomic DNA from 11 members of this four generation family were screened for the MEK2 mutation identified in the proband. Nine family members with characteristics of CFC including the mother and half-sib tested positive for the MEK2 mutation; 2 family members who did not have features of CFC including the probands father and a maternal great aunt did not. SIFT analysis determined MEK2 p.P128Q to be deleterious. To corroborate the functional alteration of the novel mutant protein, transient transfection of 293T cells with subsequent Western analysis demonstrated increased kinase activity as measured by ERK phosphorylation. The p.P128Q mutant had increased pERK compared to wildtype. The level of pERK was less than the constitutively active MEK2 S222D/S2226D mutant and CFC MEK2 p.F57C mutant which is known to have a high level of activity indicating MEK2 p.P128Q is weakly hypermorphic. This is the first identified vertically transmitted functional CFC MEK mutation reported further expanding our understanding of germline mutations within the Ras/MAPK pathway. Our findings underscore the importance of a thorough genetic evaluation of family members and that activating mutant proteins within the MAPK cascade may be compatible with human reproduction.

-308 TNF promoter polymorphism predicts outcome in patients with rheumatoid arthritis treated with the anti-TNF agent etanercept but not infliximab. *A. G. Wilson[1], C. Potter[2], K. L. Hyrich[2], A. Barton[2], J. Worthington[2], J. D. Isaacs[3], A. W. Morgan[4], J. R. Maxwell[1], BRAGGSS* 1) University of Sheffield, Sheffield, United Kingdom; 2) University of Manchester, Manchester, United Kingdom; 3) Newcastle University, Newcastle, United Kingdom; 4) University of Leeds, Leeds, United Kingdom.

Background: The introduction of agents designed to inhibit tumour necrosis factor (TNF) has revolutionised the treatment of patients with severe Rheumatoid Arthritis (RA). These therapies are however expensive, and 30% of patients fail to respond. There has therefore been great interest in identifying markers predictive of treatment efficacy, which would allow targeting of these treatments to those most likely to benefit. We have therefore investigated whether genotypes of single nucleotide polymorphisms (SNPs) in the region containing the TNF gene predict response to anti-TNF therapy in RA. Methods: In a large cohort of Caucasian RA patients treated with anti-TNF medications (n=1,050) eight candidate SNPs were genotyped. Linear regression analyses adjusted for baseline 28 joint disease activity score (DAS28), baseline health assessment questionnaire (HAQ) score, gender and concurrent disease modifying anti-rheumatic drug (DMARD) treatment, were used to assess association of these polymorphisms with response to anti-TNF therapy, defined by change in DAS28 after 6 months of treatment. Analyses were performed in the entire cohort, and also stratified by anti-TNF agent. Results: Association between DAS28 response and TNF -308 genotype (p=0.001) was detected across the whole cohort. After stratification by anti-TNF agent, the TNF -308AA genotype was associated with a significantly poorer response compared with TNF-308GG in Etanercept (p=0.001) but not Infliximab (p=0.8) treated patients. No significant associations were detected for the other SNPs. Interpretation: We conclude that TNF -308 genotype is associated with efficacy of Etanercept but not Infliximab in the treatment of RA. These data may facilitate therapeutic targeting of these expensive medications.

Candidate gene association studies aimed at identifying genetic modifiers of penetrance in DYT1 primary dystonia. *S. Gavarini[1], A. Clark[1], D. Raymond[2], A. Mitchell[1], S. B. Bressman[2,3], L. J. Ozelius[1]* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Neurology, Beth Israel Medical Center, New York, NY; 3) Department of Neurology, Albert Einstein College of Medicine, Bronx, NY.

The most severe form of the inherited primary dystonia is early onset, generalized torsion dystonia. A three-base pair deletion (946delGAG) in the gene encoding torsinA (*TOR1A*) is responsible for most cases of the disease, but only 30-40% of mutation carriers exhibit dystonic symptoms. To date, age of onset is the single reliable factor related to the prognosis of primary dystonia. Despite the identification of the *DYT1* gene, pathological changes that lead to symptoms remain unknown. D216H, a coding-sequence variation at the *TOR1A* locus, has been shown to contribute to the incomplete penetrance in mutant-gene carriers. However, its overall contribution to explaining reduced penetrance is modest suggesting other factors contribute to DYT1 dystonia. *TOR1A* is highly homologous to three other genes, *TOR1B*, *TOR2A* and *TOR3A*. These homologous genes may be able to compensate for some torsinA functions in non-manifesting carriers. Genes coding for protein interactors of torsinA are also strong candidates for mediating the genetic influence on penetrance. Here we report the results of an association study comparing non-manifesting versus manifesting carriers of the *TOR1A* mutation looking at single nucleotide polymorphisms (SNPs) within torsin-related genes and genes encoding known protein interactors of torsinA. Identification of genes influencing the penetrance of DYT1 dystonia should clarify the underlying mechanisms of the disease and provide prognostic markers that would be clinically valuable in relation to potential future pharmacological treatments.

Genetic polymorphisms in the Diasporin genes and breast cancer survival. *J. R. Long[1], X. O. Shu[1], Y. Gao[2], C. Li[3], S. Qu[1], Z. X. Ruan[2], Q. Cai[1], W. Zheng[1]* 1) General Internal Medicine, Vanderbilt Univ, Nashville, TN; 2) Department of Epidemiology, Shanghai Cancer Institute, Shanghai, China 200032; 3) of Biostatistics, Vanderbilt University, Nashville, TN 37232.

Recent data from gene expression analyses have suggested that the Diasporin pathway play an important role in tumor progression. Candidate genes involved in this pathway include the NDN, PI16, LUC7L, RRP1B, BRD4, CENTD3, SIPA1 and CSF1R. Utilizing data from an ongoing genome-wide association study of breast cancer, we investigated the association of genetic polymorphisms of these genes with breast cancer survival in a cohort of 754 patients recruited from 1996 to 1998 and were followed for a median of 7.1 years as part of the Shanghai Breast Cancer Study (SBCS). A total of 63 SNPs located in these 8 genes plus flanking 10kb and having a minor allele frequency 0.05 are included in the Affymetrix SNP 6.0 array. Five SNPs were found to be associated with breast cancer disease-free survival (DFS) at a significance level of 0.05. All of these 5 SNPs are located in the CSF1R gene, including rs1010102, rs13360152, rs6579772, rs11743220, and rs17798680. The protein encoded by CSF1R gene is the receptor for colony stimulating factor 1, a cytokine which controls the production, differentiation, and function of macrophages. There is strong LD between rs6579772 and rs11743220, all the other pairwise r2 are less than 0.5. After adjustment for age and clinic predicators, i.e. TNM stage, ER, PR status and therapy, improved DFS was seen for patients with the rs13360152 minor allele; patients with heterozygote (HR: 0.8, 95% CI: 0.6-1.1) and homozygote (HR: 0.6, 95% CI: 0.3-0.9) fared better than patients with common allele homozygote (Ptrend=0.03). Patients carrying the minor allele of the other 4 SNPs had a worse prognosis than those with major allele. SNP rs1010102 showed the strongest effect, with HR (95% CI) being 1.3 (0.9-1.9) for heterozygote and 4.0 (1.9-8.6) for homozygote (Ptrend=0.004) with comparison to homozygote for the common allele. These results are promising and are being validated in an independent sample of patients.

Mutations in *FAM83H* in a cohort of autosomal dominant hypocalcified amelogenesis imperfecta families. *P. S. Hart[1], S. Cinar[2], D. Cogulu[2], D. Ozdemir-Ozenen[3], E. Firatli[4], T. Han[5], P. Sulima[5], D. L. Domingo[5], T. C. Hart[5]* 1) NHGRI, NIH, Bethesda, MD; 2) Ege University, Izmir, Turkey; 3) Yeditepe University, Istanbul, Turkey; 4) University Istanbul, Istanbul, Turkey; 5) NIDCR, NIH, Bethesda, MD.

Amelogenesis imperfecta (AI) is a heterogeneous group of disorders that affect the amount or quality of dental enamel. A total of 14 subtypes have been recognized historically based upon the clinical phenotype and mode of inheritance. Recently mutations in *FAM83H* were described in 3 Korean, 2 Caucasian and 1 Hispanic kindred segregating autosomal dominant hypocalcified AI (ADHCAI). We studied 1 North American and 7 Turkish kindreds with the same phenotype and identified 2 novel mutations, p.Q444X (1 Turkish family) and p.Q456X (6 Turkish families), as well as a previously described p.W460X mutation (North American family). In the 6 families with the p.Q444X mutation, haplotype analysis was undertaken to determine if this mutation represented a founder mutation or a mutational hotspot. In 5 of the 6 families, it was determined that the mutation had been inherited from a common ancestor, although the families could be split into 2 distinct groups based upon the amount of haplotype sharing. In the sixth family, the proband was the only affected member of his family, suggesting that the mutation arose as a *de novo* event, an assumption supported by the haplotype data which revealed a distinct haplotype. These results bring to 8 the number of mutations described in *FAM83H*. Only 2 mutations, p.Q456X and p.W460X, have been found in more than one kindred. The p.Q456X mutation was determined to be a founder mutation in Turkey and as an apparent *de novo* mutation in another Turkish family. A *de novo* mutation was also reported by Lee et al. 2008. The finding of 2 *de novo* mutations out of a total of 8 mutations suggests that there may be a high mutation rate in this gene. Consistent with the findings of Kim et al 2008 and Lee et al 2008, the mutations found in the Turkish families were nonsense mutations. This raises the question of whether the underlying molecular mechanism is haploinsufficiency or a dominant negative effect.

Complex rearrangements in Pelizaeus-Merzbacher disease suggest a coupled homologous and nonhomologous repair mechanism. *G. Hobson[1], K. McLean[1], L. Banser[1], D. Lavoie[1], J. Garbern[2], K. Sperle[1]* 1) Nemours Biomedical Research, A I duPont Hosp Children, Wilmington, DE; 2) Wayne State University, Detroit, MI.

The X-linked leukodystrophy Pelizaeus-Merzbacher disease (PMD) is most frequently caused by duplication of the proteolipid protein 1 gene (*PLP1*). Our data and that of others suggest that these duplications are a result of a coupled homologous and nonhomologous repair mechanism (CHNR) involving a double-strand DNA break and error-prone nonhomologous end-joining (NHEJ), as microhomologies are frequently found at the junctions between duplicated regions. More recently it was suggested that many rearrangements in the *PLP1* region are complex and that they are refractory to junction analysis. A replication-based mechanism termed Fork Stalling and Template Switching (FoSTeS) involving a single-strand DNA break was proposed for these rearrangements. We present our analyses of junction regions in PMD patients with complex rearrangements by semiquantitative PCR, array CGH and interphase FISH. The complex rearrangements include interrupted duplicated regions, triplications, and higher copy numbers. We argue that the CHNR mechanism is involved in the formation of complex rearrangements.

Possible role of TOMM40L in Alzheimers disease risk: Investigation of multiple SNPs in TOMM40L/APOA2 region. *L. M. Bekris[1], N. M. Galloway[2], C. E. Yu[1,2]* 1) Dept Med, Univ Washington, Seattle, WA; 2) Veterans Affairs Puget Sound Health Care System, Seattle, WA.

Multiple SNPs in the TOMM40/APOE gene region are in linkage disequilibrium and are the source of the strongest genetic association with late-onset Alzheimers disease (LOAD) risk. Recently, we have reported a possible mechanistic link between TOMM40 SNPs and LOAD risk whereby APOE protein levels have been associated with SNPs within the TOMM40 gene suggesting the existence of an APOE regulatory element within the TOMM40 gene. Alternatively, there could be an independent effect of the Tom40 protein, encoded by the TOMM40 gene, on LOAD risk. A TOMM40 homolog (TOMM40L) has recently been identified that appears to be a functional component of the Tom40 mitochondrial membrane complex. The TOMM40L gene is located next to APOA2 near a linkage signal for LOAD. Thus, in this investigation we hypothesize that because genetic loci within the TOMM40/APOE gene region are associated with LOAD, genetic loci within the TOMM40L/APOA2 gene region may also be associated with LOAD. Specifically, the aim of this study was to genotype SNPs (n=5) within the TOMM40L/APOA2 gene region and test for association between these SNPs and LOAD patients that have at least two family members with LOAD (FAD; n=474), sporadic LOAD patients without a family history of LOAD (SAD; n=272) and cognitively normal controls (n=878). Three SNPs were found to be marginally associated with SAD risk; rs3813627 (OR: 1.29, 95% CI; 0.99-1.70,); rs3813628 (OR: 1.26, 95% CI; 0.96-1.66) and rs4233368 (OR: 0.80, 95% CI; 0.61-1.05) but not FAD risk. While taking into account gender and APOE 4, rs6413453 and rs3813627 predict SAD risk but not FAD risk. FAD females with the rs3813628 C allele have an earlier FAD age-at-onset that is independent of APOE 4. In summary, an association with both LOAD risk and LOAD age-at-onset was found with SNPs located within the TOMM40L region. An association between TOMM40L SNPs and LOAD suggests that either, TOMM40L and thus mitochondrial function has a direct impact on LOAD risk, or the paralog regions of TOMM40/APOE and TOMM40L/APOA2 share some molecular mechanism that influences LOAD risk.

HLA Haplotype Diversity in Brazil. *M. Maiers[1], L. Gragert[1], W. Klitz[9], M. Elisa Moraes[3], M. Gerbase-DeLima[4], C. Vergueiro[5], M. daGraca Bicalho[6], S. Jamil Haddad do Monte[7], M. Torres[8], M. Ferdandez-Vina[2]* 1) Bioinformatics, National Marrow Donor Program, Minneapolis, MN; 2) MD Anderson Cancer Center, Houston, TX; 3) LIG, Immunogenetic Laboratory, São Paulo, Brazil; 4) Federal University, São Paulo, Brazil; 5) FCM, Santa Casa, São Paulo, Brazil; 6) Federal University of Paraná, Curitiba, Brazil; 7) Federal University of Piaui, Teresina, Brazil; 8) Albert Einstein Hospitla, São Paulo, Brazil; 9) Public Health, University of California, Berkeley, CA.

We have analyzed HLA allele and haplotype frequencies of a cohort of 116 895 Brazilian individuals in 4 racial/ethnic categories: African (3766), Asian (1376), European (87 321), Mixed Race (13 251) (Cafuso, Mulato, Pardo/Mestizo) who reside in 3 stratified geographical regions: North (8832), South (32 901), Southeast (75 162). Haplotype frequency analysis was performed using the EM algorithm on DNA based typing results for HLA-A, -B and -DRB1. Fst was computed on combined A, B, DRB1 2-digit allele frequencies. We applied a 2-D clustering method that analyzes both genetic variation and population variation simultaneously. The clustering output revealed several general patterns. Regional variation between North and South/Southeast was more distinguishing than race for defining clusters with the exception of Asian origin which formed a unique cluster. Non-European Northern populations defined three distinct clusters. The Southern and Southeastern groups appeared to have higher proporti The significant differences between Brazilian populations within the country and in comparison with US populations stress the need to develop and maintain a local stem cell registry to allow Brazilian patients access to well HLA matched donors.

Identifying genetic determinants of diabetic complications through genome-wide association studies of the Genetics of Kidneys in Diabetes (GoKinD) collection. *M. Kalscheur[1], J. Below[1], A. Konkashbaev[1], A. Pluzhnikov[1], C. Roe[1], A. Tikhomirov[1], E. Kistner[2], D. Nicolae[1], N. Cox[1]* 1) Department of Medicine, University of Chicago, Chicago, IL; 2) Department of Health Studies, University of Chicago, Chicago, IL.

Introduction: Genetic predisposition likely plays a role in the development of diabetic complications. Identifying loci that contribute to this predisposition through a genome-wide association study (GWAS) may provide greater understanding of the pathogenesis, prevention and treatment of these complications. **Methods:** The GoKinD genetics collection contains information from close to 1900 individuals with long-standing (10+ years) type 1 diabetes (T1D) and a variety of complications including nephropathy, cardiovascular disease and peripheral vascular disease. Each study participant was genotyped using the Affymetrix Genome-Wide Human SNP Array 5.0. Quality control studies were performed to ensure sample quality, identify highly related samples, and explore population stratification. Allelic association tests that incorporated logistic regressions were performed to identify loci of interest. Phenotypes reported here include cardiovascular disease that resulted in intervention (CVDI; 91 cases, 636 controls) and peripheral vascular disease (PVD; 314 cases, 1322 controls). SNPs were evaluated based upon level of significance, quality control parameters, and robustness across covariates. **Results:** No SNPs were associated with either phenotype at a level reaching genome-wide significance. For CVDI, three SNPs reached p values $< 10^{-5}$. rs8032656 (15q26, p value = 6.2×10^{-6} to 2.6×10^{-5}) was of high quality and is located in an intron of *SLCO3A1*, a gene that encodes a transporter of prostaglandins, along with four other SNPs with p values < 0.0001. Three of these SNPs exhibit a high degree of linkage disequilibrium (LD) with both a missense and a frameshift mutation within *SLCO3A1*. For PVD, five SNPs produced p values $< 10^{-5}$. **Conclusion:** This GWAS of two T1D complications failed to identify any SNPs associated with disease at genome-wide significance; however, several interesting SNPs were found that merit further evaluation.

Natural selection on the erythrocyte surface glycoproteins in malaria-endemic human populations of Africa. *W.-Y. Ko, K. Kaercher, S. A. Tishkoff* Department of Genetics, School of Medicine, University of Pennsylvania, Philadelphia, PA 19104, USA.

Understanding the evolutionary mechanisms underlying host-parasite competition is fundamental for studying the origin and spread of infectious disease. Detecting signatures of natural selection at genes involved in host-parasite interaction may help identify variants that play a critical role in the invasion pathways. In humans, glycophorin A and B are the major glycoproteins expressed on the surface of erythrocytes and are thought to be receptors that can be recognized by several pathogens, including the *Plasmodium falciparum* parasite causing malaria. Here, we resequenced three homologous glycoproteins - glycophorin A (*gypa*), B (*gypb*), and E (*gype*) in 285 individuals across 15 African populations. Because of possible copy-number variation, which may bias our sequence analyses, we conducted quantitative PCR experiments and identified 4 individuals that may carry more than one copy in at least one of the three loci examined. Sequence analysis for the remaining individuals shows extraordinarily high genetic variation, where the estimates of average pairwise nucleotide differences () are 0.0030, 0.0024, and 0.0017 for *gypa*, *gypb*, and *gype*, respectively. Sliding-window analysis of Tajimas *D* statistic reveals an excess of intermediate-frequency SNPs at exon 2 of *gypa* (that codes for the extracellular domain) in several malaria hyper-endemic populations but not in hypo-endemic populations. Interestingly, two replacement SNPs identified at this region are located at the positions that determine the MN blood type. Our results provide strong evidence that balancing selection is maintaining MN blood-type alleles in malaria endemic populations. In addition, despite >90% sequence similarity among these homologs, we observe evidence for a different type of selection (positive directional selection) acting on the same homologous region of *gypb*, where an excess of rare-frequency SNPs was found in 3 populations. Sequence comparison among the three genes shows that gene conversion may have played a role in maintaining genetic diversity upon which natural selection could act.

Genetic and Environmental Influence on Serum Lipid Tracking: A Population-based, Longitudinal Twin Study.

S. Zhang[1,2], X. Liu[1,2], J. Necheles[1,2], H. J. Tsai[1,2], G. Wang[1,2], B. Wang[1,2], Z. Li[3], X. Liu[3], X. Wang[1,2] 1) Smith Child Health Program, Children's Memorial Hosp, Chicago, IL; 2) Department of Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL; 3) Institute for Biomedicine, Anhui Medical University, Hefei, China.

Background: Serum lipid tracking during childhood and from childhood to adulthood has been examined. However, limited studies have explored genetic and environmental influence on serum lipid tracking from childhood to adolescence. Objective: This study examined the degree of serum lipid tracking from childhood to adolescence and genetic and environmental influence on the tracking. Methods: This study included a total of 520 same-gender twin pairs who were 6 to 12 years at the baseline, and who completed both baseline and follow-up study (with ~ 6 year interval). Assessment included anthropometric, zygosity, Tanner staging and serum lipid (LDL, HDL, cholesterol, and TG) measures. Generalized estimating equations were used to examine the lipid tracking from childhood to adolescence. A Bivariate Cholesky decompositions model was applied to estimate the genetic and environmental contributions to the lipid variation at each time point and phenotypic tracking correlation. Results: Participants with high tertile lipid levels at baseline tended to remain high at follow-up across all ages and Tanner stages, while subjects with low tertile at the baseline tended to remain low at follow-up. Both genetic and environmental factors influenced the phenotypic variation for the lipids. In addition, genetic component contributed to most of the phenotypic tracking for TC, TG and LDL except for HDL, whereas common environmental factors also play a role. Conclusions: Serum lipid profile showed significant tracking from childhood to adolescence. Such phenotypic tracking was largely influenced by genetic factors. This study underscores the importance to consider both genetic and environmental factors in order to identify early precursors of dyslipidemia and to design effective clinical and public health interventions.

Use of a Rett syndrome checklist in patients referred for clinical MECP2 testing. *D. Waggoner, M. Dempsey, A. Platteter, S. Das* Human Genetics, Univ Chicago, Chicago, IL.

Rett syndrome (RTT) is one of the most common neurodevelopmental disorders in females. The clinical picture is complicated by atypical variants of RTT which have widened the phenotypic spectrum. Mutations and deletions of the X-linked *MECP2* gene are found in approximately 90% of patients with RTT. The diagnosis is not always readily apparent and Huppke et al. (2003) developed a 10-item checklist of RTT features with a score ranging from 0-12. Results of the checklist comparing the clinical features between patients with *MECP2* mutations and those without indicated that if genetic testing had been done on only those individuals with a score of 8 or higher on the checklist, 100% of mutation carriers would have been detected, and only 54% of non-carriers would have been tested. The patients used to develop the checklist included those with classic symptoms of RTT. Given the expanding phenotypic spectrum of RTT some patients with mutations may not have the classic features of RTT. We studied the utility of the Huppke checklist in 68 patients (21 mutation positive and 47 mutation negative) referred to The University of Chicago molecular diagnostics laboratory for clinical *MECP2* mutation analysis. The results showed that 14 of 21 (66%) mutation-positive patients had a clinical checklist score of 8 or greater or in other words 7 patients would have been missed by using the 8 point cutoff. Only two of the 10 necessary criteria had statistically significant differences between the two groups, namely stereotypic hand movements and normal psychomotor development in the first 6 months. Four of the seven mutation-positive patients with a checklist score less than 8 had one or both of these findings. The published RTT checklist may be a useful tool for diagnosing a child with classic RTT, but may miss patients that have atypical RTT. This study suggests modifications in the criteria for evaluating whether *MECP2* mutation analysis is warranted. In addition to using the suggested cutoff score of 8 points or greater, we suggest that the features of normal psychomotor development and stereotypic hand movements be assessed independently.

Structural Equations As a General Framework for Modeling Phenotype and Genotype Networks. *X. Fang[1], L. Luo[2], J. Reveille[3], M. Xiong[2]* 1) Mathematical Sciences, Peking University, Beijing, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030; 3) Division of Rheumatology, Medical School, University of Texas Health Science Center at Houston, Houston, TX 77030.

Diseases are a process of environmental exposure and its interaction with genetic factors. Modern molecular epidemiology measures large number of biological parameters indicating a series of events along the causal chain between exposure and disease. These measures are referred to as biomarkers or intermediate phenotypes. To incorporate intermediate phenotypes into genetic studies of complex traits will facilitate identification of disease genes. In traditional genetic analysis, one or several phenotypes are used as dependent variables, and multivariate statistical methods are used to identify genes influencing phenotypes. However, such analysis cannot simultaneously model phenotypes as both dependent and independent variables and hence cannot fully employ phenotype information. In this report, we propose to use structural equations as a general framework for modeling phenotype and genotype networks to decipher the path from genomic information to the final outcome of the disease. The model consists of two steps. At the first step, we assume that the structural relations among phenotype and genotypes are known. Then, we use two stage least square estimate method to estimate the parameters in the equations. At the second stage, we use genetic algorithms to search the structures of phenotype and genotype networks. By iterations between two stages, we finally identify phenotype and genotype networks. By hypothesis testing we can identify the genes that influence the phenotype variations. The proposed methods are applied to ankylosing spondylitis (AS) data set. We found that IL23R was associated with the phenotypes of BASDAI, BASFI, PAINSCAL and COMORB index that influence the severity and progress of AS.

Gene Screening at the 13q32 Keratoconus Locus. *B. A. Bejjani[1], L. B. Wallis[1], K. A. Bailey[1], K. Cywinska[1], A. Molinari[2], J. A. Pitarque[2], B. Yue[3], M. Gajecka[1,4]* 1) WWAMI, Washington State Univ, Spokane, WA; 2) Hospital Metropolitano, Quito, Ecuador; 3) University of Illinois at Chicago College of Medicine, Chicago, IL; 4) Institute of Human Genetics, PAS, Poznan, Poland.

Keratoconus (KTCN) is a non-inflammatory thinning and anterior protrusion of the cornea that results in steepening and distortion of the cornea, altered refractive powers, and altered visual acuity. We ascertained eighteen autosomal dominant multigenerational KTCN families from Ecuador and identified a novel locus on 13q32.1-q32.3. We narrowed the critical region to a 5.6 Mb interval. Here we present sequencing results of candidate keratoconus genes localized to 13q32. The KTCN locus contains 23 known transcripts. Twelve of the genes were chosen for the evaluation based on known functions and putative functional implications to the pathophysiology of KTCN: *FARP1, MBNL2, FGF14, ZIC5, ZIC2, EFNB2, RNF113B, DOCK9, PHGDHL1, VGCNL1, ERCG5*, and *ING1*. Genes were screened by standard techniques using genomic DNA samples from twenty three individuals from the family that exhibited the highest LOD score at this locus and selected affected and unaffected individuals from other Ecuadorian keratoconus families. Coding exons and intron-exon boundaries of the genes were examined. To date, sequencing analysis of genes has not revealed mutations segregated with the disease phenotype. Several novel single nucleotide polymorphisms were identified.

Liver differences at gestation day 19 in a mouse model of an inborn error of metabolism, GKD, suggests a moonlighting function for the GK protein. *N. MacLennan[1], A. Presson[1,2], S. Horvath[2,3], E. R. B. McCabe[1,3,4]* 1) Pediatrics; 2) Biostatistics; 3) Genetics; 4) Bioengineering; and California NanoSystems Institute, UCLA, LA, CA.

Glycerol kinase deficiency (GKD) results in increased glycerol. The dogma is that maternal enzyme should protect the fetus in utero by removing glycerol. Work from us and others suggests the GK protein has moonlighting functions beyond its enzyme activity. We proposed to identify liver networks disrupted by Gyk KO prior to birth to determine if network alterations are seen prenatally, which would suggest involvement of moonlighting functions in GKD pathogenesis. We performed microarray expression analysis on embryonic day (e) 19 KO mouse livers and compared gene expression levels to those of day of life (dol) 3 livers. Gene filtering (dChip) identified 324 differentially expressed genes (1.35 fold change) at e19. Ingenuity Pathways Analysis (IPA) revealed differential gene expression in novel network pathways at e19. The top enrichment category for e19 liver expression was apoptosis (pe-6). Pathways significantly altered at e19 between WT and KO were apoptosis, lipid and amino acid metabolism, and cell signaling (pe-32 to e-43). Gyk was in the hepatic system disease pathway (pe-15) at e19. Glucocorticoid receptor signaling was the fifth highest canonical pathway at e19 (p0.01). IPA confirmed prenatal alterations of several known postnatal network pathways. Intersection of e19 and dol3 KO networks revealed a common apoptosis network with Gyk modeled as an integral part. Plasma glycerol levels were significantly different between KO and WT at both e19 and dol3, but e19 KO glycerol did not exceed dol3 levels. In conclusion, we show enrichment of apoptosis genes and glucocorticoid receptor signaling, proposed moonlighting functions of GK in prenatal life in Gyk KO mice. Plasma glycerol levels at e19 and dol3 suggest maternal enzyme is protecting the fetus by removing glycerol, but not protecting the fetus from loss of Gyks moonlighting functions. These alterations may be responsible for onset of GKD pathogenesis by in utero disruption of these moonlighting functions.

Identification of a novel BRAF fusion gene in pediatric low-grade astrocytomas. *A. J. Sievert[1], A. C. Resnick[2], T. H. Shaikh[1], J. A. Biegel[1]* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania School of Medicine, Philadelphia, PA.

Pediatric low-grade astrocytomas (LGA) are a heterogeneous group of tumors whose pathogenesis is not well understood. Distinguishing benign and malignant gliomas can be difficult, and there has been a lack of molecular markers to aid in diagnosis. We recently described a non-random ~2Mb duplication in 7q34 in 20 of 28 juvenile pilocytic astrocytomas and diffuse fibrillary astrocytomas using the Illumina 550K SNP-based oligonucleotide array platform. Validation of the duplication by FISH demonstrated a variety of patterns in the tumors, most consistent with a tandem duplication. Based on the SNP-array results, the proximal breakpoints were clustered in a region that contains KIAA1549, an uncharacterized gene. Distal breakpoints clustered within the BRAF locus. The BRAF oncogene is involved in regulation of the mitogen activating protein kinase (MAPK) pathway. Two common activating mutations have been described in a variety of solid tumors. One LGA had a V600E BRAF mutation with no 7q34 duplication. As both KIAA1549 and BRAF are transcribed in the same orientation, we hypothesized that a tandem duplication from KIAA1549 to the BRAF gene locus could result in a novel fusion gene. Reverse transcriptase PCR and sequencing was performed on tumors with and without the 7q34 duplication. Sequence analysis of a 1kb fusion product revealed a fusion between exon 15 of KIAA1549 and exon 11 of BRAF. Interestingly, the fusion product was identified in one sample that was normal by SNP-array analysis but demonstrated 3 copies of BRAF by FISH. The predicted KIAA1549-BRAF fusion gene includes the BRAF kinase domain but lacks the auto inhibitory N-terminal portion. This could result in constitutive activation of BRAF and subsequent enhanced activation of the MAPK pathway. In summary, we have identified a novel KIAA1549-BRAF fusion gene in a series of LGAs with a 7q34 duplication. Further studies are required to characterize the function of this fusion protein and determine the diagnostic and prognostic significance in the development of pediatric low-grade astrocytomas.

An audit of PTPN11 mutations in Noonan Syndrome and LEOPARD syndrome in the UK. *T. Khan, J. Short, R. Poh, R. Taylor, K. Kalidas, A. Crosby, M. A. Patton* Medical Genetics, St George's Hospital , London , United Kingdom.

The Regional Genetics Service at St George's Hospital in London has provided a national molecular genetic service for testing for Noonan syndrome with PTPN11 mutation testing and recently testing for SOS1, KRAS, and RAF1. The laboratory has tested for PTPN11 mutations in 343 individuals referred with a possible clinical diagnosis of Noonan syndrome. PTPN11 mutations have been identified in 30%. The mutations were in exons 3,4,7,8,12 and 13 but the majority of mutations occur in exons 3 and 8. Pulmonary stenosis occurred in 71% and hypertrophic cardiomyopathy in 7%. Five patients were referred with Juvenile Myelomonocytic Leukaemia (JMML). In these cases mutations in exon 3 were found in 3 patients (214G>C, 214G>T and 182A>G), one had a mutation in exon 4 (417G>C) and one had a mutation in exon 8 (854T>C). In addition there were 31 individuals referred with a possible clinical diagnosis of LEOPARD syndrome and PTPN11 mutations were identified in 74%. In most cases the mutations were in exons 7 and 12 but in five cases the mutation was in exon 13. One patient with a mutation in exon 12 (1403C>T) illustrates the difficulty of classification as she had multiple lentigines, pulmonary stenosis with facial features of Noonan syndrome and also clinical and histological evidence of neurofibromatosis. The audit indicates the mutations are non-random and there is an emerging pattern of genotype-phenotype correlation.

Identification of the gene for the cblF defect of vitamin B12 metabolism reveals a novel lysosomal membrane protein with homology to lipocalin receptors. *F. Rutsch[1], S. Gailus[1], I. Racine-Miousse[2], T. Suormala[3], C. Sagné[4], M. Toliat[5], G. Nürnberg[5], T. Wittkampf[1], I. Buers[6], A. Sharifi[4], M. Stucki[7], C. Becker[5], M. Baumgartner[7], H. Robenek[6], T. Marquardt[1], W. Höhne[8], B. Gasnier[4], DS. Rosenblatt[2], B. Fowler[3], P. Nürnberg[5]* 1) Dept Pediatrics, Univ Children's Hosp, Münster, Germany; 2) Dept Human Genetics, McGill Univ, Montreal, Canada; 3) Dept Biochem, Univ Children's Hosp, Basel, Switzerland; 4) Dept Biochem, IBPC, Paris, France; 5) Cologne Center for Genomics, Cologne, Germany; 6) LIFA, Münster Univ, Germany; 7) Univ Children's Hospital Zürich, Switzerland; 8) Dept Biochem, Charite Univ Hosp, Berlin, Germany.

In the cblF defect of vitamin B12 metabolism, transcobalamin-bound cobalamin is endocytosed into cells, but free cobalamin accumulates in lysosomes presumably because of defective lysosomal export. Accordingly, synthesis of methylcobalamin and adenosylcobalamin is deficient, leading to hyperhomocysteinemia and methylmalonic aciduria. Microcell-mediated transfer of wild-type human chromosomes into immortalized fibroblasts from a cblF patient increased the incorporation of label from [14C]propionate towards normal values in clones isolated after the transfer of chromosome 6. Using high-density SNP arrays, we performed homozygosity mapping in 12 unrelated patients with cblF disease and identified *LMBRD1* as a positional candidate gene on chromosome 6. *LMBRD1* encodes LMBD1, a 61.4-kDa protein with 9 putative transmembrane helices, which shows significant homology to the lipocalin membrane receptor LIMR. Four different frameshift mutations, leading to premature termination codons and down-regulation of the transcript, result in a loss-of-function of both *LMBRD1* alleles in the patients. 18 of the 24 disease chromosomes analysed carry the same mutation on a common haplotype of 1.34 Mb. Transfection of cblF patient fibroblasts with the LMBD1 wild-type construct rescued cobalamin coenzyme synthesis and function. EGFP-tagged LMBD1 colocalized with the late endosomal and lysosomal membrane marker LAMP1. This identifies *LMBRD1* as the gene for cblF and suggests that it codes for a lysosomal membrane transporter for cobalamin.

The Prader-Willi syndrome (PWS) snoRNAs and those encoded by marsupial *SNRPB* and *SNRPN* are paralogous with divergent evolution from a shared therian ancestor. *W. Zhu[1], P. B. Samollow[2], R. D. Nicholls[1,3]* 1) University of Pittsburgh, Pittsburgh, PA; 2) Texas A&M University, College Station, TX; 3) Children's Hospital of Pittsburgh, Pittsburgh, PA.

The mechanisms and selective forces underlying the evolutionary acquisition of genomic imprinting and imprinted genes are not well understood. Further, the timing and origins prior to or during the eutherian expansion for some imprinted genes of extant mammals is not known. This is exemplified by several intronless genes that are located in the human chromosome 15q11.2 region associated with PWS and their orthologs, which derived by retrotransposition or retroviral insertion. In contrast, the PWS-region gene encoding the SmN spliceosomal core subunit (*SNRPN*) originated through a gene duplication putatively in the ancestor of eutherian and metatherian mammals. This study sought to determine the hitherto unknown evolutionary origins of the five classes of box C/D small nucleolar RNA (snoRNA) genes found in the PWS domain. Uniquely in metatherians the paralogous *SNRPB* and *SNRPN* loci are adjacent genes and each contain novel snoRNA paralogs, *SNORD119B* and *SNORD119N*, in their respective fifth introns. *SNORD119B* orthologs also exist in eutherian mammals, a reptile, an amphibian, and some teleost fishes (variably in intron 5 or 6) but not in birds. Based on quantitative RT-PCR on RNA from a marsupial, *Monodelphis domestica, SNRPN* is expressed at higher levels in brain and lower levels in other tissues than *SNRPB*, as is true for eutherians. Surprisingly, *SNORD119N* levels are higher than *SNORD119B* levels in all tissues possibly from increased RNA stability due to 28S rRNA targeting. Using phylogenetic sequence comparisons, we propose an evolutionary pathway for the origins of each PWS snoRNA class from an ancestral *SNORD119N* gene. Most eutherian PWS genes (*SNRPN* and each snoRNA) thus arose evolutionarily by stepwise duplication and divergence from an ancestral *SNRPB-SNORD119B* locus present in the common ancestor of metatherian and eutherian mammals. Additionally, our data support the notion that snoRNA evolution can be labile, with duplication, transposition, and loss detected in different species.

Sequencing human-gibbon breakpoints of synteny. *L. Chen[1], S. Girirajan[1], T. Graves[2], T. Marques-Bonet[1], E. Mardis[2], E. E. Eichler[1]* 1) Department of Genome Sciences, Howard Hughes Medical Institute, University of Washington, Seattle, WA; 2) Genome Sequencing Center, Washington University, St. Louis, MO.

Gibbons offer an excellent phylogenetic link between the great apes and Old World monkeys. They exhibit an extensive karyotypic diversity with an increased rate of chromosomal translocations during the hominoid evolution. We examined, at base pair resolution, 25 synteny breaks encompassing 4.4 Mb of white-cheeked gibbon (Nomascus leucogenys, NLE) sequence with respect to the human genome for its contents, effects, and dynamic nature. About 50% of the breakpoints in human syntenic region fell within a repeat-rich region. A 1.5-2-fold enrichment of LINE, SINE, and LTRs was observed in the gibbon BACs and within a 20 kb breakpoint window compared to control gibbon WGS reads (~8 Mb). We also identified a 10-fold enrichment of L1PA4 elements and an increased abundance (9.5%) of segmental duplications with a majority of gibbon-specific duplications (89%) in our study. Further, segmental duplication-associated events including formation of paralogous genes and pseudogenes were observed in the vicinity of the breaks. However, no evidence of segmental duplication-mediated NAHR contributing to the gibbon human synteny breaks was apparent in our studies. Seven genes, involved in signaling pathways (*DEPDC4*, *GNG10*), phospholipid metabolism (*ENPP5*, *PLSCR2*), -oxidation (*ECH1*), cellular structure and transport (*HEATR4*), and transcription factors associated with gonadal functions (*GIOT1*) were disrupted due to synteny breaks in gibbons. Additionally, growth hormone cluster (*GH2*, *CSH1*, *CSH2*, and *CSHL1*) and genes involved in spermatogenesis (*ALMS1*) were also mutated in the vicinity of the breaks. An evolutionary analysis of coding sequences showed that the disrupted genes are affected by different selection pressures. Our study provides a catalog of molecular events at the synteny breaks in the white-cheeked gibbons and suggests its potential genetic effects contributing to the morphological and phenotypic uniqueness in gibbons.

Two separate mutations contributing to disease severity in an autosomal dominant Retinitis Pigmentosa (RP) family. *M. Gorin[1], A. Martinez[1], E. Spector[2], P. Chiang[2]* 1) Jules Stein Eye Institute, Department Ophthalmology, UCLA School of Medicine, Los Angeles, CA; 2) 2.UCD DNA Diagnostic Laboratory, Department of Pediatrics, UCD School of Medicine , Aurora, CO.

Retinitis pigmentosa (RP) is a group of inherited disorders affecting the photoreceptors or the retinal pigment epithelium (RPE) of the retina and leading to progressive visual loss. One approach for RP molecular diagnostics is to screen for known mutations in a CHIP-based platform. A second approach is to sequence the most common RP-related genes and proceed in a sequential fashion towards screening less common causative genes. We have employed an alternative approach by sequencing every coding exon from every known adRP gene. A total of 130 polymerase chain reactions (PCR) covering every coding exon from the 17 known adRP genes were performed and sequenced. In our first trial of this approach, we selected an adRP family with a clear autosomal dominant inheritance pattern. We identified a known mutation G56R in NR2E3 and a novel variant E160K in FSCN2 in the proband. The probands severely affected son has both variants, while another family member carrying only the G56R mutation is only exhibiting night blindness at the age of 73. The probands daughter, carrying only the E160K mutation, is asymptomatic, although she is still very young. The G56R mutation in NR2E3 reportedly accounts for 1-2% of adRP. The E160K variant in FSCN2 changes a highly conserved amino acid from an acid to a base that is likely to have an adverse effect on protein conformation and function. The potential modifier effect of the E160K mutation is suggested by the presence of both G56R and E160K mutations in the two most severely affected individuals. Others within this family are being ascertained to correlate clinical findings (including night blindness) with one or both of these mutations. These findings also highlight a potential limitation of both the CHIP-based and tiered analysis approaches towards RP that would have missed this potential modifier variant. It remains to be seen if we will find similar, potential disease modifier variants in other RP families through this comprehensive screening approach.

Analysis of mtDNA and Y-chromosome haplogroups in Mexican Mestizos and Amerindian groups. *I. Silva-Zolezzi[1], B. Z. Gonzalez-Sobrino[2], J. K. Estrada-Gil[1], A. Contreras[1], J. C. Fernandez[1], E. Hernandez-Lemus[1], L. Sebastian[1], F. Morales[1], R. Goya[1], C. Serrano[2], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) Anthropological Research Institute, UNAM, Mexico.

The Mexican population is mainly conformed by Mestizos, individuals with a genetic background consisting of Amerindian, European and African contributions. Genetic heterogeneity in Mexicans results from a complex demographic history that started with the peopling of North and Central America about 15,000 yrs ago, including the settlement of at least 60 different indigenous groups in Mexico, regional differences in admixture dynamics after colonization by Spaniards in the XVI century, epidemics and migration. Y chromosome-specific and mitcohondrial (mt) DNA polymorphisms are useful to help understand the genetic structure and history of human populations, due to their uniparental inheritance and lack of recombination. In order to refine the portrait of genetic variability derived from the Mexican Genome Diversity Project, we are characterizing maternal and paternal lineages participating in admixture. For this we included genotypic data from 163 mt SNPs and 123 Y chromosome SNPs present in the Illumina Human1M chip of 450 individuals, 300 mestizos from six states located in different regions: Northern, Central and Southern; and 150 individuals from different Amerindian groups (Tepehuanes, Zapotecos and Mayas). With this information, we are measuring genetic diversity using Fst and AMOVA analysis. Admixture analysis includes average and individual ancestral contribution estimates using autosomal SNPs. Initial results show that in our Mestizo sample, 88% of the mt haplogroups are Amerindian (A, B, C or D), and the rest includes European and African lineages. We have identified differences in proportions of each haplogroup in both Mestizos and Amerindians. Knowledege about the distribution of mt and Y-chromosome haplogroups in Mexican Mestizos and Amerindian groups, will generate valuable information to better understand genetic relationships between Mexicans and other Latin American populations. In addition, it may contribute to strengthen analysis in association studies of common complex diseases.

Genome-wide analysis of GxE: genotype by smoking effects on gene expression in the small airway of the lung. *J. G. Mezey[1], C. Gao[1], M. Butler[2], A. G. Clark[3], N. R. Hackett[2], T. P. O'Conner[2], R. G. Crystal[2]* 1) Biological Statistics (BSCB), Cornell Univ, Ithaca, NY; 2) Weill Medical College of Cornell University, New York, NY; 3) Molecular Biology and Genetics, Cornell Univ, Ithaca, NY.

We applied two methods for detecting genotype by environment (GxE) interactions in a genome-wide analysis of gene expression phenotypes: linear model based hypothesis testing and Bayesian mixture prior multiple regression. We applied these techniques to assess the degree to which smoking modulates genetic effects on gene expression in the small airway epithelium (SAE) of the lung, a cell population central to the pathogenesis of pulmonary disease. Genes expressed in the airway epithelium are known to be responsive to smoking and can also be affected by an individuals genotype, although the degree to which these factors interact at a genome-wide scale is currently unknown. Gene expression levels in the SAE cells obtained by fiberoptic bronchoscopy and brushing, were assayed using Affymetrix HG-U133 Plus 2.0 arrays in 106 healthy non-smokers, healthy smokers, and smokers with Chronic Obstructive Pulmonary Disease (COPD) of African, European, and Hispanic ancestry. Single nucleotide polymorphisms (SNPs) were also identified for these individuals using the Affymetrix 5.0 SNP array. We tested for significant genotype by smoking interactions for individual markers found within 25,000 bp of over 12,000 genes for which we had measured expression, accounting for effects of ancestry. Smoking has a dramatic impact on the gene expression profile, resulting in greater than 2-fold up- and down-regulation of over 150 probe sets. Even with the relatively small sample size, our analysis was able to identify highly significant SNP associations with SAE gene expression which are modulated by smoking. In addition, the Bayesian analysis was able to identify probable false-positives and GxE effects which were hidden by the structure of local linkage disequilibrium in the sample. These results are consistent with a genetic basis for differential responsiveness in SAE gene expression to smoking and may indicate important GxE relationships which impact the susceptibility to smoking-associated disease.

Leucoencephalopathy with megalencephaly, spongy degeneration and 17p deletion: A new disease? *M. Schiff[1], S. Drunat[2], S. Passemard[2], A. Aboura[2], F. Chalard[3], A. Verloes[2]* 1) Pediatric Neurology and Metabolic disease Dept, Robert Debré Hospital, Paris, France; 2) Genetics Dept, Robert Debré Hospital, Paris, France; 3) Pediatric Radiology Dept, Robert Debré Hospital, Paris, France.

This second child from non consanguineous parents was born at term by cesarean section for unexplained hydramnios. Birth parameters were at -1 SD. After minor neonatal feeding difficulties, she was investigated at 3 years of age for moderate and non progressive psychomotor retardation (with mainly speech delay) and dysmorphic features. Clinical findings included macrocephaly (head circumference +3 SD), contrasting with growth delay (weight -1 SD, height -2 SD), wide forehead, small nose and coarse facial features. There was no hepatosplenomegaly, no joints contractures and no signs of peripheral neuropathy. Basic biological findings were normal. Brain MRI disclosed bilateral and symmetric leucoencephalopathy with triventricular dilation, micro cysts in periventricular white matter and corpus callosum and Chiari type 1 malformation. There was no abnormal lactate or N-acetyl-aspartate peak on spectroscopy and urinary organic acids were normal, excluding Canavan disease. Activities of hexosaminidases A and B measured in leukocytes were normal, excluding GM2 gangliosidosis. CGH-array (Agilent 44K) revealed a large (2 Mb) subtelomeric deletion of the 17p region between nt 48539 and nt 2104702, thus from RPH3AL (rabphilin 3A-like, without C2 domains) to SMG6 (nonsense mediated mRNA decay factor). The deletion encompassed 38 genes, none of which known to be involved in leucoencephalopathy. The aspartoacylase gene (Canavan) is located centromeric to the deletion. Although the deletion could be coincidental with the cerebral phenotype, our patients presentation suggests that the 17pter region may contain a second locus for leucoencephalopathy with spongy degeneration. Inheritance could be dominant or recessive (with haploinsufficency by deletion for one allele, and loss-of-function point mutation for the second allele).

An unbalanced translocation between chromosomes 6p and 2p associated with Axenfeld-Rieger anomaly, hearing loss, developmental delay and distinct facial dysmorphism. *D. A. S. Batista[1,2], F. Li[4], I. Maumenee[3], T. Wang[4]* 1) Kennedy Krieger Institute, Baltimore, MD; 2) Departments of Pathology; 3) Ophtalmology; 4) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Chromosome rearrangements have long provided clues that allowed mapping genes for genetic disorders. We describe a 14-year old boy with severe growth and global developmental delays, autistic behaviors, congenital hearing impairment and notable dysmorphic features including prominent eyes, down-slanting palpebral fissures, broad nasal bridge, hypoplastic maxilla, high arch palate, long and thin digits. He has reduced muscle bulk, bilateral planovalgus deformity with tight heel cord, persistent hamstring contracture, mild scoliosis and kyphosis. Ophthalmology examination revealed complex malformations of anterior segment including anomalies of anterior chamber angle, prominent Schwalbe line, iris hypoplasia, tear-drop shaped pupil and high myopia on the right, and congenital glaucoma, consistent with Axenfeld-Rieger anomaly (ARA). Normal electroretinogram was documented at age 13 years. Brain MRI studies revealed dysgenesis of corpus callosum, enlargement of ventricles, decreased volume of cerebral white matter and patchy distribution of T2 hyperintensity in the white matter surrounding lateral ventricles. High-resolution karyotype and array CGH with 4200 BAC clones (BlueGnome) showed a de novo unbalanced translocation between the short arms of chromosomes 2 and 6 resulting in 8MB gain from 2p25.1 to pter and 6MB loss from 6p25.1 to pter. The trisomic genes at 2p (n=23) include SOX11, a transcription factor that is important in CNS development. The monosomic genes at 6p (n=40) include FOXC1, a member of the forkhead gene family. Mutations or haploinsufficiency of FOXC1 are associated with defects in anterior segment of the eye. We conclude that the 6p25.1-pter deletion involving FOXC1 is responsible for ARA in this patient. Further study of this unbalanced translocation should expand the phenotypic spectrum of 6p25 microdeletion syndrome and implicate essential genes at 6p25 and/or 2p25 in normal brain and eye development in humans.

Later onset mitochondrial myopathy without hepatic disease caused by mutations in *DGUOK*. *D. Dimmock[1], S. Zhang[2], L.-J. C. Wong[2]* 1) Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background Deoxyguanosine kinase (DGUOK) deficiency was originally described as the cause of an infantile onset hepatocerebral mitochondrial disease. The key features of this disorder include significant hepatic failure with nystagmus and hypotonia. Mitochondrial DNA studies reveal significant mitochondrial DNA depletion in the affected tissues. Subsequently it has been shown that the same mutations in this gene may present with isolated acute liver failure without cerebral or hepatic involvement. Conversely, Thymidine Kinase 2 (TK2) has been shown to cause a predominantly myopathic form of mitochondrial DNA depletion with significantly elevated creatinine kinase. **Case** Here we present a juvenile patient with cardiomyopathy, cyclic neutropenia, exercise intolerance and significant hypotonia. He does not have liver failure but did have abnormal mitochondrial electron transport chain activity with profound mitochondrial DNA depletion on muscle biopsy. Mutations were not found in *TK2* but instead we found in trans, two previously published mutations in *DGUOK*. **Conclusions** This case report expands the clinical spectrum of DGUOK deficiency. It suggests that, in patients with myopathic mitochondrial DNA depletion, if mutations are not found in *TK2*, other genes should be evaluated.

Accelerated genetic drift on chromosome X during the human dispersal out of Africa. *A. Keinan[1,2], J. Mullikin[3], N. Patterson[2], D. Reich[1,2]* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) National Human Genome Research Institute, NIH, Bethesda, MD.

Comparing genetic variation on chromosome X and the autosomes enables a multi-locus study of differences in the demographic histories of men and women. We have recently identified subsets of 150,000 SNPs from phase 2 of HapMap that are free of ascertainment bias and usable for learning about history (Keinan et al. Nature Genetics 2007). We have now extended these data to chromosome X, offering the first large-scale data set that allows accurate comparison of chromosome X and the autosomes. We also generated a complementary data set by aligning more than a billion bases of sequence from individuals of known ancestry and estimating the average time since genetic divergence. Three independent lines of evidence suggest that during the dispersal of modern humans out of Africa, chromosome X experienced much more genetic drift than is expected from the pattern on the autosomes: (1) Chromosome X exhibits unexpectedly high allele frequency differentiation between Africans and non-Africans, but not amongst non-Africans. (2) We observed many more SNPs of high derived allele frequency on chromosome X in non-Africans, but not in Africans, compared with what is expected from the autosomes. (3) We showed a reduction amongst non-Africans in the time since the most recent common ancestor for chromosome X loci compared with what is expected from the autosomes. All lines of evidence account for differences in effective population size and mutation rate between the two parts of the genome. The results cannot be explained by known episodes of human history or natural selection, and suggest that men participated more than women in the dispersal out of Africa. A parsimonious explanation is that after an initial founder population was formed by migration of both men and women, much of its gene pool was replaced by subsequent male migrants, from whom non-African populations inherit most of their diversity. These results have methodological implications for human population and medical genetic studies, where it is currently commonly assumed that chromosome X and the autosomes reflect the same history.

The FTO/obesity associated locus and dietary intake in children. *G. Davey Smith[1], P. Emmett[2], T. Frayling[3], I. Rogers[4], A. Hattersley[3], M. McCarthy[5], N. Timpson[1,5]* 1) MRC CAiTE Centre, Bristol University, UK; 2) Bristol University, UK; 3) Peninsula Medical School, UK; 4) Brighton University, UK; 5) Oxford University, UK.

Variation in the fat mass/obesity associated gene (FTO) is associated with fat mass, body mass index (BMI), and obesity. We aimed to assess the role that appetite plays in this association by using detailed dietary reports from the Avon Longitudinal Study of Parents and Children. Analyses assessed possible associations between variation at the FTO locus and a range of micro and macro-nutrients, taking into account the bias often found within dietary report data when assessing factors related to BMI. We also assessed associations between FTO and dietary intake independent of BMI in order to test the hypothesis that FTO may be influencing appetite directly as opposed to indirectly via BMI and altered intake requirement. Within a sample from which those underreporting food intake were removed, relationships between a single nucleotide polymorphism characterising the FTO signal (rs9939609) and dietary variables were found; total energy, energy from food, saturated fat, monounsaturated fat, polyunsaturated fat all $p<=0.009$ and trans-fatty acid $p=0.01$ at age 10-11. In efforts to account for increases in basal metabolic rate resulting from greater BMI, we adjusted for BMI and found that association remained (and was of similar magnitude) for total energy from all food (ratio of geometric means 1.008, SE 0.0037, $p=0.03$), total fat (ratio of geometric means 1.012, SE 0.005, $p=0.02$) and saturated fat (ratio of geometric means 1.012 SE 0.007, $p=0.05$). For fat and energy consumption these can be thought of as total daily fat consumption approximately 1.5g/day difference per allele and total daily energy consumption approximately 25kj/day difference per allele. There was no difference by genotype in the percentage of total energy (kcal) consumed as fat, carbohydrate and protein. Taken together, these associations suggest that individuals carrying minor variants at rs9939609 were consuming more fat and total energy, and that this was not simply dependent upon them having higher average BMI levels.

Participation in genome-wide association studies using electronic medical records: trust is key. *S. M. Fullerton[1], S. B. Trinidad[1], J. M. Bares[1], G. P. Jarvik[2], E. B. Larson[3], W. Burke[1,2,3]* 1) Medical History & Ethics, University of Washington, Seattle, WA; 2) Medical Genetics, University of Washington, Seattle, WA; 3) Center for Health Studies, Group Health Cooperative, Seattle, WA.

Genetic research, particularly as conducted on a genome-wide population-based scale with links to medical records, poses significant new challenges for informed consent, management and protection of personal information, and the return of research findings to groups and individuals. As part of the NHGRI-sponsored eMERGE (electronic Medical Records and Genomics) network, we carried out focus group discussions with members of the Group Health Cooperative (GHC), a non-profit health maintenance organization. Ten focus groups were held with distinct classes of GHC stakeholders: current genetic research participants, surrogate decision makers of deceased or incapacitated research participants, and members not currently participating in research. Each group met for approximately 2 hours to provide their perceptions and opinions about genomic research, what should be covered in the informed consent process, and the risks and benefits of participation. Discussions were audio recorded, transcribed, and analyzed to identify topics and themes of significance. In general, participants reported a high degree of willingness to participate in genome-wide association studies and agreed that appropriately de-identified genetic and linked medical record data could be shared for broad research benefit, as long as the possibility of such sharing was outlined in the initial consent. Their reported confidence in the value of such research was directly tied to their faith in GHC as a reputable institution that would provide strong stewardship of their personal data. In contrast, most participants were uncomfortable with the possibility that their personal data might be shared with for-profit entities. Focus group participants also expressed the expectation that clinically relevant results would be returned wherever possible. Results of the focus group discussions will be used to inform a year-long internal consensus development process aimed at informing GHC policies for conduct of future genetic investigations.

Risk of Interferon-gamma (INF-) gene polymorphism (+874 A/T) to age related cataracts. *M. MANNE[1], S. G. Bhagyalaxmi[1], R. Sireesha[1], D. V. Raje[2], S. Kiran[2], M. Vidyavathy[3], K. R. Reddy[3], G. Sridhar[4], T. Nagaraju[4], T. Padma[1], M. Manne[1]* 1) Department of Genetics, Osmania University; 2) Ocimum Biosolutions Pvt. Ltd; 3) Sarojini Devi Eye Hospital & Inst. of ophthalmology; 4) Department of Zoology, Osmania University, Hyderabad, India.

Low molecular weight molecules that act as UV filters protecting retina are derived from tryptophan catabolism via, kynurenine pathway by the enzyme indoleamine-2, 3, dioxygenase (IDO). This enzyme is induced mainly by Interferon IFN in infections, inflammations etc. IFN- gene shows polymorphism that may be differentially related with induction of IDO. We studied 426 cataract cases (102 Nuclear-NC, 99 cortical-CC, 94 posterior subcapsular-PSC and 131 mixed-MC type) and 123 controls to predict risk for IFN- genotypes. In all types of cataracts there was preponderance of females and non obese subjects with later onset in NCs and early onset in PSCs. While frequencies of IFN- genotypes did not differ significantly in NC and CC, a higher frequency of AT heterozygotes was observed in PSC (50.0%) and MC (48.1%) patients as compared to controls (34.9%;). Heterozygous females showed high frequency in PSC (53.8%) and MC (44.5%) cases and that of AA homozygotes in CC (61.3%) cases compared to controls (AT-32.1%, AA-54.7%. There was high risk for AT hetrozygotes for PSC (OR-1.86; CI-1.07-3.21; p0.02) and MC (OR-1.72; CI-1.04-2.85; p0.03) and low risk for AA homozygotes for MC (OR-0.44; CI-0.27-0.74; p0.001. Between the cataract types MCs differed significantly from other types in the distribution of IFN- polymorphism (MC vs. NC x2-10.90, 2d.f. p-0.004; MC vs. CC x2 -12.99, 2d.f. p- 0.001 and MC vs. PSC x2-6.04, 2d.f. p-0.04). Considering gender variation while both the sexes showed significant difference when CCs were compared to MC type (males: x2-6.29, 2d.f. p- 0.04; females: x2-7.68, 2d.f. p-0.02) in PSCs the difference was significant only in females(x2-6.93, 2d.f. p-0.03). These results showed high risk for heterozygotes of IFN genotypes for PSCs and MCs. Study of these individuals for variation in the regulation of IDO seems worth pursuing to have better understanding of the process of cataractogenesis.

Genome-Wide Association Study Reveals a Novel Locus for Male Pattern Baldness. *J. B. Richards[1,2], X. Yuan[3], F. Geller[4], D. Waterworth[3], V. Bataille[2], D. Glass[2], K. Song[3], G. Waeber[5], P. Vollenweider[5], B. Walters[4], U. Thorsteinsdottir[4], A. Kong[4], H. Stefansson[4], K. Stefansson[4], T. D. Spector[2], V. Mooser[3]* 1) McGill University, Montreal, QC, Canada; 2) King's College London, London, United Kingdom; 3) Genetics Division, GlaxoSmithKline, King of Prussia, Pennsylvania, USA; 4) deCODE Genetics, Reykjavik, Iceland; 5) CHUV University Hospital, Lausanne Switzerland.

Objective: Androgenic alopecia is a highly heritable polygenic disorder of considerable social significance, whose genetic architecture remains to be described. We conducted a genome-wide association study for androgenic alopecia **Methods:** A genome-wide association study was performed assessing 370,102 single nucleotide polymorphisms (SNPs) from the Affymetrix gene chip human mapping 500k array using standard protocols in 578 male cases (defined as Hamilton grade alopecia V-VII prior to age 65) and 547 male controls (defined as Hamilton grade I-II before age 75). The lead SNPs from novel loci achieving a p-value of 10^{-5} were tested for replication in two independent cohorts involving 1,100 men from the United Kingdom and Iceland, phenotyped for androgenic alopecia and hair loss, respectively. Additionally, this SNP was tested for association with hair loss in 878 women from Iceland. **Results:** The previously replicated locus near AR on the X chromosome achieved genome-wide significance ($p = 5.0 \times 10^{-11}$). 26 SNPs achieved a p-value of 10^{-5} from a novel locus on chromosome 20 in the discovery genome-wide association scan. The lead SNP from this locus was strongly associated with androgenic alopecia ($p = 3.2 \times 10^{-10}$) in the discovery cohort and was also associated with androgenic alopecia in 366 men from the British TwinsUK cohort ($p = 1.5 \times 10^{-3}$) and hair loss in 734 men from the Icelandic cohort ($p = 6.1 \times 10^{-3}$). The combined odds ratio for androgenic alopecia in men for all cohorts was 1.6 ($p = 6.7 \times 10^{-13}$). Additionally, this SNP was associated with hair loss in women from Iceland ($p = 0.01$). **Interpretation:** Our findings demonstrate that a novel locus on chromosome 20 is strongly associated with androgenic alopecia.

Genetic Associations with Coronary Disease from Integer and Lipid-Weighted Genetic Risk Score Algorithms for Six Lipid Metabolism Genes. *B. D. Horne[1,2], J. F. Carlquist[1,3], N. J. Camp[2], C. P. Mower[1], J. J. Park[1], J. B. Muhlestein[1,3], J. L. Anderson[1,3]* 1) CV Dept, Intermountain Med Ctr, Murray, UT; 2) Genet Epi Div, Univ Utah, SLC, UT; 3) Cardiol Div, Univ Utah, SLC, UT.

Genetic associations with common, complex phenotypes suggest small risk effects from most single nucleotide polymorphisms (SNPs). A polygenic genetic risk score (GRS) aggregates information from multiple SNPs in many genes. This study applied two GRS approaches to tagging (t) SNPs from 6 lipid genes for associations with coronary artery disease (CAD). To select tSNPs, each genes promoter, exons, exon/intron boundaries, and 3UTR were scanned in 50 normal controls. SNPs were genotyped in 339 normals to select tSNPs. A total of 38 tSNPs were selected (*CETP*: 11, *LIPC*: 11, *LCAT*: 3, *SR-B1*: 4, *LPL*: 7, *ApoF*: 2). CAD patients (n=1,020), non-CAD angiography patients (n=552), and untreated population normals (n=570) were genotyped. A simple integer GRS (IGRS) was calculated by summing the genotype score (-1, 0, 1) based on an additive model (genotype risk was determined from lipid values in untreated normals). A weighted GRS (WGRS) integrated SNP associations with lipid parameters. For IGRS and WGRS, a separate GRS was computed for LDL-C, HDL-C, and TG. Among normals, association was found for 7 SNPs with LDL-C, 5 SNPs with HDL-C, and 4 SNPs with TG. Compared to normals, no CAD associations were found for $IGRS_{LDL}$ (p-trend=0.13), $IGRS_{HDL}$ (p-trend=0.85), or $IGRS_{TG}$ (p-trend=0.47); results were similar for cases vs. non-CAD patients (p-trend=0.13, 0.59, 0.38, respectively). For WGRS in cases vs. normals, trends were found for $WGRS_{HDL}$ (OR=0.91/quartile, p-trend=0.07) and $WGRS_{TG}$ (OR=1.09/quartile, p-trend=0.08) but not $WGRS_{LDL}$ (OR=1.03/quartile, p-trend=0.56), while for cases vs. non-CAD patients association was found for $WGRS_{HDL}$ (OR=0.91/quartile, p-trend=0.041; adjusted: OR=0.89/quartile, p-trend=0.019) but not $WGRS_{TG}$ (OR=1.04/quartile, p-trend=0.39) or $WGRS_{LDL}$ (OR=0.94/quartile, p-trend=0.16). Weighted but not integer GRS variables were associated with clinically-relevant genetic contribution to CAD. Polygenic GRS metrics combining many related low-effect SNPs may enable detection of genetic associations.

High throughput oncogene mutation profiling using MALDI-TOF Mass spectrometry. *A. O. H. Nygren, G. Hogg, R. M. McCullough, D. van den Boom, M. Ehrich* SEQUENOM Inc., San Diego, CA.

In the current era of genomics, cancer research has made great strides in dissecting the molecular basis of individual tumors. In this context multiple mutations contribute to a number of genetic subtypes in histologically homogeneous tumor class. To obtain an accurate molecular classification of large sample sets a flexible high-throughput solution is needed that can easily adapt to newly discovered mutation as well as accurately detect small amount of mutated DNA species, which may impact therapy selection or outcome determination. We have developed 20 multiplex reactions comprising more than 200 mutations in 17 oncogenes, ranging from single base changes to insertions and deletions of dozens of nucleotides. The assay relies on SEQUENOMs genotyping technology, which provides a substantial advantage over previous multiple base extension assays. For verification of this assay we have screened the NCI-60 set of cancer cell lines. The NCI-60 is a set of different human cancer cell lines derived from diverse tissues; brain, blood and bone marrow, breast, colon, kidney, lung, ovary, prostate and skin. Here we show that MALDI-TOF mass spectrometry assay is an ideal tool for high-throughput screening of these types of genetic lesions. By combining the robust SEQUENOM genotyping technology biochemistry with the sensitivity and accuracy of MALDI-TOF MS detection, an exact ratio is obtained for each pair of wild type versus mutated allele enabling assessing the impact of each individual mutation. In addition, by screening for up to 12 different mutations in each plex, we show that this assay requires a minimum of total sample DNA and many samples can be processed in parallel.

Is VEGF a modifier of the cardiovascular phenotype of the 22q11 microdeletion syndrome? *G. M. Repetto[1], J. F. Calderón[1], M. L. Guzmán[1], A. Puga[1], C. P. Astete[2], M. Aracena[2], M. Arriaza[3], T. Aravena[4], P. Sanz[5]* 1) Dept Genetics, Clínica Alemana- Universidad del Desarrollo, Santiago; 2) Hospital Luis Calvo Mackenna, Santiago; 3) Hospital Gustavo Fricke, Viña del Mar; 4) Complejo Hospitalario Dr. Sótero del Río, Santiago; 5) Hospital Clínico Universidad de Chile, Santiago, Chile.

Chromosome 22q11 microdeletion syndrome (del22q11) is a common identifiable cause of congenital heart disease (CHD). It is estimated that 50-75% of patients have CHD, mostly involving the cardiac outflow tract. The majority of patients share a common 3 Mb deletion, but the cause of the phenotypic variability is unknown. Data on animal models of the deletion, additionally deficient in VEGF, and an association study of promoter polymorphisms in patients with del22q11 suggest a role for VEGF as a modifier of the cardiovascular phenotype of this syndrome (Stalmans et al Nat Med 2003). We evaluated VEGF promoter polymorphisms -2578 AC, -1154 AG and -634CG, known to downregulate VEGF expression, in 112 patients with del22q11 and their parents. Half of the patients had CHD and the remainder had normal cardiac anatomy. Allelic and genotypic frequencies were compared by ^{2} between patients with del22q11 with or without CHD. No statiscally significant difference was observed. Transmission disequilibrium testing (TDT) was also performed, and the results showed no evidence of excess transmission of any of these polymorphisms. Our findings do not support a role for VEGF promoter polymorphisms as modifiers of the presence of congenital heart disease in Chilean patients with del22q11. Funded by Fondecyt-Chile, Grant 1061051.

A Developmentally-Imposed Fixed Alteration in Cellular Identity Contributes to Pathogenesis in Marfan Syndrome (MFS). *M. E. Lindsay[1,2], D. C. Loch[1], Y. Chen[1], H. C. Dietz[1,3]* 1) Institute of Genetic Medicine; 2) Division of Pediatric Cardiology; 3) HHMI, Johns Hopkins Hospital, Baltimore, MD.

Aortic root aneurysm is the major cause of mortality in MFS, a disorder caused by deficiency of fibrillin-1. Many features of MFS manifest failed matrix regulation of TGF, and can be prevented in mouse models by TGF antagonists including the angiotensin II (AngII) type 1 (AT1) receptor blocker losartan that reduces expression of TGF ligands, receptors, and activators such as thrombospondin-1 (TSP1). Cultured vascular smooth muscle cells (VSMCs) derived from the aortic root of patients show abnormally high expression of AT1, TSP-1, and selected VSMC markers (smooth muscle actin and calponin), but fail to express markers of terminal VSMC differentiation such as smoothelin. These cellular phenotypes are more indicative of myofibroblasts than VSMCs. In theory, TGF could impose this phenotypic switch via a reversible change from VSMCs to a less mature state or a developmentally-fixed transformation via endothelial-to-mesenchymal transition (EnMT). This question was addressed directly by lineage tracing studies using the Rosa26 reporter allele that only expresses lacZ upon Cre-mediated removal of a buffer sequence. Pairing of Rosa26 with an endothelial cell-specific Cre driver will mark blue any cell that is or ever derived from an endothelial cell. Both WT and MFS mice showed positive aortic valve and endothelial cells, but positive cells within the aortic media were unique to MFS. Pathologic EnMT was restricted to the proximal aortic root, the region of unique predisposition for aortic enlargement in MFS and the only aortic segment that is normally populated by the secondary heart field. In this light, MFS transitions from good cells being stimulated to behave poorly during development due to an altered matrix environment to bad cells being themselves as a result of convergent predispositions imposed by cellular ontogeny and genetic perturbation. This novel paradigm will likely prove relevant to other genetic conditions and has implications for therapeutic intervention; based on these data pharmacologic inhibitors of EnMT are being explored in mouse models of MFS.

Undifferentiated human adipose-derived stromal cells express human muscle proteins and improve clinical features in SjL dystrophic mice. *N. M. Vieira[1], C. R. Bueno Junior[2], V. Brandalise[1], L. V. Moraes[4], E. Zucconi[1], M. Secco[1], M. F. Suzuki[3], M. M. Camargo[4], P. Bartolini[3], P. C. Brum[1], M. Vainzof[1], M. Zatz[1]* 1) Human Genome Research Center, Biosciences Institute, University of Sao Paulo;; 2) School of Physical Education and Sport, University of São Paulo;; 3) Biotechnology Department, National Nuclear Energy Commission-IPEN-CNEN, São Paulo;; 4) Department of Immunology, Instituto de Ciências Biomédicas, University of São Paulo - Brazil.

Limb-girdle muscular dystrophies (LGMD) are a heterogeneous group of disorders characterized by progressive degeneration of skeletal muscle caused by the absence or defective muscular proteins. The murine model for Limb-Girdle Muscular Dystrophy 2B (LGMD2B), the sjl mice, carry a deletion in the dysferlin gene that causes a reduction in the protein levels to 15% of normal. The mice show muscle weakness that begins at 4-6 weeks and is nearly complete by 8 months of age. The possibility to restore the defective muscle protein and improve muscular performance by cell therapy is a promising approach for the treatment of LGMD or other forms of progressive muscular dystrophies (PMD). Here we have injected human adipose stromal cells (hASCs) in the sjl mice, without immunosupression, aiming to assess their ability to: engraft into recipient dystrophic muscle after systemic delivery; form chimeric human/mouse muscle fibers; express human muscle proteins in the dystrophic host and improve muscular performance. We show for the first time that hASCs are not rejected after systemic injection even without immunosupression, are able to fuse with the host muscle, express a significant amount of human muscle proteins and improve motor ability of injected animals. These results may have important applications for future therapy in patients with different forms of muscular dystrophies.

Pierre Robin syndrome: report of a new case. *J. SANDRA GABRIELA[1], H. LAURA[2], G. DAVID OMAR[3], H. EDUARDO[4]* 1) NEUROPSICOGIA, INSTITUTO NACIONAL DE REHABILITACION, MEXICO D.F; 2) AUDIOLOGIA, INSTITUTO NACIONAL DE REHABILITACION, MEXICO D.F; 3) INSTITUTO NACIONAL DE REHABILITACION, MEXICO D.F; 4) FACULTAD DE ESTUDIOS SUPERIORES IZTACALA, UNAM, BIOLOGIA.

Pierre Robin syndrome it corresponds to a type of the ca syndromes craneofaciales. Prevalencia is 1:8500 new born, and de 80%, associates to specific syndromes. Their inheritance recessive autosomica, with a bound variant to X with heart malformations and foot Bot. Pierre Robin sequence (posterior U-shape cleft palate, glossoptosis, retrognathia) (PRS) is a frequent and heterogeneous neonatal condition of obscure origin. Orodigestive and cardiorespiratory functional disorders are very frequent in PRS and that these functional disorders, as well as anatomical and embryological data, argue for the involvement of brainstem dysfunction in the pathogenesis of some cases of isolated PRS. Prenatal and neonatal brainstem dysfunction as a neuroembryological hypothesis to explain the onset of some cases of Pierre Robin sequence. We present a new case: female mexican child 5-year-old, is the first child of young non consanguineous parentes, obtaind termino. She presented palatine fissure. That presents inconvenience of language, characterized by being found to level of dissyllables, basing its communication with signs and carrying to object desired. Uncle paternal grandfather with Down syndrome. EEG normal. Three years six months average mental age.

Identification of muscular dystrophy (MD) linkage regions and candidate genes. *K. K. McDonald, K. Crooks, J. Rimmler, J. Stajich, T. Jafarov, A. E. Ashley-Koch, M. A. Hauser* Center for Human Genetics, Duke University Medical Center.

Muscular dystrophy (MD) consists of a heterogeneous group of disorders that are characterized by progressive weakening and degeneration of skeletal muscle. Although multiple genes have been identified for autosomal dominant MD, they are only causal for a small proportion of cases. Therefore, many causative genes remain to be identified for inherited forms of MD. In this study, whole genome linkage analysis was performed with the Illumina Linkage IV Panel, containing over 6,000 SNPs, for four families with autosomal dominant limb-girdle muscular dystrophy (LGMD) or scapuloperoneal muscular dystrophy (SPMD). In each family, a single linked region was identified, and these regions were subjected to microsatellite fine mapping in order to further reduce the linked intervals. The minimal candidate intervals include a 14 cM region on chromosome 15 for LGMD family 383, a 21.2 cM region on chromosome 21 for LGMD family 1767, and a 30.9 cM region on chromosome 8 for LGMD family 2692. For SPMD family 2277, the linked region spans 16.8 cM on chromosome 3. The maximum nonparametric LOD score achieved for each region was 3.38, 3.30, 2.05, and 2.70 respectively. The number of positional candidate genes varies greatly among the families, from 33 genes in the region of interest for family 383 to greater than 100 genes for SPMD family 2277. We have prioritized these genes for further investigation based on expression pattern and function. Among the best functional candidate genes are talin-2 in family 383 and collagen 6A 1 and 2 in family 1767. We are currently sequencing these and other candidates. The identification of novel variants responsible for muscular dystrophy will provide immediate benefit for individuals in the families under study, by making possible genetic testing and counseling, in addition to enhancing the basic knowledge of muscle biology and the genes required for normal muscle function.

Cytosine methylation profiling of cancer cell lines suggest that PRC2 target methylation is a common event in cancer. *M. Ehrich[1], J. Turner[1], P. Gibbs[2], L. Lipton[2], M. Giovanneti[2], C. Cantor[1], D. van den Boom[1]* 1) Sequenom, Inc., San Diego, CA; 2) Ludwig Institute for Cancer Research, Royal Melbourne Hospital, Parkville, VIC, Australia.

It has been shown that a set of genes with binding sites for the polycomb repressive complex 2 (PRC2) in their promoter region can be epigenetically silenced in embryonic stem cells to maintain pluripotency. PRC2 involvement has been shown for colon cancer, but it is not known if these findings are applicable to other cancer types. We used a set of more than 400 cancer related genes for DNA methylation profiling in 59 cancer cell lines derived from 9 different types of cancer. We validated our cancer cell lines findings in a set of colon cancer and adjacent normal tissue samples. We confirmed more than 85% of genes with altered methylation in the cell lines to be differentially methylated in the clinical specimen. The set of examined genes included 70 that are known to be targets for PRC2. We were able to identify PRC2 target methylation in multiple forms of cancer. In six out of seven tumor types we find the fraction of hypermethylated genes to be enriched for those with PRC2 binding sites in the promoter region. These results suggest that PRC2 target silencing is a common event in cancer. The only tumor type with no such enrichment is melanoma, a cancer type with large environmental component that retains a high degree of differentiation. Our methylation data provides an ideal starting point for genome wide methylation research to identify all differentially methylated genes. The results can be combined with existing large scale datasets to develop an approach that integrates epigenetic, transcriptional and mutational findings.

A combination of spinal muscular atrophy carrier testing and linkage analysis can be used in prenatal testing when CVS is contaminated with maternal cells. *T. Prezant[1], M. Glicksberg[2, 3], T. Tran[1], L. Cowan[4, 5]* 1) University Children's Genetics Laboratory, a Division of ProGene, Glendale, CA; 2) El Camino Real High School, Woodland Hills, CA; 3) Brandeis University, Waltham, MA; 4) Good Samaritan Hospital, Los Angeles, CA; 5) Harbor UCLA Medical Center, Torrance, CA.

A family presented for prenatal diagnostic testing for Spinal Muscular Atrophy (SMA) Type I after molecular identification of the homozygous absence of *SMN1* exons 7 and 8 in their first child, who was affected. While the chorionic villus sample (CVS) was growing in culture, the parents were tested for carrier status by a new semi-quantitative SMA carrier test, which utilizes gene-specific PCR to determine dosage of *SMN1* exon 7. We determined that both parents are one-copy carriers. Diagnostic testing of the cultured CVS showed the presence of *SMN1* in the current pregnancy, and carrier testing revealed one-copy dosage of *SMN1* exon 7 in the fetal sample. Because we detected maternal cell contamination (MCC) for several microsatellite markers, these results were inconclusive. However, since we targeted polymorphic markers in the *SMN1* region on 5q13 for MCC analysis and included DNA from the affected sibling and both parents as controls, we essentially performed linkage analysis concurrent with the SMA diagnostic tests. Initial results showed that the fetus shares only one of the at-risk haplotypes with the affected sibling, supporting the findings from carrier testing. Expanded linkage analysis allowed us to determine that the fetus most likely inherited the normal paternal allele and the *SMN1*-deleted maternal allele, with minor MCC contributed by the normal maternal allele. Although the presence of the normal paternal allele suggested that at worst the fetus would be an SMA carrier, the family was offered and chose to have repeat testing on cultured amniocytes. These results confirmed the predicted SMA carrier status of the fetus. In this family, results were informative despite the occurrence of MCC. The combination of carrier testing and concurrent linkage analysis can provide early, accurate prenatal diagnostic testing for at-risk couples despite the possible presence of maternal cell contamination.

Mutations in *ZFP57* are associated with hypomethylation of multiple imprinted loci in patients with Transient Neonatal Diabetes (TND1). *I. K. Temple[1,2], J. Callaway[1,3], S. Marks[3], H. White[4], C. Acerini[5], S. Boonan[6], P. Dyanikli[7], H. Firth[8], J. Goodship[9], A. Haemers[10], J. Hahnemann[11], O. Kordonouri[12], A. Masoud[13], E. Oestergaard[14], J. Storr[15], S. Ellard[16], A. T. Hattersley[16], D. O. Robinson[1, 3], D. J. G. Mackay[1,3]* 1) Div of Hum Genet, Univ Southampton, Southampton, UK; 2) Acad Unit of Gen Med, Wessex Clin Genet Service, Southampton, UK; 3) Wessex Reg Gen Lab, Salisbury, UK; 4) Nat Gen Ref Lab, Salisbury, Uk; 5) Dept of Paed, Univ Cambridge, UK; 6) Gen Counsel Clin, Kennedy Centre, Glostrup, Denmark; 7) American Hosp, Istanbul, Turkey; 8) Dept of Med Genet, Addenbrooke's Hosp, Cambridge, UK; 9) Instit of Hum Genet , Newcastle Univ, UK; 10) Dept of Int Med-Endo, Maria Hosp, Nord Limburg, Belgium; 11) Med Gen Lab Cent, Kennedy Centre, Glostrup, Denmark; 12) KinderKrankenhaus auf der Bult, Hannover, Germany; 13) Child Services, Northwick Park Hosp, Middlesex, UK; 14) Dept Clin Genet, Nat Univ Hosp Rigshospitalet, Copenhagen, Denmark; 15) Dept Paed, Cumberland Inf, Carlisle, UK; 16) Instit Biomed Clin Sci, Penninsular Med Sch, Exeter, UK.

Transient neonatal diabetes (TND1) is a well recognised disorder of imprinting. 20% of cases have loss of methylation at the TNDDMR resulting in overexpression of *PLAGL1*. We have previously shown that some patients have a variable pattern of mosaic DNA hypomethylation at multiple imprinted loci. Clinical features include variable combinations of macroglossia, umbilical hernia, learning difficulties, and heart defects in addition to TND. Recurrence in sibs has been recently reported. By genome wide SNP genotyping in 6 consanguineous families, we identified a shared 15Mb region of homozygosity at 6p22. Sequencing of *ZFP57*, a zinc-finger transcription factor expressed in early development, identified homozygous mutations in all six probands, while no sequence alterations were found in any control chromosomes. A further non consanguineous proband was identified who was a compound heterozygote. We conclude that this novel syndrome, which has variable epigenetic and clinical characteristics, is an autosomal recessive imprinting disorder. This is the first description of a heritable global imprinting disorder compatible with human life.

Gene expression analysis of otosclerosis stapes footplates. *M. Ealy[1], W. Chen[1], G. Ryu[2], J. Yoon[2], D. Welling[3], M. Hansen[1], A. Madan[2,4], R. Smith[1]* 1) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, IA; 2) Neurogenomic Research Laboratory, Department of Neurosurgery, University of Iowa, Iowa City, IA; 3) Department of Otolaryngology-Head and Neck Surgery, Ohio State University, Columbus, OH; 4) Institute for Systems Biology, Seattle, WA.

Otosclerosis is a complex disease that results in a common form of conductive hearing loss due to impaired mobility of the stapes. Stapedial motion becomes compromised secondary to invasion of otosclerotic foci into the stapedio-vestibular joint. Although environmental factors and genetic causes have been implicated in this process, the pathogenesis of otosclerosis remains poorly understood. To identify genetic contributors to otosclerosis we completed a microarray study of otosclerotic stapedial footplates. Because most stapes surgery is now done by laser-assisted stapedotomy, the number of pathological specimens was limited to nine. These stapes footplate samples and seven stapes footplates from control patients were used in the analysis. One-hundred-and-ten genes were found to be differentially expressed in otosclerosis samples. Ontological analysis of differentially expressed genes in otosclerosis provides evidence for the involvement of a number of pathways in the disease process that include interleukin signaling, inflammation and signal transduction, suggesting that aberrant regulation of these pathways leads to abnormal bone remodeling. Currently we are working to determine whether these genes share common regulatory elements. Further genetic and functional analyses of the differentially expressed genes along with possible common transcription factors that regulate these genes will provide us with a better understanding of the pathophysiological nature of otosclerosis.

Association of Angiotensinogen G-6A, C4072T, C6309T and A12775G polymorphisms with hypertension in Mexican population. *E. Balam-Ortiz[1], R. Gutierrez-Aguilar[1], J. Estevan-Baz[2], A. Esquivel-Villarreal[2], A. Elizalde[2], T. Gil[2], K. Carrillo[1], C. Rangel[1], V. Espinosa[1], L. Alfaro[1], A. Contreras[1], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) North Central Hospital, Mexico.

In Mexico, hypertension has a prevalence of 30.8% in population >20 years. It is a risk factor for heart and renal failure, myocardial infarction and cerebral vascular disease. Different genetic variants have been reported to be associated with hypertension, including those in angiotensinogen (*AGT*), adrenergic beta-1 receptor (*ADRB1*), angiotensin-II receptor type 1 (*AGTR1*). All these genes are involved in regulation of blood pressure. To analyze association of these variants with hypertension in Mexicans, we conducted a case-control study in 230 cases and 80 controls >65 years old from Mexico City. We genotyped 9 SNPs of *AGT*: C-532T(rs5046), G-218A(rs5049), A-20C(rs5050), G-6A(rs5051), C3889T (rs4762), C4072T (rs699), C6309T(rs2493132), A11535C(rs7079) and A12775G(rs943580); 2 SNPs of *ADRB1*: A145G (1801252), C1165G(1801253); and 1 SNP in *AGTR1*: A1166C(rs5186), using TaqMan assays (AB). We determined allele frequencies, Hardy-Weinberg equilibrium (HWE), and odds ratios (ORs) in the dominant, recessive, additive model, of each genetic variant. All variants were in HWE with a genotyping call rate higher than 95%. No association with hypertension was shown for polymorphisms in *ADRB1* and *AGTR1*. In contrast, four polymorphism in *AGT* showed a significant association with hypertension in: G-6A (OR 4.64; CI 95%=1.8-11.5; p=0.00008 in a recessive model); C4072C (OR 4.42; CI 95%=1.74-11.2; p=0.0009 in a recessive model); C6309T (OR, 12775A>G (OR 5.6; CI 95%=2.3-13.3; p=0.00004 in a recessive model); and A12775G (OR 5.2; CI 95%=1.9-13.8; p=0.00033 in a recessive model). We identified association of four variants of the *AGT* with hypertension in Mexican Mestizos. We are currently increasing the number of cases and controls in our study, and constructing haplotypes and analyze their association to hypertension in Mexicans. These studie will contribute to better understand the genetic basis of cardiovascular diseases in Mexicans.

Drosophila NnaD mutant flies model *Purkinje cell degeneration* mouse phenotypes and suggest a role for Nna proteins in mitochondrial function and mitochondrial dynamics. *R. Zahra[1], L. Chakrabarti[1], S. M. Jackson[1], L. J. Pallanck[2], A. R. La Spada[1]* 1) Depts of Laboratory Medicine; 2) Genome Sciences University of Washington, Seattle, WA.

The Purkinje cell degeneration (*pcd*) mouse is a recessive model of neurodegeneration, involving cerebellum and retina, with a phenotype of ataxia and blindness. Loss-of-function of the Nna1 gene causes *pcd*, and the Nna1 gene encodes a protein possessing a putative carboxypeptidase activity; however, neither the target substrates for Nna1 action nor the molecular pathways regulated by Nna1 are known. The fruit fly, *Drosophila melanogaster*, is a powerful system for modeling neurological phenotypes and defining mechanistic pathways for gene products of unknown function. As flies have a highly conserved orthologue of Nna1 (known as NnaD), we developed a fly model of *pcd* by characterizing a fly line carrying a P-element insertion at the NnaD gene. The NnaD fly model displayed shortened lifespan, and recapitulated key phenotypic features of the mouse Nna1 mutants including progressive retinal degeneration. Further studies of NnaD in *Drosophila* and Nna1 in *pcd* mice indicated that Nna proteins co-fractionate with mitochondria, and that loss of Nna function results in morphological and functional mitochondrial abnormalities. To investigate the role of NnaD in mitochondrial biology, we tested the hypothesis that Nna1 regulates mitochondrial dynamics and that defective mitochondrial dynamics result in oxidative stress sensitivity. NnaD mutant flies were crossed with flies carrying mutations in genes encoding the mitochondrial fission-promoting protein Drp1. Three independent Drp1 loss-of-function alleles ($drp1^{KG}$, $drp1^{T26}$ and *Df(2L)D20)* were all found to significantly suppress the NnaD phenotype. Furthermore, when we placed NnaD mutant flies on a diet containing Vitamin E and superoxide dismutase, we noted a significant extension in lifespan. These findings suggest that the Nna1 family of proteins play an important role in maintaining normal mitochondrial function through the regulation of mitochondrial dynamics, and that neurodegenerative phenotypes in *pcd* mice likely have a mitochondrial basis.

Designing Pools for High-Throughput Resequencing. *S. Prabhu, I. Peer* Department of Computer Science, Columbia University, New York, NY.

Resequencing genomic DNA from pools of individuals is an efficient strategy to detect new variants in targeted regions and compare them between cases and controls. However, naive designs of disjoint pools prevalent today obscure the individual identity of carriers of such variants. We present a framework for overlapping pool design, where each individual sample is resequenced in several pools. Upon discovering a variant, the set of pools where this variant is observed is the telltale of the identity of its carriers. We formalize the mathematical framework of such pool designs, and the requirements from such designs. We specifically address three practical concerns for pooled resequencing designs: (1) False positives due to errors introduced during amplification and sequencing; (2) False negatives due to undersampling particular alleles aggravated by non-uniform coverage; and consequently (3) Ambiguous identification of individual carriers in the presence of errors. We build on theory of error correcting codes to design pools that overcome these pitfalls. We show that in practical parameters of resequencing studies, our designs guarantee high probability of unambiguous carrier identification, while maintaining benchmarks of naive pools in terms of sensitivity, specificity and the ability to estimate allele frequencies.

Methylation profiling in Silver Russell Syndrome. *M. Penaherrera[1], S. Weindler[2], M. I. Van Allen[1], S. Langlois[1], W. Robinson[1]* 1) Dept Medical Genetics, Univ. British Columbia, Vancouver, BC, Canada; 2) Faculty of Medicine, University of Leipzig, Germany.

Silver Russell Syndrome (SRS) is a genetic disorder characterized by pre and postnatal growth deficiency, dysmorphic facial features, relative macrocephaly and body asymmetry. Efforts to determine the genetic basis of this condition have been compounded by its heterogenous nature, both at the clinical and molecular level. In previous studies of SRS, approximately 10% of cases presented with upd(7)mat and around 30% of the cases were associated with epigenetic mutations in 11p15. As part of an ongoing study of 22 SRS patients, two cases were identified as upd(7)mat and 8 cases (36%) showed hypomethylation for *IGF2/H19* ICR1 compared to age matched controls using a single nucleotide primer extension based assay (SNuPE). Clinical features were not significantly different in the ICR1-hypomethylated group. To identify additional alterations in methylation in SRS we used the Illumina Golden Gate Methylation Cancer Panel I, which assays 1505 CpG sites in a total of 807 genes, to test 21 SRS patients and 14 age matched controls. Sixty seven of these CpG sites are associated with 29 imprinted genes. Comparing the ICR1-hypomethylated group (N=8) with controls, the most significant methylation change was a reduced methylation at a CpG in the promoter region of *H19* ($p<0.001$). A positive correlation was found between the percent methylation from *H19*-ICR1 SNuPE and the average-beta methylation values from *H19*_P1411 Illumina, for the combined data of patients and controls ($r= 0.76$). Five additional CpG sites showed altered methylation (at $p<0.01$), though these did not include imprinted genes and this number was not more than expected by chance. This suggests that the changes in methylation at *H19* do not reflect global changes in methylation in this group. Two CpG sites (non-imprinted genes) were significant at the $p<0.01$ cut-off for the SRS group that showed normal methylation for ICR1. Several of the most interesting candidate changes, involving genes known to regulate growth, are being followed up by pyrosequencing.

Mecp2 Null Mice Display Multiple Skeletal Abnormalities. *R. D. O'Connor[1], M. Zayzafoon[2], M. C. Farach-Carson[1], N. C. Schanen[1,3]* 1) Department of Biological Sciences, University of Delaware, Newark, DE; 2) Department of Pathology, University of Alabama at Birmingham, Birmingham, AL; 3) Laboratory for Human Genetics, Nemours/A.I. duPont Hospital for Children, Wilmington, DE.

Rett Syndrome (RTT), a neurodevelopmental disorder, is most often caused by inactivating mutations in the X-linked gene encoding a regulator of epigenetic gene expression, methyl CpG binding protein, MeCP2. Clinical data show that, along with neurological defects, females with RTT frequently have marked decreases in Bone Mineral Density (BMD) beyond that expected from disuse atrophy. Our work with a Mecp2 null mouse model, Mecp2 -/yBIRD, reveals a difference between the wild-type and null mice, with the Mecp2 -/yBIRD mice having significantly shorter femurs and an overall reduced skeletal size. Histological studies have highlighted a shortened growth plate as well as decreased trabecular bone in the primary spongiosum of Mecp2 null femurs by 21 days of age, prior to the onset of neurological symptoms. Additionally, the trabeculae in the primary spongiosum of 60 day old Mecp2 -/yBIRD mice were abnormally shaped and hypercellularity was noted in the marrow space. Both histological and histomorphometrical analyses have shown reductions in the cortical bone parameters of Mecp2 null mice. It does not appear that these decreases in bone are owed to a primary effect on osteoclasts, as osteoclast numbers were comparable between wild-type and null animals. Also of note, serum calcium and phosphate levels were unchanged in Mecp2 -/yBIRD mice, consistent with that seen clinically in RTT patients. We speculate that Mecp2 deficiency leads to a primary dysregulation of genes critical for regulation of bone growth, differentiation and mineral homeostasis. Several genes essential to proper bone formation and maintenance of bone and calcium homeostasis have been identified as likely targets of Mecp2 in a differentiating osteoblast cell system. Current studies are underway to determine the functional significance of Mecp2 deficiency on candidate gene expression and function in osteoblastic cells.

The Autism Chromosome Rearrangement Database (ACRD): Annotation of Genomic Structural Changes in Autism Spectrum Disorder. *C. R. Marshall, J. Skaug, B. Kellam, D. Pinto, M. Manker, L. Feuk, A. Lionel, A. M. Joseph-George, S. W. Scherer* The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children and University of Toronto, Toronto, ON, Canada.

Large cytogenetically detectable chromosomal anomalies together with de novo submicroscopic copy number variants (CNVs) are associated with up to 10% of Autism Spectrum Disorder (ASD) cases. However, many studies lack the sample size to detect recurrent/overlapping loci and thus integration of multiple datasets is necessary to prioritize further screening of candidate loci. The Autism Chromosome Rearrangement Database (ACRD) is a comprehensive and curated catalogue of structural variation related to autism extracted from publicly available literature and unpublished data (http://projects.tcag.ca/autism/). The ACRD facilitates the interpretation of ASD structural variation data in relation to previously published work thus providing a valuable resource for both clinicians and researchers. The current content of the ACRD is based on results from 279 peer reviewed research articles (including case studies and whole genome scans) and unpublished data, representing a total of 887 entries. These structural variation entries are composed of 171 apparently balanced changes (including 48 inversions and 123 translocations), 323 large cytogenetically detectable unbalanced changes, and 52 CNVs (defined as gains and losses of DNA segments >1kb in size not detected by conventional karyotyping). Currently, the data are represented in table format (BioXRT) and in a genome browser format where molecular breakpoints are defined. The genome browser is based on the widely used GMOD software (GBrowse) and is ideal for viewing structural variation in relation to other genomic features, such as genes and segmental duplications. Moreover, selective data from ACRD is entered into the DECIPHER database. Here we present an overview of ACRD along with future plans for its expanded content, integration of karyotypic and CNV data, and enhanced presentation. We welcome submission of data and comments regarding the database from the research community.

Metabolic pathway transcriptional profiling reveals a signature of primary mitochondrial dysfunction that normalizes with antioxidant therapy. *M. J. Falk*[1], *Z. Zhang*[2], *D. L. Gasser*[3] 1) Human Genetics/Pediatrics, CHOP; 2) Biomedical Informatics, CHOP; 3) Dept of Genetics, UPENN, Philadelphia, PA.

Mitochondrial disease therapeutics is complicated by limited understanding of the cellular mechanisms mediating widely variable phenotypic findings. Applying metabolic pathway clustering to global genome transcriptional profiling presents a powerful opportunity to survey simultaneously very large datasets while reducing the complexity of describing metabolic regulation. We utilized this approach in two evolutionarily divergent animal models to identify cellular adaptations to single gene defects causing primary mitochondrial dysfunction. Results in *C. elegans* mutants for nuclear-encoded subunits of respiratory chain complexes I, II, and III (Falk et al, *Molecular Genetics and Metabolism*, 2008) are highly similar to those obtained in *M. musculus* mutants for Pdss2, a Coenzyme Q biosynthetic pathway enzyme (Peng et al, *PLoS Genetics*, 2008). Specifically, primary mitochondrial mutants across evolution concordantly upregulate 15 basic cellular metabolic pathways involving carbohydrate, amino acid, and fatty acid metabolism, as well as cellular defenses. Additional expression studies have now been undertaken in *Pdss2* mutant mice whose lethal kidney disease can be prevented with oral anti-oxidants to determine if metabolic pathway expression alterations normalize with therapy, and to specify which secondary metabolic alterations may be contributing to the disease phenotype. Probucol, an antioxidant/anti-hyperlipidemic agent, appears to normalize hepatic expression of pathways involved in carbohydrate, fatty acid, and steroid metabolism, P450 and other cellular defenses, and the PPAR signaling pathway in B6.*Alb/cre,Pdss2*$^{loxP/loxP}$ liver-conditional knockouts. Expression profiling in missense animals treated with Coenzyme Q or Probucol is in progress. Importantly, this work suggests identification of a systems biology-based 'biomarker' of primary mitochondrial dysfunction may be possible in humans. Furthermore, elucidation of common pathway alterations may permit the development of specific pathway-targeted therapies in the difficult to treat class of mitochondrial disorders.

Genetic variation of *CYP2D6* gene in the Mexican population. *A. Contreras, I. Silva-Zolezzi, T. Monge, L. Alfaro, S. Hernandez, H. Miranda, K. Carrillo, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Genetic variation influence how humans respond to commonly used drugs. *CYP2D6* encodes a member of the cytochrome p450 superfamily, which are monooxygenases that catalyze many reactions involved in drug metabolism. This protein metabolizes about 20% of commonly prescribed drugs, such as metoprolol, an adrenergic-blocking drugs; paroxetine and fluoxetine, antidepressants; and tamoxifen and vinblastine, anticancer agents. This gene is highly polymorphic in the population and its enzymatic activity shows a high degree of interindividual and interethnic variability caused in part, by genetic variation. *CYP2D6* is located near two cytochrome P450 pseudogenes: *CYP2D7* and *CYP2D8*. Certain alleles result in a poor metabolizer phenotype. To characterize the genetic variation of *CYP2D6* in Mexicans, we resequenced the region corresponding to 9 exons and 9 introns in 96 samples of Mestizo population from two distant states of Mexico: Guerrero and Sonora. PCR products were subject to bi-directional sequencing (BigDye Terminator, Applied Biosystems). The resulting sequence fragments were analyzed using DNASTAR Lasergene (SeqMan Module). We observed 34 previously reported SNPs (14 in exons and 20 in introns), and identified 7 novel SNPs (3 in exons and 4 in introns) and 1 novel gene conversion *CYP2D6/2D7* in exon 2. This gene conversion was observed in Guerrero with a frequency of 4% and was not found in Sonora, so we hypothesize it is of local Amerindian origin. A more detailed study including 4 indigenous populations from Mexico is underway to confirm this hypothesis. This gene conversion may have a functional effect because its predicted change of amino acids is located near the proteins active site. To test this hypothesis, we are designing an *in vitro* study to analyze the effect of this mutation. Characterization of all different novel and known genetic variations in this Mexican sample is in progress. These results contribute to describe *CYP2D6* diversity in populations from different geographic and ethnic origins, and will help clarify the relationship between ethnicity and phenotype to improve implementation of pharmacogenomics in the clinical practice.

Genetic variation at chromosome 8q24 and risk of colon cancer. *C. Hutter[1], M. Slattery[2], D. Duggan[3], J. Muehling[3], K. Makar[1], L. Hsu[4], B. Caan[5], J. Potter[1], U. Peters[1]* 1) Cancer Prevention, FHCRC, Seattle, WA; 2) Internal Medicine, Univ. of Utah Health Sciences Center, Salt Lake City, UT; 3) Translational Genomics Research Institute, Phoenix, AZ; 4) Biostatistics, FHCRC, Seattle, WA; 5) Division of Research, Kaiser Permanente Medical Care Program, Oakland, CA.

First results from genome-wide scans and subsequent replication studies have shown that single nucleotide polymorphisms (SNPs) in chromosomal region 8q24 are associated with prostate, breast and colon cancer. Independent associations have been found in three regions of 8q24 for prostate cancer. In contrast, for colon cancer statistically significant associations have been restricted to a region between 128.47 and 128.54 Mb. This study investigated common genetic variants from this 71kb region and risk of colon cancer in a large population-based case-control study of 1594 colon cancer cases and 1935 controls. We genotyped 11 SNPs and used logistic regression to calculate odds ratios (ORs) and 95% confidence intervals (95% CIs) based on a log additive model. We examined gene-environment interactions for known colon cancer risk factors (obesity, physical activity, smoking, non-steroidal anti-inflammatory drug use, family history of colon cancer and sex). All analyses were adjusted for age, sex and study center. Three SNPs were statistically significantly associated with risk of colon cancer. The strongest association was for rs9297756 (OR for the A allele under a log additive model: 1.22; 95% CI, 1.07-1.39; p=0.002). The rs6983267 and rs10505477 SNPs are in high LD (r2=0.93), and each showed a significant association with colon cancer (OR for the G allele at rs6983267 or T allele at rs10505477: 1.12; 95% CI, 1.01-1.23; p=0.02). Similar results were obtained when the analysis was restricted to whites (1461 cases; 1813 controls). The associations did not differ for proximal vs. distal anatomical location, and no statistically significant gene-environment interactions were observed for the factors examined. In conclusion, this study replicates the association between SNPs at 8q24 and colon cancer risk. Further research is needed to elucidate the biological mechanism underlying this association.

Pedigree data analysis using RELTEST, GRR, and MERLIN. *K. M. Lewis[1], S. G. Buxbaum[2], L. Ekunwe[2]* 1) Jackson Heart Study, Tougaloo College, Jackson, MS; 2) Jackson Heart Study, Jackson State University, Jackson, MS.

Abstract: Genetic information from individuals who were among the family study component of the Jackson Heart Study was used for this analysis. This data comprised 374 autosomal microsatellite markers typed by the Marshfield Mammalian Genotyping Center. Two programs, GRR (Graphical Relationship Representation) and RELTEST (a program in the S.A.G.E. package), were used to test the relatedness between relative pairs. This was done in order to decrease the amount of error within the family pedigree structures. Because the participants are all from the same metropolitan area, it seemed reasonable to expect to find relatedness across pedigrees, as well as within them. This was tested, and where clear cases of relatedness were found using microsatellite markers, pedigrees were merged. In some cases, we were able to identify unknown individuals and link pedigrees to one another. Where some links were still unclear, for example, in cousin pairs, we made use of markers on the sex chromosomes (Y only and/or X), and estimated haplotypes using MERLIN. Through the use of these programs, we have been able to minimize the number of putative unrelated individuals who are actually close relatives. We began with 291 families and found that these relationships are better described by 264 pedigree structures. This work was done to increase the power of future genetic linkage and association analyses, whether using microsatellite or single nucleotide polymorphism data, and to help to minimize false positive results in such analyses. This research from the Jackson Heart Study is supported by NIH contracts N01-HC-95170, N01-HC-95171, and N01-HC-95172 provided by the National Heart, Lung and Blood Institute and the National Center for Minority Health and Health Disparities.

Forms of Provision of Genetic Testing Services in Japan. *M. Watanabe[1], K. Dobashi[3], A. Tsuchiya[2], T. Oohata[2], T. Sumida[2], K. Muto[1], Y. Nakamura[1], F. Takada[2]* 1) Dept. of Public Policy, Inst. of Med Sci, Univ.of Tokyo, Tokyo, Japan; 2) Dept. of Clinical Genetics, Grad. School of Med.Sci. Kitasato Univ, Kanagawa, Japan; 3) Japan Bioindustry Association.

[Aim]Genetic testing is now provided in various venues outside of the specialized sites for clinical genetics, represented by direct-to-consumer marketing. Issues of DTC genetic testing services differ according to the way they are provided. Thus in order to promote detailed discussion on the genetic testing services provided outside of classic clinical genetics, it is necessary to classify the current forms of provision. In this presentation, varieties of ways in which genetic testing services are provided in Japan are introduced, and related agendas are discussed. [Method] Questionnaire surveys to 45 companies related to DTC genetic testing services and 97 general clinics providing multi factorial conditions were conducted in Japan between May and October 2007. [Result] 11 companies and 22 clinics were responded. [Discussion] Ways of marketing genetic testing services outside of classic clinical genetics in Japan can be classified in 7 styles. The biggest market is being created in the form that uses private general clinics as distributors. The survey to the clinics revealed that the most common reason for providing lifestyle test at the clinics is promotion of motivation for medical intervention. It arouses the question whether this reason of providing genetic test yet clinically validated is permissible or not. In Japan, the answer to this question has yet been sought for.

Comprehensive analysis of causative genes in sporadic ALS patients reveals multiple rare variants potentially associated with disease risks. *Y. Takahashi, H. Ishiura, J. Goto, S. Tsuji* Dept Neurology, Univ Tokyo, Tokyo, Japan.

[Objectives] To identify novel rare variants associated with disease risks in sporadic ALS (SALS) patients. [Background] Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disorder characterized by progressive degeneration of upper and motor neurons. Familial ALS (FALS) comprises 5 - 10 percent of the cases, whereas the remaining patients are sporadic. Current approaches to identify genetic risks of SALS basically employ genome-wide association studies based on common disease-common variant hypothesis, whereas the resequencing of disease-related genes is emerging as an intriguing alternative approach to identify rare variants associated with disease risks. [Materials and Methods] DNA samples obtained from 120 sporadic ALS patients with informed consent, who fulfilled the revised El Escorial and Airlie House diagnostic criteria, and 250 controls, were used in this study. We have developed a DNA microarray-based resequencing system to facilitate the comprehensive analysis of causative genes of FALS. Entire exons and flanking introns of 7 genes, *SOD1*, *ALS2*, *DCTN1*, *VAPB*, *ANG*, *CHMP2B* and *TARDBP*, were amplified with specific primers and hybridized to the custom-made DNA resequencing microarrays, TKYALS01 and TKYALS02. The rare variants identified in the above strategy were further analyzed in the controls. [Results] In total, 30 variants in addition to 2 novel *SOD1* mutations and 1 known *SOD1* mutation were found. Nineteen of the 30 variants (63 percent) were novel, including 3 nonsynonymous variants in *DCTN1*, *ANG* and *TARDBP*. These 3 variants were not found in 250 controls (500 chromosomes), and highly conserved among species. [Conclusion] Comprehensive analysis of causative genes in sporadic cases revealed not only causative mutations but also novel nonsynonymous variants, raising the possibility that substantial proportion of SALS patients may be accounted for by these rare variants. Large scale genetic studies as well as functional analysis of these extremely rare variants were necessary to further investigate the contribution to genetic risks and pathogenesis of SALS.

Bootstrap- vs. Likelihood-based methods to reduce selection bias: variance, confidence interval estimation and computational feasibility in large-scale genetic mapping studies. *L. L. Faye[1,2], S. B. Bull[1,2], L. Sun[1,3]* 1) Public Health Sciences, University of Toronto, Toronto, ON, Canada; 2) Samuel Lunenfeld Research Institue, Mount Sinai Hosplital, Toronto ON, Canada; 3) Hospital for Sick Children, Toronto ON, Canada.

Selection bias in genetic effect parameters (e.g. heritability, odds ratio) is prevalent in genome-wide mapping studies because the same sample is typically used for both gene discovery and effect estimation (e.g. linkage analysis - Goring et al, 2001; case-control association - Garner, 2007). Effect estimators that reduce selection bias have recently received much attention and mainly fall into two categories: bootstrap resampling-based methods (Sun and Bull, 2005; Wu et al, 2006; Yu et al, 2007), and likelihood-based approaches (Zollner and Pritchard, 2007; Zhong and Prentice, 2008; Ghosh et al, 2008). The statistical resampling approach is flexible and can be readily extended to detection of multiple linked markers but is computationally expensive. In contrast, the maximum-likelihood-based approach directly models the power to detect linkage or association but considers each marker in isolation. To quantify the bias, relative variance, and confidence interval (CI) coverage of the two approaches, we simulated single-marker datasets and tested for genetic association under the assumption of a normally distributed parameter estimate. We developed a two-level bootstrap method to obtain CIs for the resampling-based effect estimates. In scenarios with low power and stringent testing criterion, both estimators improve estimation accuracy, but a moderate amount of bias remains. On average the MLE over-corrects while the bootstrap estimator under-corrects. Comparison of the bootstrap-based CI with the likelihood-based CI method found that both methods yield CIs with slightly higher than nominal coverage, but the bootstrap 95%; CI is, on average, shorter than the likelihood 95%; CI. We also demonstrate the feasibility of the resampling-based methods through application to existing high-throughput GW association studies.

Proteomic analysis of astrocytoma cell lines stimulated with progesterone. *M. Rodriguez-Dorantes[1], L. Castellanos-Tapia[1], K. G. Calderon-Gonzalez[1], E. Cabrera-Muñoz[2], I. Camacho-Arroyo[2], J. P. Reyes-Grajeda[1], J. L. Gallegos-Perez[1], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) School of Chemistry, UNAM, Mexico.

Brain tumors produce several neurological symptoms as a result of their size, localization and invasive qualities. They represent 10-15% of all human neoplasias. Progesterone (P4) has been associated with tumoral growth. To determine the effects of progesterone (P4) and its antagonist, RU486, on protein expression profiles we used two human astrocytoma cell lines with different evolution grade (U373, grade III; and D54, grade IV). We treated each cell line with either vehicle, P4(10nM), RU486(10M) or P4+RU48. After 48 hrs, cells were collected, homogenized and proteins were extracted and quantified. 2D gel electrophoresis of total proteins was performed. Gels were Coomassie blue-stained and analyzed using Image Master 2D. Differentially expressed spots were extracted, trypsin-digested and desalted, prior to mass spectrometry analysis. Proteins were identified using the Paragon algorithm. Comparative analysis with P4 identified increased presence of Relaxin 3 receptor 2, glucosidase 2 subunit beta precursor, heat shock 70KDa, phosphoglycerate kinase 1, keratin type II cytoskeletal 2, stress 70 protein mitochondrial precursor, superoxide dismutase mitochondrial precursor, alpha crystallin B chain, triosephosphate isomerase, ubiquinol-cytochrome c reductasa, trypsin 3, precursor translationally-controlled tumor protein, and peroxiredoxin-6 glucosidase. Stimulation with RU486 showed increased expression of vimentin, lamin B2, and phosphatidylethamine-binding protein 1. Some of these proteins are related with tumor growth, aggressive phenotype or as a marker in tumors. These differentially expressed proteins in U373 and D54 cell lines are associated with several cellular processes such as cytoskeleton organization, biotransformation, and signal transduction. Our results indicate that P4 and its antagonist RU486 exert different effects in the protein profile of astrocytomas, suggesting a potential role of progesterone in these tumors.

Does MDS with der (1;7) constitute a distinct risk group? A retrospective analysis of clinical/pathological features compared to -7/del(7q) MDS. *M. L. Slovak[1], M. O'Donnell[2], D. Smith[3], K. Gaal[4]* 1) Dept Cytogenetics, City of Hope, Duarte, CA; 2) Division of Hematology and Hematopoietic Cell Transplantation; 3) Division of Information Sciences; 4) Dept of Anatomic Pathology.

The der(1;7)(q10;p10) has been reported in ~1-3% of the myelodysplastic syndromes (MDS) and less commonly in acute myeloid leukemia (AML) and the myeloproliferative disorders. In MDS, the der(1;7) is considered a variant of the del(7q)/-7 subgroup and assigned a POOR risk karyotype score in the IPSS, a clinical scoring system that estimates overall survival (OS) and risk of AML transformation. A recent report (Leukemia 21:992-7, 2007) suggests der(1;7) MDS should be considered a discrete MDS subgroup with an intermediate karyotype score. Moreover, the der(1;7) reported MDS cases are predominantly Asian. In this study, we performed a retrospective study to define the clinical-pathological features of 13 MDS patients (pts) with der(1;7) evaluated at the City of Hope and compared their features with 54 MDS pts with either del(7q) (n=11) or -7 (n=44). When compared to the del(7q)/-7 MDS cases, the der(1;7) pts showed a male predominance, an older age at diagnosis (mean = 13 yrs older, p = 0.0168), low platelet counts (p=0.0026), less trilineage dysplasia, fewer secondary aberrations, and lower blast counts. We found that der(1;7) patients did not differ compared to the del(7q)/-7 MDS pts with respect to the subtypes of MDS either by the WHO (p = 0.562) or FAB (p = 0.637) classifications. Increased eosinophilia and higher hemoglobin levels, as reported previously, were not observed in the current study. The proportion of therapy-related MDS or t-MDS was 25% for der(1;7), 37% for -7 and 55% for del(7q)(p=0.434). Five year OS did not differ among the three MDS groups [der(1;7) = 44.4% vs del(7q) = 35.4% vs -7 = 22.4%), p=0.69] with ~50% of each cohort receiving a stem cell transplant. Based on these preliminary data, der(1;7) MDS is associated with some unique clinical features but reassignment of der(1;7) MDS from poor to intermediate appears to be premature. A large scale international study to further characterize this unique MDS subgroup is suggested.

Variation in the Nicotinic Cholinergic Receptor Gene Cluster *CHRNA5-CHRNA3-CHRNB4* and Its Interaction with Substance Dependence Influence Cognitive Flexibility. *H. Zhang[1,2], H. R. Kranzler[3], J. Poling[1,2], J. Gelernter[1,2]* 1) Dept of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) VA Connecticut Healthcare System, West Haven, CT; 3) Dept of Psychiatry, University of Connecticut School of Medicine, Farmington, CT.

Objective: We investigated whether variation in the nicotinic receptor gene cluster *CHRNA5-CHRNA3-CHRNB4* and its interaction with substance dependence (SD) can affect cognitive flexibility. Method: Working memory of 544 African Americans (AAs) (468 cases with SD and 76 controls) and 445 European Americans (EAs) (314 cases with SD and 131 controls) were assessed using the Wisconsin Card Sorting Test (WCST). Influence of markers in this gene cluster and marker-SD interaction on cognitive flexibility was analyzed. Effects of haplotypes and haplotype-SD interaction on cognitive flexibility were also examined. Results: *CHRNB4* rs11637890 minor allele was associated with an improved performance on three WCST domains (non-perseverative errors: P=0.015; conceptual responses: P=0.040; and categories completed: P=0.010) in AA controls (but not in AA cases). A significant interactive effect of this marker and SD on these three domains was also observed. Haplotype CTCTGCG was shown to have a beneficial effect on performance in at least two WCST domains in AA controls (non-perseverative errors: P=0.0166; conceptual responses: P=0.022). An interactive effect of haplotype CTCTGCG and SD on performance in these two domains was also evidenced. In EAs, Two *CHRNA5* SNPs (rs684513 and rs615470) and two *CHRNA3* SNPs (rs6495307 and rs2869546) (these markers being in high linkage disequilibrium) were associated with cognitive flexibility on at least two WCST domains (perseverative responses: P=0.013-0.035 and perseverative errors: P=0.009-0.033) in controls (but not in cases). A significant interactive effect of these four markers and SD was observed in the same two WCST domains (perseverative responses: P=0.032-0.050 and perseverative errors: P=0.020-0.050). Conclusions: Variation in the gene cluster *CHRNA5-CHRNA3-CHRNB4* appears to affect cognitive flexibility differentially in AAs and EAs, and SD traits could moderate this effect.

Association of TPO SNPs with type 1 Diabetes in North-west Colombia. *J. Gutierrez-Achury[1], J.-M. Alfaro[1], V. Balthazar[1], G. Bedoya[2], F. Uribe-Londono[3], A. Ruiz-Linares[2,4], N. Pineda-Trujillo[1,5]* 1) Mapeo Genético, Departamento de Pediatría y Puericultura, Facultad de Medicina, Universidad de Antioquia, Medellín-Colombia; 2) GENMOL, Universidad de Antioquia, Medellín-Colombia; 3) Endocrinologia y Metabolismo, Facultad de Medicina, Universidad de Antioquia, Medellín-Colombia; 4) Department of Biology, University of London, UK; 5) Pediaciencias, Departamento de Pediatría y Puericultura, Facultad de Medicina, Universidad de Antioquia, Medellín-Colombia.

Type 1 diabetes (T1D) is a complex trait in which genetic and environmental factors are involved. We have previously found linkage and association of T1D to 2p25. Our purpose was to analyze the role of the gene TPO in the susceptibility to T1D in Colombian families. One hundred familial trios with T1D from Antioquia-Colombia were analyzed. In patients sera autoantibodies against anti-GAD, anti-IA2 and anti-TPO were tested. Two SPNs intragenic to TPO were tested (rs4927611, rs732609). These two markers were chosen considering that the polymorphism changes the encoded aminoacid and that the MAF<=0.3. The location for the SNPs was determined by using the dbSNP database at NCBI. SNPs typing was done by PCR-RFLP and Tetraprimer-ARMS methods. Genetic association analysis was done by the transmission desequillibrium test (TDT). Positive autoantibodies were found in 73%, 41% and 17% for anti-IA2, anti-GAD and anti-TPO, respectively. Together, 86% of the affected individuals were positive for at least one auto-antibody. SNP rs4927611 showed a P 0.0561 and for SNP rs732609 a P0.05 was obtained. For the haplotype analysis a P 0.002 was found. Autoimmunity was found in similar conditios to previous reports. It was also found that both SNPs at TPO gene are associated to the disease. Furthermore, a haplotype characterized by alleles at both SNPs was associated with increased risk to T1D. Our results suggest a causative participation of the gene TPO in T1D. Replication in an independent sample is required in order to confirm this finding. Acknowledgement: This study was supported by Colciencias grant # 111534319156 and CODI-Universidad de Antioquia grant # 8704-2449.

Gene Expression in human samples using SOLiD Next Generation Sequencing. *C. Barbacioru[1], M. Barker[1], J. Gu[2], S. Kuersten[2], D. Wang[1], R. Nutter[1], R. Wicki[1], R. Setterquist[2], F. De La Vega[1], G. Spier[1]* 1) Applied Biosystems, Foster City, CA; 2) Ambion Inc - An Applied Biosystems Business, Austin, TX, USA.

Analysis of gene expression patterns provides valuable insight into the role of differential expression in biological and disease processes. High density microarrays -- the standard for global gene expression analysis -- are limited in their dynamic range and can be ineffective at measuring genes expressed at a low level. Additionally, hybridization based platforms require an a priori knowledge of the mRNA sequences and are therefore unsuited for hypothesis free RNA discovery type of studies. The SOLiD System overcomes the limitations of microarray technologies by providing an ultra high throughput sequence-based platform for quantitative measurement of expression of RNA molecules. SOLiD produces 100s of millions of short reads (35-50bp) in a single run, requiring low sample input. This allows us to explore gene expression profiles at the whole genome scale, without prior RNA sequence knowledge enabling an entirely new scale of biological experimentation (alternative splice forms, allele specific expression, non-coding RNA etc.), with large dynamic range, a tunable depth of coverage for rare transcript discovery and quantification. Additionally, in this study we compare the results produced by this system with TaqMan measurements obtained from a large number of genes, generated in the original MAQC study.

Measurement of the downstream revenue generated by a clinical cancer genetics program. *K. M. Durda[2], W. S. Rubinstein[1,2], S. Weissman[1,2], S. M. O'Neill[1,2]* 1) Evanston NW Healthcare, Evanston, IL; 2) Northwestern Univ. Feinberg School of Medicine, Chicago, IL.

Background Clinical genetics centers are generally not financially self-sufficient based on directly billed services. However, these centers may generate indirect downstream revenue (DSR) for billable services that are performed in that hospital system as a direct result of medical recommendations stemming from a genetics evaluation. **Purpose** This study assessed the revenue indirectly generated from a clinical cancer genetics program, the Center for Medical Genetics (CMG), through its associated hospital system, Evanston Northwestern Healthcare (ENH). We wanted to determine if the CMG was generating DSR for ENH, and if so the amount of DSR. **Methods** We assessed total billing generated in a 4.5 year period by CMG patients who were carriers of cancer predisposing mutations. A chart review of patients with Hereditary Breast and Ovarian Cancer (HBOC) syndrome, Hereditary Non-Polyposis Colorectal Cancer syndrome (HNPCC), or Familial Adenomatous Polyposis syndrome (FAP)/MYH-associated polyposis (MAP) was done to determine whether billed encounters were attributable to the CMG; 19,117 lines of billing data were reviewed. **Results** Seventy-five of the 123 patients (61%) with available billing information had encounters at ENH that were attributable to the CMG. The DSR billed for these 75 patients was $1,708,956; this is $7,555 billed per person-year. Based on contractual deductions, actual DSR would be about half that amount. **Conclusions** This study found that the CMG generates a significant amount of DSR for ENH through increased cancer surveillance and prophylactic surgeries of patients with HBOC, HNPCC, and FAP. The DSR generated by mutation carriers with attributable billing encounters is substantially higher than the professional fees that are directly billed by the CMG for those patients. For each $1 billed directly by the CMG for the 75 patients with attributable encounters, ENH billed $17 in DSR. These data may be of interest to hospital administrators when making funding allocation decisions for genetics centers that are not financially self-sufficient based on direct revenues.

Sex-biased demographic processes shape genomic patterns of human diversity. *J. Wall[1], M. F. Hammer[2,3], F. L. Mendez[3], M. P. Cox[2], A. Woerner[2]* 1) Inst Human Genetics, Univ California, San Francisco, San Francisco, CA; 2) ARL Division of Biotechnology, University of Arizona, Tucson, AZ; 3) Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ.

We compared levels of genetic variability on the autosomes and the X chromosome from over 400 Kb of resequencing data from 90 different intergenic regions in a panel of 90 humans from six geographically diverse populations. After correcting for differences in mutation rates across chromosomes, we find that the relative levels of genetic variation are higher than expected on the X chromosome in all six human populations. We test a number of alternative hypotheses to explain the excess polymorphism on the X chromosome, including models of background selection, changes in population size, and sex-specific migration in a structured population. While each of these processes may have a small effect on the relative ratio of X-linked to autosomal diversity, our results point to a systematic difference between the sexes in the variance in reproductive success; namely, the widespread effects of polygyny in human populations.

Bilateral Aplasia of the Cochlear Nerves and Olfactory Bulb Agenesis in association with a SOX10 mutation. *C. P. Barnett[1], W. Reardon[1], S. Blaser[2], J. Gillis[1], L. Dupuis[1], A. V. Levin[3], P. W. Chiang[4], E. Spector[4], R. Mendoza-Londono[1]* 1) Clinical and Metabol. Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Neuroradiology and Otolaryngology, Hospital for Sick Children, Toronto, Ontario, Canada,; 3) Ophthalmology and Vision Sciences, Hospital for Sick Children, Toronto, Ontario, Canada; 4) University of Colorado Health Sciences Centre, Denver, Colorado.

SOX10 is a transcription factor essential for neural crest cell migration and differentiation. Mutations in SOX 10 have been shown to cause autosomal dominant cases of Waardenburg-Shah syndrome (WS4, OMIM 148820), characterized by the combination of hypopigmentation and sensorineural hearing loss (SNHL) in association with Hirschsprungs disease. We report the first case of aplasia of the cochlear nerve due to a novel SOX10 mutation in a child with profound SNHL, severe visual impairment, central nervous system hypomyelination and cutaneous hypo-and hyperpigmentation. On examination at 17 months of age the patient was noted to have fair skin and hair and multiple areas of cutaneous hyperpigmentation including numerous café au lait spots and lentigines. Neuroimaging identified central nervous system hypomyelination, bilateral cochlear nerve aplasia, olfactory bulb aplasia and optic nerve hypoplasia. Initial investigations including karyotype, array comparative genomic hybridization (aCGH) and a full metabolic screen were normal. SOX 10 mutation testing was undertaken because of his constellation of clinical findings and a novel missense mutation of the highly conserved high mobility group (HMG) domain of SOX10 was identified (Q174P:c.521A>C). This patients findings are not typical of WS4 and suggest that awareness of these clinical features as a function of SOX10 mutation may result in further cases of non-classical phenotypes being diagnosed.

Implementation of an Oral Cleft Registry in the Philippines. *E. M. C. Cutiongco[1,2], C. D. Padilla[1,2], A. L. D. Sur[1] for the Philippine Oral Cleft Study Group* 1) Institute of Human Genetics, National Institutes of Health Philippines, Manila, Philippines; 2) Department of Pediatrics, College of Medicine-Philippine General Hospital, University of the Philippines Manila.

Oral clefts are among the most common congenital anomalies. Various literature estimate global incidence of oral clefts at 1 every 500-1000 livebirths, which varies with population and gender. Orientals, in particular, are at a higher risk for oral clefts. Numerous researches have expounded on the etiologies, treatment and prevention. The most relevant etiologic factors identified include maternal exposure to tobacco smoke, alcohol, micronutrient insufficiency, corticosteroids, exogenous estrogen, organic pollutants, and occupational chemicals. A surveillance system in the Philippines was established under the Philippine Oral Cleft Research Study Group composed of the Institute of Human Genetics, the Philippine Association of Plastic, Reconstructive and Aesthetic Surgeons Inc. (PAPRAS), the Philippine Society of Otorhinolaryngology - Head and Neck Surgery (PSO-HNS), Operation Smile Philippines Foundation Inc. (OSPF), and the Philippine Band of Mercy (PBM) in 2004. The Philippine Oral Cleft Registry aims to systematically collect, analyze, and interpret data on oral clefts including maternal history and demographic profile. There were a total of 1,838 cases reported. With an estimate of 1,600, 000 livebirths per year, the prevalence of reported cases is 0.51 per 1000 livebirths, which was lower than previously reported prevalence rates. There is a consistently observed male predominance in all of the reported cases with a male to female ratio of 1:1.5. Cleft of the hard and soft palate with bilateral cleft lip is the most common type observed. The Philippine Oral Cleft Registry is one of the first initiatives to implement a registry program for patients with oral clefts in the Philippines through a network of organizations and institutions. Continued surveillance through such registry will allow evaluation of existing programs and the promotion of new public health projects that will adequately deal with the preventable causes of oral clefts in the country.

Genetic predisposition to lung cancer and the association between cancer genetic susceptibility and long-term cigarette smoking. *S. Hwang[1], D. Levy[1], C. L. Rosenberg[2], L. Atwood[3], B. E. Kerger[2], J. M. Murabito[2]* 1) The National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA; 2) Department of Medicine, Boston University School of Medicine, Boston, MA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Genome-wide-association-studies (GWAS) have demonstrated a significant association of SNPs on 15q24/15q25.1 with lung cancer. The characterized genes in this region include nicotinic acetylcholine receptor subunit genes, which are promising candidates for tobacco addiction. In the Framingham Heart Study (FHS), systematic medical records review enabled the classification of malignancies and the adjudication of coronary heart disease endpoints in study participants. Genotyping was conducted for 550, 000 SNPs in 9000 FHS participants across three generations. We examined the association of 21 SNPs in the 15p25 region with 90 lung cancer cases and 1521 cancer-free controls who has no family history of cancer. Three control groups: A) participants surviving to age 65 without family history of cancer, B) non-smokers in group A , and C) non-smoker who were free of coronary heart disease in group B. We applied the same association test for all cancer cases (n=860) and type-specific (breast n=184, colorectal n=108, prostate n=190) cancers. we tested for genetic association by applying survival analysis used a frailty model to adjust for familial correlation. Results of the analysis showed 2 SNPs with p-value less than 0.02 when comparing lung cancer cases with group C controls. The p-values for the same SNPs were less than 0.03 when compared with group B controls. Results of the study showed a consistently lower p-value with no-CVD controls for lung cancer. However, the lower statistical power is the main concern of this approach that requires further study.

PRDM8 is required for the terminal differentiation and maintenance of rod & cone bipolar cells in the mammalian retina. *D. Atan[1], C. Jung[1], K. Allen[1], M. Klein[2], D. Birch[2], R. R. McInnes[1]* 1) Hospital for Sick Children & University of Toronto, Canada; 2) Retina Foundation of the Southwest, Dallas, TX.

Knowledge of the transcriptional regulation of neuronal development has major implications for the understanding and therapy of disease. The transcription factor (TF) PRDM8 is a highly conserved Zn-finger protein of the PR domain family. We found that *Prdm8* is widely expressed in the developing CNS. Expression is maintained in adult retina, where the protein is abundant in bipolar cells, the major interneurons of the inner nuclear layer (INL) that relay visual signals to the optic nerve. In *Prdm8*$^{-/-}$ retinas at postnatal day 6 (P6), total bipolar (Chx10+) cell number & retinal morphology are normal, indicating normal bipolar cell specification. However, rod bipolar cell differentiation is impaired, since the rod bipolar marker, PKC, is undetectable at P6 and only weakly detected at P10. By adulthood, rod & cone Type 2 OFF bipolar cells are virtually absent, contributing to a 33% reduction in INL cell number. Consistent with the absence of rod bipolar cells, *Prdm8*$^{-/-}$ mice have b-wave deficits on dark-adapted ERG, confirming the compromised rod bipolar circuitry. To begin to identify Prdm8 target genes in bipolar cell development, we compared gene expression of *wt* vs *Prdm8*$^{-/-}$ retinas at P6 (FDR 10%), when normal numbers of mutant bipolar cells are present but poorly differentiated. Using the GoMiner gene ontology program, we found that genes involved in neurogenesis, neurite development and DNA-binding were over-represented in the *Prdm8*$^{-/-}$ retina ($p<0.05$). For example, *Vsx1* (a major OFF cone bipolar TF) is 80% down-regulated (by qPCR), and *Sox6* (a TF regulator of oligodendrocyte differentiation) & *Lhx4* (a bipolar cell-expressed TF) are 240% and 60% up-regulated, respectively. We conclude that i) Prdm8 is critical for the late differentiation and maintenance of rod and cone Type 2 OFF bipolar cells in the retina; ii) the differentially expressed TF genes of the P6 *Prdm8*$^{-/-}$ retina are strong candidates to be controlled by Prdm8, suggesting they may regulate late steps of bipolar cell differentiation; and iii) PRDM8 is a candidate gene, at 4q21, for human congenital blindness.

Differential expression signature in Stem Cells of non-syndromic cleft lip/cleft palate patients: A new approach to understand this orofacial malformation? *D. F. Bueno[1,2], G. Kobayashi[1], D. Yumi[1], C. Amaral[2], I. Zambra[1], M. Aguena[1], I. Kerkis[3], M. R. Passos-Bueno[1]* 1) Instituto de Biociencias, USP, Sao Paulo, Brazil; 2) SOBRAPAR, Campinas, Brazil; 3) Instituto Butantan, São Paulo, Brazil.

Non-syndromic cleft lip/palate (NSCL/P) is a complex disease determined by several interacting loci that are influenced by environmental covariates. In the present work we ivestigated if the genetic expression profile of affected NSCL/P differs from control dental pulp stem cells(DPSC). DPSC and adult stem cells extracted from other tissues are a reliable source of cells that can provide a closer parallel in understanding the evolution of NSCL/P embryonic development, given the fact that obtaining RNA from NSCL/P human embryos during embryonic development of lip and palate is unfeasible. We established DPSC cultures according to previous protocol (Costa et al, 2008). Total RNA was isolated from 5 control and 6 NSCL/P DPSC cultures. Gene expression experiments were performed using Human Gene 1.0 ST Array (Affymetrix) according to manufacturers protocols. Data was normalized using the RMA method from the Bioconductor Affy package. Two different methods were employed to select differentially expressed genes(DEGs):the Student's T-test using the MeV program and the Bioconductor Limma package. A total of 36 differentially expressed genes were identified using the Student's T-test with a $p = 0.01$ while 50 DEGs with best scores (B-value) were selected with Limma analysis. We verified 18 overlapping DEGs between the used methods. These 18 DEGs were clustered using the K-means and SOM (Self-organizing map) algorithms, available in Expander program. The highly homogenous clusters corroborated the differences between control and affected levels of expression. The DEGs were annotated with the Affymetrix NetAffx tool. Our preliminary data thus support a difference between the global signaling pathways of NSCL/P and control individuals. These results, once confirmed with different methodologies, will open new possibilities to study and understand the pathophysiology of NS CLP. CEPID/FAPESP, CNPq.

17q21.31 deletion syndrome: Are autoimmune disorders part of the phenotype? *S. Halbach, S. Schwartz, D. Waggoner* Department of Human Genetics, University of Chicago, Chicago, IL.

We present a 14yo girl with the findings of ASD, hydrocephalus, hypotonia, history of seizures, exotropia and amblyopia, sensorineural hearing loss, scoliosis, spondylolisthesis, eczema, chronic neutropenia, autoimmune primary adrenal insufficiency (confirmed by positive adrenal antibodies and 21-OH antibodies), vitiligo, alopecia, and autoimmune thyroid disease. Additionally, dysmorphic facial features including downslanting palpebral fissures, tubular pear-shaped nose, widely spaced teeth, high arched palate, and low-set ears were noted on exam. An extensive genetic work-up had been done previously, including a normal 46,XX karyotype and normal commercial, targeted microarray. Research-based whole genome SNP array revealed a 17q21.31 deletion of approximately 550 kb which was confirmed by FISH. This is similar in size to the previously defined critical region. Parental FISH studies were negative. More than 10 individuals with microdeletions of 17q21.31 have been described to date, ranging in age from 3 to 26 years, though none have been reported to have autoimmune findings. Although autoimmune disease could be an incidental finding in our patient, adrenal insufficiency is difficult to diagnose, potentially fatal, and can be treated; therefore, we feel that clinicians should be aware of this potential feature in 17q21.31 deletion syndrome. Included in the critical region is the CRHR1 (corticotrophin-releasing hormone receptor 1) gene which binds to corticotrophin-releasing hormone, a mediator of endocrine, autonomic, behavioral, and immune responses to stress. In mice lacking Crhr1, atrophy of the medulla of the adrenal gland and reduction of stress-induced release of ACTH and corticosterone have been observed. Conversely, overexpression of CRHR1 has been detected in Cushing disease. CRHR1 could be a candidate for concomitant autoimmune disease in 17q21.31 deletion syndrome.

A novel locus for autosomal dominant hereditary spastic paraplegia maps to chromosome 3q24-q26. *Y. Gong, P. Lin, Q. Liu, G. Gao, C. Shao* Institute of Medical Genetics, Shandong University School of Medicine, Jinan, Shandong 250012, China.

Hereditary spastic paraplegias (HSPs) are a group of neurodegenerative disorders characterized by progressive spasticity of the lower limbs. Clinically, HSPs are classified as either the uncomplicated or complicated form depending on whether spasticity occurs in isolation (uncomplicated HSP) or is associated with additional symptoms(complicated HSP). Moreover, the disorders manifest extremely genetic heterogeneity and considerable inter- and intra-familial variation in age at onset and severity of spasticity. To date, 38 HSP loci and 19 spastic paraplegia genes (*SPG*) have been identified. In this study, we evaluated a large Chinese kindred with autosomal dominant uncomplicated HSP. Forty individuals (18 affected, 22 unaffected) were included in this study. The study was approved by the ethical Committee in Shandong University School of Medicine and informed consent was obtained from all participants. All patients had typical signs of spastic paraplegia mainly characterized by proximal weakness of the lower extremities with brisk reflexes and spastic gait abnormalities. No additional neurological symptoms were present. After excluding linkage to 12 known HSP loci (*SPG3A, SPG4, SPG6, SPG8, SPG10, SPG12, SPG13, SPG17, SPG19, SPG29, SPG31*, and *SPG33*), a genome-wide screen provided evidence of linkage between the disease and D3S1744 on chromosome 3q (LOD=4.2). Analysis of 6 additional microsatellite markers on chromosome 3q gave significant pairwise LOD score >3 (maximum two-point LOD score 5.07 at recombination fraction 0.001). Therefore, our results clearly establish the existence of a novel locus for autosomal dominant uncomplicated HSP on chromosome 3q24-q26. Haplotype construction and analysis of recombination events narrowed the locus to a 22-cM interval flanked by D3S2326 and D3S3053. This new locus was named *SPG40*. More than 130 genes are located in this region. Sequencing of five candidate genes (*PFN2, SCHIP1, SLITRK3, MYNN, CLDN11*) in this region showed no disease-causing mutation.

The Mexican Genome Diversity Project: Analysis of genetic structure in Mexican Mestizo and Amerindian populations. *A. Hidalgo-Miranda, L. Uribe-Figueroa, I. Silva-Zolezzi, J. C. Fernandez-Lopez, J. Estrada-Gil, G. Ortiz-Ramos, R. Mojica-Espinosa, J. Cruz-Colin, A. Contreras, H. Hernandez-Lemus, S. March, G. Jimenez-Sanchez* National Institute of Genomic Medicine, Mexico.

Most Mexicans are Mestizos resulting from admixture of Amerindian, Spaniard and African populations. The admixture process has led to particular genomic ancestry structure. To optimize the use of human genome information to improve healthcare in Mexicans, we are evaluating genomic variability of the Mexican population. We genotyped 300 Mestizos from six regions: Guanajuato (GUA); Guerrero (GUE); Sonora (SON), Veracruz (VER); Yucatan (YUC) and Zacatecas (ZAC) using the Affymetrix 100K set. Heterozygosity (HET), Fst and principal component analyses were performed. HET was higher in Mexican subpopulations compared to Asian HapMap groups, SON showing the highest (0.287) and GUE the lowest (0.274). Fst values from 5 of 6 pairwise comparisons between Mestizos (0.006 to 0.019) were higher that those of the Asian groups (Fst=0.007). PCA clustered each HapMap group, and Mestizos showed a wide distribution between CEU and other source of variation not present in HapMap. To demonstrate that this ancestral component in Mestizos is Amerindian, we included 33 Zapotec (ZAP) Amerindian samples in the analyses. Fst values showed that GUE and VER are the most similar to the Amerindian sample (ZAP-GUE 0.032; ZAP-VER 0.038) and SON the most different (ZAP-SON 0.082). Fst values for the SON-ZAP comparison were higher than all comparisons between Mestizos and CEU or Asians. As expected, the highest Fst value was obtained in the African-Amerindian comparison (ZAP-YRI 0.238). PCA analysis showed that the ZAP clustered between the CEU and the Asian population. Mestizos from GUE and VER were close to the ZAP cluster, while samples from SON were closer to the CEU. Our results indicate significant heterogeneity between populations within Mexico, as well as between Mexicans and HapMap populations. We are including additional Mexican Amerindians and increasing SNP density to better understand the admixture process in Mexicans, and develop more suitable tools to analyze the genetic bases of complex diseases in this population.

Functional polymorphisms in promoter region of serotonin transporter gene are associated with NEO agreeableness domain. *C. L. Muller[1], M. E. Garrett[1], A. L. Collins[1], B. H. Brummett[2], I. C. Siegler[2], R. B. Williams[2], A. E. Ashley-Koch[1]* 1) Ctr for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC.

The 5HTTLPR functional polymorphism in the promoter region of the serotonin transporter gene has been previously associated with personality and other psychiatric traits. However, the expression of the serotonin transporter is affected not only by the 5HTTLPR polymorphism but also SNP rs25531 which resides in this region. Composite promoter genotypes may be constructed as high or low expressing based on the combined genotypes of these two polymorphisms and previously established expression levels from each genotype, resulting in three possible genotypes for analysis (HiHi, HiLo & LoLo). In light of the newer information regarding the promoter expression, we examined the factor scores of 5 NEO domains (Neuroticism, Extraversion, Openness, Agreeableness, and Conscientiousness) for association with the composite serotonin transporter polymorphism in a sample of 341 individuals (62.8% female, 63.6% Caucasian) from 162 families. Our sample consists of 297 sibling pairs (126 2-sibling pairs, 12 3-sibling pairs, 1 4-sibling pair, and 1 5-sibling pair) and 23 singletons ascertained on the basis of the Cook Medley Hostility scale (Ho), as well as 21 parents. 59.4% of subjects were classified as low hostile (Ho: 0-9), 19.7% were intermediate hostile (Ho: 10-13), and 20.9% were high hostile (Ho: 14-20). Using the QTDT, we observed that the factor score for the agreeableness domain is highly associated with the composite 5HTTLPR polymorphism ($p<0.0001$) such that individuals with the LoLo genotype are less agreeable than those with either the LoHi or the HiHi genotype. This observation is consistent with previously findings in another data set that show association between the short 5HTTLPR variant (less uptake) and lower agreeableness (Greenberg et al. 2000).

Genome-wide associations for serum bilirubin in the Framingham Heart and Rotterdam studies. *A. D. Johnson[1], M. Kavousi[2], M. H. Chen[1], A. Dehghan[2], C. van Duijn[2], A. Uitterlinden[2,3], A. Hofman[2], F. Rivadeneira[2,3], J. P. Lin[4], L. A. Cupples[5], Q. Yang[1,5], C. J. O'Donnell[1], J. Witteman[2]* 1) NHLBI's Framingham Heart Study; 2) Dept of Epidemiology, Erasmus Med Center, Rotterdam; 3) Dept of Internal Medicine, Erasmus Med Center, Rotterdam; 4) NHLBI's Office of Biostatistics; 5) Department of Biostatistics, Boston University.

Purpose: Variation in serum bilirubin has been associated with altered cardiovascular disease risk and drug metabolism. We aimed to identify genetic contributors to variability in serum bilirubin levels by combining results from high density genome-wide association studies in two white populations. Methods: Genotyping of Framingham Heart Study (FHS) participants was performed with Affymetrix 500K and 50K gene focused arrays and in the Rotterdam Study with Illumina HumanHap550 arrays. Both studies used MACH to impute 2.54 million SNPs based on HapMap CEU phased haplotypes (build 22). Both studies ran age, sex and similar multivariable adjusted models to derive residuals for log- transformed bilirubin levels in FHS Offspring cohort exam 1 (n=3,270) and Rotterdam participants (n=3,847). Imputed genotypes were then tested for association using a linear mixed effects model. We defined 16 a priori candidate loci based on bilirubin physiology. Inverse variance and sample size weighted meta-analysis was conducted using METAL. Results: The UGT1A1 locus was strongly associated with bilirubin levels with minimal p-values 8.8*10-159 and 2.2*10-190, for FHS and Rotterdam, respectively. No other regions exceed a genome-wide significance threshold of 5*10-8 in either study. In meta-analysis a number of loci showed convincing evidence for association, including the UGT locus ($p<5*10-324$) and one of the a priori candidates ($p<1.7*10-10$). Conclusions: In a high density genetic scan and meta-analysis for bilirubin levels across two large cohorts we confirmed the UGT1A1 locus as the major genetic contributor to bilirubin levels, accounting for a large proportion of the variation. We confirm in meta-analysis at least one other locus with strong evidence that influences bilirubin levels. These findings merit further study in independent populations.

High resolution DNA copy number analysis detects previously unreported alterations in human cancer cell lines.
L. Uribe-Figueroa, A. Hidalgo-Miranda, C. Rangel-Escareño, G. Ortiz-Ramos, V. Espinosa-Mateos, R. Goya-Ogarrio, J. Cruz-Colin, R. Mojica-Espinosa, M. Rodriguez-Dorantes, S. March, G. Jimenez-Sanchez National Institute of Genomic Medicine, Mexico.

DNA copy number alterations represent a hallmark of transformed cells. The exact mapping of these aberrations is thus crucial for the identification of genes with a role in cancer development. Several methods have been developed to detect such alterations. Recently, SNP arrays have increased their coverage to evaluate more than 1,800K genetic markers along the genome, including both SNP and non polymorphic copy number variation probes. We compared two SNP microarray platforms to evaluate their capability to detect DNA copy number aberrations in 15 cancer cell lines from colon (HCT15, COLO205), uterine cervix (HeLa, C33A), breast (HS578T, MCF7), leukemia (HL60, K562), lymphoma (RAJI), rhabdomyosarcoma (RD, SMS, RH30), Ewing's sarcoma (A673, HS863T), and liver (Hep-G2) along with three normal lymphoblastoid cell lines (GM1715A, GM17231A and GM17263). All cell lines were analyzed with the 500K and the SNP 6.0 Affymetrix arrays. The copy number analysis was performed using Partek Genomics Suite under the same segmentation conditions for both arrays. DNA copy number aberration patterns were similar in both platforms, considering their differences in genome coverage. The 500K array identifed 3,253 segments with DNA copy number changes, while the SNP 6.0 identified 11,300. Between the most common alterations detected by the SNP 6.0 and missed by the 500K, we found genes associated with carcinogen detoxification, such as GSTT1 (deleted in 4 and amplified in 13 of 18 cell lines) or cell cycle regulation genes, like SCAPER, (deleted in 9 and amplified in 4 cell lines). The higher probe density in the SNP 6.0 allowed the detection of previously unreported copy number alterations in these cell lines, as well as the elimination of false positive copy number calls in regions with low probe coverage in the 500K microarray set. Detection of novel genomic alterations in commonly used cellular models of human cancers will allow a more precise identification of genes involved in cancer biology.

Identifying genes affecting normal variation in human facial features using admixed populations. *D. K. Liberton[1], K. A. Matthes[1], B. McEvoy[2], R. Pereira[3], T. Frudakis[4], M. D. Shriver[1]* 1) Department of Anthropology, Pennsylvania State University, University Park, PA; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) Programa de Pós-Graduação em Ciências Genômicas e Biotecnologia, Universidade Católica de Brasília, Brasilia, Brasil; 4) DNAPrint Genomics, Sarasota, FL.

Seven selection-nominated candidate genes (*COL11A1*, *LMNA*, *FGFR1*, *FGFR2*, *TRPS*, *BRAF*, *FLNA*) known to be involved in Mendelian craniofacial dysmorphologies and to have high allele frequency differences between West African and European populations were tested for admixture linkage to normal facial feature traits. The sample consists of 254 subjects (n=131 African Americans, n=123 Brazilians) of West African and European genetic ancestry. Each individual was genotyped at 176 ancestry informative markers (AIMs), which allowed for proportional estimation of genetic ancestry from four parental populations and adjustments for admixture stratification.

3D images of faces were acquired using the 3dMDface imaging system. 3D coordinate data were collected from 22 landmarks placed on each image using the 3dMDPatient software. The 231 possible pairwise landmark distances were scaled to the geometric mean and then analyzed using Euclidean Distance Matrix Analysis.

We used both ANOVA and ADMIXMAP to control for admixture stratification and to test for associations between the 231 pairwise landmark distances and 183 AIMs, using sex, height and BMI as covariates. We used a four-population model (West African, European, East Asian, and Native American).

There is a strong concordance between the ANOVA and ADMIXMAP results. Many landmark distances, particularly on the mouth and nose, were significantly associated with genetic ancestry. Additionally, three of the candidate genes show no effects on pairwise landmark distances while four show distinct patterns of association. For example, *FGFR2* is associated primarily with the length of the face. These results represent the first identification of the first genes affecting normal variation in facial features.

Loeys-Dietz syndrome (LDS). In vitro studies of skin fibroblasts showing differences between mutations in the *TGFBR1* and *TGFBR2* genes. *D. Chitayat[1,2], C. P. Barnett[2], T. J. Bradley[3], A. Hinek[4]* 1) Prenatal Diag & Medical Gen, Mount Sinai Hosp, Toronto, ON, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Division of Cardiology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) The Heart Centre, The Hospital for Sick Children, Toronto, Ontario, Canada.

LDS is a newly described condition caused by mutations in the genes encoding transforming growth factor-beta (TGF-) receptors 1 and 2. The condition is associated with vascular tortuousity and formation and rupture of arterial aneurysms. Skin fibroblasts were cultured from 3 patients with confirmed LDS. Case 1 had dilated aortic root and tortuous aortic arch and branches. DNA analysis revealed a *TGFBR1* gene missense mutation (c.722C>T). Case 2 is a 10 year old girl with dilated aortic root requiring surgical repair at age 10, extensive arterial tortuosity of head and neck vessels and a repaired cleft palate. DNA analysis revealed a missense mutation of *TGFBR1* (c.1460G>A). Case 3 had arachnodactyly, bilateral inguinal hernias, bilateral clubfeet and joint laxity. Echocardiography revealed a dilated aortic root. A missense mutation of *TGFBR2* (c.1583G>A) was identified. *In vitro* studies of skin fibroblasts from these patients indicated that both patients carrying mutations of *TGFBR1* demonstrated a significant deficiency in the net expression of elastin and fibrillin genes (assessed by RT-PCR) and did not deposit elastic fibers in primary cultures. In contrast, they produced normal levels of auxiliary components of elastic fibers (fibulins 1, 2 and 5) and deposited normal collagen fibers. Interestingly, fibroblasts derived from patients with mutation of *TGFBR2* genes produced normal components of elastic fibers, but displayed intracellular retention of collagen type 1 and had significantly lower deposition of mature collagen fibers. Our findings indicate that the clinical manifestations associated with *TGFBR1* and *2* mutations, although similar, are caused by different mechanisms.

Knock-out of mouse Ikbkap gene leads to embryonic lethality that can be rescued by human IKBKAP gene. *Y. Chen, M. Hims, R. Shetty, J. Mull, L. Liu, M. Leyne, S. Slaugenhaupt* Ctr Human Genetics Res, Massachusetts General Hosp, Boston, MA.

Tissue specific reduction of IKAP, also known as Human Elongator Protein 1 (hELP1), leads to familial dysautonomia (FD), a devastating hereditary sensory and autonomic neuropathy. All FD patients have an intronic mutation in the IKBKAP gene that disrupts normal mRNA splicing and leads to reduced IKAP protein, particularly in the nervous system. In order to better understand the role of this gene during development, an Ikbkap knockout mouse model was created. Ablating Ikbkap leads to embryonic lethality, with no homozygous Ikbkap knockout embryos (Ikbkap-/-) surviving beyond 10.5 days post cotium. Morphological analyses of the Ikbkap-/- embryos at different stages reveals abnormalities in both the visceral yolk sac and the embryo, including stunted extraembryonic blood vessel formation, delayed entry into mid-gastrulation, disoriented dorsal primitive neural alignment, and failure to establish the embryonic vascular system. IKAP is required for efficient transcriptional elongation of a variety of genes, and we demonstrate down-regulation of several genes that are important for neurulation and vascular development in the Ikbkap-/- embryos. Finally, we show that the embryonic lethality resulting from Ikbkap ablation can be rescued by a human IKBKAP transgene.

Linkage to FEB1 in a Colombian family with autosomal dominant epilepsy with febrile seizures plus, (ADEFS+).

N. Pineda-Trujillo[1,2], J. Tejada-Moreno[1,3], M.-A. Caro-Gomez[1], D. Cabrera[1,2], G. Bedoya[4], A. Ruiz-Linares[4,5], A. Franco[6], C. Castillo-Gomez[1,2], W. Cornejo[1,2], J. Carrizosa[1,2] 1) Mapeo Genético, Departamento de Pediatría y Puericultura, Facultad de Medicina, Universidad de Antioquia, Medellín-Colombia; 2) Pediaciencias, Departamento de Pediatría y Puericultura, Facultad de Medicina, Universidad de Antioquia, Medellín-Colombia; 3) Escuela de Biología, Universidad Industrial de Santander, Bucaramanga-Colombia;; 4) GENMOL, Universidad de Antioquia, Medellín-Colombia; 5) Department of Biology, University of London, UK; 6) Hospital San Vicente de Paúl, Medellín-Colombia.

Febrile seizures (FS) is a clinical and genetically heterogeneous disorder. FEB1 was the first genetic locus associated with the disease. No replication of such association has been reported. Our purpose was to test for linkage to the loci FEB1 and FEB2 in a Colombian family with ADEFS+. Markers D8S533-D8S1795-D8S1807-D8S279 were tested in FEB1; markers D19S219-D19S1034-D19S427-D19S177 were tested in FEB2. These markers were tested by fluorescent methods in a genetic analyzer ABI-310 (Applied Biosystems). Linkage analysis was done using the package LINKAGE v5.1. Several penetrance values were used (0.50, 0.65, 0.90); two phenocopies rate were also considered (0 and 3%). Autosomal dominant inheritance, mutated allele frequency= 0.003 and equal allele frequency for the marker loci were assumed. Haplotype analysis was done with SimWalk2. The highest lod score (Z = 0.75) was obtained at =0, for marker D8S533 (FEB1). In addition, we found a haplotype consistently segregating with the disease, which is characterized by alleles 3-4-4-3 at marker loci in FEB1. These results were obtained assuming penetrance= 0.90 and phenocopies rate= 0. Locus FEB2 did not show linkage to the disorder in this family. Our data support linkage of ADEFS+ to FEB1.This study reports for the first time a replication of the association of the locus FEB1 with febrile seizures (reported by Wallace, et al. 1996). In order to increase power, additional family members are been enrolled in this study. No gene associated with ADEFS+, in this region, has been identified yet. Financial support from Colciencias, grant # 111534319158.

Replication of Associations between Parkinsons Disease and Haplotypes for Iron-Related Candidate Genes. *S. L. Rhodes[1], C. C. Bandong[1], J. M. Bronstein[2], J. C. Lambert[3], J. S. Sinsheimer[4], A. Elbaz[3], J. I. Rotter[1], K. D. Taylor[1], B. Ritz[5]* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Dept of Neurology, School of Medicine, UCLA, Los Angeles, CA; 3) National Institute of Health and Medical Research, Institut Pasteur de Lille, Lille, France; 4) Dept of Human Genetics, UCLA, Los Angeles, CA; 5) Dept of Epidemiology, UCLA, Los Angeles, CA.

Postmortem and imaging studies have observed increased levels of iron deposits in parkinsonian vs. control brains, particularly in the substantia nigra, and linked extent of deposit to severity of disease. We investigated associations between Parkinsons disease (PD) and haplotypes for iron-related genes. Stage 1: 372 incident cases and 360 population-based controls from central CA. Stages 2a and 2b: a case-control study of French farmers and the NINDS dbGAP GWAS dataset. Stage 1 candidate genes identified from published literature and prior studies of PD, and tagSNPs selected from Caucasian HapMap data. Stage 2a genotyped specific SNPs from Stage 1, and Stage 2b used imputation to construct comparable haplotypes. Odds ratios (OR) and 95% confidence intervals were estimated adjusted for age, gender, education, and smoking. Of the 90 Stage 1 SNPs, 11 had dominant model p-values <0.05 and 5 had p-values <0.1; for suggestive associations in 10 of 17 genes. We observed protective (0.7, 0.54-0.95) and suggestive risk (1.3, 0.91-1.79) haplotypes in HFE while the frequently and inconclusively investigated 282Y-carrying haplotype was not associated (0.9, 0.58-1.43) with PD. In TF, we observed two protective haplotypes (ORs 0.7, p<0.05); one promoter and one 3 coding block. While Stage 2a and 2b replications are in progress, we have completed the analysis of TF and confirmed a similar association with PD for the promoter haplotype (0.7, 0.48-0.99) but not the 3 coding region haplotype. TF promoter region variants have been associated with variation in total iron binding capacity. Our data suggest associations with PD for iron-related genes and demonstrates the utility of a haplotype tagging approach in candidate gene investigations when the causal variant is unknown.

Application of in-house array-CGH for investigation and diagnosis of congenital genomic disorders. *S. Hayashi, S. Honda, I. Imoto, J. Inazawa* Dept Molecular Cytogenetics, Tokyo Medical & Dental Univ, Tokyo, Tokyo, Japan.

Our purpose is to investigate a cause of a congenital disorder by exploring copy-number aberrations (CNAs) responsible for such disorders and to establish a system for diagnosis of multiple congenital anomalies with mental retardation (MCA/MR) using array-CGH. We formed a consortium with 20 hospitals or universities to recruit patients with MCA/MR, and screened their CNAs using several types of in-house bacterial artificial chromosome (BAC)-based array-CGH. All of the patients had no cytogenetic abnormality in conventional karyotyping. In primary screening we used MCG Genome Disorder (GD) Array containing BAC clones covering loci associated with known genomic disorders and subtelomeric regions of all chromosomes except short arms of acrocentric chromosomes, and detected CNAs in 39 of 378 cases (10.3%). In secondary screening we employed MCG Whole Genome Array-4500 harboring 4523 BACs throughout human genome for cases without any CNAs by GD Array, and detected CNA in 20 of 75 cases (26.7%). Based on the result, we created a database to clarify a correlation between genotype and phenotype and to identify a new disorder. Consequently, we identified the CASK gene as a candidate gene corresponding to X-linked recessive mental retardation in a female patient with heterozygous deletion at Xp11.3p11.4. We also suggested a possible new microdeletion syndrome as a result of analyses of two patients having same heterozygous deletion. This research has provided not only an efficient analysis of MCA/MR but also important clues to investigate each disorder. In conclusion, array-CGH is a useful strategy to investigate cryptic genomic aberrations responsible for unknown MCA/MR, and/or to establish a new syndrome.

Identification of novel genetic regulatory networks in Papillary Thyroid Carcinoma using information theoretical methods. *E. Hernandez-Lemus[1], D. Velazquez-Fernandez[1,2], J. K. Estrada-Gil[1], I. Silva-Zolezzi[1], M. F. Herrera-Hernandez[2], G. Jimenez-Sanchez[1]* 1) National Institute of Genomic Medicine, Mexico; 2) National Institute of Medical Sciences, Salvador Zubiran, Mexico.

Papillary thyroid carcinoma (PTC) is the most frequent endocrine neoplasia worldwide, insight about its molecular pathogenesis has been gained through gene expression (GE) analysis. An integrative approach of this information is still missing. Construction of genetic regulatory networks (GRN) can help understand the interplay between thousands of genes. Three main issues arise in the analysis of this data: the measurement process generates noisy signals, there are more variables involved than experimental samples, and the nonlinear character of the underlying biochemical dynamics is another source of complexity. To overcome some of these limitations, we generated an optimized tool based on the Maximum Entropy Formalism to deconvolute a GRN based on the most probable distribution of gene-gene interactions. We tested the method using GE data from G7 PTC and goiter samples analyzed with the Affymetrix HgU133 Plus 2.0 array. The optimal regulatory network was obtained from a pool of 25,593,993 probability distributions. The interactions were validated by several (mostly in silico) means. The associated PTC-GRN possessed a power-law degree distribution in which the vast majority of the genes have very few links whereas a small number of them are highly connected. This scale-free property has been recognized as characteristic of topological robustness. PTC-GRN is composed by 75 nodes and 170 links, with connectivity k values between 1 and 20, and average connectivity <k> = 2.2666 while the expected average for a random network will be <k_exp> = 2L/N = 4.5. By means of a complex network statistical analysis, we discover some regulatory interactions among genes previously related to PTC including *CTNNB1, AURKA* and *TDG*. *RXRG, KRT19* and *MAP3K10* in the RTK/RAS/RAF/MAPK pathway were also found in the highly correlated gene clusters. These approaches can be of benefit for the identification of new molecular mechanisms of disease.

SLC9A9 is associated with DSM-IV hyperactive-impulsive and total symptoms in AD/HD families. *A. E. Ashley-Koch[1], C. A. Markunas[1], K. Quinn[1], A. L. Collins[1], M. E. Garrett[1], S. Keatts[1], A. M. Lachiewicz[2], E. Morrissey-Kane[3], S. H. Kollins[4], A. D. Anastopolous[3]* 1) Center for Human Genetics, Duke Medical Center, Durham, NC; 2) Dept of Pediatrics, Duke Medical Center, Durham, NC; 3) Dept. of Psychology, University of North Carolina, Greensboro, NC; 4) Dept. of Psychiatry, Duke Medical Center, Durham, NC.

A family was identified that co-segregates a pericentric inversion, 46N inv(3)(p14:q21), with an early-onset behavioral/developmental condition, characterized by impulsive behavior and intellectual deficit (de Silva et al. 2003). The inversion breakpoints lie within intron 19 of the dedicator of cytokinesis 3 (DOCK3) and intron 13 of the solute carrier family 9 (sodium/hydrogen exchanger) isoform 9 (SLC9A9) at the p- and q-arm, respectively. Based on this report, these genes were selected as candidates to be evaluated in a family-based AD/HD genetic association study. Analyses were performed on 102 families with at least one child between the ages of 5 and 12 years who met research criteria for AD/HD. Conners Parent (CPRS) and Teacher Rating Scales (CTRS) of AD/HD symptoms were collected on 163 affected and unaffected siblings aged 5-18 years. Parents and children were genotyped using the Illumina Infinium HumanHap300 duo chip and a minimal number of tagging SNPs in each gene (DOCK3: n=10; SLC9A9: n=79) were selected for analysis. Using QTDT, each SNP was tested for association with the t-scores for the Conners DSM-IV subscales: inattentive, hyperactive-impulsive, and total symptom count. Teacher-generated t-scores were log-transformed prior to analysis. After adjusting for multiple testing, one SNP (rs1046706) in the 3 UTR of SLC9A9 remained significantly associated ($p<0.0001$, FDR-adjusted $p<0.001$) with scores on the DSM-IV hyperactive-impulsive and total symptom subscales according to the CTRS. Interestingly, SLC9A1 (member of the SLC9A family) null mice show increased hippocampal neuronal excitability (Gu et al. 2001). These results suggest that SLC9A9 may be responsible for the phenotype observed in the inversion family and that further investigation of the role of SLC9A9 in AD/HD and other behavioral disorders is warranted.

The ITMAT/Broad/CARE (IBC) Candidate Gene Array Identifies Novel Type 2 Diabetes Gene Associations with Coronary Artery Disease: The GRAND-CAD Consortium. *N. N. Mehta[1], M. Li[1], M. S. Burnett[2], N. T. Ginwala[1], A. Qasim[1], S. Restine[1], L. Pruscino[1], I. Stylianou[1], Z. Chen[1], J. He[1], M. L. Wolfe[1], J. Devaney[2], H. Chandrupatla[1], H. Hakonarson[1], B. Keating[1], J. Lindsay[2], R. Waksman[2], S. E. Epstein[2], D. J. Rader[1], M. P. Reilly[1]* 1) University of Pennsylvania, Philadelphia, PA; 2) Cardiovascular Research Institute/MRI/Washington Hospital Center, Washington, DC.

Patients with type 2 diabetes (T2D) represent a high risk population for coronary artery disease (CAD). Many candidate genes have emerged from recent genome wide association studies (GWAS) of T2D. Identifying which T2D genes are associated with increased risk of CAD may provide insight into the complex genetics of T2D and CAD. The IBC array is a custom 50K cardiovascular disease (CVD) gene centric SNP array designed to assess the genetic diversity within candidate genes (~2000) in CVD. Many T2D genes were included based on results of T2D GWAS; we focus on their association with CAD. In stage 1, we examined SNPs in T2D genes [TCF7L2, FTO, PPARG, IGF2BP2, KCNJ11, HHEX, CDKAL1, SLC30A8, 9p21 T2D locus, rs1081161] with CAD in a Caucasian, angiographic case-control study (PennCATH: 1018 CAD cases & 498 controls), with gene based Bonferroni correction. Stage 2 in silico replication was performed in a similar cohort (MedStar: 875 CAD cases & 447 controls) using Affymetrix 6.0 data. All samples & SNPs passed stringent QC; there was no significant population stratification. After adjustment for age, gender, T2D & BMI, we found significant associations in 2 of 9 T2D genes with CAD in stage 1 (CDKAL1 [rs6915037, p=0.0019] & TCF7L2 [rs11196224, p=0.0011]). There was no significant association with the other T2D loci. In stage 2, CDKAL1 (rs946598, p=0.003), but not TCF7L2 (best SNP rs7094463, p=0.04) replicated the association with CAD. Conclusion: We have identified & replicated a significant association with CAD for novel T2D genes. This CAD association appears to be independent of T2D suggesting a novel genetic mechanism modulating both T2D and CAD. Knowledge of these associations may facilitate the development of targeted risk prediction and therapy for CAD in T2D.

Effect of PNA based inhibitor on microRNA activitiy. *S. Y. Oh, H. Park* Panagene, Daejeon, Korea.

The microRNAs are approximately 22 nucleotides non-coding RNAs and are transcribed from DNA as hairpin precursors. They regulate major processes as development, apoptosis, cell proliferation, hematopoiesis, and patterning of the nervous system. miRNA inhibition using antisense oligonucleotide is unique and effective technique for miRNA functionalization and therapeutic targeting. Peptide nucleic acids (PNAs) are artificial oligonucleotides with a peptide backbone. PNAs have stronger affinity and greater specificity than DNA oligonucleotides for binding to DNA and RNA. Also, PNAs are resistant to nuclease, which is essential for a miRNA inhibitor that be exposed to abundant serum and cellular nucleases. These properties make PNAs well suited for miRNA inhibitor. We described here a new PNA inhibitor and evaluated effect of PNA inhibitors on miRNA activity. In this experiments, we confirmed that miRNA inhibition effects of PNA is over two times higher than LNA-modified DNA and 2-O-Methyl-oligonucleotide (2-OMe) by luciferase assay and northern blot. For confirmation for PNA inhibitor effects, we also observed that bcl-2 expression which is regulated by miR16 was decreased by western blot. In addition, the effect of PNA inhibitors on miRNA is active after 10 days of transfection. These results demonstrated that PNAs are more powerful and effective miRNA inhibitor than LNA-modified DNA and 2-OMe.

Absence of Association of Y1102 and C4848T variants with sudden cardiac death among African-Americans. *R. M. Faugue[1], Y. Rodriguez[1], D. El-Imam[1], ME. Ahearn[1], E. Mont[3], R. J. Myerburg[2], N. Bishopric[1]* 1) Molecular and Cellular Pharmacology , University of Miami Miller School of Medicine, Miami, FL; 2) 2Division of Cardiology, University of Miami Miller School of Medicine, Miami, FL; 3) Miami-Dade County Medical Examiner Department, Miami, FL.

BACKGROUND. Mutations in the cardiac sodium channel gene (SCN5A), such as Y1102 and C4848T, have been proposed to be over-represented in populations of AA patients being followed in an arrhythmia clinic. The same Y1102 variant was also associated with unexplained or hypertrophy-associated sudden death in 65 cases referred to the Maryland Medical Examiner. Y1102 amino acid substitution has been reported to slightly prolong Na current during repolarization phase of the cardiac action potential and enhanced sensitivity due to the use of anti-arrhythmic drugs such as amiodarone, as well as unexplained sudden cardiac death. We sought to confirm this finding or identify novel polymorphic variants in arrhythmia-associated genes in a population of sudden cardiac death victims who had post-mortem examinations by the Miami-Dade Medical Examiner. METHODS. We investigated the incidence of the Y1102 and 4848 (C>T) alleles in a series of sudden death in AA subjects. This ME group was suspected of having LQTS or unexplained arrhythmias. Most of these cases of sudden cardiac death were shown to have underlying coronary artery disease, others did not have any cardiac pathology. They were compared to a control group of 72 AA. 72 AA probands were analyzed using Custom TaqMan SNP Genotyping Assays using an ABI 7900HT Fast Real-time PCR and a novel Xmn I restriction enzyme digestion assay (New England BioLabs). RESULTS. The overall frequency of Y1102 was 15% of probands and 16% of controls. The results were not significant ($p = 0.15$). Similarly, the 4848 (C>T) SNP overall frequency was 24/72 probands (33%) and 20/50 controls (40%). Both Y1102 and 4848 results were not statistically different. CONCLUSION. We were unable to find an association between the Y1102 SNP and 4848 SNP in sudden death cases of AA. Differences in ethnicities may contribute to genetic variation but it is difficult to assign a risk in such a diverse population.

Mutations in patched domain containing 1 gene (PTCHD1) are associated with autism spectrum disorder. *A. Noor[1], C. R. Marshall[2], S. W. Scherer[2], J. B. Vincent[1]* 1) Neurogenetics Section, Centre For Addiction & Mental Health, Toronto, ON, Canada; 2) Program in Genetics and Genomic Biology and The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada.

In a study of genomic variants in autism spectrum disorder using high-density single nucleotide polymorphism (SNP) microarrays, we have identified a 167 Kb deletion in a male proband and his affected male sibling, that results in the deletion of exon 1 and upstream regulatory regions of the patched domain containing 1 (PTCHD1) gene on Xp22.11. The presence of the patched domain suggests a possible role for PTCHD1 in the Hedgehog (Hh) signaling pathway. We sequenced the entire coding region of this gene in 900 unrelated autism probands, and identified six families with PTCHD1 DNA sequence variants resulting in substitution of amino acids at highly conserved positions. All these variants were inherited from unaffected, heterozygous mothers. In two cases, these apparently deleterious variants accompanied de novo CNVs elsewhere in the genome suggesting in these individuals two or more variants may be required for phenotypic expression. The PTCHD1 deletion was not present in 1652 control individuals and the missense changes were not present in >300 controls. We confirmed expression of this gene in various human tissues, including adult and fetal brain. Localization studies revealed that PTCHD1 fusion-protein is predominantly localized in the cell membrane. Our findings suggest that loss of function or expression of PTCHD1 contribute to the etiology of Autism Spectrum Disorder (ASD). Furthermore, our findings demonstrate a possible contribution of more than one loci in the etiology of Autism, thus, supporting the oligopolygenic inheritance of this disorder.

Bohring-Opitz Syndrome or C Syndrome spectrum? Report of a Brazilian case. *F. B. Piazzon*[1,3], *M. F. F. Soares*[2], *V. F. A. Meloni*[1] 1) Centro de Genética Médica, Universidade Federal de Sao Paulo - UNIFESP, Sao Paulo, Sao Paulo, Brazil; 2) Departamento de Diagnóstico por Imagem, Universidade Federal de Sao Paulo - UNIFESP, Sao Paulo, Sao Paulo, Brazil; 3) Instituto de Genética e Erros Inatos do Metabolismo - IGEIM / UNIFESP, Sao Paulo, Sao Paulo, Brazil.

Introduction: Bohring et al. [1999] reported a new syndrome in 4 unrelated patients with specific features. Two prior, very similar cases with this new entity were reported in 1975 by Oberklaid and Danks then described as Opitz trigonocephaly (OMIM #211750). The new syndrome consisted of bulging forehead over the metopic suture, frontal nevus flammeus, hypertelorism, exophthalmos or even prominent eyes, upslanting palpebral fissures, and cleft palate and/or lip, as well as flexion deformities of the upper limbs, multiple other anomalies, and severe failure to thrive. In 2000, more cases were characterized and Bohring-Opitz was chosen to name this syndrome (OMIM #605039). **Objectives:** to describe a 6-month-brazilian girl with the present diagnostic hypothesis. **Materials and methods:** clinical follow-up with anamnesis and physical examination; subsidiary exams and photographic documentation. **Results:** in the first appointment the girl was 2 months old, an investigation for the trigonocephaly was initiated; cleft palate, cardiac murmur and other dysmorphic features were also present. The patient had microcephaly with trigonocephaly, exophthalmos, upslanting palpebral fissures and typical deformities on her hands and feet. Global development was delayed. She was fed through a G-tube, which strongly contributed to the failure to thrive. **Conclusion:** Because of close similarity between both syndromes, Bohring-Opitz syndrome is considered the more severe form of the Opitz trigonocephaly (C syndrome), therefore known as C-like syndrome. This similarity became more plausible, after the discovery of the involvement of a mutation in the *TACTILE* gene, located at 3q13.3, which encodes the CD96 immunoglobulin, in Bohring-Opitz or C Syndrome patients, that is why it has been suggested that both syndromes can be part of the same clinical spectrum of Opitz trigonocephaly.

Expression of miRNAs on Chromosome 11q in HNSCC. *B. Henson[1], S. Bhattacharjee[1], S. Gollin[1,2]* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) University of Pittsburgh Cancer Institute, University of Pittsburgh, Pittsburgh, PA.

MicroRNAs (miRNAs) are a class of small non-protein encoding RNAs that can inhibit translation by binding to the 3` UTR of target mRNAs and either sequester or degrade the transcript. Altered miRNA expression profiles have been found in numerous malignancies. Head and Neck Squamous Cell Carcinoma (HNSCC) is the sixth most common cancer in the United States; however, little is known about its miRNA expression profile and how this affects the disease. Numerous genetic aberrations are characteristic of HNSCC, with the amplification of chromosomal band 11q13 and loss of distal chromosome 11q being amongst the most prevalent. Many of the protein-encoding genes within these regions and their contributions to HNSCC have been examined. Our goal was to determine expression levels of miRNAs on chromosome 11q using RT-PCR and determine if modifying their expression affects cell proliferation (MTT assay), cell cycle progression (flow cytometry), and global gene expression (microarray analysis). We hypothesize that expression of miRNAs on chromosome 11q is decreased in conjunction with distal 11q loss and that modifying their levels will affect cellular behavior. We found that mir-125b and mir-100 levels were significantly lower in HNSCC cell lines and tumors than in controls. Increasing levels of mir-125b and mir-100 had a marginal effect on the cell cycle, but significantly decreased cell proliferation and altered global gene expression. Microarray analysis revealed that the expression levels of predicted miRNA target genes and non-target genes were significantly modified. Altered expression of non-target genes could be due to these genes being unknown targets of these miRNAs; however, it is more likely that their expression is modified via an indirect mechanism. Both mir-125b and mir-100 have altered expression levels in other malignancies and each has the capability to regulate genes involved in many vital biological functions. Thus, both have enormous potential as therapeutic agents in HNSCC as well as other malignancies.

Sign, Sign, Everywhere a Sign: High Density Haplotype Maps of the Dog, Human, and Cow Genomes Reveal Extensive Human Reorganization of Domesticated Genomes. *C. D. Bustamante[1], R. K. Wayne[2], M. Nordborg[3], M. R. Nelson[4], M. Cargill[5], R. A. Gibbs[6], E. A. Ostrander[7]* 1) Cornell University, Ithaca, NY; 2) UCLA, Los Angeles, CA; 3) U. Southern California, Los Angeles, CA; 4) GlaxoSmithKline, Raleigh, NC; 5) Navigenics, Redwood, CA; 6) Baylor College of Medicine, Houston, TX; 7) NHGRI, NIH, Bethesda, MD.

We have developed multi-population high-density SNP and Haplotype maps of the bovine, human, and domestic dog genomes. These maps came about through three separate efforts: (1) the CanMap Project (1,000 dogs and wolves from 85 breeds genotyped across 127K SNPs), (2) the Bovine HapMap project (500 bulls on 25K SNPs from 25 breeds), and (3) the GSK-POPRES project (3,835 humans of diverse ethnic and geographic origin genotyped on Affy 500K human arrays). Using phased-resolved haplotype maps, we estimate local population recombination rate along each chromosome, identify key determinant of population substructure, and develop maps of recent directional selection for each species. By comparing the recombination maps of the three species, we find that humans show a very high correlation at the megabase scale in estimated population recombination rates across subpopulations; however, cows and domestic dogs show a striking lack of correlation across breeds. We also find that dogs and cattle show pervasive signatures of recent selection using SNP and haplotype-based statistics. Simulations suggest that, surprisingly, domestication bottlenecks do not explain these patterns. Strong bottlenecks at the time of breed formation coupled with popular sire effects, on the other hand, are necessary. We also find that all breeds examined demonstrate high degrees of cryptic relatedness, even when close relatives are avoided at the time of sampling. This implies that great care must be taken in interpreting nominal and genome-wide corrected p-values in whole genome association mapping within domesticated species. Comparison of various algorithms for WGAM in structured populations suggests mixed-model approaches as well as weighted permutation tests may effectively control for the induced background relatedness.

Association study of *GPR74* and *GNB3* gene polymorphisms with obesity in Koreans. *D. Shin[1,3], J. Han[1,4], J. Im[1], S. Lee[1,2], S. Park[1,2], E. Shin[5], J. Lee[5], Y. Jang[1,2,3]* 1) Cardiovascular Genome Ctr, Yonsei Col Medicine, Seoul, Korea; 2) Division of Cardiology, Yonsei University College of Medicine; 3) Yonsei University Research Institute of Science for Aging; 4) Graduated Program in Science for Aging, Yonsei University; 5) DNA Link Inc, Seoul, Korea.

G-protein-coupled receptor 74 (*GPR74*) is a novel candidate gene for body weight regulation, and is predominantly expressed in the brain, heart, and adipose tissue. GPR74 has a high affinity for neuropeptide FF (NPFF), which is responsible for cardiovascular regulation and to have effects on food intake. Heterotrimeric G-proteins are intracellular signal transducers, and C825T polymorphism in the G-protein 3 subunit (*GNB3*) gene has been associated with obesity, hypertension, and diabetes. We carried out a case-control study to investigate how genetic variations in the *GPR74* and *GNB3* genes are associated with obesity in Koreans. We examined a sample population of 624 Koreans, comprising of 312 controls (nonobese subjects, BMI 25) and 312 cases (obese subjects, BMI 25). We analyzed 5 single nucleotide polymorphisms (SNPs) in *GPR74* (C5564T, C15539G, A63920G, A84008G, G105951A) and 3 SNPs in *GNB3* (C825T, C1429T, G5177A). All subjects were genotyped for these polymorphisms by single base primer extension assay using the SNaPShot assay. *GPR74* C5564T and C15539G variants were strongly associated with BMI status between the obese and the nonobese subjects in dominant and codominant models (*P* 0.002). *GPR74* 4 haplotypes were also significantly associated with BMI in dominant and codominant models (*P* 0.001). In analysis of gene-gene interaction, we found that there were significant interaction between the *GNB3* and *GPR74* SNPs (*P* 0.05). Odds ratios (ORs) for obesity were significantly higher in *GNB3* 825T carriers with *GPR74* 15539CC genotype (OR, 3.016; 95% CI, 1.136-8.008; *P* = 0.0232), and in *GNB3* 1429CC genotype with *GPR74* 15539G carriers (OR, 0.429; 95% CI, 0.191-0.963; *P* = 0.0385). These findings suggest that *GPR74* gene polymorphisms are associated with obesity in Koreans and imply that the interaction between *GNB3* and *GPR74* genes has the predisposing or protective effect for obesity.

Paternal Uniparental Disomy as a Mechanism for Inherited Surfactant Deficiency. *D. J. Wegner[1], L. Nogee[2], A. Kammesheidt[3], L. Kasch[2], F. S. Cole[1], A. Hamvas[1]* 1) Pediatrics, Washington University, St. Louis, MO; 2) Pediatrics, Johns Hopkins University, Baltimore, MD; 3) Ambry Genetics, Aliso Viejo, CA.

Introduction: Uniparental disomy (UPD) has not been recognized as a mechanism of genetic disruption of neonatal pulmonary surfactant metabolism. The gene that encodes the ATP binding cassette family member A3 (ABCA3) has been mapped to chromosome 16 (16p13.3), the chromosome most commonly duplicated in cases of placental aneuploidy. Recessively inherited, loss-of-function ABCA3 mutations disrupt surfactant metabolism and function and cause lethal, neonatal respiratory disease. Objective: To determine the frequency of UPD in infants homozygous for recessive loss of function mutations in ABCA3. Methods: We searched datasets from 3 laboratories that perform sequence analysis for ABCA3 for infants with respiratory dysfunction (n=600) to identify those who were homozygous for loss of function mutations and for whom parental DNA was available. For infants with only one heterozygous parent, we used 9 microsatellite markers that span the length of chromosome 16 to characterize allele inheritance. Results: We found 18 infants homozygous for loss of function mutations in ABCA3 and for whom parental DNA was available. We identified 2 cases in which the infant was homozygous for a rare loss of function mutation (K914R and P147L, respectively) and for whom only the father was heterozygous for the respective mutation. One infant (K914R) was homozygous for all 9 markers, 7 of which confirmed paternal isodisomy, while the other infant (P147L) was homozygous for 7 markers, 3 of which were informative for the paternal allele, and heterozygous for 2 markers, a pattern that suggests partial isodisomy (heterodisomy). We identified no extrapulmonary phenotypic abnormalities in either infant. Both underwent lung transplantation at 5 and 3 months of age, respectively, for progressive pulmonary failure. Conclusions: Uniparental disomy is not a rare mechanism of ABCA3 deficiency. Confirmation of parental carrier status is important to provide informed and specific reproductive counseling to families of affected infants.

Microdeletion/duplication at 15q13.2q13.3 among individuals with features of autism and other neuropsychiatric disorders. *D. Miller[1, 2], Y. Shen[2, 3], L. Weiss[3], G. Cox[1], D. Harris[1], R. Hundley[4], R. Nasir[4], A. Reinhard[1, 2], M. Sobeih[5], J. Stoler[1], W.-H. Tan[1], J. Gusella[3], M. Daly[3], B.-L. Wu[2]* 1) Dviision of Genetics, Children's Hospital Boston, Boston, MA; 2) Dept. of Laboratory Medicine, Children's Hospital Boston, Boston, MA; 3) 3. Center for Human Genetic Research and Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) 7.Division of Developmental Medicine, Children's Hospital Boston, Boston, MA; 5) 5.Department of Neurology, Children's Hospital Boston, Boston, MA.

BACKGROUND: Deletion at breakpoints (BP4-BP5) of chromosome 15q13.2q13.3 is associated with mental retardation, epilepsy, and/or EEG abnormalities. PATIENTS: 1445 consecutive DNA samples from clinical patients at Childrens Hospital Boston and from 751 families with Autism from the Autism Genetic Resource Exchange (AGRE) repository. RESULTS: We report clinical features of four patients with a BP4-BP5 deletion, 3 with a BP4-BP5 duplication, and 2 with an overlapping but smaller duplication identified by whole genome high resolution oligonucleotide array CGH. BP4-BP5 deletion cases exhibit minor dysmorphic features, significant expressive language deficits, and a spectrum of neuropsychiatric impairments that include autism spectrum disorder, ADHD, anxiety disorder, and mood disorder. Cognitive impairment varied from moderate mental retardation to normal IQ with learning disability. BP4-BP5 covers ~1.5Mb (chr15:28.719-30.298Mb) and includes 6 reference genes, while the smaller duplications cover ~500 kb (chr15:28.902-29.404 Mb and contain 3 reference genes. The BP4-BP5 deletion and duplication events span CHRNA7, a candidate gene for seizures. However, none of these individuals reported here has epilepsy, although one has an abnormal EEG. CONCLUSIONS: The phenotype of chromosome 15q13.2q13.3 BP4-BP5 microdeletion/duplication syndrome may include features of autism spectrum disorder, a variety of neuropsychiatric disorders, and cognitive impairment. Recognition of this broader phenotype has implications for clinical diagnostic testing and efforts to understand the underlying etiology of this syndrome.

Tissue specificity of SERPPINB5 promoter in gastric cancer. *M. Kim, H. Ju, B. Lim, C. Kang* Biology, KAIST, Daejeon, Korea.

SERPINB5, a member of the human serpin peptidase inhibitor family, is a multifaceted protein regulating tumor cell homeostasis through inhibition of cell growth, motility and invasion and is also called mammary serine protease inhibitor (maspin) or protease inhibitor 5 (PI5). It was associated with gastric cancer (GC) susceptibility in this case-control association study using 502 unrelated Korean patients with GC and 406 unaffected controls. Four SNPs located in the promoter region were significantly associated with both intestinal- and diffuse-type GC, and risk and non-risk haplotypes were identified. When fused to the luciferase gene, the risk-haplotype promoter had lower activity in well-differentiated GC cell-lines but higher activity in moderately- or poorly-differentiated GC cell-lines, versus the non-risk haplotype promoter. Thus, the SERPINB5 promoter showed specificity with respect to different gastric cell lines, likely due to tissue-specific presence of active transcription factors such as AP-1, AP-2, Ets and/or p53 that is known to bind to the promoter.

Treatment with Dexamethasone Reverses Impared Elastogenesis and Collagenogenesis in Cultures of Fibroblasts from Patients with Loeys-Dietz Syndrome (LDS). *A. Hinek[1], C. P. Barnett[2], T. J. Bradley[3], D. Chitayat[2]* 1) Heart Centre, Hospital for Sick Children, Toronto, Ont, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Division of Cardiology, The Hospital for Sick Children, Toronto, Ontario, Canada.

LDS is an autosomal dominant condition caused by mutations in the *TGFBR1* and *TGFBR2* genes. It is associated with facial dysmorphism, vascular tortuosity and life threatening aortic aneurysm. Recent successful use of losartan in the Marfan mouse model has raised hope for medical treatment of LDS. Here we report a promising *in vitro* response in dexamethasone-treated cultured fibroblasts from three LDS patients. Case 1 presented with LDS features and a dilated aortic root at 2 years. DNA analysis revealed a missense mutation of *TGFBR1* (c.722C>T). Case 2 was diagnosed with a dilated aortic root requiring surgical repair at age 10. A missense mutation of *TGFBR1* (c.1460G>A) was found. Case 3 presented in the neonatal period with LDS features and a dilated aortic root. DNA analysis revealed a missense mutation of *TGFBR2* (c.1583G>A). *In vitro* studies of skin fibroblasts from these patients indicated that both patients with mutations of *TGFBR1* demonstrated a significant deficiency in the expression of elastin and fibrillin genes (RT-PCR). In contrast, they deposited normal collagen fibres. Fibroblasts derived from the patient with a *TGFBR2* mutation produced normal elastic fibers, but displayed intracellular retention of collagen type 1 and significantly lower deposition of mature collagen fibers. Addition of 10-5M of DEX to cultured fibroblasts restored normal elastogenesis in cultures of fibroblasts with mutations of *TGFBR1* gene and normalized collagen fiber production in fibroblasts carrying *TGFBR2* gene mutation. Further studies are needed to establish whether DEX can have a therapeutic effect in patients with LDS. Prenatal treatment of affected fetuses may prevent or ameliorate the clinical manifestations of this disorder.

Novel mutations in the HEXA gene and corresponding enzyme activities in non-Ashkenazi Jewish Tay-Sachs carriers. *N. Park[1], C. Morgan[2], R. Sharma[2], Y. Li[1], R. Lobo[2], J. Redman[1], D. Salazar[2], W. Sun[1], J. Neidich[2], C. Strom[1]*
1) Molecular Genetics, Quest Diagnostics, San Juan Capistrano, CA; 2) Biochemical Genetics, Quest Diagnostics, San Juan Capistrano, CA.

Tay-Sachs disease (TSD) is a progressive neurodegenerative disease inherited in an autosomal recessive fashion. It is caused by mutations in the HEXA gene in chromosome 15, which encodes an alpha subunit of the enzyme hexosaminidase A (Hex A). Absence of Hex A activity leads to lysosomal accumulation of undegraded glycolipid, particularly in the nervous system. Individuals of Ashkenazi Jewish (AJ), and non-AJ origin have approximately 1:30 and 1:300 carrier frequency for TSD, respectively. Only 3 mutations account for ~99% of TSD cases in the AJ population: c.1421+1G>C (also known as IVS12+1G>C), c.805G>A (also known as G269S), and c.1277_1278insTATC. Non-AJ TSD patients, on the other hand, have much more diverse mutations across the HEXA gene, and over 90 disease causing mutations have been identified. Therefore, Hex A enzyme analysis is the preferred method for carrier detection in non-AJ population. Here, we present results of HEXA gene DNA sequencing on 30 non-AJ TSD carriers. Our sequencing assay identified mutations in 90% of the samples, and three of these mutations are novel. We also performed sequencing on samples with a "grey zone" enzyme level, and we were able to clarify the carrier status. Our HEXA gene sequencing assay can accurately identify mutations and can be used to clarify ambiguous enzyme results in non-AJ population.

Elucidation of etiologies in complex diseases under multivariate variance component-threshold model. *A. Narita[1], K. Yasuno[1], H. Nakaoka[1], A. Tajima[1], I. Inoue[1,2]* 1) Dept. Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2) Core Research for Evolutional Science and Technology, Japan Science and Technology Agency, Kawaguchi, Saitama, Japan.

Recent remarkable progress in genome science has made it possible to use hundreds of thousands of genetic polymorphisms for genome-wide association studies, and a large number of polymorphisms have been unveiled to be associated with common complex human diseases at a rapid rate. However, as already well known, these diseases are much more likely to be attributed to quite a complicated network, in which not only the polymorphisms but also other non-genetic factors are correlated and/or interacting with each other, rather than the individual effects of these polymorphisms. The aim of the study is to propose an approach to elucidate the etiologies of the multifactorial diseases by combining the multivariate variance component (MVC) model and the threshold model. Since the MVC model treats multilocus genotypes as random effects which have a normal distribution with only two parameters, mean and standard deviation, a relatively high-dimensional interaction can be tested without substantial loss of degrees of freedom, i.e., loss of power. The threshold model, which assumes that an apparently discrete variable is determined by a normally distributed liability and threshold(s), enables both categorical data such as affection status and continuous values, such as age and body mass index, to be analyzed comprehensively as multivariate normally distributed variables. Additionally, using the Markov chain Monte Carlo, the most likely combination of causal factors for a disease is efficiently searched for and missing values can be also imputed. In the study we demonstrate the validity of the proposed method using simulated data sets, and show that it can reach the correct etiological model and also provide unbiased estimates for respective parameters. The approach will be further extended to analyze a real data set, including demographic and/or clinical information, for more reliable diagnosis and prediction of onset.

Clinical and Cytogenetic Characterization of 6 Patients with Deletion 9p Syndrome. *A. Alsaegh, AM. Innes, J. Chernos* Medical Genetics, University of Calgary, Calgary, Alberta, Canada.

We report 6 cases of del (9p) syndrome (3 males and 3 females) that were referred to the Alberta Childrens Hospital from 1996 to 2008. Patients were diagnosed by routine cytogenetic analysis (chromosome karyotype/subtelomeres) and their ages at diagnosis ranged from few days of birth to 4 years. Our patients have the following cytogenetic breakpoints (3 patients with 9p22, 2 patients with 9p24 and 1 patient with 9ptel). The Clinical phenotype in our patients is similar to previously published literature on classical 9p deletion syndrome that was first described by Alfi et al in 1973. Several malformations have been described in del (9p) syndrome, two of our patients presented with rare findings seen in this syndrome, post axial polydactyl (-9p22) and U shape complete cleft palate (-9p24). Cytogenetically, 9p deletion syndrome represents a heterogeneous condition with variable deletion size. Based on previous studies no clear genotype/phenotype correlation could be established for the various features seen in this syndrome. We observe that all our patients with the deletion share the same similar dysmorphic features, however, patients with the del (9) (p22) presented with congenital malformations including trigonocephaly, congenital heart defect, ano-rectal and genital anomalies. This syndrome was rarely suspected prior to the cytogenetic diagnosis. Patients with deletion involving 9p22 have typical dysmorphic features and recognizable congenital anomalies and diagnosis should be suspected at birth.

PKU Treatment with tetrahydrobiopterin (sapropterin) during pregnancy. *G. Pridjian[1, 2], A. Cunningham[2], S. Tafti[1], H. Andersson[2]* 1) Department of Obstetrics & Gynecology; 2) Human Genetics, Hayward Genetics Center, Tulane University School of Medicine.

Tetrahydrobiopterin (BH4) has been shown to significantly reduce the level of plasma phenylalanine (PHE) in 30-50% of PKU patients. The drug was recently FDA-approved for treatment of PKU individuals in conjunction with traditional dietary therapy. Treatment of adult phenylketonuria with BH4 (sapropterin) during pregnancy has not been systematically studied and only one case has previously been reported. In the FDA use in pregnancy ratings, BH4 is classified as Class C because no pregnant animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women.

We report a case of a 29-year old pregnant PKU patient treated with BH4 during the pregnancy. She demonstrated responsiveness to BH4 prior to becoming pregnant. In the preconception period she was counseled regarding the risks and benefits of use of this medication in pregnancy. After counseling, she elected to continue BH4 administration throughout the pregnancy. Mean plasma PHE prior to BH4 administration was 480 mcM (SD=90), substantially higher than the recommended range of 120-360 mcM; after starting BH4, plasma PHE dropped to 210 mcM (SD=36) from 10 weeks prior to pregnancy and throughout pregnancy (week 16 at the time of this abstract) without any dietary modification. The patient did experience anorrhexia and nausea of the first trimester of pregnancy and had decreased caloric intake during this period according to food diaries. Despite endogenous protein catabolism, the plasma PHE value remained normal in the first trimester. The patient has tolerated BH4 well. Second trimester targeted ultrasound has revealed no fetal anomalies or growth abnormalities. Subsequent course, PHE values, ultrasounds, and birth data will be presented.

Implications of absence of clinical phenotype on Morquio A mice: Why rodents do not require skeletal keratan sulfate? *A. Montano[1,2], M. Goldim[1], Y. Satta[2], N. Takahata[2], S. Tomatsu[1]* 1) Dept Pediatrics, St Louis Univ, St Louis, MO,USA; 2) Dept. Biosystems Science, The Graduate University for Advanced Studies (SOKENDAI), Shonan Village, Hayama, Kanagawa, Japan.

Proteoglycans are a set of ubiquitous proteins found on cell surfaces, within intracellular vesicles, and incorporated into extracellular matrices. They have covalently linked to their protein core sulfated glycosaminoglycans such as heparan sulfate, heparin, chondroitin sulfate (CS), dermatan sulfate and keratan sulfate (KS). Cartilage contains heterogeneous populations of aggregating and non-aggregating large proteoglycans relatively enriched in CS or KS. It has been shown that human and bovine cartilage proteoglycans contain skeletal KS (KSII). However, mouse and rat do not synthesize KS II at any developmental stage. The Morquio A (MPS IVA) mouse has little storage material in the cartilage and absence of clinical phenotype while human Morquio A patients have systemic bone dysplasia. To gain insight into the skeletal KS metabolism in mouse and human and to clarify why KS II is deficient in rodents, we have designed subtraction experiments to identify candidate genes involved in this process. We obtained 1363 subtracted cDNA clones. Differential gene expression screening was performed, and nearly hundred genes were found to be over-expressed in either species. Two potential candidate genes involved in KS II synthesis were identified and had homologies with glycosyltransferases. The identification of genes involved in KS II metabolism will shed lights on understanding the biological significance of this glycosaminoglycan in cartilage.

Association testing for type 2 diabetes in FIND families. *A. Malhotra[1], R. Igo[2], F. Thameem[3], W. H. L. Kao[4], H. E. Abboud[3], S. G. Adler[5], B. I. Freedman[6], S. K. Iyengar[2], P. Kimmel[7], W. C. Knowler[1], O. Kohn[8], D. Leehey[9], S. B. Nicholas[10], R. S. Parekh[4], S. S. Rich[11], J. I. Rotter[10], J. R. Sedor[2], V. Shah[12], D. Thornley-Brown[13], P. G. Zager[12], FIND Research Group* 1) NIDDK, Phoenix, AZ; 2) Case Western Reserve U, Cleveland, OH; 3) U of TX, San Antonio, TX; 4) Johns Hopkins U, Baltimore, MD; 5) Harbor-U of CA LA Med Center, Torrance, CA; 6) Wake Forest U, Winston-Salem, NC; 7) NIDDK Program Office, Bethesda, MD; 8) U of Chicago, Chicago, IL; 9) Loyola U, Chicago, IL; 10) U of CA, Los Angeles, CA; 11) U of VA, Charlottesville, VA; 12) U of NM, Albuquerque, NM; 13) U of AL, Birmingham, AL.

The Family Investigation of Nephropathy and Diabetes is a multi-center study that includes African American (AA; N=1004), American Indian (AI; N=883), European American (EA; N=537), and Mexican American (MA; N=1634) families ascertained through a proband with diabetic nephropathy (DN). Association tests for type 2 diabetes (T2D) were performed utilizing 5548 SNPs in each population, which were originally genotyped for genome-wide linkage scans. The discrete trait option in the program Quantitative Transmission Disequilibrium Test was used. In MA, $p<0.001$ was observed for five SNPs (chr6, rs412735, p=0.0009; chr10, rs7899305, p=0.0009; chr13, rs1886040, p=0.0006; chr16, rs1389504, p=0.0007; chr18, rs680798, p=0.0008). The most significant p-value in EA was seen on chr18 (rs1075470, p=0.0012), in AA on chr10 (rs749694, p=0.0011), and in AI on chr3 (rs1495704, p=0.0011). In all, 21, 26, 34, and 49 SNPs showed $p<0.01$ in EA, AA, AI, and MA, respectively. Six SNPs overlapped with regions identified in linkage scans in the same populations. Furthermore, 15 of these SNPs were identified in previously published association studies. Candidate genes include insulin-like growth factor 2 mRNA-binding protein 2 (*IGF2BP2*, chr3q28) and stromal cell-derived factor 2-like (*SDF2L1*, chr22q11.2). The current study identified several SNPs associated with T2D in families ascertained for DN. Some of these associations replicate previous studies, while others require fine-mapping to determine their potential contribution to T2D susceptibility.

Development of a high-throughput linkage analysis system and application for the linkage analysis of familial multiple system atrophy (MSA). *Y. Fukuda[1], Y. Nakahara[1], H. Date[1], Y. Takahashi[1], J. Goto[1], K. Hara[2], M. Nishizawa[2], E. Nakamura[3], H. Adachi[3], S. Tsuji[1]* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Dept Neurology, Brain Research Institute, Niigata Univ, Niigata, Japan; 3) Dynacom Co., Ltd, Kanagawa, Japan.

High-throughput linkage analysis system dealing with enormous number of SNP data has been developed to enable rapid identification of the loci for disease-associated genes. In this system, SNP chip data can be directly imported and passed to pair-wise (mlink) or multipoint (allegro) linkage analysis programs. The system provides all parameter setting functions pre-included in the original programs and various marker-selecting functions such as HWE test. Furthermore, inter-marker distance can be flexibly chosen to adopt markers not in linkage disequilibrium. The current system can analyze the data of Affymetrix Genome-Wide Human SNP array 6.0 as well as Mapping 100K array and SNP array 5.0. Using this system we have conducted linkage analysis of multiple system atrophy (MSA) including seventeen individuals of six families genotyped by SNP array 6.0. All of the affected patients are sibling cases with more than one affected siblings. There are consanguineous marriages in the two families and affected patients are present in the upper generations in one family. Parametric multipoint analysis (autosomal recessive model) showed four loci with HLOD of 1.5 while nonparametric multipoint analysis showed six loci with NPL score of 2.0 and two loci of them were consistent with those found by parametric analysis. Highest HLOD and NPL of 2.22 and 2.63, respectively, were found in different genomic loci. These results raise the possibility of genetic heterogeneities of MSA, necessitating further accumulation of data to get more reliable results. Pair-wised linkage analysis employing 0.53 million SNPs was smoothly conducted by conventional PC within four hours. For multipoint analysis, process took less than 30minutes when inter-marker distances were set to 100kb. This system can be widely applied for linkage analysis using microarray-based SNP data and there one can expect high-throughput and reliable linkage analysis.

An integrated analysis workflow for high-throughput analysis of copy number variation for discovery and clinical diagnostics. *X. Gai, J. C. Perin, H. Xie, J. T. Glessner, S. F. A. Grant, H. Hakonarson, E. F. Rappaport, T. H. Shaikh, P. S. White* The Children's Hospital of Philadelphia, Philadelphia, PA.

Recent evidence suggests that genome copy number variations (CNVs) are associated with a substantial portion of inherited and acquired risk for various human diseases. The increasing availability of high-resolution genome surveillance platforms provides opportunity for rapidly assessing research and clinical samples for CNV content. To facilitate this process, we have developed a suite of software tools and resources (CHOPPY) that allows automated genome-wide CNV detection from genotyping data with high resolution and accuracy. A variety of array platforms are accommodated, including all recent Illumina and Affymetrix formats. CHOPPY is designed for high-throughput and large-scale copy number analysis using both signal intensity and allelic ratio values as input. CNVs as small as 2 SNPs can be reliably detected with a high experimental validation rate. The CHOPPY web interface is integrated with a local installation of the UCSC Genome Browser. Detected CNVs are stored in a relational database and presented either as a UCSC annotation track or in a tabular format for a given sample or cohort. The presentation layer also provides contextual genomic annotations for each CNV, including gene content, known disease loci, gene-based literature references, graphical and browsable genome representation, and prior CNV content from both the Database of Genomic Variants and the CHOP CNV Map of over 54,000 CNVs. This platform has been utilized for several disease-focused CNV surveys and has been implemented as the front-line system for assessing all clinical genetic samples received at the Hospital. In validation, CHOPPY independently identified pathogenic CNVs for 153 of 156 patients with known or suspected genomic disorders. CHOPPY represents a cohesive and convenient platform for detection, annotation, and assessment of the biological and clinical significance of human CNVs.

Incidence of vertebral fracture is associated with IL1 and IL6 polymorphisms in a large case-control sample selected from Study of Osteoporotic Fractures (SOF). *N. Aziz[1], H.-Y. Wang[1], K. Kornman[1], J. Zmuda[2], L.-Y. Liu[3], K. Stone[3]* 1) Interleukin Genetics, Waltham, MA; 2) Department of Epidemiology, University of Pittsburgh, Pittsburgh, PA; 3) Research Institute, California Pacific Medical Center, San Francisco, CA.

Vertebral fractures (VF) are a common clinical manifestation of osteoporosis which often lead to back pain, disabilities, kyphosis and subsequent fractures. Although the lifetime risk of developing a VF varies among women, relatively little is known about the genetic basis of this variability. We conducted a case-control study to test whether increased risk of VF are associated with certain alleles of the Interleukin1A (IL1A), Interleukin1B (IL1B), Interleukin1RN (IL1RN) and Interleukin6 (IL6) genes. The molecular basis of how some of these SNPs affect the IL1 gene activity have been previously investigated and may be related to the chronic hyper-inflammatory state thought to be an underlying causative factor in osteoporosis. 2527 Caucasian women (65 years) from the SOF cohort who reported never using estrogen replacement therapy were selected. Cases were defined by the presence of either prevalent VF (PVF) assessed at baseline or an incident VF (IVF) after an average of 3.7 years of follow-up. Controls were randomly selected from participants without either PVF or IVF. Logistic regression models were used to test the association between SNPs and VF, after adjustment for age and BMI. SNPs within the IL1B(rs16944), IL1A(rs17561), IL1RN(rs419598) and IL6(rs1800795) genes were strongly associated [OR ranging from 1.39-4.64, ($p<0.05$)] with IVF and/or PVF. These genetic biomarkers could be useful in the medical management of osteoporosis by identifying individuals at high risk of VF, so that preventative therapies can be administered. In addition, these markers could also be utilized as a selection tool in enriching for patients predisposed for the incidence of VF in clinical trials of investigational drugs.

Proteomic analysis to identify candidate genes influencing high-density lipoprotein particle size in obese individuals. *L. A. Collins[1], S. P. Mirza[1], T. Mersha[1], L. Martin[2], A. H. Kissebah[1], M. Olivier[1]* 1) Medical College of Wisconsin, Milwaukee, WI; 2) Children's Hospital, Cincinnati, OH.

Obesity is associated with a significant risk for cardiovascular co-morbidities, primarily mediated by a preponderance of small, dense high-density lipoprotein (HDL_3) particles which exhibit potentially pro-atherogenic capabilities. HDL_3 particles in obese individuals appear to be functionally defective as they lack their potent anti-oxidative and anti-inflammatory properties. In our Metabolic Risk Complications of Obesity Genes (MRC-OB) study, we analyzed the lipoprotein particle profile in 532 individuals from our cohort, and identified a quantitative trait locus for HDL median particle diameter on human chromosome 12p13 (LOD = 3.15). The interval contains 144 annotated genes, none of which have a known role in lipid or lipoprotein metabolism.

We isolated HDL fractions from human serum samples of obese and lean sibling pairs from our cohort using non-denaturing fast protein liquid chromatography. Proteins were isolated from HDL particles by chloroform extraction and quantified using isotopic labeling and tandem mass spectrometry. Our analysis identified six proteins significantly altered in obese individuals with small median HDL diameter (APOA2, C3, C4A, GC, HP, TTR). Using Ingenuity Pathway and Gene Ontology Enrichment analyses, we identified five genes (C1S, VWF, C1RL, CD163, PTPN6) in the QTL interval on chromosome 12 correlated to the altered proteins. We analyzed 35 SNPs spanning the von Willebrand factor (VWF) gene and detected significant association with HDL median particle diameter for four SNPs ($p = 0.004$-0.045). One of these SNPs, rs216321, alters the amino acid sequence (Arg852Gln) of the protein. Further studies will determine the functional mechanism by which VWF influences HDL particle size in obese individuals.

GSNO Reductase and $_2$ Adrenergic Receptor Gene-gene Interaction: Bronchodilator Responsiveness to Albuterol. *S. Choudhry[1], Z. Yang[2], L. Liu[1], C. Eng[1], S. O. Kim[3], G. Kumar[1], S. Thyne[1], R. Chapela[4], K. Meade[5], H. G. Watson[6], M. LeNoir[7], J. R. Rodriguez-Santana[8], W. Rodriguez-Cintron[9], P. C. Avila[10], J. S. Stamler[2], E. G. Burchard[1], L. G. Que[2]* 1) University of California, San Francisco; 2) Duke University, Durham; 3) Taeyeon Medical CO. LTD, Republic of Korea; 4) INER, Mexico; 5) CHORI, Oakland; 6) The James A. Watson Wellness Center, Oakland; 7) Bay Area Pediatrics, Oakland; 8) CSP, San Juan; 9) Veterans Caribbean Health Care System, San Juan; 10) Northwestern University, Chicago.

Short-acting inhaled $_2$-agonists such as albuterol are the mainstay of asthma treatment worldwide. There is significant variation in bronchodilator responsiveness to albuterol not only between individuals but also across racial/ethnic groups. $_2$ adrenergic receptor ($_2$AR) is the target for $_2$-agonist drugs used for bronchodilation in asthma. Recently, S-nitrosoglutathione reductase (GSNOR) has been shown to regulate endogenous bronchodilator tone. We hypothesized that variation in response to albuterol could be partly due to pharmacogenetic interactions between GSNOR and $_2$AR genes. We performed family based and cross-sectional analyses to test for association between GSNOR gene variants and asthma and related phenotypes in 684 Puerto Rican and Mexican families with asthma and 440 African American asthma cases and controls. We also tested these subjects for pharmacogenetic interaction between GSNOR and $_2$AR gene variants and response to albuterol. To test the potential effect of the GSNOR gene variants, mRNA secondary structure analyses and cell transfection experiments were performed. Among Puerto Ricans, several GSNOR SNPs and a haplotype were significantly associated with asthma and responsiveness to albuterol ($p = 0.04$ to 0.008). The GSNOR 3UTR risk haplotype affects mRNA secondary structure and luciferase reporter expression. Furthermore, GSNOR-$_2$AR interaction analysis provided strong evidence of association with responsiveness to albuterol in both Mexican and Puerto Rican (Latino) asthmatics ($p_{combined} = 0.001$). We conclude that genotyping of GSNOR and $_2$AR genes may be a useful approach for identifying subjects that might benefit from adjuvant therapy for refractory asthma.

Sixteen-year Review of the Results of Chromosomal Analysis at the Cytogenetics Laboratory of the Institute of Human Genetics, National Institutes of Health Philippines. *C. D. Padilla[1,2], N. S. Cadag[1], M. D. Chiong[1,2], E. M. C. Cutiongco[1,2]* 1) Institute of Human Genetics, National Institutes of Health Philippines, Manila, Philippines; 2) Department of Pediatrics, College of Medicine-Philippine General Hospital, University of the Philippines Manila.

The field of human cytogenetics is an increasingly important area of medicine as it has helped elucidate the etiology of many congenital malformation/mental retardation syndromes and various chromosomal abnormalities which constitute a substantial proportion of human morbidity and mortality. This paper presents a 16- year review of the results of the chromosomal analysis done at the Cytogenetics Laboratory of the Medical Genetics Unit, College of Medicine and the Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila. Results of the chromosomal analysis done on peripheral blood samples from the period of July 1991-December 2007 were retrospectively reviewed. Among the clinical indications for cytogenetic analysis were congenital anomalies, mental retardation, disorders of sex differentiation, infertility or recurrent miscarriages, hematologic malignancies and other cancers, prenatal diagnosis and exposure to radiation and toxic chemicals. Chromosomal analysis was limited to G-banding techniques and evaluation of gross numerical and structural appearance of the chromosomes. Out of 10,857 peripheral blood samples that were analyzed, 30.3% (3,293 of 10,857) had abnormal results. The major type of chromosomal aberrations seen were numerical chromosome abnormalities which accounted for 67% of the cases, of which Trisomy 21 was the most predominant of the aneuploidies reported. Sex chromosome abnormalities were the second most common chromosomal abnormalities seen with Turner Syndrome accounting for 82.6% of the cases. Different types of structural chromosome abnormalities were observed in 11.1% of all chromosomal abnormalities.

The GATA2 transcription factor gene - promoter haplotypes and preliminary association with neuropsychiatric phenotypes. *M. A. Kennedy[1], M. V. Bland[1], R. L. Roberts[1], P. C. McHugh[1], K. J. Light[2], A. L. Miller[1], P. R. Joyce[2]* 1) Department of Pathology, University of Otago, Christchurch, New Zealand; 2) Department of Psychological Medicine, University of Otago, Christchurch, P.O. Box 4345, Christchurch, New Zealand.

The central serotonergic (5-HT) neurotransmitter system is consistently implicated in mood disorders and anxiety, as well as behavioural phenotypes such as neuroticism or harm avoidance. We are exploring the hypothesis that genetic variability which may impact on the development and architecture of the 5-HT system may also be a contributing factor to relevant neuropsychiatric phenotypes. The transcription factor GATA2 plays a key role in controlling 5-HT differentiation of neuronal precursor cells. We surveyed the coding, splice junctions, 5UTR and core promoter regions of the GATA2 gene for common variants. Eight common variants were discovered in the promoter region including a 4bp indel. These variants formed six distinct haplotypes, four of which were found to be relatively common in the population (5%). Reporter gene assays in COS-7 and the rat 5-HT cell line RN46A demonstrated marked differences in basal expression between the common haplotypes. We then carried out a genetic association study in a large family-based study of depression, for whom we also had personality measures (TCI). PCR and SNaPshot assays were used for genotyping. One haplotype (containing the 4bp deletion) was significantly associated with risk of major depression (chi-square = 6.721, P = 0.0096) with a three to four-fold (95% CI 2.24 - 5.77) increased relative risk. In addition, this haplotype was associated with higher harm avoidance, when gender was included as a modifier (chi-square= 8.497, P= 0.004), with a 14% (95% CI 11% - 16%) increase in score compared to all other common haplotypes. Identification of these GATA2 promoter variants and demonstration of functional effects suggest that this gene should be considered a candidate in phenotypes linked to 5-HT dysfunction. Our preliminary association studies suggest a possible link to risk of depression and harm avoidance, although these findings require replication.

INADL and MYT1L are associated with risk for anencephaly. *C. F. Potocky[1], N. Ellis[1], A. Trott[1], C. S. Haynes[1], D. G. Siegel[1], H. Cope[1], K. Soldano[1], D. S. Stamm[2], A. Dellinger[1], P. Xu[1], T. M. George[3], S. G. Gregory[1], A. E. Ashley-Koch[1]* 1) Center for Human Genetics, Duke Medical Center, Durham, NC; 2) University of California, Davis School of Medicine, Sacramento, CA; 3) Dell Children's Medical Center of Central Texas, Austin, TX.

We previously identified INADL and MYT1L as novel candidate genes for anencephaly by a genome wide association study (GWAS) (Stamm et al., 2007) and differential expression in fetal neuronal longSAGE libraries (Xu et al., 2007). InaDL (inactivation no afterpotential D-like) helps control epithelial migration (Shin et al. 2007) and is critical in establishing cell polarity (Michel et al. 2005; Li et al. 2004). Myt1L (myelin transcription factor 1-like) is a zinc finger DNA binding protein. Both Myt1 and Myt1L are found in neurons at early stages of differentiation (Bellefroid et al. 1996; Jiang et al 1996; Kim et al. 1997; Weiner and Chun 1997; Yee and Yu 1998). Here we report fine mapping of these genes in an expanded dataset. The initial GWAS dataset contained 45 anencephaly families and 5 families with other cranial neural tube defects (NTDs). The follow-up data set was comprised of 86 anencephalic families and 22 families with other cranial NTDs, inclusive of the GWAS families. Three affection models were considered for analysis: anencephaly only, all cranial NTDs, and any NTD regardless of lesion location. These phenotypes were analyzed for association with 26 SNPs over a 400kb region including INADL and 26 SNPs over a 550kb region including MYT1L using APL and hAPL. Two nonsynonymous coding SNPs within INADL were significantly associated (rs1056513 and rs1134767, APL $p<0.01$ for both SNPs in all 3 models). One of these coding SNPs, rs1134767, creates a highly significant haplotype with rs6697273, the INADL SNP originally identified in the GWAS (hAPL $p<0.001$ for all 3 models). Association was also confirmed in MYT1L with rs12470297 showing significant association, particularly in the anencephaly subset (APL $p=0.0007$). In conclusion, fine mapping confirmed INADL and MYT1L are associated with risk for NTDs and identified two nonsynonymous coding SNPs with significant association to cranial NTDs.

Comparison of genome-wide recombination intensity from pedigree/linkage data to population recombination rates estimated from SNP genotype data in the European-American population. *X. Wang[1], J. Li[2], S. Buyske[3], T. Matise[3], A. Clark[1]* 1) Cornell University, Ithaca, NY; 2) University of Missouri-Kansas City, Kansas City, MO; 3) Rutgers University, Piscataway, NJ.

We estimated genome-wide local recombination intensity by local regression on the most comprehensive Rutgers human linkage map with 28,121 polymorphic markers and more than 1000 informative meioses. The bandwidth, local polynomial degree and weight function parameters were optimized by minimizing the local likelihood among a grid of parameters for each chromosome arm. For the genome-wide population recombination rate, we used the Illumina 317k SNP data of the 1000 control samples of the PARC study. Through a large number of simulations, we found that the widely used composite likelihood method for estimating population recombination rate (implemented in LDhat program) is sensitive to population demographic history, MAF filtering and tagging SNP selection. The population recombination rate was estimated in sliding windows spanning the genome using a window size of 40kb and an increment of 20kb, correcting for demographic history, MAF ascertainment bias, and tagging SNP selection effects based on the simulation studies. The population recombination rate was then compared with the recombination intensity from deCODE map and the Rutgers genetic map, with the matched band width parameter. The gross impression is a good correspondence between the two maps, however there are locally discrepant regions. One source for the discrepancies could be the inaccuracy of estimation caused by locally low marker density. Because the population recombination rate is defined as $=4N_e r$, where N_e is the effective population size and r is the recombination rate, natural selection could reduce N_e locally and distort the estimate of . In addition, recombination intensity represents a snapshot of the recombination rate at the present time, whereas the population recombination rate integrates the recombination rate over recent ancestral history of the sample. From the comparison of these recombination estimates, we can also make much more accurate inference about local N_e and genome average N_e than other existing methods.

Genome Wide Association Studies in Prospective, Community-Based Cohorts: the CHARGE (Cohorts for Heart and Aging Research in Genomic Epidemiology) Consortium. *C. J. O'Donnell[1,6], E. Boerwinkle[2,6], V. Gudnason[3,6], A. Hofman[4,6], B. M. Psaty[5,6]* 1) NHLBI's Framingham Heart Study, Framingham MA; 2) University of Texas Health Science Center, Houston TX; 3) University of Iceland, Reykjavik, Iceland and National Institutes of Aging, Bethesda MD; 4) Erasmus Medical Center, Rotterdam, Thethe Netherlands; 5) University of Washington, Seattle WA; 6) On behalf of the CHARGE Consortium.

Introduction: Recently, meta-analysis of findings from multiple genome-wide association studies (GWAS) have been used to discover many novel genetic variants with strong evidence for replication for common diseases. GWAS in large, prospective community-based cohorts offer a unique opportunity to discover genetic determinants of multiple well-characterized disease traits, using strategies such as longitudinal analyses for quantitative traits and time-dependent analyses for outcome measures. Methods and Results: We formed an international consortium of prospective, community based cohorts with >38,000 white participants: the Age, Gene/Environment Susceptibility Study, Atherosclerosis Risk in Community Study, Cardiovascular Health Study, Framingham Heart Study and Rotterdam Study. Hundreds of similarly measured qualitative and quantitative phenotypes in persons free of disease are used, including cardiovascular disease (CVD) risk factors, blood biomarkers, electrocardiography, and coronary artery atherosclerosis; as well as aging and CVD endpoints, such as myocardial infarction and stroke, occurring years after collection of DNA. Over twenty CHARGE Phenotype Working Groups adopted principles of collaboration/authorship and statistical analysis strategies to design and analyze GWAS. Genotyping platforms differed among the studies, so imputation methods were used to create a common set of ~2.5 million HapMap SNPs (Release 22, Build 26, CEU) for meta-analyses, scheduled to proceed during the summer and fall of 2008. Conclusion: The international CHARGE Consortium will provide GWAS data from >38,000 participants in five cohorts for multiple CVD and aging phenotypes. Genetic variants with strong evidence of replication in CHARGE will warrant further follow up.

Comparison of family-based association analysis methods for SNP-haplotypes in nuclear families and extended kindred. *M. Govil, T. Goldstein McHenry, M. L. Marazita* Center for Craniofacial and Dental Genetics, University of Pittsburgh, PA.

Many methods now exist for conducting family-based haplotype association analyses of SNP genotypic data, each with a different software package for implementation of the method. The issue that plagues most users is which of the methods/software would be most appropriate for their study design and desired analyses. If more than one method/software can be used for the desired analyses, but differences are seen in the results, which result should be chosen? In our analyses of the genetics of craniofacial birth defects in extended kindred from multiple populations, we found orders-of-magnitude differences in the results from HBAT and UNPHASED -- two commonly used family-based haplotype association analysis methods -- and decided to investigate the causes behind these differences. We selected three methods/software for comparison: the haplotype version of FBAT (HBAT), UNPHASED, and MENDEL. Both HBAT and UNPHASED compute a conditional likelihood, although via different algorithms: EM for HBAT and either DFP or Nelder-Mead for UNPHASED. HBAT computes an empirical estimate of the variance which allows one to account for correlation between nuclear sub-families. Using allele combining options along with the gamete competition model allows computation of haplotype association via MENDEL. We selected extended kindred, nuclear families and trios as the data for our comparisons, with moving windows of 2-5 SNPs across 26 total SNPs. Our tests show a difference between results from HBAT and UNPHASED even for the trios. The HBAT results were more comparable to MENDEL than were the UNPHASED results. While further testing and simulations are necessary to fully understand the reasons behind the observed differences in results, clearly a cautionary note is necessary when a genetic study design includes haplotype association analyses. Whole blood genome-wide gene expression in the KORA population. *D. D. Mehta[1], K. Heim[1], T. Illig[2], H. E. Wichmann[2,4], T. Meitinger[1,3], H. Prokisch[1,3]* 1) Institut für Humangenetik Helmholtz Zentrum München, Deutsches Forschungszentrum für Gesundheit und Umwelt Ingolstädter Landstr. 1 85764 Neuherberg Germany; 2) Institut für Epidemiologie Helmholtz Zentrum München, Deutsches Forschungszentrum für Gesundheit und Umwelt Ingolstädter Landstr. 1 85764 Neuherberg Germany; 3) Institut für Humangenetik Technische Universität Klinikum Rechts der Isar Trogerstr. 32 81675 München Germany; 4) Institute of Medical Informatics,Biometry and Epidemiology, LMU, Munich, Germany.

We have setup a large resource consisting of 350 whole blood genome-wide gene expression data and 300 LCLs from the KORA population. Normal variation in gene expression was assessed using the Illumina Human Ref6v2 whole genome microarray. Our large gene expression resource can be useful in several aspects 1) Several significant age-related genes and gender-specific gene signatures were identified. Using the PAM algorithm, it was possible to predict the gender with an accuracy of 95%. Numerous gene expression profiles correlated with metabolites such as high density lipoproteins. 2) Using KORA Affymetrix 500k genotypes, we performed a genome-wide association study to compare blood eQTLs to published LCL eQTLs. 3) Expression data can be used to test for functional SNPs. In this context, a recent genome wide association study using the KORA population found the most significant SNPs associated with urate levels mapped within an uncharacterized carrier gene SLC2A9. We carried out an isoform-specific gene expression analysis, revealing a significant association between SLC2A9 isoform 2 expression and urate levels (Doering et al, Nature Genetics 2008). 4) We used our expression resource in a candidate approach to test for previously described associations at the transcript level. Our data adds resolution to genome-wide association studies and extends the current limited knowledge of whole blood genome-wide gene expression in the general population. References SLC2A9 influences uric acid concentrations with pronounced sex-specific effects : Angela Doring, Christian Gieger, Divya Mehta, Henning Gohlke, Holger Prokisch et al, Nature Genetics 2008.

Lipin-1 Genetic Variation May Influence Liver Function and Inflammation in Hispanic Americans. *M. O. Goodarzi[1], X. Guo[1], Y. I. Chen[1], B. Fang[1], A. Xiang[2], K. D. Taylor[1], T. Buchanan[2], L. J. Raffel[1], J. I. Rotter[1]* 1) Cedars-Sinai Med Ctr, Los Angeles, CA; 2) USC, Los Angeles, CA.

Lipin-1 influences adipogenesis and insulin sensitivity in adipose tissue and the liver. It was initially identified as the locus responsible for the fatty liver dystrophy (*fld*) mouse, which is characterized by absence of adipose tissue depots throughout the body, transient neonatal fatty liver, and peripheral neuropathy. As a key factor in adipogenesis, human adipose lipin-1 mRNA levels are inversely correlated with whole-body insulin resistance, suggesting that by moving fat into adipose tissue, lipin-1 maintains insulin sensitivity by preventing fatty infiltration of liver and skeletal muscle. Furthermore, lipin-1 mRNA levels have been found to be inversely correlated with adipose tissue expression of inflammatory cytokines. Thus, we performed a pilot study to determine whether variants in the gene for lipin-1 (LPIN1) were associated with the liver enzyme gamma glutamyl transferase (GGT, a marker for fatty liver) or inflammatory markers (C-reactive protein, serum tumor necrosis factor (TNF) receptor 1 (TNFR1) and receptor 2 (TNFR2)). The study cohort consisted of 618 non-diabetic offspring from 160 Hispanic-American families ascertained through a proband with hypertension. Two SNPs on opposite ends of the LPIN1 gene were genotyped, haplotypes constructed, and tested for association using generalized estimating equations (GEE1) to account for familial correlation, adjusting for age, sex, and BMI. Haplotype 1 (most common haplotype) was associated with an increase in GGT (haplotype carriers 31.71.1 vs non-carriers 29.85.1 U/L, p=0.026). SNP rs11524 was associated with decreased TNFR1 (1.770.035 vs 1.830.020 ng/mL, dominant model, p=0.029). Haplotype 2, which carries rs11524, exhibited the same association. The functional significance of these variants is unclear and will require fine-mapping; however, computational modeling suggests that rs11524 alters an exonic splicing silencer sequence (Ong KL, et al. Am J Hypertens 2008;21:539-45). Consistent with predictions based on the biology of lipin-1, variants in the LPIN1 gene may modulate liver function and inflammation.

Haplotype Differentiation in Chromosomes 21 and 22 among the Korean and International HapMap populations. *C.-H. Yi[1,2], M.-H. Kim[1], E. J. Kang[1], H. G. Kim[1], H. J. Kang[1], S. K. Lee[1], J.-A. Pyun[1], S. S. Won[1], K.-Y. Kim[1], J.-G. Kim[1], K.-D. Lee[1], H.-J. Song[1], A.-R. Oh[1], J.-H. Chung[3], K. B. Kwack[1]* 1) Medical Genomics Laboratory, CHA Research Institute, Pochon CHA University, Seongnam, Kyunggido 463-836, Republic of Korea tel:+82-31-725-8376; 2) Institute of Environment and Ecology, 1, Anamdong 5-ga, Sungbuk-gu, Seoul136-701, Republic of Korea; 3) Kohwang Medical Institute, School of Medicine, Kyung Hee University, Seoul 130-701, Republic of Korea.

A Korean sample (KOR) has been genotyped so as to perform systematic comparison with Japanese (JPT), Northern Chinese (CHB), Caucasians (CEU), and Africans (YRI) sampled for the International HapMap Project. As the three Northeast-Asian populations share a considerable human genetic ancestry, the genetic similarity of the Koreans either to Japanese or to Chinese varied between both chromosomes, a sign of fine-scale genetic differentiation and different population history on different chromosomal regions. With the same single nucleotide polymorphism (SNP) markers (1370 and 1866 SNPs on chromosome 21 and 22, respectively) in Illumina Human 1, 153 and 230 haplotype blocks were delimited in Koreans for chromosomes 21 and 22, respectively. The total numbers of haplotype blocks in Koreans, Japanese and Northern Chinese varied between the smallest from Africans and the greatest from Caucasians. Haplotype patterns in combined samples like KOR+JPT, KOR+CHB, KOR+JPT+CHB showed variable numbers of haplotype blocks. Twenty-six chromosomal regions containing long-range haplotypes in reference to the Korean population were selected and analyzed further. Population-wise long-range haplotype blocks could be mapped out. The typically expected pattern, the Northeast-Asian triplet (KOR-JPT-CHB) in contrast to Caucasians (CEU) and Africans (YRI), came out slightly more than half of the cases compared, while variable pairing and tripling patterns had been observed. The fine-scale differentiation among KOR, JPT and CHB backs up the needs for systematic sampling and genotyping of a greater number of ethnic groups in the Northeast Asia.

Duplications in the 17p13.3 Miller-Dieker syndrome region: Increased expression of *LIS1* affects human and mouse brain development. *W. Bi[1], T. Sapir[3], O. A. Shchelochkov[1,2], F. Zhang[1], M. Withers[1], J. V. Hunter[2], T. Levy[3], V. Shinder[4], D. A. Peiffer[5], K. L. Gunderson[5], X. Lu[1], T. Sahoo[1], Y. Yanagawa[6], A. L. Beaudet[1,2], S. W. Cheung[1], S. Martinez[7], J. R. Lupski[1,2], O. Reiner[3]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Texas Children's Hospital, Houston, TX; 3) Dept. Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel; 4) Dept. Chemical Research Support, The Weizmann Institute of Science, Rehovot, Israel; 5) Illumina, Inc., San Diego, CA; 6) Dept. of Genetic and Behavioral Neuroscience, Gunma University Graduate School of Medicine, Maebashi, Japan; 7) Instituto de Neurociencias, UMH-CSIC, San Juan de Alicante, Alicante, Spain.

Deletions of the *LIS1* gene in human chromosome 17p13.3 result in isolated lissencephaly sequence and the extended deletions including the *14-3-3* gene cause Miller-Dieker syndrome (MDS). By array CGH we identified seven unrelated cases with duplication ranging from 240 kb to 3.6 Mb in 17p13.3 involving the *LIS1* and/or the *14-3-3* genes. Duplications in three cases are complex and may represent the autosomal rearrangements generated by the DNA replication FoSTeS mechanism. Real-time RT-PCR showed that the expression levels of the *LIS1*, *14-3-3*, and *CRK* genes were increased when these genes are duplicated. Using a forward genomics approach we characterized the clinical consequences of duplications. Increased *LIS1* dosage causes smaller brains, mild brain structural abnormalities, moderate to severe developmental delay, and failure to thrive. Duplication of *14-3-3* and surrounding genes increases the risk for macrosomia, mild developmental delay, pervasive developmental disorder, and results in shared facial dysmorphologies. Transgenic mice conditionally over-expressing LIS1 in the developing brain exhibited a decrease in brain size, an increase in apoptotic cells, and a distorted cellular organization in the ventricular zone including reduced cellular polarity. Collectively, our results show that an increase in LIS1 expression in the developing brain results in smaller brains and neuronal migration abnormalities in mice and human patients.

Alpha sarcoglycan gene is down-regulated by Sox9 in a TGF -dependent process during myogenesis. *J. M. Hernández Hernández[1], P. Delgado Olguín[1,2], V. Aguillón[1], M. Furlan Magaril[2], F. Recillas Targa[2], R. M. Coral Vázquez[1]* 1) UIM en Genética Humana,CMNS XXI-IMSS. Av. Cuauhtémoc 330 México DF 06725; 2) Genética Molecular, Instituto de Fisiología Celular UNAM, México DF.

The sarcoglycan sarcospan complex is composed of the transmembranal proteins , , , , SG's as well as sspn. Mutations in , , , SG cause autosomal recessive limb girdle muscular dystrophies. SG is expressed exclusively in striated muscle during myogenesis, which can be explained by multiple cis regulatory elements on their promoter region. Recently, our group has demonstrated the interaction of MyoD with the transcription factors TFIIB and TFIID in the SG promoter region to upregulate the expression of this gene. In order to know the mechanisms involved in their negative regulation, we analyzed the sox9 participation through analysis of a reporter activity driven by SG promoter in C2C12 cells cotransfected with sox9. Interestingly, the promoter was down regulated 80% in myoblasts, but not in myotubes where the endogenous sox9 protein is undetectable. We analyzed the endogenous SG mRNA level in a stable line that overexpress Sox9. The transcript was reduced 60% with respect to wild type cells, as well as the protein. To analyze the functionality of the sox elements, we carried on EMSA assays by using both nuclear extracts of myoblasts and transcription-translation extracts of sox9, and we identified complexes which were super-shifted with a specific antibody against sox9. ChIP assays showed, in myoblasts but not in myotubes, the interaction of both sox9 and p-smad3 with the three elements of the promoter. These data suggest a model where TGF modulates the repression effect of sox9 and smad3 on the SG promoter. In agreement with this, TGF increased dramatically the promoter repression induced by these transcription factors. Interestingly, the activity was recovered by the addition of a specific inhibitor of the TRI. Our results show that the repression exerted by Sox9 and smad3 on the promoter is sensible to TGF . This is the first demonstration that sox9 can directly bind to some specific DNA elements to negative regulate a muscle specific gene during myogenesis.

SNP based copy number microarrays provide cues to UPD, and recessive allele risk due to inbreeding. *P. Papenhausen, J. Tepperberg, I. Gadi* Dept Cytogenetics, Labcorp America, Res Triangle Park, NC.

SNP based chromosome microarrays can provide an extremely high density whole genome analysis of copy number variation in the clinical analysis of blood from children with developmental delay. We have studied about 2,000 cases this year using both the Affymetix 500k and 1.8 million SNP/copy number chips. The allele differentiation that the array provides allows designation of the relative distribution of homozygosity (HZ)(or loss of heterozygosity) thoughout the genome, in addition to copy number. We expected that long contiguous stretches of HZ(LCSHZ) >25Mb in a single chromosome would correlate with UPD based on the almost 2/3 of our reported 35 cases of UPD that showed regions of both hetero and iso UPD using limited numbers of microsatellites. The added significance of HZ determinations was not fully appreciated until the following cases were noted (it is important to understand that contiguous HZ over 5Mb is rarely observed in these studies): a 3yo showed 27 LCSHZ's (>10Mb) on 20 chrs, a 5yo had 8 LCSHZ's on 7 chrs, a 2yo had 10 LCSHZ on 8 chrs, a 12yo showed 12 LCSHZ's on 11 chrs, a 10yo had 11 LCSHZ's on 11 chrs and a 32yo had 9 LCSHZ's on 7 chrs. All cases proved to represent consanguinity with the first case a product of a brother-sister pairing. Additional probands from second cousin pairings showed smaller blocks with fewer chromosomes involved, as what might be expected from multi-generation recombination and dilution of consanguinous chromosomes. A separate pattern of cases showed greatly increased homozygosity, but without contiguous stretches. These cases appeared to represent geographical or ethnic isolates with limited outbreeding. It will be important to determine the LCSHZ boundaries for levels of consanguinity and a reasonable means of reporting these findings which have implications for recessive allele risk. Patterns of homozygosity with possible threshold ranges and UPD examples will be presented. Although LCSHZ in a single chromosome correlates with UPD, confirmation in an imprinted chromosome through paternal microsatellite exclusion or direct methylation specific testing is highly recommended.

Clinical testing for mutations in the *PAX2* gene and diagnosis of renal coloboma syndrome. *M. Bower[1], C. Xu[2], R. Peterson[2], L. Schimmenti[1], X. Wang[1,2]* 1) Genetics and Metabolism, University of Minnesota Medical Center, Fairview, Minneapolis, MN; 2) Laboratory Medicine and Pathology, University of Minnesota Medical Center, Fairview, Minneapolis, MN.

Renal coloboma syndrome (RCS) is an autosomal dominant disorder characterized by ocular and renal malformations. Mutations in the paired-box gene, *PAX2*, have been associated with RCS. Our laboratory developed the first clinical testing service for *PAX2* mutations in 2007. Testing involves bi-directional sequencing of all 12 coding exons of the *PAX2* gene and adjoining intronic sequences. To date, we have completed 30 cases representing 26 unique families. Mutations in the *PAX2* gene were identified in 7/26 probands. Mutations were not identified in any of the 11 probands with atypical findings, such as iris coloboma. Consistent with prior observations, the majority (6/7) of the mutations identified in this sample were frameshift mutations that would be expected to result in a truncated PAX2 protein. Three of the mutations identified in our laboratory are novel mutations (c.250 G>A, c.836delG and c.894delTinsGC). Additional findings in mutation positive individuals included short stature, elevated pancreatic amylase, and hearing loss. One mutation positive proband with renal insufficiency and optic nerve colobomas had a pregnancy with a prenatal diagnosis of bilateral renal agenesis. Of the seven mutation positive cases, five occurred in the absence of any family history, suggestive of a de novo origin for the mutation. In one case, the proband had an affected parent and multiple affected siblings. In the remaining case, the familial mutation was present in two affected siblings and absent in their father, who had bilateral abnormalities of the optic nerve. This latter case suggested the possibility of somatic mosaicism. In summary, mutations were found in approximately half of cases with classic findings for RCS. The majority of *PAX2* mutations appear to be de novo. There is evidence that mosaicism, both germline and somatic, may not be uncommon in RCS. The possibility of somatic mosaicism should be strongly considered in mutation negative cases with suggestive clinical findings.

Genetic counselors in Japan: A five-year experience. *C. Tamura* Genetic Counseling Graduate Program, Ochanomizu University, Tokyo, Japan.

Over the last several years, there has been some change in genetic counseling system in Japan. Genetic counseling has been conducted for more than thirty years by physicians. However, recently, some graduate programs have established to train non-MD genetic counselors. Japanese Board of Genetic Counseling was established in 2005 as the joint effort of two genetics societies, and certification examination was started following the accreditation of genetic counseling training programs. Until 2008, eight graduate programs have been accredited, and seventeen people were certified as genetic counselors; twelve were graduates from Japanese training programs and other five were people who had had equivalent training in some different ways. There have been some issues with these certified genetic counselors, which needs to be solved for the future. One of the critical problems is employment. It has been difficult for genetic counselors to find a job and the income is extremely low. The government and genetics societies have published some guidelines which stated that one of the major roles of clinical geneticists is genetic counseling provision, and so, the role of genetic counselors is not clear, as they tend to play an assistant role. Therefore, it has been difficult to determine the educational goal to train genetic counselors. Furthermore, it has been believed that there is a Japanese specific genetic counseling model, and this has caused confusion among genetic counselors. In Japan, prenatal testing has not been recommended, since termination of pregnancy because of fetal problems is theoretically illegal, though it is practically available under parents economical reasons. Clinical geneticists believe that it is better to for them to play a gate-keeping role for prenatal testing, considering whether the termination is permitted or not. Thus, they often try to convince women not to undergo prenatal testing which may be followed by termination, and this has become the Japanese gate-keeping model of genetic counseling. This model has tended to apply to other settings, including predictive testing, etc. In the future, non-directiveness in genetic counseling has to be discussed to appropriately train genetic counselors.

Technology as an Educational Enhancement Tool in the Fields of Human and Microbial Genetics: Impacting Students from High School through the Undergraduate Years. *T. N. Turley-Stoulig, T. Tinney* Department of Biological Sciences, Southeastern Louisiana University, Hammond, LA.

Technological advances in human genetics have presented educators with a wealth of tools to engage students when teaching and discussing complex and intriguing concepts and these tools are continually being developed and enhanced. We must stay abreast of this technology to ensure that students receive the most engaging educational experience possible. Also, as the field of genetics advances at a rapid pace, educators must make a continuous effort to familiarize themselves with new discoveries and information that may lead to revision of previous ideas and expose students to those discoveries. In connection with these advances in human genetics, the purpose of this study is to aid in the need for well-trained biologists/geneticists who are substantially exposed to these advances and to expose the public to concepts of genetics to aid them in making informed decisions regarding their future health and that of society as it relates to genetics and the advances being made. We used various tools to enhance the educational experience for students in the fields of microbial and human genetics from high school level to undergraduate level. These tools included interactive presentation, molecular genetics animation, database resources and genetics laboratory materials. At the high school level, our results showed that students became more engaged in their biology course and indicated a stronger interest in entering the biological sciences in the future. They also felt better prepared to approach, understand and make use of published news material relating to genetics. Teachers became more eager to investigate use of the tools for themselves in their classroom and more interested in providing students with material that connecting students' learning with real-life application. At the undergraduate level, our results showed that students felt better prepared when the tools were used and were more interested and often awed by the subject. We conclude that these tools improve the educational experience and we plan to extend this study to evaluate the effectiveness of these tools further.

Decreased antioxidant enzyme activity and mitochondrial DNA copy number in cellular models of Machado-Joseph disease. *M. Hsieh[1,2], Y. C. Yu[1], C. L. Kuo[3], W. L. Cheng[3], C. S. Liu[3,4,5]* 1) Dept Life Sci, Tunghai Univ, Taichung; 2) Life Science Research Center, Tunghai University, Taichung; 3) Vascular and Genomic Research Center, Changhua Christian Hospital, Changhua; 4) Department of Neurology, Changhua Christian Hospital, Changhua; 5) Department of Neurology, Chung Shan Medical University and Chung Shan Medical University Hospital, Taichung, Taiwan.

Machado-Joseph disease (MJD) is an autosomal dominant spinocerebellar degeneration caused by an unstable CAG trinucleotide repeat expansion in MJD gene. Because of the late on-set of the disease, we hypothesize that the accumulated oxidative stress or/and defective antioxidant enzyme ability may be contributory factors for the pathogenesis of MJD. In this study, we utilized SK-N-SH and COS-7 cells stably transfected with full-length MJD with 78 polyglutamine repeats to examine any alterations in antioxidant activities. We demonstrated a significant reduction in the ratio of GSH/GSSG and total glutathione content (GSH + (2XGSSG)) in mutant MJD cells as compared with the normal cells under normal or stressful conditions. We also showed that both SK-N-SH-MJD78 and COS-7-MJD78 - GFP cell lines have the lower levels of catalase, glutathione reductase and superoxide dismutase when compared to the wild-type cell lines under normal growth condition. In addition, it is known that when cells are under oxidative stress, the mitochondrial DNA is prone to damage. Our results demonstrated that mitochondrial DNA copy numbers in both mutant cells and MJD patients samples are decreased when compared to the normal controls. Furthermore, mitochondrial DNA deletion contents in MJD patients are significantly increased when compared to those from normal individuals. Taken together, mutant ataxin-3 might influence the activity of enzymatic components to remove O2- and H2O2 efficiently, and promote mitochondrial DNA mutation or deletion, which leads to dysfunction of mitochondria. Therefore, we suggest that the cell damage caused by greater oxidative stress in SCA3 mutant cells plays an important role, at least in part, in the disease progression.

The Impact of Lipid-related Gene in Memory. *H. Hsieh[1,2], Y. Yan[3], C. Liu[2,3], C. Lai.[2,3]* 1) Department of Psychiatry, Yuli Veterans Hospital, Yuli Town, Hualian County, Taiwan; 2) Graduate Institute of Neurological Sciences, Kaohsiung Medical University; 3) Department of Neurology, Kaohsiung Medical University Hospital.

Background The brain is the most cholesterol-rich organ in the human body. The metabolic syndrome, a clustering of several commonly disorders that include hyperlipidemia, may be a risk factor for memory decline in the elderly. Apolipoprotein E (Apo E) is a lipoprotein that transports cholesterol and other lipids. The Cyp46 enzyme is a member of the cytochrome P450 family of proteins. It regulates the elimination of excess cholesterol by adding a hydroxyl group to cholesterol. Previous studies have shown that high serum total cholesterol level is a risk factor for dementia, and may be as well as the clinical hallmark for progressive memory impairment. The aim of this study was to clarify the role of lipid-related gene (APOE, CYP46) in memory performance in middle-aged and elderly adults without dementia. Methods Using cross-section design, 209 cognitively intact participants were recruited. The mean age (SD) was 67.87 (6.80) years, the mean duration of education was 11.07 (3.91) years, and 49.76% were women. Memory and learning function were measured by logical memory (I) (II), world list (I) (II) and spatial span of the Wechsler Memory Scale-III (WMS-III). 3 single nucleotide polymorphisms at the APOE gene and 7 tagging single nucleotide polymorphisms (tSNPs) at the CYP46 gene were genotyped. Results After adjustment for age, gender, education and socioeconomic status, there was no significant association between those with and without APOE4 genotype on Memory performance. On the contrast, CYP46 gene polymorphisms was significantly associated with logical memory performance ($p=0.0006$). Conclusion The CYP46 gene polymorphisms may play an important role in episodic memory performance and SNP4-AA genotype may be a risk factor for memory impairment.

1p36 balanced translocation vs. monosomy 1p36: Different means to a similar end? *R. E. Schnur, C. Rennig, L. B. Coffey, J. Martin, J. Keenan* Dept Pediatrics/Genetics Div, Cooper Univ Hosp, Robt Wood Johnson Med School, Camden, NJ.

We identified three individuals from two families with features of the monosomy 1p36 syndrome who have apparently balanced translocations with 1p36 breakpoints. Patient 1 is a 20 month old girl with developmental delay, neuronal migration and myelination anomalies. She has a 46,XX,t(1;2)(p36.11;q37.3) karyotype and no detected 1p36 deletion with a 1,800,000 clone microarray (Affymetrix,Inc/LabCorp). (She has a 91 kb duplicated 2q37 CNV.) She has microcephaly, full cheeks, small palpebral fissures, nevus of Ota, and 4th finger camptodactyly. Her mother's karyotype is normal. Patients 2 and 3 are an Amerasian mother/son pair [Karyotypes:46, XX,t(1;8)(p36.3;q24.11) and 46,XY,t(1;8)(p36.2;q23)]. The mother has moderate mental retardation, poor eye contact, reduced affect, tremor, but a normal EEG and brain CT. She has microbrachycephaly, short stature, and mildly distinctive facial and skeletal features. She lost a 3 mo old daughter with IUGR, oligohydramnios, and unbalanced chromosomes. Patient 3 has no DNA gains or losses identifiable by two BAC-based CGH panels of 607 (LabCorp) and 4685 clones (Signature Genomics). Additional studies are planned. He had mild IUGR at birth, oligohydramnios, hypotonia, cryptorchidism, early myopia, and global delays. He strongly resembles his mother in personality and facial features, including deepset eyes and prominent nose with broad nasal tip. He has short stature, but a normal head circumference, scoliosis and mild skeletal changes, including 5th finger camptodactyly. In summary, our three subjects all have partial features of the monosomy 1p36 syndrome without demonstrable deletions. Although most previously reported balanced 1p36 translocation carriers are phenotypically normal, a few are not (e.g., Hussain et al. 2000). This report illustrates the difficulties in genetic counseling for individuals with apparently balanced translocations involving 1p36. It also demonstrates the continuing necessity of performing karyotypes *in addition to* CGH for all individuals who exhibit developmental and physical variations.

Identification of a new gene involved in cleft lip using the molecular analysis of an apparently balanced chromosome translocation. *HG. Kim[1], K. Norris[2], AS. Kulharya[2], LC. Layman[1]* 1) Section of Reproductive Endocrinology, Infertility, & Genetics, Dept Ob/Gyn, Institute of Molecular Medicine and Genetics, Medical College of Georgia; 2) Depts. Pediatrics & Pathology, Medical College of Georgia, Augusta, GA.

Cleft lip and/or palate (CL/P) is a congenital developmental anomaly known to have a strong genetic component. CL/P occurs either as an isolated malformation (nonsyndromic) or in association with other developmental anomalies (syndromic). It affects approximately one in every 500 births worldwide, making it the one of the most common major birth defects. Isolated CL/P is genetically heterogeneous and its genetic ethiology has been investigated extensively for many years. Although mutations in genes such as MSX1, TBX10, PVRL1, IRF6, FGFR1, and SUMO1 explain the most commonly encountered etiologies in CL/P, they only constitute about 20% of the molecular basis in these patients, suggesting that other genes have to be involved in the pathogenesis of CL/P. In a number of genetic diseases, structural chromosomal changes that segregate with the disease phenotype have served to map causative genes to specific chromosome regions. In this regard, Mendelian cytogenetics refers to the association between chromosomal rearrangements and single gene disorders. De novo chromosome translocations have been most widely used for the mapping and cloning of disease genes, in which translocation breakpoints provided important information about the gene location. To identify a new CL/P gene by positional cloning, we investigated a male cleft lip patient with an apparently balanced de novo translocation t(10;14)(p14;q31). CGH arrays did not detect additional chromosomal rearrangements, and by performing FISH we narrowed the 10p14 translocation breakpoint to 11.1 Mb containing 39 known genes between RP11-164N21 and CTD-2382H16. The breakpoint of 14q31 was refined to 14.7 Mb , which harbors 66 genes between RP11- 929J14 and RP11-353F5. Thus further refining of both breakpoint regions in our balanced translocation patient is warranted to identify a new causative gene for CL/P.

Co-transcription of genes into single transcripts: Another regulatory mechanism for gene expression in vertebrates. *T. D. Taylor, T. P. Srivastava, V. K. Sharma, N. Kumar, T. Takeda, R. Ozawa, M. Mushiake, R. Okumura, Y. Nishida, T. Fujikake* MetaSystems Research Team, RIKEN Advanced Science Institute, Yokohama, Kanagawa, Japan.

Co-transcription of two distinct genes (child genes) into a single transcript (conjoined gene) has not been well explored. Either it is a somewhat rare phenomenon, or the current methods of genome annotation are not sensitive enough to identify such genes. Towards this we have designed a new computational algorithm "Conjoin" for the identification of conjoined genes in any genome given its messenger RNA or EST information. Applying Conjoin to the human genome, we have identified nearly 750 conjoined genes of variable lengths, some with multiple isoforms. We have so far confirmed the existence of more than 200 of these conjoined genes using RT-PCR and sequencing. Thus, it appears that these conjoined transcripts are arising out of novel functional requirements and are not merely artifacts of transcription. However, the underlying mechanism controlling the formation of such conjoined genes in human and other vertebrate genomes is yet unexplored. In order to confirm the presence of conjoined genes in other vertebrates, we implemented the Conjoin algorithm on both the mouse and chimpanzee genomes. The number of conjoined genes in mouse is far less than that in human, even though there is roughly the same amount of mRNA/EST data available. Thus it appears that the conjoined genes might be performing some novel functions and are contributing to human complexity as compared to other lower organisms. The 5 and 3 flanking regions of the child genes were analyzed to search for the presence of any alternate or common regulatory elements that might be controlling the formation of conjoined genes. Ten regions in the human genome were selected which satisfy the minimum requirement for the formation of a conjoined gene and where no prior evidence existed. In eight of these selected regions existence of a conjoined gene could be confirmed. Finally a comprehensive database of all the human conjoined genes was designed to provide a repository of these specialized genes with detailed information about each gene.

PNA based microarray for microRNA expression profiling. *J. Choi, H. Park* PANAGENE, 816, Tamnip-dong, Yuseong-gu,Dea jeon, Korea.

MicroRNAs (miRNAs) are 22-25 nt non-coding RNAs that play a critical role in many important biological processes, including development, differentiation, apoptosis, metabolism, viral infection, and cancer. Therefore it is important to monitor the expression of miRNAs. PNA (Peptide Nucleic Acids) is synthetic DNA mimics in which the backbone is replaced by repetitive units of N-(2-aminoethyl) glycine. PNA probes have stronger affinity and greater specificity than DNA probes for binding to RNA. These remarkable hybridization properties of PNA suggest that PNA probes may be efficiently incorporated into microarrays. We described a novel PNA based microarray (PANArrayTMmiRNA) that take advantage of highly sensitive and accurate analysis of miRNAs expression profiles. We optimized the protocols about PNA probe design, PNA probe printing, and hybridization conditions of PNA probes-miRNAs. We demonstrated that PNA probes were accurately discriminated human miRNAs with high sequence homology and similar sizes to other miRNAs. Our data showed very low cross hybridization for miRNAs differing by single nucleotide such as human let7 family (a~i), has-mir196 (a and b), and has-mir10 (a and b). Also PANArrayTM miRNA can detect small amount of total RNA with 98% correlation between independent replicates. These results suggest that PANArrayTMmiRNA is a powerful tool to analyze miRNA expression profiles with rapid throughput and high fidelity.

Next Generation Sequencing of the Escherichia coli O55:H7 Genome and Comparison with the Closely Related Enterohemorrhagic E. coli O157:H7. *M. Rhodes[1], P. Vatta[2], C. Cummings[2], L. Wong[2], M. Barker[1], J. Ziegle[1], L. Jones[1], J. Chin[1], P. Brzoska[2], M. Furtado[2], O. Petrauskene[2]* 1) Molecular & Cellular Biology Division, Applied Biosystems, Foster City, CA; 2) Applied Markets R&D, Microbiology group, Applied Biosystems, Foster City, CA, USA.

Detection in the food supply of pathogenic E. coli, particularly strains that cause hemorrhagic colitis (HC), has become a public health priority. The O157:H7 serotype of E. coli has been responsible for most HC outbreaks to date, so detection of this type is critically important. The ideal assay must detect O157:H7, but not any other serotypes, including the vast majority of commensal E. coli that are not pathogenic. E. coli O157:H7 is very closely related to the O55:H7 serotype, which does not frequently cause HC outbreaks. Numerous lines of evidence indicate that O55:H7 is the nearest phylogenetic neighbor of O157:H7, making the design of O157:H7-specific assays challenging. The E. coli O55:H7 genome sequence would be a valuable tool for identification of assay target sequences unique to O157:H7, but no such sequence was available. To this end, the genome of one E. coli O55:H7 strain, and another O157:H7 strain, were sequenced by oligonucleotide ligation and detection using the next-generation AB SOLiD platform. Comparison of the O55:H7 and O157:H7 genomes identified 500 kb of sequence that is present on the O157:H7 chromosome and absent or divergent in O55:H7. Comparison of these putative O157:H7-specific sequences against the publicly available genome sequences of other pathogenic and non-pathogenic E. coli and Shigella strains identified regions that are conserved beyond the O157:H7 lineage, further narrowing the list of putative assay design targets. The short time requirement (two to three weeks from library construction to sequence) and deep coverage obtained (>60X), makes the SOLiD system ideally suited for microbial genome sequencing when a closely related reference genome sequence is available. This method can be sufficiently robust to permit genome sequencing of a reference organisms nearest phylogenetic neighbors.

Sequence and structural variation analysis of a human genome revealed by next-generation sequencing of paired-end libraries. *F. M. De La Vega[1], H. Peckham[2], SS. Ranade[2], S. F. McLaughlin[2], C. C. Lee[2], Y. Fu[2], Z. Zhang[1], F. Hyland[1], R. T. Koehler[1], A. A. Antipova[2], J. M. Manning[2], C. L. Hendrickson[2], L. Zhang[2], E. T. Dimalanta[2], J. K. Ichikawa[2], A. Bashir[3], V. Bansal[3], V. Bafna[3], G. Costa[2], K. McKernan[2]* 1) R&D, Applied Biosystems, Foster City, CA; 2) R&D, Applied Biosystems, Beverly, CA; 3) Dept. of Computer Science, University of California, San Diego, CA.

Ultra-high throughput sequencing allows the analysis of human genomes to discover genetic variation that could have implications in health and disease. We analyzed the genome of an anonymous individual of African origin obtained by with the Applied Biosystems SOLiD System, which allows sequencing single or paired 25-50bp reads of 10^8-10^9 templates on a single array containing beads with clonally amplified templates. We developed fragment and paired-end libraries with insert sizes ranging from 600bp to 3.5kb for a HapMap Yoruba sample (NA18507). We collected over a billion sequencing reads amounting to a total of 32 Gbp of sequence, and obtaining an average 12X haploid sequence coverage and 130X clone coverage. After aligning those reads to the hg18 reference assembly we observe over 95% of the genome bases covered with a read or more and 99.45% of the genome spanned by a paired end clone. A novel error correction technique improved the accuracy of the aligned reads to >99.95%. With such accuracy, our results suggest that over 90% heterozygote identification can be efficiently achieved at 15X coverage levels, by comparison with known HapMap genotypes. We discovered over 2 million SNPs and 117 thousand small indels (1-10bp). The analysis of the distance and orientation of the paired end reads allowed the identification of over 40,000 putative insertions and deletions ranging from 50bp to several Kb. We also predict 50 inversions and 4 gene fusions resulting from deletions, two of which have been previously reported. Depth of coverage analysis allows the inference of copy-number variants. Our results provide guidance for future studies to discover sequence and structural variants in human populations and cancer with short-read next generation sequencing.

Genome-wide linkage and large-scale association studies identify novel variants on chromosome 4q34-35 for type 2 diabetes. *M. Park[1], K. Kim[1], M. Go[1], H. Lee[1], K. Kim[1], K. Kimm[1], Y. Cho[2], H. Lee[2], H. Kim[1], J. Lee[1], K. Park[2]* 1) Division of Structural and Functional Genomics, Center for Genome Science, National Institute of Health, Seoul, Korea; 2) Genome Research Center for Diabetes and Endocrine Disease, Clinical Research Institute, Seoul National University Hospital, Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Korea.

Type 2 diabetes mellitus (T2DM) has strong environmental and genetic etiologic determinants, which are likely to interact in a complex fashion to influence the clinical course of the disease. Identifying the genetic variants that increase risk of T2DM has been a formidable challenge. We conducted genome-wide linkage analyses for T2DM in 388 affected individuals (274 sib-pairs) from 171 Korean families. Of those who had overweight (BMI 23), we found the evidence of linkage on chromosome 4q34-35 and confirmed with multi-point NPL score=2.81 (p = 0.002) through fine-mapping analysis. We also carried out association analyses with SNPs in the region of the linkage signal to identify genetic variants that predispose to T2DM from 2,641 independent individuals. We detected T2DM association signals and confirmed the replicated T2DM susceptibility variants through analyses of large samples of 17,099 individuals from multiple populations. Our systematic search from genome-wide linkage and association studies demonstrate that a replicated linkage peak for T2DM on chromosome 4q34-35 contains at least two novel T2DM-predisposing genes. Our findings suggest that novel T2DM-predisposing genes regulate mechanisms linking overweight to insulin resistance and T2DM, emphasizing independent contribution of multiple variants.

Tissue-specific DNA methylation of the IL2RA promoter: a role for epigenetics in IL2RA expression? *J. Field[1], M. Ehrich[2], M. O'Hely[3], T. Speed[3], J. P. Rubio[1]* 1) Neurogenetics Laboratory, Howard Florey Institute, Carlton, Victoria, Australia; 2) SEQUENOM, 3595 John Hopkins Court, San Diego, CA; 3) Division of Bioinformatics, The Walter and Eliza Hall Institute of Medical Research, Parkville, Victoria, Australia.

Interleukin-2 receptor alpha (IL2RA), also known as CD25, is expressed by regulatory T cells and is also up-regulated by CD4+ T cells in response to activation stimuli. The IL2RA gene has recently been identified as a susceptibility gene in both multiple sclerosis (MS) and type 1 diabetes. To determine whether IL2RA expression is epigenetically regulated, we investigated DNA methylation of a 771 bp region of the IL2RA gene, corresponding to the proximal promoter and exon 1, in neural tissue and peripheral blood mononuclear cells (PBMC) from MS patients and controls . We observed a marked tissue-specific difference in relative methylation (Sequenom MassARRAY) of CpG dinucleotides in the proximal promoter region, which contains conserved (PRRI/PRRII) regulatory elements, in neural tissue (high methylation) compared to PBMCs (low methylation). CpG dinucleotides flanking the proximal promoter displayed high levels of relative methylation in both tissues. There was no statistically significant difference in DNA methylation between MS patients and controls in either tissue type. Bisulphite-sequencing confirmed the relative methylation analyses and demonstrated heterogeneity of methylation patterns. In concordance with the relative methylation studies IL2RA expression was reduced in neural tissue compared to PBMC. In conclusion, these data show that tissue-specific DNA methylation of IL2RA is associated with differential gene expression, and this may have consequences for the pathogenesis of autoimmune diseases.

High throughput screening of genes involved in Parkinsons disease using an Affymetrix CustomSeq re-sequencing array. *J. P. Rubio[1], E. J. Wilkins[1], W. Wang[2], T. F. Cowie[3], K. Kotschet[4], M. O'Hely[5], T. P. Speed[5], M. K. Horne[1]* 1) Howard Florey Institute, Melbourne, Victoria, Australia; 2) Stanford Genome Technology Center, Palo Alto, CA, USA; 3) Applied Genetic Diagnostics, National Neuroscience Facility, Department of Pathology, The University of Melbourne, Victoria, Australia; 4) St. Vincent's Hospital, Melbourne, Victoria, Australia; 5) The Walter and Eliza Hall Institute of Medical Research, Melbourne, Victoria, Australia.

Parkinsons disease (PD) is a common neurodegenerative disease, affecting 1% of people over the age of 60. Advances in our understanding of PD have come from the identification of genes (PD genes), and mutations therein, which cause disease. It is now recognized that common (SNP) variation in some PD genes is associated with risk in late-onset sporadic disease. Our aim was to produce both a research and clinical diagnostic tool for PD to enable the investigation of DNA sequence variation in the known PD genes. Conventional sequencing methods were considered too expensive so we turned to Affymetrix CustomSeq technology. In all 185 DNA sequences, comprising 44.3 kb from 16 different genes, including SNCA, Parkin, UCHL1, DJ-1, PINK1, LRRK2, were tiled onto an array. Exons, exon/intron borders, 5 and 3 untranslated regions were also included for most genes. We found that sequence data from the PD GeneChip was both reproducible (from samples analysed in duplicate) and accurate, compared to Sanger sequencing on an ABI 3730 DNA sequencing machine. DNA samples for 100 individuals have been sequenced to date, including PD patients with either an early age-at-onset of disease (55 y.o.), a family history of disease (2 affected relatives) and/or sporadic PD, and healthy controls. A summary of these sequence data will be presented. In conclusion, Affymetrix CustomSeq technology provides a robust and cost-effective approach for high-throughput DNA sequencing, and presents as an attracted alternative for a broad range of DNA sequencing applications including mutation screening and targeted re-sequencing of small (<300 kb) chromosomal regions.

Association of familial autism with imprinted locus on 7q32. *E. Korvatska[1], G. D. Schellenberg[1,2]* 1) Division of Gerontology and Geriatric Medicine, Department of Medicine, University of Washington, Seattle, WA; 2) Veterans Affairs Puget Sound Health Care System.

Background: A strong genetic component of autism is being approached by linkage analysis, candidate gene association studies, and, most recently, by analysis of copy-number variations and whole-genome associations. Given multiple linkage signals found across the human genome, most findings cannot be replicated on different populations. Linkage to 7q is by far the most robust finding in autism. Recently, linkage signal on 7q32 was replicated in two independent studies including ours. Objectives: To search for susceptibility genes within the large genetic interval (20 cM) identified by linkage we performed association analysis of selected candidate genes. Methods: 350 multiplex autistic families were subjected to transmission disequilibrium test. Results: We detected an association with ~220 kb interval situated right under the linkage peak. Signals arose from multiple SNPs comprising several haploblocks with the largest one extending over 100 kb. The associated region contains 5 protein-coding genes, and 4 of which are expressed in the brain. At least 3 of 5 candidate genes are imprinted in human and mouse. Mutations affecting coding sequences/splice sites of 7q32 candidate genes have been searched by sequencing of 100 patients with autism and 100 control individuals. Conclusion: In association study aimed to dissect 7q31-32 susceptibility locus, we have identified a new candidate region containing a cluster of imprinted genes. The associated region is narrowed down to ~200 kb comprising 5 protein-coding gene candidates and 1 miRNA.

Evolution of spinocerebellar ataxia (SCA) genes in primates. *L. Wang[1], X. Hu[1], S. Ji[1], H. F. Liu[1], C. Huan[1], N. Kozuki[2], T. Kurosaki[2], S. Ueda[2]* 1) Medical & Animal Gen, Inst Gen, Chinese Academy Sci, Beijing, China; 2) Department of Biological Sciences, The University of Tokyo, Tokyo, Japan.

Spinocerebellar ataxia (SCA) is an inherited disorder of brain function. More than 25 types of SCA have been described. The basic defect in many types of SCA is an expansion of a CAG triplet repeat. Our previous study on *SCA* 1 gene demonstrated no repetitive structure in the region corresponding to human CAG repeats in prosimians and New World monkeys like in rodents, perfect repeats in Old World monkeys, and interrupted repeats in hominoids. Comparative analysis on secondary structures of primate *SCA* 1 transcripts suggests human prototype was built in the common ancestor of simians (Gene 373:23(2006)). To know systematically how human has acquired the CAG triplet repeats encoding poly-glutamine tracts, we farther investigated *SCA* 2 >, *SCA* 3, *SCA* 6, *SCA* 7, *SCA* 12, and *SCA* 17 genes in various species of primates. For *SCA* 3, CAG repeat expansion might have occurred in the common ancestor of primates. Both synonymous and non-synonymous interruptions have frequently occurred in the common and each lineage of primates. Different from the Q->H interruption of *SCA* 1, various types of non- synonymous (Q->K, Q->P, Q->E, and Q->L) interruptions were found. For *SCA* 17, CAG repeat expansion was widely observed in mammals, and there were a wide variation in the number of repeats. Synonymous interruptions have more frequently occurred in the common and each lineage of primates. Intriguingly, non-synonymous interruption was observed neither in all of the primates nor in all of the mammals examined, except for owl monkey and dog. Synonymous interruption might be more advantageous than non-synonymous interruption for its function as TATA-binding protein. The results show that glutamine expansion in *SCA* 17 is an evolutionarily old variation that happened in the common ancestor of mammals. Glutamine expansion in *SCA* 3 is suggested to occur immediately after divergence of Order Primates, showing an intermediate feature between *SCA* 1 and *SCA* 17. Together with the data for the other *SCA* genes, we show here evolutionary background of glutamine expansion is greatly different from each *SCA* gene.

Analyzing quantitative phenotypes of Alzheimer's disease using Principal Components of Heritability Association Tests (PCHAT). *W. L. A. Fung[1], M. B. McQueen[2], M. S. Albert[3], R. E. Tanzi[4], D. L. Blacker[1]* 1) Epidemiology Dept, Harvard School of Public Health, Boston, MA; 2) Inst for Behavioral Genetics, University of Colorado at Boulder, Boulder, CO; 3) Neurology Dept, Massachusetts General Hospital, Boston, MA; 4) Neurology Dept, Johns Hopkins University, Baltimore, MD.

Background: The extreme multiple testing problem of genome-wide association studies (GWAS) has necessitated the development of statistical methods with high power in the search for additional Alzheimers disease (AD) susceptibility genes. We previously reported on the use of neuropsychological test scores as quantitative phenotypes related to AD that may increase the statistical power for identifying AD genetic risk factors (McQueen et al, Am J Med Genet B, 2007). Power may be further enhanced by reducing multiple phenotypes to a single phenotype with maximal heritability, as is implemented in the newly developed Principal Components of Heritability Association Test (PCHAT) by Klei et al (Genet Epidemiol, 2007). The present study aimed at examining the performance of PCHAT in longitudinal neuropsychological testing data in non-demented subjects. Methods: Using data from 367 community-recruited subjects with and without memory problems, we used PCHAT to analyze the association between performance of 13 neuropsychological tests at baseline and at 1st follow-up visit (adjusted for age, sex, education) with the known AD gene APOE and five other putative AD polymorphisms (SNPs). Results: APOE-4 showed evidence for association with the empirically-derived optimal phenotype including CVLT, digit span backward and Trail Making Test A cross-sectionally (P=0.018) and longitudinally (P=0.022). Interestingly, a promoter in insulin degrading enzyme gave similar results. These P-values (corrected for multiple genotypes and phenotypes) were similar in magnitude to the P-values for the individual neuropsychological tests found in McQueen et al (uncorrected for multiple testing). Conclusions: This is the first application of PCHAT to the study of a complex genetic disorder in unrelated individuals to our knowledge. These preliminary results suggest that this approach has promise in the search for additional AD genes using GWAS.

Genetic and Molecular Evaluation of Idiopathic Male Infertilty: An Indian Perspective. *S. Abid, A. Maitra, D. Modi, J. Gokral* Molecular Endocrinology, NIRRH (ICMR), Mumbai, Maharashtra, India.

Idiopathic male infertility is an enigma, as the cause is still not understood. Genetic and molecular evaluation is being used as tools in identifying the etiology causing male infertility. Mammalian spermatogenesis is a complex cascade of events wherein the testis specific genes and their associated proteins play an important role. Objective of this study was to assess 1. Hormonal profile, frequency of Y chromosome microdeletions and phenotype/genotype association in men with non-obstructive azoospermia (NOA) and severe oligozoospermia (SOA). 2. Gene and protein expression in infertile and fertile testicular tissue. We screened 560 infertile males who attended the institutes male infertility clinic and enrolled 210 men with NOA and SOA. Informed consent was obtained from all subjects and institutional ethics committee approved the study. The frequency of Y chromosome microdeletions observed was 2.8%, which is unusually low and AZFb was the most frequently deleted region, which showed a severe phenotype of azoospermia. Hormonal evaluation revealed that FSH and LH levels were significantly higher in NOA as compared to SOA and serum Inhibin B was significantly low. Severe testicular phenotype such as sertoli cell only syndrome was seen in NOA group as compared to SOA. Men with Yq microdeletions had normal levels of FSH, LH and Inhibin B whereas testosterone levels showed significant decrease. The expression of Y chromosome specific genes RBMY and DAZ was studied using fertile and infertile human testicular tissue and human spermatozoa to understand their role in aberrant spermatogenesis. Low expression of DAZ mRNA was seen in infertile men as compared to fertile. RBMY mRNA and protein expression was also decreased in men with aberrant spermatogenesis. Overall the study shows low prevalence of Yq microdeletions and emphasizes that altered expression of gene and proteins could cause aberrant spermatogenesis leading to idiopathic male infertility. This can thus form an adjunct in evaluating and offering better clinical management to the infertile couple.

Leptin As A Correlate Of Polycystic Ovary Syndrome And Associated Obesity. *M. Pusalkar, P. Meherji, J. Gokral, S. Chinnaraj, A. Maitra* Molecular Endocrinology, NIRRH (ICMR), Mumbai, Maharashtra, India.

Polycystic Ovary Syndrome (PCOS) is one of the commonest endocrinopathies affecting about 5-10% of women in their reproductive age. It is marked by anovulation manifested as amenorrhea, clinical and/ or biochemical evidence of hyperandrogenemia and presence of cystic ovaries on ultrasound. Genetic basis of PCOS is now well established and candidate gene approach is being widely used to study the etiology of PCOS. As obesity is one of the hallmark features of PCOS it is logical to speculate that leptin, the product of obesity gene, could play an important role in pathophysiology of the syndrome. Leptin is mainly synthesized in adipose tissue and is now known as a hormone of reproduction. There is an increasing evidence to show that leptin plays a crucial role in ovarian function via its autocrine- paracrine action. Thus role of Leptin in ovarian dysfunctions such as PCOS has evoked considerable research interest in recent years. The present study was carried out to assess role of leptin in etiology of PCOS and associated obesity. The specific objectives were to compare leptin levels in control and PCOS subjects and to screen leptin gene for putative variations and its association with the phenotype. A total of 100 PCOS subjects and 100 controls were screened. Average BMI as well as plasma levels of leptin were significantly high in PCOS cases as compared to controls ($p<0.0001$). When the two groups were sub-classified as lean and obese, leptin levels were found to be significantly associated with obesity as well as PCOS. Analysis of coding regions in all the study subjects did not show any variations. A novel variation A>G in exon 2 was also identified (GeneBank Accession number DQ054472). In untranslated Exon 1, the polymorphism G>A was observed at -19 position. Polymorphic A allele was found to be associated with increased leptin levels in both control as well as PCOS subjects. The increase was significant in the PCOS group ($p<0.05$) suggesting the confounding effect of certain factors intrinsic to PCOS on this polymorphism.

Heterogeneity of the Genetic Relationship Between C-Reactive Protein and Insulin Resistance Measures. *J. Cui[1], X. Guo[1], L. J. Raffel[1], A. Xiang[2], X. Su[1], Y. Liu[1], L. Zung[1], K. D. Taylor[1], T. A. Buchanan[2], Y.-D. I. Chen[1], J. I. Rotter[1]*
1) Medical Genetics, Cedars-Sinai Med Ctr; 2) USC, Los Angeles, CA.

C-reactive protein (CRP) is an inflammatory biomarker shown to be associated with insulin resistance (IR) and to predict the occurrence of type 2 diabetes and cardiovascular (CVD) events. In an earlier study, we examined the relationship between CRP and diabetes/CVD risk factors, including IR, in a family cohort of Hispanic Americans (HA) at risk for both hypertension and the metabolic syndrome. Significant genetic correlations were found between CRP and several IR measures, including a positive correlation with fasting insulin (FI), and a negative correlation with glucose infusion rate (GINF) during a euglycemic clamp. We assess here the genetic basis of the correlation between CRP and IR measures using the same HA family sample. A 10 cM genome-wide linkage analysis was conducted in 618 individuals from 160 families for CRP, FI, and GINF on non-diabetic offspring who underwent detailed phenotyping. We then performed bivariate linkage analysis for CRP vs. FI, and CRP vs. GINF, to map the common genes underlying both CRP and IR measures,. The maximum LOD score from univariate linkage analysis for CRP was 1.68 on chr.19 (101cM). The greatest evidence for linkage was found for GINF on chr.6 (LOD = 2.82 at 0cM), followed by LOD=2.24 on chr.20 (62cM) for FI. A second linkage peak for GINF was observed on chr. 2 at 267cM (LOD=1.58). The bivariate linkage analysis revealed a maximum LOD score of 2.0 for CRP vs. GINF at the chr.6 locus, with the second highest LOD = 1.61 on Chr.2 (267cM). The maximum LOD for CRP vs. FI was 1.48 at 62cM on chr.20. Even though the LOD scores are modest, these results suggest there are common quantitative trait loci (QTL) underlying CRP and GINF on chr. 6 and 2, while a different potential common QTL for CRP and FI is located on chr. 20. These findings 1) help explain the previously identified different genetic correlations between CRP and GINF compared to CRP and fasting insulin and 2) demonstrate the existence of heterogeneity in the genetic relationships between CRP and various insulin resistance measures.

Genome-wide screening for submicroscopic chromosomal aberrations by High density oligonucleotide array (Affy 6.0) in children with unexplained mental retardation (MR) and dysmorphic features. *A. Tsai[1, 2], L. H. Li[2], F. J. Tsai[3], T. C. Chen[3], C. Wang[3], I. C. Chou[3], C. F. Chang[2], T. P. Chuang[2], J. Y. Wu[2], Y. T. Chen[2]* 1) Div Clinical Gen & Metabolism, Childrens Hosp, Denver, CO; 2) IBMS, Academia Sinica, Taipei; 3) China Medical University.

Genome-wide array is a novel technology that allows for the detection of DNA copy number changes not previously detected by conventional cytogenetic techniques. In this study, high density oligonucleotide chip Affymetrix Genome-Wide Human SNP Array 6.0 was applied to a series of children with previously undiagnosed syndromic developmental delay. Methods: The patients were enrolled from 10 tertiary care hospitals in Taiwan seen by clinical geneticists. All subjects had prior karyotype; some with neuroimaging studies without a diagnosis. All patients were re-evaluated by one clinical geneticist for final entry of array studies. Abnormalities were confirmed by qPCR. Patient and parents were ascertained concurrently with three chips performed and analyzed as a trio set to distinguish between pathogenic and familial non-pathogenic variants. Results: 23 patients were enrolled to date; 12 patients were excluded due to recognizable single gene syndromes or clearly need to rule out neurological or metabolic conditions. On array analysis, 4 of 11 children (36%) have de novo causally related chromosomal aberrations sized from 3.2 MB to 11 MB. One has complex rearrangement involving sub-telomeric region of 1p36.3: deleted from 1p36.32 to pter and duplicated from 1p36.32 to 1p36.31. The rests were noted to have 1q41-42 deletion (5.2 MB) and novel submicroscopic 16q13 deletion and 5q11.2 deletions. Discussion: while most recent data revealed aCGH, among targeted, lower resolution SNP arrays, has an etiologic yield of 13-18%; or 9-14% superior than G-banding; our data is significantly higher than the expectation. Our data revealed the diagnostic value of applying this technology subsequent to detailed history, physical examination, and targeted laboratory testing for other single gene disorders. Our data also demonstrated complex rearrangement which would have been missed by traditional FISH or low resolution SNP/BAC arrays.

Linkage Analysis of a Large Hematological Cancer Family. *D. I. Perera[1], E. M. Tegg[1], J. Stankovich[1,2], R. Thomson[1], J. Silver[2], K. Marsden[3], R. M. Lowenthal[3], C. Flowers[1], R. McWhirter[1], A. Banks[1], A. Piaszczyk[1], J. Panton[3], M. Bahlo[2], S. Foote[1], J. L. Dickinson[1]* 1) Menzies Res Inst, Hobart, Tasmania, Australia; 2) Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia; 3) The Royal Hobart Hospital, Hobart, Tasmania, Australia.

Familial aggregation studies provide strong evidence of a genetic basis for hematological malignancies such as leukemia, lymphoma and myeloma. Furthermore, multiple types of hematological malignancy often occur within individual families. This suggests that relatives may inherit a common predisposition to somatic mutation events in progenitor cells, which results in malignancies in different cell types in different family members. We have performed linkage analysis in a large family from Tasmania, Australia, with 10 cases of hematological cancer. The family includes 7 siblings whose parents are first cousins. Four siblings have been diagnosed with chronic lymphocytic leukaemia (CLL) and 1 with diffuse large B-cell lymphoma. Blood-derived DNA samples from one CLL case, one unaffected sibling, and 7 offspring of the remaining cases were genotyped using Affymetrix 250K SNP arrays, and two regions were identified where patterns of haplotype sharing were consistent with all 5 affected siblings inheriting two copies of a rare susceptibility allele homozygous-by-descent (HBD). Subsequent microsatellite genotyping of DNA extracted from paraffin-embedded tissue has confirmed haplotype sharing in one of the two regions, where four cases have inherited a haplotype HBD and the fifth case carries one copy of this haplotype. A sixth sibling showing early signs of disease has also inherited this haplotype HBD. In addition, two more distantly related cases also appear to carry segments of this risk haplotype. Sequencing and expression studies are underway to identify a causal mutation in this linked region.

Expression profiling of cultured neuronal cells from nasal neuroepithelium reveals involvement of synaptic long-term potentiation and glutamate receptor signaling pathways in schizophrenia. *O. Evgrafov[1], X. Kang[1], B. Wrobel[2], G. Simpson[1], D. Malaspina[3], J. A. Knowles[1]* 1) Psychiatry, Univ Southern California, Los Angeles, CA; 2) Otolaryngology, Univ Southern California, Los Angeles, CA; 3) Psychiatry, New York University, New York, NY.

Expression profiling has been used to identify genes that are differentially expressed between individuals with schizophrenia (cases) and controls. Because gene expression patterns are tissue-specific, cells derived from non-CNS sources are likely to be less relevant to the etiology of the disorder. CNS neuronal cells can be obtained from living subjects, without a brain biopsy, by selective culture of tissue obtained from nasal neuroepithelium biopsies. Using this technique, we have determined the level of expression of ~22,000 core transcripts (mRNAs with annotated full-length CDS regions) in cultured neuronal cells from 5 cases and 5 controls using Affymetrix Human Exon ST 1.0 Arrays, and analyzed the data using software from Partek and Genetrix. The between sample correlation coefficient in controls was very high (r=0.98), substantially greater than that of post-mortem brain samples, and is likely due to the control of environmental conditions that is possible only with cell culture. This reduction in sample variation may allow greater detection of case-control differences due to the decrease in noise. Unsupervised principal component analysis using all core transcripts separates cases from controls. When this data was analyzed using Ingenuity Pathway Analysis software we found significant differences, after correction for multiple comparison using FDR=0.05, in the genes involved in synaptic long term potentiation and glutamate receptor signaling pathway and the processes of neurotransmission and synaptic transmission. These results are consistent with previous studies of candidate genes for schizophrenia. Our study provides further evidence for involvement of these pathways in the etiology of schizophrenia and suggests that the expression profiling of cultured neuronal cells may be a powerful approach in the investigation of molecular mechanisms of neuropsychiatric disorders.

Genome-wide oligonucleotide array-based measurements of copy number variations in samples with abnormal phenotypes. *A. Tsalenko[1], H. Whitby[2], E. Aston[2], C. Hopkins[1], P. Tsang[1], G. Peters[1], D. Bailey[1], L. Bruhn[1], A. R. Brothman[2]* 1) Agilent Technologies, Santa Clara, CA; 2) University of Utah, Salt Lake City, UT.

Copy Number Variants (CNVs) are reshaping our understanding of genome biology and genetics of a growing list of normal and disease-related human phenotypic variations. Previous focused studies of these regions have included different populations of individuals, but all presumably with normal phenotypes. Array CGH analysis of patients with congenital abnormalities has become a main test assay for clinical cytogenetics and genetics laboratories, yet how to interpret normal variants from those of clinical significance has created a dilemma. In this study, we used Agilent Technologies Human Genome CNV microarray set (G4423B, AMADIDs 018897 and 018898) to profile 10 patients selected from a University of Utah database of 1275 patients referred primarily for developmental delay and mental retardation. These patients have been previously profiled by a BAC array platform and are believed to have benign CNVs independent from any clinically significant copy number abnormalities. The Agilent CNV array set of two 244K feature arrays is enriched for coverage of 19,400 previously identified CNVs, in-dels and segmental duplication regions. The median probe spacing varies from approximately 200bp for smaller intervals to as high as 2400bp for larger intervals. Remaining regions of the genome are covered with a median spacing of 27Kb. Using these arrays, we detected 440 to 721 CNVs per patient with a median size of 4.9Kb, compared to 9 calls in a self-self experiment. These CNVs represent 1547 copy number variant regions. Approximately 50% of CNVs called in more than one patient had consistent (up to 1 probe) breakpoints. These findings are in agreement with previous studies of normal samples. In 10 samples, we observed copy number variations in 27 of the 35 most frequent CNVs detected by previous BAC studies. High resolution characterization of CNVs and their boundaries in a wide variety of samples including abnormal patients can help further distinguish benign from clinically significant regions of variation.

Latent class analysis identifies a clinical schizophrenia subtype showing significant linkage to 1q23-25 in Taiwanese families. *E. Holliday[1,2], D. Nyholt[2], B. Mowry[1,2,3]* 1) Queensland Centre for Mental Health Research, Brisbane, Australia; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) University of Queensland, Brisbane, Australia.

Purpose: This study investigated the utility of empirical clustering techniques to define alternative phenotypes for genetic analyses of schizophrenia. *Methods:* Clinical and genotypic data for 607 Taiwanese affected sibling pair schizophrenia pedigrees was publicly available. For individuals with schizophrenia, latent cluster models were fitted to 13 symptoms commonly associated with a diagnosis of SZ. Models were fitted using SAS statistical software. Posterior probabilities of latent class membership were used to allocate individuals to their most likely latent class. Genomewide linkage analyses were conducted in the subset of siblings concordant for each latent class. *Results:* In the latent class analysis, a four-class model provided the best fit. Sibling concordance of latent class membership was significantly higher than predicted by class probabilities (P=0.004), indicating familial aggregation of group membership. The most prevalent latent class (LC4) described a recognisable subtype of chronically ill schizophrenia patients, with prominent negative symptoms, high disorganisation and poor social/occupational functioning. Due to its prevalence and clinical relevance, genomewide linkage analyses of sibships concordant for LC4 (n=71) was considered the primary analysis. These analyses detected genomewide significant linkage (multipoint LOD = 4.21) to 1q23-25 (genomewide empirical P=0.002). Secondary linkage analyses of sibships concordant for LC1, LC2 and LC3 detected no region with LOD>2. Analyses of the entire dataset yielded a maximum LOD of 1.8 on chromosome 10. *Conclusion:* Empirical clustering techniques may assist with identifying more genetically homogeneous phenotypes for the study of complex disorders. However, large samples are necessary to maintain adequate power in sample subsets. Variants in 1q23-25 may confer risk to a clinical schizophrenia subtype characterised by prominent negative symptoms, disorganisation and poor functioning.

Identification of a novel mutation of OTX2 in a Danish patient with microphthalmia. *K. Grønskov[1], J. Ek[1], A. Sand[1], L. Lavard[2], H. Jensen[1], K. Brøndum-Nielsen[1]* 1) Kennedy Center, Glostrup, Denmark; 2) Glostrup Hospital, Glostrup, Denmark.

The purpose of the study was to investigate OTX2 mutations as the genetic cause of microphthalmia/anophthalmia in a cohort of Danish patients. Microphthalmia is characterized by the presence of a small eye and anophthalmia of absence of an eye within the orbit. The prevalence is reported to be 3 to 30 in 100.000. Microphthalmia/ anophthalmia can occur isolated or as part of a syndrome. The cause can be chromosomal, monogenic or environmental. Of monogenic causes SOX2 is the major gene responsible for 10-15% of the cases. Other genes causing microphthalmia/anophthalmia are OTX2, PAX6, RAX, CHX10 and FOXE3, but only few mutations have been identified for each of these genes. OTX2 is a bicoid-type homeodomain containing transcription factor, expressed during development in the neural and sensory structures, in the eye, ear, nose and brain. The OTX2 gene consists of 3 exons that are alternatively spliced, resulting in at least two protein isoforms of 289 and 297 amino acids. We investigated 23 patients with microphthalmia/anophthalmia for mutations in OTX2. Mutation analysis of OTX2 was performed by direct sequencing of PCR amplified coding regions and MLPA analysis. We identified a two-basepair deletion (c.667_668delGG) in exon 3 of OTX2. This mutation is predicted to cause premature truncation of the protein (p.Gly223TYRfsX28). The patient presented with bilateral microphthalmia, agenesis of the corpus callosum, congenital hypothyroidism, ventricular septal defect, cryptorchidism and asymmetry of the lower extremities.

Detection of human copy number variations using complete hydatidiform moles carrying haploid genomes. *Y. Kukita, K. Higasa, T. Tahira, K. Hayashi* Division of Genome Analysis, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan.

Copy number variations (CNVs) of DNA segments in the human genome can confer various phenotypic variations such as risk to complex disease. Because there is an abundance of CNVs with possible population differentiation, cataloging CNV regions for each ethnic group is biomedically important. Available CNV data is far from complete, due to the limitations of detection methods and samples used. We determined a genome-wide high resolution CNV map, using a collection of Japanese complete hydatidiform moles (CHMs) as samples, and analyzing the intensity values obtained by high-density DNA array hybridization (Affymetrix Genome-Wide Human SNP Array 6.0). Using CHMs is advantageous in CNV detection, because the relative change in the hybridization signal caused by CNV is expected to be two-fold larger for CHMs than for usual diploid samples (thus, larger S/N ratio). We also determined autosomal CNVs using the data of diploid samples (HapMap JPT from Affymetrix) for comparison, and found that more CNVs per genome, and shorter mean CNV size in our CHMs than in JPT. Also, many common CNV regions defined by CHMs were not detected as the major common CNV regions by JPT. Comparing our results with those in the Database of Genomic Variants (Toronto), we found that about half of our CNV regions were not reported. In conclusion, the CNV analysis using CHM samples enables sensitive detection of CNVs.

Digital allelotyping revealed tissue specific and allele specific gene expression in human. *K. Zhang[1,5], J. Li[5], Y. Gao[2], B. Xie[2], J. Deng[2], D. Egli[4], E. Leproust[3], K. Eggan[4], G. Church[5]* 1) Department of Bioengineering, UCSD, La Jolla, CA; 2) Virginia Commonwealth University, Richmond, VA; 3) Agilent Technologies, Santa Clara, CA; 4) Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA; 5) Department of Genetics, Harvard Medical School, Boston, MA.

We developed a digital allelotyping method by capturing exonic SNPs from the transcriptome with padlock probes followed with single molecule sequencing. We applied this method to three cell lines (B-lymphocytes, fibroblasts and keratinocytes) established from a human subject in the Personal Genome Project. Approximately 30% of genes showed allele-specific gene expression, among which a fraction of genes are tissue specific, suggesting the presence of tissue specific cis-regulatory polymorphisms. We also applied the digital allelotyping assay on three human embryonic stem cell lines, two of which were derived from the fertilized eggs of a same couple (sibling lines) and hence share 50% genetic identity. The two sibling lines share more genes with the same allelic-specific pattern than with the other genetically unrelated line. Our study highlighted the prevalence of cis-regulatory polymorphisms in the human genome. Many of such polymorphisms could play causative roles in common human diseases.

DATABASE TO SUPPORT THE INTERPRETATION OF HUMAN MISMATCH REPAIR GENE VARIANTS (WWW.MMRUV.INFO). *R. Hofstra, R. Sijmons* Dept Med Gen, UMCG, Univ Groningen, Groningen, Netherlands.

Germline mutations in the mismatch repair (MMR) genes MLH1, MSH2, MSH6 and PMS2 can cause Lynch syndrome which is the most common type of hereditary colorectal cancer. The clinical implications of most missense mutations and small in-frame deletions in these genes are unclear. Clinical classification of MMR gene UVs will be a huge challenge. We have constructed an online database, www.mmruv.info , dedicated to these unclassified variants (UVs) of the MMR genes. It can be easily searched for information on the results of functional assays and other findings, including tumour characteristics (microsatellite instability, immunohistochemical staing of MMR proteins), phenotype (type of cancer, age at diagnosis, Amsterdam criteria, Bethesda criteria), segregation within families and frequency in controls. Results from in silico predictions of pathogenicity will be added as well. Data can be added by the database curators or by users through a web form after a check by the curators. We have formed a collaboration with NICTA (Australia) to automatically mine the literature more thoroughly for relevant MMR gene variant associated publications. Recently formed committees within the International Society for Gastrointestinal Hereditary Tumours (InSiGHT, www.insight-group.org) are working towards collecting data, developing classification algorithms and will act as an expert panel which classifies the MMR gene UVs. Our MMR gene missense database will be one of the tools to support that process. By moving the database and the other two MMR gene LSDBs, that of InSiGHT and of Michael Woods, to the LOVD platform (www.lovd.nl), further steps have been taken to connect and intregrate these databases.

Salla disease without sialuria: extension of the free sialic acid storage phenotype. *F. Mochel[1, 2], B. Yang[2], J. Barritault[3], U. H. Engelke[4], W. S. Benko[5], C. Kaneski[2], F. Seguin[3], R. A. Wevers[4], J. Ding[2], M. T. Vanier[6], F. W. Verheijen[7], R. Schiffmann[2]* 1) Neurogenetics, INSERM U679, Hôpital La Salpêtrière, Paris, France; 2) Institute of Metabolic Disease, Baylor University Medical Center, Dallas, TX, USA; 3) INSERM E0324, Hôpital La Milêtrie, Poitiers, France; 4) Radboud University Nijmegen Medical Center, Laboratory of Pediatrics and Neurology, Nijmegen, The Netherlands; 5) DMNB, NINDS, NIH, Bethesda, MD; 6) INSERM U499, Faculté de Médecine Laënnec, Lyon, France; 7) Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands.

Salla disease is caused by mutations in the SLC17A5 gene, which results in accumulation of free sialic acid in lysosomes. Salla patients present with early onset motor and cognitive deficits. These symptoms are usually well correlated with the brain MRI pattern mostly characterized by diffuse supratentorial hypomyelination, thin corpus callosum and variable degree of cortical and cerebellar atrophy. Elevated urinary excretion of free sialic acid, also called sialuria, is the hallmark of the disease. Using nuclear magnetic resonance spectroscopy (NMRS), we identified two siblings, aged 9 and 16 years, with elevated free sialic acid in cerebrospinal fluid, but remarkably, absence of sialuria. The clinical picture was dominated by mental retardation with minimal motor deficit in the context of mild hypomyelination but no atrophy. Tendon reflexes were decreased while nerve conduction velocity was normal. Despite a mild and unusual phenotype, both patients harbored a homozygous K136E SLC17A5 mutation. Preliminary evidence showed elevated free sialic acid in cultured skin fibroblasts. Sural nerve biopsy contained cytoplasmic endosomal inclusions in Schwann cells, and myelin lipids including gangliosides were analyzed. The presentation of our patients extends the phenotype of free sialic acid storage diseases. SLC17A5 mutations have to be considered in patients with hypomyelination, even in the absence of sialuria. Screening for free sialic acid storage disorders can be further performed by using NMRS in order to determine free sialic acid levels in cerebrospinal fluid.

Mutations of the *SYCP3* gene in women with recurrent pregnancy loss. *H. Kurahashi, H. Bolor, T. Mori, S. Nishiyama, H. Inagaki, H. Kogo, M. Tsutsumi, T. Ohye* Div Molecular Genetics, ICMS, Fujita Health Univ, Toyoake, Aichi, Japan.

Aneuploidy, a chromosomal numerical abnormality in the conceptus or fetus, occurs in at least 5% of all pregnancies and is the leading cause of early pregnancy loss in humans. Accumulating evidence now suggests that the correct segregation of chromosomes is achieved by events occurring in prophase during meiosis I. These include a synapsis between homologous chromosomes, cohesion between sister chromosomes, and meiotic recombination. In our current study, we demonstrate that mutations in *SYCP3*, a gene encoding an essential component of the synaptonemal complex that is central to the interaction of homologous chromosomes, contributes to recurrent pregnancy loss. Two out of 26 women with recurrent pregnancy loss of unknown cause were found to carry independent heterozygous nucleotide alterations in this gene, neither of which was present among a group of 150 control fertile women. Analysis of transcripts from mini-genes harboring each of these two mutations revealed that both affected normal splicing possibly resulting in the production of a C-terminally mutated proteins. The mutant proteins were found to interact with their wild-type counterpart *in vitro* and inhibit the normal fiber formation of the SYCP3 protein when co-expressed in a heterologous system. These data suggest that these mutations are likely to generate an aberrant synaptonemal complex in a dominant-negative manner and contribute to abnormal chromosomal behavior that may lead to recurrent miscarriage. Combined with the fact that similar mutations have been previously identified in two males with azoospermia, our current data suggest that sexual dimorphism in response to meiotic disruption occurs even in humans.

Dual structure of Japanese population and genetic differentiation over the genome. *Y. Yamaguchi-Kabata[1], K. Nakazono[1], A. Takahashi[1], S. Saito[2], N. Hosono[2], M. Kubo[2], Y. Nakamura[3,4], N. Kamatani[1,5]* 1) Laboratory for Statistical Analysis, Center for Genomic Medicine, RIKEN, Tokyo, Japan; 2) Laboratory for Genotyping, Center for Genomic Medicine, Yokohama, Japan; 3) Laboratory for Molecular Medicine, Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 4) Center for Genomic Medicine, RIKEN, Yokohama, Japan; 5) Institute of Rheumatology, Tokyo Womens Medical University, Tokyo. Japan.

Because population stratification can cause spurious associations in case-control studies, it is important to know whether and to what extent the population is stratified. Furthermore, it is also important to understand how the chromosomal regions have differentiated between subpopulations if the population stratification exists. Our previous study using genome-wide SNP genotypes from 7,003 individuals showed that most of Japanese individuals fell into two clusters, Hondo and Ryukyu (Okinawa) clusters. To clarity how the two subpopulations have genetically differentiated, we examined the level of differentiation and examined the differences in genotype frequencies for genome-wide 270,000 SNPs. The average F_{ST} was 0.003 between Hondo and Ryukyu clusters, while the average F_{ST} between Hondo Japanese and Han-Chinese populations was 0.006. The highly differentiated regions between Hondo and Ryukyu clusters were found in HLA region in chromosome 6, and particular regions in chromosomes 2, 4 and 9. The differentiation in nonsynonymous SNPs was the highest in a SNP in *ABCC11* gene, which is associated with ear wax type. In comparison between Hondo Japanese and Han-Chinese populations, we detected local regions showing high level of differentiation. Among nonsynonymous SNPs examined, the highest F_{ST} was observed at the first methionine codon in *PSCA* gene in chromosome 8. We show the heterogeneity in the level of differentiation over chromosomes among those subpopulations in East Asia, and discuss possibility that high differentiations in particular genomic regions were driven by positive selection.

Gender specific risk alleles and gender interaction modifies the risk for developing asthma at the Vitamin D Receptor (*VDR*) locus. *D. Daley[1], Y. Bosse[2], M. Lemire[3], D. Zamar[1], B. Tripp[1], A. Montpetit[4], A. Becker[5], A. James[6], A. W. Musk[6], L. J. Palmer[7], C. Laprise[8], P. D. Paré[1], T. J. Hudson[3]* 1) University of British Columbia, Vancouver, Canada; 2) Centre de Recherche, Hôpital Laval, Institut Universitaire de Cardiologie et de Pneumologie de lUniversité Laval; 3) Ontario Institute for Cancer Research; 4) Genome Quebec Innovation Centre; 5) University of Manitoba, Canada; 6) Sir Charles Gairdner Hospital; 7) University of Western Australia; 8) University of Quebec at Chicoutimi.

Asthma and atopy are common complex diseases that demonstrate heterogeneity in phenotypic presentation, incidence, and prevalence by age and gender. Asthma is more prevalent in males during childhood and this distribution changes during puberty. It has been postulated that there are gender-specific patterns to the genetic susceptibility of many complex traits. Recent reports of flip-flop effects, with the same associated SNP having opposite allelic associations, have been reported for a number of complex diseases including asthma and the Vitamin D receptor *VDR*. We observed a flip-flip association at this locus between a childhood sample (CAPPS) and an adult persistent asthma sample (SLSJ). We hypothesized that gender may modify genetic effects at the *VDR* locus. We conducted stratified analyses and tested for gender interaction at the VDR locus in 4 study populations: 1) a high risk birth cohort the Canadian Asthma Primary Prevention Study (CAPPS, 549 families), 2) a population-based birth cohort of children from the Study of Asthma Genes and Environment (SAGE, 723 families), 3) a French Canadian founder population (the Saguenay-Lac St. Jean Quebec family based sample (SLSJ, 306 families)) and 4) a population based sample from Australia, the Busselton Health Study population (644 cases and 751 controls). A joint analysis with 5,565 subjects found evidence for gender specific effects and interaction at rs866441(*P*=0.0050) and rs2239179 (*P*=0.0296). There was a protective effect of the GT haplotype in females (OR=0.61) compared with males (OR=1.39), haplotype interaction P-value =0.0025. We postulate that gender effects may be responsible for the flip-flop associations at the *VDR* locus.

Acylcarnitine profiles by tandem mass spectrometry are correlated with physiological condition and nutrition in sever preterm infants. *M. Wada[1], H. Usui[1], M. Yokoyama-Izumi[1], N. Ishige[2], A. Anazawa[2], S. Hosono[1], M. Minato[1], S. Takahashi[1], M. Owada[2], T. Kitagawa[2], H. Mugishima[1]* 1) Pediatrics, Nihon University School of Medicine, Tokyo, Japan; 2) Tokyo Health Service Association, Tokyo, Japan.

Background: Measurement of free carnitine and acylcarnitines allows to detect the several inborn abnormalities of metabolism in neonatal screening. Because available data for sever preterm infants is limited, their acylcarnitine profiles are still unknown and cut off value is discussed. The aim of this study was to characterize the carnitine status in preterm infants with respect to other physiological examinations and nutrition. **Methods:** Seventy-nine preterm infants were divided to three groups by gestational age, 22-27 (A), 28-31 (B), 32-36 (C) weeks and another healthy full-term 30 infants are as control (D). Blood samples were taken at 5th postnatal day and analyzed by tandem mass spectrometry. **Results:** Concentration of free carnitine were significantly (p0.01) lower in group A as very preterm infants compared with group B. While the concentration in group B and C, mature preterm infants, was same level as group D as full-term infants. Free carnitine level showed positive correlation between gestational age (p0.01) and hematocrit (p0.01). Concentrations of total acylcarnitine, short- and long-chain acylcarnitines were significantly (p0.001) lower in group A than in another three groups, but there was no difference of middle-chain acylcarnitines. In addition, in A and B groups, significant (p0.001) positive correlation was found between C3 and amount of protein intake, but not with total protein level in serum. Long-chain acylcarnitines was positively (p0.001) correlated with amount of lipid intake. Furthermore, C5OH in group A was significantly higher than other groups (B: p0.01, C, D: p0.001) and positively (p0.05) correlated with total bilirubin. **Conclusions:** Manifestation of physiological conditions such as anemia, jaundice and information of nutrition is very important to evaluate the carnitine profiles and avoid the false negative or positive of tandem mass screening in very preterm infants.

A two-stage whole genome association study of intracranial aneurysm in a Japanese cohort. *K. Yasuno[1], A. Tajima[1], T. Takahashi[1], A. Hata[2], I. Inoue[1]* 1) Department of Molecular Life Science, Tokai University School of Medicine, Kanagawa, Japan; 2) Department of Public Health, School of Medicine, Chiba University, Chiba, Japan.

Rupture of an intracranial aneurysm (IA) causes subarachnoid hemorrhage, a catastrophic form of stroke. Familial aggregation of IA suggests the existence of genetic risk factors attributing to the formation of IAs. Thus far genetic linkage and candidate-gene association studies were performed in various cohorts, however, consistent loci have not been identified. Most recently, a SNP (rs10757278) on chromosome 9p21 was found to be associated with IA in European populations. We sought to replicate this finding in a Japanese cohort of 773 IA cases and 722 controls, and found a significant association with the same risk allele ($P = 3.8 \times 10^{-5}$, odds ratio = 1.35, 95% confidence interval 1.16-1.57). We also performed a two-stage genome-wide association study in Japanese IA patients and controls (1st stage 300 cases and 200 controls, 2nd stage 460 cases and 460 controls). Completing the 1st stage analysis for over 300,000 SNPs genotyped on the Illumina platform, we performed the 2nd stage genotyping using the Illumina GoldenGate assay for 2,304 tag SNPs which showed *P*-values 0.008 in the 1st stage. Among those SNPs, we have found from a multilocus test of association in the 1st stage samples that two short genomic regions (chromosomes 3 and 17) surpassed a genome-wide significance level of 5×10^{-7}, which supports the inclusion of true positives in the 2nd stage SNPs. The results of the joint analysis of 1st and 2nd stage genotypes are presented.

Replication of *GCKR* polymorphism with triglyceride levels in Hong Kong Chinese population. *C. H. T. Tam, M. C. Y. Ng, W. Y. So, R. C. W. Ma, J. C. N. Chan* Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Shatin, Hong Kong, China.

Background: Recent genome-wide association and replication studies in European populations suggest that glucokinase regulatory protein (*GCKR*) gene located on chromosome 2p23.2-3 are associated with type 2 diabetes and related metabolic traits such as lipids, glucose and insulin levels. *GCKR* regulates glucokinase (*GCK*) which is the first glycolytic enzyme playing an important role in controlling the homeostasis of blood glucose. In this study, we aim to replicate the association of the common *GCKR* rs780094 polymorphism with extensive metabolic traits in Hong Kong Chinese population.

Methods: The single nucleotide polymorphism was genotyped in 594 adults [age mean SD = 41.3 11 years, % males = 45] and 981 adolescents [age mean SD = 15.3 2 years, % males = 47] that participate in a health screening program. Associations of rs780094 at additive model with metabolic traits including body mass index (BMI), waist circumference (WC), percentage body fat as measured by bioelectric impedance (FAT), systolic and diastolic blood pressure, lipids (total cholesterol, triglyceride, HDL, LDL), glucose at OGTT for 0, 60 and 120 min and fasting insulin were assessed by linear regression adjusted for covariates age and sex.

Results: Based on our findings, the reported risk allele T of rs780094 is consistently and significantly associated with an increased level of triglyceride ($P = 9.1 \times 10^{-7}$, geometric mean (95% CI) = 0.90 (0.85 - 0.96) mmol/l for TT carriers, 0.84 (0.81 - 0.87) mmol/l for TC carriers, 0.77 (0.74 - 0.80) mmol/l for CC carriers). However, we did not observe any association between rs780094 and other metabolic traits.

Conclusions: In summary, our study support *GCKR* as a susceptibility locus influencing triglyceride levels in Chinese population.

Mitochondrial DNA Instability and Optic Atrophy Plus Phenotypes due to OPA1 mutations. *P. Amati-Bonneau[1,2], D. Bonneau[1,2], ML. Valentino[3], P. Labauge[4], C. Verny[5], A. Furby[6], G. Mutations in OPA1, a dynamin-related GTPase involved in mitochondrial plasticity, have been linked to autosomal dominant optic neuropathy(ADOA, MIM 165500). We here report on eight patients from six ADOA families with sensorineural deafness, ataxia, axonal sensory-motor polyneuropathy, chronic progressive external ophthalmoplegia and mitochondrial myopathy with cytochrome c oxidase negative and ragged red Fibers. We demonstrate that these patients all harboured variable amounts of multiple deletions of mtDNA in their skeletal muscle. All six probands also harboured heterozygous missense mutations in the OPA1 gene. We show that certain OPA1 mutations exert a dominant negative effect responsible for multi-systemic disease, closely related to classical mitochondrial cytopathies, by a mechanism involving mtDNA instability.

The responsible genes for low HDL in Turkish coronary artery disease patients. *M. Alikaşifoglu[1], L. TokgÃ¶zoÄ lu[2], B. Volkan-Salanci[1], E. B. Kaya[2], E. Tülümen[2]* 1) Hacettepe University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey; 2) Department of Cardiology.

Background and aim: The aim of this study is to determine the genetic basis of low HDL in patients with angiographically documented CAD, and HDL <40 mg/dl compared to healthy controls with normal HDL. Methods: A total of 296 patients (M/F: 161/135) were included in the study group. Angiographically, 61% of the patients were diagnosed as CAD and 27% had low HDL (<40mg/dL). The analysis of 16 SNPs from 11 genes including lipid metabolism (Apolipoprotein (Apo) E, CETP, LPL, hepatic lipase, ABCA1, Apo A1) and inflammation (IL6, IL6 rec, IF rec, PPAR and UCP2) were carried out in a total of 200 patients. 7 SNPs were analyzed using TaqMan probes and 9 SNPs with PCR-RFLP. A subset (30/27 case/control) of the total setup was genotyped by 10K Affymetrix GeneScanner. The genotyped samples SNPs were analyzed in terms of allele frequencies, population stratification, and compliance with Hardy-Weinberg equilibrium. The whole genome analysis of the cohort will be completed. Results: HDL levels were higher in B2 allele carriers of CETP Taq1b polymorphism (Kruskall Wallis test (KWt) p: 0,007). Frequency of ApoE2 allele was higher in patients without CAD (X2 p: 0,007) and low LDL levels were observed in E2 allele carriers (JT test p: 0,047). Trigliseride levels were highest in A-allele carriers of ApoA1 mspI polymorphism (KWt, p: 0,042). Both LDL and total cholesterol levels were higher in TT genotype of UCP2 (rs660339) polymorphism (KWt, p: 0,022 and p: 0,032, respectively). ABCA1 rs2230808 GG genotype frequency was higher in control group, compared with CAD patients (X2 p:0,012). Microarray analysis revealed following SNPs to be significantly important: rs1598978 (chr12), rs3887413 (20p12.2, LOC728450), rs1587099 (chr8), rs955639 (chr3), rs1451371 (chr7, DOPA decarboxylase), rs1389455 (chr11, TMEM16C) (for all SNPs p<0.001). Conclusions: The relations of the SNP genotypes and serum lipid levels were correlated with the literature. The SNPs that were found to be significant after microarray analysis and their role on pathophysiology of CAD should be further evaluated.

Association of Vav3 polymorphism with coronary artery disease. *J. Lee[1], E. S. Shin[1], E. Y. Cho[1], Y. Yoo[1], J. lee[1], J. H. Jang[1], J. Lee[2], Y. Jang[3]* 1) DNA Link, Inc, Seoul, Korea; 2) Clinical Nutrigenetics/Nutrigenomics Lab, Department of Food & Nutrition, College of Human Ecology, Yonsei University, Seoul, Korea; 3) Division of Cardiology, Cardiovascular Genome Center, Yonsei Medical Institute, Yonsei University, Seoul, Korea.

Vav proteins contain multiple function motifs and are involved in various cellular signaling processes. Vav3 , a quanine nucleotide exchange factor (GEF) for Rho family GTPases, was an essential factor regulating the homeostasis of the cardiovascular system. Vav3-deficient mice exhibited tachycardia, systemic arterial hypertension and extensive cardiovascular remodeling. We conducted three stage Genome-wide association analysis to identify the association of CAD with VAV3 polymorphism. In stage 1, We screened random SNP(about 100 SNPs) in Vav3 using affymetrix 500K chip in 290 control and 230 CAD Korean population. Next second stage, we analyzed 12 SNPs that linked SNPs with significant SNPs of stage 1 analysis in additional sample set(1087 control vs 1172 CAD) using Molecular inversion probe technology. Then we analyzed cSNP that LD with leading intronic SNP using TaqMan analysis. The risk allele of intronic SNP has a prevalence of approximately 31%, with the risk increased 82.5% in recessive model in combined analysis(stage 1+ stage2, p=8.19 x10-6). The intronic SNP had pairwise r2 values of 0.78 with the cSNP. The risk allele frequency of cSNP is 0.26 in control and 0.30 in CAD. The OR of CAD was 1.69(95% CI, 1.27-2.25) in recessive model. The p values was 3.01 x10-4. The haplotype anlaysis also showed the significant association with CAD(p=2.91 x10-5). But we observed no interaction on the traditional CAD risk factors with cSNP in controls. This result indicates that VAV3 can play a role in the pathogenesis of CAD.

Genome-Wide Association Studies Using RapidMiner. *V. Milanov* Department of Mathematics and Computer Science, Fayetteville State University, 1200 Murchison Road, Fayetteville, NC 28301.

A current challenge of genetic epidemiology is dealing with large numbers of genetic factors. To address this problem, genome-wide association studies (GWAS) explore the human genome in an attempt to identify common genetic factors that influence health and disease. The selection of a reduced set of genetic factors in GWAS can yield insight to biological processes, increase prediction accuracy of diseases, and improve patient care. In this study, we employ the RapidMiner data mining environment to reduce an initial pool of SNP markers in the simulated rheumatoid arthritis data available from Genetic Analysis Workshop 15. Our results indicate that RapidMiner is an effective GWAS tool that can identify disease-associated SNPs with high probability.

Left Ventricular Outflow Tract Obstructions: family data and NOTCH1 mutations. *W. S. Kerstjens-Frederikse[1], R. F. M. Berger[2], Y. J. Vos[1], R. M. W. Hofstra[1]* 1) Dept Genetics, University Medical Center Groningen, Groningen, Netherlands; 2) Dept Pediatric Cardiology, University Medical Center Groningen,Groningen, the Netherlands.

Left ventricular outflow tract obstructions (LVOTO) are often familial. Early detection of (latent) LVOTO or increased familial risk can prevent unexpected cardiac death. To analyse the percentage of familial cases all new and known patients with left sided anomalies seen after april 1st 2006 by the department of pediatric cardiology (170) were offered genetic counselling. Thirty-one patients refused genetic counseling, the others were seen by the same clinical geneticist. In 44 an aortic valve stenosis was diagnosed, in 21 a bicuspid aortic valve without stenosis, in 28 a hypoplastic left heart, in 67 an aortic coarctation and in 10 other left sided anomalies. In 17 patients the family history combined with ultrasound of first degree relatives revealed a LVOTO and in another 19 probands a relative with yet another congenital heart defect was found. The first mutations in NOTCH1 were published in 2005 by Garg et al. in two families with bicuspid aortic valve and other heart defects, and so far two small series showed mutations in approximately 4% of the patients. In our patient group, sequencing has been finished in 40 patients, and 3 mutations have been found. We conclude that LVOTO is often familial and most pedigrees are compatible with autosomal dominant inheritance with incomplete penetrance. NOTCH1 mutations are found in a small percentage of familial and non-familial cases.

Estimation of association P-value at untyped SNP using the publicly available information on pairwise linkage disequilibrium. *J. Ohashi* Dept Human Gen, Grad Sch Med, Univ Tokyo, Tokyo, Japan.

In most of disease-gene association studies, a limited number of single nucleotide polymorphisms (SNPs) in a candidate gene are typed, and many SNPs remain untyped. Here we propose a method for estimating association P-values at such untyped SNPs using the publicly available information on pairwise linkage disequilibrium (LD) between typed and untyped SNPs in the reference population (e.g., HapMap population) in which both SNPs have been typed. A computer simulation revealed that the proposed method showed higher statistical power if untyped SNP to be estimated was directly associated with the disease susceptibility, compared to the case that association tests were performed only for typed SNPs. In addition, the inflation of type I error rate was negligible when the LD between typed and untyped SNPs is strong. Since our approach is mathematically simple, the proposed method would be a practical tool for assessing the necessity of further analysis for untyped SNPs in the candidate gene.

Spinocerebellar ataxia type 6 (SCA6) is associated with small 1A-calcium channel protein aggregates containing expanded polyglutamine in the cytoplasm and the nucleus of human Purkinje cells. *K. Ishikawa, T. Ishiguro, M. Takahashi, T. Amino, H. Mizusawa* Dept Neurology, Tokyo Med & Dental Univ, Tokyo, Japan.

SCA6 is an adult onset neurodegenerative disease caused by a small expansion of trinucleotide (CAG) repeat encoding polyglutamine in the 1A voltage-dependent calcium channel gene (*CACNA1A*). This polyglutamine stretch lies near the carboxyl(C-) terminus of the channel protein. Recently, the C-terminal fragments of the 1A & 1S-calcium channel proteins have been shown to translocate to the nucleus, and have a role in transcriptional regulation in normal condition. To understand the SCA6 pathogenesis, we undertook this study to see the intracellular expression of C-terminus of the 1A-calcium channel protein in human brains. A new rabbit polyclonal anti-1A-calcium channel protein antibody that recognizes polypeptide near the C-terminus was generated. The specificity of this antibody was confirmed by checking recognition of recombinant 1A-calcium channel protein on western blot. Immunohistochemistry was undertaken by the ABC method on formalin-fixed paraffin-embedded tissue sections of control (n=6) and SCA6 (n=4) brains. In controls, immunoreactivity was generally seen in the cytoplasm, but not in the nucleus of any neurons. In SCA6 brains, however, small aggregates were seen specifically in their Purkinje cells. No aggregates were found in any other neurons of SCA6 brains, or in other control brains including other polyglutamine diseases. Aggregates were small (approximately 0.5 to 1.5 m in diameter), but were numerously present in the cytoplasm of SCA6 Purkinje cells. In addition, some aggregates were also found in the SCA6 Purkinje cell nuclei. Theses small aggregates were mostly recognized by anti-expanded polyglutamine antibody *1C2*, but not by an antibody against the C-terminal end of the 1A-calcium channel protein (A6RPT-C; Hum. Mol. Genet. 8: 1185-93, 1999). The present study demonstrates that small aggregates, which consist with the 1A-calcium channel protein containing expanded polyglutamine, are formed both in the cytoplasm and the nucleus of SCA6 Purkinje cells.

Genotype-phenotype correlation of ocular manifestations in cardio-facio-cutaneous (CFC) syndrome. *S. P. Shankar[1], T. L. Young[2], K. A. Rauen[1]* 1) Medical Genetics, University of California San Francisco, San Francisco, CA; 2) Center for Human Genetics, Duke University, Durham, NC 27710.

CFC syndrome is a congenital disorder involving multiple organ systems characterized by cardiac defects, distinctive craniofacial appearance and cutaneous abnormalities. Mutations in genes of the Ras/MAPK pathway *BRAF, MEK1,* and *MEK2* have been identified as causal of the CFC syndrome. In a cohort of 25 mutation positive CFC individuals, 22 had mutations in *BRAF*, 2 had mutations in *MEK1* and 1 patient had a *MEK2* mutation. 21/25 (85%) patients reported ocular involvement; of these strabismus (85%), refractive errors (66%), nystagmus (50%), and optic nerve hypoplasia (23%) were the most commonly reported manifestations. These ocular features were seen in mutations of all three genes. All patients with Q257R, the most common mutation in *BRAF* had strabismus. 5/22 patients with mutations distributed across both the CR1 and protein kinase domains of the *BRAF* gene exhibited optic nerve hypoplasia. The only patient with a *MEK2* mutation, F57C had bilateral cataracts in addition to nystagmus, strabismus, myopia, and optic nerve hypoplasia exhibiting the most severe ocular phenotype. In this cohort of patients, we did not identify any definitive genotype-phenotype correlation; however, the study was limited because of the very small number of patients with *MEK1* and *MEK2* mutations. The high occurrence of ocular abnormalities such as strabismus and optic nerve hypoplasia suggests that the Ras/MAPK pathway plays an important role in human ocular alignment control, and in the development of the optic nerve. Investigations on therapeutics targeting the Ras/MAPK pathway are underway. Further characterization of the ocular manifestations in a larger number of mutation positive CFC patients is important to determine definitive genotype-phenotype correlations and to develop potential treatment strategies.

Cumulative Association of Five genetic variant with coronary artery disease in Korean population. *E. Y. Cho[1], M. Y. Park[1], S. Kim[1], H. Y. Jang[1], M. H. Yun[1], J. lee[2], Y. Jang[3], J. Lee[1]* 1) DNALink Inc, Seoul, Korea; 2) Clinical Nutrigenetics/Nutrigenomics Lab, Department of Food & Nutrition, College of Human Ecology, Yonsei University, Seoul, Korea; 3) Division of Cardiology, Cardiovascular Genome Center, Yonsei Medical Institute, Yonsei University, Seoul, Korea.

Coronary artery disease (CAD) is a major cause of death in both Asian and Western countries. We conducted two-stage genome-wide association study in 230 CAD and 290 controls followed by 3000 single nucleotide polymorphisms (SNPs) were tested for confirmation in 1398 cases and 1378 controls. SNPs in five chromosomal regions- 2p16, 5q31, 9p21, 12p12, 19p13- have been associated with CAD in Korean population. A significant association on chromosome 9p21.3 was independently replicated in the Korean samples. P=1.034 x 10-7 This is the same locus with the strongest association signal in a Caucasian population. Then, we evaluated combined association of the 5 SNPs with CAD. We constructed a genotype score on the basis of the number of unfavorable alleles. The genotype score was associated with CAD in models adjusted for covariates including age, BMI(OR=1.354, 95% CI 1.294-1.561, p= 3.757 x10-8). As compared with subjects with a genotype score of 3 or less (48.5% of the control vs 33.5% of the case), subjects with a score of 6 or more (6.5% of the control vs 14.9% of the case) had a increased risk of CAD (OR=3.36, 95% CI 2.50-4.52, p= 5.09x10-8). In high risk group (under age 55 years or over BMI 25), as compared with subjects with a genotype score of 3 or less subjects with a score of 6 or more have a significantly higher risk OR of CAD (OR=3.73, 95% CI 2.46 - 5.65, p=4.93x10-10); and OR=4.04, 95% CI 2.34-6.98, 5.48x10-7) respectively. This result showed genotype score of five validated SNPs was independent risk factor for incident CAD.

Long term outcome of presymptomatic testing in Huntington disease. *A. Durr[1,2,3], M. Gargiulo[1], S. Lejeune[1], M.-L. Tanguy[4], K. Lahlou-Laforêt[5], A. Faudet[1], D. Cohen[6], J. Feingold[1]* 1) AP-HP, Pitié-Salpêtrière Hospital, Department of Genetics and Cytogenetics, Paris, France; 2) INSERM, UMR_S679 Neurologie & Thérapeutique Expérimentale, Paris, France; 3) UPMC Univ Paris 06, UMR_S679, Paris, France; 4) AP-HP, Pitié-Salpêtrière Hospital, Biostatistic Departement, Paris, France; 5) AP-HP, Georges Pompidou European Hospital, Service de Psychologie Clinique et Psychiatrie de Liaison, Paris, France; 6) AP-HP, Pitié-Salpêtrière Hospital, Department of Child and Adolescent Psychiatry, CNRS FRE 2987, Paris, France.

Our study on long-term outcome of 351 presymptomatic testing for HD had two aims: comparison of the psychological well-being and social adjustment of carriers and non-carriers of the mutation, and identification of predictor for bad outcome. We performed a cross-sectional study, those who had motor signs were excluded from the comparison. A structured interview including 5 self-report scales and the MINI (Mini International Neuropsychiatric Inventory) was proposed. We interviewed 119 testees (53%), 62 non-carriers and 57 carriers after a mean delay of 3.7 years (range: 0.32 to 8.9) after their result. Depression was frequent in asymptomatic carriers (58%). The self reported impact of the test showed that 27% of non-carriers did not cope well with a favourable result, and a significant percentage of non-carriers (24%) were depressed during follow-up. Using different variables such as carrier status, sex, age at time of the result, delay between 1st contact and result, marital status, having children, history of depression, sex of the affected parent, time of being aware of the genetic risk, test motivation. Multivariate analysis showed that only previous episode of depression was predictive of depression after genetic testing in both carriers and non-carriers of the HD mutation ($p<0.0001$). Psychological support and psychiatric care should be given to both carriers and non-carriers after presymptomatic testing for HD. Particularly and regardless of the result, a history of depression before the test and previous familial burden of psychiatric events will influence the outcome after the test.

The role of HIF1-alpha and VEGF genes in gastric cancer. *S. Huang, Y. Tsai, Y. Lee, D. Wu, S. Juo* kaoshiung medical university, kaoshiung, Taiwan.

Background and Purpose Gastric cancer still represents a difficult problem in the field of oncology, in terms of morbidity and mortality. Hypoxia-inducible factor 1alpha (HIF-1alpha), and vascular endothelial growth factor (VEGF) are both important factors in the mechanisms inherent to tumor progression. In the process of tumor development, the continuing proliferation of tumor cell will lead to oxygen deficit. For survival, hypoxia tumor cells reinforce the transcription of VEGF by HIF-1alpha to enhance angiogenesis. The aim of this study sought to investigate whether polymorphisms at the HIF-1alpha and VEGF genes are associated with susceptibility to gastric cancer. Methods We conducted a case-control study. All the cases had pathologically approved gastric cancer. The controls were recruited from the patients who visited the gastroenterological clinic for gastric endoscopy. All the controls had gastric biopsy, and all the biopsy samples showed no evidence of gastric cancer. We selected two SNPs (one for each gene) that had significant association with intestinal metaplasia in our unpublished data. The genotyping was performed using the TaqMan technology. Results A total of 95 cases and 316 controls were included in the present study. Men accounted for 50.16 % of the participants and the average age was 55.412.0 year-old .For HIF1alpha-SNP, compared to the common homozygote CC (n=212) the OR for rare allele carriers CA (n=92) and AA (n=12) were 0.98 (p=0.954) and 0.67 (p= 0.462), respectively. Compared with the CA+CC genotypes, the AA genotype had an OR of 1.49 (p=0.4626). In VEGF-SNP, compared to the common homozygote CC (n=201), the OR for rare allele carriers CT (n=93) and TT (n=22) were 1.25 (p=0.42) and 1.13, (p= 0.799), respectively. Conclusions The present study did not show any significant result for the HIF-1alpha and VEGF genes, which may be due to small sample size. More case DNA samples are currently under genotyping and updated results will be presented in the conference.

To assay the association of SNP and gene expression by combining information among ethnic groups. *C. L. Hsiao[1], I. B. Lian[2], C. J. Chang[3], C. S. J. Fann[1,4]* 1) Institute of Public Health, Yang-Ming University, Taipei, Taiwan; 2) Department of Mathematical, National Changhua University of Education, Changhua, Taiwan; 3) Graduate Institute of Clinical Medical Sciences, Chang-Gung University,Tao-Yuan, Taiwan; 4) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Different gene expression (GE) pattern among ethnic groups is a popular issue in recent genomic researches, and numerous single nucleotide polymorphisms (SNP) have been identified to contribute significantly to differences in GE. Unfortunately, in study of the relationship between SNP and GE with respect to ethnic groups, the associations were estimated and tested in each group separately which could lose power in detecting significant associations. Furthermore, the genotype frequency differences between ethnic groups have rarely been accounted in such studies. Hence, more refined methods are necessary when studying the association of SNP, GE and ethnic groups simultaneously. To address this issue, a general linear model was used to estimate the relationship between genotype and GE with the entire sample. This model assumes that mechanisms of SNP regulation on GE are similar among different ethnic groups. After the distributions of GE conditional on genotypes were estimated, the amount of GE difference between ethnic groups resulted from genotype frequency difference could be measured by a linear estimator. Then, a general linear hypothesis of the SNP causing GE difference among ethnic groups was tested by an F-statistic. Furthermore, the expected genotype frequencies assuming Hardy-Weinberg Equilibrium were calculated to infer the amount of GE difference among ethnic populations. From our simulation study, this method showed higher efficiency in parameter estimation and was more powerful than testing pair-wise association one by one. In addition, this method could be applied in Genetic Genomic studies with respect to binary coding groups such as case-control study.

The use of multifactor dimensionality reduction (MDR) in study haplotype- haplotype interaction: a novel approach to increase efficiency. *A. R. Hsieh[1], I. B. Lian[2], C. S. J. Fann[1,3], C. J. Chang[4]* 1) Division of Biostatistics,Institute of Public Health, Yang-Ming University, Taipei, Taiwan; 2) Deptment of Mathematical, National Changhua University of Education, Changhua,Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 4) Graduate Institute of Clinical Medical Sciences, Chang-Gung University, Tao-Yuan,Taiwan.

Most common human diseases are caused by the complex interaction of multiple genetic and environmental factors. Efficient modeling of this complex interaction requires proper statistical methods to reduce high dimensionality. Haplotype based approaches incorporate information from multiple adjacent SNP markers and may have greater power than single-locus analysis when the SNPs are in strong LD with the risk locus. Unfortunately, the number of distinct haplotypes increases rapidly when the number of SNPs increases. Previously, Multiple Dimension Reduction (MDR) has been used to detect interactions between SNPs or tagSNPs. In this study we used an MDR-based approach to explore the feasibility of haplotype-haplotype interactions to overcome high dimension issues. To demonstrate that haplotype-haplotype interactions provide more information regarding disease association than that for tagSNP-tagSNP interactions, we simulated case-control data using six different two-locus epistasis models by using SNaP sofware. Data were analyzed by MDR with a 10-fold cross-validation. For each model, the ratio of correct classifications to the total number in the testing set was obtained to determine the best combination of attributes. These ratios were ranged from 0.48 to 0.56 for tagSNPs compared to 0.65 to 0.76 for haplotypes. Haplotype-haplotype interactions are thus shown to provide more disease-associated information than tagSNP-tagSNP interactions. Finally, a comparison was made between MDR method and logistic regression models that are commonly used to detect gene-gene interactions in various epistasis models. In the 6 epistasis models with 100 replicates that were simulated, the MDR method showed higher statistical power than that obtained from the logistic regression model.

Fifth gene behind MKS adds more information to the ciliopathy puzzle. *J. Tallila[1], E. Jakkula[1], M. Gentile[2], L. Peltonen[1,3,4,5], R. Salonen[6], M. Kestilä[1]* 1) Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Genome Informatics Unit, University of Helsinki, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) The Broad Institute, MIT Boston, MA, USA; 5) The Wellcome Trust Sanger Institute, Hinxton CB10 1SA, UK; 6) Department of Medical Genetics, Väestöliitto, Helsinki, Finland.

Meckel syndrome (MKS, [MIM 249000]) is a lethal malformation disorder characterized classically by encephalocele, polycystic kidneys and polydactyly. Although the frequency varies greatly among populations, MKS represents the most common form of syndromic neural tube defects (NTDs). Recent findings have shown primary cilia dysfunction in the molecular background of MKS, indicating that cilia are critical for early human development. In Finland, the major mutation in the *MKS1* gene explains about 70% of the cases. To locate the causative gene in the rest of the cases we looked for the homozygous regions shared by the affected fetuses without a known mutation. Based on this strategy we were able to identify the sixth locus and the fifth gene, *CC2D2A* (*MKS6*), behind MKS. The major mutation creates a new splice site leading to defective transcript. In addition, we are currently sequencing non-Finnish MKS families and have identified already six novel mutations in *CC2D2A*. Most of them are small deletions that affect the splicing. The biological function of CC2D2A is uncharacterized, but the corresponding polypeptide is predicted to be involved in ciliary functions and it has a calcium binding domain (C2). Immunofluorescence staining of patients fibroblast cells demonstrated that the cells lack cilia, providing evidence for the critical role of CC2D2A in cilia formation. In order to see the metabolic pathways that are disturbed in MKS we have done genome wide expression arrays using RNA from MKS6 fetuses and healthy controls. These analyses as well as further functional studies on the protein localization and function will bring valuable information about MKS and fetal development.

Linkage tests based on ages of onset. *H. Yoon, H. Song* Dept. of Biostatistics, The Catholic University of Korea, Seoul 137-701, Korea.

The occurrence of many diseases is highly age dependent and thus linkage analysis on age of onset trait appears to be important for many chronic diseases to detect the putative gene. Non-insulin-dependent diabetes mellitus is one of these disorders, for which many studies have shown that a single locus may have a major effect on the occurrence of the disease by influencing age of onset. The Haseman and Elston (HE) [Behav Genet 1972;2:3-19] linkage test, which defines the residuals from survival analysis on ages of onset as a continuous outcome, was shown to be powerful by Zhu et al. [Genet Epidemiol 1997;14:711-716] when a genetic effect is expected primarily due to age of onset. We propose several extensions of the HE test which incorporate information on age of onset or age at examination of sib pairs. These tests are derived from the nonparametric methods without assuming any specific distributional form of age of onset, while the residual-based method by Zhu et al. is distribution-dependent. Apart from sib pair-based linkage tests mentioned above, we propose a generalized logrank trend test based on information of age of onset or age at examination of subjects. A simulation study was performed to evaluate the power of these tests under different sampling plans of age groups, when the distributions of ages of onset are assumed to be known. The identification of a gene influencing age at onset would be important as it would lead us to understand disease development and progression and could provide new targets for therapy.

The Case for a Larger HapMap. *E. Eskin[1], N. Zaitlen[2]* 1) Dept Computer Sci, Univ California, Los Angeles, Los Angeles, CA; 2) Bioinformatics Program, Univ California, San Diego.

The HapMap provides a valuable resource to help uncover genetic variants of important complex phenotypes such as disease risk and outcome. Using the HapMap we can infer the patterns of LD within different human populations. This is a critical step for determining which SNPs to genotype as part of a study, estimating study power, designing a follow-up study to identify the causal variants, ``imputing" untyped SNPs, and estimating recombination rates along the genome. Despite its tremendous importance, the HapMap suffers from the fundamental limitation that at most 60 unrelated individuals are available per population. We present an analytical framework for analyzing the implications of a finite sample HapMap. We present and justify simple approximations for deriving analytical estimates of important statistics such as the correlation coefficient r and the non-centrality parameter lambdasqrt{N} from the HapMap. Finally, we use this framework to show that current HapMap based estimates of r^2 and power have significant errors, and that tag sets highly overestimate their coverage. We show that a reasonable increase in the number of individuals, such as that proposed by the 1000 genomes project, greatly reduces the errors due to finite sample size for a large proportion of SNPs.

Contribution of environmental and genetic modifiers to severity of the typical HFE-related haemochromatosis: a multivariate analysis. *V. Scotet, G. Le Gac, I. Gourlaouen, C. Theze, B. Chanu, A.-Y. Mercier, M.-C. Merour, C. Férec*
Inserm U613, EFS-Bretagne, Universite de Bretagne Occidentale, Brest, F-29200 France.

Background/aim: Expression of the common p.C282Y/p.C282Y HFE-related haemochromatosis genotype depends on a balance between accentuating and reducing factors. Some of these factors have been identified, but they have mainly been analyzed independently. Here, we aimed to determine contribution of different environmental and genetic modifiers to total body iron overload. Method: We studied 365 p.C282Y/p.C282Y patients (195 men and 170 women), and we used the iron removed by phlebotomy as quantitative trait (log transformed). We tested the influence of age, gender, alcohol abuse, body mass index, as well as six common variants: the 16189 T>C variant in mtDNA, the -308G>A variant in the TNF-alpha promoter, the well known duplication of the haptoglobin gene (genotypes Hp1-1, Hp1-2 and Hp2-2), and 3 SNPs located in genes involved in regulation of hepcidin synthesis (BMP2 rs23756, BMP4 rs4901474 and HJV rs16827043). Results: Univariate analyses first highlighted the relation between each potential modifiers and severity of the body iron overload. Factors with a p-value lower than 25% were included in a same multiple linear regression model. Then, stepwise elimination procedures were successively performed until a model presenting only significant predictors was found. Predictors of this last model were the male sex ($p<0.0001$), the greater age at diagnosis ($p<0.0001$), the alcohol abuse ($p=0.0008$) and the Hp2-2 genotype ($p=0.0186$). Conclusion: Our results underline the predominant influence of non-genetic modifiers in expression of the p.C282Y/p.C282Y genotype. Future investigations should address the influence of other genetic modifiers, and further look for gene/gene and gene/environment interactions.

Hereditary optic neuropathies share a common mitochondrial coupling defect. *D. Bonneau[1], A. Chevrollier[1], V. Guillet[1], D. Loiseau[1], N. Gueguen[1], M. Pou de Crescenzo[1], C. Verny[2], M. Ferre[1], H. Dollfus[3], S. Odent[4], D. Milea[5], C. Goizet[6], P. Amati-Bonneau[1], P. Reynier[1]* 1) Dept Gen & Biochem, INSERM U694, CHU Angers, Angers, France; 2) Departement de Neurologie,Centre Hospitalier Universitaire, Angers; 3) Laboratoire de Génétique Médicale EA 3949, Université Louis Pasteur, Strasbourg; 4) Service de Génétique Médicale, CHU Rennes, France; 5) Department of Ophthalmology, Glostrup Hospital,University of Copenhagen, Copenhagen, Denmark; 6) Laboratoire de Génétique Humaine, Université Victor Segalen Bordeaux 2, Bordeaux,France;.

Hereditary optic neuropathies are heterogeneous disease characterized by the degeneration of retinal ganglion cells leading to optic nerve atrophy and impairment of central vision. The two most frequent forms of optic neuropathies are Lebers hereditary optic neuropathy (LHON; MIM #535000) and autosomal dominant optic atrophy (ADOA; MIM#165500). LHON, a subacute bilateral optic atrophy, is associated with mitochondrial DNA point mutations that affect various subunits of mitochondrial respiratory chain complex I. ADOA is a progressive, bilateral optic atrophy. Mutations in the optic atrophy 1 (OPA1) gene are implicated in about 60 to 80%of cases. OPA1 encodes for a ubiquitous dynamin-related protein, anchored to the mitochondrial inner membrane involved in mitochondrial plasticity. In some cases, the clinical phenotype is aggravated by additional neurological symptoms, the so-called plus phenotype, and designated as LHON and ADOA. The third form of hereditary optic atrophy involving an identified gene concerns ADOA associated with cataract (ADOAC; MIM #165300). This rare form of optic atrophy is due to mutations in the OPA3 gene, identified as responsible for the Costeffs syndrome (MIM #258501). Like OPA1, OPA3 is located in the mitochondrial inner membrane, but its function is unknown. We found a common coupling defect of oxidative phosphorylation in fibroblasts of 16 patients affected by ADOA, ADOAC and LHON. Interestingly, the energetic defect was significantly more pronounced in LHON and ADOA patients with a more complex phenotype, the so-called plus phenotype.

The association between genetic polymorphism of ACE and hypertension in adults in central Taiwan. *R.-Y. Wang[2], K.-Y. Tung[1], K.-T. Chen[1], C.-J. Lin[3], W.-C. Shy[3], M.-C. Hung[3], C.-Y. Chen[2], T.-N. Wu[1], F.-Y. Wu[1]* 1) China Medical University, Environmental Health, Taichung, Taiwan; 2) China Medical University, Public Health, Taichung, Taiwan; 3) China Medical University, Nursing, Taichung, Taiwan.

The hypertension related cardiovascular disease account for about half of the top ten leading causes of death in recent year in Taiwan. However, hypertension is an important risk factor for cardiovascular disease and is one of the most important public health problems. Blood pressure is regulated by genetic, environmental factors and their interaction effects. The genetic polymorphism (rs1800764) locating in the upstream of angiotensin-converting enzyme (ACE) gene was suggested to have an impact on hypertension. Therefore, the aim of this study was to evaluate the association between rs1800764 genetic polymorphism of ACE and hypertension in adults aged 40 years in Sinyi village, a remote area of Nantou county in the middle of Taiwan. This is a case-control study. The subjects consisted of 153 hypertension patients and 497 normotensive subjects. Blood specimens were collected to determine the biochemical data, and demographic information were collected by conducting face-to-face interviews with structured questionnaires. The genotypes of rs1800764 were carried out by TaqMan assay. Our results showed that TT, CT, and CC genotypes of rs1800764 were all associated with blood pressure (p0.0001), and also associated with hypertension (p=0.0067). With adjusting age and gender, the analytical results of logistic regression indicated that compared to subjects with TT genotype, the subjects with CT and those with CC genotype, the odds ratios of hypertension were 1.74 (95% CI: 1.12 - 2.71) and 2.48 (95% CI: 1.45 - 4.13), respectively. In this study, we demonstrated that rs1800764 genetic polymorphism on ACE gene would associate with hypertension. Moreover, studies on the effects of rs1800764 or other variants on ACE gene and their interactions with environmental factors on hypertension or cardiovascular disease will be warranted.

CEREBELLAR ATAXIA WITH HYPOGONADISM: CLINICAL, NEURORADIOLOGICAL AND GENETIC FEATURES IN NINE FAMILIES. *C. M. Lourenco[1], C. F. R. Sobreira[2], J. M. Pina-Neto[1], W. Marques Jr.[2]* 1) Medical Genetics, University of Sao Paulo , Ribeirao Preto, Sao Paulo, Brazil; 2) Neurology,University of Sao Paulo , Ribeirao Preto, Sao Paulo, Brazil.

INTRODUCTION The association between cerebellar ataxia and hypogonadism was described in four sibs by Holmes 100 years ago, and has since become known as Holmes type ataxia. At the time of his description, it was not possible to determine whether hypogonadism was hypogonadotropic or hypergonadotropic hypogonadism. Here, we present the clinical data and molecular/biochemical studies of nine Brazilian families with cerebellar ataxia and hypogonadism. MATERIAL AND METHODS All the patients were evaluated in the neurogenetics clinics by geneticists, neurologists and endocrinologists. Brain MRI, ophtalmological exam, EMG/NCV, hormone and biochemical tests, karyotype, muscle biopsy, molecular tests for Friedreich ataxia and for SCAs (types 1, 2, 3, 6 and 7) were performed in the course of the investigation. RESULTS All patients had cerebellar ataxia, but the age of the onset was variable; it was worthy to note that ten patients had early onset ataxia. Consanguinity of parents was noted in two families; five patients had hypogononadism hypergonadotropic. Mental retardation was seen in two unrelated girls with hypogononadism hypergonadotropic. None of the patients had chromosomal anomalies and biochemical screening for CDG disorders was also norma. Molecular tests for Friedreich and SCAs 1, 2 ,3 , 6 and 7 were all negative. Optic atrophy and retinochoroidal degeneration were found in five patients; axonal neuropathy was present in four patients. Cerebellar atrophy with pons or prominent vermis involvement was a constant feature. CONCLUSIONS One family have features consistent with a rare neurological disorder , Boucher-Neuhauser syndrome; the other patients had features that may fit in the Gordon-Holmes phenotype although we believe this entity should not be an homogenous disorder. Thus, the association between cerebellar ataxia and hypogonadism comprise hetereogenous entities whose clinical investigation can elighten the pathological basis of these fascinating neuroendocrinological syndromes.

Haplotype inference of copy number variations. *M. Kato[1], Y. Nakamura[1,2], T. Tsunoda[1]* 1) Center for Genomic Medicine, RIKEN, Yokohama, Kanagawa, Japan; 2) Human Genome Center, University of Tokyo, Minato-ku, Tokyo, Japan.

Extensive studies have recently examined large-scale genetic variants called copy number variations (CNVs) in the human genome, and the universality of CNVs in normal individuals, along with their functional importance, has been increasingly recognized. However, the absence of a method to accurately infer alleles or haplotypes of CNVs from high-throughput experimental data hampers the finer analyses of CNV properties and applications to disease association studies.

We developed two algorithmic frameworks to infer haplotypes/alleles of CNVs. The first algorithm processes unrelated individuals phenotypic copy numbers, which are the total numbers of DNA copies over two homologous chromosomes and are obtained using high-throughput experimental platforms. From these data, the algorithm infers population frequencies of alleles represented as copy numbers in one homologous chromosome. It can also handle phenotypic copy numbers that are ambiguously determined, such as 2 or 3 copies, due to experimental noise. Furthermore, the algorithm can infer population frequencies of haplotypes composed of both copy number alleles and SNP alleles. The second algorithm processes the total numbers of polymorphic bases over two homologous chromosomes within a CNV region for unrelated individuals, such as two counts of polymorphic base A and one count of polymorphic base G, of which the total count is not two but three due to copy number variation. From these data, the algorithm infers population frequencies of complex haplotypes that can yield information on both sequences and numbers of DNA copies, such as three units of DNA copies: ATG, ATG, GTG.

We demonstrated good accuracies of our algorithms using a variety of simulation datasets, and also applied these algorithms to real datasets on the CYP2D6 and MRGPRX1 genes in two HapMap populations. Our algorithms will infer haplotypes of CNVs to support the rigorous analyses of population genetics for CNVs as well as association studies that detect copy-number and nucleotide differences related to phenotypic traits such as disease susceptibilities.

Finnish prostate cancer families have an increased risk to other cancers. *S. Pakkanen[1], M. P. Matikainen[2], E. Pukkala[3], P. Koivisto[1], T. L. J. Tammela[2], J. Schleutker[1]* 1) Laboratory of Cancer Genetics, Institution of Medical Technology, University of Tampere and Tampere University Hospital, Finland; 2) Department of Urology, Tampere University Hospital and Medical School, University of Tampere, Finland; 3) Finnish Cancer Registry, Helsinki, Finland.

Clinical features of families with prostate cancer (PCa) and other malignancies associated with this disease are not well known. A family with PCa is characterized as two or more PCa cases among first degree relatives. The aim of this study was to assess weather primary tumours other than prostate carcinoma aggregate in Finnish PCa families. Based on the national population based Finnish Cancer Registry (FCR), we calculated standardized incidence ratios (SIR) for 5546 members of 202 Finnish families with PCa with confirmed genealogy, either using the first diagnosed PCa among brothers as a single index or multiple indexes. Multivariate cluster analysis was used to separate families with clinically aggressive disease to a separate analysis. The total number of cancers (all sites) among males was 552 (SIR 1.79) in single index group and 234 (SIR 0.94) in multiple index group and among females 205 (SIR 0.98). Females in the sample had more stomach cancer than expected (SIR 1.88, 95% confidence interval 1.19-2.94) when compared general population. Both females and males in the age group 60-80 had more cancer in gallbladder (SIR 2.35, 1.17-4.60). Males in the families with clinically aggressive disease had more gallbladder cancer and small intestine cancer. In a subgroup analysis by age groups there was more breast, colon, kidney and ovary cancer. In most of the families with excess numbers of prostate cancer the disease appears to be site specific. However a suggestive tendency towards gastric and gallbladder cancers was detected. Inherited risk of cancer may be age dependent as in subgroup analysis other cancers have an increased risk. In addition when analyzing families with clinically aggressive disease other cancers are more common. These results suggest that there is an excess of other cancers in families with Pca and the type of cancer depend on the clinical aggressiviness of the PCa.

Hereditary cancer predisposition in a subset of uveal melanoma patients and their family members. *M. Abdel-Rahman[1,2], R. Pilarski[3], S. Ezzat[4], J. LaJeunesse[1], F. Davidorf[1]* 1) Ophthalmology, The Ohio State University, Columbus, OH; 2) Pathology, Menoufiya University, Egypt; 3) Department of Internal Medicine and Comprehensive Cancer Center, the Ohio State University; 4) Department of Public Health, Menoufiya University, Egypt.

Uveal melanoma (UM) is the most common primary intraocular malignancy in adults. The extent of contribution of familial/hereditary predisposition to the development of uveal melanoma is largely unknown. Thus we sought to ascertain the frequency of cancers in patients with UM and their family members to identify the prevalence of hereditary/familial predisposition to cancer in these patients. An unselected series of 112 patients with UM seen in a university-based tertiary referral program were consented to the study. Cancer histories (site and age of diagnosis) were obtained for all first- and second-degree relatives. Observed cancer frequencies were compared to the expected risk for development of the same cancers in the general population, as obtained from the Surveillance Epidemiology and End Results (SEER) database. Out of the 112 probands included in the study 11 (9.8%) had very early onset of uveal melanoma (40 years old at diagnosis), 23 (20.5%) had a history of at least one other primary cancer (excluding non melanoma skin and lung cancers) and 14 (12.5%) had a strong family history of cancer. Only one patient had a family history of a first degree relative with uveal melanoma. For probands the relative risk of cancer were significant for skin melanomas (RR: 8.8, 95% CI: 2.4-22.8), but not for breast cancer (RR: 2.39, 95% CI: 0.77-5.58), colon cancer(RR: 3.26, 95% CI: 0.67-9.52), or prostate cancer (RR: 1.92, 95% CI: 0.62-4.48). In conclusion, although familial uveal melanoma (i.e. multiple individuals in the same family affected with uveal melanoma) is rare, a significant subset of uveal melanoma patients and their family members may have a hereditary/familial predisposition for development of other cancers. Identifying the cancer predisposition gene(s) in these individual is important for proper management of both the patient and their family members.

Different genomic alteration pattern in acral melanoma tumors identified by an MLPA approach. *C. Badenas*[1, 3], *J. A. Puig-Butille*[1, 3], *Z. Ogbah*[2], *C. Carrera*[2], *P. Aguilera*[2], *J. Malvehy*[2, 3], *S. Puig*[2, 3] 1) Biochemistry & Molecular Genetics, Hosp Clinic & IDIBAPS, Barcelona, Spain; 2) Melanoma Unit, Dermatology Department, Hospital Clinic & IDIBAPS, Barcelona, Spain; 3) Centro Investigación Biomédica en Enfermedades Raras (CIBERER), ISCIII. Barcelona. Spain.

Recent studies have revealed distinct genetic patterns between different histopathological melanoma subtypes, suggesting that initiation/progression of melanoma could be attributable to different somatically mutated genes and different chromosomal rearrangements. Gain of CCND1 gene has been detected as a genetic marker of acral lentiginous melanoma (ALM). NRAS and BRAF genes have been described constitutively activated in a high proportion of melanoma tumors. Another locus implicated in melanogenesis process is CDKN2A (9p21) since deletions affecting the 9p21 region have been described in the majority of melanoma samples. The aim of the present study was to characterize the genetic aberrations detected in different subtypes of melanoma by using MLPA technique (9p21 region and set of oncogenes). We included 69 melanoma tumors (8 lentigo malignan -LM-, 4 nodulars -NM-, 40 superficial spreading -SSM- and 17 ALM). BRAF and NRAS mutational status was also studied. No mutations were detected in NRAS. BRAF mutations were detected in 30% of samples, but the frequency differ among the different subtypes, being more frequent in non acral (range 25-37.5%) than acral melanomas (6%). No difference in deletions affecting the 9p21 region was detected. MLPA detected amplifications in at least one region in all LM, NM and ALM, while it was detected in 42% of SSM. Six regions showed a different pattern of amplification between acral and non-acral melanomas. Two of them were statistically significant: 5p25 and 11q13 gains were detected in 31.2%of acral melanomas while only in 6.9% of non-acral (p=0.04, OR:6.1 for both regions). Moreover, MLPA analysis could differentiate three sub-types of acral melanomas: those with amplifications affecting 1p13.2 and 5p25, those with gains in 11q13 and a third subtype in which the 20q13 region was amplified. These results suggest different genomic pathways leading to acral melanoma progression.

Inferring Human Population Structure: STR or SNP? *S. Xu*[1], *L. Jin*[1,2] 1) Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China;; 2) Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology and Center for Evolutionary Biology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China.

Both microsatellites (STRs) and single nucleotide polymorphisms (SNPs) have played important roles in inferring population structure. With the availability of genome-wide STR and SNP data for the same collection of world-wide human population samples (HGDP-CEPH panel), we now have the opportunity to compare the usefulness of the two types of data in inferring population structure. We selected the same set of 940 unrelated HGDP individuals in which both 783 STRs and 650,000 SNPs were genotyped, and performed both classical (phylogenetic and principal component) analysis and STRUCTURE analysis. We found for all analyses, with the same allele number, SNP data perform better and generate more reasonable results than STR data. Notably, a) SNP data offer superior clustering of individuals and populations; b) the phylogenetic tree reconstructed using SNP data is consistent better with the geographical distribution of populations; c) SNP data reveals fine structures and reasonable admixture pattern in STRUCTURE analysis for both full samples and subset of samples, but STR can not.

Associations among metabolic genes, repair genes and DNA damage of pregnant women exposed to environmental tobacco smoke. *F.-Y. Wu[1], R.-Y. Wang[2], C.-J. Lin[3], C.-Y. Chen[2], H.-C. Tsui[1], C.-C. Yang[1], C.-J. Chan[1]*
1) China Medical University, Environmental Health, Taichung, Taiwan; 2) China Medical University, Public Health, Taichung, Taiwan; 3) China Medical University, Nursing, Taichung, Taiwan.

The aims of this study were: 1) to investigate whether the exposure to environmental tobacco smoke (ETS) in pregnant women would increase their DNA damages, and 2) to examine the associations among DNA damage, polymorphisms in metabolic genes (GST M1, NAT2) and polymorphisms in repair genes (hMLH1) in the pregnant women exposed to ETS. This is a cross-sectional study. The subject consisted of 165 pregnant women (78 passive smokers and 87 non-smokers) recruited from the National Smoking Prevention Project during 2003-2004. Results showed that the mean DNA damage score of the passive smoking group was 88.044.33, which was significantly higher (p0.0001) than that of the non-smoking group of 63.032.3. Carriers of GSTM1 null genotypes, NAT2 slow acetylators and those with the hMLH1 A allele variant were more likely to have a higher degree of DNA damage than carriers of the non-null genotype, rapid acetylators and those with the G allele variant, regardless of whether they were non-smokers (18.4%, 11.1% and 43.8% increase, respectively) or passive smokers (11.5%, 15.6% and 30.4% increase, respectively). Analysis by simple linear regression found that in passive smokers carrying one or less, two or three variant genes resulted in DNA damage scores of 79.9, 91.5 and 111.6 respectively. These were higher than the respective scores of 58.6, 65.7 and 86.8 in non-smokers. Moreover, the level of DNA damage increased as the number of variants in each of the three genes increased. Compared to the group of non-smokers carrying one or less gene variant, there were a significantly greater number of variants in EST group. In conclusion, the associations indeed existed between polymorphisms in metabolic genes and in the repair gene and smoking exposure. Genotypic variants of these polymorphisms did elevate DNA damage for pregnant women exposed to smoking hazard.

A population genetics study of the Familial Mediterranean Fever gene: evidence of balancing selection supports the heterozygote advantage hypothesis. *R. Cagliani[1], M. Fumagalli[1,2], U. Pozzoli[1], S. Riva[1], G. P. Comi[3], G. Menozzi[1], N. Bresolin[1,3], M. Sironi[1]* 1) Scientific Institute IRCCS E.Medea, Bosisio Parini, LC, Italy; 2) Bioengineering Department, Politecnico di Milano, 20133 Milan, Italy; 3) Dino Ferrari Centre, Department of Neurological Sciences, University of Milan, IRCCS Ospedale Maggiore Policlinico, Mangiagalli and Regina Elena Foundation, 20100 Milan, Italy.

Familial Mediterranean Fever (FMF) is a recessively inherited systemic autoinflammatory disease caused by mutations in the MEFV gene. The frequency of different disease alleles is extremely high in multiple populations from the Mediterranean region, suggesting heterozygote advantage. Here, we characterize the sequence variation and haplotype structure of the MEFV 3' gene region (from exon 5 to the 3' UTR) in 7 human populations. In non-African populations, we observed high levels of nucleotide variation, an excess of intermediate-frequency alleles, reduced population differentiation and a genealogy with two common haplotypes separated by deep branches. These features are suggestive of balancing selection having acted on this region to maintain one or more selected alleles. In line with this finding an excess of heterozygotes was observed among Europeans and Asians, suggesting an overdominance regime. In African populations, a minor highly divergent haplotype clade was observed; the deep TMRCA of the whole MEFV genealogy together with an analysis of the gene tree topology indicated that these chromosomes might result from admixture among subdivided archaic hominid populations. Our data, together with the previous demonstration that the MEFV exon 10 has been subjected to episodic positive selection over primate evolution, provide evidence for an adaptive role of nucleotide variation in this gene region. These data therefore support, although indirectly, the heterozygote advantage hypothesis for FMF mutations and suggest that further studies aimed at clarifying the role of MEFV variants might benefit from the integration of molecular evolutionary and functional analyzes.

Bayesian Estimation of Multi-Risk Components in Autism Spectrum Disorders (ASDs). *T. Nishiyama[1,2], K. Takahashi[3], H. Taniai[4], S. Sumi[5], H. Kishino[6], T. Toshiro[3]* 1) Department of Information and Biological Sciences, Graduate School of Natural Sciences, Nagoya City University, Nagoya, Japan; 2) Doctor of Public Health Program in Biostatistics, National Institute of Public Health, Wako, Japan; 3) Department of Technology Assessment and Biostatistics, National Institute of Public Health, Wako, Japan; 4) Nagoya Child Welfare Center, Nagoya, Japan; 5) Nagoya Western Rehabilitation Center for Children with Disabilities, Nagoya, Japan; 6) Laboratory of Biometry and Bioinformatics, Graduate School of Agriculture and Life Sciences, University of Tokyo, Tokyo, Japan.

Background Recently, cytogenetic findings point to a higher incidence of spontaneous mutation including copy number variations (CNVs) in children with sporadic autism. Zhao et al. (2007) found a simple genetic model in which most families fall into two types: a small minority for whom the risk of ASDs is near 50%, and the vast majority for whom their offspring have a low risk, mostly based on samples with at least two ASD children. However, such ascertainment scheme could bias the composition of ASD families. The purpose of this study is to examine how many risk components are found in population-based ASD sample. **Methods** Subjects in the present study ware a cohort of siblings born between 1995 and 1999 who were thoroughly ascertained through at least one proband having an ASD in the catchment area (Sumi 2006). To estimate the risk of producing offspring with an ASD, we choose to model the distribution of the risk as having two to ten discrete components and used a Markov chain Monte Carlo method. **Results** The best-fitted model in DIC(Deviance Information Criteria) was five-component risk model, whose posterior mean of each risk was 0.039, 0.090, 0.253, 0.300, 0.408 in turn, with 0.3 of penetrance in females. **Conclusions** We can interpret the risk distribution of transmitting an ASD trait as continuous rather than discrete, though the risk component of about 0.5 have also been found. Our finding is in disagreement with the previous work (Zhao et al., 2007). This may be due to their use of the biased samples which were ascertained via at least two affected children with an ASD.

Siblings with pure subtelomeric trisomy 9q due to maternal cryptic translocation. *S. Mizuno[1], D. Fukushi[2], R. Kimura[2], T. Kumagai[1], N. Wakamatsu[2]* 1) Dept Pediatrics, Central Hosp, Aichi Human Service Ctr, Kasugai, Japan; 2) Dept of Genetics, Institute for Developmental Research, Aichi Humana Service Center, Kasugai, Japan.

In recent years, subtelomeric rearrangements have been identified as a major cause of multiple congenital anomalies (MCA)/mental retardation (MR) syndromes, and some of newly diagnosed MCA/MR syndromes with subtelomeric rearrangement have distinctive features which can be phenotypically diagnosed. Here we report on female siblings with mental retardation, both showing a distinct phenotype, associated with the same 9q subtelomeric rearrangement due to maternal cryptic translocation. The proposita were borne to healthy unrelated parents with no hisotry of spontaneus abortion. Their birth weight were, 2364 g(-1.4SD), 2874 g(-0.2SD), head circumference were 33cm(+0.2SD),33.5cm(+1.0SD),respectively. Both girls showed a similar phenotype with postnatal growth retardation, moderate developmental delay, relative macrocephaly, slender fingers, and distinctive face with hypertelorism, broad flat nasal bridge, a small nose and round face. The older sibling had congenital heart disease. Routine chromosomal analysis using G- banding alone showed 46,XX in both siblings and inv(2)(p11.2q11.1) in the older. Genome-wide subtelomere FISH analysis revealed additional 9q subtelomeric signal on 13p satelite region. Parental chromosome analysis using G-banding and Genome-wide subtelomere FISH revealed that their mother has the same inversion in chromosome 2, and her 9q subtelomeric signal is translocated on 13p satelite region. By using additional FISH with bacterial artificial chromosome (BAC) probes, we comfirmed the size of trisomic segment to be less than 6Mb. Previously reported cases with 9q distal trisomy were concurred with other diatal monosomy, and deletions are generally more phenotypically penetrant than duplications. To our knowledge this is the first case report with pure 9q subtelomeric trisomy due to maternal cryptic translocation, and the characteristic features of the siblings suggest that subtelomeric trisomy 9q is a clinicallly recognizable syndrome.

A global expression atlas of genes and microRNAs in the developing mouse embryo. *G. Diez-Roux, EURExpress Consortium* Telethon Institute of Genetics & Medicine, Naples, Italy.

The EURExpress consortium has generated a global expression atlas of the developing mouse on sagittal sections from E14.5 wild type embryos by means of ISH with non-radioactive probes and used this data to establish a web-linked, interactive digital transcriptome atlas (www.eurexpress.org). This atlas includes over 15000 expression patterns, which have been thoroughly annotated using over 1400 anatomical terms. A genome-wide analysis revealed that 42% of genes show a regional expression pattern. To determine sensitivity, the EUREXpress data was compared to more high-throughput gene expression methods such as microarray. This analysis revealed that 30% of regional genes are not detected by microarray analysis. This percentage increases to 40% when analyzing genes that show exclusive expression in a specific tissue. The analysis of the EURExpress data also allowed us to identify coexpressed gene clusters shown to be both statistically and biologically significant. The coexpressed clusters seem to have much higher specificity than clusters based upon publicly available microarray data. These data highlight the importance and use of RNA in situ hybridization as an alternative to microarray analysis in large-scale gene expression studies. To complete the global expression atlas we analyzed the entire set of mouse microRNAs (miRNAs) using the same technological platform. As a result we generated the first high-resolution expression study of this class of non-coding RNAs in a mammalian organism. This analysis revealed that of 425 miRNAs analyzed, 45% are non-detectable in the E14.5 mouse embryo while the remaining 55% shows significant expression with both widespread and restricted patterns. We are presently comparing this data to the expression patterns of host and predicted target genes. This analysis will allow improving the identification of bona fide transcriptional targets of these important regulators of gene transcription and translation. In conclusion, EURExpress is a unique resource for scientists worldwide providing researchers with an atlas of gene expression at a cellular resolution, for both coding and non-coding transcripts.

Phenotypic characteristics including neurohistopathologic findings in a child with neuronopathic Gaucher disease type 3B. *H. J. Kim[1], T. H. Lee[2], D. E. Jung[3], S. Y. Jeong[1]* 1) Dept. Medical Genetics, Ajou Univ. Sch. Med., Suwon, Korea; 2) Dept. Pathology, Ajou Univ. Sch. Med., Suwon, Korea; 3) Dept. Pediatrics, Ajou Univ. Sch. Med., Suwon, Korea.

Gaucher disease (GD) is an autosomal recessive, lysosomal disorder caused by mutations in the gene for the -glucocerebrosidase (GBA) enzyme. Progressive neurologic symptoms can develop in some forms of GD, classified as type 2 (acute infantile form) and type 3 (subacute juvenile form). Here we report an autopsy case of a Korean female child with neuronopathic GD type 3B who died of aspiration pneumonia at age 31 months. The patient was presented with anemia, thrombocytopenia, and splenomegaly at age 10 months and diagnosis of GD was made with the demonstration of Gaucher cells (GC) in bone marrow biopsy and the deficient enzymatic activity of GBA. With enzyme replacement therapy of high dose of Cerezyme (>60/kg q 2wks), her clinical pictures of anemia, thrombocytopenia, splenomegaly and general condition improved makeldey in 6months, however, her neurologic symptoms of ocular apraxia and myoclonic seizures become evident. She developed a bouts of preumonia with dyspnea and in spite of antiepileptics, her myoclonic epileptic seizures became intractable requiring mechanical ventilation. Postmortem examination revealed a systemic involvement of brain, lung, visceral organs and bone marrow. The brain showed a diffused global involvement with mutifocal infiltration of GC observed in large number of subcortiacal gray-white junctional perivascular space in cerebrum. In cerebellum, multifocal patchy involvement of GC was observed in the subcortical perivascular space and cortical neuron layers, which is associated with marked neuronal loss, atrophy and gliosis. Furthermore, the brain stem abnormality was absent and hippocampal sclerosis showing marked neuronal loss, astrogial and microglial proliperation without infiltration of GC was observed. The neurohistopathologic findings in this case may contribute to a better understanding of the pathological basis of neuronopathic GD which may lead to better treatment strategy for the neuronopathic GD.

Widespread balancing selection and pathogen-driven selection at blood group antigen genes. *M. Sironi[1], M. Fumagalli[1,2], R. Cagliani[1], U. Pozzoli[1], S. Riva[1], G. Menozzi[1], N. Bresolin[1,3], G. P. Comi[3]* 1) Scientific Institute IRCCS E. Medea, Bosisio Parini, LC, Italy; 2) Bioengineering Department, Politecnico di Milano, P.zza L. da Vinci, 32, 20133 Milan, Italy; 3) Dino Ferrari Centre, Department of Neurological Sciences, University of Milan, IRCCS Ospedale Maggiore Policlinico, Mangiagalli and Regina Elena Foundation, Via F. Sforza 35, 20100 Milan, Italy.

Historically, allelic variations in blood group antigen (BGA) genes have been regarded as possible susceptibility factors for infectious diseases. Since host-pathogen interactions are major determinants in evolution, BGAs can be thought of as selection targets. In order to verify the this hypothesis, we obtained an estimate of pathogen richness for geographic locations corresponding to 52 populations distributed worldwide (HGDP-CEPH panel); out of 26 BGA loci, after correction for multiple tests and for variables different from selective forces, significant correlations with pathogen richness were obtained for multiple variants at 12 loci. Given these findings, we made use of publicly available data (SeattleSNPs Variation Discovery Resource), as well as of extensive resequencing experiments in human global populations, to gain further insight into the evolutionary history of BGA genes. By applying population genetics tests we were able to demonstrate that 5 BGA genes, namely CD55, CD151, SLC14A1, GYPC and BSG, have been subjected to balancing selection, a process, rare outside MHC genes, which maintains variability at a locus. Moreover, we identified a gene region immediately upstream the transcription start site of FUT2 which has undergone non-neutral evolution independently from the coding region. These data indicate that BGAs have been playing a central role in the host-pathogen arms race during human evolutionary history and no other gene category shows similar levels of widespread selection, with the only exception of loci involved in antigen recognition.

3q26 altered region detected in a Spanish wild-type CDKN2A melanoma-prone family. *J. Puig-Butille[1,3], M. Stark[4], C. Badenas[1,3], Z. Ogbah[2], P. Aguilera[2], C. Carrera[2], J. Malvehy[2,3], N. Hayward[4], S. Puig[2,3]* 1) Biocehm. & Molecular Genetics, Hospital Clinic and IDIBAPS. Barcelona, Spain; 2) Melanoma Unit, Dermatology Department, Hospital Clinic and IDIBAPS. Barcelona, Spain; 3) Centro de Investigacion Biomedica en red en enfermedades raras (CIBERER). ISCIII, Barcelona, Spain; 4) Oncogenomics, Queensland Institute of Medical Research (QIMR), Brisbane, Australia.

Familial Melanoma accounts for 10% of melanoma cases. CDKN2A (9p21) and CDK4 (12q14) are two major susceptibility and mutations in these loci are detected in 16% of Spanish MM families being more frequent in families with multiple primary (MPM) cases. However, a high proportion of families do not harbor mutations in these genes. Other regions (1p22 and 1p36) have been related to MM susceptibility. A dramatic Spanish family with different cancers including MM was studied. The index patient developed 7 MM and 3 Basal cell carcinomas. His son developed 3 MM and his sister had breast cancer. Mutational screening of CDKN2A and CDK4 genes was performed. Furthermore, the 9p21 region was interrogated using MLPA in order to identify deletions/amplifications affecting CDKN2A and other adjacent genes. Whole genome analysis from the two MPM cases was carried out by SNP-array chip (Illumina Sentrix HumanHap300 genotyping Beadchip array). No alterations affecting CDKN2A, CDK4 or 9p21 region were identified. In contrast, loss of heterozygosity (LOH) OF 190KB in 3q26.1 region was detected in the index patient. This LOH was not detected in his son, but a larger region (1.6 Mb) in this location presented uniparental disomy (UPD). The region of overlap between father and son comprised 30 kb. Bioinformatics softwares were used to identify known or putative genes in this region. A putative gene (NT_005612.1195) which would codify a gene product similar to CAB99359 has been predicted. CAB99359 is a novel protein with unknown function although it contains EGF-like and laminin G domains. The results presented here suggest a possible implication of the 3q26.1 region in melanoma predisposition. Acknowledgments: Exchange Programme for young researchers funding by genoMEL Consortium.

Genome-wide analysis of microsatellite mutation in humans. *A. Coghlan, W. Whitener, R. Durbin* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

To investigate the mutation patterns of human microsatellites, we have generated substantial new data on triplet repeat variation in the human population. We have developed a novel bioinformatic method to analyse data from the Trace Archive. We identify repeat-length polymorphisms by finding cases where the length of a repeat locus differs between the reference genome and a matching sequence read in the Trace Archive. Using this approach, we have found evidence of length-polymorphism in 18,503 of the 77,095 human triplet repeat loci. In bacteria and yeast, the rate of expansions and contractions is higher at microsatellites that can form non-B DNA structures such as hairpins and triplexes. For a repeat locus to form such structures, its sequence must fulfil certain requirements. For example, (AAG)n loci consist of (purinepyrimidine)n mirror repeats and this enables them to fold into triplex DNA. We find that the most variable human triplet repeat loci are those predicted to form unusual DNA conformations. For example, (AAG)n loci are significantly more variable than (AAC)n loci, which do not form hairpins or triplexes. This supports the hypothesis that unusual DNA conformations are mutagenic intermediates of microsatellite instability. Some microsatellites are 'fragile sites' susceptible to DNA lesions, and faulty repair of lesions can result in expansions or contractions. In yeast, fragile sites are located in regions that are replicated late during S-phase and are susceptible to DNA breaks. Thus, there may be a link between replication timing and microsatellite instability. Using replication timing data for 1% of the human genome from ENCODE, we found that triplet repeat loci in late-replicating regions are significantly more variable than loci in mid- or early- replicating regions. This suggests that microsatellites replicated later during S-phase have higher mutation rates. We have also developed a method to identify microsatellite length-polymorphism using paired-end Solexa/Illumina sequencing data. With tight insert-size distributions and deep coverage we can identify the majority of microsatellite length-polymorphisms in a sample. This promises to provide a deeper picture of microsatellite length-variation in the future.

Seizures and epilepsy in neurofibromatosis type 1 (NF1): a genotype-phenotype study. *A. L. Gabriele[1], M. Ruggieri[2,6], P. Iannetti[3], A. Patitucci[1], A. Magariello[1], T. Sprovieri[1], R. Mazzei[1], F. L. Conforti[1], C. Ungaro[1,4], L. Citrigno[1,4], M. Muglia[1], M. Clementi[5], A. Polizzi[6], I. Torrente[7], M. Elia[8], L. Pavone[6], A. Quattrone[1,9]* 1) ISN - CNR, Cosenza, Italy; 2) Institute of Neurological Science (ISN), National Research Council (CNR), Catania, Italy; 3) 2nd Chair of Paediatrics, Division of Child Neurology, Institute of Paediatrics, University La Sapienza, Rome, Italy; 4) Department of Neurosciences, Psychiatric and Anesthesiological Sciences, University of Messina, Messina, Italy; 5) Institute of Epidemiology and Medical Genetics, Department of Paediatrics, University of Padua, Padua, Italy; 6) Department of Paediatrics, University of Catania, Catania, Italy; 7) CSS-Mendel Institute, Roma, Italy; 8) Institute for Mental Retardation and Developmental Disabilities, Department of Neurology, Oasi Maria SS., Troina (EN), Italy; 9) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy.

The aim of this study is to define the prevalence of seizures and epilepsy in NF1 and to establish a genotype-phenotype correlation. We investigated twenty-nine patients with NF1 and seizures (including febrile seizures) and/or epilepsy. The calculated population-based: (1) prevalence of febrile seizures (FS) in NF1 was 1.35%, in line with the frequency of FS in the general population (1-3%); (2) prevalence of epilepsy in NF1 (2.9%) was lower than the frequency of seizures in the general population (3%);(3) prevalence of infantile spasms (IS) in children with NF1 (0.76%) was higher than the reported frequency of IS in the general population (0.02- 0.05%); (4) frequency of NF1 in the IS series in two out of the three clinical centres (0.62-0.90%) was lower than the estimated frequencies in the literature (1.5-3.0%). Germ-line mutations were identified in all subjects: three of these alterations were novel. This is the first genotype-phenotype study on seizures and/or epilepsy in the setting of NF1. According to the present findings epilepsy is not associated with NF1. The combination of IS and NF1 is certainly an unusual event in NF1. DNA analysis revealed NF1 gene mutations without genotype-phenotype correlation.

FAF1 is Associated with Cleft Palate and Pierre Robin Sequence. *M. Ghassibe[1], L. Desmyter[1], B. Bayet[2], N. Revencu[1], R. Vanwijck[2], V. Vikkula[1]* 1) Lab Human Molecular Genetics, de Duve Institute, Brussels, Belgium; 2) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires St Luc, Brussels, Belgium.

Nonsyndromic isolated clefts occur in a wide geographic distribution with an average birth prevalence of 1/700. Genetic factors involved in cleft lip with or without the palate (CL/P) are thought to be different from those having a role in cleft palate only (CPO). We have recently reported FAF1 as a new gene responsible for CPO and Pierre Robin sequence (PRS). Moreover, we showed that Faf1 is needed for craniofacial development in human, mouse and zebrafish. In order to replicate our positive association study, we conducted transmission disequilibrium test in an independent series of 160 European families with cleft lip and/or palate. The same FAF1 variant as in our first study was genotyped. In the replication, FAF1 showed positive tendency for association only in the small CPO/PRS subgroup (p=0.09). Pooling together our 500 patients reinforced the earlier association, giving a more stringent p-value of 0.001 for the CPO/PRS subgroup, and non-significant p-value for the CL/P subgroup. In order to identify other genes that contribute to the occurrence of this multifactorial condition, we are testing in parallel association of IRF6 and SATB2, two cleft genes, to the cleft condition in our 500-patient cohort. Preliminary results suggest that, contrary to FAF1, IRF6 predisposes to CL/P, but not to CPO. This illustrates the benefit of testing greater number of patients in complex diseases, and replicating positive associations, in order to well delineate the true predisposed subgroups. Moreover, it confirms that FAF1 and IRF6 play a role in the occurrence of isolated complex clefts, but most likely in distinct pathways. (miikka.vikkula@uclouvain.be).

Construction of research resource repository and molecular genetic study for mental retardation in Japan. *Y. Goto[1], E. Nakagawa[1], K. Takano[1], K. Inoue[1], J. Inazawa[2], H. Okazawa[2], M. Kato[3], T. Kubota[4], K. Kurosawa[5], S. Saitoh[6], E. Nanba[7], N. Matsumoto[8], T. Toda[9], T. Wada[10], Japan Mental Retardation Research Consortium* 1) Mental Retard/Birth Def Res, National Inst Neuroscience, Kodaira, Tokyo, Japan; 2) Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 3) Yamagata University School of Medicine, Yamagata, Japan; 4) University of Yamanashi, Faculty of Medicine, Yamanashi, Japan; 5) Kanagawa Childrens Medical Center, Kanagawa, Japan; 6) Hokkaido University Hospital, Sapporo, Japan; 7) Tottori University School of Medicine, Tottori, Japan; 8) Yokohama City University School of Medicine, Kanagawa, Japan; 9) Osaka University School of Medicine, Osaka, Japan; 10) 10Shinshu University School of Medicine, Nagano, Japan.

Recent advances in molecular genetics and genome medicine have pushed on with systematic analysis of mental retardation (MR) study, especially on X-linked MR in Europe and USA. Japan is behind because we do not have the system for the research resource repository of many specimen and accurate clinical information available for genetic analysis. Japan Mental Retardation Research Consortium (JMRRC) has organized a research system at NCNP for genetic analysis of mental retardation. In the past 6 years, we have already established the research resource facility and collected samples under informed consent by providing the diagnostic service for known genetic defects and/or chromosomal abnormalities, such as genes for fragile X, MECP2, ARX, ATRX, and subtelomere deletions. As of the end of March in 2008, 208 pedigrees consisted of 103 familial and 105 sporadic cases have been registered. The examined cases (about 100 cases) with positive results include 2 with FMR1 expansion, 1 with FTSJ1 gene mutation, 1 with ZNF41, 1 with PAK3, 1 with OPHN1, 1 with ARHGEF6, 2 with ATRX, 1 with repeat expansion in ARX gene, 5 with duplication of specific regions in X chromosome and 1 with deletion of subtelomeric region. We also performed genetic counseling for the families with the positive result according to the guidelines.

Cleft Palate Caused by a 12q24.33 Amplification. *L. Desmyter[1], A. Ghalamkarpour[1], M. Ghassibe[1], Ch. Labrèze[2], F. Morice-Picard[3], M. Vikkula[1]* 1) Lab Human Molecular Genetics, de Duve Institute, Brussels, Belgium; 2) Unité Dermatologie Pédiatrique, Hôpital Pellegrin Enfants, Bordeaux, France; 3) Unité de Génétique Médicale, CHU de Bordeaux, Bordeaux, France.

Orofacial clefts are the most frequent craniofacial malformations in humans. Occurrence estimates range between 1/500 and 1/2500 births for cleft lip with or without the palate (CL/P) and around 1/2000 births for cleft palate only (CPO). The majority of clefts are isolated, nonsyndromic. The remaining syndromic cases are subdivided into categories on the basis of chromosomal abnormalities, Mendelian single gene syndromes, teratogenic effects and of unknown cause. We performed regular and molecular karyotyping using Affymetrix GeneChip on a total of 200 individuals. In one female patient, we identified a reciprocal translocation affecting the chromosomes (12;22). The translocation was not balanced, since copy number analysis showed a 12q24.33 amplification and a 22q13.33 deletion. The girl was the only affected member of the family and presented congenital progressive lymphedema, mental retardation and facial dysmorphism, indicative of a 22q13 deletion syndrome, also known as Phelan-McDermid syndrome. Interestingly, she had CPO, a feature not linked to this well characterized syndrome. We hypothesize that this is due to the translocation breakpoint on the 12q24.33 amplification site. This locus has not been incriminated in CL/P nor CPO before. FISH analyses are ongoing to characterize these breakpoints. This shows that molecular cytogenetics is a valuable tool for the identification of new genes related to complex diseases. (miikka.vikkula@uclouvain.be).

IDENTIFICATION OF A NOVEL DELETION IN A COUPLE WITH RECURRENT SPONTANEOUS ABORTIONS. *S. Dudeja[1], M. Kumar[1], M. Tanwar[1], S. Venkatesh[1], R. Kumar[1], N. Malhotra[2], R. Dada[1]* 1) Lab for Molecular Reproduction & Genetics, Deptt. of Aantomy; 2) Deptt. of Obstetrics & Gynaecology, All India Institute of Medical Sciences, New Delhi, India.

Recurrent spontaneous abortion (RSA) is defined as three consecutive abortions. The etiology of recurrent abortions is often unclear and may be multifactorial. Majority of the cases remains unexplained. Couples having multiple miscarriages are at risk for carrying chromosomal abnormalities. This report shows the importance of cytogenetic studies in couples with RSA. A couple was referred for cytogenetic analysis with the history of recurrent miscarriages. Pregnancy history, age, occupation, disease information and all other medical records were reviewed. The wife had history of four abortions. The husband had occupational exposure to lead fumes. Various studies have shown that most of the chromosomal abnormalities associated with recurrent abortions are numerical and structural which may adversely affect embryonic development. The chromosomal rearrangements in couples with recurrent abortions were found to be 3.5% in Indian population. There are reports of recurrent abortions with pericentric inversion, translocations, insertions and deletions of various chromosomes. Peripheral blood was collected and lymphocyte cultures were set up for chromosomal analysis. The metaphases were analysed using GTG banding. The wife was cytogenetically normal. A novel deletions in chromosome 1 and 3 has been found in husband, karyotyped 46,XYdel1(q41)(p12q21) 3(q)(26.3-29). This finding illustrates the importance of performing cytogenetics studies on couples having recurrent abortions to prevent couples undergoing physical and emotional trauma. The detection of couples with chromosomal abnormalities can definitely aid in preventing birth of children with congenital malformations. Thus cytogenetic analysis should be done in couples with repeated pregnancy losses or having bad obstetric history.

High-density SNP association and CNV analysis of two Autism Susceptibility Loci. *A. T. Pagnamenta[1], E. Maestrini[2], J. A. Lamb[3], N. Sykes[1], I. Sousa[1], C. Toma[2], E. Bacchelli[2], A. P. Morris[1], A. J. Bailey[4], A. P. Monaco[1], IMGSAC* 1) WTCHG, University of Oxford, UK; 2) Dipartimento di Biologia, Università di Bologna, Italy; 3) Centre for Integrated Genomic Medical Research, Manchester, UK; 4) Department of Psychiatry, University of Oxford, UK.

Autism is characterised by impairments in communication and reciprocal social interaction, restricted interests and repetitive behaviour. The high genetic component inferred from twin studies has led to numerous genetic linkage studies being conducted. The International Molecular Genetic Study of Autism Consortium, has identified regions on chromosomes 7 (AUTS1) and 2 (AUTS5). Although these regions have been further implicated in independent linkage studies, screening of several candidate genes has thus far failed to identify the underlying genetic variants. In this study, 4 Illumina GoldenGate 1536 arrays were designed to optimally capture common genetic variation in AUTS1 and AUTS5. These SNPs were genotyped in 126 families, preselected for identity-by-descent sharing between affected sibs in the AUTS1 and AUTS5 linkage regions, and 188 gender-matched controls. Association analysis implicated several new genes: in the respective family-based and case-control analyses, *PLXNA4* and *IMMP2L* were the most significant genes in AUTS1 whilst *ZNF533* and *NOSTRIN* were identified in AUTS5. Due to the small number of families, association is being assessed in larger replication cohorts. Using the QuantiSNP algorithm, CNVs were detected in *IMMP2L* and *EMID2* in autistic patients and verified on a genomewide SNP platform. Despite inconclusive segregation analysis and presence of similar events in the Database of Genomic Variants, these findings should be extended to larger cohorts with enough power to determine whether these events have subtle effects on autism susceptibility. In conclusion, a high-density SNP association study of these 2 autism susceptibility loci has identified several genes showing genetic association or CNVs in this autism cohort, many of which warrant further investigation. Of particular interest is *IMMP2L*, an inner mitochondrial membrane protein, which was detected in both genetic association and CNV analyses.

Genetic variants on *NRG1* confer susceptibility to Hirschsprung's disease. *C. S. Tang[1,2], M. M. Garcia-Barceló[2], S. S. Cherny[1], P. C. Sham[1], P. K. H. Tam[2]* 1) Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HKSAR; 2) Department of Surgery, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HKSAR.

Hirschsprung's disease (HSCR, aganglionic megacolon), is a congenital disorder characterized by the absence of enteric ganglia in variable portions of the distal intestine. Besides the major HSCR gene, *RET*, and other implicating genes (e.g. *EDNRB*), existing evidence suggests that additional loci contributing to sporadic HSCR exist. To identify these loci, we conducted a genome-wide association study on 200 Chinese HSCR patients and 408 ethnically matched controls. Apart from SNPs in *RET*, the strongest overall associations were found for two SNPs (rs16879552 and rs7835688) located in intron 1 of the neuregulin1 gene (*NRG1*) on 8p12. Replication was carried out on an independent set of 190 HSCR case and 510 control subjects, yielding the combined odds ratios of 1.68 (p=1.80x10^{-8}) and 1.98 (p=1.12x10^{-9}) for the heterozygous risk genotypes of rs16879552 and rs7835688 respectively under the additive model. Significant interaction was also found between *RET* and *NRG1* (p=0.0095), which further increased the odds ratio 2.3-fold to 19.53 for the *RET* rs2435357 risk genotype (TT) in the presence of the *NRG1* rs7835688 heterozygote. The significant association suggests an important role of *NRG1* as regulator of the development of the enteric ganglia precursors.

Phenotype diversity in Iranian cohort of LQTS patients. *K. Banihashemi[1], S. Saber[2], M. Houshmand[3], M. Eftekharzadeh[4], M. Sadre Ameli[5], F. Fazelifar[5], E. V. Zaklyazminskaya[6]* 1) Dep. of Medical sciences, GPEF, Ministry of Science, Research and , tehran, tehran, Iran; 2) Member of genetic society of Iran; 3) National Research Center for Genetic Engineering and Biotechnology (NRCGEB); 4) Tehran Arrhythmia Center; 5) Rajaii Heart Hospital, Tehran; 6) Center for Molecular Genetics, Odintsovo, Russia.

Background: Long QT syndrome (LQTS) is an inherited group of diverse diseases with greatly variable Clinical manifestations characterized by QTc prolongation, syncope and high risk of SCD due to polymorphic ventricular tachycardia. Objective: To characterize the clinical diversity of LQTS patients in Iran and specify features associated with increased SCD risk in this ethnic group. Materials and methods: We analyzed clinical data from 28 Iranian LQTS families (30 affected and 93 clinically unaffected family members) in a follow-up period of 3220 months. The prevalence and intensity of cardiac events like syncope, ventricular tachycardia, cardiac arrest, and SCD estimated and efficiency of beta-blockers therapy as well. Results: Half of patients have received beta-blocker therapy. The prevalence of cardiac events among these patients was 60% (P<0.001). The risk of cardiac events was higher among LQTS with T wave shape abnormality and patients with QTc duration of <500 ms (95% [CI]; P=0.001). BY hazard function analysis other risk factor of SCD was a QT interval corrected for duration of therapy of < 25 months length (95% CI; P=0.01). Conclusion: In Iranian cohort of LQTS patients treated with beta-blockers, there is a high rate (60%) of cardiac events, especially among those had T-wave morphological and quantitative abnormalities and QTc > 500 ms. Beta-blockers had been reported as highly effective in cardiac events risk reduction (to 10-32% in different LQTS types) in European and American group of patients, But significantly higher in our population. We suppose different genetic factors could be chargeable: specific distribution of genetic forms, mutation spectrum or combination of pharmacogenetic variants. We have started molecular genetic studies of Iranian LQTS cohort to make these pointes clear.

Genomewide association analysis of metabolic phenotypes in a birth cohort from a founder population. *L. Peltonen[4,5,12], C. Sabatti[1,2], S. K. Service[3], T. Varilo[4,5], S. Gabriel[6], M. I. McCarthy[7], P. Elliott[8], M.-R. Jarvelin[8,9], N. B. Freimer[3,10,11]* 1) Dept of Human Genetics, UCLA, LA, California USA; 2) Dept of Statistics, UCLA, LA, California USA; 3) Center for Neurobehavioral Genetics, UCLA, LA, California USA; 4) Dept of Medical Genetics, U of Helsinki, Biomedicum Helsinki, Finland; 5) Inst of Molecular Medicine, Biomedicum Helsinki, Finland; 6) Broad Inst of Harvard and MIT, Cambridge, MA USA; 7) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK; 8) Dept of Epidemiology and Public Health, Imperial College London, UK; 9) Inst of Health Sciences and Biocenter Oulu, U of Oulu, Finland; 10) The Jane and Terry Semel Inst for Neuroscience and Human Behavior, UCLA, LA, California USA; 11) Dept of Psychiatry, UCLA, LA, California USA; 12) Wellcome Trust Sanger Inst, Cambridge, UK.

Joint actions of genetic variants and environmental exposures determine the distribution of common diseases and traits within a population. Genome wide association studies (GWAS) offer an opportunity to dissect the complex etiology and epidemiology of such phenotypes, given a study sample appropriate for this purpose. We report here the first GWAS of a longitudinal birth cohort, Northern Finland Birth Cohort 1966 (NFBC1966) ascertained from the homogeneous late settlement region of Finland, for nine quantitative traits: triglycerides, high and low density lipoprotein, glucose, insulin, C-reactive protein, body mass index, and systolic/diastolic blood pressure in 4763 individuals from NFBC1966. We replicated most of 42 previously reported loci for these traits with genome wide significance and identified nine novel loci: a TG locus on 15q, HDL loci on 11p and 17p, LDL loci on 1q,11q and X, Glucose loci on 7q and 11q, and an Insulin locus on 10q. Genes highlighted encode proteins directly or indirectly associated with metabolism. In total, the identified genes explain on average about 5% of the total variability of the traits. The power of a founder population for detection of infrequent high impact alleles is demonstrated by identification of such an allele, in a novel LDL regulating gene on X, associated with dramatically increased LDL in males.

Is there a reason to study genes responsible for Joubert syndrome (JBTS) or Senior Loken syndrome (SNLS) in patients affected with isolated Leber congenital amaurosis (LCA)? *I. Perrault, N. Delphin, S. Hanein, S. Gerber, A. Munnich, J. Kaplan, J.-M. Rozet* Department of Genetics - INSERM U781 - Faculté Paris-Descartes, Paris, France.

Introduction: LCA is a genetically heterogeneous disorder characterized by a severe loss of vision in the first months of life. It is usually an isolated disorder but it can be associated with systemic features especially renal dysfunction (SNLS) or neurological symptoms and developmental delay (JBTS). Recently, mutations in the CEP290/NPHP6 gene have been shown to account for either isolated LCA or SLNS or JBTS. **Purpose:** The aim of the present study was to determine whether other genes responsible for syndromic LCA could account for isolated forms. **Families and Methods:** Thus, the NPHP4, NPHP5, NPHP7, NPHP8 and AHI1 genes were screened for mutations in 96 LCA cases unrelated to the 11 LCA genes. **Results:** No mutation was found in the NPHP4, NPHP7 and NPHP8 genes. Conversely, mutations were found in the NPHP5 (n=2/96) and AHI1 (n=1/96)genes, respectively. Both patients with NPHP5 mutations harboured two mutations expected to be severe. The natural history of the disease in these two young patients was reviewed and updated. At the age of 8yrs one of them developed a renal dysfunction compatible with the diagnosis of nephronophtisis. With regard to the second one no extraocular exam was available. The patient is under clinical investigation. The patient related to the AHI1 gene was found to carry a nonsense homozygous mutation. This girl aged of 27 months was unable to walk and presented with poor balance. Although MRI was still unavailable, JBTS is highly probable. **Conclusion:** this study suggests that genes responsible for SLNS and JBTS may not account for isolated LCA. Nevertheless, since the DNA of patients is generally sent soon after birth, the screening of SNLS or JBTS genes should be proposed in LCA infants to allow a close follow-up of those carrying mutations.

Refinement of genotype-phenotype correlation in the non-lissencephalic 17p13.3 contiguous gene deletion syndrome. *C. T. Thiel, C. Zweier, K. Hofmann, J. Hoyer, U. Trautmann, A. B. Ekici, A. Reis, A. Rauch* Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany.

Various heterozygous deletions in human chromosome 17p13.3-pter have been recognized to underlie the Miller-Dieker syndrome [MDS, MIM 24720], which is characterized by classical lissencephaly distinct facial dysmorphism and variable further features such as short stature and malformations of the heart and other organs. Classical lissencephaly occurs also as isolated brain malformation [ILS, MIM 607432] and is usually associated with severe mental retardation, intractable epilepsy and spasticity. ILS was shown to be caused by point mutations or deletions of the *PAFAH1B1* gene (*LIS1*) which is located within the MDS region in 17p13.3. Since the ILS deletion-region encompasses the *LIS1* and further telomeric genes but never includes *CRK* and *YWHAE*, a MDS critical region including these two genes was proposed, while haploinsufficiency of the further telomeric region was thought to be clinically insignificant. Recently, the more severe brain phenotype of MDS was explained by the additional deletion of the *YWHAE* gene interacting with LIS1 and NUDEL during brain formation. By molecular karyotyping we identified three novel non-lissencephalic patients with different submicroscopic deletions of the terminal 17p13.3 region allowing further refinement of the 17p- contiguous gene syndrome. Patient 1 showed a terminal 2.2 Mb deletion covering the MDS critical region but not *LIS1* and had normal brain MRI, mild to moderate mental retardation, the typical facial characteristics of MDS, short stature and TOF. Patient 2 had an interstitial 1.3 Mb deletion also covering the MDS critical region but not LIS1 and showed also mild to moderate mental retardation, MDS facial features, short stature, PDA and patent foramen ovale. A terminal 1.2 Mb deletion was identified in patient 3 with learning difficulties and mild facial anomalies, only. Our data confirm association of the MDS facial dysmorphism, mental retardation, short stature and congenital heart defects to the MDS critical region and exclude deletions of *YWHAE* without deletion of *LIS1* as causative of brain malformations.

CYTOGENETIC ANALYSIS OF A PATIENT WITH BLEPHAROPHIMOSIS PTOSIS EPICANTHUS INVERSUS SYNDROME (BPES). *P. Gupta[1], M. Kumar[2], M. Tanwar[2], N. Puskar[1], R. Dada[2]* 1) Dr. R.P. Centre for Ophthalmic Sciences, All India Institute Medical Sciences; 2) Lab. for Molecular Reproduction & Genetics, Deptt. of Anatomy, All India Institute Medical Sciences, New Delhi, India.

Blepharophimosis ptosis epicanthus inversus syndrome (BPES) is a rare genetic disorder with autosomal dominant pattern of inheritance. The frequency of BPES has been estimated to be 1 in 50,000. Patients with BPES have a combination of congenital anomalies as small palpebral fissures, epicanthus inversus, low nasal bridge and congenital ptosis. Other features like microphthalmos, anophthalamos, microcornea, hypermetropia, divergent strabismus, high arched palate, cup shaped ears, mental retardation and infertility in females has been reported. Based on the presence and absence of premature ovarian failure BPES has been categorized into two types: type I with infertility in females and type II involves eye malformation in both males and females. It has been shown that penetrance is 100% in type I where there is transmission by males only and 96.5% in type II in which transmission occurs through both sexes. From the review of reported cases, it has been concluded that a locus for eyelid development is situated at the interface of long arm of chromosome 3. Since blepharophimosis, ptosis and microphthalmia are consistent features in Patients with BPES an interstitial deletion of band 3q2, the location of BPES gene at this position seems highly likely. Various reports linked the deletion in 3q21, 3q22, 3q23, 3q24, 3q25 and translocations t(3:7)(q26-qter:q+), t(X:3)(p22:q21), t(3:8)(q23:p22.1) to the BPES. Thus cytogenetically different deletions and translocations of chromosome 3 have been described in patients with BPES. We report a sporadic case of BPES. We have done the Cytogenetic analysis of the patient. Standard GTG banding showed a novel deletion of band 3q26-28. This is the first report of deletion in this region. We also found deletion in the 3qter region which has been already linked to the BPES. This finding represents a severe manifestation of the disease. BPES is a heterogeneous entity, and evaluation and counseling of affected individuals should be undertaken with caution.

A novel mutation in the 3 UTR of SPG4 gene identified in an apparently sporadic patient affected by spastic paraplegia. *A. Magariello[1], L. Citrigno[1,2], A. Patitucci[1], R. Mazzei[1], F. L. Conforti[1], A. L. Gabriele[1], T. Sprovieri[1], C. Ungaro[1,2], M. Muglia[1]* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Department of Neurosciences, Psychiatric and Anesthesiological Sciences, University of Messina, Messina, Italy.

Mutations in the SPG4 gene are the commonest cause of spastic paraplegia accounting for up to 40% of hereditary autosomal dominant and 12% of sporadic cases. The phenotype associated with disease due to mutations in the SPG4 gene tends to be pure. There is increasing evidence, however, of patients with complex forms of spastic paraplegia in which spastin mutations were identified. More than 150 point mutations have been identified in SPG4 gene and recently partial deletions of the gene were found in a significant number SPG4 point mutation negative patients. A 42 years old male with an apparently sporadic pure form of spastic paraplegia was referred for molecular diagnosis of SPG4 mutations. A novel point mutation, c. *2G>T, was identified in the 3UTR of the gene after two nucleotide from stop codon in exon 17. The mutation was not found in 200 normal chromosomes analyzed from the same geographical area. The web splice-site prediction software (http://www.fruitfly.org) revealed that the transition G>T creates a novel donor splice-site producing an alternative splicing involving the 3UTR region highly conserved and necessary to RNA stability. To predict the influence of this mutation, an RT-PCR reaction using RNA from the proband and from the normal control was carried out. Direct sequence of cDNA amplicon spanning from the exon 14 to 324 nts downstream of the termination codon revealed the presence of the wilde type but not the mutant allele thereby demonstrating skipping of 3UTR gene. In conclusion, the novel point mutation, c. *2G>T, here reported is the first pathological mutation identified in the 3 UTR of the SPG4 gene. ACKNOWLEDGEMENTS This work was partly supported by an Italian Ministry of Health grant (RF Neuro ex art56) to M.M.

Association of SNP (G-A) in the exon-1 of CRYAA gene with age related cataracts. *S. BhagyaLaxmi[1], T. Padma[1], R. Sireesha[1], M. Mamata[1], V. Dhananjay Raje[2], k. Sandhya[2], K. Ravi Kumar Reddy[3], M. Mundada[3]* 1) Department of Genetics, Osmania University, India; 2) Ocimum Biotechnologies, India; 3) Sarojini Devi Eye Hospital and Institute of Opthalmology,India.

455 age-related cataract patients (Nuclear (NC)-108; Cortical (CC)-105; Posterior subcapsular (PSC)-96; Mixed type (MT)-146 cataracts) and 144-age-matched controls were screened for SNPs in CRYAA-Ex-1 by SSCP and subsequently by sequencing. Demographic analysis showed high predilection of female (54.7%) as compared to male patients (45.2%). The mean ages-at-onset of cataracts were 59.80.92 in NC; 57.0201.1 in CC; 54.51.22 in PCS and 57.40.80 in MT. A high incidence of presenile (age-at-onset 50 years) cases were observed in PSC (34.0%) and CC (23.0%) as compared to NC (6.4%). The frequency of smokers was high in NC (53.0%) compared to CC (47.0%); PSC (38.0%) and controls (37.0%). Familial incidence was high in CC (7.6%) as compared to NC (5.6%) and PSC (3.1%). Screening of SNP (G-A) transition in the first exon-1 of CRYAA showed significantly high frequency of GA as compared to GG and AA patterns in all the patients in general and specifically in NC and CC cases (controls-17.0%, total cases -27.0%, NC -33.0% CC -29.0%; chi-square values: Total cases-2-5.87,p0.01; NC-2-9.45,p0.005; CC-2-5.06,p0.005).This suggests high risk for GA carriers for developing NC and CC cataracts. When the data was stratified, GG types showed a significant association when familial and non-familial cases (2-5.39,p0.02) were compared. Smokers and alcoholic patients of NC also showed significant association with GG genotypes as compared to controls (smokers- 2-5.77,p0.01; alcoholic- 2-8.36,p0.01). Alcoholic patients of CC showed a significant association with heterozygotes (GA-2-4.9;p0.02) as compared to other. The present results reveal difference in the association of the SNP (G-A) in exon-1 of CRYAA gene with reference to the type of cataract suggesting that this SNP may be used as a marker in predicting the risk for NC and CC types. Further this SNP may be used to follow up these cases (NC and CC) to determine the effect of pharmacotherapy used and modify treatment regimen accordingly.

Effects of extreme vs. severe hyperhomocysteinemia in mice. *S. Gupta[1], M. Slifker[1], J. Kühnisch[2], S. Lhoták[3], R. Austin[3], W. Kruger[1]* 1) Division of Population Science, Fox Chase Cancer Center, Philadelphia, PA; 2) Institute for Medical Genetics, Charitè, Universitätsmedizin, Berlin, Germany; 3) Henderson Research Centre, Hamilton, Ontario, Canada.

Cystathionine beta-synthase (CBS) deficiency in humans cause extreme elevations in plasma total homocysteine (tHcy; 200 M) resulting in vascular, skeletal, neurological, and visual phenotypes. Thrombosis is the main cause of morbidity in CBS deficient patients. Treatment with B-vitamins, betaine, and methionine restriction leads to a dramatic reduction in thrombotic events despite the patients often still having severe elevations in tHcy (80 M). To understand the difference between extreme and severe hyperhomocysteinemia we have studied two different mouse models of CBS deficiency. TgI278T Cbs-/- mice have extreme hyperhomocysteinemia with a mean tHcy of 296 M, while TghCBS Cbs-/- have severe hyperhomocysteinemia with a mean tHcy of 170 M. TgI278T Cbs-/- mice, but not TghCBS Cbs-/- mice showed osteoporosis of femur and fifth lumbar vertebrae, facial alopecia and a 20% reduction in mean survival compared to control mice. Metabolic profiling of serum reveals that TgI278T Cbs-/- mice have significantly elevated levels of homocystine, homocysteine-cysteine and homocysteine-glutathione disulfides but not protein bound homocysteine (bHcy) compared to TghCBS Cbs-/- mice. TgI278T Cbs-/- mice also showed elevated serum methionine, threonine, serine, glutamine, alanine, citrulline, ornithine and proline, and reduced cystathionine and total cysteine compared to TghCBS Cbs-/- mice. In the liver, TgI278T mice have significantly elevated Hcy, tHcy, bHcy, methionine, serine, glutamic acid, ornithine and AdoHcy in comparison to TghCBS mice. Livers from TgI278T but not TghCBS Cbs-/- mice showed ER stress as examined by immunohistochemical staining for ER stress markers and by qRT-PCR. Microarray studies on liver from TgI278T Cbs-/-, TghCBS Cbs-/-, and control mice indicate that the TgI278T Cbs-/- and TghCBS Cbs-/- mice have unique expression profiles. Our results indicate that there is a clear threshold effect in tHcy that distinguishes the phenotypic effects of extreme from severe hyperhomocysteinemia.

Absence of a functional Aurora Kinase C protein causes meiosis I arrest in men and leads to the production of large-headed multiflagellar spermatozoa. *K. Dieterich[1,2], R. Zouari[3], M. C. Jacob[4], M. Kharouf[3], J. Lunardi[1,2], S. Hennebicq[1,2,5], P. F. Ray[1,2]* 1) Génétique et Procréation, CHU de Grenoble, Grenoble, France; 2) Faculté de Médecine-Pharmacie, Domaine de la Merci, Université Joseph Fourrier, France; 3) Centre de FIV les jasmins, Tunis, Tunisia; 4) Laboratoire d'Immunologie Cellulaire, EFS Rhône Alpes, site de Grenoble. France; 5) Inserm U823, Institut Albert Bonniot, Grenoble, France.

We have recently identified a point mutation in the Aurora Kinase C (AURKC) gene (1) in infertile North African men presenting with oligoasthenoteratozoospermia (OAT) and typical large-headed multiple-tailed spermatozoa (OMIM 243060). This form of male infertility had been linked to a defect in chromosome/chromatid segregation during meiosis I and II and cytokinesis failure as suggested by the detection of 100% chromosomal abnormalities in the spermatozoa by FISH. We carried out a whole genome scan in 14 infertile men and could identify a homozygous cytosine deletion (c.144delC) in AURKC exon 3 of all fourteen patients. This frameshift mutation yields a premature stop codon at position 71 and thus a truncated protein with a reduced kinase domain. In the light of the recent understanding of the physiological and pathological role of Aurora Kinase C, large-headed multiple-tailed spermatozoa in men are expected to be tetraploid, yet FISH analyses showed a very heterogeneous ploidy pattern within the analysed spermatozoa with only a minority of tetraploid cells. We therefore developed a DNA flow cytometry assay to directly measure the quantity of DNA present in large-headed multiple-tailed spermatozoa. Our results, obtained on 5 index cases, demonstrate that all of these patients spermatozoa are indeed tetraploid. We conclude that the absence of a functional AURKC protein yields a blockage at meiosis I in spermatogenesis. These data highlight the limitation of the FISH technique, particularly in hyperhaploid cells. No haploid gametes were present in these patients sperm therefore formally contraindicating intracytoplasmic sperm injection (ICSI). 1) Dieterich et al. (2007) Nat Genet 39, 661-665.

Textile Plot: a Graphical Representaion for Multiple SNP Data. *N. Kumasaka[1], N. Kamatani[1,2]* 1) Center for Genomic Medicine, RIKEN, Tokyo, Japan; 2) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

The textile plot (Kumasaka and Shibata 2008) is a graphical representation for very high dimensional data. It can accommodate not only numerical data but also unordered or ordered categorical data, or the mixture of those with missing values. The advantages of the textile plot in the context of association studies are presented with several practical examples. On the textile plot, a genotype at each SNP locus is represented by a point on a parallel coordinate axis, and a pair of genotypes between adjacent loci are connected by a segment with a width proportional to the number of replicates associated with the pair of genotypes. The locations and scales of all genotypes are appropriately determined so that all connected segments are aligned as horizontally as possible. From genetics point of view, the horizontalness incorporated into the textile plot represents a degree of non-independency within a population of a gamete's alleles at different loci. The plot can accentuate the gametic phase disequilibrium by specific geometrical shapes. In the context of maximum likelihood estimation, the absolute linkage disequilibrium (r^2=D'=1) between two loci is represented by all connected segments horizontally aligned, and the complete linkage disequilibrium ($r^2$1, D'=1) is represented by connected segments without line crossing on the textile plot. On the other hand, the population stratification within the given data can also be observed by vertical positions of genotypes on axes. As a result, the textile plot suggests several potential avenues of association studies to reveal significant population structure within the multiple SNP data which helps to detect disease susceptibility loci in the human genome.

Assessing the combined impact of 18 common genetic variants of modest effect sizes on type 2 diabetes risk. *M. N. Weedon[1], H. Lango[1], C. N. A. Palmer[2], A. D. Morris[2], E. Zeggini[3], A. T. Hattersley[1], M. I. McCarthy[3], T. M. Frayling[1]*
1) Peninsula College of Medicine and Dentistry, Exeter, UK; 2) Ninewells Hospital and Medical School, University of Dundee, UK; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Genome-wide association studies have dramatically increased the number of common genetic variants that are robustly associated with type 2 diabetes (T2D). A possible clinical use of this information is to identify individuals at high risk of developing the disease, so that preventative measures may be more effectively targeted. Here we assess the ability of 18 confirmed T2D variants to differentiate between T2D cases and controls.

We assessed index SNPs for the 18 independent loci in 2598 controls and 2309 cases from the GoDARTS study, a population-based case-control cohort. The discriminatory ability of the combined SNP information was assessed by grouping individuals based on number of risk alleles carried and determining relative odds of T2D, and by calculating the area-under the receiver-operator characteristic curve (AUC).

Individuals carrying more risk alleles had higher risk of T2D. For example, 1.2% of individuals with >24 risk alleles had an odds ratio of 4.2 (95% CI: 2.11, 8.56) against the 1.8% with 10-12 risk alleles. The AUC (a measure of discriminative accuracy) for these variants was 0.60. The AUC for age, BMI and gender was 0.78, and adding the genetic risk variants only marginally increased this to 0.80.

Currently, common risk variants for T2D do not provide strong predictive value at a population level. However, the joint effect of risk variants identified sub-groups of the population at substantially different risk of disease. Further studies are needed to assess whether individuals with extreme numbers of risk alleles may benefit from genetic testing.

Whole genome expression analysis to study the role of severe and mild GBA mutations in Parkinson's disease. *A. Orr-Urtreger[1,3], M. Kedmi[1], A. Bar-Shira[1], N. Giladi[2,3], Z. Gan-Or[1,3]* 1) Genetics Institute and; 2) Dept Neurology, Tel Aviv Sourasky Med Ctr; 3) Sackler Faculty of Medicine, Tel Aviv Univ, Israel.

Association between GBA (-glucocerebrosidase) gene mutations and Parkinson's disease (PD) was established. The high carrier frequency of GBA mutations among Ashkenazim (1/16) renders this population important for studying GBA role in PD. Rrecently, we demonstarated a genotype-phenotype correlation between mild and severe GBA mutations and PD risk and age at motor symptoms onset (AAO) (Neurology 2008). This association is further analyzed here in an extended cohort of 600 patients and 353 elderly controls. Additionally, to detect genes that might be involved in GBA-associated PD, we initiated a global gene expression analysis of peripheral blood leukocytes (PBLs) samples from patients carrying mild and severe GBA mutations and controls. Gene expression and alternative splicing profiles were analyzed by Affymetrix GeneChip Human Exon 1.0 ST Arrays. The frequency of GBA carriers was 19.3% in PD patients compared to 4.0% in the elderly controls ($p<0.01$). The proportion of severe mutation carriers among PD patients-GBA carriers was 24% compared to 7% among average risk controls ($p<0.01$). Severe and mild GBA mutations significantly increased the risk for developing PD by 10.9 and 2.7-fold, and significantly affected the AAO of PD, 55.2 and 58.7 years, compared to 61.0 years in patients without known GBA or LRRK2 mutations. Analysis of the "core" exon-expression data (21,980 genes and 232,448 exons) revealed a differential expression of 921 and 135 genes ($p<0.05$ and $p<0.01$, ANOVA), when comparing PBLs from severe and mild GBA mutations carriers, and differential splicing of 135 genes (bonferroni corrected $p<0.05$, Alt-Splice ANOVA). Our results demonstrate the differential effects of severe versus mild GBA mutations on PD risk and AAO, and reveal different profiles of genes expression and alternative splicing in these two genotypic groups of patients. They also emphasize the uniqueness of our population for studying the complex genetic basis of PD, and suggest that PBLs may serve as a relevant surrogate tissue to examine the transcriptional changes involved in PD pathogenesis.

Genetic variants of -chemokines are associated with autoimmunity in humans and rats. *J. Öckinger[1], M. Jagodic[1], F. Lundberg[1], I. Kockum[1], L. Padyukov[2], E. Wallström[1], J. Hillert[1], T. Olsson[1]* 1) Clinical Neuroscience, Karolinska Institutet, Stockholm, Stockholm, Sweden; 2) Department of Medicine, Karolinska Institutet, Sweden.

Identification of genetic factors that regulate autoimmune disorders, such as multiple sclerosis (MS), is crucial for unraveling the disease mechanisms. In this study we have utilized a rat model of MS; myelin oligodendrocyte glycoprotein induced experimental autoimmune encephalomyelitis (MOG-EAE), in order to identify genetic regions that regulate rodent neuroinflammation. Linkage analysis in an advanced intercross line (AIL) originating from the DA and PVG.AV1 rat strains identified *Eae18b*, a 1.06Mb region on rat chromosome 10 that regulates severity of MOG-EAE. *Eae18b* includes a cluster of -chemokines, a class of molecules with immunostimulatory and chemoattractant properties.

In addition to the genetic studies in the rat, we investigated the human homologues of the -chemokines in an association study. In total 18 SNPs in 6 chemokine genes were analyzed in 1079 patients diagnosed with MS and 1198 control individuals. The results show that genetic variants of the CCL8 gene are associated an increased risk for MS, whereas haplotypes including the CCL13 and CCL1 genes are protective. Selected SNPs were also investigated in 2158 patients diagnosed with rheumatoid arthritis (RA) and 1068 control individuals. We could thereby show that genetic variants in the CCL2 gene are associated with an increased risk for RA.

The results from this study imply that genetic variants of the chemokines regulate neuroinflammation in both rats and humans, as well as other inflammatory diseases in humans.

Identification of CFTR rearrangements by a CGH locus specific array. *C. Le Marechal, S. Quemeneur, C. Benech, K. Giteau, MP. Audrezet, C. Ferec* Inserm U613,University-hospital,Brest ,France.

More than 1500 CFTR mutations have been described and deposited in the cystic fibrosis mutation data base(www.genet.sickkids.on.ca/cftr) so far .In the few past years, we(Audrezet et al ;Ferec et al) as well as others (Niels et al,Handash et al,Chevalier-Prost et al,) have developed new semi quantitative approaches to evidence gross rearrangements in this gene .We have shown that these deletions account for about 1 to 3% of the CF disease causing mutations worldwide. We have described 8 new rearrangements and characterized their breakpoint junctions .In this work we have designed a 15K locus specific CFTR array (Agilent technology) to carefully analyze the deletions/insertions or duplications at this locus. We showed that the 17 deletions /insertions collected in our lab from different countries worldwide are clearly evidenced and moreover the 5 and 3breakpoint of these deletions are accurately determined.. This allows a rapid design of primers to amplify the breakpoint junction and to obtain the sequence permitting the characterisation of the defect at the molecular level. The CGH locus specific 7q3.1 array that we have developed is an excellent new tool allowing a rapid scan and characterization of the rearrangements that could affect not only the 27 exons of the gene but also those that could be located throughout the 200 kb genomic region of the CFTR gene. Audrezet MP, et al,Hum Mut,2003, 23:343-357 Ferec C,et al ,Eur J Hum Genet,2006,14:567-576 Niels F,et al,J Med Genet 41:e118 Handash et al ,Human mut,2005,25:504 Chevalier-Prost F,Human Mut,2005,25:504-509.

AsiDesigner: exon-based siRNA design server considering alternative splicing. *Y. Kim, Y. Park, M. Won* Functional Genome Research Ctr, KRIBB, Daejeon, Korea.

RNA interference (RNAi) with small interfering RNA (siRNA) has become a powerful tool in functional and medical genomic research through directed post-transcriptional gene silencing. In order to apply RNAi technique for eukaryotic organisms, where frequent alternative splicing results in diversification of mRNAs and finally of proteins, we need spliced mRNA isoform silencing to study the function of individual proteins. AsiDesigner is a web based siRNA design software system which provides siRNA design capability to account for alternative splicing for mRNA level gene silencing. It provides numerous novel functions including the designing of common siRNAs for the silencing of more than two mRNAs simultaneously, a scoring scheme to evaluate the performance of designed siRNAs by adopting state-of-the-art design factors, a stepwise off-target searching with BLAST and FASTA algorithms and checking the folding secondary structure energy of siRNAs. To do this, we developed a novel algorithm to evaluate the common target region where siRNAs can be designed to knock down a specific mRNA isoform or more than two mRNA isoforms from a target gene simultaneously. The developed algorithm and the AsiDesigner were tested and validated as very effective throughout widely performed gene silencing experiments. It is expected that AsiDesigner will play an important role in functional genomics, drug discovery, and other molecular biological research. AsiDesigner is freely accessible at http://sysbio.kribb.re.kr:8080/AsiDesigner/.

Impact of definitive haplotypes on genetical analyses. *K. Higasa, Y. Kukita, T. Tahira, K. Hayashi* Res Ctr Gen Info, Kyushu Univ/Med Inst Bioreg, Fukuoka, Japan.

The haplotype map constructed by the International HapMap Project is a valuable source for the studies of disease genes, population structure, and evolution. In the Project, haplotypes have been inferred from experimentally determined genotypes, and are fairly accurate for Caucasians and Africans since the inference was based on the genotypes of trios. However, the inference for the Asians populations was less accurate, because of the lack of familial information. Here we assessed how the error in the inference can affect downstream studies, especially the analysis of recent positive selections, by comparing the results of the analyses using the data of HapMap JPT and of definitive haplotypes (DHaplo-DB) determined by us from a collection of Japanese complete hydatidiform moles (CHM), each of which carries a genome derived from a single sperm. We found that the error in JPT was not uniform throughout the genome, and the statistics for recent positive selection was significantly affected. The most pronounced region was MHC locus, where the signal of positive selection was not detected for JPT, when analyzed using haplotype data determined without family information, but detected when analyzed using definitive haplotype data. The long-range LD and conservation of long haplotypes may have rendered this locus particularly sensitive to phasing error. The D-HaploDB is freely accessible via the internet at http://finch.gen.kyushu-u.ac.jp.

Preprorenin signal peptide mutation in a family with uromodulin-associated kidney disease. *M. Zivna[1], K. Hodanova[1], P. Vyletal[1], J. Sikora[1], V. Baresova[1], H. Hulkova[1], M. Kalbacova[1], J. Zivny[2], R. Ivanek[1,3], K. Kapp[4], M. Elleder[1], S. Kmoch[1]* 1) Inst of Inherit Metabol Dis, Charles University, Prague; 2) Dept of Pathophysiology, Charles University, Prague; 3) Inst of Mol Genet, Academy of Science, Prague; 4) Center for Mol Biol, University of Heidelberg.

The term of uromodulin-associated kidney diseases (UAKD) emerged recently for a group of autosomal-dominant tubulointerstitial nephropathies characterized by combination of hyperuricemia, gouty arthritis, decreased urinary uromodulin (UMOD) excretion and abnormal UMOD expression in the kidney. UAKD comprise phenotypes known as a familial juvenile hyperuricemic nephropathy and medullary cystic kidney diseases type 1 and type 2. The association of these phenotypes with UMOD changes was established following the identification of disease causing mutations in the UMOD gene in most of the affected families. In a single family with no UMOD mutation we used positional cloning and identified in patients unique deletion of one of a leucine residues forming hydrophobic penta-leucin motif of the preprorenin signal peptide (L16REN). To characterize pathogenic effect of the identified mutation we performed in-vitro translation/translocation assays, expressed WTREN and L16REN in ATt-20 and HEK293 cell lines, characterized qualitative and quantitative parameters as well as cellular localization of the recombinant proteins, assessed effect of the L16REN mutation on cell viability and correlated the results with expression of prorenin and renin, other phenotype related proteins and selected tubular markers in available patient kidney. Our results have provided several lines of evidence indicating that the identified mutation causes aberrant cotranslational translocation of preprorenin, reduced rate of prorenin and renin biosynthesis and abnormal localization of prorenin and renin in patient kidney. We hypothesize that, as in renal tubular dysgenesis and animal models with renin dysfunction, the observed abnormalities may initiate endoplasmic reticulum stress and slowly progressing damage of juxtaglomerular cells, which may end up in deterioration of kidney functions and observed clinical abnormalities.

Interplay of genetic and lifestyle influences on myocardial infarction in South Asia: The Pakistan Risk of Myocardial Infarction Study (PROMIS). *P. Frossard[1], D. Saleheen[1,2], J. Danesh[2]* 1) Dept Biological & Biomed Sci, Aga Khan Univ Med Col, FHS, Karachi, Pakistan; 2) Department of Public Health and Primary Care, University of Cambridge, UK.

The Pakistan Risk of Myocardial Infarction Study (PROMIS) aims at providing a resource for the assessment of the interplay of genetic and lifestyle influences on coronary heart disease (CHD) in Pakistani South Asians. A total of 10,000 individuals aged 30-80 years (both male and female) with a first-ever confirmed myocardial infarction (MI) and 10,000 frequency-matched controls (on age and sex) is being recruited with complete medical, social, and dietary information. Serum, plasma, whole blood and extracted DNA samples are taken from each participant for biochemical and genetic analyses, and cell-lines are maintained for studies of gene expression. Preliminary data on 3000 MI cases and 3000 controls indicates that the mean age of first MI cases is 54 (SD 11) years; the prevalence of diabetes (16% among cases, 10% among controls) and the use of tobacco products (51% among cases, 41% among controls) is substantially higher than in Western populations; levels of HDL-C, however, are substantially lower (0.81 mmol/L in cases and 0.86 mmol/L in controls). This suggests that reverse cholesterol transport and metabolic dysfunction could be of particular relevance to MI in South Asians. Recent genome-wide investigations on subjects of European descent reported that two novel loci (rs599839 and rs646776) at chromosome 1p13.3 are strongly associated with reduced LDL-C levels. The first 2,806 participants of PROMIS were genotyped for rs599839 and rs646776 using a TaqMan assay. The two variants display a high level of linkage disequilibrium (R2 = 0.96) and were associated with 0.13 mmol/L and 0.15 mmol/L reduction in LDL-C levels, and with 28% and 29% reduced risks of MI, respectively, thereby confirming and validating the original findings in the PROMIS population. Establishing a large bioresource, as proposed in PROMIS, identifies the determinants of CHD in South Asia and will contribute to locally appropriate strategies to prevent and control the growing epidemic of CHD in this region.

High density oligonucleotide array identifies a submicroscopic 3.2 MB chromosomal 16q12.2 deletion in a child with Noonan-like phenotype. *C. F. Chang[1,2], A. Tsai[4], L. H. Li[1], J. Y. Wu[1], Y. T. Chen[1], F. J. Tsai[3]* 1) IBMS Academia Sinica,; 2) Molecular Medicine Program, IMI, National Yang Ming University,; 3) Department of Medical Genetics & Medical Research, China Medical University Hospital,Taiwn; 4) Div Clinical Gen & Metabolism, Children Hosp, Denver, CO.

Chromosomal aberrations are a common cause of multiple anomalies, developmental delay and dysmorphic features. Array based comparative genomic hybridization (array-CGH) that covers the whole genome can pick up rearrangement not previously detected by conventional G-banding or FISH for specific/critical regions. We report a 9- year-old boy with Noonan-like facial features without congenital heart disease. Other features include short stature and mild mental retardation. Physical exanimations were significant for broad forehead, hypertelorism, flat nasal bridge, down-turn mouth corners, high arch palate, cup-shaped/over-folded auricles, left preauricular tag, low set and posteriorly rotated ears, short neck, single palmar crease, and prominent gap between first and second toes. Karyotype and FISH for 22 were normal. Using high density oligonucleotide chip Affymetrix Genome-Wide Human SNP Array 6.0, we identified a de novo 3.2 Mb deletion from bands q12.2 to q13 on chromosome 16 (from rs8044091 to rs4783954). The study was designed to perform parental and proband samples concurrently on three chips and interpreted as a trio set. The deletion was confirmed by qPCR of SLC6A2 and FTO genes which locate in the deleted region. Chromosomal regions harboring genes associated with Noonan or Noonan-like syndrome, such as 12q21.1, 12p12.1, 2p22, 3p25 and 17q11 showed no copy number changes. Our study demonstrated the power of high density oligonucleotide array chip in identifying novel deletions and delineating unreported phenotype. Our patient also suggests another critical region for Noonan-like facial features. In patients who have Noonan -like facial features with short stature without heart finding, high density array should be included in initial work up prior than sequencing analysis for RAS/MAP kinase pathway genes.

The association among the metabolic syndrome, ABCA1 haplotype and lipid metabolism. *C.-L. Lee[1], Y.-T. Lin[1], R.-Y. Wang[2], C.-Y. Chen[2], C.-J. Lin[3], M.-C. Humg[3], W.-C. Shy[3], T.-N. Wu[1], F.-Y. Wu[1]* 1) China Medical University, Environmental Health, Taichung, Taiwan; 2) China Medical University, Public Health, Taichung, Taiwan; 3) China Medical University, Nursing, Taichung, Taiwan.

The aim of this study was to investigate the relationships among the metabolic syndrome, haplotypes with single nucleotide polymorphisms (SNPs; G1051A, G2706A and A3044G) in the ATP-binding cassette transporter 1 (ABCA1) and lipid metabolism. Participants in the National Adult Health Examination Project in Year 2007, who were residents in the middle of Taiwan, were recruited as the study subjects. 276 subjects with metabolic syndrome (MetS) were selected. The remaining 406 subjects did not have the metabolic syndrome (non-MetS). In the MetS group, 27.2% had a BMI 27-30 and 27.2% had a BMI30. And in the non-MetS group, the rates for BMI 27-30 and BMI30 were 10.9% and 6.1%, respectively. Anthropometric measures and biochemical analytical results showed that subjects in the MetS group had significantly higher glucose, triglycerides, -GT, systolic pressure, diastolic pressure, waist circumference, and BMI. MetS group subjects also had lower HDL concentrations and had more comorbidities (such as heart disease, hypertension, obesity, hyperuricemia, blood lipid abnormalities, etc.). All of these above differences between the MetS and non-MetS groups were statistically significant. The results of multivariate logistic regression analysis indicated that subjects with chewing betel nut habit would have 3.46 times the risk of having metabolic syndrome than those without (95% CI=1.27-9.4). On the other hands, subjects with drinking coffee habit would decrease the risk of having metabolic syndrome (OR=0.31; 95% CI=0.12-0.76). After adjusting for the effects of age, gender, ethnicity and BMI), the haplotype with SNPs (1051A, 2706A, 3044G) in ABCA1 was associated with the risk of metabolic syndrome (OR=7.6, 95% CI=2.37-24.31). In conclusion, there were also a greater number of total comorbidities in MetS subjects than in non-MetS subjects. People carrying the haplotype with SNPs in ABCA1 were at a higher risk of having the metabolic syndrome.

Genetic Skeletal Dysplasias in Thailand: Twenty -year experience. *P. Wasant, N. Vattanawicharn, S. Liammongkolkul* Dept of Ped/Div of Medical Gen, Siriraj Hosp/Mahidol Univ, Bangkok, Thailand.

Genetic skeletal dysplasias are a heterogeneous group of disorders associated with abnormalities in the size and shape of the limbs , trunk , and/ or skull that frequenthy result in disproportionate short stature. There are well over 100 distinct skeletal dysplasias that have been classified primarily on the basis of their clinical or radiographic characteristics. The Genetic Skeletal Dysplasia Clinic was established at the Division of Medical Genetics, Department of Pediatrics, Faculty of Medicine Siriraj Hospital, Mahidol University in Bangkok since 1992, the only one of its kind in Thailand. Main objective of the clinic is to educate Thai pediatricians and orthopedic surgeons in training (from multicenter) about various genetic skeletal disorders; and how to care and treat pediatric patients with skeletal dysplasias appropriately. There are numerous cases: achondroplasia, hypochondroplasia, pseudoachondroplasia, atelosteogenesis, pyknodysostosis, spondylo -epiphyseal dysplasia congenita, spondylometaepiphyseal dysplasia, osteogenesis imperfecta, chondroectodermal dysplasia (Ellis- van- Creveld), cleidocranial dysostosis, thanatophoric dysplasia, rhizomelic chondrodysplasia punctata, trichorhinophalangeal syndrome, mucopolysaccharidoses, (Hurler,Hunter,Sanfillipo, Morquio, Maroteaux-Lamy,Sly), osteopetrosis, campomelic dysplasia, Stickler syndrome, Kniest dysplasia, nail-patella syndrome, diastrohic dysplasia, short-rib polydactyly syndrome, Larsen syndrome, multiple epiphyseal dysplasia, metaphyseal dysplasia and hypophosphatemic rickets. The diagnoses are established at clinical, radiological and biochemical level .There are limitations in confirmation at the molecular level in developing countries. Multidisciplinary approach and genetic counseling are provided.

Search for cryptic subtelomeric chromosome imbalances in prenatal diagnosis of fetal malformations. *A. Soler[1], J. Bruguera[2], C. Morales[1], N. Clusellas[1], I. Mademont[3], I. Madrigal[3], E. Margarit[1], A. Sánchez[1]* 1) Servei de Bioquímica i Genètica Molecular, Hospital Clínic, Barcelona, Spain; 2) Fundació Clínic per a la Recerca Biomèdica, Barcelona, Spain; 3) CIBER de Enfermedades Raras (CIBERER), Barcelona, Spain.

The chromosomal abnormalities ascertained by conventional cytogenetics are responsible for part of the fetal malformations, but a majority of them show a normal karyotype. The presence of a cryptic imbalance may probably explain some of the abnormal phenotypes. MLPA (Multiplex Ligation-dependent Probe Amplification) has been developed as a reliable molecular technique to detect targeted submicroscopic imbalances. We selected 218 pregnancies presenting major fetal malformations (such as cardiopathies, skeletal abnormalities, etc), which had shown a normal conventional karyotype. MLPA using the p036 subtelomere kit (MRC-Holland) was performed in their corresponding amniotic fluid samples, and revealed 27 imbalances (12.4%). Confirmation studies were done using the complementary kit p070 (MRC-Holland); only 7/27 cases were confirmed (3.2%): deletion of 3pter, duplication of 13qter plus deletion of 20pter, duplication of 14qter, duplication of Ypter, duplication of 12qter and duplication of Xpter. FISH (Fluorescent in situ Hybridisation) was also performed to confirm some of the deletions. Discordant false positive cases are maybe due to different reasons. Some p036 imbalances have been previously reported as polymorphisms. Another reason is that p036 and p070 kits contain different probes and some imbalances are located very close to the telomere region so the more centromeric p070 kit does not confirm the results and FISH is not enough sensible to detect them. These discordant results need more accurate techniques for confirming some subtelomeric imbalances. Supported by the grant PI05/0096 to A.S. from Fondo de Investigaciones Sanitarias, Ministerio de Sanidad y Consumo, Spain.

Genetic study of SCN1A-related epilepsies in southern Italy. *E. V. De Marco[1], F. Annesi[1], G. Annesi[1], S. Carrideo[1], G. Provenzano[1], A. Labate[1,2], D. Civitelli[1], F. E. Rocca[1], L. Mumoli[2], E. Mannarino[1,3], G. Incorpora[4], G. Tortorella[3], A. Quattrone[1,2], A. Gambardella[1,2]* 1) Institute of Neurological Sciences, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 3) Dept of Paediatrics, University of Catania, Italy; 4) Division of Infantile Neuropsychiatry, University Hospital of Messina, Italy.

The gene SCN1A has been found mutated in various types of epilepsy. Approximately 10% of generalized epilepsy with febrile seizures plus (GEFS+) families carry mutations in SCN1A. Furthermore, SCN1A mutations occur in more than 70% of patients with severe myoclonic epilepsy of infancy (SMEI) and are usually de novo. We have previously reported some novel SCN1A variants in our population. We aimed to extend the sample number to estimate the frequency of the SCN1A mutations in GEFS+ and SMEI patients in southern Italy. Twenty-two GEFS+ and twenty-six SMEI patients were recruited from Calabria and Sicily. Diagnoses were based on the ILAE criteria. All 26 exons of the SCN1A gene were sequenced. Among the 22 GEFS probands belonging to unrelated families, 3 (13.6%) had SCN1A variations that were previously published (Met1841Thr, Tyr779Cys, Ile1944Thr). Among the 30 SMEI patients, 5 (16.7%) carried SCN1A mutations. Four of them were already reported by ourselves (T1289I, 3840insT, IVS24-2A>G) and other authors (S1505X). A novel mutation was found in the splicing donor site of intron 7, consisting in a deletion of a single nucleotide (IVS7+4delA). SCN1A is the most clinically relevant epilepsy gene. More than 20 mutations have been associated to GEFS+ and nearly 200 mutations to SMEI. We found 8 patients carrying different mutations, thus confirming the high genetic heterogeneity related to these diseases. In our population we found a frequency of GEFS+ mutation similar to that reported by other authors, whereas the SCN1A variations are less represented in our SMEI patients in comparison to the overall literature. In spite of this, our results confirm that SCN1A mutations represent an important cause of GEFS+ and SMEI also in southern Italy.

ASSOCIATION STUDY BETWEEN HFE, TF, TFR1 GENES AND PARKINSONS DISEASE. *V. Greco[1], F. E. Rocca[1,2], F. Annesi[1], E. V. De Marco[1], G. Provenzano[1,3], D. Civitelli[1], P. Tarantino[1,3], V. Scornaienchi[1], G. Annesi[1]* 1) Inst Neurol Sci, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro; 3) Departement of Neurosciences, Psychiatry and Anaesthesiology University of Messina, Messina Italy.

Iron overload increases oxidative stress and may lead to neurodegenerative disorders like Parkinson's disease (PD). Alterations of iron-related genes, therefore, might be involved in the pathogenesis of PD. The aim of this study is to investigate a possible association between the polymorphism C282Y of haemochromatosis (HFE) gene and the prevalence of PD in Southern Italy. Subsequently we will also analyze if the second common polymorphism H63D of the HFE gene, the polymorphisms G258S transferrin (TF) gene and S82G transferrin receptor1 (TFR1) gene are other genetic risk factors for PD. We analyzed the C282Y HFE polymorphism in 175 sporadic PD patients and in 175 controls from Southern Italy. The clinical diagnosis of PD was based according to the UK PD Society Brain Bank criteria. We carried out a genetic analysis by standard PCR and restriction digestion method. Among 175 patients screened for the HFE C282Y polymorphism, 3 (0.86%) carried heterozygous variation C282Y and we found 3 (0.86%) C282Y heterozygotes in the controls. The HFE protein is an important regulator of cellular iron homeostasis. Recent studies on the role of the HFE gene variants in PD vary from a protective effect of C282Y heterozygosity, no effect of the C282Y or H63D variant to an increased risk for PD. In a recent study on the Italian population, the HFE H63D and C282Y polymorphisms are not associated with PD. In Italy, the prevalence of C282Y is lower than in Northern European countries and it is also lower in Southern Italy than Northern Italy. Our results confirm the low frequency of HFE C282Y allele in Southern Italy. We havent found a different frequency between patients and controls, indicating no association between the C282Y HFE gene with PD. Furthermore we are still analyzing the polymorphisms H63D in the HFE gene, G258S in the TF gene and S82G in the TFR1 gene. Our study should be extended for the rarity of the HFE C282Y polymorphism.

GOLD (Gain or Loss Detection) Chip: a new array CGH tool for genetic diagnosis. *S. Comuzio[1], E. Ciabattoni[1], F. Motta[1], G. Stoico[1], E. Bartolini[1], G. Babbini[1], A. Novelli[3], G. Novelli[2], F. Gullotta[2], S. Gambardella[2]* 1) Technogenetics, Milan, Italy; 2) Department of Biopathology, Tor Vergata University, Rome, Italy; 3) Cytogenetic Service, Istituto Mendel-Casa Sollievo della Sofferenza, Rome, Italy.

We designed a new array CGH slide called GOLD (Gain or Loss Detection) Chip. The slide consist of 900 non-overlapping BAC (Bacterial Artificial Chromosome) clones spanning the whole genome, and accurately selected using public databases. The chip has a 10 Mb backbone to guarantee the detection of the aneuploidies, and has an implemented resolution for telomeres, and for regions involved in common genomic diseases. DNA was extracted from overnight bacterial cultures. Each DNA was amplified first by DOP PCR, then by amino PCR to allow the linking to the slides surface, and purified with Clean-up Kit. Each amino PCR was spotted random in six replicates, in two areas. Slides were incubated for 48 hours in a cross-linking box, then washed and blocked with 10 mg/ml BSA solution. Then the slides were validated with 45 DNA from cultured amniotic liquid and commercial cell lines, including the more common Trisomy (Klinefelter, Down, Edwards, Patau, Trisomy 9, Trisomy 22, Trisomy 16), Monosomy (Turner syndrome), and Microdeletions (Cat eye, Wolf-Hirschhorn syndrome, Cri du chat, Williams syndrome, Prader-Willi/ Angelman,Miller-Dieker, Smith-Magenis syndrome, 22q11.2 deletion syndrome). Experimental protocol consists of labeling 600 ng of DNA test and control, for dye-swap experiment, and hybridize 40 hours at 42 C in Hybridization Chambers. The slides were scanned at 5 micron and the images were analyzed using Bluefuse software (Bluegnome). Our protocol allowed to characterize all the DNA imbalances in the 45 samples analyzed. To encourage the use of GOLD Chip for both prenatal and postnatal diagnosis, we provide FISH probes correspondent to all the pathologies identifiable by our experimental protocol. For further informations visit www.technogenetics.it.

Impact of copy number variation (CNV) definition on a CNV association study of amyotrophic lateral sclerosis (ALS). *L. V. Wain[1], A. Al-Chalabi[2], P. N. Leigh[2], C. E. Shaw[2], R. H. Brown[3], J. E. Landers[3], M. D. Tobin[1]* 1) Departments of Health Sciences and Genetics, University of Leicester, UK; 2) MRC Centre for Neurodegeneration Research, Kings College London, Department of Clinical Neuroscience, Institute of Psychiatry, London, UK; 3) Cecil B. Day Laboratory for Neuromuscular Research, Massachusetts General Hospital East, Charlestown, MA, USA.

Copy number variation (CNV) is a major contributor to human genetic variation and CNV associations to disease are emerging. The development of CNV-specific microarrays is in its infancy but many studies have attempted, with varying success, to exploit existing SNP genotyping array data for use in CNV discovery and association studies. Many algorithms have been developed to screen such data for CNV but how to utilize these data in association studies still presents a major challenge. We analysed Illumina 317K SNP array data from 967 ALS patients and 1001 control individuals for CNV using a Hidden Markov Model method (QuantiSNP). Measures based on the overall and relative probe fluorescence intensities for each SNP are used to infer copy number variation across the genome. The method we used identifies putative CNVs, on a sample by sample basis, that overlap by varying degrees CNVs detected in other samples. Large overlapping or nested CNVs are known to have different clinical consequences in some genomic disorders, such as 17p11.2 deletion and duplication syndromes. A key issue in classifying CNVs or association studies is how to treat multiple overlapping hits at the same locus. Whilst analysis of sample and assay quality is essential to identify which samples should be included or excluded from the CNV detection analysis, careful downstream processing of the CNV calls is crucial to forming the basis of a good CNV association study. We explored how best to undertake this in order to retain as much information as possible for association testing whilst ensuring a low false positive rate. Our initial findings suggest that algorithms that simply combine overlapping calls may result in loss of information due to genuinely overlapping CNVs. Our results should help inform the analytical strategies for other CNV association studies.

The C allele of rs2237895 *KCNQ1* is associated with reduced pancreatic beta-cell function in middle-aged Danish people. *J. Holmkvist[1], K. Banasik[1], G. Andersen[1], H. Unoki[2], K. Færch[1], T. Jørgensen[3,5], K. Borch-Johnsen[1,3,4], S. Maeda[2], T. Hansen[1], O. Pedersen[1,4,5]* 1) Steno Diabetes Center, Gentofte, Denmark; 2) Laboratory for Endocrinology and Metabolism, Center for Genomic Medicine, RIKEN, Yokohama, Kanagawa, Japan; 3) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 4) Faculty of Health Science, University of Aarhus, Aarhus, Denmark; 5) Faculty of Health Science, University of Copenhagen, Copenhagen, Denmark.

BACKGROUND AND AIM: The objective of this study was to investigate if polymorphisms in the recently identified type 2 diabetes (T2D) gene potassium channel, voltage-gated, KQT-like subfamily, member 1 (*KCNQ1*), found on chromosome 11p15.5, are associated to T2D-related quantitative traits. RESEARCH DESIGN AND METHODS: A polymorphism associated to T2D in a recent genome-wide association scan (rs2237895 [A/C]) was genotyped in 6,038 treatment-naïve subjects of the Danish population-based Inter99 cohort involving 4567 with normal glucose tolerance, 508 with impaired fasting glucose, 707 with impaired glucose tolerance and 256 with screen-detected T2D. A general linear model was used to test quantitative variables for differences between genotype groups of the examined subjects. RESULTS: The C-allele of rs2237895 was strongly associated with reduced post-OGTT measures of insulin release under a dominant genetic model: serum insulin 30min (meanSD: 286184 vs. 302196 pmol/l, p=0.0008), incremental area under the curve for insulin (2250715960 vs. 2367316564 pmolmin, p=0.006), serum C-peptide 30min (1986720 vs. 2033710 pmol/l, p=0.007), insulinogenic index (28.619.4 vs. 30.721.1, p=0.002) and disposition index (insulinogenic index / HOMA-IR) (3.62.8 vs. 3.83.0, p=0.01). Association with reduced measures of insulin release was predominantly driven by the female gender e.g., insulinogenic index (p_{female}=0.0004, p_{male}=0.22). CONCLUSION: The C-allele of rs2237895 in *KCNQ1* is associated with reduced measures of insulin release, a reduction that is significantly more pronounced in women compared to men.

Modeling Aberrant Splicing in Mutant Genes associated with Inherited Retinal Degeneration and Bardet-Biedl Syndrome. *C. E. Willoughby, D. O'Prey, D. A. C. Simpson* Centre for Vision Science, Queen's Univ Belfast, Belfast, United Kingdom.

Up to 50% of all point mutations responsible for genetic diseases cause aberrant splicing. The aim of this study was to model the pathological impact of known mutations on the splicing process in genes associated with inherited retinal degeneration and Bardet-Biedl syndrome (BBS:MIM#209900). Firstly, we determined if splice site (SS) strength could predict alternative splicing in retinal transcripts. SS strength was calculated on 1400 exons in 60 retinal dystrophy genes using four different scoring methods: Consensus Sequence Weighted Matrices, Neural Network, Information Theory and Maximum Entropy. Based on splice site scoring and EST evidence, exons were classified into low and high SS strength with or without evidence of alternative splicing. RT-PCR on human retinal RNA was performed to validate computational predictions in selected transcripts. High SS strength exons were found to rarely undergo alternative splicing. Exons with low strength splice sites and no EST or RT-PCR evidence of alternative splicing suggest the utilisation of cis-acting elements to regulate splicing. Mutation within these exons are more likely to have a pathological impact on splicing. Secondly, mutant BBS transcripts were classified as vulnerable to aberrant or pathological splicing if sequence variations alter SS strength or splice site definition via splicing enhancers and silencers. SS strength was calculated on 190 exons in 12 BBS genes and potential mutational effects on exonic splicing enhancers and silencers were modelled using the following servers: ESEfinder, FAS-ESS, PESXs, and Rescue-ESE. 290 mutations were modelled and 21% identified in-silico as potential mis-splicing mutations. BBS9, BBS10 and BBS5 genes contained the greatest percentage of possible splicing mutations with 75%, 33% and 33% of mutations modeled affecting either SS strength or splicing enhancers respectively. A number of predicted aberrant splicing events were modelled with a minigene system in HEK293 cell lines to validate predictions. Here, we present an approach to predict and model aberrant splicing in mutant genes.

Common variants in genes underlying mendelian disorders of hypotension and hypertension: association with serum calcium and blood pressure in the general population. *M. D. Tobin[1], M. Tomaszewski[2], P. S. Braund[2], C. Hajat[1], S. M. Raleigh[2], T. M. Palmer[1], M. Caulfield[3], P. R. Burton[1], N. J. Samani[2]* 1) Genetic Epidemiology Group, Departments of Health Sciences and Genetics, University of Leicester, UK; 2) Department of Cardiovascular Sciences, University of Leicester, Leicester, UK; 3) William Harvey Research Institute, London, UK.

In 2037 white European subjects from 520 nuclear families recruited from Leicestershire, England (Genetic Regulation of Arterial Pressure of Humans in the Community - GRAPHIC study), we studied the effects on 24-hour ambulatory blood pressure (BP)and serum cations of common sequence variation in genes underlying mendelian syndromes of hypertension and hypotension. We genotyped 298 common (minor allele frequency>10%) tagging and putative functional SNPs in 11 such regions. Association tests were undertaken using generalized estimating equations (GEEs) and generalised linear mixed models implemented using Gibbs sampling in WinBUGS to account for familial correlations. We adjusted for age, age^2 and sex as covariates and for antihypertensive treatment using a semi-parametric algorithm. Associations were tested with 224 SNPs (75%) passing quality control. In KCNJ1, the type II Bartter syndrome gene which encodes the potassium channel ROMK, we found that five SNPs were associated with 24hour systolic and/or diastolic BP with false positive report probability (FPRP) <0.2 suggesting genuine association. The minor allele of rs2846679 was associated with -1.58 (95% CI -2.47 to -0.69) mmHg change in SBP (P=0.00048, FPRP=0.05). Furthermore, non-synonymous SNP rs1801725 in the calcium-sensing receptor (CASR) SNP, was strongly associated with serum calcium - each minor (T) allele copy was associated with >¼SD change in serum calcium i.e. 22.1 (95% CI 13.8 to 30.4) micromoles, P=1.86*10^{-7}. Epidemiological associations have been reported between serum calcium and cardiovascular traits, including BP. Given the substantial estimated effect size in our study, rs1801725 could prove to be a valuable instrument for mendelian randomization studies that use such genetic data to circumvent confounding and reverse causation in epidemiological studies.

Polymorphism of the leptin gene, leptin concentration and lifestyle habits in the obesity. *K.-T. Chen[1], R.-Y. Wang[2], C.-Y. Chen[2], C.-J. Lin[3], W.-C. Shy[3], M.-C. Hung[3], T.-N. Wu[1], F.-Y. Wu[1]* 1) China Medical University, Environmental Health, Taichung, Taiwan; 2) China Medical University, Public Health, Taichung, Taiwan; 3) China Medical University, Nursing, Taichung, Taiwan.

The aim of our study was to investigate the relationship among leptin gene (LEP), serum leptin concentration, lifestyle habits and other comorbidities (such as high blood pressure and diabetes) in the obesity. The residents in Hsin-I town of Nantou County and in the central-western district of Taichung City participating in the National Adult Health Examination Projoect in Year 2007 were recruited as the study subjects. A total of 682 subjects were obtained. Among them, 220 subjects (32%) with BMI27 were classified as obese and the remainder (68%) with BMI27 were non-obese. Our results showed that there were no statistically significant differences in distribution of the leptin gene (G-2548A) between obese and non-obese individuals. Subjects were divided into four groups based on leptin concentration values: low concentration (leptin4.39), medium concentration (4.39leptin8.84), medium to high concentration (8.84leptin17.64) and high concentration (leptin17.64). Using a proportional odds model analysis we found that as leptin concentration increased, the proportion of those with BMI27 and central obesity also increased. Based on the 2-test we found no relationship among single nucleotide polymorphisms (SNPs) in LEP G-2548A, leptin concentration and obesity. We divided the sample into two age groups: 40-59 yrs and 60 yrs for analysis. In those aged 40-59, we found that obesity was associated with cardiovascular disease, hypertension, blood lipid profile, diabetes mellitus, gout, smoking, alcohol consumption and regular exercise. However, in those aged 60 and over, we found that only cardiovascular disease and regular exercise were associated with obesity. This study suggested that a postivie association exist between the serum concentration of leptin and the risk of obesity. No relationships were found among SNPs in LEP G-2548A, obesity and leptin concentration. In older age groups there were less comorbidities and lifestyle habits were healthier.

N-Acetylmannosamine for the Treatment of Muscle and Kidney Disease: From Mouse to Bedside. *I. Manoli[1,2], E. Klootwijk[1], S. Sparks[1], M. Ziats[1], D. Hickey[1], C. Ciccone[1], P. Zerfas[3], M. Starost[3], D. Darvish[4], D. Krasnewich[1], W. Gahl[1], M. Huizing[1]* 1) Section on Human Biochemical Genetics, MGB, NHGRI, NIH; 2) Intramural Program of the Office of Rare Diseases, NIH; 3) Division of Veterinary Resources, NIH, Bethesda, MD; 4) HIBM Research Group, Encino, Ca.

Hereditary Inclusion Body Myopathy (HIBM) is an adult onset, autosomal recessive neuromuscular disorder characterized by progressive muscle weakness resulting in severe incapacitation within 10 to 20 years. The causative gene, GNE, codes for the enzyme UDP N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase (GNE/MNK), which catalyzes the first 2 steps in sialic acid (SA) synthesis. Paucity of SA presumably causes decreased sialylation of muscle glycoproteins, resulting in muscle degeneration. N-Acetyl-mannosamine (ManNAc), an uncharged sugar, can readily enter cells and serve as a precursor for SA synthesis, not subject to feedback inhibition. We previously administered sialic acid to 4 HIBM patients via intravenous immune globulin (which contains 8mol of sialic acid/g), achieving improved muscle strength and function. We also created knock-in mice harboring the M712T Gne/Mnk founder mutation. Homozygous mutant mice did not survive beyond postnatal day 3 (P3) due to glomerular hematuria, proteinuria, and podocytopathy. Administration of ManNAc yielded survival beyond P3 in 43% of the homozygous pups. Survivors exhibited improved renal histology, increased sialylation of podocalyxin, and increased Gne-epimerase activities. Based on these findings, we now describe a phase I/II, randomized, placebo-controlled, two period cross-over study to determine the safety and efficacy of ManNAc therapy in HIBM. The primary outcome parameter will be change in quadriceps muscle strength. This protocol has assumed increased relevance because our mouse model survivors have developed muscular tubular aggregates and vacuoles at 8-11 months. Our ManNAc trial is also pertinent to renal disorders such as minimal change nephrosis. We will discuss the Rapid Access to Interventional Development Program and the difficulty of performing pre-clinical studies for drugs not approved by the FDA.

A novel mutation at stop codon of the GJA1 gene in Korean patient with congenital heart disease. *M. Hong[1], E. J. Seo[1,2], I. S. Park[1,3]* 1) Genome Research Center for Bir, Asan Medical Center, Seoul, Korea; 2) Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Congenital heart diseases (CHD) are the most common developmental anomalies and are diagnosed in 1% of newborns. Although the causes of CHD are mostly unknown, genetic components for CHD have been elucicated through microdeletion syndromes or single gene disorders associated with CHD. GJA1 (gap junction protein alpha 1 43kDa, connexin-43), the main protein of the human cardiac gap junctions, has been shown that GJA1 plays an essential role in the regulation of the development of the heart outflow tract. The mutations in the GJA1 (Cx43) are associated with CHD. Mutation analysis was performed for the GJA1 gene in 116 patients with CHD by PCR based sequencing method. We found only one mutation in 12-year old Korean girl with double outlet right ventricle. This was the novel variation at the stop codon of the GJA1 which can result in the production of abnormal connexin-43 with additional 4 amino acids translated from the 3 UTR of the GJA1: c.1147T>C (TAG>CAG), p.X383GlnextX*4 The variation was not found in 246 control chromosomes, but identified in patients mother who was apparently normal. To evaluate the functional defect of GJA1 caused by X383GlnextX*4, X383GlnextX*4 mutant was constructed using the site-directed mutagenesis and then examined the localization of the transient expression in mammalian cells. The localization studies revealed no significant trafficking defect of X383GlnextX*4 mutant, which was found in both the Golgi apparatus and endoplasmic reticulum, not unlike wild-type GJA1. Further, we will confirm whether the mutant was transported to the plasma membrane in both HeLa and NRK cells.

Genome-wide meta-analyses of haematological traits reveal several novel loci associated with full blood counts.

N. Soranzo[1,2], C. Meisinger[3], N. Watkins[4], A. Attwood[4], P. Deloukas[1], A. Döring[3], M. Falchi[2,5], C. Gieger[3], T. Illig[3], J. Jolley[4], S. Menzel[2], W. H. Ouwehand[1,4], H. Prokisch[3,6], A. Rankin[3], D. Rosskopf[7], T. D. Spector[2], J. Stephens[4], S. L. Thein[2], E. Wichmann[3,8] 1) Wellcome Trust Sanger Institute, Hinxton, UK; 2) Twin Research Unit, Kings College London, London, UK; 3) Helmholtz Zentrum, Muenchen, Germany; 4) University of Cambridge & NHS Blood and Transplant (NHSBT), Cambridge, UK; 5) Imperial College London, London, UK; 6) Technical University Munich, Munich, Germany; 7) Ernst-Moritz-Arndt University, Greifswald, Germany; 8) Ludwig-Maximilians-Universität, Munich, Germany.

Quantitative variation in haematological traits has been linked to cardiovascular disease risk. A recent collaborative effort between German and UK groups aims to discover genetic loci affecting blood cell parameters and cardiovascular disease risk. We have undertaken genome-wide meta-analyses of eight full blood traits at 2.5 million SNPs in 5,000 individuals from three population-based cohorts (TwinsUK, the UK Blood Services Common Control Collection and KORA) and replication in 5,000 samples. A first analysis has identified several novel loci with strong and reproducible evidence for association. Three novel loci were associated with mean platelet volume. These include SNPs in or near *WDR66* (n=10,087, P-value =5.18×10^{-47}), *ARHGEF3* (n= 10,215, P-value =2.45×10^{-25}) and *PIK3CG/FLJ36031* (n=7,417, P-value =9.5×10^{-21}). In addition, we describe one novel locus associated with platelet count on 12q24.12 near *BRAP* (n=6,928, P-value = 2.42×10^{-10}) and replicate associations of the *MYB-HBS1L* locus with increased mean red blood cell haemoglobin content (n=7,268, P-value = 5.4×10^{-27}), increased mean red blood cell volume n=7,270, P-value =8.0×10^{-28}) and decreased red blood cell count (n=7,271, P-value =4.6×10^{-20}). Transcripts of all genes are present in all haematopoietic lineages albeit a different levels. Currently ongoing studies include determination of the effect of the SNPs on the transcript levels in the megakaryocytic, lymphoid and monocytic lineages and on the platelet functional response to activation with ADP and collagen.

Marinesco Sjögren syndrome (MSS): Novel SIL1 mutations and description of a less severe phenotype. *A. Roos[1], M. Baudis[2], R. S. Finkel[3], F. Stanzial[4], C. Stendel[7], A. Dufke[5], H. Topaloglu[6], K. Zerres[1], J. Senderek[1,7]* 1) Institute of Human Genetics, Aachen University of Technology, Aachen, Germany; 2) Institute of Molecular Biology, University of Zurich, Zurich, Switzerland; 3) Division of Neurology, The Children's Hospital of Philadelphia, Philadelphia, USA; 4) Institute of Genetic Medicine, European Academy, Bolzano, Italy; 5) Institute of Human Genetics, Eberhard Karls University, Tübingen, Germany; 6) Child Neurology Unit, Department of Pediatrics, Hacettepe University, Ankara, Turkey; 7) Institute of Cell Biology, ETH Zurich, Zurich, Switzerland.

Marinesco Sjögren syndrome (MSS) is a progressive multisystem disorder with autosomal recessive inheritance. The phenotype is characterized by cerebellar ataxia, congenital or infantile cataracts, progressive vacuolar myopathy, mental retardation, and short stature. Recently, mutations in the SIL1 gene, which encodes an endoplasmic reticulum (ER) resident cochaperone, were identified as a major cause of MSS. Here we describe the results of SIL1 mutation analysis in an extended cohort of patients with MSS or MSS-like conditions. We report five novel mutations in the SIL1 gene, including the first multi-exon deletion described in MSS. We could corroborate our earlier observation that cataracts in MSS are not always present at birth, and we also identified two unrelated patients with SIL1 mutations without mental retardation. In agreement with earlier observations, a subgroup of MSS patients did not carry SIL1 mutations. Our data extend the mutational and phenotypic spectrum associated with the SIL1 gene and confirm genetic heterogeneity in MSS.

Comparison of different methods to control for stratification in genome-wide association studies. *E. Salvi[1,2], G. Guffanti[1], A. Orro[2], S. Lupoli[3], F. Torri[1], S. Potkin[4], C. Barlassina[1], D. Cusi[1], L. Milanesi[2], F. Macciardi[1]* 1) Department of Science and Biomedical Technologies, University of Milan, Milan, Italy; 2) Institute of Biomedical Technologies CNR, Segrate (Mi), Italy; 3) INSPE, Milan, Italy; 4) Department of Psychiatry and Human Behavior University of California, Irvine (CA), USA.

In case-control association studies, population stratification (PS) occurs when allele frequencies differ between cases and controls due to ethnic background or even to hidden; stratification. PS can lead to spurious findings between a phenotype and unlinked candidate loci bringing either to false positive or false negative results when analyzing SNPs for association. To overcome these problems, different strategies have been proposed but currently there is no consensus about a common powerful strategy to adjust for PS. In the presented study, we evaluated different approaches in two different case-control studies of schizophrenia, in order to find the most efficient strategy to achieve enough power to correct the association results and to find the genetic variants really relevant for the disease by avoiding false-positive associations. We assessed PS in a case-control sample of 200 American subjects genotyped for 317K SNPs (Illumina HumanHap300) and in the sample containing 741 schizophrenics of the CATIE project matched with 751 controls collected from the NIMH Genetics repository of which genotype (Perlegen, Affymetrix 500K) and phenotype data are available to the scientific community. Both samples are composed by different ethnic groups. In particular, after identifying the presence of sub-structure, we compared the resulting datasets of the most significant associated SNPs before and after correction, obtained with EIGENSTRAT, PLINK and Genomic Control and we identified the SNPs associated with diseases, the false-positive and the false-negative associations. Indeed a key point is that the PS analysis corrects for false-positive associations but also helps in rescuing potential false-negatives. Each method have advantages and disadvantages and then we decided to use more than one and to follow a workflow of analysis, here presented.

A Homozygous Mutation in *ADAMTSL4* Causes Isolated Ectopia Lentis. *D. Ahram[1], H. El-Shanti[1,2], TS. Sato[2], S. Chen[2], MK. Tayeh[2], A. Kohailan[1], S. Leal[3], M. Al-Salem[4]* 1) SMGC, Doha, Qatar; 2) Univ Iowa, Iowa City, Iowa; 3) Baylor College of Medicine, Houston, TX; 4) JUST, Irbid, Jordan.

Background: Ectopia lentis is characterized by the subluxation of the lens due to the disruption of the zonular fibers, often in association with systemic disorders such as Marfan syndrome. Isolated simple ectopia lentis is reported in families with autosomal inheritance, with dominant forms being more common than recessive. We here report on the mapping and identification of the gene responsible for autosomal recessive isolated ectopia lentis in an Arab family.

Patients, materials and methods: The inbred family has 15 affecteds from 4 related sibships. Clinical and biological data were available from 4 affecteds, 3 obligate carriers and 3 normal siblings. To map and identify the gene, we performed homozygosity mapping using a whole genome linkage mapping set. LOD score analysis was performed using MLINK of the LINKAGE 5.1 computer package. Mutation screening of candidate genes was performed using direct sequencing.

Results: The gene responsible for ectopia lentis in this family was mapped to the pericentromeric region of chromosome 1 (1p13.2 1q21.1), between D1S1675 and D1S498, with a maximum pair-wise LOD score of 3.26 at D1S534 and a =0. We examined 4 candidate genes before the identification of a nonsense mutation in exon 11 of *ADAMTSL4* (Y595X; c.1785TG). This mutation segregates with the disease in the family and was not found in 200 ethnically-matched controls. *ADAMTSL4* is a disintegrin and metalloproteinase with 7 thrombospondin motifs. It is ubiquitously expressed and thought to play a role in the regulation of apoptosis. The mutation produces a truncated protein of half the original length and without 6 of the 7 thrombospondin motifs, thus, it is likely to be nonfunctional.

Conclusion: We conclude that mutations in *ADAMTSL4* are responsible for autosomal recessive simple ectopia lentis. It is speculated that *ADAMTSL4* plays a role in the development and/or integrity of the zonular fibers.

Mathematical characterization of complex disease: Analytic expressions for the multi-locus additive model. *F. Takeuchi, R. McGinnis* Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

The degree of enrichment of disease-causing alleles in affecteds versus unaffecteds is perhaps the most important parameter determining detectability of loci responsible for complex diseases. In single-locus algebraic models of disease, the enrichment is markedly increased in related affecteds (RAs) from multiplex families compared to unrelated affecteds (UAs) from simplex families. However, the enrichment can be influenced by other disease-causing loci ("background loci") distinct from the locus being tested for association with disease (the "foreground locus"). Yet despite the important influence of background loci in modulating enrichment of disease alleles in RAs, this influence has not been studied extensively for one of the two main multi-locus algebraic models (i.e. the "additive"; model in which risks conferred by each locus are added to determine multi-locus penetrance). Furthermore, the few published investigations have relied mainly on simulations. We report here success in deriving analytic expressions that describe the multi-locus additive model including enrichment of disease allele frequency in RAs. One of our key findings is that the frequency of a disease-predisposing foreground genotype in RAs varies between the highly enriched frequency in the single-locus model and the unenriched frequency in unaffecteds. The degree of enrichment within this range is determined by the fraction of the disease recurrence risk among relateds ($_R$) which is contributed by the foreground locus as a proportion of total $_R$ for the entire disease (i.e. foreground plus background loci). We have compared results from our derived equations with published simulation results for specific multi-locus additive models examined by Howson et al. (Genet Epidemiol 29:51, 2005) and Li et al. (Am J Hum Genet 78:778, 2006), and find close agreement with their results. We will illustrate how our analytic expressions can be used to address important issues such as appropriate study design and detectability of foreground disease loci by association testing given known magnitudes of familial aggregation ($_R$) in the particular disease being studied.

Methylation of the Androgen Receptor gene differs between dermal papilla and outer root sheath of human hair follicles. *J. E. Cobb[1], L. Yip[1, 2], N. Wong[3], S. B. Harrap[1], J. A. Ellis[1, 3]* 1) Physiology, University of Melbourne, Parkville, Victoria, Australia; 2) Dermatology, St Vincent's Hospital, Victoria, Australia; 3) Murdoch Childrens Research Institute, Victoria, Australia.

DNA methylation is known to regulate the expression levels of genes in specific tissues via CpG islands within the promoter region. Hair follicles provide us with an easily accessible source of tissue to investigate methylation patterns in humans. The genetic association of the Androgen Receptor gene (*AR*) and Male Pattern Baldness (MPB) has been well documented, and it would appear that *AR* confers strong risk of developing hair loss. Increased *AR* gene expression has been identified in balding (vertex) compared to non-balding (occipital) regions in the same individual, and the lower occipital expression of *AR* may contribute to retention of hair in this region. We therefore hypothesised that in hair follicles from occipital regions of MPB scalp the *AR* promoter is methylated, and thus less expressed compared to vertex hairs. With this in mind we were interested to investigate methylation at the *AR* promoter region initially in two tissues within occipital hair follicles- the dermal papilla (DP) and the outer root sheath (ORS). It is known that *AR* is expressed in both DP and ORS, however while DP is fundamental to maintaining hair growth, ORS can be more easily obtained via plucked hair rather than scalp biopsy. We collected occipital follicle biopsies from hair transplant surgeons and dissected both DP and ORS. The DNA was bisulfite converted, then base-specific cleavage and mass spectrometry was used to determine the pattern of *AR* promoter methylation . Generally, in occipital follicles, we observe DP to have increased methylation at the *AR* promoter compared with ORS. The different methylation patterns within such small and closely located tissues highlights the importance of investigating the specific tissue of interest for human methylation studies. Further studies comparing DP between balding and occipital follicles are planned to determine if increased methylation of *AR* might provide protection to the occipital scalp from androgen-driven hair loss.

Fish Odor Syndrome: Identification of Novel Moroccan Jewish mutation. *T. Yardeni, K. Geva-dayan, N. Goldstein, Y. Anikster* Metabolic Dept , Safra childre'n's hospital Sheba medical center, Tel Hashomer , Israel.

Background: Trimethylamine (TMA) is a malodorous metabolite synthesized by enteric bacteria from dietary precursors. It is normally oxidized to the odorless metabolite trimethylamine N-oxidase by the hepatic enzyme flavin containing monooxygenase 3 (FMO3). Mutations in the FMO3 gene cause the rare autosomal recessive disorder called Trimethylaminuria, also known as the Fish Odor Syndrome. Affected individuals excrete excessive amounts of TMA in body secretions. They suffer from a repelling smell which is exacerbated by certain triggers such as specific foods, especially sea fish, stress, menstruation, puberty and physical exertion. These can lead to disturbance in body perception and to psychosocial problems. It is initially recognizable at a variable age from childhood to adulthood. Methods and Results: We evaluated a family of six siblings, among whom three presented with a long medical history of fishy body odor. Both their parents were of Moroccan Jewish descent, and were first cousins, once removed. Results of molecular genetic studies revealed that they were homozygous for a novel nonsense mutation K4X (c.10A T) in exon 1. Definitive diagnosis enables genetic counseling and treatment strategy planning such as nutritional support, vitamin supplementation and drug therapy. Conclusions: Physicians should be aware of the fact that disturbing body odor may result from a biochemical defect. With the aid of molecular tools for diagnosis this family can find relief in that their unusual complaint is medical and not hygiene related. Genetic counseling and treatment options should be discussed with families diagnosed with trimethylaminuria.

Lack of Association of Caucasian Rheumatoid Arthritis Susceptibility Loci in a Korean Population. *HS. Lee[1, 2], B. D. Korman[3], J. M. Le[3], D. L. Kastner[3], E. F. Remmers[3], P. K. Gregersen[2], SC. Bae[1]* 1) Hanyang University College of Medicine and the Hospital for Rheumatic Diseases, Seoul, South Korea; 2) The Feinstein Institute for Medical Research, North Shore Long Island Jewish Health System, Manhasset, New York; 3) The National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, Maryland.

Objective: Recent advances in genetics and technology have led to the identification of a number of novel rheumatoid arthritis loci. In Asian populations, PADI4, FCRL3, SLC22A4, and STAT4 have been shown to be associated with disease while significant associations have been identified at PTPN22, TRAF1/C5, 6q23, STAT4, 4q27, CD40, and CCL21 in Caucasian populations. In this study, we sought to determine whether some of the loci identified in Caucasians are also associated with RA in a Korean case-control collection. Methods: We designed a Sequenom iPlex experiment to do a thorough investigation of the PTPN22 linkage disequilibrium region using tag SNPs and to genotype single disease-associated SNPs at other 5 other previously reported Caucasian RA-associated loci in 1123 RA Korean RA patients and 1008 ethnically matched controls. We also re-sequenced the PTPN22 gene to look for novel coding variants that might be contributing to disease in this population. Results: None of the Caucasian RA susceptibility loci contributed significantly to disease in Koreans. Tag SNPs covering the PTPN22 linkage disequilibrium block, while polymorphic, did not reveal any disease association and re-sequencing did not identify any new common coding variants in this population. The 6q23 and 4q27 SNPs assayed were non-polymorphic in this population while the TRAF1/C5, CD40, and CCL21 SNPs did not show any evidence for association. Conclusions: Caucasian and Korean rheumatoid arthritis have different genetic risk factors. While patients of different ethnic groups share the HLA region as a major genetic risk locus, most other genes shown to be significantly associated with disease in Caucasians appear not to play a role in Korean RA.

Identification of Loci for Systemic Lupus Erythematosus by Pooling-based Genomewide Association Study. *T. Tahira[1], K. Masumoto[1], Y. Kukita[1], Y. Okazaki[1], A. Yoshinaga[1], K. Higasa[1], T. Horiuchi[2], K. Hayashi[1]* 1) Div Genome Analysis, Med Inst Bioreg, Kyushu Univ, Fukuoka, Japan; 2) Med. Biosys. Science, Grad. School Med. Sciences, Kyushu Univ, Fukuoka, Japan.

Systemic lupus erythematosus (SLE) is an autoimmune disease in which multiple genetic and environmental factors are involved. Recent genomewide studies of European samples identified genes associated with the disease. However, at least some of them are unlikely to explain the disease in Asians because of the absence of the candidate alleles among the population. To identify the genetic background of SLE susceptibility in Japanese, we performed two-stage pooling-based association study, that is, by array-based hybridization analysis and by SSCP analysis, of case pools (sizes 264 and 183) and control pools (sizes 426 and 253). Each of the pooled samples was hybridized to six Affymetrix 500K array sets and the relative allele signal score (RAS) of each SNP was calculated from intensity signals of perfect-match probes. The disease association was evaluated both by z-score calculated from difference of averaged RAS values between cases and controls and by silhouette score (calculated by Genepool 0.8.1, http://genepool.tgen.org/) and interpreted by a sliding-window statistics of median rank in different window sizes (3, 5, 7, 9, 11, 15 bps). SNPs of highest scores in the top 5 regions for each window size were re-examined by quantitative SSCP (http://qsnp.gen.kyushu-u.ac.jp/placeSSCP/), and the associations (estimated $P < 10^{-4}$) for 22 SNPs in 13 regions were confirmed. The associations of these SNPs were further verified by individual genotyping using TaqMan assay. Most significant associations were found in ZPBP-IKZF1 (upstream of IKZF1, rs876039) and TNFAIP3 (a perfect proxy for non-synonymous SNP, rs2230926). Genotyping of additional samples replicated these associations, and allelic odds ratios were 1.57 ($P = 3.0 \times 10^{-9}$) for rs876039 and 2.1 ($P = 1.1 \times 10^{-8}$) for rs2230926 in the combined sample (630 cases and 988 controls). Associations ($P < 10^{-5}$) were also found near the previously reported regions, i. e. C8orf13-BLK, PRDM1-ATG5 and HLA-G.

Genetic predisposition to femoral neck stress fractures via reduced weight and body mass in military conscripts.

M. Mannikko[1], J. Korvala[1], H. Hartikka[1], H. Pihlajamaki[2,3], S. Solovieva[4], J.-P. Ruohola[3], T. Sahi[3,5], S. Barral[6], J. Ott[6], L. Ala-Kokko[1,7] 1) Department of Medical Biochemistry and Molecular Biology, University of Oulu, Finland; 2) Department of Surgery, National Military Hospital, Helsinki, Finland; 3) Institute of Military Medicine, National Military Hospital, Helsinki, Finland; 4) Finnish Institute of Occupational Health, Helsinki, Finland; 5) Department of Public Health, University of Helsinki, Helsinki, Finland; 6) Laboratory of Statistical Genetics, Rockefeller University, New York, USA; 7) Connective Tissue Gene Tests, Allentown, USA.

Stress fractures are a significant problem among athletes and soldiers. Femoral neck stress fracture is the most severe type, because it can result in devastating problems or even permanent handicap. Genetic factors may increase the fracture risk, but no susceptibility genes have yet been identified. Eight genes involved in bone metabolism or pathology were studied in terms of their roles in femoral neck stress fractures. A case-control association study of 72 military conscripts with a femoral neck stress fracture and 120 controls was performed. Search for predisposing sequence variations in the coding regions of the COL1A1, COL1A2, OPG, ESR1 and LRP5 genes was carried out, and 15 SNPs from the COL1A1, COL1A2, VDR, CTR, LRP5 and IL-6 genes were genotyped. Haplotype analyses were performed on the COL1A1, COL1A2, VDR and LRP5 genes. The LRP5 haplotype A-G-G-C associated to low weight and body mass index (BMI) leading to 2.72 times (95 % CI 1.10-6.73) higher risk of stress fractures in cases than in control subjects. The LRP5 haplotype seems to affect the development of stress fractures in an indirect manner, via reduced BMI. A significant interaction between LRP5 haplotype A-G-G-C and VDR haplotype C-A was also observed and with combined haplotype with 3.85 times higher risk of having femoral neck fractures in cases than in controls (95 % CI 1.16-12.84). These results indicate the first genetic risk factors for development of stress fractures: LRP5 haplotype A-G-G-C increasing the risk of stress fractures via reduced weight and BMI, and an additive effect when in combination with the VDR C-A haplotype.

Neuronal expression of genes involved in synaptic regulation is altered during aging in a mouse model for Parkinson's disease. *B. Chase[1], K. Markopoulou[2]* 1) Dept Biol, AH514B, Univ Nebraska, Omaha, NE; 2) Dept. Neurol, Univ Thessaly Med Sch, Larissa Greece.

-Synuclein overexpression has provided useful animal models for Parkinson's disease (PD). To comprehensively address the spectrum of CNS pathways affected by -synuclein overexpression and how these are altered during aging, we compared neuronal gene expression in pathologically characterized transgenic C57BL6 mice where human -synuclein was expressed under the PDGF- promoter to that in littermate, non-transgenic controls at ages 2 and 11 months. Gene expression profiles were obtained using Affymetrix 430 2.0 arrays (n=5 per group), analyzed using GCOS, Affyminer and Ingenuity software, and confirmed using qRT-PCR. We identified replicable robust changes in gene expression patterns that reflected significant co-regulation of genes lying in networks of interacting proteins affecting the G-protein coupled receptor, axonal guidance, cAMP, LTP, LDP, dopamine, and calcium signaling pathways. While genes in some pathways are affected in the frontal cortex and midbrain at 2 months of age, the number of signaling-pathway genes with altered expression dramatically increases in those areas in 11-month-old mice. Two features are particularly striking. First, genes with altered expression often share similar, key signal transduction functions, e.g., genes for distinct calmodulins, CAMII kinases, and adenylate cyclases are differentially expressed during aging in different pathways. Second, some genes with altered neuronal expression (CDC42, NTNG1, PLXNA2, SLITRK6, UNC18) are identical or function similarly to a subset of the axon-guidance-pathway genes whose SNPs predict PD outcomes in a whole-genome-association study (Lesnick et al., 2007). We conclude that -synuclein overexpression during aging significantly affects genes involved in synaptic regulation and transmission, and that similar key functions are often affected in different signaling pathways. Disregulation in synaptic activity may play an important role in the progression of the neurodegenerative process and perturbations to shared functions in signal transduction may underlie this disregulation.

Genome wide association analysis identifies additional loci affecting adult height in the isolated population of Sorbs in Germany. *A. Tonjes[1], P. Kovacs[1], M. Koriath[1], Y. Bottcher[1], D. Schleinitz[1], K. Dietrich[1], B. Enigk[1], K. Krohn[1], E. Zeggini[2], W. Rayner[2], M. I. McCarthy[2], M. Stumvoll[1]* 1) University of Leipzig, Leipzig, Germany; 2) WTCHG, University of Oxford, Oxford, UK.

Adult height is a strongly inherited trait. Association of a number of common variants with height has recently been reported. We performed a genome wide association study using 500K and 1000K Affymetrix GeneArrays in a recently recruited and extensively phenotyped isolated population from Eastern Germany, the Sorbs. They are of Slavonic origin, and lived in ethnic isolation among the Germanic majority during the past 1100 years. We used linear regression analyses to calculate the effects of genetic polymorphisms on adult height in 929 subjects (59% females, age 47 +/-16.6 years, height 169 +/-9.5 cm). Analyses were corrected for age and gender, for relatedness by using the inflation factor lambda determined by genomic control. Although only part of the recently published SNPs is directly available on the Affymetrix gene array and passed QC in our sample set, we were able to replicate the association of several published variants with adult height in the Sorbs population by use of our genome wide scan (rs4743034 in ZNF462, rs6440003 in ZBTB38, rs6830062 and rs16896068 in LCORL, rs6060373 and rs6088792 in GDF5/UQC, rs2814993 in C6orf106, rs10512248 in PTCH1, rs4794665 near NOG/DGKE/TRIM25/COIL). Furthermore, we identified several new loci associated with height in the Sorbs. Our five strongest associations map in MYBPC1 (p=2.6e-07 for rs11110932), CTNNA2 (p= 4.4e-07 for rs17018086), TMEM108 (p=6.1e-07 for rs9817813), KALRN(p= 7.0e-07 for rs3755702) and in a region in 13q31.1 (p= 3.2e-07 for rs9545880). In conclusion we were able to replicate the effects of previously reported variants in/near ZNF462, ZBTB38, LCORL, C6orf106, GDF5/UQCC, NOG/DGKE and PTCH1 on adult height in the isolated population of Sorbs. Furthermore, we identified additional loci in/near MYBPC1, TMEM108, CTNNA2, KALRN and 13q31.1. We are in the process of extending these findings to a second cohort of German adults as well as children.

Genotyping of the *PORCN* gene in a family with father to daughter transmission of Focal Dermal Hypoplasia (FDH, Goltz syndrome). *D. P. GERMAIN[1], N. MIRI[1, 2], C. BOUCLY[2], P. DE MAZANCOURT[3], M. F. PORTNOI[4]* 1) Department of Genetics, University of Versailles St Quentin en Yvelines (UVSQ). Hopital Raymond Poincare, GARCHES, France; 2) Laboratory of Biochemistry. Hopital Raymond Poincare, GARCHES, France; 3) Laboratory of Biochemistry and Molecular Biology, CHI, POISSY ST GERMAIN, France; 4) Department of Genetics, Hopital Armand Trousseau, PARIS, France.

Background : Focal dermal hypoplasia (FDH) also known as Goltz syndrome (OMIM 305600) is an X-linked dominant disorder of ecto-mesodermal development characterized by patchy dermal hypoplasia with digital, ocular and dental abnormalities. Recently, mutations in the *PORCN* gene which encodes the human homolog of Drosophila melanogaster porcupine, an endoplasmic reticulum protein involved in secretion of Wnt proteins, were demonstrated to cause FDH. The longest splice variant (isoform D) of the *PORCN* gene comprises 15 exons encoding a 1386 bp cDNA that is translated into a protein of 461 amino acids. **Objectives** : To investigate the molecular basis of FDH in a French family where both a 23-year-old girl and her 51-year-old father were clinically affected. **Results** : Mutation analysis by polymerase chain reaction and sequencing of genomic DNA for the entire coding region of the *PORCN* gene in the affected daughter disclosed a nonsense mutation in exon 3, which was not detected in 100 ethnic-matched unrelated control chromosomes. Allele specific restriction analysis of the appropriate PCR fragment confirmed the mutation in the daughter and detected two alleles in the fathers DNA, the mutated allele appearing much weaker than the wild type allele in the male patient. **Conclusion** : Identification of a novel nonsense mutation in the *PORCN* gene confirmed the diagnosis of FDH in a female patient and indicated that she has inherited the disease from her clinically affected father who carries the mutation as a mosaic. Our results also highlights the clinical importance of PORCN and Wnt signalling pathways in embryogenesis.

Crosstalk between NF-B and Wnt/-catenin pathways and anhidrotic ectodermal dysplasia. *C. Cluzeau[1], E. Bal[1], P. Guigue[1], N. Chassaing[2], S. Hadj-Rabia[1,3], C. Bodemer[1,3], P. Calvas[2], M. C. Vincent[2], A. Munnich[1], A. Smahi[1]* 1) INSERM U781, Hôpital Necker-Enfants Malades, Université Paris Descartes, Paris, France; 2) Service de Génétique médicale, Hôpital Purpan, Toulouse, France; 3) Service de Dermatologie, Hôpital Necker-Enfants Malades, Paris, France.

Anhidrotic ectodermal dysplasia (EDA) is an ectodermal differentiation disorder characterized by sparse hair, abnormal or missing teeth and inability to sweat. X-linked EDA, caused by mutations in *ED1* gene encoding ectodysplasin, a member of the TNF family, is the most frequent form. The autosomal dominant and recessive EDA forms, clinically identical to X-linked forms, may result from mutations in two loci : *ED3*, encoding Edar, ectodysplasin receptor and *ED2*, encoding Edaradd, Edar adapter molecule necessary in signal transduction. Edar is activated by ectodysplasin and uses Edaradd as an adapter to activate NF-B signaling pathway. Wnt/-catenin pathway plays a central role during embryonic development and is widely involved in carcinogenesis. This pathway has been recently involved in skin appendages formation. A crosstalk between NF-B and Wnt/-catenin pathway was described. We confirmed by transactivation experiments that Edar receptor inhibits Wnt/-catenin pathway. We then studied the effects of seven recessive and dominant mutations identified in Edar gene on both pathways. Dominant mutations totally impaired NF-B activation and Wnt/-catenin downregulation, while recessives ones only disrupted the Edar effect on the two pathways. We first demonstrated that Wnt/-catenin inhibition by Edar is dependent of NF-B activation using a dominant negative form of IB inhibitor. We then proved by Western Blot analysis and immunofluorescence that -catenin was neither degraded nor delocalized after NF-B activation by Edar. Furthermore, -catenin/TCF4 interaction, necessary for Wnt/-catenin transcriptional activity, was not disrupted upon Edar transfection and NF-B subunits p65 and p50 did not interact with -catenin in these conditions.

Two novel mutations in surfactant protein C, lung function and obstructive lung disease in the general population. *M. Baekvad-Hansen, B. G. Nordestgaard, A. Tybjærg-Hansen, M. Dahl* Copenhagen University Hospital, Faculty of Health Sciences, University of Copenhagen, Denmark.

Background: Mutations in surfactant protein-C (SP-C) have been associated with alveolar proteinosis and pneumonitis in children, and with interstitial lung disease among adults. We hypothesized that genetic variants in SP-C affect pulmonary function and risk of developing obstructive lung disease in adults. Methods: We resequenced SP-C in order to identify new genetic variation. We selected 760 individuals with extreme pulmonary phenotypes from the Copenhagen City Heart Study, a general population study of 10,604 adults. An extreme pulmonary phenotype was defined in those with the highest/lowest lung function, early-onset asthma, early-onset chronic obstructive pulmonary disease or interstitial lung disease. We screened the protein coding region of SP-C in all selected individuals. We subsequently genotyped two large population studies, the Copenhagen City Heart Study (n=10,604) and the Copenhagen General Population Study (n=37,337), in order to assess the clinical relevance of the SP-C mutations detected by extreme phenotype screening. Results: We identified eighteen genetic variants in SP-C, of which two were new mutations. One mutation was amino acid substituting and the other introduced a stop codon. These mutations were situated in the exon 2 and BRICHOS domain of SP-C, two conserved regions that harbour the majority of disease-associated mutations identified up to now. Screening two large and ethnically homogenous populations for these mutations, we found that they did not affect lung function or consistently change risk of developing obstructive lung disease. Conclusion: We identified two novel mutations in two conserved regions of the SP-C gene and show that adults that are heterozygous for these mutations are relatively free from common diseases of the lung. The data suggests lower penetrance than expected of pulmonary disease in SP-C heterozygotes.

CYP1B1 genotype and Risk of Myocardial Infarction, Chronic Obstructive Pulmonary Disease, Cancer, and Early Death. *D. Kaur-Knudsen, S. E. Bojesen, A. Tybjærg-Hansen, B. G. Nordestgaard* Copenhagen University Hospital, Faculty of Health Sciences, University of Copenhagen, Denmark.

Objective: Cytochrome P450 1B1 enzymes play an important role in metabolism of tobacco-smoke substances such as polycyclic aromatic hydrocarbons (PAHs) and of 17-estradiol. CYP 1B1*3 (4326CG, rs. 1056836) and 1B1*4 (4390AG, rs. 1800440) have altered enzyme activity towards metabolism of PAHs and 17-estradiol. We hypothesized that these two polymorphisms predict risk of myocardial infarction (MI), chronic obstructive pulmonary disease (COPD), cancer, and early death. Method: We genotyped and followed prospectively for 31 years 10,398 adults from the Copenhagen City Heart Study (CCHS). Significant results were re-tested cross-sectionally in the Copenhagen General Population Study (CGPS) with 37,178 participants and in a case-control study, the Copenhagen Ischaemic Heart Disase Study (CIHDS), with 2,379 cases and 33,238 controls. Results: In the CCHS, hazard ratio for MI among never smokers was 1.91 (95% CI 1.16-3.15) for CYP1B1*3 GG (19%) vs. CC (32%); however, this was not significant among smokers. On re-testing these findings in the CGPS and CIHDS, we did not find any association, and we could reject odds ratios above 1.5 in CYP1B1*3 GG vs. CC with 90% power. For COPD, cancer, female cancer and early death we found no association to CYP1B1*3 genotype; however; for tobacco-related cancer we observed with a hazard ratio of 0.80 (0.64-0.99) in CYP1B1*3 GG vs. CC. On re-testing these findings in the CGPS, we did not find any association, and we could reject odds ratios below 0.71 in CYP1B1*3 GG vs. CC with 90% power. For CYP1B1*4 genotype we did not find any association with either endpoint. Conclusion: CYP1B1*3 and CYP1B1*4 genotypes do not predict myocardial infarction, chronic obstructive pulmonary disease, cancer, or early death.

Molecular diagnosis of galactosemia in cholestasis of infancy: GALT activity and mutation detection. *R. Prasad*[1], *R. Singh*[1], *G. Kaur*[2], *BR. Thapa*[1] 1) Biochemistry, PGIMER, Chandigarh, India; 2) Government Medical College and Hospital, Chandigarh, India.

Introduction: Galactosemia is a metabolic disorder due to deficiency of galactose-1-phosphate uridyl transferase (GALT) resulting in complications like hepatocellular damage, sepsis and developmental delay in untreated infants. Till date there are no reports on molecular diagnosis from India. Objective: To determine GALT activity in infants with cholestasis and to detect mutations in GALT gene. Materials and Methods: A cohort of 178 infants (5 days -10.5 months), admitted in Pediatric Gastroenterology ward of PGI over a period of 24 months, with cholestasis were evaluated for galactosemia. Basic investigations were done in all patients, urine for non-glucose reducing substances, TORCH serology, abdominal ultrasound, mebrofenin scan (for biliary excretion) and perop cholangiography were done when indicated. Screening for GALT defeciency was done using Perkin-Elmer neonatal GALT kit. DNA was isolated from patients exhibiting decreased GALT activity. Mutation analysis for most common Q188R, N314D and S135L mutations was performed by RFLP. SSCP analysis was done for detection of unknown mutations Results: Twenty seven patients were found to have reduced GALT activity in age group of 1-7 months, M: F 18:9. Jaundice in 27 (100%), hepatomegaly in 27 (100%), splenomegaly in 17 (62%), coagulopathy in 15 (55%), UTI in 6 (22%), encephalopathy in 3 (11%), and septicemia in 3 (11%), were observed. N314D mutation was found to be most common: homozygote n=1 and heterozygotes n=19. Homozygous and heterozygous Q188R mutations were detected in one patient each. Further, we detected two novel mutations - P185L in exon 6 and S307X in exon 10 by SSCP and direct gene sequencing. None of the patient was found to be positive for S135L. Conclusion: Genotype correlation with GALT activity revealed variable enzyme activity in N314D mutation, while reduced activity in other identified mutations. Screening for GALT activity in infants with cholestasis should be undertaken and genetic analysis should be done for confirmation.

Genetic Modifier(s) of Embryonic Lethality in Type IIA Procollagen Deficient Mice. *Y. Q. Song[1], P.LF. Tang[1], S. Y. Y. Wong[1], A. W. L. Leung[1], P. C. Sham[2], K. S. E. Cheah[1]* 1) Dept Biochemistry, Univ Hong Kong, Hong Kong, Hong Kong, China; 2) Department of Psychiatry, University of Hong Kong, Hong Kong SAR, China.

Col2a1 encodes type II procollagen, the major cartilage matrix protein. During embryogenesis Col2a1 is differentially transcribed to give IIA mRNA containing an exon (exon 2) and IIB mRNA, which lacks this exon. We produced IIA procollagen deficient mice by deleting exon 2 of Col2a1 and observed that mice homozygous for the IIA null mutation (IIA-/-) display complex congenital malformations resulting in prenatal lethality to near normal phenotype, depending on the strain background of the mice. Upon backcrossing (6 generations) to C57BL background, an increasing proportion of the IIA-/- mice die in the prenatal period with heart defects. These observations led us to hypothesize that the phenotypic variability in IIA-/- mice were related to differences in the genetic background. Three congenic mouse lines backcrossed over 7 generations to different genetic backgrounds (129/sv; C57BL; ICR) are therefore established to characterize the inheritance model of the modifier(s). Our segregation analysis shows that there is a significantly underrepresention of IIA-/- offspring from a C57BL IIA+/- intercrosscross ($p=0.0137$, $df=2$), however, the ratio appears to be normal for offspring from 129/sv IIA+/-and ICR IIA+/- intercross. This data would be consistent with an inheritance model with one or a set of recessive modifier gene(s) in the C57BL mice interacting with the IIA-/- genotype and results in prenatal lethality. Having understood the characteristics of the modifier(s), we designed a mapping panel to identify its physical location by first crossing ICR IIA+/- x C57BL IIA+/- to obtain F1. IIA-/- F1 would be selected to generate a IIA-/- F2 population with presumably segregating modifier alleles. 8 families with 15 cases, 50 control and 6 unknown were collected using the mentioned mapping panel. Nonparametric linkage analysis was performed on over 200 SNPs covering the whole mouse genome. One marker on chromosome 7 was shown to have significant linkage with our phenotype of interest. Further investigation is being carried out to identify the candidate modifier.

Association of AKT-1 DNA sequence variants with schizophrenia and neurocognitive phenotypes. *D. B. Wildenauer[1], A. C. Doyle[2], M. Albus[3], S. G. Schwab[1,4]* 1) CCRN Sch Psychiatry, UWA, Claremont, Australia; 2) Western Australian Institute for Medical Research, UWA, Perth, Australia; 3) Mental State Hospital Haar, Germany; 4) School of Medicine and Pharmacology, UWA, Perth, Australia.

AKT1 has been suggested as susceptibility gene for schizophrenia by genetic association and functional studies. We tested nine single nucleotide polymorphisms (SNPs) within the gene for AKT1 in a sample of 365 families of German ancestry for association with schizophrenia and with three neurocognitive tests, i.e. trail making test A and B, and Stroop colour naming test. These tests are measures for psychomotor speed, executive function, and reaction time, and indicate neurocognitive deficits. Neurocognitive test results were available for 230 of the 365 families. Genotyping was conducted using fluorescence based technologies. Statistical analysis was performed using FBAT and PBAT. SNP rs10149779 revealed statistical significant association with schizophrenia (P=.03) for the entire sample of 365 families. When analysis was restricted to a sub-sample (N=79 families) with an ascertainment scheme likely to provide greater genetic loading for the disorder, four SNPs were significantly associated with schizophrenia with the smallest P-value revealed by a SNP located in the 5-upstream region of the AKT-1 gene (rs4983559, p=0.0005). Analysis of the neurocognitive phenotypes identified significant associations between three SNPs (rs4983559, rs1130214, and rs10149779) for both versions of the Trail-making test (parts A and B), but not for the Stroop test. Our study replicates and expands previous reports suggesting a role for AKT1 in pathogenesis of schizophrenia.

Mutation meltdown of mitochondrial DNA and Neanderthal extinction. *G. Hudson[1], D. C. Samuels[2], P. F. Chinnery[1]* 1) Mitochondrial Research Group, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom; 2) Virginia Bioinformatics Institute, Virginia Polytechnic Institute and State University, Blacksburg, USA.

There is emerging evidence that mitochondrial DNA (mtDNA) plays and integral role in the evolution of the human species. Although contentious, recent phylogenetic studies of modern humans implicate genetic variation of mitochondrial DNA (mtDNA) as a major factor underpinning the climatic adaptation of across the globe. Greater sequence diversity in the *MTATP6* gene in arctic populations led to the idea that specific mtDNA polymorphisms cause subtle uncoupling of the respiratory chain, with the subsequent generation of additional heat being adaptive in northern climes. Our knowledge of mtDNA and its affect on adaptability may help us to understand how modern humans have survived their early ancestors. Here, we characterise the mtDNA of one of these extinct hominids. Neanderthals are the closest hominid relatives of modern humans, who up until 30,000 years ago coexisted in Europe and western Asia. Recently, over 1Mb of DNA was successfully extracted and characterised from the Vi-80 Neanderthal fossil. We reanalysed 2,705 base pairs of mtDNA in order to examine the hypothesis that mitochondrial dysfunction contributed to the Neanderthals demise. We identified thirty-two nucleotide differences from the modern human mtDNA reference sequence and by treating the Vi-80 as a diagnostic sample leads us to the conclusion that sequence variants that are highly likely to be artifacts, and a large proportion of the remaining mutations could be due to nuclear pseudogene amplification. We did identify a potentially deleterious variation; however more study may be needed to ascertain the effect of mitochondrial dysfunction on Neanderthal survival.

Use of genome-wide association to identify predictors of drug efficacy in clinical development. *G. Kazeem[1], SA. Bacanu[1], H. Hong[2], M. Nelson[1], A. Bansal[1], S. Sundseth[1], A. Menius[1], K. Nangle[1], F. Goodsaid[2], B. O'Neil[2], SJ. Wang[2], M. Ehm[1]* 1) GlaxoSmithKline; 2) US Food & Drug Administration.

Several recent successes in genome-wide association (GWA) studies have provided some insights into the genetic architecture that underlies many complex human traits. However, using the GWA approach to identify genetic biomarkers that influence drug efficacy, and that could improve clinical development, remains largely untested. In a collaboration between the FDA and GSK, blinded whole-genome datasets, obtained from three phase IIb and III clinical trials, were analysed under a variety of statistical models. Data include a quantitative baseline and response variables and Affymetrix 500K SNP genotypes from 961 subjects collected from three clinical studies. To identify genetic markers that influence compound efficacy, single-point analysis was performed for each marker adjusting for covariates identified in the clinical studies. To reflect the progressive nature in which the data were obtained, analyses were first performed for the first study data, for the first two datasets combined and then for all the three datasets. Single-point tests were also performed for each study separately. Results of genetic association were interpreted using the Bayesian False Discovery Probability (BFDP). Testing for genotype-by-treatment interaction effect in the combined datasets from the three studies gave no significant association signals. However, when the analyses were restricted to the treatment arm only (testing for genotype main effect among treated subjects), loci with noteworthy effects were observed in each separate study, some of which also came up in the combined datasets (BFDP0.91 threshold for GWA and p-values$2x10^{-6}$). Simulation studies were also performed to determine the effect sizes that can be reliably detected given the phenotype distribution and the sample size. We observed that testing for genotype main effect in treated arm only gave the highest power among the models considered. These results will help to determine how genetic variants that influence drug efficacy can be identified, incorporated into classifiers and tested during the course of clinical development.

Further delineation of Pitt-Hopkins syndrome: phenotypic and genotypic description of sixteen novel patients. *C. Zweier[1], H. Sticht[2], E. K. Bijlsma[3], J. Clayton-Smith[4], S. E. Boonen[5], A. Fryer[6], M. T. Greally[7], N. den Hollander[3], M. Jongmans[8], S. G. Kant[3], M. D. King[9], S. A. Lynch[7], S. McKee[10], A. T. Midro[11], S. Park[12], V. Ricotti[9], E. Tarantino[13], M. Wessels[14], M. Peippo[15], A. Rauch[1]* 1) Institute of Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany; 2) Bioinformatics, Erlangen, Germany; 3) Department of Clinical Genetics, Leiden, The Netherlands; 4) Academic Department of Medical Genetics and Regional Genetics Service, Manchester, UK; 5) Kennedy Center, Glostrup, Denmark; 6) Department of Clinical Genetics, Liverpool, UK; 7) National Centre for Medical Genetics, Crumlin, Dublin, Ireland; 8) Department of Human Genetics, Nijmegen, The Netherlands; 9) Department of Pediatric Neurology, Temple Street, Dublin, Ireland; 10) Northern Ireland Regional Genetics Centre, Belfast, UK; 11) Department of Clinical Genetics, Bialystok, Poland; 12) Department of Clinical Genetics, Cambridge, UK; 13) Section of Clinical Genetics, Pisa, Italy; 14) Department of Clinical Genetics, Rotterdam, The Netherlands; 15) Department of Medical Genetics, Helsinki, Finland.

Haploinsufficiency of the gene encoding for transcription factor 4 (TCF4) was recently identified as the underlying cause of Pitt-Hopkins syndrome, a so far underdiagnosed mental retardation syndrome characterized by a distinct facial gestalt, breathing anomalies and severe mental retardation. To date 11 patients with PTHS and deletions or mutations in the TCF4 were reported. We now performed TCF4 mutational analysis in 117 patients with Pitt-Hopkins syndrome like features and identified 16 novel mutations. All of these proven patients were severely mentally retarded and showed a distinct facial gestalt, 56% had breathing anomalies, 56% had microcephaly, 38% had seizures, and 44% had MRI anomalies. We therefore further delineate the mutational and clinical spectrum of Pitt-Hopkins syndrome and confirm its important role in the differential diagnosis of severe mental retardation, in particular Angelman- and Rett-syndromes.

Polymorphic variants in Tenascin-C are associated with coronary artery disease. *M. A. Minear[1], D. R. Crosslin[1], B. S. Sutton[1], S. C. Nelson[1], S. G. Watson[1], A. B. Hale[1], J. J. Connelly[1], C. Haynes[1], J. M. Vance[3], D. Seo[3], S. H. Shah[1,2], P. J. Goldschmidt-Clermont[3], W. E. Kraus[2], E. R. Hauser[1,2], S. G. Gregory[1,2]* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Department of Medicine, Duke University, Durham, NC; 3) Miller School of Medicine, University of Miami, Miami, FL.

Tenascin-C (TN-C) is an extracellular matrix protein with several functions related to atherosclerosis pathophysiology, including aortic smooth muscle cell proliferation, migration, apoptosis, and neointimal hyperplasia. Previously, TN-C expression patterns were shown to discriminate between and predict atherosclerotic disease states in human aorta samples. Because TN-C is an attractive atherosclerosis candidate gene, we sought to define whether polymorphisms in TN-C were associated with a clinical manifestation of atherosclerosis, coronary artery disease (CAD). To do this, we genotyped tagging SNPs across the TN-C locus in three independent CAD samples: atherosclerotic human aortas, CATHGEN CAD cases and controls, and GENECARD (GC) early-onset CAD families. Single SNP association analyses using Caucasian subjects and multivariable logistic regression to account for known CAD risk factors identified three SNPs (rs4452883, rs3789875, and rs12347433) in high linkage disequilibrium (r^2>0.95) that were consistently associated across all three datasets. The strongest associations were observed with advanced forms of CAD, defined by the presence of raised lesions in aortas (n=222, p-values (p)=0.001-0.004, odds ratios (OR)=3.4-4.5) or by CATHGEN cases with high CAD indexes (n=230, p=0.001-0.008, OR=1.5-1.7) or left main artery disease (n=244, p=0.005-0.01, OR=1.5-1.6). Although not statistically significant, the entire GC dataset showed trends of association using the APL test (n=2954, p=0.09, rs12347433) and by comparing GC probands to unaffected controls (n=650, p=0.07-0.09, OR=1.3). The association with rs12347433, a synonymous SNP (sSNP), is noteworthy given recent studies showing that sSNPs can alter mRNA stability, translation kinetics, or alternate splicing. This work highlights the importance of TN-C as a candidate gene for CAD.

Large scale population carrier screening for spinal muscular atrophy (SMA) in Israel - effect of ethnicity on the false negative rate. *R. Sukenik-Halevy[1], R. Pesso[2], N. Garbian[2], N. Magal[1], M. Shohat[1,2]* 1) Raphael Recanati Genetic Institute, Rabin Medical Center, Petah Tikva, Israel; 2) Maccabi Health Insurance Genetic Institutes, Rehovot, Israel.

Approximately 95% of Spinal Muscular Atrophy (SMA) patients have homozygous deletions of exon 7 and/or 8 of the SMN1 gene and 5% are compound heterozygotes for deletion of exon 7 and a point mutation. Based on patient prevalence studies, the carrier frequency has been estimated to vary from 1:150 to 1:35. We undertook a survey to assess the carrier rate among healthy individuals with no family history, evaluate the false negative rate (individuals with three copies of exon 7), and determine any ethnic differences. We analyzed data from a total of 9037 subjects who were tested between February and October 2007 in two large medical centers in Israel that conduct carrier screening among the normal population using the MLPA kit. We studied the copy number of exons 7 and 8 and divided the subjects into six ethnic groups: Ashkenazi Jewish, North African Jewish, Iranian and Iraqi Jewish, Yemenite Jewish, Balkan Jewish, and a group of others, which included individuals with a mixed ethnic origin or one that did not fit into one of the six categories. Statistical analysis was performed using the chi-square test. The carrier rate (deletion of exon 7) was 1:62 and was not statistically different among the various ethnic groups. A duplication of exon 7 was found in 1 in 9 (11.1%) individuals - a false negative rate of 5.5%. There was a significant difference between the ethnic groups: 13.3% among Ashkenazim, 6% among North African Jews and 7.7% in Iraqi Jews ($p<0.001$). This difference was also found for duplication of exon 8. The pattern of results was consistent in both testing centers. These findings suggest that the frequency of duplication of exon 7 may in some ethnic groups be several times higher than that of a deleted allele. This emphasizes the importance of determining the false negative rate for each ethnic group as it may vary markedly. The discrepancy between the rates of exon 7 deletions vs. duplications may be explained by the genetic disadvantage of deletions.

Migraine with or without aura is associated with copy number variants in different genes. *L. Armengol[1,2], S. Villatoro[1,2], J. R. González[2,3], K. Rabionet[1], B. Cormand[4], A. Oterino[5], M. Toriello[5], A. Macaya[6], R. Corominas[6], E. Cuenca[6], M. J. Sobrido[7], J. Pardo[8], J. López[8], R. Leira[8], M. Camiña[6], A. Carracedo[7], E. Martí[1,2], X. Estivill[1,2,9]* 1) Genes & Disease Program, Center for Genomic Regulation; 2) CIBERESP; 3) Centre de Recerca en Epidemiologia Ambiental; 4) Departament of Genetics, Universitat of Barcelona; 5) Department of Neurology, Hospital Marqués de Valdecilla, University of Cantabria; 6) Grup Recerca Neurologia Infantil, Hospital Universitari Vall d'Hebron; 7) Fundación Pública Galega de Medicina Xenómica; 8) Department of Neurology, Hospital Clinico Universitario de Santiago; 9) Pompeu Fabra University, Barcelona, Catalonia, Spain.

Migraine is a complex and very prevalent medical condition characterized by recurrent painful headaches. Migraine is known to have a strong genetic component as suggested by the familial aggregation and the high concordance rate observed in monozygotic twins. To assess a possible role of CNVs in migraine etiology, we pooled DNA from migraine patients and hybridized it against a pool of controls on Agilent 244K arrays. Eight loci were found to be concordant among hybridization replicates. We identified the breakpoints of the two most promising CNVs and genotyped copy number variability. Preliminary association studies in a cohort of 451 cases and 448 controls revealed an association between migraine (F-test; p=0.017; OR=1.35; CI [1.06-1.72]) and the presence of the insertion allele of the CNV. The CNV is 8 kb long and lies within a gene that is highly expressed in brain nuclei involved migraine's etiology. Replication studies for the association, linkage with other markers in the region and functional studies are in progress. A second variant identified affects another candidate gene for migraine. Preliminary MLPA analyses on 77 cases and 166 controls reveal that this CNV is also associated with migraine (F-test;p=0.018;OR=1.69;CI [1.09-2.63]). These are, to our knowledge, the first CNVs associated with a complex and highly prevalent neurological disorder. Our work emphasizes the importance of CNVs in the etiology of complex disorders and sheds new light on the biological basis of migraine.

Study of candidate genes for cognitive endophenotypes of schizophrenia on cromosomes 2q33-37 and 4q13-26. *J. Wedenoja[1,2], I. Lindqvist[1], A. Tuulio-Henriksson[3,4], J. Suvisaari[3], A. Loukola[1], T. Varilo[1,2,5], S. Mottaqui-Tabar[1], P. Lahermo[6], E. Serkkola[7], S. Ripatti[1,8], M. Ranki-Pesonen[7], J. Lönnqvist[2,3,9], L. Peltonen[1,2,5,10], T. Paunio[1,3,9]* 1) Institute for Molecular Medicine Finland FIMM, National Public Health Institute, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Finland; 3) Department of Mental Health and Alcohol Research, National Public Health Institute, Helsinki, Finland; 4) Department of Psychology, University of Helsinki, Helsinki, Finland; 5) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 6) Finnish Genome Center, Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 7) Research and Development, Orion Pharma, Espoo, Finland; 8) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 9) Department of Psychiatry, Helsinki University Central Hospital, Helsinki, Finland; 10) Human Genetics, Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK.

Lack of convincing results in gene identification for psychiatric disorders has increased interest towards quantitative traits which are potentially more closely related to underlying biology. We have previously identified in Finnish schizophrenia families a locus for visual working memory on 2q36 and for verbal learning and memory on 4q21, considered as valid schizophrenia endophenotypes. We selected 70 regional, functionally relevant candidate genes from 2q33-37 and 4q13-26, and genotyped altogether 1144 intragenic tagging SNPs in a nationwide Finnish sample of 293 schizophrenia families with detailed interview and neuropsychological test data. We detected a significant association between visual working memory and PAX3 on 2q36 (p0.00001), and semantic clustering, a trait related to verbal learning and memory, with SNCA on 4q22 (p0.001). Interestingly, these genes are located on the same genomic regions as our best genome-wide linkage loci for the respective traits. Our findings support the hypothesis that the genetic risk related to psychiatric disorder candidate genes is mediated via their effect on cognitive endophenotypes.

mtDNA genetic landscapes formed in tumors and in human evolution are shaped by similar selective constraints.

I. Zhidkov[1,2], E. Livneh[1,2], E. Rubin[1,2], D. Mishmar[1,2] 1) Life Sciences, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 2) The National Institute of Biotechnology (NIBN), Ben-Gurion University of the Negev, Beer-Sheva, Israel.

Genomic landscapes in humans revealed the signatures of natural selection in mutations generated either during evolution or during the progress of cancer. The unique features of the mutational landscape in cancer are the target of extensive study. However, less attention has been drawn to similarities in the signatures of selection in tumor cells and human populations. We hypothesized, that such similarities will provide new insight into the functional constraints acting on both systems. Here we utilized the rapidly evolving mitochondrial genome (mtDNA) to compare the de novo mutational landscapes in a cancer compendium (98 sequence pairs) with mutations fixed in the mtDNA during human evolution (2400 sequences). Nucleotide positions that underwent de novo changes in the cancer compendium preferentially co-localized with ancient mutations in the human mtDNA phylogeny. An even stronger pattern was observed when recurrent combinations of mutations (COMs) were analyzed in the cancer compendium, revealing non-random COMs of up to seven mutations in length, longer than observed in reshuffling simulations ($p<2.9\times10\text{-}4$). Strikingly, 23/25 positions comprising the COMs co-localized with positions that define major human mtDNA lineages. Intriguingly, the mtDNA COMs included 14 changes not affecting protein sequences or RNA genes (9 synonymous and 5 mtDNA D-loop mutations), suggesting a functional potential for non-coding changes. Our results reveal significant similarities in the mutational landscapes of mtDNA in cancer and normal human populations suggesting similar selective constraints. This implies a functional potential for specific positions as well as combinations of positions in both de novo and inherited mtDNA mutations. Our findings propose new ways to understanding principles in cancer and natural genomic evolution.

A PCSK9 variant in a dyslipidemic disorder other than familial hypercholesterolemia. *M. ABIFADEL[1,2], L. BERNIER[3], G. DUBUC[3], JP. RABES[1,4], J. BONNEAU[1], A. MARQUES[1], M. MARDUEL[1], M. DEVILLERS[1], D. ERLICH[1], A. MUNNICH[1], M. VARRET[1], M. ROY[3], J. DAVIGNON[3], C. BOILEAU[1,4]* 1) INSERM U781, Hopital Necker, Université Paris Descartes, France; 2) Faculté de Pharmacie, Université Saint-Joseph, Beirut, Lebanon; 3) Institut de recherche clinique, Montreal, Canada; 4) Laboratoire de Biochimie et de Génétique Moléculaire, CHU Ambroise Paré (AP-HP et Université Versailles-Saint-Quentin-en-Yvelines), Boulogne, France.

Hypercholesterolemia is one of the major causes of coronary heart disease (CHD). The genes encoding the low density lipoprotein receptor (LDLR) and its ligand apolipoprotein B (APOB), have been the two genes classically implicated in autosomal dominant hypercholesterolemia (ADH). Our discovery in 2003 of the first mutations of PCSK9 gene causing autosomal dominant hypercholesterolemia shed the light on an unknown actor in cholesterol metabolism that has been extensively investigated since. Several PCSK9 variants have been identified, some of them (p.S127R, p.D129G, p.F216L, p.R218S, p.357H, p.D347Y, p.D374H) are gain of function mutations causing ADH or hypercholesterolemia by a reduction of LDL receptor levels; while others are loss of function mutations (p.Y142X, p.C679X) associated with a reduction of LDL-cholesterol levels and a decreased risk of CHD. PCSK9 variants are unequally distributed in different ethnic groups contributing to the variability of cholesterol levels and CHD incidence in these populations. We sequenced PCSK9 in 25 French and French-Canadian probands with ADH with no mutations in the LDLR or APOB genes, and in 25 other French-Canadian dyslipidemic probands. We identified a new variant of PCSK9 in one of the 25 French-Canadian ADH families and in 2 families with dyslipidemia other than ADH. Furthermore this variant was not found in 100 French and 100 French-Canadian controls. Statistical studies and family based test (FBAT) studies showed an association of this variant with the dyslipidemic phenotype present in these families. Thus, in this report we show for the first time that a PCSK9 variant might be implicated in a multifactorial dyslipidemic disorder.

Fine scale analysis of ~1 million genome-wide SNPs on 250 individuals from the HGDP-CEPH panel. *M. Bauchet[1], D. Lopez-Herraez[1], K. Tang[4], I. Pugach[1], M. Scholz[2], A. Gro[2], M. R. Nandineni[3], M. Stoneking[1]* 1) Max Planck Institute for Evolutionary Anthropology, Dept of Evolutionary Genetics, Leipzig, Germany; 2) University of Leipzig, Institut fuer medizinische Informatik, Statistik und Epidemiologie, Leipzig, Germany; 3) Centre for DNA Fingerprinting and Diagnostics, Nacharam, Hyderabad, India; 4) CAS-MPG Partner Institute of Computational Biology, Shanghai, China.

We analyzed genome-wide SNPs typed on a world-wide panel of 250 individuals from the HGDP-CEPH panel, genotyped on Affymetrix Human SNP Array 5.0 chips. Data are available for these same samples from the Illumina HumanHap650K BeadChip; some 96k SNPs overlap between the two arrays. For the Affymetrix arrays, we first devised the best genotyping call method (Chiamo) and optimized its parameters by choosing the set that minimizes mismatches with the Illumina data. We then merged both arrays, filtered out ambiguous and potentially biasing SNPs. We obtained approximately 1 million SNPs for 250 individuals5 from each population of the HGDP-CEPH panel. We performed principal component analysis (PCA) on this dataset at two different thresholds applied to the Chiamo posterior probabilities. We discuss the shape and directions of clustering at the worldwide and regional levels, and identify ancestry informative markers (AIMs) at both geographical levels whenever possible. In addition we phased the merged set and searched for signals of natural selection using contrasting extended haplotype homozygosity (EHH) profiles between populations. These results add substantially to our knowledge of human population history, and provide lists of between and within continent AIMs, as well as candidate genomic regions that have been subject to selection in different populations.

CYTOGENETIC ANALYSIS IN PREMATURE OVARIAN FAILURE. *D. Pathak[1], R. Kumar[1], A. Sharma[1], A. Kriplani[2], AC. Ammini[3], R. Dada[1]* 1) Dept Anatomy, All India Inst Medical Sci, New Delhi, India; 2) Dept Obstetrics and Gyneocology,All India Inst Medical Sci, New Delhi, India; 3) Dept Endocrinolgy ,All India Inst Medical Sci, New Delhi, India.

Premature ovarian failure is premature cessation of menses before 40 years of age. The condition is characterized by primary amenorrhea, gonadal dysgenesis and elevated gonadotrophin levels. The aetiology of POF is complex and several causes like auto antibodies, chemotherapy, autoimmune disease and diabetes mellitus are associated with POF. In order to study genetic aberrations in idiopathic POF, conventional cytogenetics of 50 idiopathic POF cases was performed, after informed consent and ethical clearance. Chromosome preparations were obtained by 72 hour peripheral blood culture by GTG banding. 39 cases revealed a normal 46, XX karyotype and 11 cases revealed an abnormal karyotype. Out of 11 cases 6 cases are mosaic with 45 ,XO, 46, XX chromosomal complement. In 2 cases there were structural defects in X chromosome, where as in one case had 46, XX q del (13.3-Xq21.1) [60%] karyotype and one case had 46, X iso Xq [90%], 46 XX [10%]chromosomal complement. One case revealed 46, XY chromosomal complement with pure gonadal dysgenesis, PCR for SRY did not show amplification. This case had complete AZF deletion. In 2 cases there were structural autosomal defects , where as one case had 45, XO [25%]/ 46, X ring X [75%] and [30%] of cell line also showed 46 XX iso 2q chromosomal complement and One case had 46, XX[80%], 46 XX iso 22q[20%]. The results of this preliminary study showed the association of chromosome abnormalities in aetiology and pathogenesis of POF. Thus genetic study must be included in evaluation of idiopathic POF cases and cases with genetic abnormalities should be counselled comprehensively.

A Piece in the Puzzle of the INSIG2 rs7566605 SNP Association With Obesity Based on a Meta-Analysis Including 76,548 Individuals: It is the Study Population That Matters! *I. M. Heid[1], C. Huth[1], R. J. F. Loos[2], F. Kronenberg[3], B. Langer[1], C. Lange[4], N. Laird[4], H. E. Wichmann[1], INSIG2 Meta-Analysis Group* 1) Helmholtz Zentrum München, Neuherberg, Germany; 2) MRC Epidemiology Unit, Cambridge, UK; 3) Innsbruck Medical University, Austria; 4) Harvard School of Public Health, Boston, USA.

The INSIG2 rs7566605 SNP was identified to be associated with obesity (body-mass-index, BMI 30kg/m^2) in one of the first genome-wide association studies. Subsequent replication was shown in many, but not in all studies. We thus performed a meta-analysis to clarify the association and to explore potential sources of heterogeneity. We collected association statistics (recessive model) from general population based studies (GP, n=16), studies selected from a healthy population (HP, n=5), or case-control studies on extreme obesity (OB, n=6) involving 76,548 participant. We found no heterogeneity among GP studies (n=48,844, I^2=11%, p=0.329). Adding HP or OB introduced heterogeneity (I^2=44%, p=0.008). Thus, we conducted separate analyses for GP, HP and OB. The GP meta-analysis suggested increased obesity risk for the CC-homozygotes (OR=1.10, p=0.015) with increasing ORs for more extreme degrees of obesity: 1.20 (BMI 32.5kg/m^2), 1.26 (BMI 35.0kg/m^2), 1.31 (BMI 37.5kg/m^2), 1.41 (BMI 40.0kg/m^2) compared to <25kg/m^2 (p-values between 0.048 and 0.0002). Two out of 3 pre-defined subgroups indicated significant heterogeneity: studies from more obese populations (more than average proportion of obese) and studies with obesity assessed more recently (after year 2000) showed higher associations than the less obese or less recent studies. In the OB studies, a consistent association between the rs7566605 and extreme obesity was observed (OR=1.16, p=0.038). No association was found in HP meta-analysis. In one of the largest genetic studies on obesity, we conclude that there is evidence for association of the INSIG2 rs7566605 CC genotype with increased obesity, which is most pronounced when using more extreme comparisons. Our data also suggests heterogeneous effects when pooling different study populations, which may mask underlying associations.

Dymeclin, the protein defective in Dyggve-Melchior-Clausen syndrome is a peripheral membrane protein dynamically associated with the Golgi apparatus. *A. Dimitrov[3], V. Paupe[1,2], C. Gueudry[3], J. B. Sibarita[3], G. Raposo[3], O. Vielemeyer[3], Z. Csaba[4], T. Attie-Bitach[2], P. Gressens[1], P. Rustin[1], F. Perez[3], V. El Ghouzzi[1,2]* 1) INSERM U676, hôpital Robert Debré, Paris, France; 2) INSERM U393, hôpital Necker, Paris, France; 3) UMR CNRS 144, Institut Curie, Paris, France; 4) INSERM U686, Université Paris Descartes, Paris, France.

Dyggve-Melchior-Clausen (DMC) syndrome is a rare inherited dwarfism with severe mental retardation resulting from loss-of-function mutations in the Dym gene which encodes Dymeclin, a 669-aminoacid protein of yet unknown function. Despite a high conservation across species and several predicted transmembrane domains, Dymeclin could not be ascribed to any family of proteins. To obtain additional clues on Dymeclin function, we studied the expression pattern of Dym in human embryo-foetal tissues using in situ hybridization and we used the recombinant protein fused to GFP to investigate its sub-cellular localization. The transcript is widely expressed in human embryos, especially in the cortex, the hippocampus and the cerebellum and that the protein co-localizes with Golgi apparatus markers. Electron microscopy revealed that Dymeclin associates with the Golgi apparatus and with transitional vesicles of the reticulum-Golgi interface. Dymeclin is myristoylated in vitro but the myristoylation is not essential for Golgi localization. Permeabilization assays further revealed that Dymeclin is a peripheral protein of the Golgi apparatus as it can be completely released from the Golgi after permeabilization of the plasma membrane. Moreover Fluorescence Recovery After Photobleaching experiments have shown that the half time of recovery is as short as 2.8 seconds for the entire Golgi apparatus. Interestingly, in the presence of nocodazole which depolymerizes microtubules, Dymeclin did not associate with mini-stacks but only with membranes of the old, pre-existing, Golgi apparatus, in a highly dynamic manner. These results indicate that Dymeclin recognizes specifically a subset of mature Golgi apparatus and shuttles extremely rapidly between the cytosol and these membranes, and suggest that DMC results from an impairment in Golgi/ER membrane trafficking .

Allelic background of 9p21 loci associated with type 2 diabetes and coronary heart disease in 51 global populations. *K. Silander[1], S. Myles[2], H. Tang[3], E. Jakkula[1], L. Cavalli-Sforza[3], N. Timpson[4,5], L. Peltonen[1,4]* 1) Institute of Molecular Medicine and NPHI, Helsinki, Finland; 2) Institute for Genomic Diversity, Cornell University, Ithaca, NY, USA; 3) Stanford University School of Medicine, CA, USA; 4) Wellcome Trust Centre for Human Genetics, Oxford, UK; 5) MRC CAiTE Centre, University of Bristol, UK.

A 100kb region on 9p21.3 harbors two major disease susceptibility loci: one for type 2 diabetes (T2D) and one for coronary heart disease (CHD). The SNPs associated in Europeans reside on two adjacent haplotype blocks having independent effect on disease. HapMap phase 2 data suggests that identification of functional variants and selection of the most relevant SNPs for studies in global populations will be challenging in this region due to the diverse LD and haploblock structure in different populations. We analyzed the allelic background of this region in 938 unrelated individuals from 51 populations (HGD panel). We used the Illumina 650Y SNP dataset (Li et al. 2008), supplemented with 5 additional critical SNPs. The T2D risk allele tagged by rs10811661 was found on wide diversity of haplotype backgrounds, whereas a short (5.5 kb) shared haplotype was tagged by the protective allele of this SNP (0.03 in Africa, 0.16 in Europe and 0.27 in Asia). This 5.5kb region and even this particular SNP might represent the actual functional domain. Opposite to T2D locus, for the CHD locus all populations shared a core risk haplotype spanning 30 kb, tagged by the risk allele of rs4977574 (0.11 in Africa, 0.65 in Middle East, 0.57 in Europe, 0.51 in Asia). Interestingly, the SNP most strongly associated with CHD, rs10757278, is in perfect LD with rs4977574 25kb upstream in the YRI HapMap population, suggesting these SNPs would probably be the most appropriate for further analyses in non-Europeans. Our results demonstrate the importance of allelic background data when selecting SNPs for replication in global populations. Intriguingly, these initial data also imply increase in prevalence of T2D protective allele versus increase of CHD risk allele in out of Africa populations implying different population histories for these two adjacent disease loci.

***homruns*: A graphical tool to locate and visualize runs of homozygosity in whole-genome SNP data.** *R. Karlsson, S. Paddock* Department of Neuroscience, Karolinska institutet, Stockholm, Sweden.

We present the cross-platform software package *homruns* for finding and visualizing runs of homozygosity in whole-genome SNP datasets.

The interest for examining the role of copy number variations in human genetics has been increasing lately. One way to search for these relatively hard-to-get polymorphisms is to screen whole-genome SNP datasets for genotype patterns indicative of copy number variation, such as runs of homozygosity. Many such datasets are already available with even more on their way. In order to identify runs of homozygosity, one searches for coherent runs of homozygous markers. Such runs, if long enough that the likelihood of all markers being homozygous by chance becomes vanishingly small, can be an indicator of a deletion event, which would give false homozygous signals from a part of the genome that is hemizygous. In addition to detecting deletions, the same pattern of homozygosity can also be seen as the effect of a recent recessive mutation.

homruns uses a sliding window to calculate the per marker likelihood of being part of a homozygous region. Coherent stretches of markers with a high likelihood for being in such a region are then identified and displayed as a graph in the user interface, as well as saved in a plain text file for further analyses.

Parameters such as window size and the threshold for including a marker in a homozygous run can easily be adjusted by the user. The main calculation uses the *plink* toolset (Purcell et al, 2007; http://pngu.mgh.harvard.edu/purcell/plink/), which means that input data can be in any format readable by *plink*. The software program *homruns* is released under the GPL, and can be downloaded from the author's website for free.

Williams-Beuren Syndrome TRIM50 gene defines highly dynamic and mobile cytoplasmic bodies that localize with autophagosomes LC3 marker. *G. Merla[1], C. Fusco[1], M. Egorov[2], L. Micale[1], P. Turturo[1], B. Augello[1], M. Monti[3], R. S. Polishchuk[2], P. Pucci[3], F. Cozzolino[3], A. Reymond[4]* 1) Medical Genetics Unit, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; 2) Unit of Membrane Sorting and Biogenesis Department of Cell Biology and Oncology, "Mario Negri Sud Consortium" Santa Maria Imbaro, Italy; 3) CEINGE Advanced Biotechnology and Department of Organic Chemistry and Biochemistry, Federico II University, Naples, Italy; 4) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

We recently showed that the protein encoded by the TRIM50 gene was part of the E3-ubiquitin ligase family that catalyze the transfer of ubiquitin moieties to specific substrates. These post-translational modification either contribute to the fine regulation of the substrate or to its tagging for degradation by the proteasome. TRIM50 is hemizygous in the Williams Beuren Syndrome (WBS), a contiguous genetic disorder characterized by a number of physical and developmental disabilities. WBS is caused by a 1.5 Mb deletion at 7q11.23 that includes at least 25 genes. To get insight on the role of TRIM50 we performed fluorescence and electronic microscopy to study the TRIM50 cellular localization and we used functional proteomic strategies to identify proteins interacting with this E3-ubiquitin ligase. We found that the TRIM50 protein localizes in highly mobile, labile and dynamic cytoplasmic bodies, it is capable of assembling larger cytoplasmic bodies from several individual smaller particles and importantly it colocalizes with LC3, a specific marker of autophagosomes. Consistently, nano LC MS/MS identified a number of putative TRIM50 interacting proteins known to be implicated in the proteasome and autophagy pathways. These results show an unexpected role for TRIM50 on protein degradation pathways. We speculate that the haploinsufficiency of TRIM50 could account for a consistent part of WBS phenotype through the accumulation and/or abnormal degradation of TRIM50 substrates.

Activating FGFR3 mutation cause hearing loss and inner ear defect in a new mouse model of thanatophoric dysplasia. *S. Pannier[1], V. Couloigner[2], N. Messadeq[3], M. Elmaleh-Bergès[4], A. Munnich[1], R. Romand[3], L. Legeai-Mallet[1]* 1) INSERM U781, Hopital necker, Paris, France; 2) Service Oto-Rhino-Laryngologie-Chirurgie Cervico faciale-Hopital Necker, Paris, France; 3) IGBMC, Illkirch, France; 4) Service d'imagerie pédiatrique, Hôpital Robert Debré, Paris, France.

Fibroblast growth factor receptor 3 (FGFR3) is a key regulator of skeletal development and activating mutation in FGFR3 cause several skeletal dysplasias, including hypochondroplasia, achondroplasia and thanatophoric dysplasia. Here, we described a new mouse model for thanatophoric dysplasia. We introduced the Y367C mutation corresponding to the human TDI mutation (Y373C) into the mouse genome. The mice displayed dwarfism with a skeletal phenotype remarkably similar to that of human chondrodysplasia. To investigate the role of activating FGFR3 mutation in auditory function, we examined heterozygous mutant $fgfr3^{Y367C/+}$ mice. We show here, for the first time, that mutant $fgfr3^{Y367C/+}$ mice exhibit mild deafness with a significantly elevated ABR threshold for all frequencies tested. A severe ossification delay in the cochlea and the ossicular chain is observed in the mutant mice. The inner ear defect is mainly associated with an increased number of pillar cells or modified supporting cells in the organ of Corti. Hearing loss in fgfr3 mouse model confirms the crucial role of FGFR3 in the development of the inner ear and provides novel insight on the biological consequences of FGFR3 mutations.

CYTOGENETIC ASPECTS OF MYELODYSPLASTIC SYNDROMES. *R. kumar[1], D. Pathak[1], R. Chaubey[2], p. Tiwari[2], R. Saxena[2], R. Dada[1]* 1) Deptt ofAantomy, AIIMS, Delhi, India; 2) Deptt of Hematology,AIIMS,Delhi,India.

Myelodysplastic Syndrome (MDS) is a clonal disorder of haematopoietic stem cells and results in progressive cytopenia and defect in erythroid, myeloid and megakaryocytic maturation. The diagnosis of MDS is difficult to establish based on morphological features alone because dysplasia is not always be detectable and the presence of dysplasia is not itself evidence of clonal disorder. As a result, the detection of clonal cytogenetic abnormality has a major role in diagnosis and classification of MDS and determining its prognosis. In an attempt to assess the frequency and characteristics type of abnormal clones, cytogenetic analysis was carried in 25 MDS cases. Cytogenetic analysis of bone marrow cells and peripheral blood cells was carried by 24 hour unstimulated cell culture and 72 hour stimulated blood culture respectively. Chromosomes were obtained by GTG bands. On analysis 12 out of 25 patients had abnormal karyotypes. In 8 patients cytogenetic changes were characteristic of those reported for MDS: del(5q)[n=2], monosomy [n=3], monosomy 7[n=2] and 1 had Y chromosome loss. Out of 12 cases with cytogenetic abnormalities 4 cases had cytogenetic abnormalities which have not been previously reported in MDS cases. Out of these cases trisomy 9, t(12q-6q), iso(9q) and t(12p-6q) were found in each case each. Long term follow-up and larger studies of such cases are required to determine the malignant potential of these clones and prognosis in MDS cases.

Absence of coding region mutations in predicted mitochondrial proteins within the X-chromosomal candidate interval linked to visual failure in Leber hereditary optic neuropathy. *P. Yu Wai Man, G. Hudson, P. F. Chinnery*
Newcastle University, Newcastle Upon Tyne.

Leber hereditary optic neuropathy (LHON, OMIM 535000) is an early onset (median = 24yrs) bilateral visual failure, resulting from retinal ganglion cell loss, which predominantly affects males (4:1). 95% of all LHON is caused by one of three mtDNA point mutations in genes which encode complex I subunits; 3460G>A in *MTND1*, 11778G>A in *MTND4* and 14484T>C in *MTND6* . However, mtDNA mutations cannot explain why only ~50% of male and ~10% of female carriers develop symptoms. This incomplete penetrance indicates the influence of epigenetic factors on the onset of symptoms. Until recently attempts to map the locus were inconclusive. We recently identified a 60cM region of the X-chromosome (Xp21.1 - Xq21.1. In recent years proteomic based approaches have been developed to assist the determination of nuclear encoded mitochondrial proteins and Integrative genomics has been applied to the identification of two nuclear encoded mitochondrial disease genes; *LRPPRC*. We replicated this strategy to attempt to identify the nuclear encoded mitochondrial protein thought to modulate the onset of LHON. Mitochondrial prediction tools (*Masetro*, *MitopII*, *Mitoprot*, *TargetP*, *WolfPsort*) were used to construct a candidate gene list which could be screened in a panel of patients. Our bioinformatic analysis identified 25 candidate genes, subsequently screened in 8 discordant siblings. We identified 24 single nucleotide polymorphisms in 11 of the candidate genes. One synonymous single nucleotide polymorphism was found in LD (1350T>C, P=0.0067) between cases and controls. However, screening of the remaining indentified SNPs in a larger patient cohort revealed no significant difference to controls. No significance was found when comparing LD or when constructing complex genotypes. Although we have sequenced the entire coding regions of 25 genes, we cannot rule out the possibility of a non-coding, UTR or promoter region change which may modulate the phenotype of LHON. In conclusion, previously successful bioinformatic tools have failed to identify the LHON nuclear modifying locus.

Allelic alterations in epithelial ovarian carcinomas uncovered by Affymetrix SNP Array 5.0. *A. Tajima[1], K. Yoshihara[2], I. Inoue[1], K. Tanaka[2]* 1) Dep Molecular Life Sci, Tokai Univ Sch Medicine, Kanagawa, Japan; 2) Dep Obstet & Gynecol, Niigata Univ Graduate Sch Med & Dent Sciences, Niigata, Japan.

Ovarian cancer is the most lethal form of gynecological malignancy. Complex cytogenetic alterations due to chromosomal instability are regarded as an underlying mechanism of ovarian carcinogenesis. Many previous studies have contributed to the identification of recurrent changes in genomic copy number and loss of heterozygosity (LOH) in ovarian cancers. Despite such knowledge, however, genetic factors underlying the changes remain poorly understood. To further extend our knowledge of genomic instability in ovarian cancers, we here attempt to make a high-resolution map of cytogenetic aberrations using Affymetrix SNP Array 5.0, featuring over 920,000 genetic markers (500,000 SNPs and 420,000 non-polymorphic probes) for the measurement of genetic differences. To obtain a comprehensive catalog of copy number alterations, we analyzed matched tumor and non-tumor genomes from 43 patients with epithelial ovarian cancers (33 sporadic; 10 familial with *BRCA1* germline mutations). Partek Genomics Suite software was used to identify regions of copy number gain and loss, and estimate the copy number. The number of somatic copy number changes per cancer genome and the relative proportion of gains to losses varied between tumors, indicating cytogenetic heterogeneity in ovarian carcinomas. Of note, monoallelic alterations accounted for the vast majority of the observed copy number changes. These features were commonly observed in two groups of sporadic and *BRCA1*-associated tumors. Allele-specific gains were frequently observed on 3q, 5p, 7q, 8q and 20p, as were losses on 4q, 5q, 17p and 18q among the 43 tumors examined. We will discuss the implications in carcinogenesis, combining with our recent findings from genome-wide gene expression analysis.

Analysis of epidermal stem cells in a mouse model of Hutchinson-Gilford Progeria Syndrome. *Y. Rosengardten[1], H. Sagelius[1], T. McKenna[1], B. Rozell[2], M. Eriksson[1]* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Karolinska University Hospital, Huddinge, Novum, SE-141 86 Stockholm, Sweden; 2) Clinical Research Center, Department of Laboratory Medicine, Karolinska Institutet, Karolinska University Hospital, Huddinge SE-141 86 Stockholm, Sweden.

Hutchinson-Gilford progeria syndrome (HGPS) is an extremely rare genetic disorder characterized by symptoms suggestive of accelerated aging. Most cases of HGPS are due to a *de novo* single point mutation in exon 11 of the *LMNA* gene, 1824CT (G608G). The *LMNA* gene encodes the A-type lamins, which are major proteins of the inner nuclear lamina. The HGPS mutation activates a cryptic splice site resulting in a truncated lamin A protein, progerin. In this study we have utilized our previously published transgenic mouse model with epidermal expression of the HGPS mutation that replicates several features of the HGPS skin phenotype. Histopathological examination of these mice showed a progressive phenotype with early stages characterized by regions of epidermal hyperplasia, and hyperproliferative epidermal cells, and later stages characterized by epidermal hypoplasia, hypoplastic sebaceous glands, loss of hypodermis and a fibrotic dermis (JCS 121, 969-978, 2008). In this study we have used FACS analysis with antibodies directed against CD34 and 6-integrin on keratinocytes isolated from these mice. CD34 and 6-integrin are commonly used markers for keratinocytes with stem and progenitor cell characteristics. Our results showed that within 27 weeks of transgenic expression, there was a decrease in the 6-integrin/CD34 positive cell population compared to wildtype mice. Additional results from label-retaining cell analysis and colony-forming assays on epidermal stem cells in our HGPS model will be presented.

Kidney and muscle phenotypes due to hyposialylation in a mouse model of Hereditary Inclusion Body Myopathy.

M. Ziats[1], D. Kurland[1], D. Hickey[1], R. Klootwijk[1], I. Manoli[1,2], K. Patzel[1], C. Ciccone[1], P. Zerfas[3], M. Starost[3], D. Darvish[4], WA. Gahl[1,2], M. Huizing[1] 1) MGB, NHGRI, NIH; 2) Office of Rare Diseases, OD, NIH; 3) Div Vet Res, NIH, Bethesda, MD; 4) HIBM Research Group, Encino, CA.

Hereditary Inclusion Body Myopathy (HIBM) is a recessive adult-onset neuromuscular disorder, characterized by progressive muscle weakness due to mutations in UDP-GlcNAc 2-epimerase/ManNAc kinase (GNE), the key enzyme in sialic acid (SA) synthesis. We created a *Gne* knock-in mouse model harboring the human M712T mutation. We previously showed that these mice died before postnatal day 3 (P3) of glomerular disease, involving effacement of podocytes due to hyposialylation. Administration of the SA precursor ManNAc partially rescued the kidney phenotype and allowed survival of mutant mice. Here we evaluate SA itself as a therapeutic agent, by oral administration to pregnant and nursing mice. SA feeding did not significantly increase the number of surviving mice beyond P3, likely due to the negative charge of SA (impairing transmembrane transport) compared to the neutral charge of ManNAc. We also evaluated the evidence of a muscle phenotype in older surviving mutant mice. Electron microscopy studies of the gastrocnemius, gluteus, and quadriceps muscles of 6 and 11 month old mutant mice showed tubular aggregates (TAs). TAs presumably originate from the sarcoplasmic reticulum, and may be precursors of the rimmed vacuoles (RVs) seen in the muscles of HIBM patients, who are diagnosed late, after RVs have already formed. Further analysis of TA formation and sialylation status of affected muscles is being pursued, as well as evaluation of the effect of ManNAc on their formation. Other human disorders characterized by TAs, including sporadic limb girdle weakness, familial myasthenia gravis, and unexplained exercise-induced muscle cramps, may be caused by local sialic acid deficiency. Our *Gne* M712T mouse is a model for further evaluation of these hypotheses. In sum, our *Gne* M712T mouse unexpectedly serves as the first genetic model of podocyte injury due to hyposialylation, and may also prove to be a model of the myopathy of HIBM.

No significant association of 768 markers in 68 candidate genes with major depression in the STAR*D cohort. *M. Lekman[1], D. Charney[2], H. Manji[3], A. J. Rush[4], F. J. McMahon[3], S. Paddock[1]* 1) Department of Neuroscience, Karolinska institutet, Stockholm, Sweden; 2) Mount Sinai School of Medicine, NY, NY; 3) NIMH, NIH, Bethesda, MD; 4) University of Texas, Dallas, TX.

Major depressive disorder (MDD) is a highly debilitating disorder affecting a large proportion of the global population. So far, no genetic predictor for the disorder has been identified consistently, although a genetic predisposing factor has been reported in many epidemiologic studies. Large sample sizes are needed in order to identify genetic contributors for disease with only modest effect. Therefore, the large DNA sample available from the STAR*D study (N=1953) provides a good chance to elucidate genetic factors of small effect. Included individuals were between 18-75 years of age, diagnosed according to the DSM-IV criteria as non-psychotic MDD, and had a baseline score on the Hamilton Rating Scale for Depression HAM-D17 14. A sample of 1256 affected individuals of White Caucasian ancestry was matched with 634 controls. The control sample DNA was obtained from the NIMH Genetic Initiative for schizophrenia. All control samples were screened (DSM-IV) for not being affected by either major depression, bipolar disorder or psychosis. Markers (SNPs) were located in 68 genes previously implicated in the pathogenesis of major depressive disorder (for a complete list of all markers see McMahon et al. Am J Hum Genet. 2006 May;78(5):804-14.). Genotyping was carried out by Illumina with a success rate of 99.78%. The cocaphase software program was used in order to test for allelic association of each marker with disease status. A total of 47 SNPs (6% of the total markers) showed nominally (p0.05) significant p-values, located on chromosomes 3, 4, 5, 6, 9, 11, 12, 13, 16, 18, 21 and X. The most significant p-value (p=0.00031) was found at a marker nearby the GRIA3-gene on the X-chromosome. However, after correction for multiple testing, none of the associations remained significant. In an ongoing study, we now aim to replicate the nominally significant associations using the even larger GAIN case-control cohort for MDD.

Isolated CDH1 germline small deletion in a family with early onset breast cancer detected by Array-CGH. *C. Palka[1], G. Calabrese[1,2,3], A. Novelli[4], E. Morizio[3], P. Guanciali Franchi[1,3], C. Nuzzi[3], G. Palka[1,3], B. Dallapiccola[4]* 1) Biomed Science Dept./Medical Genetics, University G. DAnnunzio, Chieti, Italy; 2) Center for Ageing, DAnnunzio Foundation, Chieti, Italy; 3) Medical Genetics "Spirito Santo" Hospital, Pescara, Italy; 4) CSS-Mendel Institute, Rome, Italy.

We evaluated a 3,5-year-old boy because of psychomotor delay and craniofacial dysmorphisms. Probands standard karyotype resulted as normal 46,XY. Therefore, we performed an array-CGH analysis, with a 75Kb resolution, which disclosed a microdeletion of 0.24Mb on chromosome 16q22.1. The chromosomal abnormality was confirmed with FISH analysis. Parents investigation demonstrated that his mother had the same alteration. This deletion encompasses a small chromosomal region which includes few genes, such as ZFP90, cerebrally expressed, and CDH1, coding for E-cadherin, involved in pathogenesis of invasive lobular carcinoma of the breast. Probands family history was positive for tumours. In particular, his mother had a right invasive lobular breast carcinoma combined with a carcinoma in situ, both surgically removed when she was 35-year-old. She was negative for germline BRCA1 and BRCA2 mutations. Proband's maternal grandfather died for right colon cancer, while his great-grandmother from maternal line died for breast cancer. To our knowledge this is the first case of breast lobular carcinoma harbouring germline, isolated CDH1 partial deletion without involvement of other tumor-related flanking genes previously reported as rearranged together with CDH1 within 16q22 in breast lobular cancer. Fine molecular characterization of 16q22 deletion region is currently underway, also including uniparental disomy analysis to verify possible correlation between proband's phenotype and chromosome 16q22, a known imprinted region containing a number of genes or putative genes expressed in brain.

ABL-DEPENDENT PHOSPHORYLATION OF MEGAP/SRGAP3 AFFECTS ITS BINDING TO WAVE1. *G. Rappold, V. Endris, L. Hausmann* Dept. of Human Molecular Genetics, University of Heidelberg, Heidelberg, Germany.

Mental retardation affects up to two percent of the population and is accompanied by impaired learning and memory. Loss of function mutations of the MEGAP/SrGAP3 (Mental disorder associated GAP protein) gene has been previously described in patients with mental retardation, ataxia and complete lack of speech (Endris et al, 2002). MEGAP/srGAP3 is a member of the Slit-Robo GAP family which is involved in the transduction of repulsive guidance signals. Slit/Robo signaling plays an important role in the migration of neuronal precursor cells and axon guidance during the development of the nervous system. MEGAP represents a Rac1-specific GTPase activating protein, which binds to and inhibits the functions of the WASP related protein WAVE1. Here, we report on the regulation of MEGAP by c-Abl. Protein binding analysis revealed that MEGAP interacts with c-Abl through a region distal to its SH3 domain. We identified two MEGAP phosphorylation sites, one located within the Abl-binding interval (Y845) and one within the SH3 motif (Y755). Phosphorylation of Y755 leads to a charge change that abolishes the binding of MEGAP to WAVE1, a key regulator of actin-dependent morphological processes. Our results suggest that c-Abl regulates the function of MEGAP via phosphorylation, thereby uncoupling the inhibitory effect of MEGAP on the WAVE1 complex.

Genotype-phenotype analysis in patients with the L1 syndrome. *Y. J. Vos, J. A. Stegeman, H. E. K. de Walle, I. Stolte-Dijkstra, R. M. W. Hofstra* Dept of Genetics, University Medical Centre, Groningen, The Netherlands.

The L1 syndrome is an X-linked recessive disorder with an incidence of one in every 30,000 newborn males. It comprises four neurological syndromes, all being found associated with mutations in the *L1CAM* gene. These syndromes being: HSAS (X-linked Hydrocephalus with Stenosis of the Aqueduct of Sylvius), MASA (Mental retardation, Aphasia, Spastic paraplegia and Adducted thumbs), SPG1 (X-linked complicated hereditary spastic paraplegia type 1) and X-linked ACC (Agenesis of Corpus Callosum). In our laboratory an efficient mutation screening method has been developed and used to analyse the DNA of more than 300 patients. As a result, a pathogenic mutation has been found in only 25% of all L1 syndrome patients, which is a rather low score. Since the costs of mutation analysis are relatively high, a study has been undertaken to define (clinical) criteria which would able us to increase the efficiency in actually finding a relevant mutation, i.e. a higher detection rate. As a result we found that in families with more than one affected family member, the detection rate is about 60%. In patients with three or more clinical characteristics, belonging to the L1 syndrome, the detection rate is about 65%. Combining these two, i.e. patients having a positive family history and having more than three characteristics of the L1 syndrome, the detection rate is almost 85%, all findings being statistically significant. These calculations are based on the identification of both truncation mutations and missense mutations. We also looked for possible correlation between the seriousness of the disease and the type of mutation found. No statistically significant differences were detected in the seriousness of the disease in patients with a truncation mutation compared to patients with a missense mutation.

BAC Clone FISH approach to determine the breakpoint in the chromosomal rearrangement. *E. Shin[1], S. Li[2]* 1) Genome Research Center, NeoDin Medical Institute, Seoul, Korea; 2) Departments of Pediatrics, the University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104, United States of America.

Identification of chromosomal rearrangements involving derivative chromosomes was considered as difficult and sometimes impossible with classical cytogenetic banding methods. The determination of their chromosomal breakpoint is now easier with fluorescent in situ hybridization (FISH) techniques using BAC Clone and enables an exact correlation between chromosomal aberration and phenotypic features to be established. FISH using BAC Clone was performed to define the breakpoints involved in the formation of der(10), der(15) and der(X). Molecular cytogenetic analyses of the chromosome breakpoints revealed the localization of the breakpoint in 10q26 between BACs RP11-113M14, RP11-7P17 and RP11-184L4, each BACs harbour the OAT gene, the FGFR2 gene and the DOCK1 gene, respectively. In 15q21-26, a breakpoint-spanning clones (RP11-243M9 and RP11-289H7) were localized which contain the genes THSD4 and ETFA. On chromosome Y, BACs RP11-49G16 and RP11-1036K16 were used to confirm the genes TSPY1 and RBMY1A1 on chromosome der(X)t(X;Y), respectively. In conclusion, these studies identified der(10) case as 46,XX,der(10)dup(10q26).ish del(10)(qter-)(OATX2,FGFR2X2,DOCK1X2), der(15) case was also characterized as 46,XY,der(15)del(15)(q26)dup(15)(q26q21).ish der(15)(PML++,15qter-,THSD4X2,ETFAX2) and 46,X,der(X)t(X;Y) with the presence of the YRRM and TSPY gene to help the understanding the clinical phenotype of each case by breakpoint analyses.

***POLG1* variants and sporadic idiopathic Parkinsons disease.** *D. Burn[1], G. Hudson[2], A. Stutt[1], M. Eccles[3], L. Robinson[3], P. F. Chinnery[1]* 1) Institute for Ageing and Health, Newcastle University, UK; 2) Mitochondrial Research Group, Newcastle University, UK; 3) Institute for Health and Society, Newcastle University, UK.

The prevalence of Parkinsons disease is estimated at ~0.3% of the population. Clinically, PD is homogenous however PD genetics are heterogeneous. PD aetiology is complex, and likely multifactorial, with several biochemical abnormalities relevant to disease onset; including mitochondrial dysfunction, reinforced by the identification of a complex I deficiency in PD brains. Mitochondrial DNA polymerase gamma (*POLG1*) is a nuclear encoded gene required for the synthesis and replication of the mitochondrial genome. Mutations in the gene encoding polg have been reported in a wide range of clinical phenotypes. Genetic variation in *POLG1* could contribute to the etiology of parkinsonism in a number of ways. The absence of a clear family history is common in late-onset medelian disorders, raising the possibility that dominant *POLG1* mutations are responsible for sporadic parkinsonism. Secondly, common POLG1 variants affect polymerase activity, and thus might contribute to the risk of developing sporadic idiopathic PD. We compared 7 previously investigated common POLG1 variants (c.722C>T - P241L; c1174C>G - L392V; c.2165G>A - R722H; c.2492A>G - Y381C and c.3689T>C - S1230F), in addition to seven common alleles, previously described in the UK population, (c.1399G>A- A467T; c.2209G>C - G737R; c.2243G>C - W748S; c.2557C>T - R853W; c.2864A>G - Y955C; c.3248G>A - E1143G and c.3708G>T - Q1236H), as well as the *POLG1* CAG repeat, in 221 community based UK-PD cases to 159 ethnically, gender and age matched controls. Our analysis indicates that common variants within *POLG1* do not contribute to the etiology of PD. We found no association between individual alleles, compound genotypes or the number of *POLG1* substitutions in cases and controls. Rare (CAG)n repeat lengths have been previously associated with, however we found no evidence that (CAG)n repeat lengths are associated with U.K. PD. We conclude that it is unlikely that common genetic variation in *POLG1* is a major contributor to sporadic idiopathic PD.

Histone H3 lysine 27 trimethylation in adult differentiated tissue associated to cancer DNA hypermethylation. *C. Wadelius[1], A. Rada-Iglesias[1, 2], S. Enroth[2], R. Andersson[2], A. Wanders[1], L. Påhlman[3], J. Komorowski[2, 4]* 1) Dept Genetics & Pathology, Uppsala Univ, Uppsala, Sweden; 2) Linnaeus Centre for Bioinformatics, Uppsala University, SE-75124 Uppsala, Sweden; 3) Department of Surgical Sciences, Uppsala University Hospital, SE-75185 Uppsala, Sweden; 4) Interdisciplinary Centre for Mathematical and Computer Modelling, Warsaw University, Poland.

DNA methylation at promoters is a common epigenetic abnormality in cancer which is associated with silencing of the genes. Several recent reports have suggested that the instruction for this methylation is present already in embryonal stem (ES) cells in the form of another epigenetic mark, namely trimethylation of histone 3 at lysine 27 (H3K27me3). We used chromatin immunoprecipitation and detection on promoter arrays (ChIP-chip) to generate H3K27me3 and H3K4me3 profiles for normal colon mucosa from a patient with colon cancer and compared them to similar profiles for ES cells. There was a considerable overlap between genes with H3K27me3 modification in normal colon and ES cells ($p=0$). At the same time the cell identity is present in the histone profiles in colon since the genes marked by H3K4me3 are on average highly to moderately expressed whereas the genes with the H3K27me3 modification are inactive, consistent with previous data. By comparing to a set of genes that are DNA methylated in colon and/or prostate cancer, we found that a significant number of them are marked by H3K27me3 in both normal colon and ES cells. Genes marked by H3K27me3 in ES cells and normal colon are both overrepresented among genes that are DNA-methylated in five common cancers. When dividing 68 genes that are DNA methylated in one or more of these cancers in methylated/unmethylated for each cancer, the H3K27me3 status in normal colon was a good predictor of DNA-methylation in colon cancer ($p=.0003$) but not in other cancer types, whereas H3K27me3 in ES cells could not predict DNA-methylation in any cancer type. This suggests that H3K27me3 pre-marking of genes for cancer DNA hypermethylation is not necessarily restricted to ES or early precursor cells but can occur later in differentiated tissues.

SMS and PTLS mouse models to study effects of genome structural changes on expression. *G. N. S. Ricard[1], J. Chrast[1], N. Gheldof[1], J. Molina[2], S. Pradervand[1], J. R. Lupski[3], K. Walz[2], A. Reymond[1]* 1) Center for Integrative Genomics, Lausanne, Switzerland; 2) Centro de Estudios Cientificos, Valdivia, Chile; 3) Baylor College of Medicine, Houston, TX, USA.

To study the effect of structural changes on expression we assessed gene expression in genomic disorder mouse models. Both a microdeletion and its reciprocal microduplication mapping to the B2 region of murine chromosome 11, which model the rearrangements present in Smith-Magenis (SMS; MIM182290) and Potocki-Lupski (PTLS; MIM610883) syndromes patients, respectively, have been engineered. These models show phenotypic features similar to those identified in human SMS and PTLS patients. Using Affymetrix arrays, we profiled the transcriptome of five different tissues affected in human patients in mice with 1n (Deletion/+), 2n (wild type; +/+), 3n (Duplication/+) and 2n on a single allele (Deletion/Duplication) copies of the same region in an identical genetic background. The most differentially expressed transcripts between the four studied genotypes were ranked. 23 to 28 of the top 100-ranked differentially expressed genes, a highly significant propensity, are mapping to the engineered SMS/PTLS interval in the different tissues. These genes are expressed on average 1.5 fold less and 1.35 fold more in the tissues of the mice carrying the deletion and the duplication, respectively. Interestingly, a statistically significant overrepresentation of the genes mapping to the flanks of the engineered interval was also found in the top 100 and top 500-ranked differentially expressed genes. An effect that extends over more than ten megabases from the breakpoints. Our results obtained on five different tissues suggest that this phenomenon is efficient across multiple cell lineages. We will also discuss the molecular networks that are altered in the different models. This network analysis enables the identification of metabolic pathways that potentially play a function in the SMS/PTLS phenotypes and allows a better comprehension of the roles of the different genes of the interval, in particular Rai1.

Expression of R1, R2 and p53R2 subunits of the ribonucleotide reductase in human and mouse tissues during the perinatal period. *A. Bourdon[1], F. Foufelle[2], I. Hainault[2], P. Ferré[2], A. Munnich[1], A. Rötig[1]* 1) INSERM U781, Hopital Necker, Paris, France; 2) INSERM UMRS872, Centre de Recherche des Cordeliers, Paris, France.

Mitochondrial DNA (mtDNA) depletion is a reduction in mtDNA copy number. We have identified mutations of the p53R2 gene encoding the cytosolic p53-inducible ribonucleotide reductase (RNR) small subunit in patients with mtDNA depletion, demonstrating how cytoplasmic dNTP pools are important for mtDNA replication. RNR is responsible for conversion of NDP into dNDP, essential for DNA synthesis. This enzyme consists of two R1 subunits and two R2 or p53R2 subunits. R2 is expressed only during the S phase but R1 is constantly expressed. p53R2 is present at low level during all the cell cycle. This implies that non proliferative tissues entirely rely on p53R2/R1 complex for dNDP synthesis and mtDNA replication. Patients with p53R2 mutations were normal at birth but then developed hypotonia and tubulopathy and present a severe mtDNA depletion in muscle. In order to investigate this tissue specificity we wonder how the three RNR subunits are regulated. We first observed that R1 and R2 are expressed at high level in various human fetal tissues. At 9 months of age, R1 showed a low expression level whereas R2 was almost undetectable. We have then followed the expression of R1, R2 and p53R2 from 14 days of prenatal development to 30 days after birth in tissues from control mice. We observed a constant and rapid decrease of R2 expression until day 8 after birth, whereas its expression became then very low in brain, liver, heart and kidney. R1 expression slowly decreased but remained significantly expressed after birth. On the contrary, p53R2 was constantly expressed in all tissues at all periods of time but significantly increased in liver and heart after birth. The regulation of RNR has been extensively studied during cell cycle but its expression during development has never been investigated. Our study shows that RNR subunits are differentially expressed in various organs in the perinatal period and this could partially been related to the organ involvement observed in patients with p53R2 mutations.

Genome-wide association study in 2,800 French identifies new susceptibility loci for extreme polygenic obesity. *D. Meyre[1], J. Delplanque[1], S. Lobbens[1], S. Gallina[1], C. Lecoeur[1], S. Visvikis-Siest[2], B. Balkau[3], A. Walley[4], C. Dina[1], P. Froguel[1,4]* 1) CNRS UMR 8090, Lille, France; 2) INSERM CIC 9501, Nancy, France; 3) INSERM U780-IFR69, Villejuif, France; 4) Section of Genomic Medicine, Imperial College, London, UK.

Recently, GWA studies have conferred to FTO and MC4R genes a convincing role in body weight variation. To identify additional susceptibility variants influencing risk of obesity, we analyzed genome wide association data (Illumina Human CNV370 duo) from 2,862 French individuals informative for body mass index (BMI). After discarding 62 individuals having less than 90% of European ancestry, we analyzed three affection binary traits (childhood obesity, adult obesity, pooled childhood / adult obesity) in 685 lean children (BMI Z score: -0.140.97, age: 11.932.27, male: 48.5%), 685 children with extreme familial obesity (BMI Z score: 4.281.24, age: 10.893.27, male: 45.3%), 731 lean adults (BMI: 21.771.87, age: 50.228.19, male: 24.8%) and 695 adults with morbid familial obesity (BMI:47.267.60 , age: 44.1311.97 , male: 21.03%), using both additive, dominant and recessive models. The best association signal was observed in the FTO intron 1 region for risk of pooled childhood and adult obesity under the additive model (rs8050136, P=3.10-13). The association upstream of MC4R gene was also confirmed in our study, again under the additive model (rs12970134, P=8.10-8). We identified 14 independent SNPs showing association with childhood obesity (N=3), adult obesity (N=7) or pooled childhood / adult obesity (N=4) at the genome wide level of significance (P<5.10-7). These SNPs were located in regions not previously associated with obesity. The genotyping of these SNPs is currently underway in 3,239 lean controls, 2,444 moderately obese and 3,178 extremely obese unrelated subjects, in 1,263 obesity-enriched pedigrees and in 10,489 population-based individuals (all of European ancestry), in order to confirm the associations found in WGA stage I. These results suggest that the study of extreme familial forms of disease is useful for the genetic dissection of complex traits.

Mutations of PEO1 gene encoding Twinkle helicase causes mitochondrial DNA depletion. *E. Sarzi[1], S. Goffart[2], D. Chrétien[1], V. Serre[1], A. Slama[3], A. Munnich[1], J. Spelbrink[2], A. Rötig[1]* 1) INSERM U781, Necker Hosp, Paris, France; 2) Institute of Medical Technology and Tampere University Hospital; 3) Laboratoire de Biochimie du Kremlin-Bicêtre.

Twinkle is a mitochondrial 5-3 DNA helicase is important for mitochondrial DNA (mtDNA) maintenance. Twinkle dominant mutations have been reported in progressive external ophthalmoplegia with multiple mtDNA deletions (adPEO) whereas Twinkle recessive mutations are associated with infantile onset spinocerebellar ataxia (IOSCA). It has been previously shown that Twinkle control mtDNA copy number renders Twinkle gene (PEO1) a candidate gene for mtDNA depletion. We selected a series of 10 patients born to consanguineous parents and presenting a severe mtDNA depletion of yet unknown origin. We then studied the segregation of microsatellite markers flanking PEO1 in these patients. Homozygosity of the microsatellite markers was found for two patients of the same family. They presented neonatal lactic acidosis, trunk hypotonia, seizures, cytolysis and cholestasis. A combined defect of complexes I, III and IV of the mitochondrial respiratory chain was found in liver of both patients as well as severe mtDNA depletion (8% of the normal mtDNA content). This prompted us to sequence PEO1 and to identify a homozygous mutation at a conserved position of the protein (T457I). The similarity of Twinkle and GP4D helicase from phage T7 prompted us to model the structure of this human helicase using the X-ray coordinates of the homohexameric GP4D protein as a tertiary template. Interestingly, the point mutation is located in the interface between two monomers of the hexameric enzyme, and can probably induce a local conformational change. During the in vitro validation, we have demonstrated that the T457I mutation leads to a decrease of the helicase activity in relation to a series of control. Then, we have shown that this mutation is responsible for a significant modification of the UTP Twinkle affinity. This work reports the first description of a PEO1 mutation responsible for mtDNA depletion in human.

Re-sequencing of the GRIK2 gene as a candidate gene for bipolar disorder and development of a software utility for search of interesting homozygous stretches in sequence data. *L. Hörnblad[1], R. Karlsson[1], F. J. McMahon[2], S. Paddock[1]* 1) Department of Neuroscience, Karolinska institutet, Stockholm, Sweden; 2) NIMH, NIH, Bethesda, MD.

Bipolar disorder is a severe mood disorder that affects about 1% of the adult population world wide. Symptoms include episodes of severe depression and mania with normal mood variability in between. Bipolar disorder has been shown to be highly heritable (Taylor L et al, 2002). The genetic background appears to be very complex with many different genes involved (Craddock and Jones, 1999). The chromosomal region 6q16.3-22.1 has shown linkage to bipolar affective disorder in single studies (Schultze TG et al, 2004) and meta-analysis (McQueen et al., 2005). One candidate gene located in that region is GRIK2, coding for an ionotropic glutamate receptor, GluR6. As a candidate gene for bipolar disorder, the exons and promoter region of GRIK2 were sequenced in 96 individuals from the NIMH genetics initiative collection diagnosed with bipolar disorder. 37 SNPs or rare variants were found in the GRIK2 gene in our study. Seventeen of the SNPs were known before and were reported in dbSNP. Twenty new SNPs or rare variants were found in our material. An additional 6 SNPs, previously reported to be located within the sequenced regions of the GRIK2 gene, were not found in our sample. Sequencing results may not reveal the presence of large heterozygous deletions of genomic sequence, since sequences from the other DNA strand do not show any abnormalities. However, such deletions lead to the presence of homozygous stretches of polymorphic markers within the deleted region. We have developed a software program that enables automatic search for long, homozygous stretches based on sequence data. The program takes into account local linkage disequilibrium (either based on the sequence data or public databases) and gives the user the option to specify several parameters such as definition of haplotype blocks and marker frequency cut-offs. We have identified two individuals with large stretches of homozygous markers, which are currently followed up by dense SNP genotyping.

Molecular determinants of Mammographic Density. *f. Odefrey[1], m. Southey[1], j. Stone[2], c. Apicella[2], s. Treloar[3], j. Hopper[2]* 1) department of pathology, university of Melbourne, Melbourne, VIC, Australia; 2) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The University of Melbourne, VIC, Australia; 3) Centre for Military and Veterans Health, The University of Queensland, Herston Road, Herston QLD,Australia.

Mammograms have been used for decades for the detection of breast cancer (BC). This radiographic representation of the breast usually includes light/white areas (also called dense area, corresponding to the epithelial/stroma tissue) and non-dense (radiographically dark) area recognized as fat tissue (adipocytes) (Boyd et al. 1998). Mammographic Density (MD) has been shown to be associated with BC risk. A high percentage of MD (dense area as a proportion of total area of the breast) and a high absolute area MD are associated with an inter-quintile BC risk of about 4-fold (Boyd et al.,1998; Boyd et al.,2005).Twin studies have suggested that MD is highly heritable (Boyd et al., 2002). About 60% of the population variation in age-adjusted MD may be due to as yet unknown genetic variants. One approach to the investigation of the genetic determinants of MD has been to utilize the results of recent BC genome wide association studies (GWAS) that have identified common SNPs in or near several genes or loci (e.g. FGFR2, TNRC, MAP3K1, LSP1, H19 and 8q) that are associated with very small differences in BC risk (<10% per allele) and explain4% of the presumed population polygenic variance and a similarly small proportion of the population familial risk (Easton et al., 2007; Hunter et al., 2007). Given the relationship between BC and MD one or more of these common BC susceptibility variants could explain some of the variation in dense area, especially those suggesting a biological plausibility, such as FGFR2 which is involved in stroma development. We have genotyped the 7 SNPs that were the most strongly correlated with BC in the BCAC study (Easton et al., 2007). We used the Australian Twins and Sisters Mammographic Density Study (ATSMDS) which collected blood samples and mammograms for approximately 3000 Australian women (600 of whom are from monozygotic twin pairs). We will present the results of our investigation.

Search for genomic regions and genes within these regions possibly involved in MMR-related cancer. *H. Westers, P. van der Vlies, P. Jager, R. Sijmons, R. Hofstra* Genetics, University Medical Center Groningen, University of Groningen, P.O. box 30.001, 9700 RB, Groningen, the Netherlands.

Lynch syndrome is an autosomal dominantly inherited disorder that is the most common cause of hereditary colorectal cancer. It is well-established that germline mutations in the mismatch repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2* cause Lynch syndrome. Although microsatellite instability (MSI-H), a hallmark for mismatch repair deficiency, is a common feature in tumours from families clinically fulfilling the Amsterdam criteria for Lynch syndrome, mutations in the mismatch repair genes account for only 50 % of these Lynch syndrome families. In those families that do not fulfil the Amsterdam criteria but that do fulfil the less strict Bethesda criteria, only 20 % of the families have a pathogenic mutation. Our studies focus on the identification of genes that might explain the yet unsolved cases. Our database in which study data on Lynch Syndrome (suspected) families were collected consists of 132 HNPCC-suspected patients with one or more MSI-H tumours. 94 of these patients did not have a mutation in the three major MMR genes, *MLH1*, *MSH2*, and *MSH6*. Immunohistochemical (IHC) screening was performed and 32 of these patients had normal immunohistochemistry stainings for the proteins encoded by these genes. From these patients DNA was isolated from paraffin-embedded tumour tissue material (when available) for array CGH experiments. Hybridisations were performed on home-made BAC arrays and 105k Agilent arrays. The array CGH data that were obtained so far were analysed with NEXUS CGH software, which is a tool for the analysis of array CGH-based data from multi-array experiments supporting any platform. Some copy number changes were detected at chromosomes 3p (deletions), 8p (deletions), 8q (duplications), and 20q (duplications). Data on genes within these regions possibly involved in MMR-related cancer will be presented.

Complete sequencing of the coding region of the CFTR gene using the new generation GS-FLX sequencing technology. *H. Cuppens, L. Vliegen, J.-J. Cassiman* Center for Human Genetics, KULeuven, Leuven, Belgium.

The CFTR test is most probably the most common used genetic test in the Caucasian population. Given the heterogeneity of CFTR mutations, the sensitivity of the current mutation-specific CFTR tests mostly not exceeds 88-92%. A negative DNA test result does not guarantee absence of a mutation, which is especially of high relevance in the CFTR mutation screening programs that have been introduced. Only with sequencing, a 100% mutation detection rate is obtained in DNA fragments that are analyzed. This used to be too expensive. Sequencing costs, however, are going down through the introduction of next-generation sequencing technologies. Next-generation sequencing technology, such as picotiter pyrosequencing on a GS-FLX system, was initially developed for whole genome sequencing purposes. We have adopted this technology for complete sequence analysis of the CFTR coding region, and its exon/intron junctions. To this aim we have developed a robust multiplex amplification assay in which biotinylated amplicon-specific primers are locally restricted through streptavidin/biotin crosslinking. Indeed, 30 amplicons should be analyzed for the CFTR gene, and this can be only economically feasible if all amplicons are amplified in one, or a limited number, of PCR multiplex reaction(s). For a 50x coverage, only half a million nucleotides are needed for CFTR sequence analysis, i.e. 0.5% of the full capacity of the GS-FLX system. Therefore, 100-200 samples should be pooled in order to use the full capacity of the GS-FLX system. We therefore also developed an economically feasible universal sample tagging approach allowing the pooling of 100 samples with one set of 260 primers (60 CFTR amplicon-specific primers and 200 tagging primers). This compares to 6000 primers if amplicon-specific PCR primers are tagged as such. This assay now allows us sequencing of the CFTR gene in an economically feasible way, obtaining a mutation detection rate of 100%, with the potential of becoming the CFTR genetic test.

Oligonucleotide DNA microarray profiling of lung cancer revealed vasoactive peptide receptor 1 and osteopontin as potential biomarkers. *V. Mlakar[1], M. Strazisar[1], M. Sok[2], D. Glavac[1]* 1) Department of Molecular Genetics, Faculty of Medicine, Institute of Pathology, University of Ljubljana, Korytkova 2, 1000 Ljubljana, Slovenia; 2) University Medical Centre Ljubljana, Clinical Department for Thoracic Surgery, Zaloska cesta 2, 1000 Ljubljana, Slovenia.

Despite extensive research on lung adenocarcinoma (AD) using different DNA microarray platforms, recent evidence shows that the majority of genes involved in its development are still unknown, thus showing that the search for genes involved in lung carcinogenesis needs to continue in order to understand events leading to lung cancer development. The purpose of this study is to find novel gene(s) involved in the development of ADs using an oligonucleotide based DNA microarray platform with a selected set of genes. In order to analyse expression profile and expression of VIPR1 and SPP1 gene on 19 ADs and 5 squamous cell lung cancers (SCLC) microarrays and real time PCR were used. Moreover, real time PCR was used to assess gene copy number of the VIPR1 gene in all 24 samples. 31 up-regulated and 8 down-regulated genes were identified. Up-regulation of the SPP1 gene and down-regulation of the VIPR1 gene was confirmed using real time. We describe losses and gains of the VIPR1 gene in 6 and 3 ADs, respectively, and loss of the VIPR1 gene in 2 SCLCs. No correlation was observed between the histological status of ADs and the copy number of the VIPR1 gene. Samples with 1 and 3 copies of the VIPR1 gene had 2,2 times less and 15 times more VIPR1 mRNA than normal copy samples, respectively. No significant change was observed due to high variation of expression within 3 groups. We found reverse correlation between SPP1 and VIPR1 expression. Down-regulation of VIPR1 gene in ADs and SCLCs corroborates with its proposed tumour suppressor role. This observation is also supported by reverse association with SPP1. No association between changes in expression or copy number of VIPR1 gene with histological data shows that both, changes in expression and copy number, must occur early in AD development. The high variation in VIPR1 mRNA amounts also suggests that VIPR1 gene is extensively regulated.

Follow-up analysis of two independent genome-wide association studies of bipolar disorder provides evidence for *JAM3* as a susceptibility gene. *T. W. Muehleisen[1], J. Vollmer[1], S. Herms[1], M. Mattheisen[1], A. E. Baum[2], F. J. McMahon[2], C. C. Diaconu[3], M. Grigoroiu-Serbanescu[4], G. Babadjanova[5], V. Krasnov[6], R. Abou Jamra[7], J. Schumacher[2,7], R. Breuer[8], S. Witt[8], A. Georgi[8], T. G. Schulze[2,8], P. Propping[7], M. Rietschel[8], M. M. Nöthen[1,7], S. Cichon[1,7]* 1) Dept Genomics, Life & Brain Ctr, Univ Bonn, Bonn, Germany; 2) National Inst Mental Health, Bethesda, USA; 3) Stefan Nicolau Inst Virology, Bucharest, Romania; 4) Alexandru Obregia Psychiatric Hospital, Bucharest, Romania; 5) Russian State Medical Univ, Moscow, Russia; 6) Moscow Research Inst Psychiatry, Moscow, Russia; 7) Inst Hum Genet, Univ Bonn, Bonn, Germany; 8) Dept Genet Epidemiol in Psychiatry, Central Inst Mental Health, Mannheim, Germany.

The first two genome-wide association studies of bipolar disorder (BD) applied different approaches: Baum *et al*. (2007) analysed DNA pools from US-American and German samples on Illumina HH550 arrays and reported consistent findings between both samples; the Wellcome Trust Case Control Consortium (WTCCC, 2007) employed individual genotyping in a UK patient-control sample on Affymetrix 500K arrays. Here, we aimed to (1) identify genes that showed evidence for association in both studies, (2) individually genotype Affymetrix SNPs from these genes in our German sample, which was part of Baum *et al*., to make the results comparable, and (3) follow-up promising SNPs in independent BD samples. A gene-based comparison of both studies resulted in 9 genes with overlapping signals. From these genes, we selected 21 Affymetrix SNPs and individually genotyped them in the German sample (691 patients, 944 controls) and in an independent Russian sample (212 patients, 179 controls). We found that SNPs in *JAM3* (*junctional adhesion molecule 3*) were significantly associated with BD in both samples (best *P* value=1.95E-03). In summary, genetic variation in *JAM3* shows consistent association with BD in three independent samples (Baum et al, WTCCC, Russian) and can therefore be regarded as a very promising susceptibility gene for BD. To further strengthen our findings, we are currently testing *JAM3* SNPs in additional independent BD samples.

Integrating methods for detecting copy number variations in Han Chinese population. *T. P. Chuang[1], H. C. Yang[2], Y. J. Shih[1], J. Y. Wu[1], Y. T. Chen[1], L. H. Li[1]* 1) IBMS, Academia Sinica, 128 Sec. 2, Academia Rd. Nankang, Taipei 115, Taiwan; 2) ISS, Academia Sinica, 128 Sec. 2, Academia Rd. Nankang, Taipei 115, Taiwan.

After human genome was decoded, the idea that genomes between two individuals are similar has been challenged by more and more discoveries on genomic variations. Among all types of genomic variations, copy number variation (CNV) gets more and more attention in the post-genome era because of its potentiality in influencing gene expression, and thus susceptibility to diseases. Up to present, most reports of CNV study with large sample size are based on Caucasian and African populations. Since some genomic variations are ethnic specific and a large proportion of CNVs are at low frequency, it is necessary to identify CNVs in Han Chinese population with a large sample size. Here, we reported the construction of a fine-scale CNV map for Han Chinese residing in Taiwan. In this study, genomic DNA was isolated from EBV transformed B cell lines established from 390 unrelated healthy individuals. Subsequently, the DNA was genotyped by using Affymetrix GeneChip Human Mapping 500K Array Set. Intensity data was processed by using Partek Genomic Suite to detect copy number alterations. Moreover, regions with allelic imbalance (AI) resulted from long contiguous stretch of homozygosity (LCSH), deletion, or amplification were identified using Microarray Pooled DNA Analyzer (MPDA). A total of 2292 common autosomal CNV regions (CNVRs) were identified in the 390 individuals; among them, 865 were unique in Han Chinese. 257 out of the 865 (29.71%) CNVRs are 10kb, 497(57.46%) 10kb and 50kb, 97(11.21%) 50kb and 100kb, and 14(1.62%) 100kb. Collectively, 248 Han-Chinese unique CNVRs were deletion type, 463 were amplification type, and 154 possessed deletion and duplication at the same locus. Our preliminary results showed that 14 out of 16 tested regions were true positive while 2 were false positive. Intriguingly, in addition to autosomal CNVs, we observed whole chromosome gain or loss of chromosome X in some female subjects by copy number analysis. Whether this unexpected observation is biologically relevant or it is resulted from cell culture artifact will be further investigated.

Oligonucleotide array-based comparative genomic hybridization (CGH) analysis of MNS antigen genes of donors with rare phenotypes. *Y. Suto[1], H. Tsuneyama[2], M. Hirai[3], K. Ogasawara[1], M. Uchikawa[2], H. Okazaki[1], K. Tadokoro[1]*
1) Research and Development, Japanese Red Cross Central Blood Institute, Tokyo, Japan; 2) Japanese Red Cross Tokyo Metropolitan Blood Center, Tokyo, Japan; 3) IREIIMS, Tokyo Women's Medical University, Tokyo, Japan.

[Summary] This is the first report of a rare individual showing a heterozygous genotype of *En*/*MiV* analyzed by array-based comparative genomic hybridization (CGH) technique. [Purpose] The MNS blood group system consists of more than 40 distinct antigens. These antigens are carried on glycophorin A, glycophorin B or hybrid proteins that arise from rearrangements within the *GYP* gene family, *GYPA*, *GYPB* and *GYPE*. These genes are located on chromosome 4q31.2 and share over 95% sequence identity. In this study, we applied array-based CGH for donors with rare phenotypes of En^{a}FR-. [Methods] By serological screening of rare blood type donors at our center, a donor [A] showing M+N-S+s+Hil+, two donors [B] and [C] showing En(a-) and eight normal donors were selected. CGH analysis was performed using their lymphocyte DNA, 244K Human Genome CGH microarray and CGH Analytics (ver.9.5)(Agilent Technologies). Further analysis using a high-density custom CGH microarray covering the whole region of 5-*GYPA*-*GYPB*-*GYPE*-3 (Agilent Technologies) was performed. The result was confirmed by sequencing the genomic DNA and cDNA derived from reticulocyte mRNA of donors using appropriate primer sets. [Results and discussions] By high-resolution CGH analysis of the donor [A], a 95-kb deletion including 3-part of *GYPA* and the intergenic region between *GYPA* and *GYPB* was found. There was a partial loss of *GYPB*, whereas no loss was detected in *GYPE*. In the donors [B] and [C], a 104-kb deletion including intron 1 to exon 7 of *GYPA* and the intergenic region was detected. No distinct loss was detected in their *GYPB* and *GYPE* genes. Genotype of the donor [A] was suggested to be heterozygous for *En* and *MiV* (*GYPA/B* fusion gene for Hil+ phenotype). It was confirmed by DNA sequencing for the donor [A], where a normal *GYPB* and the fusion gene were identified. Breakpoints were suggested to lie within intron 3 of *GYPA* and its homologous region in intron 2 of *GYPB*.

Detection of genomic copy number changes in Estonian patients with mental retardation by SNP genotyping microarrays. *A. Kurg[1], K. Männik[1], O. Zilina[1], H. Puusepp[1,2], S. Parkel[1], P. Palta[1], A. Veidenberg[1], K. Õunap[2,3]* 1) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 2) Pediatrics Dept, University of Tartu, Tartu, Estonia; 3) Medical Genetics Centre, United Laboratories, Tartu University Hospital, Tartu, Estonia.

Mental retardation (MR) is a highly heterogeneous condition with a prevalence of ~1-3%. Despite extensive investigations the underlying reason remains unknown in about half of the cases. It was established that in up to 30% of the patients MR may be caused by changes in chromosomal structure. We started the first comprehensive study in Estonia in order to find out causative factors in families with idiopathic MR and help to shed light on molecular mechanisms underlying MR. To date, we collected more than 220 DNA samples from MR patients with normal karyotypes and their unaffected family members. Infinium-2 whole-genome genotyping assay with Human370CNV-Duo BeadChips (Illumina Inc.) was applied for detection of DNA copy number changes. Acquired data were analyzed using BeadStudio v3.1 (Illumina Inc) and QuantiSNP (Colella et al 2007) software. Relevant results were confirmed by RT-qPCR or FISH. To maintain the information an ad hoc database was developed allowing to integrate and manage the phenotype-related data and genomic profiles in order to distinguish genomic alterations with possible clinical significance. So far, first 115 individuals from 29 families were screened. About 20 DNA copy number changes per individual were detected, most of which are reported in the Database of Genomic Variants or present recurrently in our samples. In six families, possible disease-related imbalances were found: 3.9Mb del(15)(q13.1q13.2), 8.3Mb del(7)(q31.1q32.1), 3.9Mb del(2)(q37.1), 1.6Mb dup(X)(p22.31), 1.4Mb dup(7)(q11.23), 4.5Mb dup(11)(q24.3-q25) and 3.9Mb del(12)(p13.33-13.32) (the last two aberrations were found in the same patient). The detected rearrangements were not present in unaffected family members. Cases with similar phenotypes and aberration(s) in the overlapping regions are also reported in the DECIPHER database. Involvement of these aberrations in the etiology of MR is currently under investigation.

Rearrangement breakpoints of PARK2 and DMD are clustered and randomly distributed at the common fragile site, FRA6E and FRAXC, respectively. *J. Mitsui[1], Y. Takahashi[1], H. Tomiyama[2], S. Ishikawa[3], H. Yoshino[2], J. Goto[1], H. Aburatani[3], D. Smith[4], A. Brice[5], I. Nishino[6], N. Hattori[2], S. Tsuji[1]* 1) Dept of Neurology, Tokyo University, Japan; 2) Dept of Neurology, Juntendo University, Japan; 3) Research Center for Advanced Science and Technology, Tokyo University, Japan; 4) Dept of Laboratory Medicine and Pathology, Mayo Clinic Cancer Center, US; 5) Federal Institute for Neuroscience Research, Pitié-Salpêtrière Hospital, France; 6) National Center of Neurology and Psychiatry, Japan.

Background: Gross rearrangements in PARK2 and DMD have been frequently observed not only in germlines (patients with AR-JP and DMD/BMD) but also in cancer cell lines, but the genomic structure prone to rearrangements underling above observations have been poorly understood. Methods: We designed two high density microarrays to cover the entire PARK2 and DMD, which enable identification of rearrangement. The high resolution of the microarray enables design of PCR primers flanking the rearrangements. We conducted array CGH analyses on the 230 AR-JP cases and 120 cancer cell lines employing the microarrays for PARK2, and 144 DMD/BMD cases employing the microarrays for DMD. Results: We identified 162 breakpoints in 230 AR-JP patients and 32 breakpoints in 120 cancer cell lines. We also identified 135 breakpoints in 144 DMD/BMD patients. Interestingly most of the breakpoints are different, suggesting that these rearrangements have occurred independently. The rearrangement breakpoints of PARK2 are clustered and randomly distributed at the center of the common fragile site (CFS), FRA6E. In addition, the rearrangement breakpoints of DMD are also clustered and randomly distributed within the region of the FRAXC. Interpretations: Although several lines of evidences have demonstrated that CFS holds associations with somatic cell rearrangements in cancers, CFS has rarely drawn attention as genomic structures associated with germline rearrangements. Our observations, however, suggest that chromosomal instability associated with FRA6E and FRAXC play an important role in in vivo rearrangements not only in somatic cells but also in germinal cells.

Mutation analysis of exons coding transmembrane and intracellular part of Notch3 protein in patients with cerebral angiopathy different from CADASIL. *H. Vlaskova[1], M. Bouckova[1], L. Dvorakova[1], M. Hrebicek[1], R. Matej[2], M. Elleder[1]* 1) Institute of Inherited Metabolic Disorders, 1st Faculty of Medicine and University Hospital, Charles University, Prague, Czech Republic; 2) Czech National Reference Laboratory of Transmissible Encephalopathies and Creutzfeldt-Jakob disease, University Thomayer Hospital, Prague, Czech Republic.

CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy, OMIM 125310) is an inherited small vessel disease causing migraine, early strokes, cognitive impairment and premature death. The hereditary angiopathy is caused by mutations in NOTCH3 gene located at 19p13.2-p13.1. The mutations regularly result either in a gain or loss of cysteine residues in the EGF-like repeats in the extracellular amino-terminal region of Notch3 protein. Recently, a mutation was identified in the intracellular part in patient with small vessel disease (Fouillade et al., 2008). We have examined 20 probands with clinical suspicion of CADASIL and 18 family members by DNA analysis of the region encoding the extracellular part of Notch3 (23 exons). We have found the heterozygosity for cysteine changing mutations in six probands: p.C144F, p.R182C, p.Y189C, p.G296C (this mutation is novel), p.R332C and p.R421C. In other proband, there was a different missense mutation - p.V644D. This mutation was analysed by predictive programs as a non tolerated substitution. Inspection of other family members and segregation of p.V644D with phenotype would futher support our suggestion that the mutation is deleterious. Mutations in the extracellular part have not been identified in thirteen probands. In these patients we analysed mutations in the region encoding the transmembrane and intracellular part of Notch3 protein. We have found no pathologic variation as yet, but we identified 10 previously published SNPs. This early result supports hypothesis that pathogenic mutations in these parts of Notch3 protein are not common in patients with small vessel disease. Support: VZ MSM CR 0021620806, VZ MZ CR 64165.

Medical management patterns differ between physician specialties engaged in the care of patients with Hunter syndrome (MPS II). *G. Cohn* Shire HGT, Cambridge, MA.

Hunter syndrome is an X-linked inborn error of glycosaminoglycan metabolism caused by a deficiency in the activity of the lysosomal enzyme, iduronate-2-sulfatase. Multiple organs and systems are adversely affected in MPS II, and thus the management and treatment of patients is often provided by multiple specialists (eg, pediatricians, medical geneticists, pulmonologists). This study was conducted to determine whether medical management differs between various specialists engaged in the management of individuals affected with Hunter syndrome. Methods:The Awareness, Trial and Usage Study was a market research survey commissioned by Shire Human Genetic Therapies, Inc. to develop a greater understanding of the management and treatment of Hunter syndrome, including the use of enzyme replacement therapy (ERT). Physicians engaged in the medical management of Hunter syndrome in the US were surveyed regarding their practice specialty, the number of MPS II patients managed, whether ERT had been discussed or recommended, and what surveillance strategies they used for patients receiving ERT. Results: Seventy-five physicians managing a total of 244 MPS II patients responded. Among those surveyed, physicians identified themselves as pediatricians (P) (47%), medical geneticists (MG) (44%), or other (O) (9%). The percentage of physicians that did not discus the option of ERT varied by specialty (P 37%, O 14%, MG 9%, ^{2} =7.93, P = 0.02). Furthermore, a significant difference in the reported use of abdominal measurement (A) and echocardiography (E) for the surveillance of patients prescribed ERT was observed between MG and P (A: MG 75%, P 33%, ^{2}=5.43, P=0.02; E: MG 81%, P 46%, ^{2}=4.04, P=0.04). Conclusions: The medical management of Hunter syndrome appears to differ between various medical specialties, as do surveillance strategies for patients receiving ERT. Where appropriate, consensus should be sought on management strategies for MPS II patients. Practice guidelines developed by the various medical specialties involved in the management of MPS II may be helpful in encouraging greater uniformity and consistency in the care of individuals with Hunter syndrome.

New target genes for microsatellite instable endometrial tumors. *A. M. Monteiro Ferreira[1,5], F. Gerbens[1], H. Westers[1], K. Kooi[1], K. Bos[1], C. Esendam[1], T. van der Sluis[2], M. Zazula[4], J. Stachura[4], A. G. van der Zee[3], R. Seruca[5], H. Hollema[2], R. M. W. Hofstra[1]* 1) Department of Genetics, University Medical Center Groningen, Netherlands; 2) Department of Pathology, University Medical Center Groningen, Netherlands; 3) Department of Gynecology, University Medical Center Groningen, Netherlands; 4) Department of Patomorfology, Medical College, Jagiellonian University, Poland; 5) Institute of Molecular Pathology and Immunology of the University of Porto, Portugal.

Endometrial carcinoma (EC) is the most common extra colonic cancer in Lynch syndrome. This syndrome is characterized by functional inactivation of mismatch repair (MMR) genes. MMR deficiency leads to an accumulation of mutations at microsatellites, leading to a phenotype known as microsatellite instability (MSI-H). Genes containing microsatellites are therefore frequent targets of mutations in tumors with MMR deficiency. Previous studies show that the profile of affected target genes differs between MSI-H EC and colorectal tumors (CRC), and that important target genes remain to be found. The aim of this study was to identify new target genes for MSI-H EC. 20K expression microarrays were used to select a total of 2338 genes highly expressed in normal endometrial tissue, which were then screened for repeats in their coding sequence. 574 repeats (in 432 genes) were sequenced in 40 MSI-H EC samples. Mutations were found in 47 genes and mutation frequencies equal or higher than 15% were found in 7 of those genes. Surprisingly, none of these has been previously reported either in MSI-H EC or CRC. Our list includes genes encoding proteins with various functions in the cell, such as a docking protein, methylation-related proteins and tyrosine-kinases. Interestingly, the second gene on the top list, with a 33% mutation frequency is a gene encoding a known co-repressor protein of the estrogen-receptor pathway. Functional studies are being done at our group and have to prove how these genes are involved in EC development. However, we believe that our results give new insights in EC development and might prove helpful in developing (new) EC therapeutics.

Identification of a novel PRPF31 mutation in a multiplex family segregating retinitis pigmentosa (RP) with highly incomplete penetrance. *J.-M. Rozet[1], N. Delphin[1], A. Munnich[1], J.-L. Dufier[2], O. Roche[2], J. Kaplan[1]* 1) Genetics, INSERM U781 & Université Descartes, Paris, France; 2) Dpt Ophthalmology, Hôpital des Enfants Malades, Paris, France.

Retinitis pigmentosa (RP) are the most common inherited retinal dystrophies. They are widely genetically and clinically heterogeneous. We report here the genetic study of a 13 year-old girl presenting with night blindness and an annular scotoma. While her visual acuity was strictly normal, these symptoms suggested the diagnosis of RP. Her maternal first-cousin, a 21 year-old male, was reported to be affected with RP since the age of nine. Besides, her maternal uncle and a first cousin of the maternal grand-mother were known to be affected with RP. The aim of the present study was to identify the disease gene in this family segregating RP with uncertain mode of inheritance. We first considered X-linked transmission but no linkage was found at the RP2, RP3 and RP24 loci, respectively. Besides, the mother of the proband and the mother of her first-cousin did not complain of visual dysfunction and had normal ERGs while that of their respective child were close to extinction. The lack of visual dysfunction, the absence of refraction errors and the normality of ERG recordings in the mothers prompted us to exclude the X-linked transmission. Subsequently, we considered the autosomal dominant transmission of the disease with incomplete penetrance and the involvement of the PRPF31 gene. Indirect studies at the RP11 locus were compatible with this hypothesis and the direct sequencing of the gene revealed the segregation of a novel missense mutation in all affected and some unaffected members of the family. Interestingly, the segregation of the second PRPF31 allele in individuals harbouring the mutation suggests the existence of a PRPF31 trans-element acting as a modifier of the phenotype. This hypothesis will be studied by examining the expression of the second PRPF31 allele.

Preliminary Results of a Phase 2 Clinical Trial of Genz-112638 in Patients with Type 1 Gaucher Disease. *N. Watman[1], E. Lukina[2], E. A. Arreguin[3], M. Banikazemi[4], M. Iastrebner[5], H. Rosenbaum[6], A. Zimran[7], F. O'Brien[8], S. E. Smith[8], A. C. Puga[8], J. Peterschmitt[8]* 1) Hospital Ramos Mejia, Buenos Aires, Urquiza, Argentina; 2) Hematology Research Center of Russian Academy of Medical Sciences, Moscow, Russia; 3) 2Hematology Research Center of Russian Academy of Medical Sciences, Moscow, Russia; 4) NYU, New York, USA; 5) Instituto Argentino de Diagnostico y Tratamiento, Buenos Aires, Argentina; 6) Rambam Medical Center, Haifa, Israel; 7) Shaare Zedek Medical Center, Jerusalem, Israel; 8) Genzyme Corporation, Cambridge, USA.

Introduction: Genz-112638, an investigational compound, is a novel oral small molecule inhibitor of glucosylceramide synthase being developed for the treatment of Gaucher disease type 1 (GD1). Objective: To assess the efficacy, safety, and pharmacokinetics of Genz-112638 in patients with GD1. Methods: An ongoing open-label Phase 2 clinical trial of Genz-112638 (50 or 100mg bid orally) enrolled patients with GD1 in Israel, North America, Russia, and South America. The main efficacy endpoints of the study were changes in hemoglobin level, platelet count, and spleen volume after 52 weeks. An extension study will follow. Results: Data were available for up to 21 and 13 patients receiving Genz-112638 at 26 and 52 weeks, respectively. All 9 males and 12 females (age range: 18-55y) were Caucasian. Four were of Ashkenazi Jewish and 1 was of Hispanic descent. At 26 and 52 weeks mean hemoglobin increased by 0.9g/dL and 1.3g/dL, respectively; mean platelet count increased by 18% and 34%; mean spleen volume decreased by 27% and 40%; mean liver volume decreased by 7% and 14%; mean chitotriosidase activity decreased by 30% and 50%. Plasma glucosylceramide levels normalized in all patients. Seven related adverse events were reported in 6 patients and all were mild and transient in nature. Conclusions: Initial observations suggest that Genz-112638 may represent a safe, effective, and convenient oral therapy for patients with GD1. Clinical development of Genz-112638 will proceed in ongoing and additional clinical trials.

Mavlonic Aciduria in a Child Featuring Hepatic Fibrosis and Novel Mevalonate Kinase Mutations. *Y. Anikster, N. Goldstein, M. Harel-Meir* Metabolic Disease Unit, Safra Children's Hosp, Tel-Hashomer, Israel.

Mevalonic aciduria (MVA, OMIM# 610377) is a rare inborn error of isoprene biosynthesis featuring recurrent attacks of fever, developmental delay, ataxia, dysmorphic features, failure to thrive, cataracts, and retinal dystrophy. Mutations in the mevalonate kinase (*MVK*) gene responsible for MVA, also account for Hyper Immunoglobulin D syndrome (HIDS), an autosomal recessive periodic fever syndrome. Most cases of HIDS and MVA have been described in patients of western European ancestry, mostly Dutch or French. The following report details a Palestinian patient diagnosed with MVA. This patient presented with some of the typical signs and symptoms of MVA including hepatosplenomegaly, recurrent fevers, and a developmental delay, as well as with scantly described phenotypic features such as hepatic fibrosis. Sharing clinical features of both MVA and HIDS, this patient emphasizes the phenotypic continuum of these two entities. Molecular analysis of this patient's DNA revealed a unique newly reported genotype - compound heterozigousity to V8F (t25a), and F38I (t112a). Although *MVK* gene mutations have been previously described in a Palestinian HIDS patient, this to our knowledge is the first report of MVA in a patient of Palestinian descent, and the first MVA patient to be described in Israel.This case emphasizes that MVA must be included in the differential diagnosis of hepatic fibrosis.

Characterizing genetic variants predisposing to MS in a Finnish sub-isolate. *V. Leppa[1], E. Jakkula[1,2], J. Saarela[1], S. Kallio[1], P. Tienari[3], K. Koivisto[4], S. Purcell[2,5], A. Palotie[1,2,6], M. J. Daly[2,5], L. Peltonen[1,2,6]* 1) Institute of Molecular Medicine (FIMM), National Public Health Institute and Univ of Helsinki, Helsinki, Finland; 2) The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Dept. of Neurology, Helsinki Univ. Central Hospital, Helsinki, Finland; 4) Central Hospital of Seinäjoki, Seinäjoki, Finland; 5) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA; 6) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Prevalence of multiple sclerosis (MS) in the Southern Ostrobotnia region of Finland with a limited number of founders is two fold compared to the rest of Finland. We used genealogical information reaching up to 15 generations back to construct two regional megapedigrees. We hypothesize that one or more relatively penetrant variants predisposing to MS may be regionally enriched and shared haplotype analysis can be used to identify MS loci using a genome wide, high density SNP screen. 72 MS cases and 68 controls from Southern Ostrobotnia were genotyped using the Illumina 317K HumanHap panel. A five SNP sliding window haplotype analysis was used and 46 regions were found to be associated with p-value 10^{-4}. These haplotypes were then extended to putative recombination hotspots and their frequencies estimated in two additional control groups (regional and general population, n= 175/466). Twenty-one of these regions were found to have at least 10% haplotype frequency difference between the MS cases and all three control groups and were further analyzed in an independent sample set from the high-risk region (n= 125/MS and 360/controls). Six of the regions (1p32, 1q25.3, 3p14.2, 5p13.1, 6p21, 17q11.2) showed association ($p=10^{-2}$-10^{-6}) in the independent replication set, including the HLA-DRB1. We are currently evaluating the role of the identified risk alleles in MS susceptibility of the general population in 700 MS cases and 700 controls. This approach offers a complementary strategy to large scale GWAs and should provide insight to putatively more penetrant risk alleles enriched in special populations.

Role of DNA copy number variation in susceptibility to childhood cancer. *A. Shlien[1,2], U. Tabori[1,3,5], C. R. Marshall[1,4], M. Pienkowska[1], L. Feuk[1,4], A. Novokmet[1,5], S. Nanda[5], H. Druker[5], S. W. Scherer[1,4], D. Malkin[1,2,3,5]* 1) Genetics & Genome Biol; 2) Medical Biophysics; 3) Pediatrics; 4) Centre for Applied Genomics; 5) Hematology/Oncology, Hospital for Sick Children, Canada.

DNA copy number variations (CNVs) are a significant form of inter-individual genetic variation, affecting more than 10% of the human genome. The size and plasticity of CNV regions makes them particularly intriguing to the study of cancer, yet their potential as genetic risk factors to cancer predisposition has not been explored. Li-Fraumeni syndrome (LFS) is an autosomal dominantly inherited disorder associated with germline mutations of TP53 which is characterized by an increased risk of early-onset breast cancer, sarcomas, brain tumors and other neoplasms. LFS is clinically and genetically heterogeneous and TP53 mutational status alone does not explain the variable phenotype in these families. As part of a wider study of CNVs and cancer, we conducted a genome-wide profile of germline CNVs in LFS families. We examined genomic DNA from a large healthy population (n=770) and an LFS cohort using high-density arrays and show that the number of CNVs per genome is well-conserved in the healthy population, but noticeably increased in cancer-prone individuals. This represents a significant increase in CNVs among carriers of germline TP53 mutations with a familial cancer history ($p=0.01$). Further, our data suggests an association between the number of CNVs and the severity of the phenotype in these cancer-prone families. Refined mapping of these regions in pediatric cancer patient blood and tumor have led to the observation that CNVs are fertile ground on which larger somatic chromosomal deletions and duplications can develop in cancer cells. We continue to examine the mechanisms by which specific germline CNVs can inform the more dramatic chromosomal changes of TP53-related tumors. Our results suggest that examining CNVs in families predisposed to cancer may identify individuals with an abnormally high number of these events and provide insight into the earliest genomic alterations associated with the human carcinogenic process.

Cleidocranial Dysplasia RUNX2 R225Q Mutation Alters Dental Cell Gene Profile. *J. Dong[1], I. Gay[1], S. Chen[2], M. MacDougall[1]* 1) University of Alabama at Birmingham, School of Dentistry, Institute of Oral Health Research, Birmingham, AL; 2) University of Texas Health Science Center at San Antonio, Dental School, San Antonio, Texas.

Cleidocranial Dysplasia (CCD, MIM 119600) is an autosomal dominant condition that affects skeletal and tooth development characterized by clavicular hypoplasia, short stature, supernumerary teeth, and delayed tooth eruption. Mutations in the transcription factor RUNX2 (also known as CBFA1) have been shown to cause CCD. In this study we analyzed the potential consequences of a recurrent RUNX2 R225Q mutation in dental cells obtained from a CCD family seen in our dental clinic. Supernumerary teeth extracted for clinical reasons were used to establish primary periodontal ligament (PDLR225Q) cell cultures for analysis of RUNX2 cellular localization and gene expression profiles. Extracted CCD supernumerary teeth were obtained, PDL cells were isolated and primary cells were established. PDLR225Q cells as well as age/gender matched controls (PDLR225) were grown for phenotypic analysis using immunochemistry and gene microarray. Total RNA was hybridized to a human U133 GeneChip (Affymetrix) and altered genes expression levels (>2 fold) were confirmed by qRT-PCR. Our results indicate that the PDLR225Q cells showed decreased proliferation rates and accumulated RUNX2 protein in the cytoplasm. Microarray analysis revealed disregulation of 38% of the genes tested: 5520 (14%) up-regulated and 9462 (24%) down-regulated. The genes confirmed by qRT-PCR included members of the BMP and FGF signaling pathways such as dentin sialophosphoprotein, osteonectin and MMP-20. Selected target genes were shown to have potential RUNX2 binding sites in their 5 promoter sequences. These results indicate that the RUNX2 R225Q interferes with nuclear transport resulting in a haploinsufficiency that leads to disregulation of a large cadre of genes critical for normal tooth development. Supported by UAB SOD IOHR and Deans Faculty Award.

High-Resolution Mapping and Analysis of Copy Number Variations in the Human Genome. *P. S. White[1,2], X. Gai[1], T. H. Shaikh[1,2], J. C. Perin[1], J. T. Glessner[1], H. M. Xie[1], T. Casalunovo[1], M. D'arcy[1], E. C. Frackleton[1], C. E. Kim[1], K. Murphy[1], R. O'Hara[1], R. Grundmeier[1,2], M. Imielinski[1], S. Ostapenko[1], R. M. Chiavacci[1], E. F. Rappaport[1], S. F. A. Grant[1,2], H. Hakonarson[1,2]* 1) Joseph Stokes, Jr. Research Institute, Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA; 2) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA, 19104, USA.

There is growing evidence that copy number variation (CNV) in the human genome significantly influences human diversity and predisposition to disease. However, the frequency and distribution of copy number variations (CNVs) in the human genome remains to be characterized in large sample sets of healthy subjects. We catalogued and characterized copy number variations (CNVs) in 2,026 disease-free individuals. A total of 54,462 CNVs were detected, of which 77.8% were identified in multiple unrelated individuals. These non-unique CNVs mapped to 3,272 distinct regions of genomic variation spanning 5.9% of the genome; 51.5% of these were previously unreported, and >85% are rare. Certain CNVs demonstrated significant frequency differences between Caucasians and African Americans, indicating the presence of ethnic-specific CNV signatures. Our CNV set distribution is positively correlated with regions of segmental duplication, long interspersed repeats (LINEs), and recombination hot spots. CNVs were found to be negatively correlated with gene density in general, but the subset of genes previously implicated in human disease were found to be more enriched within the CNV regions, suggesting that CNVs may influence disease susceptibility through natural selection. Certain gene functional categories were also found to be preferentially associated with CNVs. We demonstrated the clinical utility of this CNV set in distinguishing a pathogenic CNV from normal variants in a patient with multiple congenital anomalies. Together, this analysis and annotation provides a timely resource to assist with the assessment of CNVs in the contexts of human variation, disease susceptibility, and clinical molecular diagnostics.

Identification of Novel Benign Juvenile Epilepsy Gene in Dogs. *E. H. Seppala[1,2], T. Jokinen[1,2], A.-K. Anttonen[1,2,3], M. Kousi[1,2,3], S. Cizinauskas[4], E. Karlsson[5], B. Minassian[6], M. Perloski[5], M. Webster[7], T. Leeb[8], K. Lindblad-Toh[5,7], H. Kalimo[9], A.-E. Lehesjoki[1,2,3], H. Lohi[1,2]* 1) Dept of Medical Genetics and Dept of Basic Veterinary Sciences, Univ of Helsinki, Finland; 2) Folkhälsan Institute of Genetics, Finland; 3) Neuroscience Center, Univ of Helsinki, Finland; 4) Referral Animal Neurology Hospital Aisti, Vantaa, Finland; 5) Broad Institute of Harvard and MIT, Cambridge, USA; 6) Hospital for Sick Children, Toronto, Canada; 7) Dept of Medical Biochemistry and Microbiology, Uppsala Univ, Sweden; 8) Inst of Genetics, Vetsuisse Faculty, Univ of Bern, Switzerland; 9) Dept of Pathology, Univ of Helsinki, Finland.

Childhood epilepsies with benign outcomes are well-known and several genes have been identified. Epilepsies are common in dogs too but only five genes have been discovered in progressive myoclonic epilepsies. We have recently identified a new epilepsy syndrome in Lagotto Romagnolo (LR) breed. LRs manifest benign juvenile epilepsy with simple and complex focal seizures appearing in puppies at the age of five to nine weeks. Seizures resolve spontaneously at the age of eight to thirteen weeks. EEG activity is present in most affected puppies and some dogs present neurological signs including generalized ataxia and hypermetria. MRI, EMG and brainstem auditory-evoked potentials appear normal. Histopathology revealed cerebellar inclusions in Purkinje cells. To map the epilepsy gene we performed genome-wide association analysis using Affymetrix 27K SNP array in 11 sib pairs. We recognized a single 2.7Mb critical region in the chromosome 3 containing ten genes. Evaluation of the genes revealed an obvious candidate gene for sequencing. We identified a homozygous nonsense mutation in affected dogs resulting in the truncation of the protein. The identified gene has not been associated with epilepsy before. The function of the gene is not known and our ongoing studies aim to discover its role in epileptogenesis. We are also sequencing the gene in human epilepsy patients. Identification of the LR gene establishes the breed as a model for childhood epilepsies and will improve our understanding of juvenile epilepsies both in human and dogs.

Identification of a new mutation in FGD4. Discussion of the phenotypic heterogeneity in Charcot-Marie-Tooth disease 4H: implications for molecular diagnosis. *C. BAUDOT[1], Y. POITELON[1], T. HAMADOUCHE[2], I. BOCCACCIO[1], A. MEGARBANE[3], N. LEVY[1,4], V. DELAGUE[1]* 1) UMR_S 910, INSERM, Faculte de Médecine de la Timone, Université de la Méditerranée, Marseille, France; 2) Laboratoire de Biologie Moléculaire, Institut Pasteur, Algers, Algeria; 3) Unité de Génétique Médicale, Université Saint-Joseph, Beirut, Lebanon; 4) AP-HM, Département de Génétique Médicale, Hôpital d'enfants Timone, Marseille, France.

Charcot-Marie-Tooth (CMT) disorders are a clinically and genetically heterogeneous group of hereditary neuropathies characterized by chronic distal weakness and sensory loss. We recently identified FGD4, encoding the Rho GDP/GTP Exchange Factor (RhoGEF) FRABIN, is the gene responsible for CMT4H, a rare autosomal recessive demyelinating CMT subtype, that we previously mapped at chromosome 12p11.21-q13.11, in two consanguineous families of Mediterranean origin (De Sandre-Giovannoli et al.2005). We identified two mutations at the same codon in exon 7 of the gene: the c.893T>G transversion and the c.893T>C transition in a Lebanese and an Algerian family respectively (Delague et al 2005). Whereas the mutation in the Algerian is a missense mutation (p.Met298Thr), the c.893T>G transversion proved to be a splicing mutation leading to a premature STOP codon (p.Met298fsX8). Subsenquently, Stendel et al.(2007) identified three other nonsense (c.670C>T, p.Arg224X and c.1756G>T, p.Gly586X)) or frameshift (c.1627_1628delGA, p.E543fsX5) mutations in exons 5, 15 and 13 respectively. In this study, we present the results of the screening of FGD4 in a cohort of 96 patients affected with CMT, and for whom no mutations have been identified to date in any of the known CMT genes. We describe the identification of a new missense mutation in FGD4 in one Lebanese girl and discuss the phenotypic heterogeneity among published patients with mutations in this gene. Identification of a new mutation in FGD4/FRABIN points to a major role of FRABIN in the pathogenesis of CMT disease. Our results also clearly suggest that the screening of FGD4 should be performed not only in early-onset, slow progressive forms of CMT, but also in later-onset, less severe forms.

An overall very mild phenotype associated with the CFTR mutation R117H, irrespective of the second mutation.

Munck[2,3], G. Bellon[2], C. Binquet[6], L. Faivre[1], M. Roussey[2,3], E. Girodon[4,7], R117H Collaborativ Group 1) Genetics Centre, Dijon,France; 2) CF Care Centres, France; 3) AFDPHE,Paris,France; 4) CF laboratory Network,France; 5) INED,Paris,France; 6) CIC-EC,Dijon,France; 7) Molecular Genetics Laboratory,Créteil,France.

Over 1500 CFTR sequence variations have been identified in cystic fibrosis (CF) and CFTR-related disorders (CFTR-RD), such as congenital bilateral absence of the vas deferens (CBAVD). They can be of severe, mild, or neutral clinical effect. R117H mutation, initially considered as a mild CF-causing mutation with pancreatic sufficiency and rare early pulmonary symptoms, was found predominantly associated with pure CBAVD, and incidentally observed in asymptomatic individuals. Out of a large French collaborative study collecting 278 patients until 2007 with two CFTR mutations including at least one R117H, we explored data from 179 patients recruited on the basis of symptoms or a positive family history. Median age at last follow-up was 31.5 years (IQR [27.3-35.7]). Clinical data available in 165 patients revealed 49% pure CBAVD, 40% other CFTR-RD, 8% totally asymptomatic individuals, and 3% with a severe pulmonary disease (FEV1 <60%) of late onset. 42 different mutations were identified: 95% of severe (F508del: 68%), 3% of mild and 2% of unknown effects. The IVS8 T5 variant was found in only 5 patients. Phenotype-genotype correlation studies showed no significant clinical difference between patients, according to the mutation class of the 2nd allele. This study confirmed the overall mild phenotype associated with compound heterozygosity for R117H and a severe mutation, irrespective of the mutation class. Even if the numbers were too small to obtain a significant difference, we observed that the 8 patients with mild mutation of the 2nd mutation had CBAVD, and only 3 also presented mild asthma. The very low frequency of mild mutations on the 2nd allele (3%) let to suggest that the clinical penetrance of genotypes combining R117H and a mild mutation is very low.

Testing haplotype association using Bayesian structural equation models. *T. Price* MRC SGDP Centre, Institute of Psychiatry, London, United Kingdom.

I propose a test of haplotype association embedded in a Bayesian structural equation model, a versatile method that allows one to test complex causal hypotheses involving both latent and observed variables. In the simplest case of a single response variable, the technique is equivalent to testing haplotype association within a generalized linear model using the prospective likelihood. Using a demonstration dataset, I apply this method to simultaneously test hypotheses about haplotype-environment association and haplotype-environment interaction. The potential applications for this technique are vary varied indeed, but include testing the causal influence of haplotypes on (a) multiple interrelated phenotypes; (b) latent factors loading on multiple observations, including growth curves or latent trajectories abstracted from longitudinal measurements; (c) the utility of treatment in a Bayesian decision-theoretic model incorporating personalized predictors of cost and efficacy.

Neuropathology of Chromosome 15 Duplication and Autism. *W. Brown, T. Wisniewski, i. Cohen, E. London, M. Flory, H. Imaki, I. Kuchna, J. Wegiel, S. Ma, K. Nowicki, K. Wang, J. Wegiel* NYS Inst Basic Research, Staten Island, NY.

Background: Duplications of the proximal long arm of chromosome 15 cause mental retardation, seizures, autistic features, functional deterioration with age and increased risk of sudden death. The pattern of neuropathological changes caused by this genetic defect is not known. Objective: Detection of (a) developmental changes contributing to mental retardation, (b) markers of neuronal degeneration contributing to clinical deterioration, and (c) pathology contributing to sudden death. Methods: Brains of four subjects (11, 15, 20, 25 year old) with chromosome 15 duplication, and four age matched control subjects were examined in the light and electron microscope. Results: The most consistent finding is a reduced size of the brain, volume of neurons and neuronal nuclei in the amygdala, accumbens, entorhinal cortex and Purkinje cells, indicating a delay in neuronal development. Microdysgenesis in the hippocampus represented by hyperconvolution and duplication of the granule cell layer in the dentate gyrus observed in two subjects may contribute to seizures and sudden death. Enhanced accumulation of amyloid beta protein in phagosomes/dense bodies in all four subjects is a marker of modified APP processing and amyloid beta trafficking and deposition. Amyloid beta positive inclusions in the dendrites in the CA1 sector are another marker of neuronal deterioration. Osmophilic inclusions in the mitochondrial matrix might be an indicative of mitochondrial degeneration. Chaslin's gliosis observed in one subject reflects epilepsy-related brain damage. Conclusion: In subjects with chromosome 15 duplications reduced size of the brain and delayed growth of neurons appears to be the main contributor to developmental deficits, whereas behavioral worsening could be the result of early neurodegeneration. Sponsor: Autism Speaks and the NYSOMRDD. The Harvard Brain Tissue Resource Center (R24-MH 068855), and Brain and Tissue Bank at the University of Maryland, Baltimore provided tissue. Autism Tissue Program coordinated tissue acquisition.

Genetic testing for epidermolysis bullosa in a commercial setting. *E. Pfendner, S. Bale, J. Compton* GeneDx Inc, Gaithersburg, MD.

Epidermolysis Bullosa (EB) is an inherited muco-cutaneous disorder characterized by skin fragility due to relatively minor trauma and exhibiting a broad spectrum of severity. Ten genes are known to be involved in the three major and two minor EB subtypes. Since testing for the Dystrophic (DEB) and Junctional (JEB) forms of EB was instituted at GeneDx in 2005, 56 samples have been studied for mutations in the COL7A1 gene mutated DEB, 36 samples for mutations in the 4 genes involved in JEB; (LAMB3, LAMC2, LAMA3 and COL17A1), and 9 samples in the ITGB4 gene involved in EB with pyloric atresia (EB-PA). Full coding region sequencing was employed to examine the candidate genes for mutations and resulted in a detection rate of 99% of COL7A1 mutations (16 autosomal dominant cases with 16 of 16 alleles detected and 40 autosomal recessive cases with 79 of 80 alleles detected) and 94% of JEB mutations (64 mutations from 68 alleles). Of the 34 JEB samples submitted, 20 harbored mutations in the LAMB3 gene, 7 in the LAMA3 gene, 4 in the LAMC2 gene and 3 in the COL17A1 gene. Of the 20 samples harboring LAMB3 mutations 10 carried one of the common mutations (R42X, R635X, 957ins77) on both alleles (50%) and 5 (25%) carried one of the common mutations on one allele. Nine samples were submitted with a diagnosis of EB-PA for ITGB4 sequencing and mutations were identified on one or both alleles in 7 cases. Detection rate for ITGB4 was 79% (11 of 14 alleles) with the two remaining cases presumably harboring mutations in one of the two EB-PA genes that were not studied (ITGA6 and PLEC1). Compared with results from the academic laboratory offering testing on a research basis during an equivalent time period, sample submission to GeneDx was 18% lower (101 vs 123 samples submitted) while detection rate overall was higher (99% vs 77% for DEB, 94% vs 76% for JEB, 79% vs 86% for ITGB4). The cost of testing is presumably responsible for lower sample volume while methodology (sequencing vs dHPLC screening followed by sequencing) was responsible for the higher detection rates. Novel mutations were identified in each of the genes studied.

GWA data of a founder population highlights substructure and multiple bottlenecks reflected by wide LD intervals and homozygosity regions. *E. Jakkula[1,2,9], K. Rehnström[1], T. Varilo[1], O. P. H. Pietiläinen[1], T. Paunio[1,3], N. L. Pedersen[4], N. Freimer[5], S. Ripatti[1,4], S. Purcell[2,6], A. Collins[7], M. J. Daly[2,6], A. Palotie[2,8,9], L. Peltonen[1,2,8]* 1) NPHI and Institute for Molecular Medicine (FIMM), Helsinki, Finland; 2) The Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Helsinki Univ Central Hospital, Helsinki, Finland; 4) Karolinska Institutet, Stockholm, Sweden; 5) Univ of California, Los Angeles, California, USA; 6) Massachusetts General Hospital, Boston, USA; 7) Univ of Southampton, Southampton, UK; 8) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 9) FIMM, Univ of Helsinki, Helsinki, Finland.

The genome-wide SNP datasets enable detailed association studies, but also offer new insight into population genetics. Here we present an example of a founder population by scrutinizing 11 geographically and historically distinct Finnish subpopulations representing different eras in the inhabitation.

Multidimensional scaling of pairwise identity-by state (IBS) sharing matrix was performed to delineate the population structure. The two primary dimensions corresponded with the east-west and north-south directions closely reflecting the geographical distribution of parents birthplaces. The youngest subisolates in northeastern Finland showed highest within-group IBS similarity, widest LD intervals and highest number of extended regions of homozygosity. These parameters were slightly higher in early settlement southwestern regions compared to CEU and Swedish samples. Tests of IBS similarity and genomic inflation factors revealed significant differences compared to general Finnish population of the capital.

The patterns identified correlate remarkably well with population sub-divisions based on extensive historical and linguistic information, and clarify the impact of consecutive bottlenecks and founder effects on the current population. Further, this data provides useful information for future studies aiming at identification of rare variants in common diseases, potentially enriched in subpopulations with fewer founders.

(dCA)10 and (dTG)10 oligonucleotide invasion into homologous internal region of DNA duplexes containing CA/TG repeats. *N. V. Ryadninskaya, V. K. Gasanova, A. A. Belyakova, G. A. Belitsky, M. G. Yakubovskaya* Institute of Carcinogenesis, Blokhin Cancer Research Center RAMS, Moscow, Russian Federation.

CA/TG microsatellites are well known to be the hot spots of genetic recombination. One of the reasons for this phenomenon may be formation of nonB DNA structures by CA/TG repeats because of intra- and intermolecular DNA-DNA interactions. Previously we have shown that oligonucleotide of random sequence could invade into homologous duplex end via consecutive strand displacement mechanism, while oligonucleotide invasion into the internal homologous region of the duplex have never been observed. In this work we studied oligonucleotide invasion into different types of duplexes containing (CA/TG)31-repeats: 1129 bp PCR product, 835 bp restricted fragment of plasmid DNA and 2384 bp circular plasmid. Purified PCR products and restricted fragments were incubated with radioactively labeled 20-mer oligonucleotides homologous either to the duplex end sequence or the internal CA-repeat region using molar ratio duplex/oligonucleotide equal to 1/50. After mixture incubation the probes were loaded on agarose gel followed by electrophoresis and gel autoradiography. Formation of invasion complexes was visualized by appearance of radioactivity in the duplex bands. For the linear DNA fragments both the duplex end invasion and also invasion of (dCA)10 into the internal repetitive regions of the duplexes were demonstrated. Then (dTG)10-oligonucleotide invasion into the linear duplexes was demonstrated at molar ratios 50 times lower than that for (dCA)10-oligonucleotide. The phenomenon of duplex-oligonucleotide interaction was also demonstrated for circular DNA plasmid containing CA-repeats. Moreover, it was found that both (dCA)10 and (dTG)10 invaded preferentially supercoiled form of the plasmid, when supercoiled and linearized plasmids were in mixture. Results of this study propose some structural lability of canonical B-form DNA in CA/TG-repeats with formation of single-stranded DNA region.

A common SNP of MCPH1 is associated with cranial volume variation in Chinese population. *B. Su[1,2], JK. Wang[1,2,4], Y. Li[3]* 1) Kunming Inst Zoology, Chinese Academy Sciences, Kunming, Yunnan, China; 2) Kunming Primate Research Center, Chinese Academy of Sciences, Kunming, Yunan,China; 3) Department of Biochemistry, Qujing Normal University, Qujing, Yunnan, China; 4) Graduate School of Chinese Academy of Sciences, Beijing, China.

The microcephaly genes are informative in understanding the genetics and evolution of human brain volume. MCPH1 and ASPM are the two known microcephaly causing genes that were suggested undergone recent positive selection in human populations. However, previous studies focusing only on the two tag SNPs of MCPH1 and ASPM failed to detect any correlation between gene polymorphisms and variations of brain volume and cognitive abilities. We conducted an association study on eight common SNPs of MCPH1 and ASPM in a Chinese population of 867 unrelated individuals. We demonstrate that a nonsynonymous SNP (rs1057090, V761A in BRCT domain) of MCPH1 other than the two known tag SNPs is significantly associated with cranial volume in Chinese males. The haplotype analysis confirmed the association of rs1057090 with cranial volume, and the homozygote males containing the derived alleles of rs1057090 have larger cranial volumes compared with those containing the ancestral alleles. No recent selection signal can be detected on this SNP, suggesting that the brain volume variation in human populations is likely neutral or under very weak selection in recent human history.

Towards a revised Ghent nosology for the Marfan syndrome. *B. Loeys[1], B. Callewaert[1], J. De Backer[1], L. Faivre[2], G. Jondeau[3], R. Devereux[4], R. Pyeritz[5], P. Sponseller[6], P. Wordsworth[7], D. Milewicz[8], H. Dietz[6], A. De Paepe[1]* 1) Dept Medical Genetics, Ghent Univ Hosp, Gent, Belgium; 2) CHU Dijon, France; 3) AP-HP, Hopital Bichat, Paris, France; 4) Weill Medical College of Cornell University, New York; 5) University of Pennsylvania, Philadelphia; 6) Johns Hopkins University, Baltimore; 7) University of Oxford, Oxford, UK; 8) University of Texas, Houston.

The diagnosis of Marfan syndrome (MFS) relies on a set of international criteria, outlined by expert opinion. In 1996, the initial Berlin nosology was revised because of the risk of overdiagnosis and redefined as the Ghent nosology, a more stringent set of major and minor criteria. These Ghent criteria have proven to work well since with improving molecular techniques, confirmation of the diagnosis is possible in over 95% of patients. However, concerns with the Ghent criteria are that some of the diagnostic manifestations have not been validated as hinge points (eg. dural ectasia) and others necessitate cumbersome imaging studies. Moreover, in the absence of aortic dilation, the diagnosis can be stigmatizing, hamper career aspirations and restrict life-insurance opportunities. The label MFS may cause psychosocial burden by restricted exercise permission and situational depressions. Following an international expert meeting, we propose a revised Ghent nosology in which aortic root aneurym and ectopia lentis are cardinal features. In absence of any family history, the presence of these two manifestations is sufficient for the unequivocal diagnosis of MFS. In absence of any of these two, the presence of bonafide FBN1 mutation or a combination of systemic features is required. For the latter a new scoring system has been designed and validated. In this way FBN1 testing is not mandatory but useful when available. The proposed new nosology puts more weight on the cardiovascular manifestations of the disease. We anticipate that the new nosology can delay a definitive diagnosis of MFS but decreases the risk of premature or mis-diagnosis and facilitates discussion of risk and follow-up / management guidelines.

A New Recurrent Translocation with 3:1 Meiotic Non-Disjunction: The Palindrome Mediated t(8;22)(q24.13;q11.21). *M. B. Sheridan[1], C. Haldeman-Englert[1], G. R. Jalali[1], J. M. Milunsky[2], Y. Zou[2], R. Klaes[3], A. M. Hacker[1], J. Brown[1], D. Tomkins[1], T. H. Shaikh[1,4], E. H. Zackai[1,4], B. S. Emanuel[1,4]* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) Boston University School of Medicine, Boston, MA; 3) Zentrum f. Humangenetik Mannheim, Mannheim, Germany; 4) University of Pennsylvania School of Medicine, Philadelphia, PA.

Several genetic disorders are associated with rearrangements of chromosomal region 22q11.2, such as translocations which give rise to the recurrent t(11;22) malsegregation-derived supernumerary der(22)t(11;22) syndrome. Cloning and sequence analysis of junction fragments from numerous different translocation carriers has indicated that these recurrent 22q11.2 breakpoints (BPs) occur at the center of a nearly perfect palindromic AT-rich repeat (PATRR). A patient carrying a supernumerary der(22) derived from a 46,XY,t(8;22)(q24.1;q11.2) rearrangement was recently reported. The BPs were mapped and found to occur within PATRRs on both 8q and 22q. We have identified a second patient carrying a similar supernumerary der(22). A comprehensive search of the literature has revealed at least eight prior reports of this translocation. Several of these reports indicated gross molecular positioning of the 8q and 22q BPs consistent with what would be predicted based on our two cases. We subsequently received samples from two of these cases and have performed additional analyses. As predicted, the BPs are identical by FISH, PCR plus sequencing, or array analysis. Preliminary data from PCR analysis of two sperm samples suggests that in some normal males the t(8;22) arises during gametogenesis, similar to the t(11;22). Thus, we have discovered a new recurrent translocation that involves 22q11.2. Like the t(11;22), this translocation can malsegregate 3:1 to produce unbalanced karyotypes and involves identical BPs within PATRRs on both 8q and 22q. The existence of at least twelve cases of this rearrangement provides an opportunity to examine additional aspects of recurrent chromosomal rearrangements involving 22q11.2 and to begin to further evaluate the mechanisms and factors that are likely to produce such rearrangements.

Identification of rearrangements in causative genes of hereditary spastic paraplegia based on a high-resolution array comparative genomic hybridization method. *H. Ishiura, Y. Takahashi, J. Goto, S. Tsuji* Dept Neurology, Univ Tokyo, Tokyo, Japan.

[Objective] A high-resolution array comparative genomic hybridization method (aCGH) was developed to allow efficient detection of rearrangements including deletions/duplications of the causative genes of hereditary spastic paraplegia (HSP). [Background] HSP is a neurodegenerative disorder characterized clinically by progressive lower limb spasticity and pyramidal weakness. To date, as many as 18 causative genes have been identified. Since large rearrangements have been found at least in *spastin*, *paraplegin*, *REEP1*, *atlastin*, and *PLP1*, development of a high throughput system allowing detection of these rearrangements is required. We developed a high-resolution aCGH system to allow simultaneous detection of gene rearrangements of many causative genes for HSP. [Method] We designed a custom made array for CGH (Agilent) to detect genomic rearrangements in 16 causative genes of HSP which included *L1CAM* (SPG1), *PLP1* (SPG2), *atlastin* (SPG3A), *spastin* (SPG4), *CYP7B1* (SPG5A), *NIPA1* (SPG6), *paraplegin* (SPG7), *strumpellin* (SPG8), *KIF5A* (SPG10), *spatacsin* (SPG11), *HSP60* (SPG13), *BSCL2* (SPG17), *spartin* (SPG20), *maspardin* (SPG21), *REEP1* (SPG31), and *ZFYVE27* (SPG33) in 8X15K format (average length between probes: 197bp). Eighty-six HSP patients in whom a comprehensive resequencing analysis of the causative genes did not detect any mutations were enrolled; 21 with ADHSP, 12 with ARHSP, 7 with unknown mode of inheritance, and 46 sporadic patients. [Results] Five rearrangements in *spastin* were identified; 3 deletions and 1 duplication in ADHSP (4/21=19%) and 1 deletion in a patient with a possibly affected sibling. Genomic rearrangements in genes other than *spastin* were not detected. In our previous studies, we have identified 23 mutations of *spastin* in 44 ADHSP (23/44=52%). Taken together, the present study revealed that the overall proportion of SPG4 in ADHSP were 61% (27/44). [Conclusion] Our comprehensive and high-resolution aCGH analysis system successfully detected genomic rearrangements. The proportion of SPG4 in ADHSP in our population was considerably higher than previous reports.

Mothers' Attitudes toward Collection of DNA for Gene-Environment Studies. *M. M. Jenkins[1], E. Reed-Gross[2], W. D. Barfield[1], C. E. Prue[1], M. L. Gallagher[1], S. A. Rasmussen[1], M. A. Honein[1]* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Westat, Rockville, MD.

To assess attitudes toward DNA collection, focus groups were conducted with Atlanta mothers who had participated in the National Birth Defects Prevention Study, a multi-site case-control study of birth defects. Within 3 years of completing the interview and being mailed a kit containing cytobrushes for buccal cell collection from themselves, their child, and the childs father, mothers were recruited. Focus groups were segmented based on participation in DNA collection (participators/non-participators), mothers race/ethnicity, childs birth defect status (case/control), and childs birth weight. 3 groups of participators and 3 groups of non-participators each included 1 group of African-American mothers of case-infants, 1 group of mothers of any race/ethnicity who had case-infants of low birth weight, and 1 group of mothers of any race/ethnicity who had control-infants. 8-10 women attended each participator group and 2-5 women attended each non-participator group. Moderator-led discussions probed mothers attitudes toward providing DNA, factors that affected their decision to participate in DNA collection, and preferred collection methods. Non-participators voiced concerns about their DNA being used for purposes they had not agreed to (e.g., cloning or paternity testing) and were especially concerned with government access to their DNA. Information provided (or not provided) on DNA use, storage, and disposal influenced decision-making. Many women reported that fathers skepticism was a significant barrier to participation. Women were asked to rank options for DNA collection (cytobrushes, saliva, mouthwash, blood spots, and whole blood). Attitudes toward whole blood collection for DNA were overwhelmingly negative. Methods that were convenient and non-invasive were preferred. Non-participators expressed concerns about sterility of DNA collection materials and were less comfortable with self-collection methods. Better understanding attitudes toward DNA collection might reduce risk of racial disparities in participation and benefit future studies of gene-environment interaction.

Differential Expression of Dendritic Cell Immunoregulatory Receptor. *M. Ronninger, C. Eklöw, J. C. Lorentzen, L. Klareskog, V. Malmström, L. Padyukov* Department of Medicine, Karolinska Inst & Hosp, Stockholm, Sweden.

Accumulating evidence from human rheumatoid arthritis (RA) and experimental animal studies suggest that Dendritic Cell Immunoregulatory Receptor (DCIR) is an important etiological factor in development of autoimmunity, specifically in RA. Previously we have described the association of variations in the human *DCIR* gene with the level of expression of mRNA isoform 4, which lack the transmembrane domain sequence. To investigate the distribution and regulation of *DCIR*, we analyzed *DCIR* mRNA expression in peripheral blood mononuclear cells (PBMC), synovial fluid mononuclear cells and in synovial tissue using real time RT-PCR. The protein expression was determined by flow cytometry and immunohistochemistry. Results were analysed together with extensive SNP genotyping data across the locus. We confirmed association of SNP rs204301 with expression of *DCIR* mRNA isoform 4 in PBMC from an independent cohort of 20 asthma patients and 20 healthy controls analysed together ($p=0.002$, Kruskal-Wallis test). The mRNA expression of *DCIR* isoforms detected in PBMC from RA or asthma patients was however not different in comparison with healthy controls. DCIR protein was not detected in synovial tissue from healthy donors, while it was abundantly expressed in synovial tissue from RA patients. In PBMC a predominant expression of isoform 1 was detected, while in DCIR-positive T-cells from synovial fluid an equal level of expression of *DCIR* isoform 1 and 4 was observed. Our data demonstrate that genetic variations may regulate expression of *DCIR* isoforms and a pronounced expression of putative soluble isoform of DCIR in T cells from rheumatic joints. We suggest such a soluble variant of DCIR may play a role in immunological regulation and in the development of autoimmunity.

DNA copy number variation of a leptin receptor gene locus associates with symptoms of metabolic syndrome. *S. Shim, J. Jeon, H. Nam, G. Ryu, J. Lee, Y. Cho, T. Chung, J. Kim, H. Kim, B. Han* Korea BioBank, Center for Genome Sciene, Korea NIH, Seoul, Korea.

Structural genomic variations are frequent and widespread in healthy individuals. Recent efforts have been made to link some complex human traits and disease susceptibilities to gains or losses of DNA copy numbers in the genome. In an attempt to identify DNA copy number variations (CNVs) associated with type 2 diabetes mellitus (T2DM) and metabolic syndrome, we initially selected potential candidate genes (n=12) which exhibited DNA copy number variations among Koreans according to SNP chip data. DNA copy numbers were determined by the QMPSF method in blood DNA from community based cohort samples (n=1342). Our candidate gene approach led to identify a biallelic copy number polymorphism of an intronic sequence at leptin receptor (LERP) gene locus. The high copy number allele of the LEPR gene locus was associated with a lower fasting glucose level among nondiabetic subjects ($p < 2.4 \times 10^{-9}$ in men and $p < 2.4 \times 10^{-7}$ in women). The association of total cholesterol with the high copy number allele was also found in among nondiabetic subjects while the association was stronger in men ($p < 2.4 \times 10^{-8}$) than women ($p < 0.019$). In addition, the significant associations between fasting and postprandial insulin levels and copy number variation of LEPR gene locus were evident in only nondiabetic women ($p < 0.004$ and $p < 0.0004$, respectively). This observation indicates that a structural variation at the LEPR gene locus is associated with symptoms of metabolic syndrome.

Outcome of prenatal screening among Ashkenazi Jewish carrier couples for the common non-neuronopathic genotype of Gaucher disease. *Y. Eitan, A. Abrahamov, M. Phillips, D. Elstein, A. Zimran* Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel.

Background: The aim of elective pre-marital/prenatal carrier testing is to identify couples at risk of having offspring with serious autosomal recessive disorders. Carrier screening for Gaucher disease among Ashkenazi Jews in whom there is a predilection for the non-neuronopathic form of the disease has been available in Israel since 1995, but is controversial because this form is not lethal, is often asymptomatic, and, should signs and symptoms require specific intervention, has effective and safe treatment. The purpose of this study was to evaluate the outcome of counseling given to carrier couples of a fetus with the common non-neuronopathic Ashkenazi Jewish genotype, N370S/N370S. Methods: The records of all couples who were seen for individualized prenatal consultation with a Gaucher expert and whose fetus was N370S/N370S were reviewed to ascertain the fate of their child and whether symptomatic disease was noted during long-term follow-up. Results: Among 38 carrier couples who requested consultations over 12 years, 12 children (4 girls) with the N370S/N370S genotype were seen during the past 9 (range: 0.8-8.5) years. Of these, 8 children had no signs or symptoms attributable to Gaucher disease; 4 children had some questionable sign or symptoms. No child had signs or symptoms that were definitively due to Gaucher disease. No child required enzyme replacement therapy. Three pregnancies were aborted. Conclusion: Consultations with Ashkenazi Jewish couples carrying a N370S/N370S fetus should be aimed at relieving anxiety as the majority of children will probably be asymptomatic. Policies for establishing appropriate criteria for inclusion in screening panels may be useful to the Ashkenazi Jews and to clinicians so as not to instill unwarranted concerns.

Subcellular localization of UDP-GlcNAc 2-epimerase/ManNAc kinase in cells of HIBM and sialuria patients. *K. Patzel, C. Ciccone, I. Manoli, D. Adams, D. Krasnewich, WA. Gahl, M. Huizing* MGB, NHGRI, NIH, Bethesda, MD.

UDP-GlcNAc 2-epimerase/ManNAc kinase (GNE/MNK) is a rate limiting, bifunctional enzyme in sialic acid (SA) synthesis, which is feedback inhibited by CMP-SA in its allosteric site. Mutations in GNE/MNK cause two human disorders, Hereditary Inclusion Body Myopathy (HIBM) and sialuria. Sialuria, clinically characterized by variable symptoms, including hepatomegaly and mental retardation, is caused by dominant mutations in the allosteric site of GNE/MNK, leading to a loss of feedback-inhibition and increased excretion of SA. HIBM is characterized by adult onset progressive muscle wasting and results from recessive, mostly missense, mutations in GNE/MNK outside the allosteric site, leading to decreased GNE/MNK enzyme activities, and decreased SA production. Recent immunofluorescence studies showed that GNE/MNK not only resides in the cytoplasm and Golgi, as expected, but also in the nucleus. This nuclear localization is remarkable, since GNE/MNK performs its enzymatic role within the cytoplasm. However, GNE/MNK contains a putative nuclear export signal and the nucleus contains CMP-SA synthase, which converts all cellular SA to CMP-SA. We propose that GNE/MNK is stored in the nucleus, in its inactive, CMP-SA bound, feedback-inhibited form. If the cell needs SA, there is less SA to enter the nucleus and form CMP-SA, so there is more free GNE/MNK to translocate to the cytoplasm (through its nuclear export signal) and produce more SA. To study this proposed mechanism, we obtained preliminary data using normal, HIBM and sialuria patients fibroblasts. Pilot immunofluorescence studies revealed a higher nuclear GNE/MNK content in sialuria cells and a lower content in HIBM cells compared to normal. Subcellular fractionation followed by Western blotting revealed similar results; higher nuclear amounts of GNE/MNK in sialuria and lower amounts in HIBM. In addition, Western blots of nuclear fractions of both sialuria and HIBM cells showed unexplained GNE/MNK bands compared to normal. These bands, as well as the function of the nuclear export signal, are being analyzed and may provide intriguing insights into the regulation of cellular SA synthesis.

Identification of a RPGR mutation in a male sporadic patient presumed to be affected with Stargardt disease. *J. Kaplan[1], N. Delphin[1], I. Ghazi[2], A. Munnich[1], J.-L. Dufier[2], O. Roche[2], J.-M. Rozet[1]* 1) Genetics, INSERM U781 & Université Paris Descartes, Paris, France; 2) Dpt Ophthalmology, Hôpital des Enfants Malades, Paris, France.

Purpose: The aim of the study presented here was to identify the disease mutation in a sporadic male patient reported to be affected with autosomal recessive Stargardt disease. **Patient and Method:** A young man without familial history came to the genetic counselling consultation of the Hopital Necker in Paris to know the risk for his offspring to be affected with Stargardt disease (STGD). Indeed, he presented with a sudden loss of visual acuity at the age of 24. Ophthalmoscopic and angiographic examinations showed a bulls eye aspect of the macula but no dark choroid and no yellowish perimacular spots. Abnormal colour vision with a green-red confusion axis was noted as well as a central scotoma at the visual field recordings. Nevertheless, he wore corrective glasses for high myopia (OD -11; OG -14) since the age of 3 while his mother presented with a highly asymmetrical myopia (OD -9.75; OG -0.75) resulting in a moderate amblyopia. Recently, electroretinogams of the patient showed a severe alteration of the photopic responses. These last findings in a male sporadic case and in his mother prompted us to challenge the diagnosis of STGD and to consider that of X-linked cone dystrophy. Subsequently, the 3 end of the ORF15 of the RPGR gene, known to contain all cone dystrophy-associated mutations, was screened by direct sequencing. **Results:** The hypothesis of the involvement of RPGR in this family was confirmed by the identification in the proband's DNA of a frameshift mutation in the ORF15 exon of the gene (c.delA1523, p.Lys507Lysfs+3X). Up to date, his mother did not accept to be genotyped. **Conclusion:** This observation highlights the necessity to be particularly cautious when making the diagnosis of STGD in young male patients presenting with the bulls aye phenomenon only. A careful interview of the parents and the follow-up of the patient may direct towards the diagnosis of X-linked cone dystrophy that can easily be confirmed by the restricted screening of the 3 region of the RPGR-ORF15.

A single base transition is the likely cause of persistent Mullerian duct syndrome (PMDS) in a canine model. *S. Pujar[1], X. Wu[3], S. Wan[3], M. M. Lee[3], M. E. Haskins[4], D. H. Schlafer[2], V. N. Meyers-Wallen[1]* 1) J A Baker Institute for Animal Health, Cornell University, Ithaca NY, 14853; 2) Department of Biomedical Sciences, College of Veterinary medicine, Cornell University, Ithaca, NY, 14850; 3) Pediatric Endocrine Division, Department of Pediatrics and Cell Biology, University of Massachusetts School of Medicine, Worcester, MA, 01655; 4) Department of Pathobiology, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA 19104.

Mullerian ducts, precursors of the fallopian tubes, uterus, cervix and cranial vagina in mammals, are present in male and female embryos at the sexually indifferent stage. Later, fetal testes produce Anti-Mullerian hormone (AMH), which binds to its specific type 2 receptor (AMHR2) and leads to Mullerian duct regression. Persistent Mullerian duct syndrome (PMDS) results from failure of Mullerian duct regression in XY males. Approximately 85% of human PMDS cases are caused by mutations in *AMH* or *AMHR2*. The canine model was studied to identify additional mutations underlying PMDS. Canine PMDS, known in miniature schnauzer (USA), bears striking resemblance to the human disease. In the model, derived from the miniature schnauzer, testicular AMH expression and bioactivity are present in affected embryos during the critical period for Mullerian duct regression. The target organ defect could lie in any effector downstream of AMH, including AMHR2. Individuals from the canine PMDS pedigree subset were screened for mutations in the *AMHR2* coding region. Sequencing revealed a C to T transition in *AMHR2* that was concordant with the PMDS phenotype. All affected males were homozygous for the mutation, while normal males were either heterozygous or homozygous for the wild type allele. The mutation introduces a premature stop codon, which likely results in a truncated protein that contains only the extracellular domain, similar to the human mutations causing PMDS. The canine model may provide further insights from correlation between clinical phenotype and the molecular defect.

Evidence that different genes influence bone metabolism at different ages. *C. Kammerer[1], J. Shaffer[1], J. Bruder[2], S. Cole[3], T. Dyer[3], L. Almasy[3], J. MacCluer[3], J. Blangero[3], R. Bauer[2], B. Mitchell[4]* 1) U Pittsburgh, Pittsburgh, PA; 2) U Texas Health Science Center, San Antonio, TX; 3) Southwest Foundation for Biomedical Research, San Antonio, TX; 4) U Maryland, Baltimore, MD.

Low bone mineral density (BMD) is the principal risk factor for osteoporosis and a cause of hip fracture in women and men. Bone metabolism changes over the lifespan, with peak BMD acquisition occurring during the 3rd or 4th decade and BMD loss occurring thereafter and accelerating with age. Although peak BMD and BMD loss are heritable, genetic studies have identified and replicated few genes influencing BMD variation, possibly due to genetic heterogeneity among populations of differing ancestry, age, and recruitment criteria. To explore the hypothesis that different genes influence determinants of BMD during different phases of bone metabolism, we performed genome-wide linkage analysis on 3 measures of the BMD age-trajectory, (1) peak BMD, (2) early BMD loss, and (3) late BMD loss. Femoral neck (FN) and total hip (TH) BMD were measured at two time points (5.6 years apart) in members of 34 extended Mexican American families, from which peak BMD (in all participants; n=884), early BMD loss (in those <45 years; n=337) and late BMD loss (in those >45 years; n=300) were calculated. Heritability of peak FN BMD, early loss, and late loss were 0.57, 0.22, and 0.00, respectively. Heritability of peak TH BMD, early loss, and late loss were 0.55, 0.34, and 0.44, respectively. Linkage analyses provided evidence of a quantitative trait locus (QTL) on chromosome 2p in men (LOD=3.04) for peak FN BMD, but not for early or late FN BMD loss. Likewise, evidence of a QTL for early FN BMD loss, but not peak FN BMD or late FN BMD loss, was observed on chromosome 1q (LOD=3.6). Suggestive evidence of a QTL for peak TH BMD (LOD=2.9) in men, but not early or late TH BMD loss, was observed on chromosome 13q. These results indicate that genes influencing peak BMD, early BMD loss, and late BMD loss may differ. Moreover, analyzing trajectory parameters for other traits that change over time, such as cardiovascular disease, may clarify conflicting results and facilitate identification of genes influencing disease.

Is there genetic heterogeneity of celiac disease among populations? *J. Romanos[1], D. Barisani[2], G. Trynka[1], A. Zhernakova[3], M. T. Bardella[4,5], C. Wijmenga[1]* 1) Dept. Genetics, UMC Groningen, University of Groningen, the Netherlands; 2) Dept. Experimental Medicine, University of Milano Bicocca, Italy; 3) Complex Genetics Section, DBG-Dept. Medical Genetics, UMC Utrecht, the Netherlands; 4) Fondazione IRCCS Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy; 5) Dept Medical Sciences, University of Milan, Italy.

Celiac disease (CD) is an inflammatory disorder of the small intestine triggered by gluten peptides and we are studying the involvement of susceptibility genes for CD in different populations. Allelic variants of the HLA-DQ locus (HLA-DQ2/DQ8) contribute to ~40% of CD etiology, while other genes, like *MYO9B*, *CTLA4*, *PARD3* and *MAGI2*, have a modest effect. Most of these minor genes show heterogeneity within European populations since they were not replicated in all studied populations. In southern Europe, individuals carrying DQ2.5 trans are more prevalent than in the north, where individuals carry DQ2.5 cis. Recently, the first genome-wide association study (GWAS) on CD and its follow-up identified 8 new loci that contribute significantly towards CD risk in UK (2 cohorts), Dutch and Irish populations. Seven of these contain genes controlling adaptive immune responses, including *IL2/IL21*, *RGS1*, *IL18RAP*, *CCR3*, *IL12A*, *TAGAP* and *SH2B3*. We selected the 9 most associated single nucleotide polymorphisms to tag the 8 new loci in an Italian cohort composed of 538 CD cases and 593 healthy controls. Common variation in *IL2/IL21*, *RGS1*, *IL12A/SCHIP*, *LPP*, *TAGAP* and *SH2B3* loci was associated with susceptibility to CD in our Italian cohort, but we were unable to detect association between the *CCR3* or the *IL18RAP* loci and CD. This could be due to a low power to detect an OR = 1.2, but it might also be due to genetic heterogeneity among populations. We looked at the separate results of the 4 populations analyzed for the GWAS and noticed that not all of the loci were associated in all of the cohorts. This is the first replication study of 6 of the 8 new CD loci. It is also the first in a southern European cohort. Our results may imply there is a genuine population difference across Europe regarding the loci contributing to CD.

Modeling the RET gene to search for other genetic factors in Hirschsprung disease. *A. Jannot[1,2], J. Amiel[2], F. Clerget-Darpoux[1], S. Lyonnet[2], the Hirschsprung Disease consortium* 1) INSERM, U535, Villejuif F-94817, France; 2) INSERM, U781, Paris F-75743, France.

The genetic background of Hirschsprung disease (HSCR) involves one major gene, the *RET* protooncogene. Many studies demonstrated that both coding sequence mutations and several polymorphisms at the *RET* locus are associated with the disease risk, but up to now, the *RET* gene has never been modeled with a unified approach. Moreover, other genes are involved in addition to *RET*, but most of them have not been yet identified. The International HSCR Consortium, which gathers French, American, Italian, Dutch, Spanish and Chinese teams, has collected 780 families for whom RET mutations on coding sequence have been searched for and 16 SNPs have been genotyped. Moreover, 220 Caucasian trios from this consortium were characterized on a 500K SNP chip. The first step of this study was to precisely define the role of *RET* in HSCR. We found a geographic genetic heterogeneity, but no sex and phenotypic heterogeneity for *RET* SNPs involvement in HSCR, in contradiction with the results of many studies. Using the combination test (1), we have then identified the variants that are the most associated to HSCR and shown that several common variants are necessary to explain *RET* involvement in the disease. The combination of SNPs that best explained the association was used to estimate genotypic risks and their confidence interval using the MASC method (2), which uses both linkage and association information. This combination of SNPs was also used to analyze the genome-wide data to search for a joined association of *RET* and other genetic factors focusing on *RET* gene pathway and on X chromosome, as the high sex-ratio (4/1) in favor of girls for HSCR remains unexplained. HSCR being regarded as a model for complex diseases, this study promotes a stepwise strategy to model candidate genes and gene pathway and to refine associated risks, a necessary step towards a better understanding of the disease and a personalized genetic counseling. 1. Jannot, A.S. et al (2003). Genet Epidemiol, 25, 158-67. 2. Clerget-Darpoux et al (1988). Ann Hum Genet, 52, 247-58.

Common type 2 diabetes and raised fasting glucose variants reduce size at birth. *R. M. Freathy[1], A. J. Bennett[2], S. M. Ring[3], B. Shields[1], C. J. Groves[2], N. J. Timpson[2,3], A. Pouta[4,5], A. Ruokonen[5], E. Hypponen[6], C. Power[6], P. Elliott[7], D. P. Strachan[8], M.-R. Jarvelin[4,5,7], G. Davey Smith[3], M. I. McCarthy[2], T. M. Frayling[1], A. T. Hattersley[1]* 1) Peninsula Medical School, Exeter, UK; 2) University of Oxford, Oxford, UK; 3) University of Bristol, Bristol, UK; 4) National Public Health Institute, Oulu, Finland; 5) University of Oulu, Oulu, Finland; 6) UCL Institute of Child Health, London, UK; 7) Imperial College London, UK; 8) St. Georges, University of London, UK.

Small size at birth is associated with a higher risk of several common late-onset diseases, including type 2 diabetes (T2D), but the cause of these associations is unknown. The fetal insulin hypothesis proposes that the association might be explained by the inheritance of common variants that reduce insulin secretion/action, thereby predisposing to T2D and also to reduced birth weight, since insulin is a key fetal growth factor. To date, we have examined 6 T2D (*TCF7L2*, *CDKAL1*, *CDKN2A/B*, *HHEX-IDE*, *IGF2BP2*, *SLC30A8*) and 2 fasting glucose (*GCK*, *G6PC2*) loci for their impact on birth weight in upto 7887 mothers and 18958 offspring from 4 studies of white Europeans. Three of the 8 variants were associated with reduced size at birth when carried by the fetus. Each T2D or hyperglycemia risk allele at the *CDKAL1*, *HHEX-IDE* and *G6PC2* loci was associated with a 21g [95%CI:11-31g; $P=2\times10^{-5}$], 14g [95%CI:4-23g; $P=0.004$] and 39g [95%CI:18-60g; $P=0.0002$] lower birth weight, respectively. The *G6PC2* association was only observed when adjusting for maternal genotype, which had an opposing, increasing effect on birth weight, and is 50% correlated with fetal genotype. Each maternal copy of the *G6PC2* variant increased birth weight by 25g [95%CI:4-46g; $P=0.02$]. This is consistent with our previous findings that maternal *TCF7L2* and *GCK* risk alleles are associated with higher offspring birth weight. Our results show how common maternal and fetal genotypes can have competing effects on birth weight. Our data are consistent with the fetal insulin hypothesis and provide the first robust evidence that common T2D and fasting glucose variants can reduce birth weight directly via the fetal genotype.

Identification of Highly Conserved Non-coding Sequences in the Distal Region of 9p. *X. Hauge[1], J. Flowers[1], C. Lese Martin[2]* 1) Dept Biology & Physics, Kennesaw State Univ, Kennesaw, GA; 2) Dept Human Genetics, Emory University School of Medicine, Atlanta, GA.

Deletions of the terminal region of the short arm of chromosome 9 (9p-) are associated with trigonocephaly, dysmorphic facial features, and mental retardation. The majority of deletions in patients encompass cerberus 1 (CER1) at 14.7 Mb of 9p. The heterozygous deletion of the CER1 gene has been postulated to cause trigonocephaly. However, we have previously described a group of patients who have deletions smaller than 12.4 Mb, and thus have an intact CER1 gene. Yet, some of these patients exhibit trigonocephaly. This finding opens the possibility that distant cis-regulatory elements for CER1 gene could reside within the first 12.4 Mb of 9p. Although the identification of regulatory elements is difficult, methods of identifying them include searching for highly conserved non-coding regions across species. However, only a limited number of highly conserved sequences have been characterized for chromosome 9 and none of them are localized in the first 12.4 Mb region of 9p. We systematically examined human sequences in increments of 500 bp in the 10 -12.4 Mb region of 9p, eliminating known gene sequences, and compared these human sequences with those of the mouse and zebrafish using the UCSC Genome Browser. The sequences shared by human and mouse or human and zebrafish were aligned. To date, we have identified 39 human sequences which are at least 75 bp long (ranging from 75 bp to 290 bp) and share 70% identity (ranging from 70-92%) with mouse sequences. We have also identified 15 human sequences which are at least 77 bp long and share 60% identity with zebrafish sequences. A clustering of these conserved non-coding sequences was observed. The knowledge of these highly conserved non-coding sequences will be useful in identifying regulatory elements of the candidate genes for 9p- syndrome.

Pathway analysis of genome-wide association and transcript profile data in autism spectrum disorders. *H. Kilpinen[1,2], K. Rehnström[1,3], J. Saharinen[1,4], L. von Wendt[5], I. Hovatta[1,2], L. Peltonen[1,3,6,7]* 1) Institute for Molecular Medicine, Finland (FIMM) and Dept. of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 2) Research Program of Molecular Neurology, University of Helsinki, Helsinki, Finland; 3) Dept. of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) Genome Informatics Unit (GIU), Helsinki, Finland; 5) Unit of Child Neurology, Hospital for Children and Adolescents, Helsinki, Finland; 6) The Broad Institute, MIT and Harvard University, Cambridge, MA, USA; 7) Wellcome Trust Sanger Institute, Cambridge, UK.

Autism spectrum disorders (ASD) have a strong genetic component, but most of the predisposing variants identified have only a minor effect on the disease. Thus, to identify biological pathways altered in ASDs, alternative approaches that take into account multiple affected genes and pathways simultaneously need to be applied. To initiate such studies in the Finnish ASD study sample we first reduced genetic heterogeneity of our samples by analyzing genetic and transcript profiles from an internal isolate of Finland. 54 ASD probands and matched controls were genotyped using Illumina HumanHap300 BeadChip. Transcript profiles were produced from accessible mononuclear cells of ASD patients and matched controls with Affymetrix Human Genome U133Plus2.0. In order to identify biological pathways different between cases and controls, we applied a custom-made non-parametric pathway analysis algorithm to the association analysis results of the genome-wide SNP data. The goal was to identify autism-related pathways by including also "grey zone" SNPs not reaching genome-wide significance in point-wise analysis. Gene annotation data was obtained from the GeneOntology Consortium. After permutation, most significantly affected pathways were those related to developmental processes and synaptic functioning. We are currently obtaining transcript profile data to identify expression-guided pathways in ASD patients. The aim is to compare affected genes, pathways, and genomic distribution of signals in these two datasets, and pave the way towards system biology based analyses to define the molecular pathology behind autism.

Mutations in DMXL1 gene gives rise to a PWS-like phenotype. *K. Gokhale, B. Kulkarni, ELH. Chin, M. Adam, ST. Warren, M. Hegde* Department of Human Genetics, Emory University, Atlanta, GA.

Prader-Willi syndrome (PWS) is a developmental disorder characterized by mental retardation, infantile, hypotonia, poor suck reflex, growth retardation, and childhood onset of pronounced hyperphagia resulting in morbid obesity. PWS is a classic imprinting disorder with most cases resulting from paternal deletions of 15q11-q13 or maternal uniparental disomy 15. However, not all patients who present with PWS-like phenotype have identifiable chromosome 15 involvement, suggesting genetic heterogeneity. We have recently identified 14 novel missense mutations in the DMXL1 gene on chromosome 5 in 12.3% (14/114) of patients with a PWS-like phenotype who previously tested negative for known chromosome 15 etiologies. Analysis of parental samples from three cases showed these missense mutations to all be de novo. While the function of DMXL1 gene is unclear, it is a member of the highly conserved WD repeat protein family, found in all major eukaryotic taxa. Indeed, all but three mutations (79%) replace an amino acid conserved in DMXL1 from human to yeast. We therefore hypothesize that patients with mutations in the DMXL1 gene may present with a PWS-like phenotype. We have made a knock-out mouse model of Dmxl1 which is currently undergoing behavioral assessment. We are also investigating Rav1, the yeast orthologue of DMXL1, to identify DMXL1 interacting proteins and to model the human mutations. This study suggests a novel genetic disorder resembling PWS due to mutations in the highly conserved DMXL1 gene.

Systematic assessment of the effects of population structure on genome-wide association studies. *H. Xu, V. George*
Dept Biostatistics, Med Col Georgia, Augusta, GA.

Large-scale genome-wide association studies are promising for unraveling the genetic basis of complex diseases. Population structure is a potential problem, the effects of which on genetic association studies are controversial. Systematic quantification of the effects of population structure on large scale genetic association studies is needed for valid analysis of the data and correct interpretation of the results. In this study, we performed extensive coalescent-based simulations of samples with varying levels of population structure to investigate the effects of population structure on large-scale genetic association studies. The effects of population structure are measured by the multiplicative changes of the probability of type I error, which is then correlated with the levels of population structure. It is found that at each nominal level of association tests, there is a positive relationship between the level of population structure and its effects, which could be summarized well with a regression function. It is also found that at a specific level of population structure, its effect on association study increases drastically as the significance level of the test decreases. Therefore in genome-wide association studies, the effects of population structure cannot be safely ignored and must be accounted for with proper methods. This study provides quantitative guidelines to the effects of population structure on genome-wide association studies. The results are important for genome-wide association studies in structured or admixed populations.

Fetal Genotype For The Xenobiotic Metabolizing Enzyme NQO1 Influences Intrauterine Growth Among Infants Whose Mothers Smoked During Pregnancy. *T. Grosser[1], T. Price[2], R. Plomin[2], S. Jaffee[2]* 1) Institute for Translational Medicine and Therapeutics, University of Pennsylvania, Philadelphia, PA; 2) Social, Genetic, and Developmental Psychiatry Centre, Institute of Psychiatry, King's College, London, UK.

Maternal smoking during pregnancy retards fetal growth and depresses infant birthweight. The magnitude of these effects may be moderated by fetal genotype. We investigated the relationships between maternal smoking, fetal genotype, and fetal growth in a large population sample of dizygotic twins. Maternal smoking retarded fetal growth in a dose-dependent fashion. In a subsample of 497 twin pairs whose mothers smoked during pregnancy, a functional polymorphism in the NAD(P)H:quinone oxidoreductase gene (NQO1 Pro187Ser; rs1800566) was significantly associated with fetal growth; within twin pairs, possession of the low-activity Ser allele was associated with greater fetal growth. This effect was strongest among moderate smokers. This is the first demonstration that fetal genotype for an enzyme involved in tobacco smoke metabolism influences intrauterine growth independent of maternal genotype.

Supernumery der(22)t(8;22) syndrome occurs by 3:1 meiotic nondisjunction of a recurrent reciprocal translocation. *E. H. Zackai, M. C. Ciano, B. S. Emanuel* Division of Human Genetics, The Children's Hospital of Philadephia, University of Pennsylvania School of Medicine, Philadelphia, PA.

A 3-year-old male with mild developmental delay, large ears, short first metacarpal, fifth finger camptodactyly and a karyotype of 47,XY,+der(22)t(8:22)(q24.13;q11.21)mat prompted a literature review leading to the definition of a new syndrome. The supernumerary der(22)t(8:22) was found to be secondary to 3:1 meiotic nondisjunction of a site specific parental reciprocal translocation. There are 10 cases of +der(22)t(8:22), individually described in the literature, including two sets of siblings. The site specific balanced translocation in the nine families (including our new case) is paternally derived in three and maternal in five (one case unknown). Nine of the eleven cases are male. Birth weight and subsequent growth has been normal. Dysmorphia has been mild with ear abnormalities including large prominent ears (4/11), preauricular pit (3/11), and atretic ear (1/11). Extremity anomalies were noted in the majority - clinodactyly (6/11), camptodactyly (1/11). Three of the nine males had cryptorchidism. All patients presented with mild developmental delay of milestones. IQ, where available, ranged from 50-70. There are no life-threatening structural abnormalities. The ages of the cases ranged from < 5 years (4), 5-20 years (5), to 20-45 years (2). This, after the t(11;22), represents the second most common recurrent reciprocal non-Robertsonian translocation involving chromosome 22. Through 3:1 meiotic nondisjunction it has also been found to produce a specific new syndrome as a result of the presence of a supernumerary der(22).

Characterization of the molecular overlap between Waardenburg syndrome type 2 and 4. *V. Pingault[1,2,3], F. Dastot-Le Moal[1,3], D. Ente[3], T. Attie-Bitach[4], R. Touraine[5], J. Amiel[4], M. Goossens[1,2,3], S. Marlin[6], N. Bondurand[1,2]* 1) INSERM U841, IMRB, Département de génétique, Equipe 11, Créteil, France; 2) Université Paris 12, Faculté de Médecine, IFR10, Créteil, France; 3) AP-HP, Groupe Albert Chenevier-Henri Mondor, Service de biochimie et génétique, Créteil, France; 4) INSERM U781, Hôpital Necker, AP-HP, Paris, France; 5) CHU-Hôpital Nord, Service de Génétique, Saint Etienne, France; 6) Service de Génétique, Centre de référence Surdités génétiques, INSERM U587, Hôpital Armand Trousseau, France.

Waardenburg syndrome (WS) is a rare (1/40000) auditory-pigmentary disorder that exhibits varying combinations of sensorineural hearing loss and abnormal pigmentation of the hair and skin. Depending on additional symptoms, WS is classified into four subtypes, WS1 to 4. Absence of additional features characterizes WS2. The association of facial dysmorphic features defines WS1 and 3 whereas the association with Hirschsprung disease (aganglionic megacolon) characterizes WS4, also called Waardenburg-Hirschsprung disease. Mutations within the genes encoding *MITF* and *SNAI2* have been identified in 15 % of WS2 cases, mutations within the *PAX3* gene explain almost all WS1 and WS3 cases, whereas mutations of *EDN3*, *EDNRB* and *SOX10* are responsible of 40-60% of WS4. Recently, we described the first *SOX10* deletions in patients presenting with WS2. After the involvement of *PAX3* in WS1 and 3, the identification of *SOX10* mutations in WS2 and 4 further documented the molecular complexity and close relationship that link the different subtypes of WS and invited to fully characterize the molecular overlap between WS2 and WS4. We took advantage of the point mutation detection systems routinely used in the laboratory, but also of other strategies such as QMF-PCR assay and looked for point mutations and rearrangements within the *EDN3/EDNRB* and *MITF/SNAI2* genes in both 30 WS4 and 30 WS2 cases. We identified new mutations within the *MITF*, *EDN3*, and *EDNRB* genes. These comprehensive studies are necessary to fully document the complexity of WS, and show that the molecular overlap between WS2 and 4 mostly involves the *SOX10* gene.

Array-based comparative genomic hybridization identifies high frequency of 15q11-q13 duplications in patients with non-syndromic autism spectrum disorders. *A. Battaglia[1], T. Filippi[1], B. Parrini[1], R. Igliozzi[1], A. Novelli[2], L. Bernardini[2], I. Torrente[2], R. Tancredi[1]* 1) Child NeuroPsychiatry, Stella Maris Inst, Pisa, Italy; 2) CSS-IRCCS, S Giovanni Rotondo Inst Mendel, Roma, Italy.

Autism spectrum disorder (ASD) is a heritable developmental disorder in which chromosomal abnormalities are found at a higher rate than the general population. Amongst those, maternally inherited duplications of chromosome 15q11-q13 have been reported in about 1-3%, and recurrent microdeletions and a reciprocal microduplication at 16p11.2 in about 1% of ASD individuals. To assess the frequency of cryptic chromosomal rearrangements in patients with non-syndromic ASD, we studied 23 patients presenting with non-syndromic ASD, using a DNA microarray constructed from 60-mer oligonucleotides spaced at approximately 75 Kb intervals across the genome. All patients were diagnosed as having ASD (with exclusion of the Rett syndrome) after the administration of the ADI-R, and the ADOS-G. Both instruments assess the symptoms of ASD, including autism, as defined in DSM-IV. In addition, a clinical diagnosis was made by the child psychiatrist evaluating the child, on the basis of presence or absence of DSM-IV criteria of autism. Physical and neurological examinations were performed, with particular attention to growth parameters, to any dysmorphic trait or minor anomaly especially involving the face, limbs, and skin, and to variations in muscle tone or to the presence of involuntary movements. All patients underwent karyotype, molecular Fra-X studies, brain MRI (to exclude the presence of any brain abnormality). Blood was collected on the subjects and on their parents. Parental bloods were banked to determine if any detected anomalies were de novo or inherited. Three clinically relevant rearrangements were identified in 3 (13%) patients: two maternally (5 Mb) and one paternally (300 Kb) inherited duplications of chromosome 15q11-q13. All three patients had autism. No differences could be found in the neuropsychological profile between them and the other 20 ASD patients. These results clearly show that aCGH should be considered to be an essential aspect of the genetic analysis of all ASD patients.

Orofacial Clefts in the National Birth Defects Prevention Study, 1997-2004. *A. E. Genisca[1,2], J. L. Frias[1,3], C. S. Broussard[2], M. A. Honein[2], E. J. Lammer[4], C. A. Moore[2], G. M. Shaw[5], J. C. Murray[6], W. Yang[5], S. A. Rasmussen[2]* 1) Centers for Disease Control and Prevention; 2) The CDC Experience Fellowship; 3) McKing Consulting Corp; 4) Children's Hospital Oakland Research Inst; 5) March of Dimes, California Research Division; 6) Dept of Pediatrics, Univ of Iowa.

Orofacial clefts are one of the most common types of birth defects, but their clinical presentation has not been well described in a geographically diverse U.S. population. We used data from the National Birth Defects Prevention Study (NBDPS), a multi-site, population-based case-control study aimed at identifying genetic and environmental risk factors for major birth defects, to characterize the prevalence and phenotype of nonsyndromic orofacial clefts. Included in the analysis were infants born during 1997-2004 with a cleft lip only (CL), cleft lip with cleft palate (CLP), or cleft palate only (CP). Infants with clefts associated with single-gene disorders, chromosomal abnormalities, holoprosencephaly, or amniotic band sequence were excluded. A total of 3,344 infants with orofacial clefts meeting the NBDPS case definition [including 751 (22%) with CL, 1,399 (42%) with CLP and 1,194 (36%) with CP] were identified among 2,731,853 live births. Prevalence estimates for CL, CLP, and CP were 0.3, 0.5, and 0.4/1,000 live births, respectively. The majority (92% of CL, 85% of CLP, and 79% of CP) were classified as having isolated defects (no unrelated major defects). Among those with specified laterality, about twice as many infants with CLP had unilateral vs. bilateral involvement while for CL there were over 10 times as many with unilateral vs. bilateral involvement. For both CL and CLP, involvement was most often left-sided. About one quarter of CP cases had Robin sequence. In infants with CL and CLP, the most common additional major defects were heart defects, limb defects, and musculoskeletal defects, while defects of the heart, limb, and central nervous system were most common in infants with CP. Better understanding of the clinical presentation and the major defects associated with clefts may help guide clinical care as well as contribute to an improved understanding of pathogenesis.

Analysis of hypouricemic patients with respect to the SLC22A12 (URAT1) gene. *B. Stiburkova[1], M. Hosoyamada[3], K. Ichida[4], I. Sebesta[1,2]* 1) Charles University, 1st Faculty of Medicine, Institute of Inherited Metabolic Disorders, Czech Republic; 2) Charles University, 1st Faculty of Medicine, Institute of Clinical Biochemistry and Laboratory Diagnostic, Czech Republic; 3) Department of Pharmacotherapeutics, Kyoritsu University of Pharmacy, Japan; 4) Department of Pathophysiology, Tokyo University of Pharmacy and Life Sciences, Japan.

Hypouricemia is defined as a serum urate levels less than 2 mg/dl and is related to several purine metabolic disorders. URAT1, encoded by the SLC22A12, is the major urate-anion exchanger in the kidney regulating blood urate levels and is presumed to play the central role in reabsorption of urate from glomerular filtrate. Genetic variations of the SLC22A12 gene are associated not only with idiopathic renal hypouricemia (OMIM 220150) but also with reduced renal urate excretion and with elevated serum uric acid levels. Within the scope of selective screening for inherited metabolic disorders conducted from 1999 till 2006 in our department, serum and/or urine levels of the uric acid were investigated in group of 18 854 patients. Purine metabolites were investigated approximately in 3 000 patients. Hypouricemia was found in 569 cases. From these group were carefully selected suspected patients for molecular analysis of the SLC22A12 gene. Detailed purine metabolic investigation revealed repetitively very low serum uric acid in blood (63 mol/l) and elevation of excretion fraction of UA (43%). No one patients had exercise-induced acute renal failure. Subsequent seq. analysis of SLC22A12 (promotor region, 10 exons and intron-exon boundaries) in the 13 subjects revealed 3 sequence variations in the promotor and 5'-UTR region and 5 sequence variations in exonic regions. 3 heterozygous nucleotide missence transition and one heterozygous and homozygous deletion, yet unpublished, were found. Five patients had SLC22A12 sequence variations: one homozygotes, two compound heterozygotes and two heterozygotes. The function and imunohistochemistry analysis by *in vitro* in *Xenopus* oocytes showed significantly decreased urate transport activity of these SLC22A12 sequence variants. This study was supported by grant MSM0021620806 Czech Republic.

Genome wide array diagnostics by high resolution BAC array CGH and 250k SNP array analysis in 1,300 patients with mental retardation. *N. de Leeuw, R. Pfundt, J. Hehir-Kwa, A. Simons, D. Koolen, I. Neefs, N. Leijsten, T. Machielsen, B. van Bon, H. Yntema, W. Nillesen, T. Kleefstra, J. Veltman, B. de Vries, D. Smeets* Dept Human Genetics, Radboud University Nijmegen MC, Nijmegen, Netherlands.

We evaluate our procedures and findings after genome wide array-based Comparative Genome Hybridisation (array CGH) analysis was implemented in 2003 in our diagnostic cytogenetic laboratory for patients with mental retardation with or without multiple congenital anomalies. DNA samples from 500 patients have been analysed by array analysis using a tiling-resolution array consisting of 32,447 BACs and an additional 800 patients using the 250k Affymetrix SNP array platform. In order to achieve fast and reliable interpretation of the copy number variants (CNVs) detected by genome wide array analysis, research and diagnostic colleagues from various disciplines within our department work closely together. All CNV data are stored for potential future analyses and our clinically relevant CNVs are also made available to others through the ECARUCA database (www.ecaruca.net). In ~13% of patients with a normal karyotype and without subtelomeric imbalances a clinically significant CNV was detected by genome wide array analysis, ranging in size from ~50 kb to 15.7 Mb, excluding one mosaic trisomy 8. In an additional 4% of these patients, CNVs were detected that were inherited from either the father (43%) or the mother (57%). Apart from the detection of several new microdeletion syndromes reported by us and others, so far, many novel genes have been identified. Moreover, confirmation and follow-up experiments using FISH revealed a mosaic aberration in two patients. A cryptic, balanced chromosome rearrangement was identified in the respective parent from each of three other patients, thereby explaining the familial occurrence of the clinical phenotypes. Considering the high additional detection rate of clinically relevant CNVs by genome wide array analysis observed in this study, we recommend to start with array analysis in the diagnostic work-up of patients with mental retardation with or without multiple congenital anomalies.

Testing the genes and pathways behind fetal motoneuron disease as candidate ALS genes. *H. O. Nousiainen[1], H. Laaksovirta[2], H. Kaariainen[1], K. Silander[1], M. Kestila[1], L. Peltonen[1,3,4,5]* 1) Institute of Molecular Medicine and National Public Health Institute, Helsinki, Finland; 2) Department of Clinical Neurosciences, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) The Broad Institute, MIT, Boston, MA, USA; 5) The Wellcome Trust Sanger Institute, Hinxton CB10 1SA, UK.

Amyotrophic Lateral Sclerosis (ALS) is a late-onset, rapidly progressing neurodegenerative disease affecting motor neurons. ALS usually leads to complete loss of voluntary muscle movement and death within a few years of the appearance of the first symptoms. The etiology of most ALS cases remains unknown, but mutations in Cu/Zn superoxide dismutase *SOD1* and *TARDBP*, encoding the RNA binding protein TDP-43, have been implicated in a small fraction of cases of both familial and sporadic ALS. Here we have taken a pathway based approach in searching ALS genes triggered by our recent findings on exceptional, early onset motoneuron diseases. We recently identified mutations in a gene encoding the mRNA export mediator protein GLE1 in patients with two forms of fetal lethal motoneuron disease. Interestingly, increasing evidence of the involvement of TDP-43 in mRNA processing has also been emerging recently, implicating that mRNA processing and regulation of localized protein synthesis may be a key mechanism in the development, maturation, and functioning of anterior motoneurons in general, and potentially provide clues of the molecular pathogenesis of ALS. We are currently analyzing a nationwide cohort of 300 Finnish ALS patients including both familial and sporadic cases. We first excluded patients with mutations in SOD1 and are currently performing targeted genotyping of the remaining patient samples for 90 SNPs of critical genes involved in mRNA transport and processing using the Sequenom iPLEX Gold chemistry. The study will potentially provide additional information of the molecular mechanisms behind ALS and increase our understanding of the pathogenesis of this devastating disease.

Putative role for miR-562 in kidney development and cancer. *K. Drake, B. Gopalan, M. Aldred* Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic, Cleveland, OH.

We have identified a 360 kb minimal region of deletion at chromosome band 2q37.1 in up to 5% of Wilms tumors, strongly suggesting the presence of a tumor suppressor gene that predisposes to this childhood kidney cancer. *DIS3L2*, a putative mitotic control homolog is the only gene within this minimally deleted region. Intron 9 of *DIS3L2* contains a previously uncharacterized micro-RNA, miR-562. Recent studies have revealed that miRNAs have key roles in diverse regulatory pathways, including control of developmental timing, apoptosis, cell proliferation and organ development. miRNAs and their targets seem to form complex regulatory networks. For example, a single miRNA can bind to and regulate many different mRNA targets. Bioinformatic analysis of putative miR-562 targets has identified several genes with established roles in kidney development. *EYA-1* encodes a gene that is essential for cell survival and proliferation in early metanephric development. *EYA-1* has also been shown to be highly expressed in Wilms tumors compared to fetal kidney and mutations of this gene occur in branchio-oto-renal dysplasia syndrome, a syndrome associated with renal abnormalities that range from mild hypoplasia through to the complete absence of the kidneys. Other targets include *MET* a hepatocyte growth factor receptor with known oncogenic activity and *PSEN1* a gene involved in Notch and *Wnt* signaling with a role in renal and urological system development and function. These targets suggest that miR-562 may play a role in fetal kidney development. Using RNase protection assays we have shown that miR-562 has tissue-restricted expression, which is highest in the fetal kidney, present in several kidney derived cell lines and absent in the fetal heart and liver as well as MCF7 cells. Screening of 176 Wilms tumor samples revealed a 19 bp deletion of miR-562 in 3 cases. This polymorphism is also present in the normal population, albeit at a low frequency (0.023) and may be a predisposing factor in the development of Wilms tumor. We are currently undertaking a study of putative miR-562 targets, including *EYA1*, *MET* and *PSEN1*, using luciferase reporter assays.

Structural variation in patients with multiple sclerosis. *R. Rabionet[1], E. Docampo[1], M. García[1], L. Armengol[1], E. Munteis[2], J. E. Martínez[2], F. Matesanz[3], A. Alcina[3], J. Roquer[2], X. Estivill[1,4]* 1) Genes & Disease programme, Centre de Regulació Genòmica and Public Health and Epidemiology Network Biomedical Research Center (CIBERESP), Barcelona, Barcelona, Spain; 2) Neurology Service, Hospital del Mar-IMAS, Barcelona, Catalonia, Spain; 3) Instituto de Parasitologia y Biomedicina "López-Neyra", CSIC, Granada; 4) Universitat Pompeu Fabra (UPF), Barcelona, Spain.

Multiple sclerosis (MS) is a chronic inflammatory demyelinating disease that affects the central nervous system. Several studies provide evidence that MS is a complex disorder involving genetic and environmental factors. Several different approaches have been undertaken to elucidate the genetic causes of MS, including linkage and association studies. These have consistently shown association to the major histocompatibility complex (MHC) region, specifically the DR15 haplotype. Other MS genes have been more elusive, with ILR7, CD58 and IL2RA as the most consistent. The aim of this study was to evaluate a possible contribution of genomic structural variation to MS susceptibility. Forty relapsing-remitting MS samples were divided into two pools and comparative genomic hybridization (CGH) against a pool of 50 control samples was performed using Agilent 244K arrays. Initial selection criteria (three consecutive probes with a log2 ratio above 0.29) showed differential hybridization between both groups of cases and controls only at the chromosome 6 MHC region, spanning four to six probes (depending on the pool). In addition, one region in chr1 spanning 4 probes appeared as a CNV only in one of the two pools of MS samples (relapsing-remitting). This region has been further characterized and tested for association in a larger sample size (120 samples), obtaining a p-value of 0.051. Further characterization in an additional sample set of 800 samples is under course. Finally, when considering only one probe, seven regions showed differential hybridization in cases versus controls in both pools and were selected for follow-up by RTqPCR experiments.

Analysis of Copy Number Variation within the Chromosome 4 GABA Region in Autistic Individuals. *D. Hedges[1], H. Cukier[1], M. Rayner[1], D. Ma[1], J. Jaworski[1], P. Whitehead[1], H. Wright[2], R. Abramson[2], J. Hussman[3], J. Haynes[4], M. Cuccaro[1], J. Gilbert[1], M. Pericak-Vance[1]* 1) Miami Institute for Human Genomics, University of Miami, Miami, FL,; 2) University of South Carolina School of Medicine, Columbia, SC; 3) Hussman Foundation, Ellicott City, MD; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Autism has a strong genetic component. Studies over the past decade have demonstrated that the underlying genetics are complex. Research suggests an important role for copy number variants (CNVs) in autism risk. The GABRA4 gene lies among a 1.5Mb cluster of GABA-related genes on chromosome 4 (chr4), which include GABRA2,GABRA4 and GABRB1. The chr4 GABR cluster has been implicated in autism patients through cytogenetic alterations as well as association with SNPs in the GABRA4 gene. These data point to GABRA4 and potentially other GABR genes in the cluster as autism candidate genes. We examined the GABR cluster on chr4 for CNVs associated with autism. To assess structural variation, we designed custom 4x44k Agilent CGH arrays across the entire chr4 cluster, spanning the 1.49 Mb region with a density of approximately 1 probe every 40 nucleotides. We evaluated 44 individuals who met DSM IV criteria for an autistic spectrum disorder and 30 control individuals. Results show putative CNVs in thirteen distinct sites within the chr4 GABA region. Eleven sites fell within the GABRB1 gene, one site fell between GABRG1 and GABRA2, and the final site was located between GABRA2 and GABRA4. Five CNVs, all within the GABRB1 gene, were unique to the autism population sampled. Three sites contained duplications, one was a putative deletion, and the remaining site exhibited both. Across all 13 loci, there was a trend towards significance ($p \sim 0.062$) for an increased number of deletions in autism cases vs. controls. The statistical trend in this limited sample size suggests that investigation of CNVs in the chr4 cluster in a larger sample set is warranted. We are validating CNVs detected via standard and real-time PCR methods and testing the GABR cluster by CGH on an expanded population size of 250 autistic probands and 50 controls individuals.

Serum uric acid concentrations and sequence variants in methylenetetrahydrofolate reductase (MTHFR)gene. *I. Sebesta[1,2], M. Sedova[3], B. Stiburkova[1], M. Pavlikova[3], J. Zvarova[3], V. Kozich[1]* 1) Institute of Inherited Metabolic Disorders; 2) Institute of Clinical Biochemistry and Laboratory Diagnostics, First Faculty of Medicine, Charles University in Prague; 3) Department of Medical Informatics, Institute of Computer Science of the Academy of Sciences of CR, v.v.i., Czech Republic.

Recent data suggest that an elevated serum uric acid (UA) concentration may play a role in the development of cardiovascular, renal disorders and of metabolic syndrome. We investigated biochemical, anthropometric, and genetic determinants of serum UA levels including the MTHFR sequence variants in the group of 569 healthy subjects (275 men and 294 women). Methods: The association of biochemical, anthropometric, and genetic variables with the UA levels was evaluated in both univariate and multivariate linear regression models. Variables that were significantly associated with UA levels in univariate analysis were used as a set of initial predictors in the backward selection procedure to find the model which best explains the variability of UA levels. Results: The median UA concentration was 5.5 mg/dL for men and 3.8 mg/dL for women. The univariate analysis revealed that individuals homozygous for the c.1298A>C MTHFR variant had significantly reduced UA concentration. In average, individuals with C/C genotype had 0.3 mg/dL lower UA compared to the group of individulas with A/A or A/C genotype. On the other hand, the c.677T>C variant in the MTHFR gene had no significant effect on UA levels. The final model explained variability of serum UA concentration with R2 =0.5721 and included: age, sex, BMI, alcohol consumption, presence of hypertension, c.1298A>C MTHFR variant and concentrations of cystatine, creatinine, hemoglobin, cysteine, triglycerides and activity of enzyme GGT. Conclusions: Our results did not confirm the role of common c.677T>C variant in MTHFR gene as a determinant of hyperuricemia. In contrast, homozygosity for the c.1298A>C MTHFR variant was associated with reduced serum UA concentration. Supported by grant VZMSM0021620806.

Disruption of highly conserved, very distant regulatory elements on either side of *SOX9* is associated with Pierre Robin sequence. *S. Benko[1], JA. Fantes[2], J. Amiel[1], DJ. Kleinjan[2], S. Thomas[1], J. Ramsay[2], N. Jamshidi[3], A. Essafi[2], CT. Gordon[3], C. Golzio[1], N. Kilpatrick[3], P. Thomas[3], M. Vekemans[1], ND. Hastie[2], A. Munnich[1], A. Pelet[1], PG. Farlie[3], DR. FitzPatrick[2], S. Lyonnet[1]* 1) INSERM U781, Université Paris Descartes, Hôpital Necker, Paris, France; 2) MRC Human Genetics Unit, Edinburgh EH4 2XU, UK; 3) Murdoch Childrens Research Institute, Royal Childrens Hospital, Parkville, Australia.

Most evolutionarily conserved human DNA has no protein-coding function but may have regulatory functions whose mechanism and size of the domains controlled remains largely unknown. We show here that disruption of very distant cis-regulatory highly conserved non-coding elements (HCNE) on either side of the *SOX9* gene is associated with Pierre Robin sequence (PRS), an orofacial cleft anomaly with mandibular hypoplasia. We demonstrate the existence of a PRS locus at 17q24 through linkage analysis in a large PRS family, mapping of 3 independent translocation breakpoints that cluster 1.06-1.23 Mb upstream of *SOX9*, and identification of microdeletions containing HCNEs immediately upstream of these breakpoints, or at a similar distance downstream of *SOX9*. The pattern of histone modifications associated with both the centromeric and telomeric regions suggests tissue-specific enhancer function. A heterozygous point mutation was identified in an additional PRS family within one of the upstream deleted HCNEs, capable of driving mandibular expression in transgenic mouse embryos. ChIP experiments demonstrated that this HCNE binds MSX1 protein and the human mutation both alters this binding and abrogates enhancer function in a mandibular mesenchymal cell line. 3D FISH analysis indicates that chromatin decompaction occurs specifically in Sox9 expressing cells within the developing mandible of mouse embryos, suggesting that the enhancer is more likely to be regulating *Sox9* than other flanking genes. Our data, combined with existing evidence from human and animal phenotypes, suggests that the disruption of distant, tissue-specific regulatory elements, required for the normal development of the mandibula, perturbs embryonic expression of *SOX9* and accounts for the PRS phenotype.

Genetic-radiological correlation study in 48 children with characterized genetic mutation responsible for mitochondrial diseases. *A. S. Lebre[1], M. Rio[1], P. de Lonlay[1,2,4], F. Brunelle[3,4,5], A. Rotig[2], A. Munnich[1,2,4], N. Boddaert[3,4,5]* 1) AP-HP, Hôpital Necker-Enfants Malades, Département de Génétique, Paris F-75015 France; 2) Inserm, U781, Hôpital Necker-Enfants Malades, Paris F-75015 France; 3) AP-HP, Hôpital Necker-Enfants Malades, Service de radiologie pédiatrique, Paris F-75015 France; 4) Université Paris Descartes, Faculté de Médecine René Descartes, Paris F-75015 France,; 5) Inserm, U797, CEA, Neuroimagerie en psychiatrie, Service hospitalier Frédéric Joliot, Orsay F-91400 France.

Purpose : Mitochondrial diseases are very complex to study because of the large number of disease-causing genes. For patients with neurological symptoms, we looked for common cerebral imaging pattern according to the type of genetic mutation. Methods used: We report here a retrospective study of cerebral imaging for 48 patients with mitochondrial diseases. Tomodensitometry and Magnetic resonance imaging were usually performed in the Department of Pediatric Imaging. Patients presented mitochondrial diseases with isolated or multiple respiratory chain deficiencies. Causing mutations were identified for all of them. Results : For a same group of mutations, the lesionnal pattern in cerebral imaging was often very similar. For patients with complex I deficiency (n=16), large abnormalities were observed in brainstem (16/16), associated with basal ganglia abnormalities (15/16). Some patients presented sus-tentorials stroke-like (4/16). One of these patients had also an associated leukodystrophy. Patients with complex V deficiency (n=10) presented putamen abnormalities (9/10), associated with cerebellar atrophy in 3 y.o. patients (6/6). Patients with quinone deficiency (n=8) presented with cerebellar atrophy (8/8) and sus-tentorials stroke-like (3/8). Patients with the MELAS mutation (n=7) presented cerebellar atrophy (7/7) and basal ganglia abnormalities. For patients with mutations in POLG gene (n=7), normal imaging was observed in 6/7 patients but 1 patient presented thalamic abnormalities. Our study is the first evidence of a good contribution of cerebral imaging in mitochondrial diseases for orientation of genetic studies and a faster identification of the causing mutations.

Association of polymorphisms in genes related to renin-angiotensin-aldosterone system with left ventricular structure and function and incident heart failure in four ethnic groups; the Multi-Ethnic Study of Atherosclerosis (MESA). *H. Bahrami[1], B. Fang[2], D. A. Bluemke[1], S. Heckbert[3], J. Kaufman[3], J. H. Young[1], X. Guo[2], V. Fernandes[1], D. Herrington[4], S. Shea[5], J. I. Rotter[2], W. Post[1], J. A. Lima[1]* 1) Johns Hopkins Univ; 2) Cedars-Sinai Medical Ctr; 3) Univ. of Washington; 4) Wake Forest Univ; 5) Columbia Univ.

Introduction: Our objective was to determine the associations of the genes encoding the renin-angiotensin-aldosterone (RAA) system with MRI-measured parameters of cardiovascular structure/function and incident CHF in four ethnic groups. **Methods:** 55 tagging SNPs were genotyped in angiotensinogen (AGT), angiotensin converting enzyme (ACE), and angiotensin II receptors 1 and 2 (AGTR1 and AGTR2) genes in 2,847 participants [712 Caucasians (CA), 712 African Americans (AA), 705 Hispanics (HIS) and 718 Chinese Americans (CHN)]. Multiple linear regression was used to determine the associations of these SNPs with LV mass, LV ejection fraction (LVEF), cardiac output, and Cox regression models for CHF, while adjusting for risk factors stratified by racial/ethnic group. Empirical p-values were then calculated for p-values 0.0125 to account for multiple genes tested. **Results:** During follow-up, 38 participants developed CHF. SNPs in AGTR1 [rs422858-C (adjusted HR: 2.9, p:0.011) and rs2638363-A (adjusted HR: 2.4, p<0.001)] were associated with increased risk of CHF in AA; these associations were more pronounced after adjustment for risk factors. SNPs in AGT (rs2478545-A, p:0.002) and AGTR1 (rs275645-G, p<0.001) were independently associated with lower LVEF in CA and HIS, respectively. Lower cardiac output was independently related to polymorphisms in AGTR1 (rs275646-A, p<0.001) in HIS and in AGTR1 (rs4681443-G and rs718858-G, p: 0.002) and AGT (rs3789671-T, p:0.001) in CHN. A SNP in the AGTR2 (rs5950586-A, p:0.0075) was an independent predictor of LV mass in HIS men. **Conclusions:** Polymorphisms in genes encoding RAA system, particularly in AGTR1, appear to be associated with LV function (in HIS & CHN) and incident CHF (in AA). This potential genetic heterogeneity may contribute to ethnic differences in LV function and incidence of CHF.

Associations Between Lactating Womens Vitamin D Levels, Their Breastfed Infants Vitamin D Levels, and VDR Polymorphisms and VDR Expressions in Hair Follicles. *F. Ozkinay[1,2], H. Onay[2], C. Gunduz[3], A. Aykut[1], A. Ekmekci[1], C. Biray[3], H. Akin[2], O. Cogulu[1,2], G. Koturoglu[1], S. Kalkan[1], S. Pehlivan[4], M. Coker[1]* 1) Dept Pediatrics, Ege Univ, Izmir, Turkey; 2) Dept Medical Genetics, Ege Univ, Izmir, Turkey; 3) Dept Medical Biology, Ege Univ, Izmir, Turkey; 4) Dept Medical Biology, Gaziantep Univ, Gaziantep, Turkey.

In human body vitamin D plays a role in the metabolic regulation of a number of systems. Both environmental factors and genetic factors have important influences on vitamin D metabolism. In this study the factors which may effect vitamin D levels in serum and breast milk, the association between vitamin D receptor (VDR) polymorphisms and vitamin D metabolism and VDR expression in hair follicles have been investigated in lactating women and in their 1-6 month-old breastfed babies. The study included 101 lactating women and their 101 exclusively breastfed babies. A questionnaire was applied to the mothers to evaluate their sun exposure, diary vitamin D consumption and diet. The relationships between those environmental factors, six VDR polymorphisms, Cdx2, FokI, BsmI, ApaI, TaqI and Poly A, VDR expression levels in hair follicles and vitamin D metabolites were evaluated. Insufficient sun exposure and vitamin D consumption, low serum 25(OH)D levels were detected in the mothers. The serum 25(OH)D levels of the mothers were well correlated with calcium and vitamin D levels in their milk and their babies' serum 25(OH)D levels. In the condition of normal serum 25(OH)D levels, BB genotype of BsmI polymorphism was significantly associated with low Ca levels in breast milk (p0.04). When serum 25(OH)D levels lower than the normal levels in the mothers, low vitamin D levels (p0.01), in the milk and low VDR expression(p0.04) in the hair follicles were detected, beside low calcium levels in the milk (p0.01). In the mother having high levels of Ca in their milk the frequency of aFBGtS haplotype was significantly higher (p0.02) while both aFBGtS and AfbGTS haplotypes frequencies were significantly higher in mothers having high levels VDR expression in their hair follicles.

Clinical features of Paternal Uniparental Disomy 14 in four related patients with a typical methylation pattern but biparental inheritance of chromosome 14. *G. Morin[1], L. Cuisset[2], A. G. Le Moing[1], B. Demeer[1], A. Receveur[3], J. Andrieux[4], H. Copin[3], M. Mathieu[1]* 1) Clinical Genetic Unit -University Hospital - Amiens - France; 2) Molecular Genetic Laboratory - Cochin Institute - Paris - France; 3) Cytogenetic Unit - University Hospital - Amiens - France; 4) Medical Genetic Laboratory - Jeanne de Flandre Hospital - Lille - France.

Paternal uniparental disomy 14 [upd (14) pat] is responsible of a well recognizable phenotype that includes facial dysmorphism, small bell-shaped thorax, abdominal wall defects, polyhydramnios and developmental delay. Skeletal defects include a distinctive bowing of the ribs with a coat-hanger appearance that gives a good diagnostic clue. So far less than 15 cases with upd (14) pat have been reported. Recently, Kagami et al published 8 additional patients with a paternal upd (14)-like phenotype, but without upd (14). They found deletions of the 14q32.2 region in 4 patients and hypothesized epimutations of this imprinted region in the 4 other patients. Here we report on four patients, a mother and her 3 daughters, born of two separate unions, with clinical features of paternal upd (14). They show a typical methylation pattern of upd (14) pat, but biparental inheritance for chromosome 14. All the classical or molecular cytogenetic investigations were negative suggesting a dominantly transmitted genetic alteration. To our knowledge, this is the first familial report of paternal upd (14)-like phenotype without microdeletion.

13 new patients with 13q deletion syndrome : genotype-phenotype analyses in progress and first report of a Steinfeld syndrome. *C. Quélin[1], C. Bendavid[2,3], C. Dubourg[2,3], C. de la Rochebrochard[1], J. Lucas[4], C. Henry[4], S. Jaillard[2,4], P. Loget[5], L. Loeuillet[6], D. Lacombe[7], JM. Rival[8], V. David[2,3], L. Pasquier[1,2], S. Odent[1,2]* 1) Service de Génétique Médicale, Rennes, France; 2) CNRS UMR 6061 Génétique et Développement, Rennes, France; 3) Laboratoire de Génétique Moléculaire, Rennes, France; 4) Laboratoire de Cytogénétique, Rennes, France; 5) Département dAnatomie et cytopathologie, Rennes, France; 6) Service dAnatomie et Cytopathologie, Poissy, France; 7) Service de Génétique Médicale, Bordeaux, France; 8) Service de Génétique Médicale, Nantes, France.

13q deletion is characterised by a wide phenotypic spectrum resulting from a partial deletion of the long arm of chromosome 13. The main clinical features are mental retardation, growth retardation, craniofacial dysmorphy and various congenital defects. Only one recent Italian study was aimed at determining genotype-phenotype correlations among 13q deletions from a group of mainly live born children, using array-CGH and FISH. In order to improve the molecular characterisation of 13q monosomy, 13 new patients (of which 10 foetuses), were collected based on a cohort of holoprosencephaly linked to ZIC2 gene deletion and/or patients with 13q deletion diagnosed by standard caryotype. First, quantitative gene screening using MLPA was performed to look for ZIC2 gene deletion and then, CGH array analysis was carried out using the Agilent Human Genome CGH microarray 4x44K (Agilent Technologies, Santa Clara, CA). All the foetuses had severe cerebral midline malformations associated with a deletion including the ZIC2 gene. Further candidate genes are suspected to explain the malformations associated with cerebral anomalies in the hypothesis of a contiguous gene syndrome: SPRY2 in 13q31.1 is implicated in lens cell proliferation and differentiation for congenital cataract; GPC5 in 13q32 is mainly expressed in the mesenchyme of the developing limb bud for upper limbs anomalies. Moreover, we reported the first patient with Steinfeld phenotype linked to a chromosomal anomaly, and suggested that some of the associations between cerebral midline malformation and limb defects might be related to a small 13q deletion.

PTCH1 GENE AND RISK OF NON MELANOMA SKIN CANCER AFTER ORGAN TRANSPLANTATION.

A. Begnini[1], M. Gomez Lira[1], G. Tessari[2], L. Naldi[2], G. Remuzzi[2], L. Boschiero[2], A. Forni[2], C. Rugiu[2], S. Piaserico[2], G. Girolomoni[2], A. Turco[1] 1) Dept Mother Child/Biol Genetics, University of Verona, Italy; 2) Dept Biomedical and Surgical Science, Section of Dermatology, University of Verona, Italy.

Organ transplant recipients (OTR) are at higher risk of non melanoma skin cancer (NMSC), particularly basal cell carcinoma (BCC) and squamous cell carcinoma. Risk factors for NMSC in OTR include skin type, UV light exposure, immunosuppression, human Papilloma virus infections, and genetic susceptibility. PTCH1 is a negative regulator of the Hedgehog pathway, that provide mitogenic signals to basal cells in skin. PTCH1 gene mutations cause nevoid basal cell carcinoma syndrome (NBCCS or Gorlin syndrome), and also occur in sporadic forms of BCC. Associations have been demonstrated between PTCH1 polymorphisms and BCC susceptibility in non transplanted recipients. This study was designed to investigate if known polymorphisms of PTCH1 gene contribute to NMSC risk after transplantation and to identify novel genetic polymorphisms in the proximal 5 regulatory region of the gene. We analyzed three PTCH1 gene SNPs (rs2297086, rs2066836 and rs357564) in 302 Northern Italian OTR patients (149 cases and 153 controls). Single locus and haplotype frequencies analysis showed no significant association. We also analyzed a polymorphism involving a GGC trinucleotide repeat located 4 bp upstream of the first methionine codon. No significant difference in allele and genotype frequencies was observed between case and controls. We discovered two novel alleles containing five and six repeats. Screening for polymorphisms was performed by heteroduplex analysis in 30 cases and 30 matched controls. Two polymorphisms, -198A>G and -195G>C, were identified in the 5flanking region. Both variants were in linkage disequilibrium and showed a frequency of 0.005 in 200 tested individuals. Well investigate the effect of the trinucleotide repeat length and of the 2 novel variants on the gene expression using the luciferase reporter gene assay. These results seem to exclude an important role of the PTCH1 gene in NMSC susceptibility after organ transplantation. Further studies on a larger sample are warranted to confirm these findings.

UNC5 genes and breast cancer: LOH analysis and mutation screening. *I. Kurelac[1], E. Bonora[1], C. Evangelisti[1], M. Vargiolu[1], D. Fusco[1], A. Bernet[2], P. Mehlen[2], G. Romeo[1]* 1) Unità di Genetica Medica-Policlinico S. Orsola, Bologna, Italy; 2) CNRS UMR 5238 Laboratoire Apoptose, Cancer et Développement, Centre Léon Bérard, Lyon, France.

Human UNC5 genes encode for membrane receptors that play a role in netrin-1 mediated signaling. They act as mediators of netrin-1 chemorepulsive effect on axon migration during neural development. UNC5 receptors are also considered to be dependence receptors (DR). DRs display the common feature of inducing two completely opposite intracellular signals: in the presence of the ligand they transduce a positive survival signal, whilst in its absence, they induce apoptosis. Expression of human UNC5 genes is down-regulated in multiple types of cancers including breast and colorectal cancers. In the latter, downregulation of UNC5 genes is associated with loss of heterozygosity (LOH). In order to verify whether LOH of UNC5 genes is present also in breast cancers, a panel of 57 normal and tumor breast tissues was analysed using intragenic microsatellite markers. However, no LOH was detected. Since mutations impairing mRNA or protein levels would not have been detected by LOH analysis only, a mutation screening of PCR amplified exons was performed. Four new DNA changes were found in UNC5B and UNC5C genes, three of which were not identified in control samples. All changes result in silent substitutions at the protein level. However, *in silico* analysis predicted that these variants alter the exon splicing enhancer (ESE) binding domains which could modify mRNA processing. A possible pathogenic effect of the variants will be further investigated using a splicing assay with a synthetic minigene. The analysis is currently ongoing and the final results will be presented.

Genome-Wide Association Analysis Identifies Novel Susceptibility Genes for Ulcerative Colitis. *A. Franke[1], T. Balschun[1], T. H. Karlsen[2], S. Schreiber[1]* 1) Institute of Clinical Molecular Biology, Kiel, Germany; 2) Medical Department, Rikshospitalet University Hospital, Oslo, Norway.

Inflammatory bowel disease (IBD) manifests as either of two related subtypes, ulcerative colitis (UC) or Crohn disease (CD), both of which are characterized by diarrhea, abdominal pain and intestinal mucosal inflammation and ulceration. Systematic identification of susceptibility genes for IBD has thus far focused mainly on CD, while little is known about the genetic architecture of UC. Here, we report on a genome-wide association study with 440,794 SNPs genotyped in 1167 UC patients and in 777 healthy controls. The 20 most significantly associated SNPs were tested for replication in three independent European case-control panels comprising a total of 1855 UC patients and 3091 controls. Among the four consistently replicated markers, a SNP immediately flanking a cytokine gene, showed the most significant association in the combined verification samples (P=1.35×10-12; OR=1.46 [1.31-1.62]). Fine mapping of the corresponding region supported the initial finding and confined the disease association. The strongest associations were observed immediately 3 of the gene, in the vicinity of a binding site of the AP-1 transcription factor known to be activated by bacterial lipopolysaccharide. Association between the lead SNP and CD (1848 cases, 1804 controls) was weak (P=0.013; OR=1.17 [1.01-1.34]). Our findings strongly suggest that defective cytokine function is central for the pathogenesis of the UC subtype of IBD. All above mentioned SNPs and susceptibility genes will be reported on the meeting.

Identification of Immortalization Gene Signature of EBV-transformed Lymphoblastoid Cell Lines from a Long-term Subculture Collection. *J. Jeon, H. Nam, S. Shim, T. Chung, J. Kim, B. Han* Korea BioBank, Center for Genome Sciene, Korea NIH, Seoul, Korea.

EBV-transformed lymphoblastoid cell lines (LCLs) are used as a resource for human genetic, immunologic and pharmacogenomic studies. However, there is a limitation of the extensive utilization of LCLs due to possible genetic changes and its relevant gene expression changes during the LCL generation and maintenance. In order to investigate expression phenotype changes during long-term subculture of LCLs, we compared differentially expressed genes from microarray data between early (p4) and late (p161) passages of 17 LCL strains. Microarray data analysis showed that transcript sequences of 16 genes were differentially expressed (> 2-fold changes) in at least 16 out of 17 LCL strains. CD38 downregulation and PTPN13 upregulation were represented in all 17 LCL strains at the late passage (p161), compared to the early passage (p4). These differentially expressed genes (DEGs) included lymphocyte growth and apoptosis related genes. When LCLs proliferate up to a passage number of 160, the LCL is considered as terminally immortalized. Thus, this result suggests that the completion of LCL immortalization may require appropriate expression changes of this cellular immortalization-related gene signature.

Genomewide Association Study for Susceptibility Genes Contributing to Familial Parkinson Disease. *N. Pankratz[1], J. B. Wilk[2], J. C. Latourelle[2], A. L. DeStefano[2], C. A. Halter[1], E. W. Pugh[3], K. F. Doheny[3], J. F. Gusella[4], W. C. Nichols[5], T. Foroud[1], R. H. Myers[2], and the PSG-PROGENI and GenePD Investigators, Coordinators and Molecular Genetic Laboratories* 1) Indiana University, Indianapolis, IN; 2) Boston University, Boston, MA; 3) Johns Hopkins University, Baltimore, MD; 4) Massachusetts General Hospital, Boston, MA; 5) Cincinnati Childrens Hospital, Cincinnati, OH.

Parkinson disease (PD) is the second most common neurodegenerative disorder. Five genes have been identified with mutations that result in autosomal dominant or autosomal recessive forms of PD; however, these mutations have been found in fewer than 5% of patients, suggesting that additional genes contribute to disease risk. Recent genomewide association studies have utilized primarily sporadic PD. In contrast, we have performed the first genomewide association study in familial PD. Genotyping was performed with the Illumina HumanCNV370Duo array in 857 familial PD cases and 867 controls. A logistic model was employed to test for association under additive and recessive modes of inheritance after adjusting for gender and age. The strongest association result was with SNPs in the GAK/DGKQ region on chromosome 4 (additive model: $p = 3.4 \times 10^{-6}$; OR=1.69). Consistent evidence of association was also observed to SNCA (additive model: $p = 5.5 \times 10^{-5}$; OR= 1.35) and the chromosomal region containing MAPT (recessive model: $p = 2.0 \times 10^{-5}$; OR=0.56; additive model: p = 7.8 x 10-5; OR=0.75). Both of these genes have been implicated previously in PD susceptibility; however, neither was identified in previous GWAS studies of PD. Meta analysis was performed using data from a previous case control genomewide association study, and p-values improved for several regions, including GAK/DGKQ (additive model: $p = 2.5 \times 10^{-7}$) and the MAPT region (recessive model: $p = 9.8 \times 10^{-6}$; additive model: $p = 4.8 \times 10^{-5}$). These data suggest the identification of new PD susceptibility genes, particularly in the GAK/DGKQ region, and also provide further support for the role of SNCA and MAPT in PD susceptibility.

New linkage analysis by the Autism Genome Project (AGP) reveals strong evidence of linkage to multiple loci as well as gene-gene interactions. *V. Vieland, Autism Genetics Cooperative and Autism Genome Project* Battelle Ctr Math Medicine, Res Inst Nationwide Child Hosp, Columbus, OH.

The international AGP consortium has assembled a very large autism mutiplex family collection. The original linkage and CNV study (1181 multiplex families, 10K SNP data), published in Nature Genetics, yielded a peak ZLR = 3.6 on 11p12-p13 in the whole data set; no other loci met criteria for suggestive linkage. Here we use a quasi-Bayesian framework to reanalyze the data, sequentially updating linkage evidence across data collection sites, separately for low IQ (LIQ) and normal IQ (NIQ) families, which might differ genetically. We find strong evidence of linkage to one locus in NIQ, posterior probability of linkage (PPL)=65% on 11p15.4-15.3; as well as PPL=24% over the original 11p12-p13 peak and 22% at 11q14.1. Overall 98% of the genome shows PPL < 5%, and 90% of the genome gives evidence against linkage (PPL<2%). In the LIQ group we obtain a similarly clean plot, with several striking linkage peaks: PPL=55% on 1q31.3, 25% on 2p25.1, 50% on 11p15.2; 32% on 11p12p-13 (the original peak), 46% on 13q22.1 (previously implicated AD/specific language impairment locus), and 95% on 16q21. Other than the original peak on 11p12-13, there is no overlap in findings between LIQ and NIQ groups. Small positive evidence (PPL = 3%-17%) is also seen over CNTNAP2, the 16 microdeletion region, CENTG2, the Prader-Willi Angelman region on 15q, and the MET region on 7, all of which have been implicated in AD. In preliminary analyses using a subset of the data, we incorporated genotypes for an associated SNP in the engrailed 2 (EN2) gene and repeated the genome scan allowing for two-locus (2L) epistasis. We find evidence of interaction with EN2 at the 15q del/dup region (2LPPL=25%) in NIQ; and strong evidence at the 11p14, p15 regions (69%, 46%) and at 13q22 (54%) in LIQ, as well as at several additional loci not detected in the single-locus scan. Molecular follow up is underway, as are additional analyses involving sex differences and interactions with other candidate genes. In summary, we have obtained multiple strong linkage and epistasis signals in the largest AD linkage study to date.

Manipulation of Salience of Family History of Coronary Heart Disease: Does it Affect Intention to Screen? *C. D. Nichols[1], R. N. Rimal[2], H. P. Levy[3], E. K. Reed[3], J. A. Scott[4]* 1) Medical Genetics, Hospital of the University of Pennsylvania, Philadelphia, PA; 2) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins, Baltimore, MD; 4) Genetics and Public Policy Center, Johns Hopkins, Washington, D.C.

Family history has been suggested as an accessible and valuable public health tool for promoting preventive behavior change by increasing awareness of risk for common, complex diseases like coronary heart disease (CHD). The analytic and clinical validity of family history for CHD risk assessment is established, but its efficacy in promoting behavior change has not been well studied. We manipulated the salience of family history as a risk factor to determine its effect on screening intentions. A general population sample was queried about intentions for blood cholesterol screening and beliefs that may influence the likelihood of taking preventive action based on the Health Belief Model. To study the role of family history salience, subjects were randomly assigned to read information about family history as a CHD risk factor and answer questions about their personal family history of CHD either before (n=96) or after (n=90) completing the study measures. Results: Regardless of salience manipulation, individuals with a positive family history (n=89) had higher levels of perceived susceptibility ($t=5.92$, $p<0.001$), perceived severity ($t=2.07$, $p<0.04$) and heart disease worry ($t=3.91$, $p<0.001$), compared to those with a negative family history (n=93). Perceived susceptibility and heart disease worry were associated with higher intention to screen. Multivariate regression ($R^2=0.39$) showed that important factors in intention for cholesterol screening included age, perceived barriers to screening, self-efficacy for screening, past screening behaviors, and heart disease worry. Conclusion: Individuals appear to have an exisiting understanding of family history as a risk factor for CHD. However, factors other than having a positive family history may be more significant in determining intention to get cholesterol screening.

Prolyl 3-Hydroxylase 1 and CRTAP are Mutually Stabilizing in the Endoplasmic Reticulum Collagen Prolyl 3-Hydroxylation Complex. *W. Chang, A. M. Barnes, W. A. Cabral, J. C. Marini* BEMB, NICHD, NIH, Bethesda, MD.

We recently identified null mutations in cartilage associated protein (CRTAP) and prolyl 3-hydroxylase 1 (P3H1/LEPRE1) as the cause of two novel recessive forms of OI, Types VII and VIII, respectively. CRTAP and P3H1, along with cyclophilin B, form a complex in the endoplasmic reticulum (ER) which 3-hydroxylates the Pro986 residue of 1(I) and 1(II) collagen chains. We used cultured dermal fibroblasts from type VII and VIII OI probands to investigate the interaction of CRTAP and P3H1. P3H1, which contains the enzymatic activity of the complex, is absent in CRTAP-null fibroblast lysates and, conversely, CRTAP is minimally detectable in P3H1-null lysates. Immunofluoresence microscopy confirmed reduced CRTAP levels in P3H1-null cells and support ER localization of CRTAP. However, P3H1 or CRTAP mRNA levels, respectively, were normal in cells in which null mutations in the other gene caused reduced transcript levels due to NMD. Moreover, CRTAP and P3H1 are stable in normal fibroblasts after translation inhibition with cyclohexmide. These data imply that P3H1 and CRTAP are normally mutually stabilizing. In contrast, cyclophilin B was as abundant in both sets of mutant cell lines as in control. Stable transfection of a full-length CRTAP expression plasmid into CRTAP null fibroblasts restored both CRTAP and P3H1 protein levels, and reduced type I collagen overmodification. A series of CRTAP deletion constructs was also transfected to explore crucial interaction domains. CRTAP was not restored in P3H1-null fibroblasts treated with the proteosomal inhibitor MG132; instead, the increased CRTAP in media may reflect absence of a CRTAP ER retention signal. P3H1 is detectable in lysates of CRTAP-null cells treated with MG132. However, some P3H1 apparently occurs in insoluble pellets from CRTAP-null cell lysates, suggesting P3H1 aggregates in the absence of the complex. The mutual stabilization of P3H1 and CRTAP in the ER collagen prolyl 3-hydroxylation complex may be the underlying mechanism for the similar characteristics of types VII and type VIII OI.

Searching for nucleotide changes in miRNAs and their target genes in circadian clock modulators for mood disorders. *E. Saus[1], V. Soria[2], F. Vivarelli[1], J. M. Crespo[2,3], J. M. Menchón[2,3], M. Urretavizcaya[2,3], X. Estivill[1,4], M. Gratacòs[1]* 1) CIBERESP (CIBER en Epidemiología y Salud Pública), Genes and Disease Program, Center for Genomic Regulation (CRG), Barcelona; 2) Mood Disorders Clinical and Research Unit, CIBER-SAM, Psychiatry Department, Bellvitge University Hospital, LHospitalet de Llobregat; 3) Department of Clinical Sciences, Bellvitge Campus, Barcelona University, Barcelona; 4) Experimental and Health Sciences Department, Pompeu Fabra University, Barcelona, Catalonia, Spain.

It is widely supported that the pathophysiology of mood disorders (MD) is influenced by circadian rhythms. Recently, two independent studies have reported five different miRNAs (hsa-miR-219-1/132/183/96/182) as modulators of the endogenous circadian clock located in the suprachiasmatic nucleus in mice, and have shown experimental evidence for some of the genes involved in the molecular clock machinery as targets sites. Thus, we hypothesized that variations in the miRNAs sequences involved in circadian rhythms or in their target sites could be related to a higher susceptibility to MD. Once the five miRNAs with their respective targets sites were confirmed in humans, we re-sequenced them in a sample of 365 MD patients and 342 control individuals. When analyzing 360 MD patients, no variation was found in hsa-miR-132, hsa-miR-219-1, or their respective target sites in RFX4 and PHLPP genes or hsa-miR-183. Two changes were found in the precursor form of pre-miR-96, one present in MD patients and in controls and the other only found in one MD patient. Regarding hsa-miR-132, changes were also found in the precursor form: two changes found each in one MD patient, one new change found in one MD patient as well as in two control subjects, and one variation found in a high frequency in both MD and control individuals. This is the first time that the circadian clock regulation by miRNAs is explored in MD patients, which could represent a first step to elucidate its underlying mechanisms.

Genetic polymorphisms of the insulin receptor substrate-1 (IRS1) gene and profiles of clopidogrel-induced antiplatelet effects in type 2 diabetes mellitus patients with coronary artery disease. *M. Zanoni[1], P. Prandini[1], D. J. Angiolillo[2], E. Bernardo[3], A. Fernandez-Ortiz[3], C. Macaya[3], T. A. Bass[2], E. Trabetti[1], P. F. Pignatti[1]* 1) Department of Mother and Child, University of Verona, Verona, VR, Italy; 2) Division of Cardiology, University of Florida College of Medicine-Shands Jacksonville, Jacksonville, FL, United States; 3) Cardiovascular Institute, San Carlos University Hospital, Madrid, Spain.

Background: Patients with T2DM have reduced responsiveness to the platelet P2Y12 receptor antagonist clopidogrel compared to non-diabetics. However, variability in clopidogrel-induced antiplatelet effects has been observed among T2DM and those with elevated platelet reactivity have a higher risk of atherothrombotic events. Since variation in insulin sensitivity modulates platelet P2Y12 signaling, the aim of this study was to evaluate if SNPs of the insulin receptor substrate-1 (IRS-1) are associated with variation in the response to clopidogrel in T2DM patients. Methods: A total of 7 tagSNPs (rs1801278, rs11683087, rs1801123, rs1896832, rs956115, rs2251692, rs6725330) were determined in 180 T2DM patients with coronary artery disease in a steady state phase of clopidogrel therapy. Patients were classified into carriers and non-carriers of the variant allele for each SNP according to a dominant model. In addition, haplotype distribution of IRS-1 genes within our population was assessed. Platelet function was determined by LTA following 20 M adenosine diphosphate stimuli (ADP). Platelet aggregation according to genotype and haplotype was determined. Results: The 7 tagSNPs were accountable for 93% of the haplotype distribution of the IRS-1 gene. Platelet aggregation was 5515% in the overall population. Preliminary results showed an association between carriers of the variant C allele of the rs956115 SNP (n=34) and the highest degree of platelet reactivity (6014%; $p<0.05$). Conclusions: rs956115 polymorphism of IRS-1 gene is associated with lower clopidogrel-induced antiplatelet effects in T2DM patients with coronary artery disease.

Differential miRNA-mediated regulation of two isoforms of the receptor for neurotrophin-3 (NTRK3). *M. Guidi[1,2], B. Kagerbauer[1,2], M. Muinos-Gimeno[1,2], X. Estivill[1,2,3], Y. Espinosa-Parrilla[1,2]* 1) Genes & Disease Program, Center for Genomic Regulation (CRG), Barcelona, Spain; 2) Public Health and Epidemiology Network Biomedical Research Center (CIBERESP); 3) Pompeu Fabra University (UPF), Barcelona, Spain.

Neurotrophins are a family of key signaling molecules in the development of the nervous system. NTRK3 is the preferential receptor for neurotrophin-3 (NT-3). Several NTRK3 isoforms are known; the best studied are the full-length kinase-active form (150 kDa) and a truncated non-catalytic form (50 kDa) lacking the kinase domain. The full-length and the truncated isoform show different 3UTR regions, suggesting possible differences in their post-transcriptional regulation. Fifty-four miRNAs were tested on the two 3UTRs using a luciferase-based assay in HeLa cells; eleven miRNAs causing a significant down-regulation of the reporter gene were identified, with no overlapping between the subsets of miRNAs regulating the two isoforms. Overexpression of the eleven miRNAs were performed in SH-SY-5Y neuroblastoma cells, to validate on endogenous NTRK3 the results obtained with the luciferase constructs. Morphological changes have been observed upon overexpression of some of the miRNAs; interestingly, one of them is the brain-enriched miR-128, which is involved in neuronal differentiation. The consequences of miRNA-mediated downregulation of NTRK3 are now being evaluated analyzing downstream elements in the pathways activated by the two isoforms.

Array CGH Uncovering Cancer Predisposition Genes in Children with Syndromic Presentations: Important Tool for Genetic Counseling and Medical Management. *L. Medne, P. Goldenberg, M. J. Falk, T. H. Shaikh, E. H. Zackai* Div Hum Gen, Children's Hosp Philadelphia, Philadelphia, PA.

We present two patients with multiple congenital anomalies and developmental delays where array CGH identified novel genomic microdeletions. Further review of the genes in the deleted regions revealed haploinsufficiency for a tumor suppressor gene in both cases leading to cancer predisposition syndromes and need for appropriate surveillance. Patient 1 presented at 20 months for evaluation of hypotonia, severe, global delays, non-specific dysmorphic brain anomalies, dysphagia, GERD, unexplained immunodeficiency requiring monthly IVIG treatments, dermoid cysts, retinal hamartomatous lesion, iris hypoplasia, strabismus, and renal and ovarian cysts. Extensive prior genetic and metabolic work-up was normal. Given the multi-system involvement, oligonucleotide-based array analysis was pursued. While the 100K array was normal, 550K SNP array identified a de novo ~900 Kb deletion at 17p13.1 encompassing the *TP53* tumor suppressor gene. Germline mutations in *TP53* are known to cause Li-Fraumeni syndrome. Patient 2 presented in the newborn period for evaluation of central apnea, feeding and swallowing difficulties, ventricular septal defect, microcephaly, simplified gyral pattern, under-opercularizaton, bilateral camptodactyly, abnormal neurologic examination, and dysmorphia. Clinical BAC-based CGH analysis revealed 9.3 Mb deletion at 1p36.13-1p36.22 encompassing ~60 genes. The deletion includes the *SDHB* gene with germline mutations causing familial paraganglioma and pheochromocytoma with age-dependent penetrance. Her deletion does not include *NBL1,* which predisposes to neuroblastoma. The deletion includes *MFM2* and *KIF1B* genes, thus predisposing to Charcot-Marie-Tooth, type 2A2 and type 2A1 respectively. Interpretation of copy number variations on the arrays can be challenging as the findings are often novel, but it is of the utmost importance to carefully review all the genes in the deleted region. In both cases, cancer predisposition syndrome identification was unexpected based on the presenting features but significantly altered genetic counseling and patient management.

Mutations of *AFG3L2* gene (SCA28) in autosomal dominant cerebellar ataxias. *C. Cagnoli[1], G. Stevanin[2], A. Durr[2,3], P. Ribai[2], S. Forlani[2], A. Brussino[1], P. Pappi[1], L. Pugliese[4], M. Barberis[1], R. L. Margolis[5], S. E. Holmes[5], S. Padovan[1,6], N. Migone[1], D. Di Bella[7], F. Taroni[7], A. Brice[2,3], A. Brusco[1]* 1) Dept Genetics, Biol & Biochem, Univ Torino, Torino, TO, Italy; 2) INSERM/UPMC UMR_S679, Paris, France; 3) Dept. Genetics and Cytogenetics, Pitie-Salpetriere Hosp., Paris, France; 4) SAFAN, Bioinformatics Turin; 5) Dept. Psychiatry and Behavioral Sciences, The Johns Hopkins University, Baltimore, MD, USA; 6) CNR Torino; 7) Genetics of Neurod. & Metabolic Diseases, Fondazione IRCCS, Ist. Neurologico C.Besta, Milan, Italy.

Spinocerebellar ataxias (SCA) are a genetically heterogeneous group of autosomal dominant neurodegenerative disorders. At present, 26 loci and 16 genes are known. Recently, we have identified *AFG3L2*, encoding a mitochondrial protein, as the causative gene for SCA28 (18p11-q11)(DiBella et al.,ASHG 2008). We have screened the 17 coding exons of *AFG3L2* in a group of 376 unrelated adult patients with autosomal dominant cerebellar ataxia (ADCA). Patients were Caucasian, negative for triplet-expanded SCA1-3, 6, 7 genes. Using DHPLC followed by direct sequencing, we found six different missense mutations (T654I, M666R, M666T, M666V, G671R and G671E) in eight patients (8/376, 2.1%). T654I and M666V mutations were present in two different families that shared a common haplotype. All mutations clustered in exons 15-16, corresponding to the peptidase M41 domain. The mutations hit evolutionary conserved aminoacids. Five changes are predicted to destabilize the protein folding by bioinformatics analysis. None of these mutations was found in a survey of 200 chromosomes from healthy controls. Age at onset was 6-60 (mean 27yr) in 18 affected patients from the mutated families. Examination of affected individuals revealed universal gait and limb ataxia (18/18, 100%) and frequent lower limb hyperreflexia (11/17, 64%), nystagmus (11/16, 69%), and ophtalmoplegia (10/17, 59%). In conclusion, SCA28 seems a rare ADCA (>1%), caused by mutations grouped in the carboxy-terminal region of AFG3L2 protein. The clustering and the missense nature of the mutations are not indicative of haploinsufficiency as pathogenetic mechanism.

The relative effectiveness and efficiency of genomic test-based algorithms in the identification of Lynch syndrome index cases among unselected Colorectal cancer population. *M. Williams[1], R. Burt[2], J. Williams[3], W. Samowitz[4], J. Gudgeon[5]* 1) Dir, IHC Clinical Genetic Inst, LDS Hosp, Salt Lake City, UT; 2) Dir, Huntsman Cancer Institute, University of Utah, Salt lake City, UT; 3) Intermountain Healthcare Oncology Genetic Services Salt Lake City, UT; 4) Associated Regional and University Pathologists, Salt Lake City, UT; 5) IHC Clinical Genetic Inst, LDS Hosp, Salt Lake City, UT.

Statement of Purpose: Identifying patients with Lynch syndrome (LS) using clinical data, family history and tumor histology (for those presenting with colorectal cancer (CRC)) has been hampered by relatively poor predictive value. Recently, several published papers have explored models using molecular analysis of CRC specimens to identify patients with LS. The purpose of this study is to use decision analysis to explore the viability, effectiveness, and costs of different testing algorithms in anticipation of implementing this in an integrated healthcare system. Methods: Decision analytic models were constructed to estimate the diagnostic performance of different molecular screening pathways for unselected CRC patients to detect those at risk for LS. Screening tests considered were immunochemistry (IHC), microsatellite instability (MSI), and *BRAF*. Additional tests modeled in reflex cascades were gene sequencing and deletion (duplication, rearrangement) testing of the four mismatch repair genes involved in LS. Outcomes were limited to test results: true and false positive and -negative. The proportions of these parameters were then used to calculate sensitivity, specificity, positive and negative predictive values, and efficiency of the different test algorithms. Test costs were based on charges from the reference lab. Summary of Results: Modeling demonstrates that screening with IHC without incorporation of BRAF or MSI testing maximizes identification of LS index cases as well as minimizing costs compared to other screening algorithms that start with MSI or *BRAF* or that start with IHC and include *BRAF* or MSI. Conclusions: IHC of unselected CRC tumors optimizes detection of patients with LS while minimizing cost of the screening program.

Prognosis and treatment based upon genetic subtypes of Hermansky-Pudlak syndrome. *M. Huizing[1], R. Hess[1], A. Helip-Wooley[1], R. Fischer[1], K. O'Brien[2], G. Golas[2], WA. Gahl[1,2]* 1) MGB, NHGRI, NIH; 2) Office of Rare Diseases, OD, NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) comprises a group of autosomal recessive disorders of lysosome-related organelle (LRO) biogenesis. Eight human genes (*HPS1-HPS8*) are associated with eight clinical subtypes. Oculocutaneous albinism, due to abnormal melanosome formation, and prolonged bleeding, due to absent platelet dense bodies, occur in all HPS subtypes. Sporadic features include a fatal pulmonary fibrosis, granulomatous colitis and neutropenia. Over the past 10 years we extensively studied and subtyped 232 HPS patients. HPS-1 (166 patients, 23 mutations) constitutes the largest group due to a founder mutation in NW Puerto Rico. HPS-2 (3 patients, 4 mutations) results from mutations in *AP3B1*, coding for a subunit of adaptor complex-3, a coat protein that mediates vesicle formation. Our study of HPS-3 yielded 29 patients (19 mutations), with *HPS3* founder mutations in central Puerto Rico and in Ashkenazi Jews. We also identified 12 HPS-4 patients (10 mutations), 6 HPS-5 patients (8 mutations) and 4 HPS-6 patients (7 mutations). Our nearly 100 non-Puerto Rican patients are more than the total number reported elsewhere in the world. Our clinical characterization of these patients allowed us to draw several critical conclusions. First, only HPS-1 and HPS-4 patients develop pulmonary fibrosis. This knowledge allows us to enter appropriate patients into our clinical trial of pirfenidone, an antifibrotic agent previously shown to slow the decline in pulmonary function in HPS-1 patients. Second, compared with HPS-1 and HPS-4 patients, HPS-3, HPS-5 and HPS-6 patients are clinically milder and have no pulmonary involvement. Third, HPS-2 patients are the only subtype prone to infections, and their neutropenia is G-CSF responsive. Fourth, our 12 unclassified HPS patients provide opportunities to identify new HPS-causing genes. These studies provided important insights into genotype-phenotype correlations. An accurate subtype diagnosis now carries important prognostic and therapeutic implications, and future studies can provide insights into the cell biology of LROs.

Consanguineous matings, partial selective sweeps, and population-specific founder effects detected from patterns of homozygous tracts. *A. R. Boyko, A. Auton, A. R. Indap, K. E. Lohmueller, A. G. Clark, C. D. Bustamante* Cornell University, Ithaca, NY.

The degree to which deleterious recessive mutations contribute to disease is largely dependent on the rate of autozygosity or identity by descent. Runs of homozygosity (ROHs) are indicative of autozygosity and can be easily detected with dense SNP genotyping arrays. Here, we develop a novel hidden Markov model to detect ROHs and apply it to a global panel of 4000 individuals genotyped on the Affymetrix 500K SNP array. This panel includes European and Asian populations that have undergone founding bottlenecks, Latin American populations founded through recent admixture, and Middle Eastern populations with less severe demographic histories and relatively high levels of genetic diversity. Our HMM is more robust to SNP ascertainment biases, variation in SNP density, and population substructure than the inbreeding statistic (F) or previous sliding window approaches for ROH detection. All populations contain individuals with long ROHs (>2cM) indicative of consanguinity, although the average individual from each population contains few if any such tracts. In contrast, shorter ROHs (<2cM) are found in all individuals and the cumulative length of these tracts differs significantly between populations. The location and distribution of shorter ROHs correspond to regions of low population-wide haplotype diversity often caused by founder effects or partial selective sweeps. Long ROHs, although rarer and distributed more or less at random across the genome, account for more than 20% of the genome in some individuals and contribute 10-25% of the autozygous SNPs found in a population. The proportion of highly autozygous individuals differs significantly between populations largely due to marriage customs. Simulations show a good correspondence between the observed and expected proportion of the genome that is in ROH. Surprisingly, the rate of purging of deleterious recessive alleles inferred from the distribution of ROHs is only marginally faster than the rate in a randomly mating population, suggesting that such alleles account for an appreciable fraction of human genetic disease risk.

Recurrent reciprocal deletions and duplications within 1q21.1: risk factors for developmental abnormalities with variable expressivity and incomplete penetrance. *N. Brunetti-Pierri, J. Berg, F. Scaglia, C. Bacino, T. Sahoo, S. Lalani, P. Stankiewicz, S. W. Cheung, A. Patel, Referring phisicians* Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX.

The chromosome 1q21.1 is a highly complex region containing large low-copy repeats (LCRs). Microdeletions within the distal 1q21.1 region have been associated previously with congenital heart defects and mental retardation, while reciprocal microduplication of the same region has also been reported in a patient with dysmorphic features and mental retardation. Recently, a distinct, more proximal region within 1q21.1 was implicated in Thrombocytopenia-Absent Radius (TAR) syndrome. We have identified 21 probands with 1q21.1 microdeletion and 13 probands with 1q21.1 microduplication using targeted array comparative genomic hybridization (array-CGH) in a population referred to for a variety of clinical indications. These copy-number variants (CNVs) clustered into groups involving only the distal 1q21.1 region or both distal 1q21.1 and TAR regions. The CNVs were inherited in the majority of cases in which parental studies were available, leading to difficulty in determining causation of the associated clinical phenotypes. The most consistent features appear to be microcephaly in microdeletion cases and a trend toward macrocephaly in microduplication cases. In our experience, the phenotypes observed in individuals with 1q21.1 CNVs are highly variable and cardiovascular malformations are uncommon. Familial CNVs are frequently observed in array-CGH studies and often raise concerns regarding incomplete penetrance for some CNVs. We cannot rule out that the phenotypes observed in our probands result from the combination of 1q21.1 microdeletion or microduplication and some as-yet unidentified recessive alleles or other CNVs inherited from the two parents. However, our findings suggest that CNV within the 1q21.1 region may predispose or contribute to developmental abnormalities, albeit with variable expressivity and incomplete penetrance.

When a case is not a case: effects of phenotype misclassification on the power of the transmission disequilibrium test for affected child trios. *S. Buyske[1, 2], G. Yang[2], T. C. Matise[2], D. Gordon[2]* 1) Statistics and Biostatistics Dept, Rutgers Univ, Piscataway, NJ; 2) Genetics Dept, Rutgers Univ, Piscataway, NJ.

Phenotype misclassification in genetic studies can decrease the power to detect association between a disease locus and a marker locus. Many studies have looked at genotyping errors, but phenotype misclassification can have far greater effects. Studies of phenotype misclassification to date have focused on case-control designs. We examine the effect of phenotype misclassification on the transmission disequilibrium test (TDT) applied to complete case-parent trios.

We study misclassification by computing the effect on the non-centrality parameter associated with the TDT statistic where there is linkage and association of a marker locus with a disease locus. Simulations verify our analytic work.

To maintain equivalent power under phenotype misclassification, the sample size must be increased over the no-error size. The required increase grows as the disease prevalence decreases and as the misclassfication rate increases. A misclassification rate of 5% in a disease with prevalence 1% can require almost 40 times the sample size for equivalent power of a study with zero misclassification.

Given the potentially substantial power loss for the TDT in the presence of misclassification, we recommend that researchers incorporate power loss due tophenotype misclassification into their study design for genetic association using trio data. We have developed freely available software that computes power loss for a fixed sample size or sample size for a fixed power in the presence of phenotype misclassification.

Sequence variants analysis of celiac disease candidate genes TAGAP and VIL2. *A. Szperl[1], G. Trynka[1], A. Zhernakova[2], C. Wijmenga[1]* 1) Genetics Department, UMC Groningen, The Netherlands; 2) Complex Genetics Section, DBG-Dept Medical Genetics, UMC Utrecht, The Netherlands.

Celiac disease (CD) is the most common food intolerance in Western populations; it is caused by a strong immune response to gluten. The HLA-DQ2/DQ8 locus explains 40% of the heritable risk. To identify additional CD genes, we have performed both whole genome linkage analysis and genome-wide association studies (GWAS). One of the linkage peaks in a large CD family mapped to chromosome 6q25.3, with the strongest signal at marker D6S969, located ~175 kb upstream of the T-cell activation Rho-GTPase activating protein (TAGAP) and ~96 kb downstream of the villin-2 gene (VIL2). We also identified TAGAP as a CD susceptibility gene in our GWAS. TAGAP is highly expressed in bone marrow, spleen, and thymus. It belongs to the RhoGAP family of proteins, which are known to be key regulators that link signaling pathways with the organization of cytoskeleton in the cell. Our group recently identified the myosin IXb (MYO9B) gene, which is also a Rho-GTPase activating protein (RhoGAP), as a risk factor for CD in a Dutch population. Since our two independent studies pointed to the TAGAP gene, we investigated TAGAP for putative mutations by sequence analysis in ten members of the large CD family (7 patients and 3 unaffected as controls). We sequenced 12 kb of genomic DNA, including the coding part, promoter and conserved regions, but found only two sequence variants in one of the controls. Since we cannot exclude a duplication or deletion in this CD locus, we are now investigating it. In addition to TAGAP, VIL2 could also be a perfect CD disease gene; it is highly expressed in the epithelial cells in the small intestine where it functions as a connection between the plasma membrane and actin cytoskeleton. Using the same strategy as for TAGAP, we sequenced VIL2 and identified 25 sequencing variants. Two variants segregated with the disease phenotype in the linkage region but were absent in the controls. Interestingly, one is located in the predicted Vil2 promoter region and the second may be involved in splicing. We are studying both variants further.

Structural insights on molecular pathogenesis of novel ornithine carbamoyl transferase (OTC) mutations in OTC deficiency. *S. GOBIN-LIMBALLE[1], M. MAGEN[1], V. SERRE[2], P. DE LONLAY[3], R. GESNY[1], V. VALAYANNOPOULOS[3], J. BENGOA[1], D. RABIER[4], N. GIGAREL[1], A. MUNNICH[1], J. STEFFANN[1], J. P. BONNEFONT[1]* 1) Genetics Dpt,; 2) INSERM Unit U781 and Université Paris Diderot; 3) Pediatrics Dpt; 4) Biochemistry Dpt, hopital Necker, Paris, France.

Ornithine Transcarbamylase (OTC) deficiency is the most common inherited defect of the urea cycle. This X-linked semi-dominant disease manifests through distinct phenotypes, considered as more severe in male vs female. The neonatal form usually occurs in males, as life-threatening hyperammonemia episodes, while the late-onset form variably presents as Reye-like attacks, acute liver failure, or psychomotor retardation. While over 250 OTC mutations have been reported, the genotype-phenotype relationships remain unclear. We detected novel OTC mutations in 18 OTC-deficient families, being missense ones (11), frameshift mutations (5) or large deletions (2). We analyzed the missense mutations, using a 3-D structural model of the human dodecamer enzyme, based on alignment of the human monomer and the P. furiousus dodecamer crystal structures. These mutations were predicted to impact the catalytic domain (6/10), or structural domains implied in the protein stability (2/10) or in putative interaction with other proteins (2/10). They predominantly involved proline residues, suggested to result in alpha-helixes destabilization. We matched molecular-, in silico-, and clinical data. Truncating mutations/deletions predominantly resulted in a neonatal form (7/9) in females (3) and males as well (4). Irrespective of their predicted structural/functional impact, missense mutations i) were as serious as truncating mutations (death in 9/11 and 3/7 families with missense and truncating mutation/deletions, respectively); ii) resulted either in neonatal presentation, predominantly in males (6/7), or in delayed form, irrespective of the patient gender (4 males/5 females). Comparison with data of literature indicated that different substitutions affecting the same amino acid may result in various clinical presentations. We are carrying a large-scale in silico structural analysis of hitherto reported missense mutations to assess potential relationships between predicted impact and the resulting phenotype.

Association of BRCA1 founder mutations prevalent in Latvia with haplotype tagged SNPs. *L. Tihomirova, L. Pliss, S. Skudra* Latvian Biomedical Research and Study Centre, Riga.

It has been shown that the BRCA1 mutation 4154delA detected in unrelated individuals from Latvia, Poland and Russia is a founder mutation with common ancestral origin (Skudra et al Familial cancer, in press) We have compared the age at onset of disease in Latvian breast and ovarian cancer patients carrying the 4154delA or 5382insC mutation (the two most prevalent mutations in Latvia). Regardless the numbers of mutation carriers are not large (40 and 60 respectively, altogether detected) we have found similar, 5 year difference in the age at onset of disease between breast as well as between ovarian cancer patients ($p=0.01$). The further analysis of genetic variation in the BRCA1 region revealed several haplotype tagged SNPs specific for both mutation carriers. The association of the 185delAG mutation with the genetic variant in the NBR2 gene, not detected in carriers of 4154delA or 5382insC, was found as well. The analysis of specific, haplotype tagged genetic variants are useful for epidemiologic studies and possible finding new susceptibility loci associated with breast cancer.

Knockout Models in Mice and Men Suggest a Proatherogenic Role for USF1. *P. P. Laurila[1], K. J. Merikanto[1], J. Perttilä[1], J. Saharinen[1], M. Gentile[1], J. Naukkarinen[1], P. K. Laurila[2], A. Tuomainen[3], C. Ehnholm[1], V. M. Olkkonen[1], M. Jauhiainen[1], L. Peltonen[1,4]* 1) Institute of Molecular Medicine, NPHI, Helsinki, Finland; 2) Helsinki Univ Central Hospital, Helsinki, Finland; 3) Institute of Dentistry, Univ of Helsinki, Finland; 4) The Wellcome Trust Sanger Institute, Cambridge, UK.

Disturbances in body lipid homeostasis are tightly linked with cardiovascular disease. We recently established the association of USF1 transcription factor with familial combined hyperlipidemia, a common dyslipidemia characterized by high blood triglycerides (TG) and cholesterol in Finnish families. We have generated a strain of Usf1 knockout (-/-) mice which along with their +/- and +/+ littermates (n=12) were fed with Western diet rich in TG and cholesterol for 8 weeks. After the diet Usf1 -/- mice had significantly lower blood ($p<0.05$) and VLDL ($p<0.01$) TG than their +/+ littermates. By using Affymetrix expression arrays, we observed that lipoprotein lipase (Lpl) and ApoA5 mRNA levels were elevated ($p<0.01$) in -/- mice liver and muscle as compared to controls, consistent with the TG phenotype. In -/- mice adipose tissue, the cholesterol biosynthetic pathway was significantly down-regulated when compared to their +/+ littermates. We also established a cellular model representing USF1 knock-down, transfecting human hepatoma cells (HuH7) with USF1 targeting siRNAs. We incubated the cells for 30 min in [3H]acetic acid, followed by a chase, and quantified the [3H]cholesterol and TG synthesized. A decreased amount of both [3H]cholesterol and [3H]TG ($p<0.05$) was observed in siRNA treated cells as compared to controls. Again, with Affymetrix microarrays we observed that several cholesterol biosynthetic pathway enzymes were down-regulated in USF1 knockdown cells in addition to up-regulation of a number of apolipoprotein, many of which are thought to be antiatherogenic by nature. Since the loss-of-function of USF1 caused a decrease in plasma TG in vivo as well as cholesterol and TG biosynthesis in vitro, we hypothesize that USF1 might be proatherogenic and its knockdown in appropriate tissues actually has a favorable cardiovascular effect.

Genetic Background of Severe Obesity among Finns. *K. J. Merikanto[1], J. Naukkarinen[1], K. Silander[1], T. Tanninen[1], K. Pietiläinen[2], V. Salomaa[3], K. Kontula[4], P. Mustajoki[4], A. Rissanen[2], J. Kaprio[5], L. Peltonen[1,6]* 1) Institute of Mol. Medicine , National Public Health Institute, Helsinki; 2) Obesity Research Unit, Dept. of Psychiatry, Helsinki Univ Central Hospital; 3) Dept of Epidemiology and Health Promotion, National Public Health Inst, Finland; 4) Dept of Med, Helsinki Univ Central Hospital, Helsinki, Finland; 5) Finnish Twin Cohort Study, Dept. of Public Health, Univ of Helsinki; 6) The Wellcome Trust Sanger Institute, Cambridge, UK.

The increase in obesity in the Western world poses an enormous challenge to public health. In addition to sedentary lifestyle, evidence of the genetic component of obesity is now accumulating. We selected six previously well established obesity and dyslipidemia associating genes (PPAR, APOB, CDH2, GCKR, FTO and INSIG2) as well as a frequently replicated CHD locus on chromosome 9p21 to test whether variants in these regions were associated with obesity (BMI>30). 54 haplotype-tagging SNPs were genotyped in our case-control material. The cases (n=421, BMI>30) selected for genotyping were either obese individuals of Finrisk97 (FR97) population cohort or severely overweight patients from the obesity clinic at the Helsinki Univ Hospital. The controls (n=439, BMI <25) were selected from the lean FR97 subjects. Associations were obtained for PPAR (p=0.009), APOB (p=6x10-5), FTO (p=5x10-5) and for 5 SNPs in the 9p21 locus. The association signals at 9p21 were followed up by evaluating the expression levels of nearby transcripts in fat biopsies of a collection of MZ twin pairs most discordant for BMI (n=14 pairs, 15.2 kg mean weight difference). We identified the CDKN2B gene in the 9p21 locus as expressed significantly higher in the obese twin fat tissue (1.6-fold change, p=0.0003), suggesting that CDKN2B may be a functionally relevant obesity gene in this locus. Conclusion: We were able to replicate association with obesity in 3 out of 6 previously identified genes, and by combining SNP association data with global transcript profiles in fat, identify a potentially novel obesity associated gene immediately adjacent to the 9p21 locus previously associated with CHD.

Gene x Gene Interaction at the allelic level using a generalize linear model. *J. Jung* Medical & Molecular genetics, Indiana Univ Sch Medicine, Indianapolis, IN.

It has been widely recognized that genexgene interaction is likely to have an important role in the risk of complex disease. We propose a statistical approach that can detect genexgene interactions at the allelic level contributing to a variety of traits related with disease based on generalized linear regression. Our proposed method assigns a score to each unrelated subject according to their allelic combination inferred from the observed genotypes at two or more unlinked SNPs, and then tests for association of the allelic score at the all possible allelic combinations with a dependent trait. By testing for the association of allelic combinations at multiple unlinked loci, the interaction can be assessed both in cases where the SNP allelic association can and cannot be detected as a main effect. Based on simulation study, we investigate the analytical properties of the proposed methods in terms of type I error rate and power and demonstrate that the allelic approach achieves greater power than the more commonly used genotypic approach to test for gene x gene interaction.

Role of the C1236T (rs1128503) polymorphism of the MDR-1 Gene on Clopidogrel Responsiveness. *P. Prandini[1], M. Zanoni[1], D. J. Angiolillo[2], E. Bernardo[3], A. Fernandez-Ortiz[3], C. Macaya[3], T. A. Bass[2], E. Trabetti[1], P. F. Pignatti[1]*
1) Dept of Mother and Child, University of Verona, Verona, Verona, Italy; 2) Division of Cardiology, University of Florida College of Medicine-Shands Jacksonville, Jacksonville, FL, United States; 3) Cardiovascular Institute, San Carlos University Hospital, Madrid, Spain.

Background: Clopidogrel intestinal absorption and active metabolite formation are influenced by P- glycoprotein-mediated efflux. The functional activity of P-glycoprotein is under genetic control by the Multi Drug Resistance-1 (MDR-1) gene. If genetic variations of MDR-1 contribute to variability in clopidogrel response in patients with coronary artery disease remains poorly explored. Methods: The C1236T (rs1128503) polymorphism of the MDR-1 gene was assessed in 62 patients. Patients were divided into 2 groups: carriers and non-carriers of the T allele. Platelet aggregation was performed before and 24 hours after clopidogrel administration. Standard (300mg; n=45) and high (600mg: n=17) loading dose regimens were used. All patients were on treatment with aspirin (100mg/day). Peak platelet aggregation was assessed by LTA using 6 mol/L ADP stimuli. Post-treatment platelet reactivity and percentage inhibition of platelet aggregation (IPA) were determined. Results: 71% and 29% of the study population were T and non-T allele carriers, respectively. At baseline, there were no differences in platelet aggregation between the two groups. At 24 hours there were no differences in post-treatment platelet reactivity between groups following a 300mg loading dose administration. However, following a 600mg loading dose administration, post-treatment platelet reactivity was significantly higher in T allele carriers (3511% vs 163%; p=0.006). Accordingly, there were no differences in IPA following a 300mg dose and IPA was significantly lower in T allele carriers following a 600mg dose (4418% vs 735%, p=0.001). Conclusions: The C1236T polymorphism of the MDR-1 gene modulates clopidogrel responsiveness in the acute phase of treatment when using high loading dose regimens.

The Indications Leading to Termination of Pregnancy in a Referrence Hospital: Two Years Experience. *E. Ataman Arikan[1], H. Onay[1], A. Alpman[1], S. Sagol[2], O. Bilgin[2], S. Ozbek[3], O. Zekioglu[4], N. Kultursay[5], M. Akisu[5], I. Ulman[6], F. Ozkinay[1,5]* 1) Dept Medical Genetics, Ege Univ, Izmir, Turkey; 2) Dept Obstetrics and Gynecology, Ege Univ, Izmir, Turkey; 3) Dept Radiodiagnostic, Ege Univ, Izmir, Turkey; 4) Dept Pathology, Ege Univ, Izmir, Turkey; 5) Dept Pediatrics, Ege Univ, Izmir, Turkey; 6) Dept Pediatric Surgery, Ege Univ, Izmir, Turkey.

Recently, a number of major abnormalities could be able to detected prenatally in the fetus leading to termination of pregnancy (TOP). In this study, the distrubution of indications in cases undergone TOP was investigated in our medical school hospital. Between 2006-2008 years, 132 cases were referred to prenatalogy council of Ege University Medical School Hospital for TOP. They were classified into two groups, early (20 weeks) and late (20-24 weeks) gestational age. TOP are not performed after 24th week of gestation in our hospital. TOP was performed in 74 (56.1%) out of 132 cases before the 20th week of pregnancy. In both groups the most common indication was major ultrasonographic abnormalities in the fetus with a frequency of 67.4%. This was followed by chromosomal abnormalities which was detected in 12.8% of cases. Among the abnormalities detected on ultrasonographic examination central nervous system abnormalities (46.5%), urinary system abnormalities (21.5%) and skeletal abnormalities (10.2%) were the most common indications for TOP. Karyotype analysis was performed after termination in 44 fetuses having abnormal ultrasonographic findings and it was found to be normal in 34 cases (77.2%). Turner Syndrome in 2 fetuses, Trisomy 13 in fetus, Trisomy 18 in 1 fetus and Trisomy 21 in 1 fetus were detected. As a conclusion, before the 24th week of gestation, the most common indications for TOP are major ultrasonographic abnormalities and chromosomal abnormalities in the fetus.

Comprehensive genetic analysis and thorough evaluation of phenotypes according to Ghent criteria in 135 Japanese patients with suspected Marfan syndrome. *H. Morisaki[1], K. Akutsu[2], H. Ogino[3], T. Morisaki[1]* 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Osaka, Japan; 2) Dept Cardiovasc Med, Natl Cardiovasc Ctr, Osaka, Japan; 3) Dept Cardiovasc Surg, Natl Cardiovasc Ctr, Osaka, Japan.

Marfan syndrome (MFS) is an autosomal dominant connective tissue disorder primarily involving skeletal, ocular, and cardiovascular systems caused by mutations of *FBN1* gene. Loeys-Dietz syndrome due to mutations of *TGFBR1* or *TGFBR2* has many overlapping phenotypes with MFS. In order to evaluate the contribution of *FBN1*, *TGFBR1*, and *TGFBR2* mutations to the MFS phenotypes, we conducted a comprehensive genetic study including genomic sequencing of all exons, cDNA sequencing and MLPA analysis of these genes in 135 Japanese patients with MFS phenotypes. We also re-evaluated the clinical diagnostic criteria (exclusive of genetic criteria) by a thorough examination of phenotypes including the evaluation of ectopia lentis by ophthalmologists and dural ectasia by radiologists. Molecular study of 104 probands revealed 72 mutations in *FBN1* gene, 4 in *TGFBR1* and 6 in *TGFBR2*. Of the 50 patients who fulfilled the Ghent criteria, 41 (82%) had mutations in *FBN1*, 1 (2%) in *TGFBR1* and 3 (6%) in *TGFBR2*. *FBN1* mutations were also identified in 45 of 68 patients who did not fulfill the criteria, as well as *TGFBR1* in 3 and *TGFBR2* in 5 patients. Major aortic involvement was observed in 76% of patients with *FBN1* mutations, ectopia lentis in 40%, and dural ectasia in 43%. Although most patients showed distinctive skeletal phenotypes, only 14% met the 4 major criteria for skeletal involvement in our study. All patients with ectopia lentis were identified to have *FBN1* mutations, meaning that it has a high diagnostic value. Genotype-phenotype correlation study revealed no significant difference among mutation types in the incidence of aortic involvement, skeletal involvement or dural ectasia, but ectopia lentis was significantly more prevalent in patients with alterations of cysteine residues than in those with other mutation types (p=0.009). In total, out of 100 patients harboring *FBN1* mutations, 41 fulfilled the criteria and 45 did not. 33% (4/12) of patients with *TGFBR1*/*TGFBR2* mutations also fulfilled the Ghent criteria.

THAOS - Transthyretin Amyloidoses Outcomes Survey, A New Global, Web-Based Registry. *R. H. Falk[1], J. Packman[2], D. Grogan[2] for the THAOS Scientific Board* 1) Harvard Vanguard Medical Associates, Boston, MA; 2) FoldRx Pharmaceuticals.

Background: TTR amyloidosis (ATTR) is caused by dissociation of the TTR tetramer into monomers that misfold due to genetic mutations or aging, and ultimately form amyloid deposits in various organs. The >80 known TTR mutations associated with the autosomal dominant disease result in variable phenotypic expressions commonly affecting the peripheral nerves and heart. Symptom onset is in the third to fifth decade of life, consisting primarily of peripheral and autonomic neuropathy, or sixth decade on, presenting with a restrictive cardiomyopathy. Survival for most mutations is 9-11 years after onset, with median survival of 5-7 years in cardiomyopathy patients. Methods: THAOS is a new global, longitudinal observational survey designed to characterize the natural disease history of ATTR, including regional differences in disease expression and the genotypic-phenotypic relationship. Symptomatic and asymptomatic patients with TTR disease will be enrolled and followed for up to 10 years. It is anticipated that several thousand patients will be enrolled across 50 or more survey sites. Patients will continue to receive the current standard of care for their disease, with frequency and type of clinical and laboratory assessments performed according to the physicians practice. Data on cardiac and neurologic examinations, renal/bladder function, quality of life, hospitalizations, medication use, and transplant history will be recorded in the database. Data analysis and publications will be coordinated by the THAOS Scientific Board, an international group of amyloid experts, and complimentary to data collected in the Familial Amyloid Polyneuropathy World Transplant Registry. The THAOS database, a secure interactive web-based system, is an intuitive tool for physicians to enter and review patient data. Results: Identification and initiation of sites in a number of countries is on-going and patient enrollment has begun. Conclusions: Data will be analyzed and reported at least annually. Any physician who cares for these patients is invited to participate. Initial data are expected in late 2008.

The molecular evolution of an inversion polymorphism region 8p23 during human migration. *L. Deng, W. Chen, C. Zeng* Beijing Institute of Genomics, Beijing, China.

Chromosome 8p23.1 is a region of inversion polymorphism found in various populations. Based on HapMap data, previously we identified four haplotype clades in this ~4.7 Mb region, among which clades 1/2 and clades 3/4 correspond to the different orientation respectively [1]. By haplotype analysis we have also speculated that the geographically restricted selection might play a role in the evolution history of this inversion polymorphism. In this study, with the criteria of population size over 20, we analyzed 742 samples of Human Genome Diversity Project (HGDP) from 26 populations in 6 geographic groups, including African (AF), Middle East (ME), European (EU), Southern Asian (SA), Eastern Asian (EA), and Native American (NA). By principle component analysis on genotypes of 1447 SNPs in 8p23, three major haplotype subgroups, named as Hap 1, 2, and 3, were resolved. Previously identified clade 1 and 4 containing HapMap YRI samples exclusively appear to cluster within Hap 1 which mainly consists of African haplotypes also. Hap 2 and Hap 3 correspond to clades 2 and 3 respectively. In addition to these three subgroups among populations, all these 6 geographic groups contain more or less admixture haplotypes in between and the most isolate clusters come from NA and ES samples. As measured by Wrights FST, a clear population differentiation between geographic groups was observed. In particular, NA and EA populations showed considerable genetic difference, suggesting further positive selection events after the migration out of African. Furthermore, multi tests by site frequency spectrum and extended haplotype homozygosity indeed demonstrated strong signatures of positive selection at XKR6 in 8p23 region in these populations. On the other hand, in contrast with AF haplotypes, large diversity was shown in populations from geographic groups of ME, SA, and EU. Although both gene flow and genetic drift could be an explanation for such a phenomenon, most likely the role of complex selection is the mechanism in the maintenance of such unique genetic patterns at 8p23 region. Reference [1] Deng et al. Hum Mutat., 2008 May 12. [Epub ahead of print].

X-linked Cohesin Structural Component SMC1A: Expression and Mechanism of Pathogenicity in Cornelia de Lange Syndrome. *J. Liu[1], R. Feldman[1], Z. Zhang[2], M. Kaur[1], M. A. Deardorff[1,3], D. Clark[1], I. D. Krantz[1,3]* 1) Division of Human Genetics, Children's Hosp Philadelphia; 2) Bioinformatics Core Facility, The Childrens Hospital of Philadelphia; 3) 3 The University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Cornelia de Lange Syndrome (CdLS) is a dominant genetic disorder with multi-system defects. 60% of probands with CdLS have heterozygous mutations on the *Nipped-B- like* (*NIPBL*) gene, while 5% are due to mutations in the *SMC1A* gene, and 1 patient was found to have mutation in the *SMC3* gene. Cohesin complex is a ring like structure consisting of a SMC1A and SMC3 heterodimer and two non-SMC subunits, it controls sister chromatid cohesion with NIPBL facilitating cohesin loading and unloading. Cohesin complex mediates long distance regulation of gene expression in *Drosophila*, CdLS phenotype is believed to be caused by gene dysregulation rather than chromosomal segregation effects. *SMC1A* is located on the human X chromosome and is reported to escape X inactivation in mice. Our laboratory has identified 22 CdLS probands with *SMC1A* mutations including one male adult. Eleven individuals carry missense or in frame small deletion mutations scattered across the *SMC1A* coding region. Seven mutations are located at a possible mutation hotspot c.1487G>A.Using lymphoblastoid cell lines (LCLs), RT-PCR has revealed both males and females express SMC1A, with females quantitatively expressing twice the amount of *SMC1A* mRNA. There is no difference between patients and controls within the same gender. Allele specific quantitative RT-PCR demonstrated identical levels of expression between the wild type and mutant alleles. Genome wide expression studies did not identify dysregulated *NIPBL* expression among CdLS patients with *SMC1A* mutations, and *vise versa*.Western blotting has showed an equal amount of SMC1A protein expressed among probands and controls. Our study confirms biallelic expression of *SMC1A* in females, and further suggests that mechanistically CdLS is not due to altered levels of *SMC1A* RNA or protein, but rather the produced mutant proteins maintain a residual but reduced function in males and a dominant negative effect in females.

Silver-Russell syndrome with hypomethylation of H19 gene in consanguineous background. *C. Sibille, X. Pepermans, K. Dahan* Center of Human Genetics, Cliniques Universitaires St-Luc, Bruxelles, Belgium.

Silver-Russell syndrome (SRS) is characterized by a pattern of intrauterine growth retardation, postnatal growth with relatively normal head circumference, classical facial phenotype and hemihypotrophy. The most frequent genetic abnormality seen is a uniparental disomy of chromosome 7, found in 7-10% of patients. Recently, a new site of hypermethylation was described, underlying the growing importance of epigenetic factors in clinical genetics. We present the case of a 3 year-old boy born at 39 weeks from consanguineous Moroccan parents with a birth weight of 1,74 kg (-4.7 SD), a length of 42cm (-4.5 SD) and a cranial perimeter of 34.5cm (-1 SD). He was followed for feeding difficulties and bronchial hyperractivity. The clinical examination revealed a dysmorphic child with a prominent forehead, relative macrocephaly, pectus carinatum, lower limbs asymmetry, micrognathism. A verrucous hamartoma was found in the left axillary region. Suspicion of Russell-Silver syndrome was evoked but the search for mUPD7 was negative. A molecular analysis using the ME030BWS/RSS kit by MRC-Holland (the MS-MLPA method) determines of a panel of genes in particular region 11p15. In the present case report, we observe the absence of partial methylation of the H19 gene. Eggermann et al. 2006 identified a loss of methylation in the imprinting domain of *H19* promoter (*ICR1*) in a population of 51 SRS patients, with a frequency 31%. Interestingly, an opposite alteration is found in 10% of cases of Beckwith-Wiedemann syndrome. With hypermethylation of the same maternal region, leading to overexpression of *IGF2*. It seems also that *ICR1* hypomethylated patients have a more typical SRS phenotype than maternal duplicated cases. Exact phenotypical implications stay to be clarified, but body asymmetry and growth retardation are the main clinical features included in our case. Additional Silver-Russell cases in young children are suspected in relatives. Therefore, a genetic counseling and specific familial follow up are ongoing in this family. Search for potential parental unidisomy of *ICR1* is under study.

Genome-wide Association Study of Attention Deficit Hyperactivity Disorder-Combined Type (ADHD-CT); Adjustment for Genetic Heterogeneity in a Large Multicentre Study. *R. J. Anney, M. J. Hill, C. T. O'Dushlaine, E. Kenny, M. Gill, IMAGE consortium* Neuropsychiatric Genetics Research Group, Trinity College Dublin, Institute of Molecular Medicine, Trinity Centre for Health Sciences, St. James' Hospital, James' Street, Dublin 8 Ireland.

As modern humans have spread throughout the world, allele frequencies and linkage disequilibrium (LD) have become more varied between populations. Population admixture is a major source of bias in the case-control study design. Family-based designs, such as the Transmission Disequilibrium Test, can be used to limit this bias. However, the power of the TDT to detect disease susceptibility loci (DSL) can also be influenced by population admixture through its impact on the degree of LD between the genetic marker and the DSL. We have examined the population clustering of a large multicentre study of approximately 950 ADHD-CT families collected from the European population. We have applied selection criteria to try to reduce heterogeneity at the clinical and genetic level. We present data from this pre-cleaning step and discuss the implications to large multicentre studies. Moreover, we present the results of the application of this data to GWAS data using data generated from the IMAGE ADHD-CT study.These data are examined at the marker, gene and hypothesis-free and hypothesis-driven gene-network analysis. Moreover, we examine the functional variation of genes tagged by associated SNP markers.

Idiopathic Nephrocalcinosis: Possible Genetic Causes. *G. Nesterova, W. J. Introne, G. A. Golas, C. Ciccone, M. Huizing, W. A. Gahl* Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Nephrocalcinosis (NC) consists of calcium deposition mainly within the medullary portion of the kidneys. Many known etiologies of secondary NC exist, including Dents disease, exogenous and endogenous forms of hypervitaminosis D, distal renal acidosis, hyperparathyroidism and others. In addition, many patients with renal calcifications have isolated, idiopathic NC, sometimes causing significant renal impairment. Some of these patients could have disorders of vitamin D metabolism not yet discovered. We evaluated two unrelated patients (ages 5 years and 12 years) at the National Institutes of Health with hypercalciuria and isolated nephrocalcinosis. Both children have high normal serum calcium, mildly elevated serum vitamin D_3 levels, and undetectable parathyroid hormone. Neither child has evidence of rickets or a history of excessive vitamin D_3 consumption. Given the high vitamin D levels despite high normal serum calcium, we hypothesize that the underlying mechanism involves dysregulation of vitamin D_3 metabolism. The enzyme 1-alpha-hydroxylase (CYP27B1) converts the inactive form, 25-dihydroxyvitamin D_3 to the active form,1-,25 dihydroxyvitamin D_3(1- 25$(OH)_2D_3$). This biologically active form plays a critical role in intestinal and renal calcium absorption, as well as in binding to the vitamin D receptor (VDR) within distal tubules of the kidney, further regulating CYP27B1 gene expression. 1-,25$(OH)_2D_3$ is inactivated by the enzyme 24-hydroxylase (CYP24). A loss of function mutation within this gene could theoretically lead to increased 1-,25$(OH)_2D_3$. Two additional molecules critical for calcium transport along the cells of the distal tubule are VDR and the active calcium transporter, TRPV5. Our initial investigation has targeted the enzymes responsible for regulating the active vitamin D_3, CYP24 and CYP27B1. Sequencing of both these genes is currently underway. Sequence analysis of the VDR and TRPV5 genes could be the next step.

Reporting cystic fibrosis (CF) modifier gene effects to study participants: Pilot survey. *R. Hayeems[1], F. Miller[1], R. Christensen[1], N. Anderson[2], M. Corey[2], J. Zielenski[2], P. Durie[2], The Canadian Consortium for CF Genetics Studies* 1) Dept Health Policy Management Evaluation, University of Toronto 155 College Street, 4th Floor, Toronto, ON M5T 3M6; 2) The Hospital for Sick Children 555 University Avenue, Toronto, ON M5G 1X8.

Background: Some argue that the principle of respect for persons obligates researchers to proactively disclose genetic research results to participants. Others contend that these results are inherently provisional and that in the context of a research relationship, this is an inappropriate obligation. Unlike the scholarly commentaries fueling this debate, this novel pilot study used an empiric approach. **Methods:** Following academic publication reporting the co-modifying effect of MBL-TGFB1 genes on lung function among a pediatric CF population (Dorfman et al 2008), a lay newsletter and survey were sent to a sample of this study population to explore their understanding of this discovery as well as their expectations of research related disclosure. **Results:** While 84.3% of 115 respondents reported that the newsletter was easy to understand, 60% had remaining questions about the discovery. Only a slim majority correctly agreed that this discovery was related to the *average* severity of CF disease for the participants in this study and correctly disagreed that this discovery was related to the severity of CF disease in an *individual* (53.9%, 54.8%, respectively). The majority of respondents (74.8%) desired more detailed information and 87.0% felt researchers are always obligated to communicate discoveries to participants. While not statistically significant, trends indicate that participant expectations may be driven by misunderstanding the nature of the discovery, a belief that researchers are indeed obligated to report discoveries, or by individual characteristics (e.g. being a parent, being female, having more severe CF disease). **Discussion:** While participant misunderstanding and their perception of researchers obligations to report results may be driving expectations, whether these factors actually justify such an obligation remains unanswered by these data and warrants further empiric consideration.

Phase 2 clinical trials of the pharmacological chaperone AT1001 for the treatment of Fabry disease. *R. Schiffmann[1], D. P. Germain[2], J. Castelli[3], A. Shenker[3], D. J. Lockhart[3]* 1) Institute of Metabolic Disease, Baylor Research Institute, Dallas, TX, on Behalf of the AT1001 Study Group; 2) Université de Versailles, Hôpital Raymond Poincaré, Garches, France; 3) Amicus Therapeutics, Cranbury, NJ.

PURPOSE: AT1001 (migalastat hydrochloride) is an orally administered, small molecule pharmacological chaperone designed to selectively bind -galactosidase A (-Gal A), thereby increasing the enzymes stability, trafficking to the lysosome, and cellular activity. METHODS: 18 men and 9 women between the ages of 17 and 65 were enrolled in four open-label, multinational Phase 2 trials designed to evaluate the safety, tolerability and effects of AT1001 given at different doses and dose regimens. Twenty-six subjects completed a primary treatment arm and all entered the optional treatment extension. Seventeen subjects have been treated with AT1001 for at least 48 weeks and 6 subjects have been treated for more than two years. RESULTS: AT1001 was generally safe and well-tolerated at all doses evaluated. Twenty-four of the 26 subjects demonstrated an increase in -Gal A as measured in leukocytes, kidney, and skin. The average leukocyte -Gal A increase observed in males was greater than four fold. Kidney globotriaosylceramide (GL-3) levels as measured in urine or biopsies were decreased in subjects who demonstrated greater increases in levels of -Gal A. Renal and cardiac function results were encouraging, including data in subjects after 96 weeks of treatment. Subjects in vivo -Gal A responses were consistent with predictions based on in vitro testing of Fabry mutations, suggesting a pharmacogenetic approach may be used to select likely responders for future studies. CONCLUSION: These data suggest AT1001 merits further investigation as a potential therapy for Fabry disease.

Gene variants associated with respiratory distress syndrome in newborns. *H. Heins, J. Wambach, D. Wegner, P. An, A. Muzzarelli, P. Yang, L. Walther, F. Cole, A. Hamvas* Washington University, St. Louis, MO.

Respiratory distress syndrome (RDS) in newborns is a complex disease. To identify genes associated with RDS, we genotyped 588 tag SNPs for 38 candidate genes in 7 pathways of lung function and 83 ancestry informative SNPs in unrelated European American (EA, n=344) and African American (AA, n=286) infants with and without RDS. We used STRUCTURE to estimate genetic admixture. We tested SNP association with the risk of RDS using logistic regression adjusted for gestational age, gender, and admixture. P-values were corrected for multiple tests using a revised false discovery rate approach. Among EA infants, a variant in an epithelial sodium channel (SCNN1G) was independently associated with RDS (P=0.01). Among AA infants, 5 variants in 5 genes along different pathways were independently associated with risk for RDS (P-SNP, Table). Effect size for each variant was moderate (r^2). Gestational age and sex were consistently significant predictors; genetic admixture was not. We conclude that variants in genes expressed in the lung confer risk for newborn RDS. We speculate that epistatic interactions among these genes contribute to diverse mechanisms and outcomes of RDS.

Gene	Function	rs #	Location	# tags	Race	r^2 (%)	P-SNP

Strong evidence of epistatic interactions involving NOS1AP in schizophrenia. *L. M. Brzustowicz[1], Y. Huang[2], V. Saviouk[1], A. S. Bassett[3], V. J. Vieland[2]* 1) Dept Genetics, Rutgers University, Piscataway, NJ; 2) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Childrens Hospital, Columbus, OH; 3) Dept of Psychiatry, University of Toronto, ON.

We have previously shown linkage between 1q23 and schizophrenia and linkage disequilibrium (LD) with markers within NOS1AP in a set of Canadian families of European descent. We have reported significantly increased expression in schizophrenia of NOS1AP in postmortem brain samples. We have shown that rs12742393 is in strong LD with schizophrenia, and that the associated allele can significantly increase expression from the NOS1AP promoter in a cell culture system. To search for possible epistatic interactions with NOS1AP we have reanalyzed our microsatellite genome scan data from these families conditioning on rs12742393 genotype. A baseline scan without conditioning produced four peaks (1p, 2p, 13q, 17q) with Posterior Probabilities of Linkage >20% in addition to the peak at NOS1AP (PPL=97%). Excluding the region around NOS1AP, the conditional analysis produced 8 peaks with a PPL>20%. In addition to the baseline scan peaks, new peaks were seen on 2q, 7p, 9q, and 12q. The location of the 12q peak is near NOS1, a known binding partner of NOS1AP. The baseline scan produced a maximum PPL of 6% in this area, increasing to 36% in the conditional scan, indicating epistasis. We have begun evaluating this interaction in other datasets. Samples of Chinese ancestry from the NIMH HGI collection were genotyped for rs12742393, but showed no evidence of LD (PPLD<2%). Analysis of linkage data from 12q in this sample produced a baseline PPL of 4%, rising to 10% in the conditional analysis. Sequential updating of the conditional results for the Canadian and Chinese datasets produced a final PPL of 63%, indicating that both datasets support the genetic interaction of NOS1AP with a 12q locus. Our results demonstrate that epistatic interactions can obscure linkage and association signals, leading to inconsistent replication across data sets. Despite this, we have demonstrated strong evidence of gene x gene interaction between NOS1AP and additional schizophrenia susceptibility loci.

DNA methylation surveying of the Major Histocompatibility Complex - a twin study. *K. Gervin[1], H. E. Akselsen[1], M. Hamerø[1], R. Moe[1], J. Harris[2], D. E. Undlien[1,3], R. Lyle[1]* 1) Department of Medical Genetics, Ullevål University Hospital, Oslo, Norway, Oslo, Norway; 2) Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway; 3) Institute of medical genetics, Faculty Division Ullevål University Hospital, University of Oslo, Oslo, Norway.

Phenotypic differences between individuals are an outcome of genetic (DNA sequence) and epigenetic (DNA methylation/histone modifications) variation. Whereas variation at the genetic level has been studied extensively, little is known about epigenetic variation. Disturbance of DNA methylation leading to aberrant gene expression has been shown to be involved in many diseases, and variation in DNA methylation may be a contributing factor in common diseases. However, much is still unknown regarding the mechanism, variation and biological function of DNA methylation. In this study we use monozygotic (MZ) and dizygotic (DZ) twins to explore variation, heritability and patterns of DNA methylation in the classical major histocompatibility complex (MHC). The MHC is a gene-dense and highly polymorphic region on human chromosome 6p21.3, containing genes with a broad range of functions within the innate and adaptive immune systems. We performed bisulphite sequencing of 1670 CpG sites in 190 regions in the MHC in 50 MZ and 50 DZ healthy Norwegian twin pairs. We isolated lymphocyte subpopulations (CD19+, CD8+, CD4+ and CD4+CD25+) and study single-cell types to overcome the problem of epigenetic heterogeneity in whole blood. Regions of interest include CpG islands, other CG-rich sequences, the 5end of genes not associated with defined CpG islands and conserved non-coding regions. Individuals show significant variation in DNA methylation both between and within regions. In addition, many regions have a complex pattern of variation. Globally, there appears to be a bimodal distribution of DNA methylation, with regions tending to show either low or high methylation. Interestingly, intra-pair differences are generally lower than inter-pair differences, and MZ pairs show lower intra-pair differences than DZ pairs, indicating a level of genetic control of DNA methylation variation.

The Genetics Of Prostate Cancer - Is It Time To Consider A New Cancer Hypothesis? *B. Gottlieb[1,2], L. K. Beitel[1,2,3], M. Trifiro[1,3]* 1) Dept Cell Genetics, Lady Davis Institute Medical Research, Montreal, PQ, Canada; 2) Dept. Human Genetics, McGill University, Montreal, PQ, Canada; 3) Dept. Medicine, McGill University, Montreal, PQ, Canada.

We investigated the genetics of prostate cancer by examining the androgen receptor gene (*AR*) in both diseased and non-diseased prostate tissues and comparing them to *AR*s in other androgen-responsive tissues and blood. In both diseased and non-diseased prostatic tissue, we identified as many as 10 variants, of a well-known functional polymorphism (a CAG repeat) of the *AR*. In almost all cases the CAG repeats were shorter and therefore the AR proteins were more active than normal. In addition, the majority of these variants were present in very small quantities, which we have termed minority variants. In contrast, in blood and other androgen-sensitive tissues only a single variant was found. The presence of multiple *AR* variants in non-diseased prostate tissues, further suggests that *AR* could play a role in the increased susceptibility of prostate tissue to cancer. Based on these observations we are proposing a new cancer hypothesis in which the critical carcinogenic-promoting event is selection as opposed to current mutation-based hypotheses. In our theory one or more minority *AR* variants may replace the majority normal variants in prostate tissues due to strong selection pressures, as a result of altered environmental conditions or epigenetic factors. This hypothesis could then explain why environmental factors such as diet and exercise are found to be risk factors for prostate cancer, even though they cannot be considered mutagenic agents. Of more immediate interest is its relevance to treatment, as this hypothesis could explain how it is that almost all prostate tumors, while initially responding to anti-androgen-based chemotherapy, become resistant to therapy due to becoming androgen-independent, often within a relatively short time period. According to our theory anti-androgen therapy is likely to result in the selection of the shorter *AR* CAG repeats in tumors, which would be functionally much more responsive to low androgen levels, and so still be able to grow.

Large non-recurrent CNVs in children with autism spectrum disorders from a founder population. *K. Rehnström[1,2], E. Jakkula[1,3,4], H. Kilpinen[1], M. Rossi[1], O. P. H. Pietiläinen[1], L. von Wendt[5], L. Peltonen[1,2,4,6]* 1) National Public Health Institute and Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland; 2) Univ of Helsinki, Finland; 3) FIMM, Finnish Genome Center, Univ of Helsinki, Finland; 4) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 5) Unit of Child Neurology, Hospital for Children and Adolescents, Helsinki, Finland; 6) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Autism spectrum disorders (ASDs) are a group of severe, childhood-onset neuropsychiatric disorders. Twin- and family studies have shown a strong genetic component in ASDs but few, if any, common predisposing variants have been identified and convincingly replicated. Recent reports of have implicated copy number variants (CNVs) as significant predisposing factors in ASDs. In an effort to address potential enrichment of rare alleles predisposing to ASDs among Finns, we have genotyped 164 patients with ASDs from Finnish families using Illumina HumanHap 300 and HumanHap 550 BeadChips. A subset of 54 patients originate from an internal subisolate in Central Finland, and several families have been genealogically linked further reducing the genetic heterogeneity. The GWA data did not show significant enrichment of shared homozygosity or haplotype regions among patients. We next used the dataset to monitor for potential enrichment of sizeable chromosomal aberrations We used QuantiSNP to call large CNVs, and identified several large chromosomal aberrations but again no enrichment of large CNVs across families. Among 164 cases we identified 8 CNVs 1-2.5Mb in size. These included 4 individuals with amplifications of 15q11-12, a chromosomal region well known as a predisposing locus for ASDs. Other large aberrations included duplications spanning 1Mb or more on 1q42, 9q21, 22q11 and a deletion spanning approximately 1Mb on 22q13. The relevance of these findings for ASD was further confirmed in the GWA dataset of a population cohort of ~5000 Finns. Based on this data we conclude that even in a founder population, with genealogically linked individuals, the causes for autism are heterogenous, and only evidence for non-recurrent large CNVs could be established.

Is the thrifty genotype hypothesis (TGH) supported by evidence based on confirmed type 2 diabetes (T2D) susceptibility variants? *L. Southam[1], N. Soranzo[2], SB. Montgomery[2], K. Chapman[1], MI. McCarthy[1], I. Barroso[2], E. Zeggini[1]* 1) WTCHG, University of Oxford, Oxford, UK; 2) WTSI, Hinxton, UK.

The TGH suggests that the high prevalence of T2D may be partly due to common genetic variants that have risen in population frequency due to natural selection having favoured alleles that were once advantageous in periods of famine. The recent detection of 18 robustly replicating T2D susceptibility loci enables us for the first time to look for evidence in support (or otherwise) of the TGH using proven loci. We have examined several characteristics that might indicate evidence for selection at the 18 loci: we have determined whether the risk allele at index single nucleotide polymorphisms (SNPs) is the derived or ancestral allele and whether the risk allele is the major or minor allele (in terms of allele frequency) in the reported studies. We find that the risk allele is the ancestral allele at 12 loci, compared to 9 expected by chance (binomial test p=0.12). We also find no significant difference between risk and non-risk allele frequency; 10 risk alleles are major and 8 minor (p=0.41). We determined the integrated haplotype score (iHS) statistic for each locus. Two loci had iHS > 2: rs10923931 (NOTCH2) & rs8050136 (FTO). One locus had an iHS < -2: rs7901695 (TCF7L2). The extended haplotype is associated with the risk allele at rs8050136 (FTO) only. Finally, we assessed the population differentiation statistics FST for the 18 loci for all pairwise comparisons of 11 worldwide populations genotyped by the HapMap phase 3 and compared them to the neutral expectation, defined as the 95% quantile of the empirical FST distribution calculated over 1.5 Million genome-wide loci. We found an excess of high FST values for rs5215 (KCNJ11) in African populations and rs7901695 (TCF7L2) in East-Asian populations (both p=0.019), indicating possible diversifying selection at these loci. Our results do not provide conclusive evidence to support the TGH. However, the number of robustly replicating T2D loci identified to date is small. In addition, the causal variants for most susceptibility loci have not yet been determined -this could affect the SNP-specific analyses we have carried out.

Analysis of the CNTNAP2 Gene in Autism. *J. L. Haines[1], N. Schnetz-Boutaud[1], K. Brown[1], K. Gainer-Luci[1], M. L. Cuccaro[2], J. R. Gilbert[2], M. A. Pericak-Vance[2]* 1) Center for Human Genetics Research, Vanderbilt Univ Medical Center, Nashville, TN; 2) Miami Institute for Human Genomics, Univ. Miami, Miami, FL.

Autism Spectrum Disorders (ASDs) encompass several diagnoses with the three most prevalent being autism, Aspergers Syndrome and Pervasive Developmental Disorder (PDD-NOS). ASDs are complex neurodevelopmental disorders with an onset early in childhood and ~4:1 male:female ratio. The ASDs are characterized by impairments in language and reciprocal social interactions, combined with repetitive and stereotypic behaviors. Concordance rates for MZ twins have been estimated between 60%-90% and 0%-10% for DZ twins, suggesting a strong genetic etiology. Despite strong evidence of a genetic component and substantial efforts, very little of the genetic etiology has yet been explained. Based on the results of a Genome Wide Analysis Study (GWAS) of autism, the Contactin Associated Protein Like-2 (CNTNAP2) gene on chromosome 7q was implicated in autism risk, and has already been confirmed in 2 additional datasets. We examined two previously associated CNTNAP2 SNPs in our independent dataset of 403 Caucasian multiplex and trio families whose affected individuals meet DSM-IV and ADI criteria for autism. Analysis of the overall dataset generated a p-value of 0.03 using the pedigree disequilibrium test (PDT) for RS7794745, confirming the previous results. To test for the specificity of the results we examined two subsets of the data. This result was stronger in the subset of male-only families (p=0.004, N=303), and in the severe subset of families where the probands has >50%tile scores on each of the subdomains of the ADI (p=0.003, N=96). There was no enrichment of the male-only families in the severe subset. These results confirm (1) that variations in CNTNAP2 are broadly important in ASDs; and (2) that GWAS is a powerful tool to unravel the genetics of even behaviorally complex traits. The specificity of these results lends further credence to the concept that multiple genes likely contribute to different subphenotypic expressions of ASDs.

Multidisciplinary Clinic for BRCA1/2 Carriers at Guys Hospital, London: Experience after 24 months. *L. P. Izatt[1], C. Jacobs[1], C. Firth[1], C. Langman[1], H. Hamed[1], A. Tutt[1], S. Rose[1], S. Hyams[1], G. Pichert[1], I. Jacobs[2], U. Menon[2], Guys & St. Thomas Charity* 1) Clinical Genetics, Guy's and St.Thomas' NHS Foundation Trust, London, UK; 2) Women's Institute, University College, London, UK.

BRCA1/BRCA2 carriers have increased breast & ovarian cancer risks & face complex decisions over ca risk management strategies, including risk-reducing (RR) surgery, & surveillance. Our multidisciplinary clinic (MDC) for BRCA1/2 carriers is a new service that has run for 24 months. All patients would see a geneticist & could choose to see an oncoplastic br surgeon, oncologist, gynae-oncologist, or psychologist in a one-stop clinic. All patients were discussed at a MDT meeting before the clinic to co-ordinate best practice care in conjunction with local clinicians. **Aims** To offer all BRCA1/2 carriers an annual MDC review, to address their needs, update them on new developments, & invite participation in research trials. We audited uptake & satisfaction of the MDC, the impact of the service on uptake of surveillance, RR surgery & research trial entry. **Results** 79% (201/254) patients invited were interested in attending the MDC. Of 170 BRCA1/BRCA2 carriers seen, 8 were male. The age range was <20 to >70, median 40-50. Patients were seen by:-Geneticist/genetic counsellor, 170, br. surgeon, 95, gynae-oncologist, 103, oncologist, 13, clinical psychologist, 64, research nurse, 130. Recommended br surveillance was altered in 44% (65/147) eligible women after MDC with 2 screen detected brca during f/u. 27% (42/157) patients had RR breast surgery prior to MDC and 54% (62/115) were considering/had decided to have RR mastectomy after. 33% (45/134) patients had bilat. oophorectomy before the MDC & 85% (76/89) patients were considering/ had decided to have bilateral salpingo-oophorectomy after. Recruitment to the EMBRACE trial rose from 17% (29/170) before MDC to 84% (114/141) after. Questionnaires completed by 76% of attendees showed high satisfaction, with a median 9 out of a 1-10 scale, citing the one-stop facility as key. **Conclusion** Our MDC is a novel, successful one-stop clinic leading to improved patient-centred care with increased uptake of cancer risk reducing strategies & research trial participation.

A silent variant in the *WAS* gene causing Wiskott-Aldrich syndrome. *M. J. van Belzen[1], M. W. Boogaard[1], M. M. ten Dam[2], M. Losekoot[1], R. G. M. Bredius[2]* 1) Clinical Genetics, Laboratory for Diagnostic Genome Analysis, Leiden University Medical Center, Leiden, The Netherlands; 2) Pediatrics, Division of Immunology, Hematology, Oncology, Bone Marrow Transplantation and Autoimmune Diseases, Leiden University Medical Center, Leiden, The Netherlands.

Wiskott Aldrich syndrome (WAS) is a rare X-linked disease, characterized by microthrombocytopenia, eczema and immunodeficiency causing recurrent infections, a high incidence of autoimmunity and of lymphoid malignancies. The disorder is caused by mutations in the *WAS* gene, in which over 300 mutations have been described. Mutations include nonsense, frameshift and missense mutations that occur over the entire coding region. In addition, several splice site mutations have been described, mainly occurring at the exon/intron boundaries. The effects of *WAS* mutations on the function of the WAS protein (WASp) are variable, resulting in a wide range of phenotypes. The case presented here is a one year old boy with a clinically moderate phenotype of the Wiskott-Aldrich syndrome (Zhu score: 3 to 4, pre-stem cell transplantation (SCT)). Sequence analysis of the entire coding region of the *WAS* gene revealed only one silent variant in exon 7: c.687G>T, p.Gly229Gly. Analysis with splice predict software indicated the creation of a strong donor splice site in the middle of exon 7. RNA studies were performed to determine whether this new splice site was active. The major RNA transcript in blood of the patient lacked the last 49 bp of exon 7, resulting in a frameshift and the introduction of a premature stop codon: r.686_734del, p.Lys230MetfsX15. Flowcytometry and western blot analysis of WASp showed that this protein could not be detected in the patients blood, thereby confirming the pathogenicity of the silent DNA variant. In conclusion, we have shown that a silent variant in the *WAS* gene can cause classical Wiskott-Aldrich syndrome, a mechanism which has not been reported before in Wiskott-Aldrich patients.

3.8 MB deletion of chromosome 5q in a newborn tracheal agenesis patient. *E.de Jong[1,2], H. Douben[1], B. Eussen[1], D. Tibboel[2], A. de Klein[1]* 1) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands; 2) Department of Pediatric Surgery, Erasmus Medical Center - Sophia Children's Hospital, Rotterdam, Netherlands.

The department of Pediatric Surgery, in collaboration with the department of Clinical Genetics has collected a large cohort of patients with tracheal and foregut-related anomalies. The most prevalent are Esophageal Atresia (EA) with or without Tracheo-Esophageal Fistula (TEF), associated with VACTERL anomalies (Vertebral, Anal, Cardiovascular, Tracheo-Esophageal, Renal and Limb) occurring in around 25% of patients. Tracheal agenesis (TA), a congenital anomaly of the respiratory tract with an incidence of 1 in 50,000 births, is less frequent. Routinely, EA/TEF and also TA patients are karyotyped and screened for subtelomeric aberrations with MLPA (Multiplex Ligation-dependent Probe Amplification). Array-CGH (105K Agilent) was used to screen for small deletions or duplications in cell lines (n=6) and paraffin embedded tissues (n=6) of twelve TA patients. Our TA patients showed a variety of copy number variations of which many were parental inherited variants. In one of our TA patients we observed a 3.8 MB deletion on chromosome 5q11.2, not present in the mother: the father was not available. This 3.8 MB deletion was confirmed with FISH and Q-PCR. The deleted region contains 17 genes and we are currently investigating, using prioritizing programs, whether we can relate any of these genes to the TA or other phenotypes, since in addition to TA this patient also suffered from other foregut-related anomalies, such as cartilage rings in the esophagus, aberrant right bronchus and rib abnormalities.

Molecular characterization of a large cohort of Cornelia de Lange Syndrome Italian patients and related phenotypes. *A. Selicorni[1], S. Russo[2], C. Gervasini[3], M. Masciadri[2], P. Castronovo[3], A. Passarini[1], D. Milani[1], L. Larizza[2,3]* 1) Pediatric Dep.Fondazione Ospedale Maggiore Policlinico Mangiagalli Regina Elena Milan Italy; 2) Molecular Genetics Istituto Auxologico Italiano Milan Italy; 3) Medical Genetics San Paolo School of Medicine University of Milan Italy.

Cornelia de Lange syndrome (CdLS) is a rare multiple congenital disease characterized by facial dysmorphisms, growth/mental retardation, hirsutism, small hands and feet or upper limb reduction defects. Mutations in the NIPBL gene (5p13.2) are responsible of about half of CdLs cases while a small percentage of pts shows molecular defects in the SMC1L1 gene (Xp11.22). SMC3 gene has been associated with CdLS, although its impact on the CdLS syndrome remains to be defined. We report on the thorough molecular characterization of major genes and submicroscopic genomic rearrangements in a clinically heterogeneous sample of 97 Italian CdLS pts. Mutational screening of NIPBL, carried on by DHPLC and direct sequencing identified 7 missense, 1 in frame deletion, 11 splice-site, 9 nonsense and 13 frameshift mutations, while application of MLPA led to disclose three large multiexon deletions. In selected cases transcript analysis showed the limits of mutation classification at the genomic level, as in two prenatal diagnoses in which the mutation observed in a previous child turned out to be a splicing defect (Q1640Q substitution) or was confirmed to lead to missplicing (c.6108+6T->G, causing the skip of exon 34).Two SMC1L1 mutations were detected, among 36 NIPBL-negative pts and one genomic imbalance and two CNV were disclosed by array-CGH among 24 NIPBL-SMC1L1-negative cases. The stepwise application of this molecular diagnostic flow-chart enabled to disclose the molecular lesion in 51/97 patients (52,5%) also providing a selected cohort of pts to be investigated for candidate genes. Increasing numbers of molecularly characterised CdLS pts should permit to address genotype-phenotype correlations. Even in the case of NIPBL inactivating mutations, the degree of mental retardation is highly variable, due to different effects of the mutation depending on early or late truncation, and to other unknown genetic and epigenetic factors.

Ofd1 limb mesenchymal inactivation results in abnormal anteroposterior patterning and shortening of long bones. *S. Bimonte[1,2], L. Quagliata[1], R. Tammaro[1], M.-G. Ascenzi[3], B. Franco[1,4]* 1) Telethon Institute of Genetics and medicine, TIGEM, Naples, Italy; 2) European School of Molecular Medicine (SEMM), Naples; 3) Department of Orthopaedic Surgery, Biomechanics Research Division, University of California, Los Angeles; 4) Department of Pediatrics, Medical Genetics Services, University Federico II, Naples.

Oral-facial-digital type I (OFDI) syndrome is an X-linked dominant male lethal developmental disorder characterized by oral, facial and digital abnormalities. Recent data ascribed OFDI to the growing number of diseases due to dysfunction of primary cilia. Ofd1 null mutants recapitulate the phenotype observed in OFDI patients and displayed skeletal defects. To overcome the embryonic male and perinathal female lethality observed in Ofd1 null mutants we have generated a conditional model with Ofd1 limb mesenchyme specific inactivation. These mice displayed a severe polydactyly with loss of antero-posterior digit patterning, aberrant cilia formation, and shortening of long bones. Defective digit pattering was found to be associated to progressive loss of Shh signaling and impairment of Gli3 processing. Shortening of long bones was found to be associated to defective Ihh signalling and to abnormalities of proliferating chondrocytes as revealed by RNA in situ studies. Finally Von kossa staining and RNA in situ studies demonstrated defective bone mineralization accompanied by loss/reduction of bone collar development suggesting a defect in osteoblast differentiation. Intriguingly, IF analysis demonstrated that cilia are present although shorter than those observed in wild-type animals. This data suggest that, in the limb bud, Ofd1 is not essential for cilia outgrowth although its presence is necessary for formation of normal cilia, contrary to what observed at the embryonic node of Ofd1 null animals. Altogether our data demonstrate that Ofd1 is a pattering factor that plays multiple roles in limb and endochondral bone development.

Genome-wide association study of intraocular pressure in 1304 individuals. *S. M. Hosseini[1], D. Waggott[2], A. P. Boright[3], S. B. Bull[2], W. Sun[4], P. A. Cleary[4], A. D. Paterson[1], DCCT/EDIC Research Group* 1) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Canada; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada; 3) Department of Medicine, University of Toronto, Toronto, Canada; 4) Biostatistics Center, The George Washington University, Rockville, MD.

Background: Intraocular pressure (IOP) is clinically important as one of the primary risk factors for the common form of glaucoma. Diabetes is associated with an increase in both IOP and glaucoma. Twin and family studies show a genetic basis for both glaucoma and IOP. Identifying genetic variants associated with IOP might shed light on pathophysiological mechanisms of glaucoma. **Purpose:** To identify quantitative trait loci associated with IOP in Diabetes Control and Complications Trial (DCCT) cohort **Methods:** DCCT was a clinical trial to compare the effect of intensive and conventional diabetes treatment on the development and progression of complications. IOP has been measured annually in DCCT probands using applanation tonometry. DNA samples from the probands (n=1419) was genotyped using Illumina 1M beadchip. After removing poor performing SNPs and outliers based on population stratification, genotype data was available for ~842K SNPs with a minor allele frequency 1%; on 1304 white probands. Primary non-parametric statistical analysis using a univariate model was performed on IOP measurements as a continuous trait at DCCT baseline. **Results:** Several SNPs show evidence of association with IOP (5 with a P-value 10^{-5}).Of these rs8077655 on 17q (P-vlaue= 9.61E-6) coincides a linkage peak for primary open angle glaucoma (Wiggs et al, 2000). rs177667 (P = 2.31E-6) is located on 7q within a locus recently linked to IOP (Duggal et al, 2007). Collaborative efforts to replicate these primary results are underway. **Conclusion:** This genome-wide association study of intraocular pressure identified a number of interesting loci, some of which present in regions linked to IOP or glaucoma. More comprehensive analysis of IOP data including the use of repeated IOP measurements are underway and may increase the power to detect modest genetic effects.

Concerns of South Korean Patients and Family Members Affected with Genetic Conditions: An Interpretive Analysis. *H. Kang[1], P. McCarthy Veach[2], B. LeRoy[1]* 1) Institute of Human Genetics, University of Minnesota, Minneapolis, MN; 2) Educational Psychology, University of Minnesota, Minneapolis, MN.

Genetic counseling is expanding globally. However, many countries such as South Korea lack healthcare professionals specifically trained as genetic counselors. Currently in South Korea, nurses working in genetics clinics provide some services: also several websites are devoted to genetic conditions. To date, no one has empirically examined needs of South Korean patients and family members who have genetic concerns. Therefore, the present study investigated patients and family members general concerns by accessing and analyzing messages posted to the websites. Eighteen websites were accessed: 1 concerns general genetic conditions and 17 concern specific conditions [e.g., Muscular Dystrophy (3 sites), ataxia, Down syndrome, Rett syndrome, Turner syndrome, Ehlers Danlos, Treacher Collins syndrome, Wilson, MPS, Angelman syndrome, Osteogenesis Imperfecta, dwarfism, RP, VCFS, Charcot Marie Tooth). A random sample of 700 messages posted to the websites message boards was obtained. Messages were translated into English, analyzed and audited using interpretative content analysis. Messages were written by patients and family members; most were detailed and specific. Three major themes and 33 categories were extracted: 1) Medical Questions (e.g., clinical symptoms, diagnosis, prognosis, recurrence risk, prevention, inheritance); 2) Management Needs (e.g., therapy and treatments, education, nutrition, medical facilities and devices, parenting issues, financial support, folk remedies); 3) Psychosocial Issues [e.g., emotions (fear, worry, sadness, disbelief, depression, etc.), physical and psychological depletion, social issues (stigma, secrecy, etc.), and need for social support]. The tone of the messages suggests that writers were sincerely seeking help and would trust the responses that they received. Message content further indicates that most writers lacked basic genetic/medical information, resources are limited, and there are unique cultural issues. Representative messages, unique cultural features, and practice and research recommendations will be presented.

The assessment of confounding in genetic epidemiology may not be reliable in cases of low minor allele frequency. *A. Yesupriya, R. M. Ned, M. H. Chang, N. F. Dowling for the CDC/NCI NHANES III Genomics Working Group* National Office of Public Health Genomics, CDC, Atlanta, GA.

The confounding of associations by environmental risk factors or population structure may affect the validity of study findings in genetic epidemiology. Appropriate methods for identifying confounders include assessing if the odds ratio that is adjusted for potential confounders differs from the unadjusted odds ratio by some pre-specified amount (e.g., 10%). However, adjusted and unadjusted odds ratios may also diverge if these estimates are unstable. Previous studies have reported that estimates of effect may be unstable for genetic variants when the minor allele frequency (MAF) is low (e.g., <10%). We examined if MAFs were correlated with the percent difference (absolute value) between adjusted and unadjusted odds ratios using simulated data and genetic data from the Third National Health and Nutrition Examination Survey (NHANES III). Data for the simulation study included 1000 single nucleotide polymorphisms from a hypothetical study of 1000 cases and 1000 controls. Data from NHANES III was used to examine the association of 33 candidate genetic variants and chronic kidney disease. Odds ratios were calculated from logistic regression models. Adjusted models included two randomly generated dichotomous covariates for the simulation study and age (<50, 50 years) and sex for the NHANES III study. Both additive and co-dominant modes of inheritance were considered. We found that MAFs were correlated with the percent difference between the adjusted and unadjusted odds ratios for the additive ($p< 0.01$) and co-dominant modes of inheritance (heterozygous contrast: $p=0.014$; homozygous contrast: $p< 0.01$) in the simulation study. In the NHANES III study, we found that this relationship was significant for the additive mode of inheritance ($p< 0.01$) and the homozygous contrast of the co-dominant mode of inheritance (p 0.02). We show that MAFs can be associated with the percent difference between adjusted and unadjusted odds ratios. We conclude that the evaluation of confounding may not be reliable in genetic association studies when minor allele frequencies are low.

Meta-analysis of genome-wide association studies identifies many additional height loci and highlights new biological pathways in human growth. *G. Lettre[1,2], M. N. Weedon[3], H. Lango[3], GIANT Consortium* 1) Broad Institute, Cambridge, MA; 2) Childrens Hospital Boston, Boston, MA; 3) Peninsula College of Medicine and Dentistry, Exeter, UK.

Adult height is a highly heritable and polygenic human trait. Using meta-analyses of genome-wide association (GWA) studies, we and others identified 43 loci that robustly associate with height variation in European populations. Remarkably, however, the associated variants at these 43 loci account for <10% of the variation in height, suggesting that many other genetic variants influence stature. To find additional height loci, we performed a larger meta-analysis, including all GWA datasets available through the GIANT Consortium (13 GWA studies; >32,000 participants). This meta-analysis identified 111 independent loci with $P<1x10^{-5}$ (~10 expected) and 50 with $P<5x10^{-7}$ (0.5 expected). More than 50 of these loci have not been previously associated with stature, indicating that the search for common variants influencing height continues to be productive as sample sizes increase. Among new interesting associations, we found an intronic SNP in *JAZF1*, a gene previously implicated in the etiology of type-2 diabetes and prostate cancer, and a SNP upstream of *KCNE2*, a potassium channel mutated in long QT syndrome and ventricular fibrillation. Pathway analysis of height associated loci revealed an enrichment of genes involved in cancer and development, and the emergence of networks that connect genes functionally. Furthermore, many of the associated loci encompass genes that are mutated in syndromes characterized by abnormal skeletal growth. Thus, our results offer an excellent list of candidate genes for human syndromes of unknown genetic etiology that have skeletal abnormalities, short stature or overgrowth as features. To help determine whether these variants also influence height in populations of African ancestry, we are testing these SNPs for association in African and African-American cohorts. In conclusion, our study of the genetic of height provides unprecedented insights into the biology of human growth and development, and also into the architecture of complex human traits and diseases.

Balloon occlusion catheter-based delivery of HDAd permits efficient hepatic transduction using clinically relevant low vector doses in nonhuman primates. *P. Ng[1], G. Stapleton[2], M. Law[2], D. Palmer[1], N. Grove[1], A. Beaudet[1], C. Mullins[2], N. Brunetti-Pierri[1]* 1) Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX; 2) Pediatric Cardiology, Baylor College of Medicine, Houston, TX.

Helper-dependent adenoviral vectors (HDAds) hold tremendous potential for liver-directed gene therapy by providing long-term transgene expression without chronic toxicity. The main obstacle hindering clinical application of these vectors is a dose-dependent acute toxicity. In humans, a systemic dose of $6x10^{11}$ vp/kg of an earlier generation Ad vector was lethal in one of two partial OTC-deficient patients whereas a ½-log lower dose ($2x10^{11}$ vp/kg) was well tolerated. Unfortunately, while safe, systemic intravenous (IV) injection of lower doses yield little to no hepatocyte transduction. Therefore, we have developed in nonhuman primates a minimally invasive method to achieve efficient hepatic transduction using low and safe HDAd doses. Briefly, a balloon catheter was percutaneously positioned in the inferior vena cava to occlude hepatic venous outflow and an HDAd expressing the baboon -fetoprotein (bAFP) reporter was injected via a hepatic artery catheter and this method was compared to simple systemic peripheral IV injection. Two baboons injected with $3x10^{10}$ vp/kg HDAd by simple systemic peripheral IV injections showed little to no transgene expression. In contrast, when the same dose of $3x10^{10}$ vp/kg was administered to two baboons using the balloon occlusion catheter approach, an increased level of transgene expression (up to 80-fold) was observed compared to peripheral IV injection. Transgene expression persisted at this high level for the duration of the observation period of at least 56 days. When an even lower dose of $1x10^{10}$ vp/kg was administered to two baboons by the balloon occlusion catheter approach, the level of transgene expression was 30-fold higher than systemic peripheral IV injection of the higher $3x10^{10}$ vp/kg dose. Thus, the balloon occlusion catheter technique permits delivery of clinically relevant low HDAd doses to achieve efficient hepatic transduction and may be a first step towards clinical application of HDAd for liver-directed gene therapy.

A Mouse Model for Hypomorphic Atr Expression. *R. L. Ragland, M. F. Arlt, T. W. Glover* Department of Human Genetics, University of Michigan, Ann Arbor, Michigan.

Both the ATM and ATR checkpoint pathways respond to DNA damage during the S/G2 phases of the cell cycle and are activated early in tumorigenesis. Unlike ATM, the investigation of ATRs role in development and tumor initiation and progression is complicated by the lethality of homozygous knock-out mice and the limited effects of heterozygous deficiency. The identification of a hypomorphic ATR mutation in the human disease Seckel syndrome-1 (SCKL1) provides a novel approach to this problem. The SCKL1 mutation leads to aberrant splicing of ATR and homozygous individuals have a 90% reduction in ATR protein expression. Here we report the creation and initial characterization of a SCKL1 mouse model. Homozygous SCKL1 mice were generated by knock-in targeting of the SCKL1 mutation, crossing to FLP transgenic mice to remove the neo cassette used for selection in ES cells, and backcrossing to C57BL/6 mice. Western blot and RT-PCR analysis established that homozygotes have no reduction in Atr protein or increase in mis-splicing as is seen in humans with SCKL1. Thus, the effects of the SCKL1 mutation differ in humans and mice. However, homozygous SCKL1 mice retaining the neo cassette have a 73-95% reduction in total Atr protein levels due to strong mis-splicing into the neo cassette, yet are viable. These mice do not show an overtly abnormal physical phenotype as of ~10 months of age, but do demonstrate aberrant Atr checkpoint activity. Under conditions of replication stress, primary fibroblasts from homozygous mice have an increase in both total gaps and breaks on metaphase chromosomes and an increase in gaps and breaks at specific common fragile sites. In addition, when compared to wild type cells, mutant cells display a significant delay in checkpoint induction as assayed by Chk1 phosphorylation. These mice have lower levels of Atr expression than heterozygote knock-out mice and have several cellular phenotypes indicative of Atr deficiency, thus providing a unique model system for studies of Atr deficiency in development and tumorigenesis.

Confirmation and Localization of Major Type 1 Diabetes MHC Telomeric Locus Near UBD. *E. Baschal, A. Steck, J. Jasinski, S. Babu, G. Eisenbarth, Type 1 Diabetes Genetics Consortium* Barbara Davis Center, University of Colorado Denver, Aurora, CO.

We believe there are additional genes, beyond HLA-DR and DQ, in the MHC region that contribute to type 1A diabetes risk, based on evidence that there is an 80% risk for the development of anti-islet autoantibodies in DR3/4 individuals who are identical-by-descent with their proband sibling. We began our search for additional genes at the furthest telomeric MHC peak of association with type 1 diabetes, near the UBD gene. We have previously reported an association with the far telomeric SNP rs1233478. We therefore analyzed the complete Type 1 Diabetes Genetics Consortium MHC panel in this region, with complete typing on 1,240 affected sib-pair families. In the additional data, rs1233478 is still highly significantly associated with type 1 diabetes (p=2.2E-24, OR=1.8). We now report an association with two additional SNPs adjacent to rs1233478, rs3131020 and rs1592410 (p=3.7E-21, OR=1.6 and p=3.0E-20, OR=1.6, respectively). These three SNPs form a haplotype, with three additional SNPs, that is present in high risk, protective, and neutral forms. The high risk haplotype (AACAAC) is transmitted to affected children 1439/2327 times (62%, p=2.1E-30). A protective haplotype (GCTGGC) is also present in our data (transmitted 1314/3054=43%, p=1.3E-14), as are neutral haplotypes. We also performed logistic regression on our data, adding the 3 SNP haplotype, HLA-DR, HLA-DQB1, HLA-B and HLA-A as explanatory variables. The final model, using forward logistic regression, contains HLA-DR, HLA-DQ, HLA-B, HLA-A, and the 3 SNP haplotype (p=8.24E-3, OR=1.3), indicating that the effect from the 3 SNP haplotype is independent of the effects of HLA-DR, HLA-DQ, HLA-B and HLA-A. The region of conservation for the high risk allele of the 3 SNP haplotype is approximately 20,000 base pairs and contains a single EST.

Shared genetics of autoimmune and inflammatory disorders: overlap of celiac disease, rheumatoid arthritis and inflammatory bowel disease. *C. C. van Diemen[1], A. Zhernakova[2], G. Trynka[1], L. Franke[1], E. A. M. Festen[1], R. K. Weersma[1], M. A. van Leeuwen[3], C. Wijmenga[1]* 1) Genetics, University of Groningen, University Medical Center Groningen, the Netherlands; 2) Medical Genetics, University Medical Center Utrecht, the Netherlands; 3) Rheumatology, University Medical Center Groningen, the Netherlands.

Recent genome-wide association studies and their follow up studies have revealed genes in autoimmune diseases (i.e. type 1 diabetes , rheumatoid arthritis, celiac disease) and inflammatory diseases (i.e. inflammatory bowel disease (IBD)) that overlap between two or more disorders, which points to a shared disease pathogenesis. In our recent celiac disease genome wide association study we have identified 8 novel loci (*RGS1*, *CCR2/CCR3*, *IL12A/Schip*, *LPP*, *TAGAP*, *SH2B3*, *IL18RAP*, *IL2/IL21*). Subsequently, we showed association of *IL2/IL21* with rheumatoid arthritis, type 1 diabetes, and IBD, and of *IL18RAP* with IBD. We have also investigated the association of the remainder of the celiac disease loci in rheumatoid arthritis and are currently analyzing them in IBD. We tested SNPs in *RGS1* (rs2816316), *CCR2/CCR3* (rs6441961), *IL12A/Schip* (rs17810546 and rs9811792), *LPP* (rs1464510), *TAGAP* (rs1738074), *SH2B3* (rs3184504), and *IL18RAP* (rs917997) in 418 rheumatoid arthritis-affected Dutch patients and 888 blood donor controls. We found no significant associations between any of the SNPs and rheumatoid arthritis (p values >0.12). The lack of association was further confirmed by imputed data from the rheumatoid arthritis dataset of the Wellcome Trust Case Control Consortium (p values >0.015). Genotyping of 518 IBD subjects is currently in progress. Thus far, this study does not provide further overlap of celiac disease genes and rheumatoid arthritis, besides the *IL2/IL21* locus. However, recent advances made in genetics of autoimmune and inflammatory disorders point to a shared genetic background for these disorders, like the association of *IL23R* with rheumatoid arthritis, celiac disease, autoimmune thyroid disease, IBD and psoriasis. This indicates that further studies are warranted using multiple inflammatory and autoimmune disorders.

Noonan syndrome and marfanoid habitus in a patient with SOS1 mutation. *M. Mathieu[1], G. Morin[1], B. Demeer[1], A. G. Le Moing[1], H. Cavé[2], C. Boileau[3], J. M. Lebrun[4], A. Verloes[2]* 1) Clinical Genetic Unit - University Hospital - Amiens - France; 2) Genetic Department - Robert Debré Hospital - Paris - France; 3) Molecular Genetic Laboratory - Ambroise Paré Hospital - Boulogne - France; 4) Service of Pediatrics - General Hospital - Soissons - France.

We report the observation of a 24-year-old male patient exhibiting features suggesting Noonan syndrome (mild mental retardation, low-set hair, hypertelorism, bilateral ptosis, dysplastic low-set ears, and webbed neck), and others compatible with Marfan disease (height at 1m83, joint hyperlaxity, arachnodactyly, pectus carinatum, severe scoliosis, myopia). Cardiac ultrasound examination was normal. Familial stature was tall (mother 1m73, father 1m83, and brothers 1m95 and 2m). Blood standard karyotype was normal. Noonan syndrome was confirmed by molecular analysis of SOS1 gene [heterozygous mutation 1654 A>C (R552G)]. However Marfan disease was not documented with a negative screening of FBN1 gene. We discuss the hypothesis of a pleiotropic effect of the SOS1 mutation, the influence of the familial stature, and the eventuality of two concomitant independent diseases.

Application of next generation sequencing technology to the identification of mouse mutations. *J. L. Moran[1], T. Fennell[1], K. Tibbetts[1], R. Levine[1], J. Wilkinson[1], K. Ardlie[1], J. Schimenti[2], M. Meisler[3], D. R. Beier[4], S. Gabriel[1]* 1) Broad Institute of MIT and Harvard, Cambridge, MA; 2) Cornell University College of Veterinary Medicine, Ithaca, NY; 3) University of Michigan Medical School, Ann Arbor, MI; 4) Brigham and Women's Hospital, Harvard Medical School.

We have established the Mouse Mutant Resequencing Initiative in order to apply high-throughput sequencing technology to the identification of mouse mutations, with the goal of expediting the recovery of biological information from existing collections of genetically mapped ethylnitrosurea-(ENU) induced and spontaneous mutants. Our first project is to sequence all exons, 5 and 3 regions in non-recombinant intervals for 11 ENU-induced mutants utilizing a pooling approach. The affected pool contains a mixture of genomic DNA from one affected animal or one heterozygous carrier for each of the 11 mutants. The control pool contains genomic DNA from the background strains for all mutants. In addition, one individual affected mutant and the corresponding control strain will be analyzed in parallel to compare sequence coverage and mutation detection in pooled vs. singleton libraries. Hybrid selection from each of the 4 libraries will be performed on Agilent oligo-arrays and resulting capture products then sequenced with the Illumina Genome Analyzer to achieve a minimum of 15X coverage per DNA sample. The total target territory for the 11 mutants is 1.78 Mb and encompasses 405 RefSeq genes and 4901 exons. Our data analysis pipeline includes identification of sequence variants within the pools and comparison of variants across affected and control pools to identify candidate single base-pair mutations. Validation of candidate mutations and assignment to individual DNAs within the pools will be performed by genotyping the observed variants in all affected and control strains individually. We anticipate that the application of next generation sequencing technologies to mouse genetics will permit rapid and cost-efficient identification of mutations in monogenic mutants as well as identification of quantitative trait loci.

POSSIBLE ROLE OF SRPX2 GENE IN BILATERAL PERISYLVIAN POLYMICROGYRIA. *S. S. Tsuneda[1], D. A. Souza-Kols[1], F. R. Torres[1], R. Secolin[1], C. V. Maurer-Morelli[1], M. M. Guerreiro[2], F. Cendes[2], I. Lopes-Cendes[1]*
1) Medical Genetics Dept., UNICAMP, Campinas SP, Brazil; 2) Neurology Dept., UNICAMP, Campinas SP, Brazil.

RATIONALE: Polymicrogyria is a malformation of cortical development characterised by multiple small gyri with abnormal cortical lamination. In bilateral perisylvian polymicrogyria (BPP), the cerebral cortex on the border and in the depth of the Sylvian fissures is thickened and abnormally infolded, more vertically oriented and, in some cases, extending more posterior up to the parietal lobes. Approximately 28 familial cases of BPP have been described, from which 75% are compatible with an X-linked heritance pattern. We have recently described a candidate locus for BPP on chromosome Xq27.2-27.3 and the SRPX2 gene is mapped in the most centromeric limits of this candidate locus. In addition, there is a report of mutations in the SRPX2 (sushi-repeat protein X-linked 2) gene in a patient with BPP and two female relatives. The objective of the present study was to perform mutation screening in the SRPX2 gene in patients form our large cohort with BPP. METHODS: Total genomic DNA obtained from 31 patients with BPP and normal controls was used as template for polymerase chain reactions (PCR) with primers for each exon sequence of the SRPX2 gene. The amplified fragments were submitted to DHPLC analysis and automated sequenced. RESULTS: DHPLC chromatography showed a different pattern of retention time in fragments of exon 1 from 2 patients belonging to different families. Sequencing analysis revealed a substitution of a guanine by a cytosine at the 30th base position of exon 1, which is predicted to be transcribed but not translated. CONCLUSION: We identified a point-mutation in the SRPX2 gene in two unrelated patients with BPP. The base-pair substitution we identified has not been reported previously and samples from control individuals are still being sequenced. In addition, the fact that the base-pair change occurred in a position that is not translated raises the possibility of a non-pathogenic mutation. Financial support: FAPESP.

The need for a well characterised UK Control Population. *B. Winney, A. Boumertit, R. Bowden, D. Davison, S. Day, E. Echeta, I. Evseeva, K. Nicodemus, S. Tonks, X. Yang, P. Donnelly, W. Bodmer* Dept. Clinical Pharmacology, University of Oxford, Oxford, OX3 7DQ, UK.

Until the recent advent of Whole Genome Association studies (WGAs), there were problems replicating significant associations between gene variation and complex diseases in studies that were generally underpowered. Population structure was widely considered to be the most significant reason. A powerful approach to this problem may be to characterise genetically both the cases and controls. Individuals from the controls can then be chosen to match the cases so as to minimise the stochastic differences between the two populations. Such a well-characterised control population would complement the current generation of WGAs. Importantly, the samples would be a resource that could be key to the search for rare variants that can be associated with disease susceptibility. We are assembling a UK control population as a resource for future studies. It will comprise 3,500 samples (3,200 collected so far), which will have been carefully selected from throughout the UK. Rural regions are targeted to avoid the admixture observed in large urban environments and volunteers are sought who were born in the same place as their parents and grandparents to ensure historical integrity. The collection will be genotyped for around 3,000 markers, with the aim of identifying about 200 ancestrally informative markers, which will then be used to match controls to cases. DNA from the samples will then be made available as a resource for future studies. An initial pilot project on about 400-500 samples, using a variety of markers, indicates that this approach is valid. MC1R data suggest structure differentiating the Celtic Fringe from Eastern England, whilst NRY data show evidence of Norse incursions into Orkney. Preliminary analyses of a larger pilot project, comprising about 700 samples and 400 markers, including HLA, provide further signals of population structure when all the samples are combined. There is also evidence of differentiation between some pairs of populations and simple admixture analyses suggest that there is an east-west gradient of Anglo-Saxon ancestry across England.

Genomic Landscapes of Pemetrexed Induced Cytotoxicity. *S. Duan[1], W. K. Bleibel[1], E. O. Kistner[2], R. S. Huang[1], S. M. Delaney[1], M. E. Dolan[1]* 1) Dept Medicine, Univ Chicago, Chicago, IL; 2) Dept Health Studies, Univ Chicago, Chicago, IL.

Pemetrexed is a novel antifolate for the treatment of mesothelioma and non-small cell lung cancer. The major toxicities of the pemetrexed-based therapy include neutropenia, leukopenia. Folate and vitamin B12 supplementation are administered clinically to reduce the side effect. In the present study, we performed a genomewide association study (GWAS) to reveal the genetic background of the pemetrexed-induced cytotoxicity using 90 human lymphoblastoid cell lines (LCLs) from the HapMap CEU population. Cell growth inhibition was evaluated following pemetrexed treatment for 72 h in media with/without additional folate-supplement. Six pemetrexed dosages (0.02, 0.1, 0.5, 1, 5 and 10 M) were evaluated in LCLs. The GWAS were performed between greater than 2 million HapMap SNPs and the area under the survival-dosage curves (AUC) after pemetrexed treatment with/without additional folate. Altogether 33 and 32 genomic regions with 87 and 87 SNPs were significantly associated with pemetrexed AUCs in the folate-supplemented and regular media, respectively (P 1×10^{-5}, FDR 0.22). Combined with the above genetic findings with the genomewide gene expression phenotypes, we identified 4 and 7 genomic regions with 23 and 25 SNPs as expression quantitative trait loci significantly associated with 22 and 21 gene expression phenotypes in the folate-supplemented and regular media, respectively (P 3.9×10^{-6}, corrected P 0.05). Significant associations between 8 SNPs and 11 gene expressions were found in both media. A general linear regression test showed 12 and 14 gene expression phenotypes significantly associated with the pemetrexed AUCs in the folate-supplemented and regular media, respectively (P 0.0012, corrected P 0.05). Multivariate linear regression analysis shows that a maximum of 68.9% and 68.6% of the overall variation for the cellular sensitivity to pemetrexed can be predicted by 6 and 8 SNPs in the folate-supplemented and regular media, respectively. The genomic landscapes of pemetrexed-induced cytotoxicity are presented through our stepwise triangular approach which can be applied in a wide range of genotype-phenotype-mapping studies.

Isolated generalized congenital anhidrosis maps to chromosome 12p11-p12. *J. Klar[1], M. Rasool[2], M. Tariq[2], A. Ali[2], I. Ahmad[2], S. M. Baig[2], N. Dahl[1]* 1) Dept Genetics & Pathology, Uppsala University, Uppsala, Sweden; 2) Health Biotechnology Division, National Institute for Biotechnology and Genetic Engineering NIBGE, Faisalabad, Pakistan.

Generalized anhidrosis (GA) is a congenital or acquired disease characterized by heat intolerance and loss of sweating, The condition is most often recognized in systemic diseases such as ectodermal dysplasia, diabetes mellitus or polyneuropathies. The pathogenesis may involve intrinsic sweat gland abnormalities or postgangliotic nerve dysfunction. Isolated congenital generalized anhidrosis (CGA) is very rare. We have identified and studied a consanguineous family of Pakistani origin with five members affected by isolated CGA. The patients suffer from severe heat intolerance without other ectodermal symptoms or any systemic disease. Skin biopsies from affected individuals revealed altered eccrine sweat gland morpholgy with absent excretory ducts and disorganized structure of secretory cells. Thermoregulatory test at 45C disclosed inability to downregulate body temperature in affected individuals when compared to controls. A genome wide autozygosity scan was initiated on the family using a 250K SNP array (Affymetrix). One large homozygous genomic region on chromosome 12p was found to be shared in all affected individuals. Microsatellite marker analysis confirmed linkage to 12p with a maximum two-point lod score of 3.42. The candidate region spans 5.8 Mb of DNA and DNA sequence analysis of candidate genes is in progress.

Molecular studies in patients with OTC deficiency. Does X-inactivation modify the genotype of heterozygtes? *L. Dvorakova[1], M. Hrebicek[1], L. Stolnaja[1], M. Bouckova[1], H. Treslova[1], H. Vlaskova[1], J. Minks[1], E. Hruba[1], O. Luksan[2], M. Jirsa[2]* 1) Inst Inherit Metabol Disorders, Charles Univ, 1st Sch Medicine, Prague 2, Czech Republic; 2) Lab. Exp. Hepatology, Inst.Clin and Exp. Medicine, Prague, Czech Republic.

Ornithine carbamoyltransferase deficiency (OTCD;OMIM 311250) is the most common inherited defect of the urea cycle. The clinical signs supported by biochemical results led to suspicion of OTCD in 28 Czech and Slovak patients, one patient came from Japan. The diagnosis was proved by mutation analysis in OTC gene (Xp21.1) in 21 patients. Five and ten male patients had neonatal and late onset form, respectively, six patients were heterozygous females. We have found 16 different mutations, 7 of them being novel. The novel mutations include c.1065AT abolishing the stop codon and c.867GA (p.K289K), which leads to a splicing defect (r.856_867del). Novel mutations p.A102P and p.S207N associated with neonatal form indicate biological importance of these amino acid residues. Among de novo mutations observed in 7 patients (4 males and 3 females), c.717+1GT (IVS7+1GT) and p.S340P were described earlier suggesting mutational hotspots in these loci. No causative mutation was found in other 4 male and 4 female patients. Haplotype analysis using intragenic polymorphisms did not support involvement of OTC gene in the family of one patient with intermitent ataxia, normal amino acids and positive allopurinol test. As liver samples of the female patients were not available, we studied X chromosome inactivation (HUMARA assay) in peripheral blood cells, urine and buccal cells of five manifesting heterozygotes and three asymptomatic carriers. X-inactivation was random in manifesting heterozygotes with null mutations and substantially skewed (75:25) in heterozygotes with missense mutations. Carriers with missense mutations and random X-inactivation were asymptomatic. Preliminary results from this small cohort of patients suggest that extreme skewing of X-inactivation is not necessary for manifestation of the OTCD phenotype in nonsense mutation carriers. Protective role of a *PER3* gene polymorphism in a model of transient insomnia. *S. N. Mitkus, G. Birznieks, A. Thompson, C. A. Czeisler, C. Lavedan* Vanda Pharmaceuticals Inc., Rockville, MD.

Insomnia is the most common sleep disorder, affecting approximately 60 million Americans. Although the genetic basis of insomnia is unclear, several sleep-regulating genes have been identified. A 4-5 repeat polymorphism in a molecular clock gene, *Period 3 (PER3),* has been associated with diurnal preference and delayed sleep-phase syndrome and is thought to influence sleep structure and waking performance. We analyzed the effect of this *PER3* polymorphism on several sleep parameters, evaluated by polysomnography in healthy individuals subjected to transient insomnia. Transient insomnia was induced in 76 subjects through a 5-hour phase advance protocol and a first night effect. *PER3* 5/5 individuals had significantly greater sleep efficiency over an 8-hour sleep episode compared with non-5/5 individuals (6.2 vs 5.3 hours, p=0.023). Rate of rapid eye movement (REM) sleep accumulation was faster in 5/5 than in non-5/5 individuals (5.8 vs. 3.7 hours to accumulate 30 minutes of REM, p=0.000055), but non-REM accumulation rates did not differ. *PER3* 5/5 individuals were significantly less disrupted by induced transient insomnia than the non-5/5 individuals, suggesting that the *PER3* 5-allele protects against symptoms of insomnia induced via circadian and stress-based challenges. These results support the hypothesis that genetic variations in clock-regulating genes such as *PER3* may contribute to susceptibility to insomnia. This finding may have important implications for understanding the potential selective advantage of the *PER3* 4-5 repeat polymorphism and its role in the pathophysiology of transient insomnia.

The Johns Hopkins Center for Hypotonia: New Multidisciplinary Clinic for Diagnosis and Support of Individuals with Hypotonia. *E. Lisi, R. Cohn* Inst Genetic Medicine, Johns Hopkins Univ, Baltimore, MD.

Hypotonia is defined as diminished tone of skeletal muscle in conjunction with decreased resistance of muscles to passive stretching. It is associated with over 500 disorders, though many hypotonic patients have no underlying diagnosis for their condition. The Johns Hopkins Center for Hypotonia was started in 2007 to focus on identifying, supporting, and treating patients with conditions associated with hypotonia. Through May, 2008 a total of 108 patients were seen during 24 clinic days with varying degrees of hypotonia with or without other anomalies. Most patients had seen several other physicians prior to their referral. Fourteen patients came with established diagnoses for multidisciplinary care. Of the remaining 79 patients, a total of 29 new diagnoses were made (31%), including chromosomal abnormalities, syndromic diagnoses such as Rett, Angelman Joubert, Cohen, Greig cephalopolysyndactyly, Bannayan-Riley-Ruvelcaba, and Madelung disease. In addition,we diagnosed several forms of muscular dystrophies, metabolic myopathies, mitochondrial and connective tissue disorders. We have also identified a cohort of nine patients with hypotonia, macrocephaly and variable degrees of developmental delay. We are currently in the process collecting more patients to elucidate the molecular basis for this association using SNP genotyping. In summary, the ultimate goal of our center is to combine clinical and basic science approaches to gain a deeper understanding of the causes and natural history of hypotonia. We hope to use these insights to develop novel therapeutic strategies to help the individual patient to achieve their maximum cognitive and physical performance.

Two intragenic NIPBL deletions and one contiguous gene syndrome detected by MLPA in CdLS patients. *S. Russo[1], C. Gervasini[2], M. Masciadri[1], P. Castronovo[2], D. Milani[3], A. Cereda[3], G. Zampino[4], A. Selicorni[3], L. Larizza[1,2]* 1) Molecular Genetics Institute Auxologico Italiano Milan Italy; 2) Medical Genetics San Paolo School of Medicine University of Milan Italy; 3) Pediatric Dep Fondazione Ospedale Maggiore Policlinico Mangiagalli Regina Elena Milan Italy; 4) Department of Pediatrics Cattolica University Rome.

Cornelia de Lange syndrome (CdLS) is a rare, multiple congenital anomaly/mental retardation disease, characterized by facial dysmorphisms, growth deficiency, psychomotor delay and malformations of the upper limbs. About half of CdLS patients are mutated in the NIPBL gene (5p13.2) encoding for a member of the adherins family, involved in the processes of chromatid cohesion and enhancer-promoter communication. Mutations in the SMC1L1 and SMC3 genes (two subunits of the cohesin complex) responsible for an X-linked and another autosomal form respectively are thought to contribute to up 5% of all CdLS cases. We screened for NIPBL and SMC1L1 mutations the first Italian cohort of CdLS patients which has been evaluated by the recently approved diagnostic system and a global score (Selicorni et al. 2007). By this analysis besides detecting NIPBL and SMC1L1 mutations we sorted out a platform of CdLS patients to be further screened by other approaches. Here we report on a refinement of NIPBL mutation scan by MLPA kit. Analysis of 50 pts allowed us to detect three partial deletions of NIPBL gene: two encompassing exon 2 and exon32, and the third affecting exons 1-10. Segregation analysis by DNA polymorphic markers showed that the latter deletion also involves sequences upstream NIPBL. By refined FISH characterization the deletion turned out to extend 2Mb from AGXT2 gene to NIPBL IVS10. It includes 14 genes apart NIPBL, thus featuring a contiguous gene syndrome associated with an extremely severe phenotype of the patient. A mild phenotype was observed in the pt carrying exon 2 deletion and a severe clinical presentation is present in pt carrying exon 32 deletion. Application of MLPA to CdLS pts found negative to standard mutation screening is an adjunct tool to disclose full NIPBL mutation spectrum and address genotype-phenotype correlations.

NRAMP1 Polymorphisms and Susceptibility to Tuberculosis in Turkish Population. *A. Y. EKMEKCI[1], F. Ozkinay[1], H. Onay[1], F. Bacakoglu[1], A. Sayiner[1], S. Z. Guclu[2], S. Pehlivan[3], O. Cogulu[1], A. Aykut[1], C. Gunduz[1], C. Ozkinay[1]* 1) Ege University, Faculty of Medicine, Turkey; 2) Suat Seren Chest Diseases and Thoracic Surgery Training Hospital, Turkey; 3) Gaziantep University, Faculty Of Medicine, Turkey.

Tuberculosis(TB) is the most common mycobacterial disease that is caused by Mycobacterium tuberculosis (M. tuberculosis). Twin studies in different ethnic populations have suggested that host genetic factors are as effective as environmental factors in susceptibility to tuberculosis disease. NRAMP1 protein localises on macrophage membrane and regulates macrophage functions against M. tuberculosis and other intracellular microorganisms. In NRAMP1 gene, $5(CA)_n$ is a functional repeat polymorphism and controls the NRAMP1 expression in a luciferase reporter system. INT4 (469+14G C) polymorphism is a single base change in intron 4. 3UTR (1729+55del4) polymorphism is 4 bp deletion in the 3untranslated region and D543N polymorphism is a G to A base change in exon 15. In our study we aimed to investigate the association between the four polymorphisms and compound genotype frequencies of those polymorphisms of the NRAMP1 gene, and susceptibility to TB including clinical severity of disease in different age groups. Four hundred and seventy two HIV negative Turkish TB patients (340 males, 132 females) and 571 age-matched healthy controls(432 males, 139 females) were included in the study. Mean ages of the patient and control groups were 39,21 18.597, 36,48 13,963 respectively. All TB patients were divided subgroups as pediatric TB patients who were younger than 18 years of age and as adult TB patients who were older than 18 years of age (n: 57, n:415, respectively). Our results indicate that none of the NRAMP1 polymorphisms investigated are associated with the disease susceptibility but they might effect the age of onset, clinical variations and the progression of the disease.

Association of *IL2/IL21* variants with ulcerative colitis. *E. A. M. Festen[1,2], A. Zhernakova[3], C. Wijmenga[1,3], R. K. Weersma[2]* 1) Genetics, University Medical Center Groningen, University of Groningen, Groningen, the Netherlands; 2) Gastroenterology and Hepatology, University Medical Center Groningen, Groningen, the Netherlands; 3) Medical Genetics, University Medical Center Utrecht, Utrecht, the Netherlands.

Both celiac disease and inflammatory bowel diseases (IBD) are characterized by inflammation of the intestinal mucosa and dysregulation of the immune system. IBD consists of ulcerative colitis (UC) and Crohns disease (CD). Previous studies have identified shared susceptibility genes for both IBD and celiac disease. Genetic variants in a region harbouring *IL2* and *IL21* have been found to be associated with celiac disease susceptibility in a genomewide association study performed by van Heel et al (Nat Genetics 2007;39:827-9). *IL2-/-* mice develop a disease that strongly resembles UC. Furthermore IL21 has been proven to be produced in excess in the inflamed mucosa of IBD patients. We hypothesized that the *IL2/IL21* region is a shared susceptibility gene region for both IBD and celiac disease and performed a case-control study to look for an association between variants in *IL2/IL21* with IBD. The study population consisted of 518 Dutch IBD patients (311 CD and 207 UC) and 1422 healthy UK controls. We analyzed the strongest celiac disease associated SNPs, namely rs6822844, rs13151961 and rs6840978, by Taqman genotyping. SNP rs13151961 showed a protective effect of allele G with UC (p = 0.035) with an OR of 0.73 (CI 1,02 to 1,86). Allele T of rs6822844 was also found to have a protective effect for UC (p = 0.033) with an OR of 0.72 (CI 1.03 to 1.88). Allele C of rs6840978 was found more frequently in UC patients (82.5%) compared to normal controls (78.1%), although this association was not significant. None of the SNPs tested showed any association with CD. CONCLUSIONS: We have shown that genetic variants in the *IL2/IL21* region are associated with UC. We found a protective effect for UC of allele G of rs13151961 and a protective effect for UC of allele T of rs6822844. These findings confirm that *IL2/IL21* is a susceptibility gene for both celiac disease and UC and suggests a shared common pathogenesis for these diseases.

Familial clustering of superior orbicularis oris muscle defects in families with cleft lip and cleft palate. *C. M. Klotz, M. E. Cooper, T. McHenry, K. Neiswanger, M. L. Marazita* Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA.

Cleft lip (CL) with or without cleft palate (CP) is common, with average birth prevalence of 1 per 1000 live births. CL/P phenotypes range from overt clefts to minimal microforms. Occult defects of the orbicularis oris (OO) muscle appear to be part of this spectrum (Neiswanger et al, 2007). The purpose of the current study is to investigate familial clustering of OO defects in families with a history of CL versus CP. Breaks in the continuity of the OO muscle visualized on ultrasound were scored as affected. All participants were placed into one of five family groups: CL = all affecteds in the family have CL only; CP = all have CP only, CLP = all have CL+CP; CL/CLP = at least one affected has CL and at least one has CL+CP, CP/CLP = at least one has CP and at least one has CL or CL+CP. Two larger groups were also assigned: a cleft lip group, including CL, CLP, and CL/CLP, and a cleft palate group, including CP and CP/CLP. 1101 unaffected family members were included in these analyses, of whom 76 (6.9%) had OO defects. By family group: CL - 6/106 (5.7%), CP - 0/27 (0.0%), CLP - 41/501 (8.2%), CL/CLP - 26/407 (6.4%) and CP/ CLP - 3/60 (5.0%). Fishers exact tests comparing the percent OO defects across all groups resulted in a p-value of 0.51. Similarly, the cleft lip group (73/1014, 7.2%) compared to the cleft palate group (3/87, 3.4%), resulted in a p-value of 0.27. Notably, there is an increase in OO defects seen in the unaffected relatives from cleft lip families versus cleft palate families. However, the difference is not statistically significant and will require larger sample sizes to investigate further. If the difference is confirmed, there will be implications for recurrence risk estimation in families with different cleft types. NIH grants: R01-DE016148, R21-DE016930, P50-DE016215, R37-DE08559.

SLC30A8 Variant Is Associated With Muscle Size and Response To Resistance Training. *F. Orkunoglu-Suer[1], J. M. Devaney[1], R. Patel[2], K. Adham[2], J. Larkin[2], H. Gordish-Dressman[1], C. C. Brandoli[1], L. L. Tosi[1], E. P. Hoffman[1], FAMUSS study group* 1) Res Ctr Gen Med, Children's Nat Med Ctr, Washington, DC; 2) George Washington University School of Medicine, Washington DC.

Objective: SLC30A8 encodes the protein zinc transporter-8 (ZnT8), which is expressed mainly in the islets of Langerhans of the pancreas. Zinc deficiencies and transport problems have been associated with Type II diabetes. Exercise improves glucose metabolism and has been demonstrated to help reduce the negative impact of these disorders. We hypothesized that the single nucleotide polymorphism (SNP) rs13266634 (C37447T; R325W) of the SLC30A8 gene would be associated with an individuals measures of physical fitness and response to exercise. Methods: Healthy young adults (n = 626) enrolled in the FAMUSS study were placed on a scheduled resistance-training program for 12 wks. Baseline and post training measurements of muscle volume, subcutaneous fat volume, baseline strength as measured by one-repetition max (1RM) and triglyceride levels were ascertained. DNA samples were genotyped using Taqman assays. A semi-automated MRI analysis tool, RAPIDIA, was used to calculate humeral muscle volume before and after training. Analysis of covariance (ANOVA) was used to identify statistically significant differences in measures of muscle and fat volume, strength, and triglyceride levels among genotypes.Results: Female participants (n = 323) with two copies of the T allele were more likely to gain muscle volume ($p = 0.03$) and lose fat ($p = 0.003$) following the resistance-training program. Males (n = 303) with two copies of the T allele had higher 1RM strength ($p = 0.04$), higher baseline whole muscle volume ($p = 0.002$) and higher triglyceride values ($p = 0.006$).Conclusions: The T allele of rs13266634 is associated with greater muscle hypertrophy in response to exercise training in females and increased baseline strength/muscle volume in males. Our results suggest that this SNP may play a protective role against type II diabetes.

Chromosome 5q14.3-q21 deletion in a patient with overlapping features of Oculo-Oto-Dental Syndrome. *M. F. Walsh[1], N. L. Sobreira[1], E. Lisi[1], D. A. S. Batista[2,3], T. Wang[1]* 1) Institute of Genetic Medicine; 2) Pathology Department, Johns Hopkins University; 3) Kennedy Krieger Institute, Baltimore MD.

The association of bilateral high-frequency sensorineural hearing loss, dental anomalies, and iris coloboma was described previously in one British family as oculo-oto-dental syndrome (OOD). Autosomal dominant inheritance with variable expressivity was implicated. A 12-cM critical region for OOD was initially identified at 20q13.1 by linkage study (Vieira et al., 2002). A recent genome-wide scan in this family and two others with otodental syndrome (OD, MIM166750) identified a shared 43 kb deletion involving FGF3 at 11q13 in all three and a larger deletion involving FADD in the family with OOD (Gregory-Evans et al, 2007). Here we describe an eleven-year old male with bilateral iris coloboma with small optic nerves, duplicate rows of frontal incisors, and high frequency hearing loss. Additional features include brachydactyly, a shawl scrotum, moderate intellectual disability, attention deficit disorder, aggressive and stereotyped behaviors. Family history was negative. Consanguinity and prenatal exposure were denied. CT and ultrasound studies revealed normal ossicles in the middle ear and renal structure. A high-resolution karyotype and BAC-microarray CGH with 4200 clones (BlueGnome) identified a genomic deletion 5q14.3-q21.1 that was confirmed by FISH. The size of the deletion estimated from the array CGH is between 7.3 to 8.9 Mb including 23 annotated genes. None of these genes is known to cause hearing loss, dental or iris anomaly. Outside this deletion on 5q, there are 26 genes related with hearing loss, one with iris coloboma, and one with supernumerary teeth. Clinical phenotype in this patient overlaps with key features of OOD syndrome but also includes other malformations, intellectual disability, and behavioral issues. This may represent a contiguous gene syndrome suggesting locus heterogeneity for OOD-like phenotype. Study of the breakpoint and expression profile of genes that may be affected will help to understand genetic basis for OOD-like phenotype and identify novel genes that are important to normal hearing, ocular, and dental development in humans.

Genome-wide scan identified a copy number variation in VPS13B associated with bone strength. *L. Zhao[1], T. B. Jin[2], Y. F. Pei[3], X. G. Liu[3], B. Y. Sha[1,4], Y. Z. Liu[2], Y. J. Liu[2], R. R. Recker[1], H. W. Deng[2,3,4]* 1) Osteoporosis Res Ctr, Creighton Univ Med Ctr, Omaha, NE; 2) School of Medicine, University of Missouri - Kansas City, Kansas City, MO; 3) Xi'an Jiaotong University, Xi'an, P.R.China; 4) Hunan Normal University, Hunan, P R China.

Background: DNA copy number variation (CNV) is a rich and important source of genetic diversity for human diseases. Hip fracture is a severe and common injury in the elderly. The major risk factor of hip fracture is reduced femoral bone strength, which is under strong genetic control and the genetic factors are largely unknown. Materials and Methods: We conducted a genome-wide CNV analyses for femoral neck bone strength in 985 unrelated subjects using Affymetrix 500K array set. Femoral neck bone mineral density (BMD) was measured by dual energy X-ray absorptiometry (DXA). Femoral neck cortical thickness (CT), cross-sectional area (CSA), and buckling ratio-an index for bone structural stability, were estimated using DXA-derived femoral neck BMD and bone area. Results: A CNV located in the VPS13B (vacuolar protein sorting 13 homolog B (yeast)) gene is significantly associated with femoral neck BMD (P= 0.0001), CT (P=0.0001), BR (P=0.017), and CSA (P=0.003) in the whole sample. The association results for femoral neck BMD and CT remain significant even after conservative Bonferroni correction (P=0.026 for femoral neck BMD and P=0.027 for CT). Significant results (P<0.05) are also found for all the bone strength phenotypes in both male and female subgroups. We further compared raw bone strength values between subjects with one copy number and two copy numbers of the CNV. Comparing to the normal subjects, those with one copy of the CNV have higher femoral neck BMD (P = 0.003), higher CT (P = 0.004), lower BR (P = 0.02), and higher CSA (P = 0.05), which consistently leads to good bone strength. Conclusions: This is the first report of a genome-wide CNV association for femoral bone strength. Our results suggest that VPS13B gene is important for femoral bone strength.

Analysis of telomeres in peripheral blood mononuclear cells from patients with Diamond-Blackfan Anemia. *I. Dianzani[1], E. Pavesi[1], F. Avondo[1], A. Aspesi[1], E. Garelli[2], P. Quarello[2], F. Campagnoli[2], A. Carando[2], C. Dufour[3], U. Ramenghi[1]* 1) Dept Med Sci, Univ Piemonte Orientale, Novara, Italy; 2) Hematology Unit, Dpt.Pediatrics, Univ.Torino; 3) G. Gaslini Childrens Hospital, Genova.

Diamond Blackfan Anemia (DBA, MIM 105650) is an autosomal dominant erythroid hypoplasia in which erythroid progenitors do not differentiate efficiently and are susceptible to apoptosis. All known genes mutated in DBA encode proteins of the 40S and 60S ribosomal subunits. Since RPS19, mutated in 25% of DBA patients, is required for the maturation of the 40S ribosomal subunit, the erythroid hypoplasia observed in DBA may be the result of a defect in ribosome biogenesis. However, an explanation for the tissue specific clinical manifestations is still elusive. Other hypotheses suggest that DBA may be due to loss of an alternative function of the mutated RP. In a proteomic study, we identified 159 proteins associated with RPS19 in a pull-down assay. Included among this group were components of the H/ACA small nucleolar Ribonucleoprotein Particles (H/ACA snoRNP) complex: dyskerin, NOLA1 and NOLA3. This complex, which also includes NOLA2 and specific H/ACA RNAs, is required for three basic cellular functions, ribosome biogenesis, pre-mRNA splicing and telomere maintenance. Several components of this complex have been identified as mutated in another bone marrow failure syndrome, dyskeratosis congenita (DC). It appears that the defect in telomere maintenance is primarily responsible for the clinical features of DC. Our study linked RPS19 to another possible function implicated in bone marrow failure. To ascertain whether a defect in telomere maintenance was present in DBA patient cells, we have evaluated telomere length in DNA obtained from peripheral blood mononuclear cells of 46 DBA patients (16 mutated in RPS19) and 93 age-matched controls using a real-time quantitative PCR method [Cawthon Nucl Acids Res 2002]. Only one patient showed a defect in telomere length and may be affected by an atypical form of DC. Our data agree with the study of Alter et al. [Blood 2007], performed on 14 DBA patients not characterised for mutations. Telomere maintenance does not seem involved in the pathogenesis of DBA.

The Allelic Architecture of Common Diseases and Its Consequences. *C. C. A. Spencer, E. Hechter, P. Donnelly* The Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Road, Oxford, OX3 7BN.

Genome-wide association studies have been extremely successful in finding loci associated with common complex human diseases. Where only a handful of such loci had been reliably established a few years ago, there are now around 100 across more than 20 diseases. For the first time we are beginning to gain real insights into the allelic architecture of common diseases. However our view is currently distorted and incomplete: for the majority of diseases there remain many more loci to be found and, of those loci already identified, we are yet to pinpoint the causal variants. In most cases, when we see a signal in an association study it will arise at SNPs which are different from, but correlated with, true causal variants. Effect sizes estimated at the SNPs discovered from association studies will thus tend to be smaller than the true effect sizes. We study this issue, and show that true effect sizes could be substantially larger than those being reported. We describe a Bayesian approach to assess probabilistically the true distribution of genetic effects for common diseases. Our results have important implications for fine-mapping, future study design and choice of genotyping chip and for assessments of genetic risk in a population context.

Efficiency of CGH-Array in detecting chromosomal mosaicism: a case of Tetrasomy 12p. *N. Marle[1], P. Callier[1], AL. Mosca[1], C. Thauvin[2], A. Masurel[2], N. Madinier[3], C. Bonnet[4], L. Faivre[2], F. Mugneret[1]* 1) Laboratoire de Cytogénétique, CHU Le Bocage, Dijon, France; 2) Département de Génétique Clinique, Hôpital dEnfant, Dijon, France; 3) Clinique Sainte-Marthe, Dijon, France; 4) Unité de Cardiologie Pédiatrique, Hôpital dEnfants, CHU Dijon, France.

Array-CGH provides a higher level of genomic analysis over the standard chromosome analysis. Therefore, it has become a powerful tool in the screening of patients presenting with idiopathic mental retardation. Less expected is the ability of array-CGH to detect low-level chromosomal mosaicism in peripheral blood, as mosaicism for a supernumerary metacentric isochromosome 12p resulting in Pallister-Killian syndrome. Here we report on the first child of healthy non consanguineous parents. He was born at 36 weeks of gestation, after a normal pregnancy. Birth weight, length and head circumference were respectively 3440 g, 46 cm and 33.5 cm. Clinical examination revealed a short forehead, short webbed neck, short ears, fissures of the auricular lobes and multiple pits, unique palmar crease, micropenis and umbilical hernia. Renal and cardiac ultrasound showed enlarged kidneys and atrial septal defect, cerebral MRI revealed partial agenesis of corpus callosum. At last Postnatal cytogenetic analysis on peripheral lymphocytes with RHG and GTG banding revealed a 46,XY chromosome pattern. BAC-array (Integragen, 4898 clones) was performed on DNA extracted from peripheral blood sample. It showed a gain of the entire short arm of chromosome 12. FISH analysis with CEP12 probe on peripheral blood culture was normal in 200 cells examined. Chromosome analysis on culture fibroblasts from a skin biopsy showed a 47,XY,+i(12)(p10)[24]/46,XY[1] karyotype. FISH analysis with CEP12 probe revealed a 90% mosaic 12p tetrasomy on culture fibroblasts and a 1% mosaic 12p tetrasomy on a second peripheral blood sample. As expected, parental karyotypes were normal. Here we report the third case of Pallister-Killian (second case resulting from a supernumerary isochromosome 12p) identified using array-CGH. Based on published data, we discuss the usefulness of array-CGH in the detection of low-level chromosomal mosaicism.

Mutation analysis of the *CREBBP* gene in a cohort of Rubinstein-Taybi syndrome patients. *M. Losekoot[1], C. A. C. van der Lans[1], D. J. M. Peters[2], M. J. van Belzen[1]* 1) Clinical Genetics, Laboratory for Diagnostic Genome Analysis (LDGA), Leiden University Medical Center, Leiden, The Netherlands; 2) Human Genetics, Leiden University Medical Center, Leiden, The Netherlands.

Rubinstein-Taybi syndrome (RSTS) is a rare disorder affecting approximately 1/100,000 newborns. The syndrome is characterized by mental and growth retardation and a particular dysmorphology mainly concerning the face, hands and feet. The most frequent cause of RSTS are mutations in the *CREBBP* gene, which are found in 30-50% of patients. Furthermore, microdeletions involving the *CREBBP* gene have been found in ~10% of patients and a further 1-3% can be explained by mutations in *EP300*. Mutations in *CREBBP* are primarily nonsense, frameshift and splice site mutations that occur over the entire coding region, although also several pathogenic missense mutations have been identified. These are predominantly located in the conserved, functional regions of the gene. We tested a cohort of 30 patients suspected of having RSTS for mutations in the *CREBBP* gene and detected 11 pathogenic mutations (37%). In addition, 8 variants of unknown clinical significance were found, of which 3 are likely to be pathogenic, leading to an overall mutation detection rate of ~42%. Therefore, sequence analysis of *CREBBP* is an important part in the diagnostics of RSTS. Mutation analysis by direct sequencing of the entire coding region of *CREBBP* is now available as a diagnostic service at the LDGA laboratory. This service is available both in and outside the Netherlands (see also our website www.lumc.nl/4080/). Recently, MLPA analysis of all exons of the *CREBBP* gene has been added to our diagnostic package for RSTS (data not available yet).

Genome-wide mapping of protein microarray-generated pollen allergy phenotypes in a founder population. *K. Vigh[1], D. Preuss[2], C. Ober[1]* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept Molecular Genetics and Cell Biology, Univ Chicago, IL.

Mapping genes for complex diseases, such as allergy, that are influenced by many genes and strong environmental factors remains challenging. The increasing accessibility of high-resolution genotyping has aided these studies. However high-resolution phenotyping, which is also integral to successful genetic mapping, is still an obstacle for many traits. Here, we studied quantitative, intermediate allergy phenotypes in the Hutterites, a young founder population who live a communal lifestyle. We developed a protein microarray to measure allergen-specific IgE (AS-IgE) to a multitude of allergens, and screened serum from 564 Hutterites. We estimated the heritability of 38 traits (AS-IgE to 38 allergens) and found that 18 were significantly heritable with narrow heritabilities (h^2) ranging from 0.18-0.41 and broad heritabilities (H^2) ranging from 0.46-0.71. AS-IgE to groups of allergens, such as all grasses ($p=5.96x10^{-6}$), all trees ($p=6.07x10^{-5}$), and all pollens ($p=5.11x10^{-6}$) were the most heritable phenotypes. We, therefore, performed genome-wide linkage and association mapping with these 3 traits and 1520 markers comprising microsatellites and SNPs. Significant linkage was seen for all 3 traits in a region on chromosome 22q11 that contains several genes, including the *XKR3*, *IL17RA*, and *CERCR-1*, *-5*, *-6* (minimum $p=1.47x10^{-5}$; genome-wide p=0.007 determined by 1000 permutations). Evidence of suggestive linkage for all 3 traits was observed on chromosome 9p21 with a SNP in the single exon of the class I interferon (*IFNB*) (minimum $p=4.68x10^{-4}$) and with two microsatellites (minimum $p=3.09x10^{-4}$) flanking the *PLAA* and *TEK* genes. Association mapping showed that AS-IgE to all trees (locus $p=1.11x10^{-7}$; genome-wide $p<0.001$) and all pollens (locus $p=2.44x10^{-6}$; genome-wide p=0.004) was associated with a SNP in the *EIF2AK2* gene on chromosome 2p22, which is induced by class I interferons. These results indicate that variation in genes on chromosomes 2p22, 9p21, and 22q11 contribute to multiple allergy phenotypes assayed by our array, with possible interaction between some of the genes.

Analysis of Tetrahydrobiopterin Associated Genes in Autism. *N. Schnetz-Boutaud[1], K. Brown[1], K. Gainer-Luci[1], M. L. Cuccaro[2], J. R. Gilbert[2], H. H. Wright[3], R. K. Abramson[3], M. A. Pericak-Vance[2], J. L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt Univ. Medical Center, Nashville, TN; 2) Miami Institute for Human Genomics, Univ. Miami, Miami, Fl; 3) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Autism, Aspergers Syndrome, and Pervasive Developmental Disorders (PDD-NOS) are all classified as Autism Spectrum Disorders (ASDs). ASDs are neurodevelopmental and neurobehavioral disorders with an onset early in childhood and a preponderance of affected males (~4:1). The ASDs are characterized by social communication impairments and the presence of repetitive and stereotypic behaviors. ASDs have a strong genetic component, suggested by numerous different measures including the high concordance rates for MZ twins (60%-90%) compared to DZ twins (0%-10%). However, the genetic architecture of ASDs has so far eluded explanation. Disturbances in the dopamine and serotonin pathways have been consistently reported in ASDs; genetic analyses of many of the genes underlying these pathways have not yielded strong associations with ASDs. Tetrahydrobiopterin (BH4) is the essential cofactor in the synthesis of both dopamine and serotonin. We therefore genotyped 25 SNPs in 9 genes (SPR, QDPR, PCBD1, PTS, GCH1, GCHFR, PAH, TH, and TPH2) of the BH4 pathway in a total of 403 families. The most significant result was in the PTS (6-@pyruvoyltetrahydropterin synthase) gene on chromosome 11q22 (p=0.003, pedigree disequilibrium test), but this did not survive correction for multiple comparisons (p=0.07). Examining the male only subset (n=303), or testing for 2- or 3-way interactions did not reveal any further association. We thus conclude that variations in genes related to tetrahydrobiopterin are not strong risk factors for autism.

Profiles of structural variantion between ethnic groups in human populations. *L. Bassaganyas[1,2], M. García-Aragones[1], M. Montfort[2], G. Escaramís[2], M. Cáceres[1], L. Armengol[1,2], X. Estivill[1,2,3]* 1) Genes and Disease Program, Center for Genomic Regulation; 2) Public Health and Epidemiology Network Biomedical Research Center (CIBERESP); 3) Pompeu Fabra University, Barcelona.

Genetic variation contributes to common phenotypic differences between individuals, populations and species. It is also a key element for disease predisposition and is an evident potential substrate for natural selection. Recently, the use of genome-wide molecular methods such as array-based comparative genome hybridization (aCGH) and comparative genome intensities (aCGI), have revealed the existence of an unexpected amount of copy number variants (CNVs), genomic segments ranging in size from one kilobase to several megabases present at variable copy number in comparison with a reference genome. The aims of our study were to determine the existence of population-specific genomic copy number variation and to identify genes located in these regions that might contribute to phenotypic differences, as well as to differential susceptibility to common disease and environmental exposures of human populations. We have selected 343 individuals from eleven human populations of diverse geographic ancestry from the Human Genome Diversity Panel and 86 individuals from two populations of the HapMap collection. To detect population-specific CNVs we have used aCGH (H244K Agilent) and have identified a total of 199 loci that fulfilled our inclusion criteria. 124 of these regions were already described in the Database of Genomic Variants, and 153 genes were totally or partially overlapping the identified loci. Interestingly, in this set there is a significant enrichment of genes involved in neurophysiological functions, metabolic activity, immune response and sensory perception, and mainly, encode for membrane proteins. We propose that the CNVs detected in this study could explain, at least in part, differences in disease predisposition among individuals from different populations and could provide important clues on the recent adaptation of humans to different environments.

An apparent paradox of prevalence of Metabolic Syndrome by different definitions and its reconciliation. *B. M. Chakraborty, S. M. Pinney, W. Niu, R. Chakraborty* Dept Environmental Health, Univ Cincinnati Col Medicine, Cincinnati, OH.

Abdominal obesity, high blood pressure, high blood sugar, high triglycerides, and low high density lipoprotein often occur together in individuals throughout the world. Joint occurrence of several of these conditions is known as the Metabolic Syndrome (MS). Since the components of MS are risk factors of cardiovascular diseases, diabetes, and hypertension, MS has been studied in relation to morbidity/mortality of these diseases. Several definitions of MS have been suggested which vary by the components that must be included in MS and their cut-off values. Consequently, prevalence of MS by different definitions is not readily comparable, making inter-study comparisons difficult. We studied differences of prevalence of MS by two definitions (ATPIII, suggested by the NIH National Cholesterol Education Program Panel of 2001; and IDF, prescribed by the International Diabetes Federation in 2003) in a cohort of the Fernald Medical Monitoring Program (FMMP) of Ohio, USA. From physical examination data of 2005-2006 on 2,985 Caucasian subjects (1,232 men and 1,753 women) of age 30 to 94 years, we estimated crude, age-specific and age-adjusted rates of MS by both ATPIII and IDF criteria. While a substantial proportion of individuals in this cohort has MS by both definitions (30.5% of total, 33.8% of men, and 28.2% of women), in both genders the IDF-definition yields a higher prevalence compared with that by ATPIII (48.1% vs. 36.1% in men, and 36.7% vs. 28.2% in women) due to the more inclusive criteria of abdominal obesity and glucose abnormality in the IDF-definition. Apparent paradox arises in the observation that a small but significant number of individuals (1.4% of total, 2.4% of men and 0.7% of women) have MS by the ATPIII criteria, but not by that of IDF. The IDF requirement that all MS must have abdominal obesity (with 2 or more of the other components), but by ATPIII any 3 or more defines MS explains this observation. With increasing trend of MS by age, the gender difference (MS more prevalent in men than women) and increased rate of MS by IDF holds true for age-specific and age-adjusted rates.

The neuronal nitric oxide synthase gene (*NOS1*) contributes to increased risk of stroke. *H. Manso[1,2], T. Krug[1,3], J. Sobral[1,2], B. V. Fonseca[1,3], I. Albergaria[2], G. Gaspar[2], J. M. Ferro[3], S. A. Oliveira[1,3], A. M. Vicente[1,2], PORTuguese Stroke GENetics (PORTSGEN) Group* 1) Inst Gulbenkian de Ciencia, Oeiras, Portugal; 2) Inst Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal; 3) Inst Medicina Molecular, Lisboa, Portugal.

Stroke is a complex disease resulting from the interplay between genetic and well-established environmental risk factors. Despite the existence of drugs that control the latter, it has not been possible to reduce the incidence of stroke in developed countries, reinforcing the importance of genetics in stroke risk. Several lines of evidence suggest that carotid atherosclerosis may contribute to ischemic stroke risk, as atherosclerotic plaques are vulnerable to mechanical fissure, leading to thrombus formation and stroke. Nitric oxide (NO) is known to have several vasoprotective or anti-atherosclerotic properties. This, together with the finding that the neuronal nitric oxide synthase (nNOS/NOS1) protein and mRNA are detected in early and advanced atherosclerotic lesions but not in normal tissue, suggests that the *NOS1* may contribute to stroke risk. 31 *tag* SNPs covering genetic variation in coding and flanking regions of *NOS1* were tested for association with stroke risk in a Portuguese sample of 566 ischemic patients and 530 controls. Logistic regression analysis was carried out to adjust for significant stroke risk factors age, sex, smoking, hypertension and diabetes. 11 *NOS1* SNPs were associated with stroke risk (0.0003*P*0.0483); 2 SNPs remained significant after Bonferroni correction for multiple testing. In addition, 10 haplotypes containing at least one of the associated SNPs, and 3 other haplotypes were associated with stroke (0.0007*P*0.0483). Given the well documented neuroprotective properties of nNOS after stroke, we tested *NOS1* SNPs for association with stroke functional recovery, assessed using the modified Rankin Scale (mRS) at 3 months in 430 ischemic stroke patients (good recovery: mRS1), adjusting for clinical severity parameters. No significant association was found with stroke recovery. These results indicate that *NOS1* gene variants influence the risk of ischemic stroke, but not functional recovery.

A graphical model approach for inferring large-scale networks integrating gene expression and genetic polymorphism. *J. Chu, S. T. Weiss, V. J. Carey, B. A. Raby* Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Graphical models (e.g. Bayesian networks) have been used frequently to describe complex interaction patterns and dependent structures among genes and other phenotypes. Estimation of such networks has been a challenging problem when the genes considered greatly outnumber the samples, and the situation is exacerbated when one wishes to consider the impact of polymorphisms in genes. Here we describe a multi-step approach to infer a gene-SNP network from gene expression and genotyped SNP data. Our approach is based on 1) identification of candidate genes from previous integrative genomic analysis. 2) construction of a graphical Gaussian model (GGM) based on estimation of partial correlations among all genes and FDR multiple testing. 3) extraction of a sub-network of genes directly linked to the candidate genes based on the GGM in step 2. 4) Cis-association SNPs within 200Kb of the genes in the sub-network added to complete the network. We demonstrate the method by building a complex gene-SNP network around Interleukin 1B (IL1B) -- a biologic candidate in asthma pathogenesis. The model was built using 534,290 genotyped SNPs (Illumina Infinium 550K array) and gene expression data on 22,177 genes from total RNA derived from peripheral blood CD4+ lymphocytes in 154 asthmatics. Significant gene-gene and gene-SNP associations have been identified based not just on their co-expression but through whole network modeling. Specifically, GGM identified 271 genes demonstrating direct association with IL1B (posterior probability >0.5). The model revealed evidence of cis-acting genetic variants for 26 of these genes that also manifested evidence of trans-effects on IL1B gene expression, including Interferon Regulatory Factor 5 and Complement 3a Receptor 1. The preliminary results from our methods suggest that graphical models based on integrative genomic data are computationally efficient, work well with small sample size, and can describe complex interactions among genes and polymorphisms that could not be identified by pair-wise association tests. Supported by: P01HL083069 and R01HL086601.

Inference of human demographic parameters using haplotype patterns from genome-wide SNP data. *K. E. Lohmueller[1,2], A. Auton[2], C. D. Bustamante[2], A. G. Clark[1]* 1) Dept Mol Biol and Genetics, Cornell Univ, Ithaca, NY; 2) Dept Biol Stats and Comp Biol, Cornell Univ, Ithaca, NY.

Accurate inference of human demographic history from genetic data is essential for identification of single nucleotide polymorphism (SNP) association with disease and for inference of natural selection. Haplotype diversity and haplotype sharing carry additional demographic information to that obtainable from SNP frequency spectra, and so we propose a novel method using haplotype summary statistics to fit demographic models to genome-wide SNP data. We divide the genome into 0.25 cM windows and for each we tabulate the number of distinct haplotypes and the frequency of the most common haplotype. We summarize the data by the genome-wide joint distribution of these two statistics. Coalescent simulations are then used to evaluate whether different demographic models are compatible with the observed data. Application of our method to simulated data shows that our method can reliably infer parameters from complex demographic models (such as bottlenecks) and is relatively robust to the levels of SNP ascertainment bias found in many genome-wide datasets. We have applied our method to data collected by the International HapMap Consortium and find that a bottleneck model best fits the CEU population. We have also analyzed a large dataset consisting of Affymetrix 500k data from ~2,900 individuals with ancestry from Taiwan, Japan, India, Mexico and many European countries. Since this dataset includes ~2,300 European individuals, we are able to study haplotype patterns at a fine scale within Europe. Interestingly, we find that within Europe there is a south-to-north gradient with decreasing levels of haplotype diversity moving north, consistent with south to north migrations. We also find that the southwestern European sample has higher haplotype diversity than the southeastern European sample. Additionally, a higher proportion of haplotypes are shared between the southwestern European sample and the Yoruba sample than between southeastern European sample and the Yoruba sample. These two patterns are consistent with recent admixture across the Mediterranean from Northern Africa.

Managing incidental results of newborn screening: Health care provider reasoning about disclosure. *J. Allanson[1], F. Miller[2], R. Hayeems[2], J. Bytautas[2], J. Carroll[3], P. Chakraborty[1], R. Christensen[2], M. Paynter[2], J. Little[4], B. Wilson[4]*
1) Dept Genetics, Children's Hospital Eastern Ontario, Ottawa, ON; 2) Dept Health Policy, Management & Evaluation, University of Toronto, ON; 3) Dept Family & Community Medicine, Mount Sinai Hospital, Toronto, ON; 4) Dept Epidemiology & Community Medicine, University of Ottawa, ON.

Background: Attention to incidental results generated through newborn screening (NBS) is essential in an era of expanded technologic capacity (Bailey, 2008). The views of stakeholders are relevant to decisions about managing incidental results (e.g., carrier), but how attitudes should inform policy remains unclear. **Methods:** We conducted a mixed methods study of health care providers (HCPs) in Ontario, Canada with a potential role in NBS for sickle cell disorders (SCD), including: a cross-sectional survey of a stratified random sample of 7 HCPs (N=3,113), and open-ended, semi-structured interviews (N=47) with a purposeful sample of group members. In this setting, SCD was a new addition to the NBS panel, and the program did not routinely disclose carrier results. **Results:**With a response rate of 63%, support for reasons favoring disclosure was high (65-93%), as was disagreement with reasons opposing disclosure (67-90%). Genetics professionals expressed less support for arguments favoring disclosure (35-79%), and less disagreement with arguments opposing disclosure (29-75%). A slim majority of genetics professionals (52%) agreed that a reason to avoid disclosure was the importance of allowing the child to decide. Qualitatively, the dominant theme was a duty to disclose. For most HPCs, this duty was incumbent on the clinician: if possessed, carrier results could not be withheld. **Discussion:** While majority/ dominant opinion was clear, questions remain about how opinion should guide public policy, specifically: (1) how policy should balance descriptive ethics (i.e., what HCPs believe) with normative ethics (i.e., what duty-based principles require); (2) how dissenting opinion should be considered; and (3) how moral principles grounded in clinical obligations should inform policy for *public health* initiatives.

Chitinase-3-like 1 (CHI3L1) and schizophrenia: investigation of functional mechanisms for genetic susceptibility.

E. Kenny[1], M. Hill[1], S. Roche[2], M. Gill[1], D. W. Morris[1], R. Anney[1], A. Corvin[1], The International Schizophrenia Consortium 1) Neuropsychiatric Genetics Research Group, Dept. of Psychiatry and Institute of Molecular Medicine, Trinity College Dublin, Ireland; 2) Smurfit Institute of Genetics, Trinity College Dublin, Ireland.

Introduction: Genetic and gene expression data supports Chitinase-3-like 1 (CHI3L1), as a SZ candidate gene. Two studies report association with the same allele at a SNP (rs10399805) which disrupts the C/EBP-AML-1 binding site in the gene promotor and is predicted to increase CHI3L1 expression (Yang et al, 2008; Zhao et al, 2007). We investigated genetic association in the International Schizophrenia Consortium (ISC) sample and explored cis-acting regulation of CHI3L1 expression in lymphoblasts and post-mortem brain. Methods: We examined 13 SNPs at the locus using GWAS data from the ISC, a European consortium including >3,000 cases. We investigated allele specific expression imbalance (AEI) by measuring relative mRNA levels attributable to each SNP allele in RNA isolated from individuals heterozygous for a marker SNP within mRNA from lymphoblasts from the Caucasian HapMap sample (n=45) and post-mortem human brain tissue (BA46) (n=42). Results: We found no significant evidence for association at CHI3L1. We identified potent cis-acting variation regulating CHI3L1 expression in lymhoblasts, but not brain: this was mostly, but not exclusively, attributable to rs4950928. Conclusions: We did not confirm association with common variation at CHI3L1 in the ISC sample. SNP rs4950928 explains the majority of cis-acting variation at the locus in lymphoblasts; additional AEI observed is not attributable to common SNPs within +/- 10kb of the locus. CHI3L1 is subject to tissue/cell specific regulation and does not contain cis-acting variation influencing steady state transcription in post-mortem brain.

Association studies between clinical features of the Marfan syndrome spectrum within a cohort of 1013 patients with or another type I fibrillinopathy: a clue for a better understanding of the pathogenesis? *L. Faivre[1], G. Collod-Beroud[2], A. Child[3], A. De Paepe[4], C. Binquet[5], E. Gautier[5], C. Stheneur[7], C. Bonithon[5], M. Claustres[2], C. Beroud[2], L. Ades[6], C. Boileau[7], G. Jondeau[8]* 1) Dept Genetics, Dijon, France; 2) U827, Montpellier, France; 3) St. Georges, London, UK; 4) Ghent University Hospital, Belgium; 5) CIC-EC, CHU Dijon, France; 6) Sydney, Australia; 7) Génétique moléculaire, Hôpital Ambroise Paré, France; 8) Centre de Référence Marfan, Hôpital Bichat, France.

The cardinal features of MFS involve the ocular, cardiovascular and skeletal systems, as well as the skin, the lung and dural systems. Taking advantage of the data of a large collaborative study designed for a genotype-phenotype correlation study including 1013 probands with a pathogenic FBN1 mutation, we searched for an association between clinical features of the MFS spectrum. We first perform a multiple correspondence analysis in order to guide the choice of the associations to further test using chi-square tests. We found preferential associations within systems rather than between systems. Within the skeletal system, when considering a clinical feature typical of bone overgrowth in MFS such as arachnodactyly, we found a significant association between a majority of other skeletal features part of the Ghent criteria, including dolichostenomelia, pectus deformity, scoliosis, protrusio acetabule, joint hyperlaxity and facial dysmorphism ($p<0.001$). Not surprisingly, we found a significant association between ascending aortic dilatation (AAD) and aortic valve regurgitation ($p<0.001$) as well as between mitral valve prolapse and mitral regurgitation ($p<0.001$) or between striae and herniae ($p<0.001$). When studying associations between systems, we found a significant association between major skeletal involvement and AAD, striae, dural ectasia and pneumothorax ($p<0.001$). The search for other associations was non significant: in particular no association was found between ectopia lentis and other systems of the MFS spectrum. These results were concordant with the implication of the TGF in the cardiac, skeletal, dural and skin phenotype but not in the ocular phenotype.

Diversity profile of the human skin microbiome in health and disease. *E. A. Grice[1], H. H. Kong[2], S. P. Conlan[1], A. C. Young[3], N. I. S. C. Comparative Sequencing Program[3], G. G. Bouffard[3,4], R. W. Blakesley[3,4], M. L. Turner[2], J. A. Segre[1]* 1) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD; 2) Dermatology Branch, Center for Cancer Research, NCI, NIH, Bethesda, MD; 3) NIH Intramural Sequencing Center, NHGRI, NIH, Bethesda, MD; 4) Genome Technology Branch, NHGRI, NIH, Bethesda, MD.

The concept that the human body is host to trillions of microbes is revolutionizing our view of the human genome while underscoring the role of the gene-environment interface in complex disorders. One such disorder, with a known genetic component, is the very common inflammatory skin disorder atopic dermatitis (AD; eczema) whose incidence has tripled in the past 30 years. The skin is not only the first line of defense against invasion, but also host to a diversity of microbes associated with human health and disease. To assess cutaneous bacterial diversity and abundance, we employ 16S rRNA gene phylotyping. Our previous analysis of the most commonly affected human site in AD, the antecubital fossae (inner elbow), demonstrated a unique skin core microbiome dominated by *Janthinobacteria* and *Pseudomonas* (both phylum *Proteobacteria*) with less representation from five other bacterial phyla. Skin provides an unprecedented opportunity to sample multiple sites from the same individual, many with underlying left-right symmetry. Skin sub-sites have unique environmental niches: moist/dry, haired/non-haired, acid/basic, sebaceous (oily)/non-sebaceous. Associated with these specific areas are stereotyped human disorders; e.g. psoriasis affects outer elbow and eczema affects the inner elbow. We are currently ascertaining a wide physiological range of skin sub-sites from healthy humans to comprehensively survey the resident microbiota and address the fundamental question of whether there is a baseline cutaneous microbiome. This data is a foundation for our studies investigating alterations of skin microbiota in a disease state, specifically AD. Our long term goal is to elucidate the contribution of the cutaneous microbiome to complex skin disorders and translate this into novel pharmacological treatments.

Gene-gene interaction between 5-HT2A receptor (HTR2A) and HLA-DRB1 in rheumatoid arthritis. *L. Padyukov[1], H. Källberg[2], L. Alfredsson[2], L. Klareskog[1], M. Seddighzadeh[1]* 1) Rheumatology Unit, Karolinska Inst, Stockholm, Sweden; 2) Department of Environmental Medicine, Karolinska Inst, Stockholm, Sweden.

Background: 5-HTR2A is a gene of importance in schizophrenia but it has also been shown to be involved in the immunity. Previously we demonstrated that variations in the HTR2A gene are associated with rheumatoid arthritis (RA). However, since the association is moderate and RA is a complex disease we aimed to study the interaction between the HTR2A gene and HLA-DRB1-shared epitope (SE) alleles, a major genetic susceptibility risk factor for RA.

Methods: In the current investigation more than 3000 individuals from a Swedish EIRA study were included. Haplotype analysis was performed by HaploView and the individual haplotype was estimated using the PHASE. The degree of interaction was quantified by calculating the attributable proportion due to interaction (AP) together with 95% CI.

Results: The single nucleotide polymorphism (SNP) rs1328674 was shown to interact synergistically with HLA-DRB1 SE alleles with an AP = 0.6 (95% CI 0.4-0.9). Haplotype frequency analysis based on the SNPs rs1328674 and rs6314 showed lower representation of the TC haplotype in patients compared to controls (Chi-square=7.88, p=0.043). Moreover, this haplotype was interacting with HLA-DRB1-SE alleles in an antagonistic manner resulting in a decrease of the risk of developing RA from OR 2.8 to 1.8 (AP = 0.4 (95% CI 0.1-0.6).

Conclusions: The presents study demonstrates that there is a significant interaction between HTR2A gene and HLA-DRB1-SE alleles, which might have an impact on the risk of developing RA similar to the interaction between HLA-DRB1-SE alleles and PTPN22. The biological mechanisms of this interaction on the functional level remain to be studied.

MPO genetic variation is associated with birthweight, particularly among African American women. *G. K. Swamy[1], N. Ellis[2], M. E. Garrett[2], P. Maxson[3], M. L. Miranda[3], R. B. Williams[4], A. E. Ashley-Koch[2]* 1) Ob-Gyn, Duke University, Durham, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC; 3) Nicholas School of the Environment, Duke University, Durham, NC; 4) Behavioral Medicine Research Center, Duke University Medical Center, Durham, NC.

Oxidative stress is caused by an imbalance between the production of reactive oxygen and the ability to detoxify the reactive intermediates or repair the resulting damage. Elevated markers of oxidative stress have been associated with adverse pregnancy outcomes such as gestational diabetes and preeclampsia. We sought to determine whether genetic variability in oxidative-stress-related enzymes contributes to preterm birth (PTB 37 weeks gestation) and infant birthweight (BWT). The Healthy Pregnancy, Healthy Baby Study is a prospective cohort of pregnant women in Durham, NC aimed at identifying genetic, social and environmental contributors to disparities in pregnancy outcomes among women in the US South. Data and genotyping results were available for 621 women, of which 67% were non-Hispanic Black (NHB) race. Haplotype tagging SNPs were genotyped for 4 enzymes involved in the oxidative stress pathway - CYP2E1, CYP2A6, NQO1 and MPO. Using generalized estimating equations and controlling for race, maternal genotypes for each SNP were evaluated for association with PTB and BWT. Within the CYP2E1 gene, two SNPs were marginally associated with PTB (rs743535 p=0.03) and BWT (p=0.02). Within the MPO gene, SNP rs35921530 was strongly associated with BWT (p=0.006), with the association being primarily restricted to the NHB mothers (p=0.02). In addition to the oxidative stress pathway, MPO is involved in the inflammatory response as it is released from neutrophilic granules and exhibits significant antimicrobial oxidative activity. This is an intriguing finding, given the known associations between inflammation and adverse pregnancy outcomes. Future analyses will examine the role of gene x environment interactions, specifically with maternal infections and pollutant exposures, both of which have been associated with adverse pregnancy outcomes and oxidative stress.

A novel autosomal dominant cardiac arrhythmia of hisian type and associated dilated cardiomyopathy as a cause of sudden death. *S. Saal[1], L. Faivre[1], G. Bertaux[2], S. Falcon-Eicher[2], C. Thauvin[1], A. Masurel[1], P. Charron[4], P. Richard[4], C. De Chillou[3], S. Beziau[3], F. Kyndt[3], JJ. Schott[3], JE. Wolf[2], G. Laurent[2]* 1) Genetique, Dijon, France; 2) Cardiologie, Dijon, France; 3) Cardiologie, Nantes, France; 4) Cardiologie, La Pitie Salpetriere, France.

We report a novel autosomal dominant cardiac arrhythmia (CA) resulting in polymorphic ventricular ectopic beats (VEB) and non sustained ventricular tachycardia (NSVT) originated from the His bundle. In contrast to baseline rest, VEB and NSVT had the tendency to disappear during exercise. Familial investigations revealed 4 males and 4 affected females in three generations with an age at diagnosis ranging from birth to 37 years. The main symptomatology included palpitations, heart failure, but also syncopes in 2 patients and sudden death in 1 male at age 29 during rest. A dilated cardiomyopathy (DCM) was diagnosed in 3 females and was considered as a complication of CA since it never pre-existed to CA. Several antiarrhythmic drugs (AAD) were tried out in 2 females with permanent DCM but were poorly effective. Because of the bradycardia induced by AAD, a double chamber pacemaker was implanted. An additional cryoablation of the His bundle has also been planned for one patient because of unsatisfactory results. Electrophysiological investigations did not show any atrio-ventricular conduction abnormality. Neither rapid ventricular burst pacing, nor Isoproterenol infusion were able to induce more CA. Normalization of the surface ECG during exercise testing may be due to the sinus node overtaking control of the rhythm when reaching a certain threshold rate. Direct sequencing of the *Lamin A/C* and *ABCC9* genes was performed since these genes have been associated with CA and DCM, but was normal. The ankyrin-B gene sequencing revealed a previously described E1813K variant in the most severely affected patient but which did not segregate with the disorder. This variant could act as a modifier gene in this patient, but the major gene remained to be determined. The report of other families with such symptomatology would be helpful in order to better describe this new entity.

Familial autosomal dominant hyperinsulinism due to SUR1 (ABCC8) mutation. *A. G. Le Moing[1], G. Morin[1], C. Bellanné-Chantelot[2], F. Moreau[3], B. Demeer[1], M. Mathieu[1], A. Leke[3]* 1) Clinical Genetic Unit, University Hospital, Amiens, France; 2) Genetic Unit of Metabolic Disorders - Groupe Hospitalier Pitié-Salpétrière - Paris - France; 3) Neonatology - Department of Pediatrics - Amiens - France.

Familial congenital hyperinsulinism is responsible of prolonged hypoglycemia, secondary to mutations of genes involved in the regulation pathway of insulin secretion by Langerhans cells. Most of the cases are in relation with recessive mutations of two genes, located in 11p15.1, named SUR1 (ABCC8) and KIR6.2 (KCNJ11), and coding for two subunits of the same potassium channel. Dominant mutations of SUR1 (ABCC8) were only published in two families reported by Thornton (1998 and 2003) and Huopio (2000 and 2003). In these families, the hypoglycaemia was sensible to diazoxide. In the family reported by Huopio, the eventuality of transformation in diabetes with age was noticed. We report the observation of a female newborn presenting with severe hypoglycaemia at 36 hours of life, requiring continuous gastric nutrition at the beginning, but compatible with a normal breath feeding when diazoxide was started. Her father had similar symptoms in childhood, improved by diazoxide. In the two patients, a missense heterozygous mutation of SUR1 (ABCC8) was discovered (2143G>A - V715M). Screening of other genes involved in familial dominant hyperinsulinism was negative (HNF4, KIR6.2). The mutation was not present in the two paternal grand-parents of the index case.

A Posterior Probability of Linkage & Association Study of 111 Autism Candidate Genes. *F. Chen[2], N. Gharani[2], C. Dong[1], Y. Wang[1], D. Gordon[2], Y. Huang[4], J. Millonig[3], V. Vieland[4], H. Wang[1], J. Tischfield[2], T. Matise[2], L. Yu[2], W. Huang[1], L. Brzustowicz[2]* 1) Chinese National Human Genome Center, Shanghai, China; 2) Dept of Genetics, Rutgers University, Piscataway, NJ; 3) CABM, UMDNJ-RWJMS, Piscataway, NJ; 4) Research Institute at Nationwide Children's Hospital and Ohio State University, Columbus, OH.

Autism is a neurodevelopmental disorder with a complex genetic basis. We tested 111 biologically relevant candidate genes for genetic association with autism in 265 nuclear families from the Autism Genetic Resource Exchange (AGRE). Candidate genes were selected from three categories: 1) genes with similar function as the previously identified autism susceptibility gene ENGRAILED 2 (EN2); 2) genes from the serotonin and GABA neurotransmission pathways; and 3) genes from previously identified genomic linkage and association regions. Utilizing genotype data from the International HapMap Project, a total of 1497 tagSNPs were selected to efficiently capture the haplotype information of each gene. These SNPs were genotyped using the Illumina Bead Array assay and subsequently subjected to a strict QC and error checking procedure. Cleaned genotype data were analyzed by the Posterior Probability of Linkage (PPL) and the Posterior Probability of Linkage Disequilibrium (PPLD), which directly measure the probability of linkage and/or association. 8 SNPs from three gene regions on Chr 4, 6 and 7 showed 2-point PPL >10%. However, only the EPHB6-EPHA1 locus on Chr7 gave a multipoint PPL exceeding 5% (PPL=6.5%). Six additional SNPs from EPHB6-EPHA1 (Chr7) and MECP2 (ChrX) provided some evidence for association (PPLD=10%). Next we analyzed the recently released AGRE Affymetrix 500K SNP array data for our top candidate gene regions in our families. Evidence for association was obtained for 6 further SNPs at the 7q33-q35 region (PPLD range 21%~40%). Furthermore, some support for association (PPLD=9%) was detected at additional SNPs within MECP2. These preliminary data identify members of the Ephrin receptor tyrosine kinase gene family as potential novel candidate autism susceptibility loci and provide further support for a role of MECP2 in autism etiology.

Polymorphism in -synuclein gene (SNCA) confers susceptibility to late-onset Parkinson disease. *G. Wang, G. Mayhew, D. Casadesus, S. Zuchner, W. K. Scott, E. R. Martin, J. M. Vance* Inst Human Genomics, Univ Miami, Miami, FL.

The alpha-synuclein gene (SNCA) was originally found to cause the rare familial form of Parkinson disease (PD) by missense mutations and locus multiplication. Further studies suggest that common polymorphisms in SNCA, especially Rep1 in the promoter region, are associated with sporadic PD, though the association has not been consistent across different populations. To determine the association of SNCA variants with the common complex form of PD, we genotyped eight single nucleotide polymorphisms (SNP) located in the 3UTR and promoter regions in a family based sample set (727 families [307 singleton and 420 multiplex] , all are American whites). In the overall data set, we found strong associations between PD and four SNPs, including rs356165 ($p=1.1X10^{-5}$) in the 3UTR and 3 other SNPs (RS2619363, p=0.0094; RS2619364, p=0.013; RS2583988, p=0.023) in the promoter region. Interestingly, these associations vary after the sample set is stratified by age-at-onset. Specifically, the association is not significant in the early-onset (40 years old) subset, whereas the associations strengthen in the late-onset (>40 years old) subset. We suggest that these associated SNPs may confer susceptibility to the common complex late-onset form of PD by changing SNCA transcription levels through regulation of promoter activity or translation levels through modified miRNA targeting of the 3 UTR.

Genetic associations between dental caries in children and taste preference and saliva pathway genes. *S. Wendell[1], XJ. Wang[1], G. Barkanic[1], RJ. Weyant[1], R. Crout[2], D. McNeil[2], ML. Marazita[1]* 1) School of Dental Medicine, University of Pittsburgh; 2) School of Dentistry, West Virginia University.

Background: Dental caries (tooth decay) is one of the most common oral diseases and is influenced by a complex interplay of genetic and environmental factors. We investigated the association of caries with genes from multiple relevant oral processes including saliva, taste preference, and tooth structure. Methods: The Center for Oral Health Research in Appalachia (COHRA) recruits families in Northern Applachia, and collects biological samples, demographic data and clinical assessment of oral health. Genetic association was investigated using FBAT software TDT analysis of 29 SNPs in 24 genes. Phenotypic scores were no caries (score=0) and caries (score1). Analysis was conducted for two non-overlapping groups: children 6yrs (n=669 in 422 families); 7-15 (n=523 in 357 families), as well as the entire cohort All. Results: Three SNPs in taste receptor TAS2R38 were associated with protection from caries in 6yrs (p=0.006, 0.05, 0.04). A SNP in sweet receptor TAS1R2 was associated with protection in 6yrs (p=0.02) and borderline significant in 7-15yrs (p=0.06). GNAT3, a G-protein involved in downstream taste pathways, was associated with caries risk in 7-15yrs (p=0.04). The saliva pathways genes CALR and CACNA1A were associated with caries risk in 7-15yrs (both p=0.02). Additionally, NFATC4 was protective in 6yrs (p=0.04). Notably, the G allele of CACNB4 was also protective in 6yrs (p=0.04) while the C allele was borderline significant for risk in All (p=0.10). Proteinases MMP8 and CTSB were associated with caries risk in 7-15yrs (p=0.02, p=0.04) while MMP9 was protective in 6yrs (p=0.04). AMELX was associated with risk in 7-15yrs and All (p=0.03, p=0.04). Additional suggestive significance was seen in TUFT, AQP5, CACNA1A, NFATC4, MMP8, and CTSB. Conclusions: We have identified several significant associations of candidate genes from a variety of relevant oral processes with dental caries risk or protection. Notably, genes in the taste sensing pathways were associated with dental caries. NIH Grant # DE014899.

Replication stress induces submicroscopic copy number changes in normal human cells. *M. F. Arlt[1], J. G. Mulle[2], V. M. Schaibley[1], S. T. Warren[2], T. W. Glover[1]* 1) Dept. of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Dept. of Human Genetics, Emory University, Atlanta, GA.

We previously reported that aphidicolin (APH)-induced replication stress leads to a high frequency of submicroscopic deletions, or copy number changes (CNCs), within the FRA3B fragile site that closely resemble those frequently found in cancer cells (Durkin et al. PNAS, 105: 246-251, 2007). We now show that replication stress leads to a high frequency of both deletions and duplications of tens to hundreds of kilobases across the entire human genome. These CNCs closely resemble normal copy number variants (CNVs) and *de novo*, pathogenic CNCs seen in humans with genetic and developmental disorders and in cancer cells.

We exposed normal human fibroblasts to APH-mediated replication stress and generated clonal cell populations. These clones were analyzed for CNCs using high-resolution array comparative genomic hybridization (aCGH). We identified and validated via a second technique 28 *de novo* CNCs (21 deletions and 7 duplications) from 8/14 (57%) clones isolated from the APH-treated fibroblasts and 2 *de novo* CNCs (2 deletions) from 1/11 (9%) clones from untreated controls. These CNCs ranged in size from 11 kilobases to over two megabases. To date, our efforts at sequencing deletion breakpoint junctions have yielded 6 breakpoint junction sequences. All of these breakpoint junctions are characterized by small (<5 bp) microhomologies, consistent with the hypothesis that these rearrangements are the result of NHEJ-mediated repair processes and not homologous recombination repair. Additional breakpoints are currently being sequenced. Our results demonstrate that replication stress induces a high frequency of submicroscopic CNCs in cultured normal cells that closely resemble those found *in vivo*. This is a previously unrecognized consequence of replication stress and our findings lead us to hypothesize that replication stress is an important mechanism in the formation of human CNVs and pathogenic CNCs.

Complete sex reversal in alpha thalassemia X-linked mental retardation (ATRX) syndrome. *K. Kessler[1], J.-S. Saldivar[2], L. Mehta[1]* 1) Div. of Medical Genetics, Schneider Children's Hospital, Manhasset NY; 2) Clinical Molecular Diagnostic Laboratory, City of Hope, Duarte, CA.

We describe an infant with a complex disorder of sexual development (DSD), presenting with complete sex reversal, developmental delays and dysmorphic features. This was the first pregnancy for a 28 y.o mother. Prenatal sonograms showed a left multicystic kidney and possible congenital heart defect. Amniocentesis revealed a 46,XY karyotype, though the fetus appeared female. FISH for SRY was positive and 7-dehydrocholesterol, 22q11 FISH and androgen receptor gene sequencing were normal. At birth, the infant had microcephaly and dysmorphic features, consisting of prominent occiput, short nose, downturned and open mouth, small jaw, low-set overfolded ears, and contracted digits. Genitalia appeared unambiguously female and a pelvic ultrasound did not show a uterus or any detectable gonads. Endocrine evaluation did not suggest any specific abnormalities. Cardiology evaluation noted a bicuspid aortic valve. On follow up the infant had significant developmental delays, failure to thrive, bilateral sensorineural deafness, high myopia and delayed visual maturation. Skeletal survey was normal. Chromosomal microarray analysis (Baylor version 6.2/100K array), and sterol profile were normal. ATRX gene sequencing detected a hemizygous deletion of exon 35, predicted to be deleterious. The exact boundaries of the deletion are unknown. RBC indices did not suggest alpha thalassemia, however an unexplained leukocytosis (30-50 K /uL) with high platelet count, was present. The parents went on to have another affected pregnancy which was terminated. ATRX is a syndromic DSD, but complete sex reversal, as seen in our patient, is only rarely reported. A severe genital phenotype is felt to correlate with mutations in the helicase domain of the ATRX gene (Gibbons et al, 2008), particularly in exons 35 and 36, and the findings in our case support this association. Discordance between fetal karyotype and sonographic gender, and genital abnormalities in a syndromic infant are important clues to early diagnosis of this severe mental retardation syndrome.

Patterns of association of microRNAs with schizophrenia symptoms. *M. Muinos-Gimeno[1,2], A. Brunet[1,3,4], J. Real[4], V. Vallès[5], A. Labad[6], R. Guillamat[5], M. Guitart[4], X. Estivill[1,2,3,7], Y. Espinosa-Parrilla[1,2]* 1) Dept Genes & Disease, Centre de Regulació Genòmica, Barcelona; 2) CIBERESP, CRG, Barcelona; 3) CeGen, CRG, Barcelona; 4) Corporació Sanitària Parc Taulí, Sabadell; 5) Consorci Sanitari de Terrassa, Terrassa; 6) Hospital Universitari Institut Pere Mata, Reus; 7) Pompeu Fabra University, Barcelona, Spain.

Schizophrenia (SZ) is a severe neuro-developmental disorder characterized by disturbances in nearly every function of the brain: cognition, perception, affect and thought. Albeit having a strong genetic disposition its aetiology is still largely unknown. MicroRNAs (miRNAs) are small non-coding RNAs that regulate the expression of many mRNAs. Little is known about the functional mechanisms regulated by miRNAs in the brain but miRNA mediated gene regulation has already been involved in the control of neuronal development and differentiation as well as synaptic plasticity. In addition, differential expression of several miRNAs in the pre-frontal cortex of SZ patients has been reported, suggesting that miRNAs might be good candidate genes for this disorder. In order to evaluate this hypothesis we constructed a panel of 768 SNPs covering miRNA regions (MiRBase 7.1) and genotyped a group of 341 controls and 235 patients with SZ (custom Golden Gate assay, Illumina). Association studies showed 8 miRNAs to be associated with SZ (p0.005, sex adjusted) and two other miRNAs to be strongly associated with age at onset, being the association significant after correction for multiple testing ($p<8.8x10^{-5}$). Moreover, we performed association analysis with different quantitative traits from the Positive and Negative Syndrome Scale (PANSS) and found a highly significant association for one miRNA with total PANSS score ($p=4.0x10^{-5}$). Furthermore, two other miRNAs were significantly associated ($p=1.0x10^{-5}$) with higher scores for the positive and disorganized factors extracted from factor analysis of PANSS. Interestingly, one of the latter miRNAs is differentially expressed in the prefrontal cortex of patients with SZ, further supporting a role for this miRNA in the aetiology of SZ. Our results propose miRNAs as important contributors to the genetic basis of SZ.

Human Subtelomeric Gaps and Structural Variation. *H. Riethman[1], E. E. Eichler[2], R. Wilson[3], T. Graves[3], C. Fronick[3], L. Courtney[3], S. Hu[1], S. Paul[1]* 1) Wistar Inst, Philadelphia, PA; 2) Dept of Genome Sciences and HHMI, University of Washington, Seattle, WA; 3) Washington University Genome Sequencing Center, St. Louis, MO.

Structural variation is abundant in subtelomeric DNA, and is likely to have important consequences for transcriptional activity as well as for regulation and stability of (TTAGGG)n tracts. Both copy number variation and alternative sequence organizations are major components of this structural variation. Our current focus is on DNA comprising the the most distal subtelomeric sequences, subterminal DNA. These regions are both more divergent than other subtelomeric repeat regions and very important for understanding telomere biology. Many (TTAGGG)n-adjacent sequences are still missing from the reference sequence itself, and a large number of structural variants carrying new common subterminal alleles remain to be discovered and characterized. We are using end-sequenced fosmid libraries from the Human Structural Variation Initiative to characterize subterminal structural variation. Importantly, because the libraries were prepared using sheared source DNA, terminal fosmids with one mate pair corresponding to part of the terminal (TTAGGG)n sequence tract can be identified. Several large structural variants and telomeric gap-spanning fosmids were identified and sequenced, extending the reference sequence to (TTAGGG)n tracts for these subterminal alleles. In addition, one fosmid library (G248) was exhaustively screened for terminal fosmids using its paired-end sequences; the global collection of subterminal alleles from this genome was characterized by restriction mapping and directed sequencing. Our results demonstrate the feasibility of isolating novel subterminal structural variants using this approach and show that, while distal terminal (TTAGGG)n tracts are truncated in the clones, subterminal DNA remains intact. We plan to systematically identify and characterize subterminal sequences from common telomere alleles, filling a major gap in our knowledge of subtelomere structures in the human genome and permitting development of new tools for studying telomere biology.

Linkage Analysis of a Large Tourette Syndrome Pedigree. *S. Knight[1], N. J. Camp[1], H. Coon[2], M. Johnsom[2], W. McMahon[2]* 1) Dept of Biomedical Informatics, University of Utah, Salt Lake City, UT; 2) Dept of Psychiatry, University of Utah, Salt Lake City, UT.

Tourette Syndrome (TS) is a neuropsychiatric disorder characterized by multiple motor or phonic tics that wax and wan over a lifetime. The heritability of TS has been well established, yet few genetic studies have found significant results or replicated results. The purpose of this study was to perform a genomewide linkage analysis to identify regions of the genome that may harbor susceptibility genes for TS. Our resource consisted of one large pedigree of 260 individuals that contains a total of 67 affected individuals with a definite TS diagnosis. Two-point and multipoint linkage analyses were performed on a 10cM spaced microsatellite autosomal marker set. Since the pedigree was too large to allow for analysis using exact methods, MCLINK, a Monte Carlo Markov chain method, was used for the multipoint analyses. General dominant and recessive affecteds only models were used, in addition to nonparametric linkage (NPL). Under a recessive model, there was significant linkage with a two-point LOD score of 3.44 on chromosome 3p; the multipoint maximum was 3.47 in this region. Under a dominant model, nominal linkage results were also found on 4q (multipoint LOD=1.57). The NPL results were a LOD equivalent of 1.12 for chromosome. 3 and 0.94 for chromosome 4. The linkage peaks on 3p and on 4q are in regions that have been previously reported in linkage studies of TS. The statistical recombinant mapping of chromosome 3 indicated the region of sharing was between 37 and 88 cM and 26 cases shared the same haplotype in this region.

Copy number variations in schizophrenia : from association to individual patterning. *F. Torri[1], S. Lupoli[1,2], A. Orro[3,5], S. Potkin[4], E. Salvi[1], P. Cozzi[5], A. Calabria[5], J. Turner[4], J. Fallon[4], B. Lerer[6], G. Guffanti[1], C. Barlassina[1], C. Cosentino[1], V. Tieran[1], F. Taddeo[1], L. Luciano[3], D. Cusi[7], F. Macciardi[1]* 1) University of Milan, Milan, Italy; 2) INSPE, Scientific Institute San Raffaele, Milan, Italy; 3) CILEA Consortium, Segrate, Milan, Italy; 4) University of California, Irvine,Usa; 5) ITB, CNR, Milan, Italy; 6) Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 7) San Carlo Borromeo Hospital, Milan, Italy.

Copy Number Variations (CNVs) role in determining susceptibility to complex disorders is becoming a key hypothesis. The outstanding challenge is now to understand disease model underlying CNVs involvement in diseases like schizophrenia (SCZ). Beside the common variants - common disease hypothesis for complex diseases, the rare variants - common disease one is emerging centered on the possible interplay of a network of individual rare CNVs. Starting from the cytogenetic evidence of a deletion of ~3.5 Mb on chromosome 13q encompassing many genes in a patient with a bipolar-schizoaffective picture, we assessed CNVs patterns in an Illumina HumanCNV370 case control study of SCZ of ~200 individuals. We cross-validated our findings on a subset of patients using MLPA. To detect CNVs we used different analytical algorithms, the Hidden Markov Model based QuantiSNP and the Circular Binary Segmental modified implemented in Nexus (Biodiscovery Inc.). We found that schizophrenics tend to have significantly more deletions than controls (p=1E-21), encompassing both heterozygous and homozygous events. In particular our logistic regression approach showed that cases and controls differ mainly in terms of heterozygous deletion (p=1E-3). Moreover we detected a significant association to SCZ of CNVs mapping in genes involved in synapse functionality and axon guidance, even after correction for multiple testing. We also found that patients show other CNV regions, including a highly significant CNV on chromosome 8. Considering each single subject individual CNVs patterning, we found that several pathways involved in regulation of neurodevelopmental functions are significantly enriched in many patients.

Mutations in the *GGCX* and *ABCC6* Genes in a Family with Pseudoxanthoma Elasticum-like Phenotypes. *Q. Li[1], D. K. Grange[2], N. L. Armstrong[2], A. J. Whelan[2], M. Y. Hurley[3], M. Rishavy[4], K. Hallgren[4], K. L. Berkner[4], L. J. Schurgers[5], Q. Jiang[1], J. Uitto[1]* 1) Department of Dermatology and Cutaneous Biology, and Biochemistry and Molecular Biology, Jefferson Medical College, Philadelphia, PA; 2) Division of Gentics and Genomic Medicine, Department of Pediatrics, Washington University School of Medicine, St. Louis, MO; 3) Divisionof Dermatopathology, Department of Dermatology, St. Louis University School of Medicine, St. Louis, MO; 4) Department of Molecular Cardiology, Lerner Research Institute, Cleveland Clinic Lerner Colleg eof Medicine at Case Western Reserve University, Cleveland, OH; 5) Cardiovascular Research Institute and VitaK BV, University of Maastricht, Maastricht, The Netherlands.

A characteristic feature of classic PXE, an autosomal recessive disorder caused by mutations in the *ABCC6* gene, is aberrant mineralization of connective tissues. Here, we report a family with PXE-like cutaneous features in association with multiple coagulation factor deficiency, an autosomal recessive disorder associated with *GGCX* mutations. The proband and her sister, both with severe skin findings with extensive mineralization, were compound heterozygotes for missense mutations in the *GGCX* gene, which were shown to result in reduced -glutamyl carboxylase activity and in under-carboxylation of matrix gla protein. The probands mother and aunt, also manifesting with PXE-like skin changes, were heterozygous carriers of a missense mutation (p.V255M) in *GGCX* and a null mutation (p.R1141X) in the *ABCC6* gene, suggesting digenic nature of their skin findings. Thus, reduced -glutamyl carboxylase activity in individuals either compound heterozygous for a missense mutation in *GGCX* or with haploinsufficiency in *GGCX* in combination with heterozygosity for *ABCC6* gene expression results in aberrant mineralization of skin leading to PXE-like phenotype. These findings expand the molecular basis of PXE-like phenotypes, and suggest a role for multiple genetic factors in pathologic tissue mineralization in general.

A genome-wide association study of 2,300 migraine with aura patients and 9,300 population-based controls. *V. Anttila[1,2], U. Todt[3], T. Freilinger[4], M. A. Kaunisto[2,5], M. Kallela[6] for the International Migraine Genetics Consortium*
1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) Center of Excellence for Complex Disease Genetics, University of Helsinki, Helsinki, Finland; 3) Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany; 4) Department of Neurology, Klinikum Grohadern, Ludwig-Maximilians-University Munich, Munich, Germany; 5) Folkhälsan Research Center, Helsinki, Finland; 6) Helsinki University Central Hospital, Helsinki, Finland.

Migraine affects 15% of the adult population and is the most common cause of chronic episodic severe headache. Despite a well-established genetic component based on family and twin studies, no variants influencing migraine susceptibility have been convincingly identified and no genome-wide association studies reported. Given its recent successes, we use a genome-wide association strategy to identify genomic variation predisposing to common forms of migraine. To obtain sufficient sample size for the study, we formed the International Migraine Genetics Consortium with participants from seven leading migraine research centers. The discovery sample consists of 1,000 Finnish and 1,300 German comprehensively phenotyped migraine with aura patients. Control genotypes consist of 6,000 Finnish and 3,300 Central European population-based individuals genotyped in other studies. Genotyping is performed using the Illumina platform, and association analyses are performed using the PLINK software. Best ranked signals from the discovery sample will be replicated in a follow-up sample of 7,000 migraine with aura cases from Leiden, the Netherlands, Brisbane, Australia, and the HUNT study in Norway, as well as 20,000 additional controls to assess the population impact of identified variants. Here, we present the most likely associated signals and estimates of their population-specific effects.

Construction of a weighted genetic score and integration with clinical risk factors to predict the presence of diabetes in the population. *V. E. Mooser[1], K. Song[1], N. Lim[1], X. Yuan[1], T. Johnson[2,3], A. Abderrahmani[2], P. Vollenweider[2], H. Stirnadel[1], S. Sundseth[1], P. Matthews[1], G. Waeber[2], L. R. Cardon[1], D. M. Waterworth[1], X. Lin[1]* 1) Genetics Division, Discovery Analytics, Worldwide Epidemiology and Clinical Imaging Center, GlaxoSmithKline, King of Prussia PA, RTP NC and London UK; 2) Division of Medical Genetics and Department of Medicine, CHUV University Hospital, Lausanne, Switzerland; 3) Swiss Institute of Bioinformatics Lausanne Switzerland.

Many susceptibility genes for Type 2 diabetes have been discovered recently. Individually, these genes only increase the disease risk minimally. The risk in subjects who carry risk alleles within multiple susceptibility genes, and the value added by genetic information over the clinical risk factors in the prediction of diabetes remain to be determined. We constructed an additive genetic score using the most replicated SNP within 15 diabetes susceptibility genes, weighting each SNP with its reported effect size , but using the conservative lower bound of the CI as the estimate. We first tested this score in a study nested within the population-based CoLaus study in Lausanne, Switzerland (n = 5479), comprising 325 diabetic individuals and 599 controls matched 1:2 for age, gender and BMI. The diabetes risk, after adjustment for family history of diabetes, was 2.9 (1.8-4.7, p = 0.000007) for individuals with a genetic score within the top quintile, compared to the bottom quintile. Adding the weighted genetic score to the clinical covariates improved the area under the ROC curve by 2.7% (0.8%-5.2%, p = 0.009, from 68.6% to 71.3%). A similar OR was observed when analyzing the entire CoLaus population; however the gain in ROC analysis was not significant. In this nested case-control study, a simple, weighted 15 SNP-based score provides additional information over conventional clinical predictors of prevalent diabetes. The cumulative effect of these SNPs is not mediated solely by an increase in BMI, but the score and BMI appear to have a synergistic effect on T2D risk.

Eliminating redundant SNPs improves power in Genome Wide Association analyses. *R. W. Davies, A. F. R. Stewart, L. Chen, R. Roberts, G. A. Wells* University of Ottawa Heart Institute, Ottawa, Ontario, Canada.

Background: Genome Wide Association analyses involve testing hundreds of thousands of SNPs; as such, meaningful interpretation of results requires correction for multiple testing. However, as many SNPs show very similar characteristics, applying corrections which assume independence of SNPs is overly harsh. Objective: To block together and remove redundant SNPs in a GWA dataset using population specific measures of LD from control genotype data. Methods: Written using R-2.5.1, for a given chromosome the program starts with the SNP with the lowest physical position. Scanning forward in a 1Mbp window, the first SNP whose r2 value with the original SNP exceeds a pre-specified threshold is blocked with the original; subsequent SNPs are added to the growing block if their r2 value with each block member exceeds the r2 threshold. Once the 1 Mbp window is exhausted, a representative SNP is chosen from the block, and the process continues with the next unselected SNP on the chromosome. Results: Using data common to Affymetrix 5.0 and 6.0 arrays from our ongoing GWA, the Ottawa Heart Genomics Study, yields 482,251 SNPs from 1542 cases and 1422 controls. Removing the X chromosome, correcting for 5% MAF cases and controls, p0.001 HWE in controls and call rate 95% left 324,492 SNPs. Using a stringent r2 threshold of 0.90 on the refined dataset leaves 207,340 SNPs, a 36% reduction, while a threshold of 0.80 leaves 184,130 SNPs, a 43% reduction. Using Hapmap genotype data on the same SNPs gives reductions of 37% and 43% for thresholds of 0.90 and 0.80, respectively. Preliminary analysis of 2.5M potential SNPs for use in imputation, run using Hapmap genotype data on chromosomes 10 and 11, suggests a reduction of about 62%. A relative increase of 56% in the Bonferroni corrected p-value is realized with the removal of 117,152 SNPs from our data with an r2 threshold of 0.90. Conclusions: With a negligible loss of information, redundant SNPs can be removed from a GWA dataset, allowing for a less stringent correction for multiple testing and more power for a given sample size.

Mutatome of microsatellite unstable colorectal cancer. *P. Alhopuro[1], H. Sammalkorpi[1], J. Saharinen[2], D. Phichith[3], HL. Sweeney[3], D. Arango[4], A. Karhu[1], LA. Aaltonen[1]* 1) Department of Medical Genetics, University of Helsinki, Finland; 2) Biomedicum Bioinformatics Unit, University of Helsinki, Finland; 3) Department of Physiology, University of Pennsylvania, USA; 4) CIBBIM, Vall d'Hebron Hospital Research Institute, Spain.

Defects in the mismatch repair (MMR) system lead to microsatellite instability (MSI). MSI underlies the malignant progression of hereditary non-polyposis colorectal cancer and a subset of sporadic tumors, including colorectal cancer (CRC). Short repetitive DNA sequences in coding regions are prone to strand slippages under MMR deficiency and therefore frameshift mutations commonly occur in MSI tumors. In the MSI pathway a large number of random mutations are generated throughout the genome. Mutations that result in malignant advantages are selected for and show as high mutation frequencies in MSI cancers. The aim of this work was to identify novel MSI tumor suppressor target genes, and to gain understanding of the mutatome of MSI CRC. We analyzed mutation frequencies in coding microsatellites of 709 genes chosen based on expression array data (reduced expression in MSI CRC) and existence of a mononucleotide repeat. The mutation analysis was performed in 30 MSI CRCs and the genes that showed a somatic mutation rate 20% were evaluated in an extended set of 70 MSI CRCs. Normal tissue DNA was analyzed to confirm the somatic origin of mutations. The genes showing a somatic mutation rate 20%, were sequenced for somatic mutations in the entire coding region in 30 microsatellite stable (MSS) CRCs. We identified 16 novel candidate MSI target genes, which were somatically mutated in 23-55% of MSI CRCs. One of the genes identified was MYH11 encoding smooth muscle myosin, which was somatically mutated in 55% of MSI CRCs. MYH11 mutations were also identified in MSS CRC, as well as in the germline of a patient with Peutz-Jeghers syndrome. Functional analysis of MYH11 mutations suggests a role for unregulated myosin in CRC development. This is the first unbiased work to characterize somatic mutation rates in MSI cancer giving significant insight into MMR driven tumorigenesis and increasing our knowledge on mutation rates in cancer.

Differentiated SNP Selection and Multivariate Visualization of Structured Populations in Association Studies. *K. Miclaus[1,2], R. Wolfinger[2]* 1) Statistics Dept, North Carolina State University, Raleigh, NC; 2) JMP Genomics, SAS Institute Cary, NC.

In the new era of large-scale, collaborative Genome Wide Association Studies (GWAS), population stratification has become a critical issue that must be addressed. In order to build upon the methods developed to control the confounding effect of a structured population, it is extremely important to visualize and quantify that effect. In this work, we develop methodology for SNP selection and subsequent visualization based on deviation from Hardy-Weinberg Equilibrium in conjunction with Non-metric Multidimensional Scaling; a distance-based multivariate technique. Current preferred methodology advises the use of independent markers to avoid confounding, yet this is computationally difficult in studies with many markers and individuals and researchers may resort to random SNP selection for simplicity. Through simulation, it is shown that SNP selection based on HWD is robust against confounding linkage disequilibrium patterns that have been problematic in past studies and methods. Results show that selection based on HWD yield a set of substructure informative SNPs that contain a highly significant smaller proportion of SNPs that are from confounding LD regions compared to random SNP selection. Additionally HWD selected SNPs results in a significantly higher measure of differentiation, F_{ST}, on average than randomly chosen SNPs as well as randomly chosen SNPs that were NOT in a confounding LD region. Non-metric MDS is shown to be an appropriate multivariate visualization tool in conjunction with HWD SNP selection through theoretical and empirical study from HapMap samples. Comparisons show that the standard method PCA may find differentiation in an unstructured population due to the nature of maximizing explained variance by the eigenvectors, while MDS finds coordinates that attempt to encompass the true structure of the data. Results give promise to the development of future methods to correct for population stratification in association testing based on these methodologies.

Multiple approaches to use GWA data to identify variants impacting on age of type 2 diabetes diagnosis. *M. McCarthy[1,2], I. Fernandez-Cadenas[2,3], I. Prokopenko[2], N. Timpson[2,4], V. Boraska[2,5], N. Rayner[2], A. Hattersley[6], T. Frayling[6], E. Zeggini[2], C. Lindgren[1,2]* 1) OCDEM, University of Oxford, UK; 2) WTCHG, University of Oxford, UK; 3) LIN, HVH, Spain; 4) MRC Center for Causal Analyses in Translational Epidemiology, Bristol University, UK; 5) University of Split, Department of Biology, Croatia; 6) Peninsula Medical School, Exeter, UK.

Many common variants influencing T2D have been identified through GWA studies. This study used data from the Wellcome Trust Case Control Consortium (1924 cases, 2938 controls; 500k Affymetrix chip) to identify variants influencing T2D age of diagnosis (AoD). We examined: (a) T2D associations after stratifying cases by median AoD (51 years, 1002 early-AoD; 922 late-AoD cases) compared to 2938 WTCCC controls; (b) AoD associations by comparing early- and late-AoD cases, and by continuous trait analyses of AoD within cases; (c) evidence for AoD-dependent heterogeneity in T2D effect size by Breslow-Day analysis of early-AoD/control and late-AoD/control comparisons. These analyses identified several interesting signals associated with AoD itself, or for which T2D association was influenced by case AoD stratum. Amongst the former were rs6068566 (near *TSHZ2*), which showed significant differences in genotype frequency between early- and late-AoD cases ($p=3.7x10^{-6}$) and with AoD as a continuous trait ($p=7.9x10^{-5}$); and rs7317049 (near *SPRY2*) associated with AoD on the continuous ($p=9.9x10^{-7}$) and dichotomous ($p=2.8x10^{-4}$) tests. The most promising signal for AoD-stratum related differences in T2D association lies at rs11155055 (near *PRDM13*: Breslow-Day $p=1.1x10^{-6}$, late-AoD cases/controls, $p=7.4x10^{-4}$, early-AoD cases/controls, p=0.85). Another signal after stratification lies at rs10806665 (near *THBS2*: $p=3.4x10^{-8}$ for T2D association in early-AoD cases only) but was not significant in the Breslow-Day test (p=0.06). None of the previous established genes for T2D were associated with AoD or showed heterogeneity of T2D effect size by AoD-stratum. Whilst replication in additional data sets will be required to substantiate these findings, the multifaceted approach has identified several candidate regions potentially involved in influencing AoD of T2D.

VDR genetic variation is associated with birthweight among African American mothers. *M. E. Garrett[1], G. K. Swamy[2], N. Ellis[1], P. Maxson[3], M. L. Miranda[3], R. B. Williams[4], A. E. Ashley-Koch[1]* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Ob-Gyn, Duke University Medical Center, Durham, NC; 3) Nicholas School of the Environment, Duke University, Durham, NC; 4) Behavioral Medicine Research Center, Duke University Medical Center, Durham, NC.

The Vitamin D receptor (VDR) mediates Vitamin D activity and its primary role in calcium homeostasis. However, research suggests that polymorphisms in the VDR gene modulate circulating levels of lead, a heavy metal that has been associated with adverse pregnancy outcomes such as preterm birth and low birthweight. Furthermore, higher blood lead levels have been documented among Black women as compared to White women in the US. It is unclear if these higher lead levels are due to differential environmental exposure, to genetic variability, or a combination of both. Therefore, we hypothesize that genetic variation in the VDR gene may contribute to the racial disparity in preterm birth (PTB 37 weeks gestation) and infant birthweight (BWT). The Healthy Pregnancy, Healthy Baby Study is a prospective cohort of pregnant women aimed at identifying genetic, social and environmental contributors to disparities in pregnancy outcomes among women in the US South. Data and genotyping results were available for 621 women, of which 67% were non-Hispanic Black (NHB) race. Haplotype tagging SNPs were genotyped for VDR via Taqman assays. Using generalized estimating equations and controlling for race, the mothers genotype for each SNP was evaluated for association with PTB and BWT. Of the 19 SNPs examined, two SNPs were associated with PTB (rs2853559 p=0.03) and BWT (rs7975128 p=0.04), respectively. In the NHB subset, two SNPs were strongly associated with BWT only (rs7975232 p=0.009; rs7975128 p=0.003). Although the mechanisms by which VDR genetic variation may contribute to pregnancy outcomes is unknown, the strong association with BWT among NHB women may function through altered lead metabolism and blood lead levels. Future analyses will examine the association between VDR genetic variability and circulating maternal blood lead levels and gene x environment interactions, particularly heavy metals exposures.

Association between genetic polymorphisms of Protease Inhibitor 3 and risk of acute respiratory distress syndrome. *P. Tejera[1], Z. Wang[1], R. Zhai[1], L. Su[1], CC. Sheu[1], DC. Christiani[1,2]* 1) Harvard School of Public Health, Boston, MA; 2) Massachusetts General Hospital, Boston, MA.

Background: Proteinase inhibitor 3 plays important roles in infection and inflammation. Our previous genome-wide gene expression analysis has revealed that PI3 was down-regulated in patients with acute respiratory distress syndrome (ARDS). In this study we hypothesized that genetic variations in PI3 might be associated with ARDS risk. Methods: We resequenced the entire PI3 gene in 29 healthy Caucasians. Based on the results of resequencing, haplotype-tagging single nucleotide polymorphisms (SNPs) were selected for genotyping. An additional four SNPs located in the promoter and in the 3 region of PI3 were also included. The study population included 441 ARDS cases and 1023 critically ill patients, nested within a prospectively enrolled cohort of the Molecular Epidemiology of ARDS study (Massachusetts General Hospital, Boston, MA). The associations between PI3 variants and ARDS risk were estimated by multivariate logistic regression models. Results: We identified 24 polymorphisms, 21 SNPs and 3 in/del, in the PI3 gene. Among them, ten were novel variants not previously described in Caucasians. Three tagging-SNPs (rs1983649, rs6032040, rs2664581) and four additional SNPs (A-1077G, rs35632684, rs17333381 and rs2267864) were genotyped and analyzed for the association with ARDS. We found that the variant genotypes of PI3-4 (OR, 1.35; 95% CI, 1.08-1.69; p=0.009), rs2664581 (OR, 1.36; 95% CI, 1.10-1.69; p=0.005), rs17333381 (OR, 1.34; 95% CI, 1.08-1.67; p=0.009) and rs2267864 (OR, 1.31; 95% CI, 1.06-1.62; p=0.012) were significantly associated with increased ARDS risk in both crude and adjusted analyses. In subgroup analyses, we found the associations of PI3 variants with ARDS development were even stronger in subjects aged<65 years and in subjects with risk factors for indirect lung injury (e.g., sepsis). In haplotype analysis the haplotype GTTTCTG was associated strongly with a higher risk of ARDS in subjects aged<65 (OR, 1.63; 95% CI, 1.14-2.32; p=0.007). Conclusion: Polymorphisms in PI3 gene are significantly associated with ARDS risk, particularly in subjects aged < 65.

Influence of genetic polymorphisms in circadian rhythm-related genes on polysomnographic sleep parameters in patients with primary insomnia. *K. Mack, S. N. Mitkus, A. Thompson, N. Wang, G. Birznieks, C. Lavedan* Vanda Pharmaceuticals Inc., Rockville, MD.

Insomnia is a highly prevalent sleep disorder, estimated to affect 30% of the adult population worldwide. Recent advances in circadian rhythm biology have identified genetic variations in several key molecular clock genes that are associated with circadian rhythm disorders and/or that influence sleep-wake behavior in healthy individuals. However, it is not known whether these genes play a role in insomnia. We have analyzed the effect of several polymorphisms in clock genes, including the period genes *PER2* and *PER3*, the circadian locomoter output cycles kaput *(CLOCK)* gene, and the gene for the adenosine A2a receptor *(ADORA2A)* on sleep parameters in 192 individuals between the ages of 18 and 64 years diagnosed with primary insomnia. Polysomnographic assessments measuring sleep efficiency, onset and maintenance, and sleep architecture were conducted in a sleep laboratory for 2 consecutive nights. Diurnal preference using the Owl-Lark questionnaire was also evaluated. Polymorphisms in several clock genes were found to influence sleep characteristics as well as diurnal preference in patients with insomnia. These results indicate that polymorphisms in sleep-regulating genes may not only play a role in advanced/delayed sleep phase syndrome but may also be important in primary insomnia. These findings also suggest contributions of common polymorphisms to the pathophysiology of both circadian rhythm disorders and primary insomnia. A greater understanding of clock-related genes may provide insights into the etiology of sleep disorders.

Conditional Mutant Mouse Models of Human Disease. *S. Rockwood, R. Babiuk, J. Eppig, C. Heffner, C. Lutz, S. Murray, M. Ringwald, M. Sasner, Y. Sharma* Genetic Research Science, The Jackson Laboratory, Bar Harbor, ME.

Genetically modified mice have greatly contributed to our understanding of basic biology and disease processes. In order to facilitate access to these mice, the Mouse Repository at The Jackson Laboratory was established to serve as a centralized resource for the archiving and distribution of genetically engineered mice at a high health status. As the number and complexity of alleles increase, so does the importance of providing adequate information to facilitate their selection and use. Conditional mutants represent a significant portion of the new alleles reposited; many have floxed alleles and serve as models of human disease such as: *Smn1*, Spinal Muscular Atrophy; *Mecp2*, Rett Syndrome; *Sirt1*, aging research; the RosaHD strain (JAX Stock7708) that expresses a neuropathogenic polyQ-mutant variant of the human Huntingtin protein (mhtt-exon1; 103Q) upon exposure to Cre recombinase. Others are experimental tools such as Brainbow mice (JAX Stocks 7901,7910,7911,7921), where Cre-induced recombination causes individual neurons to be uniquely and stably labeled with one of over 100 colors to enable studies of neuronal lineage and connectivity. Equally important are the Cre-expressing strains that are used in conjunction with these mutants. Because most of the existing Cre strains have not been fully characterized and ectopic expression of Cre can confound analysis of experimental results, we have undertaken a project to comprehensively characterize Cre activity in embryonic and adult mouse tissues. We will present a database of Cre expression data that includes images and expression patterns curated with terms from the Mouse Anatomical Dictionary, and an online interface searchable by site of Cre expression in various developmental stages. Donating a strain to the Repository fulfills the NIHs requirements for sharing of mice. Researchers wishing to have strains considered for inclusion in the Repository may submit their strains at: http://www.jax.org/grc/index.html. Support for this project has been provided by the NCRR (RR09781, RR11083, RR16049), NIA, HHMI, The Ellison Medical Foundation and from private charitable foundations.

Joint analysis of germline variants in the IGF pathway and prostate cancer risk. *S. Lindstrom, P. Kraft* Harvard School of Public Health, Boston, MA.

Technological advances have enabled researchers to genotype large numbers of Single Nucleotide Polymorphisms (SNPs) for assessment of association with different outcomes. These variants are often tested individually but joint analysis of multiple SNPs may be more powerful to detect association if marginal effects are small and interaction effects exist (i.e. epistasis). However, the ability of detecting SNP-SNP interaction is highly dependent on several factors including allele frequency, penetrance, number of causal loci and sample size. The insulin-like growth factor (IGF) pathway has consistently been implicated in prostate cancer. Both plasma levels of IGF1 in blood and genetic variation in genes involved in IGF metabolism have been associated with disease. To elucidate the role of genetic variation involved in the IGF pathway in prostate cancer, we genotyped 591 SNPs from a total of 24 genes in the Breast and Prostate Cancer Cohort Consortium (BPC3). The BPC3 constitutes of seven prospectively collected nested case-control studies, including in total 6,600 prostate cancer cases and 7,500 controls of Caucasian origin. We performed a comprehensive investigation by applying four different statistical methods for simultaneously analyzing multiple genetic variants. These methods included single SNP analysis, forward stepwise logistic regression and kernel machine procedures. We performed the analysis gene by gene as well as on an overall pathway level. Overall, we found no association with the IGF pathway and prostate cancer risk. We discuss the obstacles faced when analyzing multiple SNP interactions on a large scale basis including the impact of missing data, data complexity and computational burden. We also emphasize the importance of large-scale datasets such as the BPC3 in order to identify higher-order interactions in genetic epidemiology. We gratefully acknowledge the BPC3 investigators for access to data.

Pharmacogenetic studies in patients with temporal lobe epilepsy. *M. S. Silva[1], K. M. Siqueira[1], E. Bilevicius[2], R. Secolin[1], F. Cendes[2], I. Lopes-Cendes[1]* 1) Departament of Medical Genetics, Faculty of Medical Sciences, University of Campinas - UNICAMP - Campinas, São Paulo, Brazil; 2) Department of Neurology; Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, São Paulo, Brazil.

Rationale:Mesial temporal lobe epilepsy (MTLE), the most common form of partial epilepsy, is associated with a high proportion of drug-resistant patients. One of the theories to explain the lack of success in the clinical treatment of patients with MTLE suggests that drug transporter genes overexpressed in the blood-brain barrier, such as members of the ATP-binding cassette (ABC) family, could decrease the entry of antiepileptic drugs (AEDs) in the central nervous system (CNS). Furthermore, there is functional evidence that genetic variation, such as single nucleotide polymorphisms (SNPs), can affect the expression of drug transporter genes. The purpose of this study was to evaluate whether SNPs in two drug-transporter genes: ABCB1 and ABCC2, could be associated with pharmacoresistance to AEDs in a large group of patients with MTLE. Methods:We included a total of 101 drug-resistant and 64 drug-responsive MTLE patients. We genotyped 5 SNPs from the dbSNPs database in the ABCB1 gene, and 6 dbSNPs from ABCC2 gene. Genotyping was carried out using the TaqMan system (Applied Biosystems). The significance of allelic association was assessed using logistic regression, logistf function in R environment. Results:Sample power calculation showed an statistical power of 0,98 for the sample studied. Logistic regression showed no significant association between any of the SNPs studied in ABCB1 gene and pharmacoresistance to AEDs. However, logistic regression showed a significant association between an intronic SNP (rs3740067) at the ABCC2 gene and pharmacoresistance to AEDs (p=0.0015); OR = 4.90 (95% CI: 1.48 - 16.2). Conclusion:We could not confirm the previous reported association between polymorphisms in the ABCB1 gene and pharmacoresistance to AEDs in our cohort of patients with MTLE. However, we found a significant association with an intronic SNP in the ABCC2 gene and pharmacoresistance in this group of patients.

microRNAs deregulation in disease progression and neuronal dysfunction in Parkinsons disease. *E. Minones-Moyano[1], S. Porta[2,1], M. Banez-Coronel[1], X. Estivill[1,2,3], E. Marti[1]* 1) Genes and Disease program, Center for Genomic Regulation (CRG-UPF), Barcelona, Barcelona, Spain; 2) Public Health and Epidemiology Network Biomedical Research Center (CIBERESP); 3) Pompeu Fabra University (UPF).

MicroRNAs (miRNAs) are small non-coding RNAs that modulate gene expression. Recent studies link miRNA deregulation to psychiatric disorders and neurodegenerative diseases, including Parkinson disease (PD). The characteristic neuropathological changes associated to PD progress in a topological predictable manner. The degeneration of the nigrostriatal dopaminergic pathway leads to disabling motor manifestations that characterize the symptomatic phase of the disease. The expression levels of some of genes relevant to PD neuropathology, in particular PARK2, PARK7 and SNCA, have been associated to changes in the cell susceptibility to stressing stmuli, such as oxidative stress. In addition, deregulation of the transcriptome has been widely reported in PD brains. Whether these altered expression profiles are associated to miRNA deregulation or dysfunction has not yet been addressed. Here we have analyzed miRNA expression profiles in brain samples of PD to discover gene expression networks modulated by miRNAs relevant in PD neuropathology. Our results show strong downregulation of a specific miRNA in amygdala samples of PD patients at the neuropathological Braak stage V. In the same patients this miRNA was also significantly downregulated in the frontal cortex, an area that presents mild inclusion body pathology. The expression of this miRNA in the cerebellum, a non-affected area, was similar to the control samples. Functional studies showed that downregulation of this miRNA in differentiated neuroblastoma cells leads to a moderate decrease in cell viability. Together, these results suggest that the downregulation of this miRNA positively correlates with the neuropathological changes associated with PD. Changes in the expression of this miRNA may underlie the initial transcriptome deregulation in PD, leading to neuronal dysfunction and disease progression.

Association of MHC region SNPs with airflow obstruction in severe Alpha 1-Antitrypsin Deficiency. *D. DeMeo[1], E. J. Campbell[2], S. I. Rennard[3], T. M. Delorey[1], A. F. Barker[4], M. L. Brantly[5], E. Eden[6], N. G. McElvaney[7], R. A. Sandhaus[8], J. M. Stocks[9], J. K. Stoller[10], C. Strange[11], G. Turino[6], E. K. Silverman[1]* 1) Dept Medicine, Channing Laboratory, Boston, MA; 2) U of Utah; 3) U of Nebraska; 4) Oregon Health and Science U; 5) U of Florida; 6) St. Luke's/Roosevelt; 7) Beaumont Hospital, Dublin; 8) National Jewish Medical and Research Center; 9) U of Texas at Tyler; 10) Cleveland Clinic; 11) Medical U of South Carolina.

Severe alpha 1-antitrypsin deficiency (AATD) (OMIM 107400) is an autosomal recessive condition characterized by variable susceptibility for the development of chronic obstructive lung disease (COPD) in individuals homozygous (PI ZZ) for the deficiency allele. Recently, it has been suggested that COPD may be an autoimmune disease. Although many autoimmune diseases have demonstrated association with Major Histocompatibility Complex (MHC) loci, to date there have been no large scale studies of polymorphic variation in MHC loci in individuals with AATD. We hypothesized that polymorphic variation in the MHC gene rich region of chromosome 6 contributes to the variable susceptibility to develop COPD in PI ZZ individuals. In a cohort of 378 PI ZZ individuals from 167 families, we evaluated 2,360 MHC region SNPs using the Illumina MHC Combined Panel set. All analyses were performed using the pedigree-based association test (PBAT) with covariates for smoking. Spirometric phenotypes included pre- and post-bronchodilator forced expiratory volume in one second (FEV1) as a percent of predicted and the ratio of FEV1/Forced vital capacity (FVC), both key intermediate phenotypes of COPD. Significant associations with spirometric phenotypes ($p<.01$) were identified for SNPs in multiple HLA loci, including HLA-A,-B,-C,-E,-F,-G and -DRA. SNPs in HLA-C approached the threshold for significance defined by a Bonferroni correction for 2,360 SNPs ($p<10-5$). We conclude that HLA genes may be important modifier genes in severe AAT deficiency. These findings suggest that genetic features of autoimmunity may have relevance for the development of COPD. Funding: HL072918, HL68926.

Combined mRNA and miRNA expression profiling of the CNGA3 mouse - a mouse model of cone dystrophies.

M. Bonin[1], K. Schäferhoff[1], S. Poths[1], S. Michalakis[2], M. Biel[2], O. Riess[1] 1) Medical Genetics Dept, Inst. Human Genetics, Tuebingen, Germany; 2) Munich Center of Integrated Protein Science and Dept. of Pharmacy, Munich Center of Integrated Protein Science and Dept. of Pharmacy.

The CNGA3-/- mouse is an animal model lacking the A subunit of the cone specific cyclic nucleotide gated channel. The phenotype is characterized by a loss of cone photoreceptor function and a progressive degeneration of the cones. To elucidate the biological events leading to the loss of photoreceptors we combined mRNA expression experiments with whole genome miRNA expression profiling. Expression analysis of CNGA3-/- and wildtype retinas in 2 age stages was performed using Affymetrix MOE 430 2.0 microarrays. Differential regulated transcripts with a minimum change in expression level of 1.5 fold with a p-value less than 0.05 were obtained and gene regulation networks were generated by the Ingenuity Pathways Analysis software. To verify the data 20 transcripts per time point were analyzed by qRT-PCR. miRNA expression profiling was conducted on a whole genome mouse miRNA array. 496 transcripts were differentially regulated in the retinas of the 4 week old mice and 204 in those of the 8 week old animals. Gene regulation networks revealed misregulations of genes associated with RNA post-transcriptional modification and cellular growth. 90 % of the transcripts chosen for real-time validation could be verified. In the miRNA array analysis of 4 week old mice we found 27 differently regulated miRNAs which have potential target genes included in the differential gene list of our previous transcriptional analysis. Expression analysis of the CNGA3-/- mouse highlighted a misregulation of the phototransduction cascade in accordance with the loss of visual function that characterizes the phenotype. The combination of mRNA and miRNA expression profiling permits a closer monitoring of the neurodegenerative events in the retina occurring during the course of degeneration.

Mutations in the Valosin Containing Protein Gene Result in Vacuolization of Human Myoblasts and Deficiencies in Multiple Cellular Processes. *J. Vesa[1], H. Su[1], W. Fan[2,3], GD. Watts[4], S. Krause[5], MC. Walter[5], JH. Weiss[6], DC. Wallace[2,3,7], VE. Kimonis[1]* 1) Dept. of Pediatrics, Div. of Genetics and Metabolism, University of California, Irvine, CA; 2) Center for Molecular and Mitochondrial Medicine and Genetics, University of California, Irvine, CA; 3) Dept. of Biological Chemistry, University of California, Irvine, CA; 4) Dept. of Orthopedic Surgery, Children's Hospital Boston, Harvard Medical School, Boston, MA; 5) Dept. of Neurology, Ludwig-Maximillians-University, Munich, Germany; 6) Dept. of Anatomy and Neurobiology, University of California, Irvine, CA; 7) Depts of Ecology and Evolutionary Biology and Pediatrics, University of California, Irvine, CA.

Inclusion body myopathy associated with Pagets disease and frontotemporal dementia (IBMPFD) is caused by mutations in the valosin containing protein (VCP). A mutated gene results in progressive proximal muscle weakness, inclusions and vacuoles in muscle fibers, malfunction in the bone remodeling, and premature frontotemporal dementia. VCP is involved in several cellular processes including the degradation of defective proteins. We have studied cellular consequences of VCP mutations in human primary myoblasts. Our results reveal that patients myoblasts accumulate large ubiquitin positive vacuoles that are able to fuse with lysosomes. Lysosomal membrane proteins Lamp1 and Lamp2 are defectively N-glycosylated in patients myoblasts. The maturation processes of mutant cells are affected suggesting that the myopathy in IBMPFD patients may be caused by a defective myotube formation. Additionally, mutant myoblasts show decreased proliferation activity and increased autophagy when cultured in the absence of nutrients, as well as increased apoptosis. Mitochondrial enzyme activities are upregulated in mutant cells suggesting that they attempt to compensate the cumulative energy deficiency. Our results elucidate that VCP mutations result in disturbances in several cellular processes in IBMPFD myoblasts, and these myoblasts can be used to clarify pathological mechanisms resulting in muscle weakness in patients. The observed cellular phenotype of mutant myoblasts can also be utilized as a model to help develop new therapies for IBMPFD.

Mutational spectrum of *TCF4* and cardinal manifestations of Pitt-Hopkins syndrome. *I. Giurgea[1], C. Missirian[2], P. Cacciagli[2], S. Whalen[1], T. Fredriksen[1], T. Gaillon[1], J. Rankin[3], M. Mathieu-Dramard[4], G. Morin[4], D. Martin-Coignard[5], C. Dubourg[6], B. Chabrol[2], J. Arfi[2], F. Giuliano[7], J.-C. Lambert[7], N. Philip[2], P. Sarda[8], L. Villard[2], M. Goossens[1], A. Moncla[2]* 1) INSERM U841 and APHP, Hosp Mondor-CRETEIL, France; 2) INSERM U491 and APHP, Hosp La Timone-Marseille, Fr; 3) Genetics, Royal Devon and Exeter NHS Foundation Trust, UK; 4) Genetics, CHU Amiens-Nord, Fr; 5) Genetics, CH du Mans, Fr; 6) Genetics, CHU Pontchaillou, Rennes, Fr; 7) Genetics, Hosp L'Archet 2, Nice, Fr; 8) Genetics, CHU de Villeneuve, Montpellier, Fr.

Background Pitt-Hopkins syndrome (PHS) appears to be an underdiagnosed, syndromic mental retardation disorder, marked by hyperventilation and characteristic dysmorphism. PHS was shown to be caused by *de novo* heterozygous mutations of the *TCF4* gene located in 18q21. To expand the spectrum of phenotypic features associated with mutations and deletions of *TCF4*, we studied 30 unrelated patients whose phenotype overlapped PHS. **Material and methods** Among a cohort of patients without molecular abnormalities for Angelman, Mowat-Wilson, or Rett syndromes, we selected those with severe mental retardation and one or more of the flowing: PHS dysmorphologic features, microcephaly, epilepsy, and hyperventilation. *TCF4* was analysed by QMF-PCR and sequencing. Larger deletions were characterised by CGH array. All patients were karyotyped. **Results** We identified ten novel mutations in 11 patients. Cardinal manifestations were facial dysmorphism, severe developmental delay, late or absent walking, no speech, microcephaly, strabismus, and myopia. The majority had episodic hyperventilation, happy disposition and repeated mouthing of hands. **Conclusion** We report ten novel mutations, recapitulate the current knowledge of *TCF4* molecular pathology, and implement a *TCF4* database (http://www.LOVD.nl/TCF4). The large number of deletions and small deletions/insertions observed in *TCF4* leads to initiate the molecular study by QMF-PCR. No obvious departure was observed between the patients harboring point mutations and large deletions at the 18q21 locus, further supporting *TCF4* haploinsufficiency as the molecular mechanism underling PHS.

ARC syndrome - Two case reports. *I. M. FURQUIM[1], R. S. Honjo[1], G. Porta[2], A. P. R. Hirschfeld[2], J. R. Vasconcelos[2], D. R. Bertola[1], L. M. J. Albano[1], C. A. Kim[1]* 1) Genetic Unit - HC-FMUSP-São Paulo - Brazil; 2) Hepatology Unit - HC-FMUSP-São Paulo - Brazil.

ARC syndrome is an autosomal recessive multisystem rare disorder. It is characterized by neonatal cholestatic jaundice with a low GGT activity, renal tubular leak and hypotonic-related arthrogryposis. Others features reported variably are ichthyosis, mild dysmorphic signs, absent corpus callosum and recurrent febrile illness. Most patients die by the age of 7 months, but rarely some survive until 16 months with severe developmental delay. Gissen et al. (2006) characterized the molecular features of 62 individuals with ARC from 35 families, the largest cohort studied. Germline VPS33B mutations were found in 28 of 35 families (48 of 62 individuals); heterozygosity was found in the VPS33B locus in some cases of ARC, suggesting the possibility of a second ARC syndrome gene. Several different germline VPS33B mutations were restricted to specific ethnic groups. We studied two infants, both males and first child of non-consanguineous parents, born in good conditions, with normal birth weight and length. The first patient presented with bilateral hip dislocation and joint contractures in elbows and knees and the second had club foot only. Both developed neonatal cholestatic jaundice and renal tubular defects, Fanconi type, after 10 days of age. The liver biopsy revealed paucity of bile ducts and bile plugs in the first patient. He developed ichtyosis by 3 months of age and he is still alive at 5 months. The second patient died at 46 days of life due to recurrent pulmonary infections. A liver biopsy post-mortem showed severe cholestasis with hepatic regeneration and deposit of lipofuscin. Our study reinforces the high morbidity and mortality of ARC syndrome. The diagnosis of ARC syndrome should be considered in every newborn that develops cholestatic jaundice associated to any degree of joint contracture and signs of renal dysfunction. The study of the VPS33B gene is important to confirm the diagnosis and is essential for a proper genetic counselling.

Pathway-Level Analysis in a Genome Wide Association Study (GWAS) of Total Serum IgE Levels. *B. Linsay[1], C. Ober[1], D. L. Nicolae[1,2]* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Departments of Medicine and Statistics, University of Chicago, Chicago, IL.

GWAS are quickly becoming the standard approach for studying the genetics of complex phenotypes. However, they often lack the statistical power to yield p-values small enough to pass stringent thresholds of genome-wide significance. Here, we describe a method of statistical analysis that enhances power by considering the results of a GWAS in a biological context during analysis. This approach uses databases that catalogue biological pathways to group SNPs into smaller, biologically motivated subsets. Each subset of SNPs is examined for an excess of small p-values. To evaluate this method, we performed a GWAS of total IgE levels in 693 Hutterites using the Affymetrix GeneChip Mapping 500k Array. High quality genotypes for 295,307 SNPs with minor allele frequencies 0.05 were analyzed. SNPs were assigned to 150 pathways using the PANTHER Pathway database, and evidence for association in a pathway was quantified using a false discovery rate. Using this pathway-based approach, we identified a significant enrichment of small p-values for SNPs in or near genes involved in a serotonin signaling pathway (p=0.005 after correcting for multiple testing). While additional study is required to confirm these results, our data suggest that a pathway-based method is a useful approach for analyzing GWAS data. Supported by HL56399, HL66533, and HL85197 to C. O. and RR00055 to the University of Chicago GCRC.

CRISPLD2 assessed with multiple orofacial cleft (OFC) phenotypes in multiple ethnicities. *M. L. Marazita[1], M. E. Cooper[1], A. R. Vieira[1], A. Letra[1], R. Menezes[1], M. Mansilla[2], J. C. Murray[2], E. E. Castilla[3], I. M. Orioli[4], A. E. Czeizel[5], R. Martin[6], B. C. Chiquet[7], J. T. Hecht[7]* 1) Univ of Pittsburgh; 2) Univ of Iowa; 3) FIOCRUZ, Rio de Janeiro, Brazil; 4) Fed Univ of Rio de Janerio, Brazil; 5) Fndn Commun Ctl of Hered Dis, Budapest, Hungary; 6) Wash Univ, St. Louis; 7) Univ of Texas Med Sch, Houston.

OFC is a common birth defect with prevalence varying by ethnicity and phenotype. Significant linkage results were found at 16q24 (820 OFC families, LOD=3.55). Thus, we analyzed 4 SNPs in CRISPLD2, a 16q24.1 candidate gene () based on previously reported association in Texas families. Data: Families from Asia (287 China/Philippines), N. America (614 Iowa/Pittsburgh/St Louis/Texas), Latin America (319 Guatemala /S. American registry), and Europe (110 Madrid/Hungary/Turkey) were genotyped using Taqman assays. The Texas data included both Hispanic (82) and Caucasian (262) families. We identified 4 OFC phenotypic subgroups by family history: all affecteds with cleft lip only (CL), all with cleft palate (CP) and CL (CLP), both CL and CLP in the family (CLCLP), and at least one affected with CP only (Palate). A combination of CL, CLP and CLCLP subgroups totals CL with or without CP (CL/P). Association analyses (allelic and genotypic TDT using FBAT) were performed for all cleft and population subgroups. Results: None of the association results met the Bonferroni-adjusted alpha level for significance (0.0025). Of interest, Asian groups showed near-significant association with Palate (rs1546124 common allele G, G/G genotype; $p<0.004$). Latin American and Hispanic groups also had borderline association with Palate but with the opposite allele than in Asians (rs1546124 common C allele and C/C genotype; $p=0.03$). Non-Hispanic Caucasian North American groups showed borderline association with CLP and CL/P (rs1546124 common C allele; $p<0.03$). Conclusions: These results continue to suggest that CRISPLD2 may be involved in risk of OFC. Further genotyping and expression studies are necessary to further characterize the involvement of CRISPLD2 and to identify the causal variant(s). DE09886, DE08559, DE016148, DE016930, DE016215.

A role for genetic variation at HOMER2 in schizophrenia: further evidence from Irish and other European populations. *W. P. Gilks, E. H. Allott, M. Gill, A. P. Corvin, D. W. Morris, The International Schizophrenia Consortium*
Neuropsychiatric Genetics, Department of Psychiatry and Institute for Molecular Medicine, Trinity College Dublin, Ireland.

SCHIZOPHRENIA (SZ) is a complex disorder of uncertain aetiology but which may involve dysfunction at glutamatergic synapses of the brain. Based-on linkage and proteomic data we identified HOMER2 (OMIM 604799) as a plausible candidate gene for SZ. Homer2 proteins localise to the post- synaptic density linking glutamate receptors with the cytoskeleton. We previously reported evidence of association at HOMER2 in a sample of 375 cases and 812 cases from Ireland (Gilks et al. 2007 World Congress in Psychiatric Genetics XV). The best result was an allelic association at rs869498 ($p=0.016$, OR 1.39). Three other SNPs (rs1817658, rs12913501 and rs2306428) were also associated ($p<0.05$, OR1.2) and independent of LD (r2 cut-off 0.7). The strongest haplotypes were (rs2306428- rs12913501, $p=9x10^{-4}$ and rs869498- rs1871658, $p=0.0025$). The International Schizophrenia Consortium have conducted a genome-wide association study of schizophrenia using 3,380 cases and 3,593 controls from Europe (Affymetrix 5.0 and 6.0 platforms). Across HOMER2, 44 SNPs were genotyped of which 11 were associated with disease status at $p<0.05$. Of our four previous LD-independent associations, two (at rs2306428 and rs869498) were reproduced by proxy (rs17158194, $p=0.001$, OR 1.15 and rs17158155, $p=0.02$, OR 1.27 respectively). We have also found evidence for association in this dataset at genes regulated by HOMER2 . These data support a role for HOMER2 in SZ susceptibility and further genetic and functional studies are warranted to investigate molecular pathways involving HOMER2 in SZ.

Regulatory mechanisms of the expression of WNK1, a serine-threonine kinase involved in Familial Hyperkaliemic Hypertension (FHHt). *E. E. Elvira-Matelot[1,2,3], C. D. Delaloy[1,2,3], X. Z. Zhou[1,2,3], X. J. Jeunemaitre[1,2,3], J. H. Hadchouel[1,2,3]* 1) INSERM U772; 2) College de France; 3) Universite Paris Descartes.

The genetic study of Familial Hyperkalaemic Hypertension (FHHt), a rare form of hypertension, revealed a new mechanism of blood pressure regulation, through the identification of WNK1 and WNK4. These kinases, expressed in the renal distal tubule, play a complex role in renal ionic transport regulation. WNK1 and WNK4 mutations were found in only two of the 34 FHHt families recruited by our group. WNK1 gives rise to long isoforms ubiquitously expressed (L-WNK1) from the proximal promoters P1 and P2, and to a short renal isoform (KS-WNK1) from the promoter rP. FHHt mutations are large deletions in the first intron 1 of WNK1. We showed that these deletions lead to an overexpression of L-and KS-WNK1 in the DCT and to a generalized ectopic expression of KS-WNK1. These data suggest the presence in intron 1 of one or several repressor and/or insulator elements. Our first objective was to identify and characterize these different elements. Five conserved non-coding sequences (C1-5) were identified in intron 1 by cross-species sequence comparison. Transfection assays showed that C1 represses rP transcriptional activity while C5 plays the role of an insulator. FHHt could therefore be the consequence of the deletion of at least one repressor and one insulator. Our second objective was to study more generally the different mechanisms regulating the expression of WNK1 in order to identify other sequences potentially mutated in the remaining FHHt patients. In silico analysis identified in the 3UTR region of WNK1 target sequences for micro-RNAs miR-192 and miR-215. We showed in vitro that these miRs could negatively regulate WNK1 expression at the post-transcriptional level. We also showed that potassium and sodium intake modulates the expression of WNK1 and these miRs. We are now studying the detailed miRs expression pattern and their contribution to WNK1 regulation in vivo.

Association-study of polymorphisms in the GAD2 gene-region in patients with anxiety-disorder, unipolar depression and healthy controls. *P. G. Unschuld, M. Ising, M. Specht, A. Erhardt, S. Ripke, A. Heck, S. Kloiber, T. Brueckl, B. Müller-Myhsok, F. Holsboer, E. B. Binder* Max Planck Institute of Psychiatry, Kraepelinstr.2-10, 80804 München, Germany.

Glutamate decarboxylase (GAD) is the rate limiting enzyme for conversion of glutamic acid to gamma-aminobutyric acid (GABA). GABA is the major inhibitory neurotransmitter in the vertebral central nervous system and a promising target for anxiety medications. The GAD 65kDa isoform is encoded by the gene GAD2 and is mainly expressed in synaptic terminals. It serves as an apoenzyme, which shows enhanced availability in situations of stress, responding to short term demands for GABA. We analyzed 18 single nucleotide polymorphisms (SNPs) in the GAD2-gene region and derived nine tagging SNPs. These nine SNPs were evaluated for associations with psychiatric diagnosis and behavioral inhibition (BI) derived from the personality traits neuroticism and extraversion as defined by the Eysenck Personality Questionaire (EPQ). A total of 268 patients with anxiety disorder (AD) and 537 with unipolar depression (MD) and 545 matched healthy controls, were analyzed for disease associations. 413 of these patients and 537 healthy controls were further analyzed for associations with BI. We observe significant associations for five tag-SNPs with behavioral inhibition in the AD- and control samples as well as one additional case-control association in the MD-sample. One associated tagging-SNP lies within a 16kb linkage disequilibrium-block, including putative 5 GAD2-promotor-elements as well as the 3 end of the gene MYO3A. Using Hap-map expression data we could show that BI-associated SNPs appear to be associated with differences in MYO3A- but not GAD2 lymphocyte-mRNA expression levels. These results support earlier studies that suggest associations of polymorphisms within the GAD2 locus with anxiety and affective disorders. However, data from expression studies may indicate that these polymorphisms could tag functional effects on the neighboring gene MYO3A, which is also expressed in the brain, including the cingulate cortex and the amygdala.

Comparison of genotyping consistency between genomic and whole-genome amplified DNA using the Illumina GoldenGate and Infinium-II assays. *P. Hoffmann[1,2], S. Herms[1], M. Alblas[1], K. Kemmerling[1], T. W. Mühleisen[1], M. M. Nöthen[1,2], S. Cichon[1,2]* 1) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 2) Institute of Human Genetics, University of Bonn, Bonn, Germany.

High-throughput SNP genotyping has become an important research strategy in human genetics. Although most genotyping assays require minimal amounts of DNA, repeated use often leads to depletion of the mostly irreplaceable samples. To address this problem whole-genome amplification technologies have been developed in the last years and are meanwhile commercially available. Albeit the amplification seems to be mostly successful, it is controversially discussed whether the whole genome amplified DNA (wgaDNA) represents an exact copy of the genomic DNA (gDNA) template. In the present study, we aimed to assess the genotyping consistency between 45 wgaDNAs (generated using the REPLI-g DNA Amplification Kit, Qiagen, Hilden) and their corresponding gDNA samples. The gDNAs were of different age and quality. In a first step we compared genotype consistency between wga and gDNA. in 20 high quality sample pairs genotyped using Illuminas HumanHap550V3.0 BeadChips (565.000 SNPs) and 25 sample pairs of different DNA quality genotyped for 384 SNPs using Illuminas GoldenGate assays. All samples genotyped on the BeadChips performed well, with average call rates of >99%. The average consistency between gDNA and wgaDNA was 99.99% when comparing SNPs successfully genotyped in the corresponding samples. Of the 25 sample pairs genotyped with GoldenGate assays, 22 performed well with average call rates >99% (gDNA) and >98% (wgaDNA). Genotype consistency between wga and gDNA was 100% for all SNPs successfully genotyped in both corresponding samples. The remaining 3 sample pairs showed noticeably worse results with an average genotype call frequency of 99.8% (gDNA) versus 60.1% (wgaDNA) and a genotype consistency of only 89%. Possible explanations for the observed discrepancies are age of gDNA, extraction method as well as presence of unknown inhibitors interfering with the amplification process.

Genomic rearrangements encompassing and upstream of *SHOX* identified using MLPA and a newly developed qPCR assay. *B. D'haene[1], M. Craen[2], J. De Schepper[2, 5], K. Devriendt[3], G. Massa[4], J. P. Fryns[3], K. Keymolen[5], B. A. Bejjani[6], A. de Klein[7], E. M. De Jong[7], B. Loeys[1], J. G. Leroy[1], G. Matthijs[3], L. Mutesa[8], K. Segers[8], P. Willems[9], N. Van der AA[10], A. De Paepe[1], G. Mortier[1], E. De Baere[1]* 1) Ctr Medical Genetics, Ghent Univ Hosp, Ghent, Belgium; 2) Dpt of Pediatrics, Ghent University Hospital, Belgium; 3) Ctr for Medical Genetics, University of Leuven, Belgium; 4) Virga Jesse Hospital, Hasselt, Belgium; 5) Ctr for Medical Genetics, Free University of Brussels, Belgium; 6) Signature Genomic Laboratories, WA, USA; 7) Clinical Genetics, Erasmus MC, Netherlands; 8) Ctr for Human Genetics, University of Liège, Belgium; 9) Gendia, Antwerp, Belgium; 10) Ctr for Human Genetics, University of Antwerp, Belgium.

The human *SHOX* gene is the only known disease gene within the pseudoautosomal region 1 (PAR1) of the sex chromosomes. Haploinsufficiency of this gene due to intragenic mutations, total gene deletions or microdeletions upstream of *SHOX* has been reported in patients with idiopathic short stature (ISS) and Leri-Weill dyschondrosteosis (LWD). We screened 161 patients with ISS, LWD and some other indications for copy number variations of the *SHOX* region using MLPA (P018, P018B and P018C, MRC-Holland) and/or quantitative PCR (qPCR) with 11 amplicons for the *SHOX* gene and PAR1 region. Using MLPA we identified a copy number change in 17 patients, including 10 *SHOX* deletions, 4 duplications and 3 upstream deletions. Second, a new qPCR assay for the *SHOX* region was developed and validated. Using this we identified 5 new rearrangements, including 3 deletions and 2 duplications of *SHOX*. Overall, a genomic rearrangement in the *SHOX* region was found in 14% (22/161) of the probands. In this study we designed and validated a new qPCR assay for *SHOX* and the PAR1 region. This technique is very flexible in terms of adding new amplicons, and does not require parental DNA as compared to microsatellite analysis. Our assay is an alternative strategy for the identification of genomic rearrangements in LWD and ISS that can be applied in both research and clinical settings.

Analysis of polymorphic variations in genes of the dopamine and serotonin pathways with iloperidone efficacy in the treatment of patients with schizophrenia. *S. Volpi, K. Mack, C. Lavedan* Vanda Pharmaceuticals, Inc, Rockville, MD.

Schizophrenia is a chronic, severe, and disabling disorder that affects about 1% of the population worldwide. Molecular components of the dopaminergic and serotoninergic systems are believed to play an important role in the pathophysiology of schizophrenia and the mechanisms of action of antipsychotics. Iloperidone is a novel mixed D2/5-HT2 antagonist with significant affinity for the dopamine D2 *(DRD2)* and D3 *(DRD3)* and the serotonin 5-HT2A *(HTR2A)* receptors. It has moderate affinity for the D4 *(DRD4)* receptor and low affinity for the serotonin 5-HT2C *(HTR2C)* and 5-HT1A *(HTR1A)* receptors. In an ongoing effort to identify patients with schizophrenia who could benefit the most from iloperidone treatment, a pharmacogenetic analysis was conducted in a phase III clinical trial to discover genetic markers predictive of response. We investigated the effect of various DNA polymorphisms in genes suspected to play a role in schizophrenia and/or antipsychotic treatment response on iloperidone efficacy: *DRD2* (-241A/G, -141C Ins/Del, His313Cys), *DRD3* (Ser9Gly), *DRD4* (-521C/T), *HTR1A* (-1019C/G), *HTR2A* (102T/C) and HTR2C (-759C/T). A general linear model analysis of variance was performed by genotype on improvement of symptoms assessed by the Positive and Negative Syndrome Scale (PANSS) Total score. None of the polymorphisms evaluated were found to be significantly associated with iloperidone efficacy. These results suggest that the genetic variations tested in this study do not contribute significantly to inter-individual differences in the therapeutic efficacy of iloperidone; genetic markers of response for a particular drug may not be applicable to the whole class of antipsychotics, reflecting differences in receptor binding profiles and in chemical and metabolic characteristics. In addition, these findings support the application of pharmacogenetics to differentiate medication options and improve individualized treatments for schizophrenia.

Gene-gene interaction between Parkin and NOS2A in Parkinson disease. *L. Wang, G. Mayhew, A. Burt, M. Slifer, G. Wang, S. Zuchner, W. Scott, J. Vance, E. Martin* Miami Inst Human Gen, Univ Miami,Miller Sch Med, Miami, FL.

Exonal deletions and duplications (del/dup) in Parkin cause autosomal recessive early-onset Parkinson disease (PD). A synonymous single nucleotide polymorphism (SNP), rs1060826, in the NOS2A gene has shown association with sporadic PD in Finnish, French and United States populations. The protein product of NOS2A, inducible nitric oxide synthase, is responsible for massive production of nitric oxide (NO). Excessive NO leads to S-nitrosylation of parkin, the post-translational modification which inhibits parkins ubiquitin E3 ligase activity and leads to abnormal accumulation of misfolded proteins Therefore, we hypothesize that variants in Parkin and NOS2A interact in their contribution to PD risk. To test this hypothesis we investigated gene-gene interaction between polymorphisms in NOS2A and del/dup of Parkin in a sample of 757 PD probands (drawn from our family sample) and 176 unaffected controls. Parkin del/dup was measured using real time PCR. For this analysis, we scored an individual as a Parkin mutation carrier if they carry any del/dup in the gene. We studied 18 HapMap tagSNPs in NOS2A previously genotyped in our entire family-based samples. We conducted case-only analysis as our primary gene-gene approach due to the low frequency of Parkin mutations in controls. We found evidence of interaction between Parkin del/dup status and two synonymous SNPs in NOS2A (rs1137933, p=0.044 and rs1060826, p=0.024). Inspection of NOS2A genotype frequencies shows that NOS2A genotypes in controls are similar to PD probands with Parkin del/dup (p=0.718) but are significantly different from PD probands without a Parkin del/dup (p=0.033). These results suggest that NOS2A variants exert their effects only in individuals without a Parkin del/dup. This could indicate that the variants in NOS2A increase PD risk through altering the function of wild type parkin by S-nitrosylation of the protein. Our study highlights the interaction between NOS2A and parkin in PD. This interaction has important implications for future analysis of these genes and our understanding of the molecular mechanism underlying the etiology of PD.

Large deletions account for a significant fraction of mutations in Marfan syndrome. *B. M. Rhode[1], L. Föhse[1], M. Stuhrmann[1], D. Steinemann[2], T. Hellwig[1], A. Hein[1], J. Schmidtke[1], M. Arslan-Kirchner[1]* 1) Institute of Human Genetics, Hannover Medical School, Hannover, Germany; 2) Institute of Cell and Molecular Pathology, Hannover Medical School, Hannover, Germany.

Marfan syndrome (MFS, OMIM 154700) is caused by heterozygous mutations in the *FBN1* gene. Cardinal features involve the ocular, cardiovascular and skeletal systems. Overlapping syndromes such as the Loeys-Dietz syndrome (LDS1A, OMIM 609192; LDS1B, OMIM 610168; LDS2A, OMIM 608967; LDS2B, OMIM 610380) are caused by mutations in the *TGFBR1* or *TGFBR2* genes and show either a Marfan-like phenotype (LDS2A, LDS2B) or a more severe phenotype characterized by arterial tortuosity and aneurysms as well as craniofacial involvement (LDS1A, LDS1B).

We screened over 600 patients with suspected Marfan syndrome or Loeys-Dietz syndrome for a mutation in the *FBN1* and/or the *TGFBR1* and *TGFBR2* genes by direct sequencing and present a selection of previously not described mutations in these genes. The detection rate of mutations in the *FBN1* gene in patients with Marfan syndrome lies between 70 to 90%, while sequencing of the *TGFBR1* and *TGFBR2* genes adds another 5 to 10%. In 91 patients, we applied MLPA (multiplex ligation-dependent probe amplification) to screen for large deletions in the *FBN1* and *TGFBR2* genes. All patients were tested negative for a mutation in *FBN1* by sequencing. 60 of these patients were also tested for a mutation in the *TGFBR1* and *TGFBR2* genes by sequencing, and were found to be negative for such a mutation. To date, we have identified six large deletions in the *FBN1* gene (exons 24-26, 50-54, 55-58, 58-63, 1-65, and 6-65). Breakpoints of the deletions were either determined by long-range PCR techniques followed by sequencing or by high resolution array CGH. Patients phenotypes range from a classical syndrome spectrum to a severe neonatal Marfan syndrome. The detection rate of deletions in this pre-screened patient group is 6.7%. Our MFS patient cohort thus harbors the highest *FBN1* deletion rate reported so far. Our data suggest that the overall mutation detection rate in patients with Marfan syndrome can be increased significantly by MLPA analysis.

Tissue Specific Genetic Variation and Vulnerability To Disease: The BAK Gene and Abdominal Aortic Aneurysms. *M. Schweitzer[1,2,3], L. E. Chalifour[1,2,3], B. Gottlieb[2,4]* 1) Sir Mortimer B. Davis -Jewish General Hospital, Montreal, PQ, Canada; 2) Lady Davis Institute for Medical Research, Montreal, PQ, Canada; 3) Dept., Medicine, McGill University, Montreal, PQ, Canada; 4) Dept., Human Genetics, McGill University, Montreal, PQ, Canada.

Abdominal aortic aneurysm (AAA) is a multifactorial disease with both genetic and environmental factors playing crucial roles in disease ontogeny. We sought to examine why the abdominal aorta is more susceptible (80 percent) to aneurysms than other arteries. To examine the role of genetics, we studied sequence variation in the BAK gene (*BAK*) that codes for an apoptotic-promoting protein, as apoptosis activation has been linked to AAA development and progression. We sequenced *BAK* cDNA from 31 patients as well as from non-diseased individuals and compared the *BAK* abdominal aorta cDNA sequence to *BAK* genomic sequence obtained from matching blood samples. Our results revealed specific *BAK* alterations (SNPs) in both healthy abdominal aortic tissue as well as aneurysms, which were not present in the matching blood samples. These same *BAK* SNPs have been reported, though rarely, in reference *BAK* DNA sequences. Our results suggest that in diseases such as AAA, tissue disease susceptibility is related to pre-existing genetic alterations that are selected for in specific tissues. Based on this and other similar observations, we propose a new hypothesis, for the origin of tissue-specific diseases that can help explain the role of both environmental and genetic factors. Our hypothesis postulates that mutant genes preexist in minority forms within non-diseased tissues and are selected for, when tissue and cellular conditions change. We believe that such a theory can better help explain the ontogeny not only of cardiovascular diseases, such as AAA, but other multifactorial diseases as well.

Microarray analysis of candidate genes in a child with 18p subtelomeric deletion and atypical early onset of dystonia and neuroregression. *E. Cole, J. Y. Lee, S. Li, S. E. Palmer* Dept. of Pediatrics, Section of Genetics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK.

18p- syndrome, like most deletion syndromes, is usually considered a static disorder. However, a few patients with large 18p deletions on karyotype have developed dystonia, with onset from adolescence to adulthood. All deletions included distal 18p, some confirmed by subtelomere FISH. Severity of dystonia varied from mild to mostly disabling. We report a female with normal karyotype and smaller 18p deletion diagnosed by subtelomeric FISH. Presenting features were developmental delay, seizures, hypotonia, and mild dysmorphic features. Before age 3 years, she developed dystonic and choreoathetotic movements much earlier than reported; this was accompanied by atypical neuroregression of all milestones. Work-up of the neurologic features has been non-diagnostic. The etiology of dystonia in 18p- patients was reconsidered. Whole genome oligo array CGH showed this patients deletion was estimated at 2.7 Mb involving p terminus to p13.11. This includes approximately 21 known genes; all but one have no known association to human disease, although several have proposed roles in neurologic function. The deletion includes most of the *DYT7* locus reported to be linked to an autosomal dominant late-onset distal focal dystonia, with a phenotype much milder than the dystonia reported in most 18p- patients. Several of the case reports of 18p- with dystonia have shown their larger deletions also include the *DYT7* locus. The 18p dystonia locus, *DTY15*, is more proximal and not deleted here. This patients much smaller deletion supports the hypothesis that a gene for disabling dystonia in 18p- maps just to the subtelomeric region; whether *DYT7* is the same gene remains unclear due to its milder phenotype. The earlier onset of dystonia with additional atypical neuroregression in this child raises the question of the exact frequency, severity, type, and age range of onset of movement disorder in the natural history of these patients. The identification of the deleted genes now localized to a much smaller ~2.7 Mb region provides the basis for additional studies of candidate genes for this dystonia.

Genomic Approaches to Identifying the Molecular Basis of Morphological Variation in Avian Beaks. *K. Powder[1], S. Brugmann[2], J. Helms[2], M. Lovett[1]* 1) Washington Univ, St Louis, MO; 2) Stanford Univ, Stanford, CA.

Vertebrates, particularly birds, exhibit remarkable facial variation. Previous work by JH used cell grafting to show that cranial neural crest (NC) cells transplanted between embryonic quails and ducks developed facial features reminiscent of the donor species. This showed that NC cells provide facial patterning information, but left unresolved which specific genes or pathways differ between these species. Here we describe the molecular signatures, pathways and transcription factor (TF) gene expression changes between NC populations of the presumptive beak in three bird species (chicken, duck, and quail) at two developmental stages. We observed that prior to morphological distinctions between the species, NC cells have established a species-specific gene expression profile that is largely unchanged even to stages when morphological differences are evident. 335 genes were differentially expressed (>2-fold with p-values < 0.05) between the three species. The majority of these genes (145) and those with the largest fold changes were differentially expressed in the duck compared to the chicken and quail. Known developmental pathways such as TGF and Fgf, plus an additional 24 previously identified regulators of craniofacial development, exhibited large changes between species. We also observed large changes in 74 TF genes with, as yet, unknown functions. Duck NC cells show a dramatic 20-fold up-regulation of the WNT signaling components *Dkk2*, *Fzd1*, *Wnt1*, and *Wnt10b*, and a 10-fold up-regulation of the putative WNT interactors *Klhl12* and *Tbx20*. The *Calmodulin1* and *Calmodulin2* genes, previously shown to contribute to elongated beak shapes in Darwins finches, are down-regulated in the duck relative to the other two species. We confirmed microarray observations by RNA in situs that also revealed differences in spatial patterns of expression. We have further investigated the pathways of beak development by knocking down differentially expressed TFs using siRNAs in NC cell populations. By conducting gene expression analysis on knockdowns, we have begun to identify novel interactions between TF genes involved in vertebrate facial development.

New analytic methods to detect a polygenic or locus specific genetic effect from large families adjusting for non-genetic environmental factors: single and multiple trait cases. *H. Lee*[1], *M. C. Paik*[2], *J. P. Krischer*[1] 1) Pediatrics Epidemiology Center, University of South Florida, Tampa, FL; 2) Department of Biostatistics, Columbia University, New York, NY10032, U.S.A.

New analytic methods for quantitative genetics are proposed using regression models for correlation parameters, which is proper for large family studies. We interpret conventional heritabilities as regression parameters adjusting for subject or pair specific non-genetic differences. This approach provides statistical tests robust to normality assumption on quantitative traits. For single trait analysis, we implement the efficient three generalized estimating equations (efficient 3GEEs) proposed by Lee et al.(2008a), and for multiple trait analysis, the method for multivariate familial correlation analysis proposed by Lee et al.(2008b) is applied. The example data in SOLAR manual were used to illustrate our proposed methods.

Genetic testing for Leber Congenital Amaurosis (LCA): a 3-year experience. *F. Coppieters[1], T. de Ravel[2], I. Casteels[3], F. Meire[4], N. Van Regemorter[5], S. De Jaegere[1], A. De Paepe[1], P. Coucke[1], B. P. Leroy[1,6], E. De Baere[1]* 1) Ctr for Medical Genetics Ghent, Ghent University Hospital, Ghent, Belgium; 2) Ctr for Human Genetics, Leuven University Hospitals, Leuven, Belgium; 3) Dept of Ophthalmology, Leuven University Hospitals, Leuven, Belgium; 4) HUDERF, Hopital Des Enfants Reine Fabiola, Brussels, Belgium; 5) Centre de Génétique de Bruxelles, Free University of Brussels, Brussels, Belgium; 6) Dept of Ophthalmology, Ghent University Hospital, Ghent, Belgium.

LCA is genetically highly heterogeneous with an involvement of large disease genes, which hamper genetic testing. The purpose of this study was to determine the prevalence of mutations in 6 common LCA genes in 98 LCA patients, mainly of Belgian origin, in order to optimize a genetic screening strategy for LCA. First, LCA chip screening revealed a mutation in 34% of all patients. Second, direct sequencing of *AIPL1*, *CRB1*, *CRX*, *GUCY2D*, and *RPE65* in chip-negative tested patients revealed causal mutations in 3%. Third, we performed targeted mutation analysis of *CEP290* mutation c.2991+1655A>G. We found this mutation in both homozygous (2/98) and heterozygous (16/98) state. A second mutation was identified through sequencing of the total coding region. Subsequently, the remaining patients were screened for 4 additional recurrent *CEP290* mutations. The allele frequencies of the most common mutations p.Lys1575X and c.[3310-1G>A;3310C>A] were respectively 13% and 9%. Finally, sequencing of the total coding region of *CEP290* is being performed in the remaining cases. So far, this revealed a homozygous mutation in one case. In addition, we identified *RDH12* mutations in 2 families with early-onset retinal dystrophy, and *CEP290* mutations in 3 families with Senior-Loken syndrome. In conclusion, we found both disease causing mutations in 59% of all LCA patients (22% in *CEP290*; 18% in *CRB1*; 8% in *RPE65*; 6% in *GUCY2D*; 3% in *AIPL1* and 2% in *CRX*). A combined genetic testing strategy consisting of LCA chip analysis and targeted mutation screening of 3 recurrent *CEP290* mutations represented an efficient first-pass screening, revealing causal mutations in 55% of our LCA population.

An in vivo unbiased screen for enhancer activity using lentivector-mediated transgenesis. *M. Friedli[1,5], I. Barde[2,5], C. Attanasio[1,5], A. Quazzola[2,5], S. Verp[2.5], M. Arcangeli[1,5], F. Spitz[3,4,5], J. Zakany[3,5], D. Duboule[2,3,5], D. Trono[2,5], S. E. Antonarakis[1,5]* 1) Genetic Med & Development,Univ Geneva,Geneva,CH; 2) School of Life Sciences,EPFL,Lausanne,CH; 3) Department of Zoology and Animal Biology, University of Geneva, CH; 4) EMBL,Heidelberg,Germany; 5) National Research Centre Frontiers in Genetics.

Finding sequences that control spatial and temporal expression of genes is important to understand genome function. Here, we present an in vivo screen for enhancers in a contiguous 200 kb DNA fragment using lentivector-mediated transgenesis. Previous studies have used evolutionary conservation as an indicator of regulatory potential, but increasing evidence suggests that this criterion systematically overlooks functional sequences. We thus designed our study without any bias towards a particular sequence feature. We chose a mouse BAC corresponding to a region of Hsa21 because it contains the olig genes that are expressed specifically in the CNS. In order to screen systematically for enhancer activity, we generated a library of 134 overlapping clones in a LacZ reporter lentiviral construct containing a minimal promoter. We generated lentivectors individually for each segment and injected them in pools of 10 or 20 in mouse oocytes. LacZ staining was performed on E11 embryos to identify expression patterns. The seven pools tested yielded 70 of 301 LacZ positive embryos with ~2.5 transgenes per embryo. Several fragments of the 64 assessed were identified that potentially contain gene expression regulators. Individual injection of candidates confirmed 2 elements (one evolutionary conserved) as tissue specific enhancers with stainings in the spinal chord/brain and trigeminal ganglion compatible with olig expression. For one element, orthologous human and chicken sequences were injected and showed similar expression patterns, demonstrating that these activities are conserved in other species. ISH confirmed that these elements likely contribute to the expression pattern of olig genes. The method could be scaled up to cover large chromosomal regions, and determine what fraction of the constrained and non-constrained genome has regulatory potential.

Rare copy number variants reveal novel candidate genes for schizophrenia. *T. Vrijenhoek[1], J. E. Buizer-Voskamp[2, 3], I. van der Stelt[1], R. S. Kahn[4], C. Sabatti[5], R. A. Ophoff[3, 6], J. A. Veltman[1]* 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Rudolf Magnus Institute of Neuroscience, Department of Psychiatry, University Medical Centre Utrecht, Utrecht, The Netherlands; 3) Complex Genetics Section, DBG-Department of Medical Genetics, University Medical Centre Utrecht, Utrecht, The Netherlands; 4) Division of Neurosciences, Department of Psychiatry, University Medical Centre Utrecht, Utrecht, The Netherlands; 5) Department of Human Genetics, University of California, Los Angeles, USA; 6) Centre for Neurobehavioral Genetics, University of California, Los Angeles, USA.

Schizophrenia is severe psychiatric disease with complex etiology, affecting approximately one percent of the general population. Most genetic studies so far focused on disease association with variation at the SNP level, but it has become apparent that genomic copy number variants (CNVs) may be involved in disease susceptibility as well. To assess the role of CNVs in schizophrenia, we screened 54 patients with deficit schizophrenia with Affymetrix GeneChip© 250K SNP arrays. We identified in total 90 CNVs, 76 of which have been reported previously to be present in the general population. Among the genes disrupted by the 14 rare CNVs are MYT1L, CTNND2, NRXN1 and ASTN2, three of which have never been associated before with schizophrenia. These genes play an important role in neuronal function, including axon guidance, neuron adhesion and neuron migration, and they are highly expressed in the brain. We further studied these regions in a cohort of 752 patients and 706 controls from The Netherlands and identified an additional 7 patients and 1 control subject with CNVs affecting these same loci (Combined P = 0.007; OR = 9.7). Our study supports the role of rare variants involved in schizophrenia susceptibility and identifies three novel candidate genes important in brain development.

Optimal methods to map quantitative trait loci using extreme trait values. *D. Covarrubias[1], S. M. Leal[2]* 1) Department of Statistics, Rice University, Houston, TX; 2) Molecular and Human Genetics, Baylor College Med, Houston, TX.

For mapping quantitative trait loci, one study design is to select a subset of individuals with extreme high and low quantitative trait (QT) values. This study design has been implemented to increase power while reducing the number of individuals who are either genotyped or sequenced. This study design was recently used to identify genes for HDL cholesterol and cardiovascular disease. There are several frameworks for extreme QT sampling which can be used: phenotyping study subjects until a set sample size of individuals meeting a predefined QT criterion are obtained, or using an existing sample and analyzing only a subset of individuals based upon a QT threshold. For this study, we examined the latter sampling framework for a variety of sampling proportions, allele frequencies and total sample sizes. Thresholds which optimize power were determined when the QT is dichotomized. Additionally, type I and II error was evaluated for ANOVA, linear regression, Cochran-Armitage test for trend, and ^{2} test of independence. For the analysis of QTs the highest power is obtained when the entire sample is analyzed and the power decreases with increasing extreme QT sampling. When the QT is dichotomized, using only those individuals with the highest and lowest QT values, the optimal power is obtained when ~50% of the total sample is analyzed. For this situation, the ^{2} test is most powerful when the underlying genetic model is either recessive or dominant; however for an additive model the Cochran-Armitage test for trend is the most powerful. If thresholds of > 25% are used for sampling, linear regression is the most powerful test among those evaluated however ANOVA may have superior power in some situations. Additionally for all the test which were assessed type I error was well controlled.

Grammatical Evolution Neural Networks (GENN) to detect gene-gene and gene-environment interactions that predict quantitative traits. *N. E. Hardison, A. A. Motsinger-Reif* Bioinformatics Research Center, Department of Statistics, North Carolina State University, Raleigh, NC.

The advent of increasingly efficient collection of genetic information has resulted in a great insurgence of data, leading to a need for novel methods of analysis beyond that of traditional parametric statistical approaches. Recently, we introduced a Grammatical Evolution Neural Network (GENN), a machine-learning approach to detect gene-gene or gene-environment interactions, also known as epistasis, in high dimensional genetic epidemiological data. GENN has previously been shown to be highly successful in a range of simulated and real datasets, but has been limited to case-control study designs. In the current study, we extend the GENN method to evaluate continuous traits, by incorporating an r-squared fitness function into the evolutionary process, and conduct a power study in a wide range of simulated data. We demonstrate that the GENN method is capable of detecting both single-locus models and purely epistatic two-locus models. Additionally, we demonstrate the timing of GENN analysis is amenable to large-scale genotype data. GENN software is open source, and available from the authors on request.

Conditional APL-OSA for evaluation of multiple risk variants. *X. Lou[1,2], S. Schmidt[1], E. Hauser[1]* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Bioinformatics Research Center, North Carolina State University, NC.

Genetic models applied in association studies of complex disease often assume a single susceptibility variant in a small region or in a gene. However, once susceptibility genes are identified, it is often the case that multiple variants can individually change the functional qualities of a gene. Thus the models under consideration must include allelic heterogeneity models along with the single variant model. However it is difficult to tell whether multiple associated SNPs are reporting on a single disease risk variant or on multiple risk variants. We performed a simulation study to evaluate whether APL-OSA, a family-based association method for identifying genetic heterogeneity using a trait related covariate, could be applied to family-specific association evidence itself to identify allelic heterogeneity. We used the simulation package SIMLA to generate models from a two disease locus system. We simulated a common disease with prevalence of 0.20 with two marker haplotypes independently associated with two recessive disease loci, each having a GRR of 3.0 and risk allele frequency of 0.15, with different levels of LD between (i) the disease and marker alleles and (ii) between the marker alleles. The LD ranged from r2=0.18 to r2=1.0. We applied APL-OSA conditioning on the family-specific association statistics at other markers as covariates, with the goal of identifying subsets of families preferentially segregating one of the disease alleles. Simulation under the null hypothesis of no association showed that APL-OSA using family-specific APL statistics as covariates at other markers maintained the appropriate 0.05 type I error rate. Simulation studies under the alternative models showed excellent power (>0.95) to discriminate among the first and second risk locus, even at the lowest r2 of 0.18. Thus, a conditional test such as APL-OSA is a powerful tool for evaluating the presence of multiple risk variants.

Comparison between automated FISH analysis and RQ-PCR as monitoring tools for minimal residual disease (MRD) in CML. *G. Calabrese[1,2,3], D. Fantasia[1], F. Pompetti[4], R. DiGianfilippo[3], D. Romagno[1], E. Morizio[1], P. Guanciali-Franchi[1,3], M. Alfonsi[1,3], C. Nuzzi[3], R. DiLorenzo[5], A. Iacone[4], G. Fioritoni[5], G. Palka[1,3]* 1) Scienze Biomed/Genetica Medica, Univ G D'Annunzio, Chieti, Italy; 2) Center for Ageing, DAnnunzio Foundation, Chieti, Italy; 3) Servizio di Genetica Umana; 4) Dip. Med Trasfusionale; 5) Dip. Ematologia, Ospedale di Pescara, Italy.

To compare RQ-PCR method, to date the gold standard approach for MRD monitoring in CML, with a novel FISH analysis approach based on a fully automated FISH slide scanner and image analyzer (Duet BioView, Israel), we investigated 51 CML patients in clinical and cytogenetic remission following imatinib therapy (IM; 44 patients), or hematopoietic stem cell transplantation (7 patients). Ninety samples, 75 bone marrow aspirates and 15 peripheral blood withdrawals, were tested with both RQ-PCR using TaqMan protocol (Applied BioSystems, USA), and FISH slide scanner by scoring 1600-4500 cells for BCR-ABL rearrangement using a dual-fusion FISH probe (Kreatech, DK). Leukemic cell levels in the samples were arbitrarily grouped in 3 classes: 1%; 0.99%-0.04%; and <0.04% of scored cells. FISH/RQ-PCR concordance was 100% for class 1%, 96% for class 0.99%-0.04%, and 84% for class <0.04% leukemic cells. Samples with FISH/RQ-PCR discordant results showed leukemic cells as evidenced by FISH close to the detection limit of FISH procedure (i.e. 0.04%) with <0.01% Bcr-Abl transcript level and molecular remission in the following 18 months of treatment. In 2 patients FISH unravelled 3/1900 (0.16%), and 8/3800 (0.21%) leukemic cells carrying 2 copies of BCR-ABL fusion, i.e. double Ph, which were undistinguishable from those with a single copy of BCR-ABL rearrangement as by RQ-PCR. IM dose escalation (800mg/day) resulted in disappearance of double BCR-ABL leukemic cells, which are still absent 30 and 38 months from high-dose therapy start, respectively. In conclusion, automated FISH results largely overlapped with RQ-PCR data. Furthermore, double Ph-positive cells could also be early recognized by automated FISH analysis allowing appropriate therapy protocol modification.

Fundamentals of Allele Flipping in Association Studies. *G. Clarke* Dept Bioinformatics, Oxford Univ, Oxford, United Kingdom.

The Fundamentals of Allele Flipping in Association Studies G.M.Clarke(1), L.R.Cardon(2) (1) Wellcome Trust Centre for Human Genetics, University of Oxford, UK (2) GlaxoSmithKline, Philadelphia, USA Replication of initial findings in an independent sample is the gold standard for confirmation of a genuine disease-marker association. Replication is generally taken to mean association of the same SNP with the same direction of effect. Reports of allele flips, where an initial study finds an allele to be protective but a follow-up study finds it to be causative, are increasing. It is therefore of practical interest to determine when an allele flip is genuine, that is, when a high risk allele in an original study is, in fact, the low risk allele in a replication study. Allelic heterogeneity, locus heterogeneity, variation in environmental exposures and population differences are all examples of factors that can combine to create scenarios for a genuine allele flip. Instead of examining various scenarios in turn, we instead identify the common underlying parameters that must be affected in order to trigger an allele flip. We show that unless the sign of the mean of the distribution of the association test statistic varies between studies, the probability of observing an allele flip at a genuine causal locus in samples ascertained similarly from a common population is negligible. When the sign of the mean is reversed between studies, the probability of an allele flip increases directly with the power of the studies. We derive expressions for the mean of the odds ratio test statistic under common models that illustrate clearly how the behaviour of key model parameters impacts the probability of a genuine allele flip. In particular we show how genuine allele flips can occur even under constant LD and in regions of zero LD. Using HapMap data, and r rather than r2 to highlight previously unobserved effects, we show that well-powered studies able to detect significant associations in regions of low LD can exhibit genuine allele flips. We conclude that consideration of local LD is a critical tool for providing evidence in support of a genuine allele flip.

FOXG1 is responsible for the congenital variant of Rett syndrome. *F. Ariani[1], G. Hayek[2], D. Rondinella[1], R. Artuso[1], M. A. Mencarelli[1], A. Rosseto[1], M. Pollazzon[1], S. Buoni[2], O. Spiga[3], S. Ricciardi[4], I. Meloni[1], I. Longo[1], K. Krumina[5], M. Zappella[2], V. Broccoli[4], F. Mari[1], A. Renieri[1]* 1) Medical Genetics, Univ of Siena, Italy; 2) Child Neuropsychiatry, AOUS, Siena, Italy; 3) Biochemistry and Molecular Biol, Univ of Siena, Italy; 4) S. Raffaele Scientific Institute, Dibit, Milano, Italy; 5) Medical Genetics, Children's Univ Hospital, Riga, Latvia.

In the classic form of Rett syndrome (RTT), females are heterozygous for mutations in the X-linked MECP2 gene and the few reported males have an XXY karyotype or MECP2 mutations in a mosaic state. A number of RTT variants have been described including the congenital variant, firstly reported by Rolando in 1985. In this form, girls are floppy and retarded from the very first months of life. Using array-CGH, we identified a de novo 3 Mb deletion of chromosome 14q12 in a 7 year-old girl with dysmorphic features and a RTT-like clinical course. The deleted region contained only 5 genes. Among them, FOXG1 was very interesting since it encodes a brain specific transcriptional repressor. We analyzed this gene using both DHPLC and qPCR in 63 MECP2/CDKL5 mutation-negative RTT patients. FOXG1 point mutations were identified in 3 congenital variant patients. Two were de novo truncating mutations (p.W255X and p.S323fsX325) and one was a missense mutation (p.N227K) affecting the forkhead domain. FOXG1 encodes a protein that is highly expressed and plays an essential role during early embryonic development of the telencephalon. We found that FoxG1 expression is also detectable in the differentiating cortical compartment during post-natal stages with a profile overlapping with that of MeCP2. At single cell level, we showed that both proteins have a large co-localization domain in the nucleus but FoxG1 is excluded from the MeCP2 positive heterochromatic foci suggesting that it is not a transcriptional repressor stably associated with heterochromatin. These results suggest that FoxG1 might share common molecular mechanisms with MeCP2 during neuronal development, exhibiting partially overlapping expression domain in post-natal cortex and subnuclear localization.

The hunt for de novo chromosomal aberrations in patients with MR/MCA. *K. Kok, G. B. van der Vries, A. de Boer, Y. Swart, H. Alkema, N. Halsema, H. Zorgdrager, T. Dijkhuizen, C. M. A. van Ravenswaaij-Arts, B. Sikkema-Raddatz*
Genetics, UMCG, University of Groningen, Groningen, Netherlands.

Array-based comparative genomic hybridization has become an indispensable tool in the analyses of genome integrity and thus in the hunt for small de novo chromosomal aberrations that are presumed to be present in patients with multiple congenital abnormalities and/or idiopathic mental retardation. With the increasing resolution of this technique it was expected that the discovery rate of causally related aberrations would equally increase. The discovery of neutral copy number variants has complicated these analyses, especially since it has become clear that these variants constitute well over 5 % of the genome. There is thus a need for procedures that efficiently distinguish inherited from de novo aberrations. We have recently implemented an oligo-based array platform for the postnatal screening of patients with MR/MCA for cryptic microdeletions and duplications. Validation studies have resulted in a standard operating procedure for the routine analysis of patients using a custom designed Agilent 2x105K array in addition to karyotyping. Every patient is analysed simultaneously with his or her parents. On one array of the slide, the patient is hybridized to a reference sample constituted of a pool of either 40 males or females. On the second array, the parents are hybridized with opposite dyes. Separate 2logR files for the parents are subsequently generated by home made software of which the export files can be uploaded into several commercial data analysis platforms. In this procedure ~89% of all aberrations detected by the patient could directly be traced back to either of the parents. This approach thus constitutes a cost-efficient and fast way to determine the de novo nature of the aberrations that are seen in the patient. Detailed results on the analysis of 50 trios will be presented.

Impact of the Winner's Curse on Gene-Environment Association Studies. *M. Zawistowski, S. Zöllner* Department of Biostatistics, The University of Michigan, Ann Arbor, MI.

The challenge of replicating initial genetic associations is partly due to the Winners Curse, the systematic overestimation of effect parameters. As researchers begin to incorporate environmental exposure data into association studies it is important to understand how the Winners Curse will impact parameter estimation and false positive rates in studies of gene-environment interaction.

To explore this question we simulate case-control datasets under various models of gene-environment interaction and test for genetic association. We consider two alternative approaches for assessing association: (1) a standard Chi-Square Test (CST) for allelic association that ignores environmental status and (2) a likelihood ratio test (LRT) for marginal genotype association and/or genotype-environment interaction in a logistic regression that controls for environment. If a simulated marker is significantly associated with the phenotype ($p<10^{-6}$), we estimate its penetrance effect parameters assuming a model of additive genetic and environmental main effects and a non-additive gene-environment interaction term. Thus, we obtain the sampling distribution of genetic and interaction effects for genome scans that generated significant association in the initial test.

In the presence of main and interaction effects, both testing strategies lead to similar overestimates of effect with bias increasing as power of the initial test decreases. More surprising is the potential for the Winners Curse to induce false positives. If there are main genetic and environment effects but no interaction, subsequent hypothesis tests of interaction based on data that had a significant test result have elevated Type I Error rates. The CST introduces a slight overestimation of the interaction term but inflates the Type I Error rate by as much as 50%. The LRT results in unbiased but highly variable estimates that lead to a false positive rate nearly double what is expected. Through our simulations, we show the Winners Curse leads not only to biased estimates but also to increased false positives in gene-environment studies.

Absence of weight gain association with the *HTR2C* -759C/T polymorphism in patients with schizophrenia treated with iloperidone. *A. Thompson, C. Lavedan, S. Volpi* Vanda Pharmaceuticals Inc., Rockville, MD.

Most antipsychotics are associated with adverse effects on metabolic parameters, such as weight gain, hyperglycemia, and dyslipidemia. The identification of genetic markers associated with antipsychotic-induced weight gain may provide a powerful tool to predict individual patient response and may ultimately lead to a reduced risk for this unwanted effect. Iloperidone, a novel mixed D2/5-HT2 antagonist, has demonstrated in multiple clinical trials a low or neutral effect on metabolic parameters, such as serum levels of glucose, cholesterol, and triglycerides, and a modest short-term weight gain. Several genes have been studied for their potential role in drug-induced weight gain, including the gene for the serotonin receptor 2C *(HTR2C),* for which several antipsychotics have binding affinity. Among antipsychotics, clozapine and olanzapine are known to induce the most clinically significant weight increase, and weight gain with these drugs has been reported to be associated with the C allele of the *HTR2C* -759C/T polymorphism. In an ongoing effort to identify patients who could benefit most from iloperidone treatment, a pharmacogenetic analysis of weight changes and the *HTR2C* -759C/T polymorphism was conducted in a phase III clinical trial that included a 28-day double-blind placebo-controlled period followed by a 6-month open-label extension of iloperidone treatment. The *HTR2C* -759C/T genotype was obtained for 392 patients. A general linear model analysis of variance was performed on the change in weight from baseline up to day 203. In this study, we observed no association between weight change and the -759C/T polymorphism. Our results suggest that either this polymorphism does not play a significant role in response to iloperidone, or that the weight change observed with iloperidone is too modest to detect such an effect. Alternatively, different alterations of *HTR2C* or other unknown factors, genetic or environmental in nature, may be responsible for the weight changes observed in our study.

Amplitude-integrated electroencephalography (aEEG): a bedside monitoring tool to assess encephalopathy and seizures in patients with metabolic disorders. *C. Theda[1], C. Aygün[2], M. Toet[3], R. Hunt[4], M. Olischar[4], D. Azzopardi[5], M. DiFazio[6], A. Hamosh[1], L. DeVries[3], L. Hellstrom-Westas[7], E. Shany[8]* 1) Johns Hopkins University, Baltimore USA; 2) Ondokuz Mayis University, Samsun Turkey; 3) Wilhelmina Children's Hospital, Utrecht The Netherlands; 4) Royal Children's Hospital, Melbourne Australia; 5) Imperial College, London UK; 6) Uniformed Services University of the Health Sciences, Bethesda USA; 7) Uppsala University, Uppsala Sweden; 8) Ben-Gurion University of the Negev, Beer-Sheva Israel.

Amplitude-integrated electroencephalography (aEEG) is increasingly used, mainly in the neonatal intensive care setting, for monitoring of patients with encephalopathy and/or seizures. A limited number of electrodes are needed; the signal obtained is processed and displayed as a time compressed tracing. Pattern recognition is used to assess tracings. aEEG patterns for different degrees of encephalopathy have been defined. Seizures are identified through the combination of aEEG pattern recognition and review of the raw EEG signal. We report aEEG findings in 22 patients (pts) with metabolic disorders, including 4 pts with glycine encephalopathy (GE; non-ketotic hyperglycinemia), 4 pts with hyperammonemia (HA), 8 pts with disorders of energy metabolism (DEM), 4 pts with peroxisomal disorders and two pts with disorders of amino acid metabolism (DAAM). aEEG patterns consistent with encephalopathy (discontinuous tracing, burst suppression pattern) were present in 12 of 22 pts - most severe in pts with GE, HA and certain DEM. Seizures were detected in 14 of 22 pts: seizures accompanied encephalopathy in pts with HA, DEM and DAAM. Seizures without encephalopathy were seen in peroxisomal disorders - possibly related to the neuronal migration defects seen in these conditions. We feel that aEEG is a valuable tool in the assessment of patients with metabolic disorders manifesting with encephalopathy and/or seizures and could potentially be used to guide treatment regimens available. Efforts to develop monitoring protocols for aEEG use and data collection in metabolic patients and a web-based repository for case submission are under way (contact first author: ctheda@jhmi.edu).

Increasing the power of genetic association studies by family-based enrichment. *A. L. Maes*[1, 2, 3], *S. R. Diehl*[2, 3] 1) Early Development Statistics, Merck & Co, Inc, Rahway, NJ; 2) Center for Pharmacogenomics and Complex Disease Research, New Jersey Dental School, University of Medicine and Dentistry of New Jersey, Newark, NJ; 3) Department of Health Informatics, School of Health Related Professions, University of Medicine and Dentistry of New Jersey, Newark, NJ.

Genetic association studies of complex disease require very large sample sizes. Now that SNP genotyping costs have been greatly reduced, a studys power is often determined by number and kind of cases and controls that can be recruited. Here, we demonstrate very substantial benefits of studying cases and controls with or without, respectively, a family history of the disease. Through simulation, we compared the statistical power of various ascertainment strategies: traditional cases/controls, family history enrichment of unrelated cases/controls, reference controls and nuclear families. A disease gene along with SNPs in high, moderate and low LD to the disease gene were simulated following multiplicative, dominant and recessive models with prevalences ranging from 1% to 25%. Data sets of equal sample size were analyzed with the LAMP test of association and an Armitage trend test adjusted to account for families. For all models examined, designs with genetic enrichment of both cases and controls had the most power. In circumstances where unrelated cases with genetic enrichment did not provide a clear advantage over traditional cases (disease with highest prevalence), studying affected sibling cases did so. Choosing controls with a negative family history of disease was especially advantageous for diseases with prevalence > 10%. Nuclear families with 2 affected siblings performed better than traditional unrelated cases and controls. However, family-based designs generally were not as powerful as case-control designs with family history enrichment. Pairing genetically enriched cases with reference controls provided greater statistical power than traditional cases/controls at a 50% savings in genotyping costs. We conclude that genetic enrichment by family history is a statistically powerful ascertainment strategy for genetic association studies.

Absence of BRCA1 mutations in Familial Pancreatic Cancer Patients. *J. E. Axilbund[1], P. Argani[1,2], M. Kamiyama[2], E. Palmisano[2], M. Raben[1], M. Borges[2], K. A. Brune[2], M. G. Goggins[1,2,3], R. H. Hruban[1,2], A. P. Klein[1,2,4]* 1) Department of Oncology, Johns Hopkins University, Baltimore, MD; 2) The Sol Goldman Pancreatic Cancer Research Center, Department of Pathology, Johns Hopkins University, Baltimore, MD; 3) Department of Medicine, Johns Hopkins University, Baltimore, MD; 4) Department of Epidemiology, Bloomberg School of Public Health, Baltimore MD.

Purpose: Recent studies have suggested that mutations in the BRCA1 gene may confer an increased risk of pancreatic cancer. To determine if BRCA1 mutations explain a significant proportion of familial pancreatic cancer, we sequenced the BRCA1 gene in a large series of well-characterized patients with familial pancreatic cancer and we evaluated the pathology of breast neoplasms that developed in relatives of pancreatic cancer patients.

Patients and Methods: The BRCA1 gene was fully sequenced in 66 pancreatic cancer patients who had at least two additional relatives with pancreatic cancer from families enrolled in the National Familial Pancreas Tumor Registry. Estrogen receptor (ER), progesterone receptor (PR), HER-2 and cytokeratin (CK) 5/6 expression were evaluated by immunolabeling of 23 invasive breast carcinomas that developed in the relatives of pancreatic cancer patients.

Results: None of the 66 (0/66: 97.5% one-side CI 0-0.054%) familial pancreatic cancer patients were found to have a deleterious mutation in the BRCA1 gene. While patients were not selected based upon their family history of breast and ovarian cancer, over half of the patients whose samples were sequenced reported a family history of breast and/or ovarian cancer. One triple-negative, CK 5/6 positive breast carcinoma was observed among the 23 carcinomas evaluated.

Conclusions: Our findings suggest that mutations in the BRCA1 gene are not highly, or even moderately, prevalent in families with a clustering of pancreatic cancer, including pancreatic cancer families who report a family history of breast and/or ovarian cancer.

Detection of Low-Level Mosaicism and Placental Mosaicism Using Oligonucleotide Array CGH. *S. Scott, N. Cohen, T. Brandt, L. Edelmann* Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

Microarray-based comparative genomic hybridization (array CGH) interrogates the genome for gains and losses of material with significantly higher resolution than conventional cytogenetics. Our clinical laboratory validated a previously reported whole genome oligonucleotide array design using constitutional cytogenetic abnormalities, yet little was known about the ability of this custom Agilent Technologies 44K array to detect mosaic abnormalities. To address this, we tested artificial mosaic trisomy 21 and Turner syndrome samples at various percentages of mosaicism (100% - 0%) and found as low as ten percent mosaicism to be successfully detected by array CGH. Furthermore, aneuploid fibroblast cell lines and peripheral blood specimens with mosaic karyotypes that ranged from 30% to 94% and 17% to 80%, respectively, also were successfully detected by array CGH. Interestingly, when array CGH was performed on DNA of direct chorionic villi from product of conception (POC) specimens, the results were not always concordant with the karyotype results obtained from the cultured specimen. Specifically, a male POC specimen that displayed 40% mosaicism for trisomy 2 in cultured cells had an array CGH result consistent with a balanced male karyotype when performed on DNA from the direct specimen. To further investigate discrepancies between direct and cultured POC specimens, we performed array CGH on direct DNA from POC samples with abnormal cultured karyotypes. Surprisingly, three of four samples with double trisomies on cultured cell karyotypes had only a single aneuploid abnormality by direct array CGH and all harbored the more common trisomy. This suggests that the placental mosaicism detected in these samples could reflect true fetal mosaicism as multiple trisomies in the fetus would be expected to arrest development prior to implantation. Taken together, our results indicate that oligonucleotide array CGH can detect low-level mosaicism and that analysis of POC DNA from direct villi with this technique may not yield the same result as traditional karyotype analysis, especially in cases of rare abnormalities, such as double aneuploidies and uncommon trisomies.

Association of Paternal DNA Copy Number Variation with Risk of Sporadic Retinoblastoma in an Offspring. *E. C. Chao[1], K. Wang[1], S. Walther[1], J. A. Richards[1], G. Bunin[2], A. Ganguly[1]* 1) Dept Genetics, Univ Pennsylvania, Philadelphia, PA; 2) Children's Hospital of Philadelphia, Philadelphia, PA.

Retinoblastoma(RB) is a malignant neoplasm of the retina, which occurs in infants and young children. This tumor is universally associated with mutation of the RB1 gene. In sporadic, bilateral RB, 94% of germline RB1 mutations occur prior to conception on the paternal gamete[Zhu et al., Nature 1989]. We hypothesize that paternal genotype contributes to risk of fathering a child with a de novo RB1 germline mutation. Multiple studies have identified DNA sequence and copy number variants (CNV) associated with risk of common diseases, including cancer [Wellcome Trust, Nature 2007, Xu et al., Nat Gen, 2008]. To study association of CNVs with RB risk, we analyzed genomic DNA from 69 fathers of children with de novo, bilateral RB. We used an array-based approach (Affymetrix, SNP5) to genotype >1 million loci. We applied PennCNV [Wang et al., Gen Res, 2007], a hidden Markov model based algorithm, to detect genome-wide CNVs from SNP genotyping data. In this cohort we identified 37 copy number variants >500kb, including a 1.4Mb duplication of 15q11.2 (18671827-20088816bp) in 9% of fathers.

Previous studies have linked environmental and genetic exposures to specific types of DNA mutations. We classified our subjects based on the type of mutation in their gamete as point mutations or frameshifts (small insertions/deletions). Fathers of frameshift mutations were significantly more likely (14/38 vs 3/31) to harbor a 50kb deletion within 12p13.31, downstream of the KLRB1 gene (p=0.012). This deletion contains a highly conserved noncoding element, retained over 400 million years of evolution, which suggests a regulatory role. In conclusion, heritable copy number variation may be associated with increased risk of de novo RB1 mutation on the paternal allele, and specific copy number variants may contribute to risk of different types of DNA mutations. While these preliminary results require further validation, they nevertheless suggest a novel mechanism for cancer predisposition and have broader implication for other types of de novo cancer causing mutations.

Worldwide Population Structure using SNP Microarray Genotyping. *D. J. Witherspoon, J. Xing, W. S. Watkins, Y. Zhang, L. B. Jorde* Dept Human Genetics, Univ Utah, Salt Lake City, UT.

We genotyped 348 individuals sampled from 24 populations world-wide using the Affymetrix 250k NspI microarray chip. For context, we added matching genotypes from 210 HapMap individuals for a total of 250,823 loci genotyped in 543 individuals from 28 populations. We included populations from India and Daghestan to provide detail between the genetic poles of Western Europe, East Asia, and sub-Sahara Africa. With so many markers, principal components analyses reveal genetic differentiation between almost all identified populations in our sample. Northern and southern European populations (FST = 0.004, $p<0.01$) are statistically distinguishable, as are upper and lower caste groups in India (FST = 0.005, $p<0.01$). All individuals are accurately classified into continental groups, and even between closely-related populations, genetic- and self-classifications conflict for only a minority of individuals (e.g. ~2% between upper and lower Indian castes; k-means clustering.) As expected, the HapMap CHB+JPT, CEU, and YRI samples are most similar to our east Asian, west European, and African samples, respectively. The HapMap CEU samples and our northern European ancestry samples were both collected from Utah. Although individual samples cannot be reliably classified into their collection of origin, the groups are statistically distinguishable despite their high similarity (FST = 0.0005, n.s.). Our Japanese group is also statistically distinguishable from the HapMap JPT group (FST = 0.006, $p<0.01$), and in this comparison, most samples can be correctly classified. With such large numbers of genotypes, significant differences can be found even between very similar population samplings. Our results provide guidelines for researchers in selecting suitable control populations for case-control studies.

TARDBP gene mutations in a large cohort of Italian patients with Amyotrophic Lateral Sclerosis (ALS). *L. Corrado[1], A. Ratti[2], C. Gellera[3], E. Buratti[4], B. Castellotti[3], N. Ticozzi[2], L. Mazzini[5], L. Testa[5], Y. Carlomagno[1], F. Taroni[3], F. E. Baralle[4], V. Silani[2], S. D'Alfonso[1]* 1) Dept. Medical Sciences, A. Avogadro University, Novara, Italy; 2) Dept. Neurological Sciences, IRCCS Istituto Auxologico Italiano, University of Milan, Milano, Italy; 3) U.O. Biochimica e Genetica Fondazione IRCCS - Istituto Neurologico Carlo Besta, Milano, Italy; 4) ICGEB, AREA Science Park , Trieste, Italy; 5) Dept. Neurology, A. Avogadro University and Maggiore della Carità Hospital, Novara, Italy.

ALS is a progressive and fatal adult-onset disorder characterised by the degeneration of motor neurons in the brain and spinal cord. About 5-10% are familial cases (FALS). Mutations in SOD1 are detected in 20% of FALS and 3% of sporadic (SALS) cases. However, in the majority of FALS and SALS cases the disease cause is unknown. Recent studies identified missense mutations in 1% of ALS patients in the gene (TARDBP) encoding TDP-43, the major protein of ubiquitinated inclusions in the cytoplasm of spinal motor neurons, a ALS pathological hallmark. The aim of this study was to further define the spectrum of TARDBP mutations in a large Italian cohort of ALS patients and to study the TDP-43 integrity in patients non neuronal tissue. We screened 690 ALS patients (134 FALS and 556 SALS) for TARDBP mutations. We sequenced the entire coding region for 281 patients and only exon 6 (mainly affected by mutations in the previous studies) for the remaining 409 cases. We identified 12 different heterozygous missense mutations in exon 6 (A382T in 7 patients, G287S, M337V and 9 newly identified variations) in 18 patients (6 FALS) and 0/350 healthy matched controls. The frequency of TARDBP mutations seems particularly high in Italian ALS patients (2.6% vs 1% in patients mainly of Northern European origin). Western Blot analysis of lymphocyte preparations showed aberrant TDP-43 bands (30-32 kDa) in 2 patients carrying TARDBP mutations not detected in 7 patients negative for TARDBP mutations and 4 healthy controls indicating that TARDBP mutations may affect the stability of this protein even in non neuronal tissues and that blood cells could be used to design ALS diagnostic/prognostic tools.

Views of U.S. Geneticists and Mothers of Newborns Differ Widely Regarding the Use of Residual Newborn Screening Blood Samples. *M. Lewis[1], M. Diener-West[2], G. Cutting[3]* 1) Humanities, Penn State Hershey Med Ctr, Hummelstown, PA; 2) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Johns Hopkins University School of Medicine, Baltimore, MD.

Background: The potential research use of residual newborn screening blood samples raises many ethical questions. Yet, little is known about how mothers of newborns view these issues. Geneticists are more likely than mothers to be involved in the policy process regarding the use of these samples. Purpose: The purpose of this study is to evaluate the views of U.S. geneticists and mothers of newborns regarding these issues. Methods: The two groups were administered identical surveys in which they were asked to assume that they had just had a baby and the state could retain their babys residual newborn screening blood sample. The survey was administered orally in-person prior to discharge from the hospital to 144 mothers (response rate 95%)in Arlington, Virginia. Members of the American Society of Human Genetics with an M.D. degree, a Ph.D., or both (n=2609) were contacted by e-mail; 344 respondents completed the survey online (response rate 13%). Results: Geneticists were seven times more likely than mothers to respond that it is somewhat or completely unacceptable to seek parental permission to use residual newborn screening blood samples for research (OR= 7.1; 95% CI 1.7-29.9). Geneticists were seven times more likely than mothers to respond that permission should be obtained only once to use residual newborn screening blood samples for research rather than obtain parental permission every time researchers want to use the residual blood sample (OR= 7.3; 95% CI 4.4-12.1). Geneticists were fourteen times more likely than mothers to respond that researchers should not be required to recontact parents if they find out something that might be important to the babys health (OR= 14.1; 95% CI 4.4 -45.7). Conclusion: Views of geneticists and mothers differ significantly. These findings indicate that the public must be adequately represented in the development of policies governing the use of residual newborn screening blood samples for population-based genetic research.

A novel method to detect runs of homozygosity. *L. Licamele, N. Wang, C. Lavedan* Vanda Pharmaceuticals, Inc, Rockville, MD.

Recently there has been a large increase in the use of microarrays for whole genome association studies in search of susceptibility genes for various traits. This has led to a vast amount of data being generated but has largely failed to result in reproducible candidate genes. Lencz et al. proposed using runs of homozygosity (ROHs) to detect areas of association using microarray data because of their potential in identifying recessive traits. ROHs identify regions where individuals have inherited identical material from both parents. It is possible that some diseases may be caused by the lack of variation across one or multiple genes. We developed a precise ROH method and applied it to the study of schizophrenia. Schizophrenia is a severe psychotic disorder affecting approximately 1% of the population worldwide. The disease carries a high rate of mortality, with approximately 10% of patients committing suicide. Identification of schizophrenia susceptibility genes has remained challenging, even though genetic epidemiology studies have revealed high heritability estimates (70-80%). Our Exact ROH (eROH) method can efficiently detect ROHs in large datasets, eg, hundreds of individuals across hundreds of thousands of markers. eROH comprises three steps. 1) ROHs are selected in each individual sample according to the minimum ROH length, eg, 100 single nucleotide polymorphisms (SNPs). 2) These data are then stored into a compressed matrix containing ROH information for each SNP across all individuals. 3) Statistics are calculated across this table to dynamically find the longest ROHs that meet individual coverage criteria, eg, present in 10% of the population. Previous methods have counted SNPs present in ROHs across individuals, with no guarantee that the full ROH is in fact shared between the individuals. We evaluated eROH on a set of 426 schizophrenia samples and compared the results of the two methods. eROH is able to dynamically detect the largest ROHs in sizeable datasets while meeting the defined requirements of ROH length and individual coverage. We believe this method will allow researchers to perform informative ROH analysis while not requiring the computational power of a naive approach of evaluating every possible alignment.

Epistasis-list.org: A Curated Database of Gene-Gene and Gene-Environment Interactions in Human Epidemiology. *A. A. Motsinger-Reif[1], S. J. Wood[1], S. Oberoi[1], D. M. Reif[2]* 1) Bioinformatics Research Center, Department of Statistics, North Carolina State University, Raleigh, NC; 2) National Center for Computational Toxicology, U.S. Environmental Protection Agency, Research Triangle Park, NC.

The field of human genetics has experienced a paradigm shift in that common diseases are now thought to be due to the complex interactions among numerous genetic and environmental factors. This paradigm shift has prompted the development of myriad novel methods to detect such interactions in epidemiological studies. The success of these new methods, as well as the appropriate application of traditional approaches, in detecting such interactions is evidenced by the increasing number of epistatic models found in studies of human genetics. We have manually curated a list of such interactions from PubMed literature references, and have developed a searchable web-based tool compiling these results. This curated list is available at www.epistasis-list.org and will be updated regularly. The website is organized into a searchable list of all interactions found, as well as a searchable list of analytical tools available to detect such interactions. The organized list of interactions is searchable by disease, genetic or environmental factors detected, study design used, analytical method used, etc. The list of analytical methods is searchable by pertinent details such as study design or outcome and risk factor variable characteristics. Through the end of 2007, over 450 gene-gene and/or gene-environment interactions have been found. Breakdowns according to analytical methods and study designs used indicate some important trends. For example, ~63% of all interactions were discovered with traditional statistical methods, while ~37% used novel techniques; over 96% of studies used an association mapping approach, with only 10% of those using family-based data. It is our hope that this curated database will assist investigators in evaluation of epistasis in their own work by highlighting successful applications of appropriate experimental design and analysis. Although this work was reviewed by EPA and approved for publication, it may not necessarily reflect official Agency policy.

Analyses and visualisation of sequence data from Roche GS FLX, Illumina Genome Analyzer and ABI 3730XL.

K. A. Stangier[1]*, V. Tischler*[2] 1) GATC Biotech AG, Konstanz, Germany; 2) Fachhochschule Gelsenkirchen, Fb Angewandte Naturwissenschaften, August-Schmidt-Ring 10, 45665 Recklinghausen, Germany.

The technical capability of the Next-Gen sequencing systems, particularly embodied by the Roche GS FLX and the Illumina Genome Analyzer, generate huge amounts of sequence information. The profound bioinformatic analysis and the focused visualisation of this data is the crucial point for an in-depth comprehension of its biological relevance. GATC presents data of genomes that have been sequenced using single and paired end sequencing methods on the different systems. We recommend to use paired end reads for resequencing in order to find SNPs and other differences like InDels. With these read pairs, especially from libraries of large inserts, structural variations can be easily identified. We use a wide range of bioinformatic solutions for genome assembly, transcriptome analysis and other studies. Proprietary tools are applied for the analysis and handling of next-gen sequencing data, while third party tools are available for optimised de novo assembly of sequence data from the Genome Analyzer or improved hybrid assemblies. The GATC Genome Browser desktop application for data visualisation allows a convenient overview of e.g. whole genome de novo or re-sequencing, ChIP or SAGE experiments. The visualisation of the coverage helps to identify smaller InDels and rearrangements within the genome. In addition SNPs, coding regions and other annotations can be displayed. Conclusion: There are two main parameters which need to be observed to ensure the in-depth understanding and interpretation of the sequence data: a) the use of various next-gen systems to take advantage of each technology and b) the combination of different bioinformatic tools and their stepwise application.

The HGNC Database: an essential resource for the human genome. *M. W. WRIGHT, S. M. GORDON, M. J. LUSH, R. L. SEAL, E. A. BRUFORD* HUGO Gene Nomenclature Committee (HGNC), EMBL-EBI, Hinxton, United Kingdom.

The HUGO Gene Nomenclature Committee (HGNC) is an essential component of human genome management, and since 1989 has been the single authority for providing unique and user-friendly names and symbols for every gene in the human genome. Of the 25,000+ genes in our database most are protein-coding; we also name pseudogenes, phenotypic loci, some genomic features, and to date have named over 1,000 human non-coding RNA genes. Approved gene symbols are based on names describing structure, function or homology wherever possible. Researchers are encouraged to contact the HGNC to request or confirm the approved nomenclature for specific genes and gene groupings, or to comment on the current gene names. A panel of over 100 specialists advise on the nomenclature of specific gene families, and we consult with our International Advisory Committee on policy issues. Coordination with nomenclature committees for other species has proven invaluable; the HGNC has a very strong and active collaboration with the Mouse Genomic Nomenclature Committee (MGNC), which has proven essential in the parallel naming of orthologous human and mouse genes. In order to identify genes for orthologous naming we have developed our HGNC Comparison of Orthology Predictions search tool, HCOP (www.genenames.org/hcop) as a useful one-stop resource to summarise, compare and access various sources of orthology data. When sources agree on 1:1 orthologs between human and other mammals then these orthologs could directly adopt the human gene nomenclature. The HGNC also has a strong working relationship with other databases including Entrez Gene, Ensembl, SwissProt/UniProt and Vega. All of these databases, and many more, prominently display HGNC gene symbols; using these symbols in an online search will then allow the user to retrieve information about the genes, including the structure and function of the encoded proteins, known genetic variation and clinical phenotypes, and related genes both in humans and in other species. For further information please visit www.genenames.org or email hgnc@genenames.org. The HGNC is supported by the NHGRI & the Wellcome Trust.

Genetic profile for five common variants associated with age-related macular degeneration in densely affected families: a novel analytical approach. *L. Sobrin[1,2], J. B. Maller[2,3], B. M. Neale[2,3,4], R. C. Reynolds[5], J. A. Fagerness[2], M. J. Daly[2,3], J. M. Seddon[5]* 1) Department of Ophthalmology, Harvard Medical School, Boston, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Social, Genetic and Developmental Psychiatry Centre, King's College, London, UK; 5) Ophthalmic Epidemiology and Genetics Service, Tufts-New England Medical Center, Boston, MA.

Approximately half of the genetic variance of age-related macular degeneration (AMD) is explained by common variation at five single nucleotide polymorphisms (SNPs). We evaluated the degree to which these variants explain the clustering of AMD in densely affected families. In order to determine if the actual number of risk alleles in affected families matched the expected number, we used a novel analytical technique to simulate a comparison set of families and determine if their genetic profile differed from the observed profile in families with AMD. We genotyped 1265 siblings from 322 families with probands with advanced AMD. We used the statistical package R to create a comparison population of families. We simulated phenotypes based on the heritability and environmental variance of AMD, the allele frequencies of the five SNPs, and a liability threshold model of disease. A mean genotypic load was determined separately for simulated and actual families that shared the same configuration, i.e. the same number of affected siblings and total siblings. For most family configurations, there was no statistically significant difference between the mean genotypic loads of the actual vs. simulated families. In addition, most of the individual families genotypic loads fell within the 95% confidence interval of their expected mean genotypic load from the simulation. However, the mean genotypic load was lower than expected by the simulation in families with 4 out of 4 and 4 out of 5 siblings affected ($p=0.05$ and $p=0.020$, respectively). Given that these densely affected families may harbor more penetrant, rarer variants, linkage analyses could uncover additional implicated genes.

The role of menin in DNA damage-dependent cell cycle checkpoints. *M. C. Kottemann, A. E. Bale* Dept of Genetics, Yale University, New Haven, CT.

MEN1, the gene responsible for the cancer predisposition syndrome multiple endocrine neoplasia type I, has been implicated in DNA repair, cell cycle control, and transcriptional regulation. It is unclear to what degree these processes are integrated into a single encompassing function in normal cellular physiology and how deficiency of the MEN1 protein, menin, contributes to cancer pathogenesis. In this study, we found that loss of *MEN1* in mouse embryonic fibroblasts caused abrogation of the G1/S and intra-S checkpoints following ionizing radiation. The cyclin-dependent kinase inhibitor, p21, failed to be upregulated in the mutant although upstream checkpoint signaling remained intact. Menin localized to the p21 promoter in a DNA damage-dependent manner. The MLL histonemethyltransferase, a positive transcriptional regulator, bound to the same region in the presence of menin but not in MEN1 -/- cells. These data indicate that menin participates in the checkpoint response in a transcriptional capacity, upregulating the DNA damage-responsive target p21.

Novel 1p36 Deletion and 1q41-44 Duplication: Further Delineation of the Distal Partial Trisomy 1q Phenotype. *J. A. Gold, R. A. Cox, T. Huang* University of California Irvine Department Pediatrics Division of Genetics and Metabolism 101 The City Drive, ZC 4482 Orange , CA 92868.

Various cytogenetic abnormalities of chromosome 1 have been reported to date. The most common of these is a distal deletion of the short arm, resulting in characteristic facial features, mental retardation, growth abnormalities, and various other phenotypic anomalies. Deletions and duplications also occur on the long arm of chromosome 1, but with less reported frequency. A relatively new phenotype comprised mainly of characteristic facial features, growth retardation, microcephaly, and long and overriding toes has been postulated to arise from the distal partial duplication of the long arm of chromosome 1. We report an infant with a novel chromosomal rearrangement resulting in a deletion of 2.9 Mb at 1p36.33-p36.32 and a duplication of approximately 25.53 Mb at 1q41-q44. He presented with intrauterine growth retardation, hydrocephalus with aqueductal stenosis, and hypotonia. Clinical evaluation revealed characteristic facial features including straight eyebrows, upslanting palpebral fissures, a flat nasal bridge, a short neck, and dysplastic ears in addition to anomalies such as small hands, bilateral single palmar creases, overlapping 1st and 5th fingers, short 5th finger and clinodactyly, cryptoorchidism, a small phallus, rocker bottom feet, and 3-4 toe syndactyly. Although some of these features are consistent with the well-described 1p36 deletion syndrome, the others may contribute to distal partial trisomy of 1q.

High-quality oligonucleotide array CGH analysis using direct amniotic fluid. *A. M. Breman, P. A. Eng, S. F. Venable, W. Bi, A. Patel, S. W. Cheung, L. D. White* Medical Genetics Laboratories, Dept of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

The use of array CGH to detect chromosome imbalance has been a major advancement in the field of cytogenetics, and the recent transition from BAC arrays to oligonucleotide arrays has greatly improved the resolution and sensitivity of this assay. Array CGH has recently been applied to prenatal diagnosis of genomic imbalance in the clinical laboratory setting, which has the potential to produce more rapid results compared to traditional karyotype analysis when direct uncultured specimens are used. While reliable results have been obtained using both direct and cultured amniocytes, direct amniotic fluid specimens often yield smaller quantities of DNA and produce noisy results on oligonucleotide arrays. We present the results of array CGH analysis on 22 direct amniotic fluid specimens. High-quality results were obtained from 20 (91%) of these uncultured samples using a minimum of 300 ng of genomic DNA. In two cases, limited DNA was isolated and whole genome amplification (WGA) was used. The results of this study include 4 cases with chromosome abnormalities and one case with a familial copy number variation. In case 1, array CGH revealed a loss of copy number on the distal short arm of chromosome 9 and a gain of copy number on the distal long arm of chromosome 16. G-band analysis revealed a derivative chromosome 9 in this fetus. In cases 2 and 3 (monozygotic twins), a loss of copy number on the short arm of chromosome 8 at band 8p23.1, including the GATA4 gene, was observed. In case 4, array CGH detected a gain in copy number on the short arm of chromosome 20. FISH analysis showed an additional partial isochromosome 20p, reported as a supernumerary marker chromosome by the laboratory performing G-band analysis. The turn-around time for array CGH analysis of direct amniotic fluid surpasses that of standard karyotype analysis. This facilitates rapid results and short reporting time (averaging 6 days). The consistent high-quality results reported here demonstrate the reliable advantage of array CGH analysis compared to conventional karyotype analysis for copy number change.

Genetic Screening in a *Drosophila* Fanconi Anemia Model. *A. P. Clark, A. E. Bale* Genetics Department, Yale University , New Haven , CT.

Fanconi Anemia (FA) is a rare, recessive, autosomal and X-linked disorder characterized by sensitivity to cross-linking agents, congenital abnormalities, pancytopenia and cancer susceptibility. FA is a genetically heterogeneous disease with 13 known complementation groups (A, B, C, D1, D2, E, F, G, I, J, L, M and N). Of these complementation groups, there are known *Drosophila* homologs for FANCD1, FANCD2, FANCI, FANCL and FANCM. A *Drosophila* FA model using a RNAi knockdown construct targeted against dmFANCD2 was previously validated in our lab. When constitutively expressed, this RNAi construct causes pupal lethality. FANCD2 knockdown flies also exhibit sensitivity to cross-linking agents, hypermutability and S phase arrest defect, demonstrating that *Drosophila* FANCD2 functions similarly to its mammalian homolog. An EP element screen was performed to identified genes that, when misexpressed, rescue the pupal lethality phenotype associated with dmFANCD2 knockdown. Two EP element lines that partially rescue pupal lethality were identified: line 17396 and line 20140. The EP element in line 17396 sits upstream of CG30122, the *Drosophila* homolog of heterogeneous nuclear riobonucleoprotein U like 1 (hnRNPUL1) and causes hnRNPUL1 overexpression in combination with an actin Gal4 driver. The EP element in line 20140 is positioned upstream of Vha44, a component of the vacuolar H+ ATPase. Neither of these EP elements rescue the S phase defect seen in FANCD2 knockdown flies. Current efforts are focused on elucidating the function of hnRNPUL1 and Vha44 in DNA repair and apoptosis.

Shared Genetic Loci for Language Impairment and Reading Disability. *S. D. Smith[1], M. L. Rice[2]* 1) Dept Pediatrics, Univ Nebraska Medical Center, Omaha, NE; 2) Dept Speech, Language, Hearing, University of Kansas, Lawrence, KS.

Specific language impairment (SLI), reading disability (RD), and speech sound disorder (SSD) are clinically distinguishable learning disorders with a high degree of comorbidity. All three disorders have substantial heritabilities, leading to the hypothesis that they share genetic risk factors affecting a common neurodevelopmental pathway. At least 9 loci have been linked to RD, and SSD has been linked to 3 of those loci on chromosomes 3, 6, and 15, indicating that genes may exist in these regions that affect both disorders. In contrast, genome-wide linkage analyses of SLI have identified loci on chromosomes 16 and 19, with other loci possible on chromosomes 7 and 13. This suggests that SLI has a different genetic etiology and therefore follows a different developmental pathway. To test whether previous genome wide searches were underpowered to detect shared but lesser influences from the RD/SSD loci, we performed a targeted linkage analysis in families of probands with SLI. Probands and their siblings from 86 families totaling over 150 sib pairs were assessed for measures of language, reading, and articulation, and genotyping was performed for microsatellite markers at 2 cM intervals covering 5 chromosomal regions: RD candidate regions on chromosomes 1p36, 3p12-q13, 6p22, and 15q21, and the language candidate region on 7q31. Quantitative sib-pair linkage analysis was done using two different analytical methods, and replication of linkage was accepted only if both methods indicated linkage of the same phenotypes to the same markers. Linkage was replicated or suggestive in all of these regions, and phenotypic analysis indicated that the genetic influences may be domain-specific. Language phenotypes showed greater linkage with 7q, speech phenotypes showed greater linkage with chromosome 3 markers, and reading phenotypes showed greater linkage with 1p, 6p and 15q, consistent with previous findings for these regions. These results support a multiple gene model of the comorbidity between language impairments and reading disability and have implications for neurocognitive developmental models and maturational processes. Funded by NIDCD DC01803.

Analysis of atypical patients with features overlapping Pallister-Hall and Greig cephalopolysyndactyly syndrome. *J. J. Johnston, J. Sapp, J. Turner, L. G. Biesecker, Clinical Collaborators* NHGRI, NIH, Bethesda, MD.

Pallister-Hall and Greig cephalopolysyndactyly syndromes are caused by mutations in the *GLI3* transcription factor on chromosome 7p14.1. Although variant phenotypes, including isolated polydactyly, acrocallosal syndrome, and severe mental retardation, have been attributed to mutations in *GLI3*, atypical phenotypes attributable to such mutations are not adequately delineated. To better understand the clinical variability resulting from mutations in *GLI3* we have studied a cohort of patients who have features of PHS and/or GCPS but do not fulfill the clinical criteria for either disorder. The group consisted of 55 probands and 6 family members. Twenty-two probands had features of GCPS including polydactyly, syndactyly, hypertelorism, macrocephaly, and/or agenesis of the corpus callosum. Twenty-three probands had features of PHS including polydactyly, hypothalamic hamartoma, panhypopituitarism, imperforate anus, and/or hypoplastic nails. Ten probands had either hamartoma or polydactyly without additional overlapping features of either disease. We identified a total of 17 mutations including one missense variant. *GLI3* has a well-established genotype/phenotype correlation with truncating mutations in the middle third of the gene, between nt 1198-3481, causing PHS and mutations outside this region causing GCPS. Of the 6 probands with features of GCPS, 3 had truncating mutations in *GLI3* that fell outside the middle third of the gene, one had a splice site mutation upstream of the middle third of the gene, one had a missense alteration, p.S903L, and one had a mutation at nt 3474 at the PHS/GCPS boundary. Nine probands with features overlapping PHS had truncating mutations in *GLI3*, all fell in the middle third of the gene. No individuals with polydactyly or hamartoma in the absence of other overlapping features had mutations in *GLI3*. In summary, individuals with multiple features of PHS and GCPS should be considered for *GLI3* mutation screening.

Increased Attention Deficit Hyperactivity Disorder (ADHD) and Major Depression (MD) symptoms in Nail Patella Syndrome (NPS): potential association with LMX1B loss-of-function. *I. McIntosh[1,2], E. Sparrow[3], C. Slavin[2,3], J. James[3], J. E. Hoover-Fong[2], E. Tierney[2,3]* 1) American University of the Caribbean, St Maarten, Netherlands Antilles; 2) Inst of Genetic Med, Johns Hopkins Univ, Baltimore, MD; 3) Kennedy Krieger Inst, Baltimore, MD.

ADHD has a prevalence of 2-7% in USA adults, with a male to female ratio (M:F) of 4:1. MD has a prevalence in USA adults of 5% (M:F 1:1.7). NPS (OMIM 161200) is an autosomal dominant disorder that is the result of loss-of-function mutations in LMX1B, a LIM-HD transcription factor. Lmx1b has been shown to be expressed in mesencephalic dopaminergic neurons including the substantia nigra pars compacta & ventral tegmental area. We hypothesized that individuals with NPS would present with ADHD & MD symptoms (sxs) and that NPS may yield additional information about the etiology of ADHD & MD. The Conners CAARS-S:L Scale (CAARS) & Beck Depression Inventory-II (BDI), to assess for presence and severity of ADHD & MD sxs respectively, were completed by 51 adults with NPS (39 females & 12 males, age 46.313.9 yrs). The Brief Pain Inventory (BPI) was also completed by 17 of 51 (14 females & 3 males, age 52.512.7 yrs). The CAARS scores are based on ratings of the 18 DSM-IV criteria for ADHD. Of the 51 NPS subjects, the following had scores that reached the threshold of sxs consistent with ADHD: TE-Inattention 11 (22%); TF-Hyperactive-Impulsive 7 (14%); TH-ADHD Index 8 (16%). The threshold TH M:F was 1.1:1. Nineteen (37%) had BDI-Total score (BDI-T) that reached threshold of 14, consistent with depression (M:F 1:1.5). Multiple regression analysis (MRA) showed the higher the TH, the greater the BDI-T (p=.009). TE, TF, TH & BDI-T did not correlate with sex or age. MRA of BDI-T & BPI Interference was significant only for walking ability (p=.05). The rate of clinically significant ADHD sxs in NPS was 2-8 times greater than the USA prevalence and did not show a M:F bias. The rate of significant MD sxs was 7 times the USA rate and did not correlate with report of pain. Future studies should be designed to better assess cognitive abilities, mood & motor deficits, and to confirm the increased rates of ADHD & MD found with screening tests.

Adult osteogenesis imperfecta model (*oim*) mice do not exhibit inherent muscle weakness or pathology. *C. Phillips[1], B. Weber[2], S. Carleton[1], A. McCambridge[1], J. Ferreira[2], M. Brown[2]* 1) Dept Biochemistry/Child Health, Univ Missouri, Columbia, MO; 2) Dept Veterinary Pathobiology, Univ Missouri, Columbia, MO.

Bone is inherently mechanosensitive, responding and adapting to its mechanical environment. Bone formation occurs in response to high mechanical loads; often changing geometry to strengthen the skeleton. The largest physiological loads bones typically experience are from muscles; bone strength is proportional to muscle mass. Osteogenesis imperfecta (OI) is a heritable connective tissue disorder characterized by small stature, reduced bone mineral density (BMD) and frequent fractures. OI patients reportedly have muscle weakness, though it is unclear if this is due to inactivity or inherent pathology. We used *oim* (osteogenesis imperfecta model) mice with reduced bone biomechanical integrity and BMD to investigate whether *oim* mice have inherent muscle pathology. At 4 months of age (peak femoral bone mass in mice) wildtype (wt), heterozygous (*oim*/+) and homozygous (*oim/oim*) mice were weighed and the contractile tension generating capacity of the gastrocnemius (G), soleus (S), plantaris (P) and tibialis anterior (TA) muscles measured. *Oim/oim*, *oim*/+ and wt quadriceps (Q), G, S, P, and TA muscles were harvested and histologically evaluated for morphology, muscle fiber types (myofibrillar ATPase activity), and fiber cross-sectional areas. Muscle mass/body mass ratios for the G, Q, S and P muscles are similar between wt, *oim*/+ and *oim/oim* mice. Q, TA, G, P and S muscles in *oim*/+ and *oim/oim* mice do not show evidence of necrosis, degeneration, regeneration, atrophy or hypertrophy upon microscopic evaluation. Cross-sectional fiber areas of the TA, S, and Q muscles are not significantly different in *oim/oim* or *oim*/+ mice as compared to wt mice. Muscle fiber type composition in the S muscle is similar between wt, *oim*/+ and *oim/oim* mice. Contractile generating capacity [peak tetanic tension] and nerve conduction of muscles is not impaired in *oim*/+ or *oim/oim* mice as compared to wt mice. Our findings suggest that *oim* mice do not have inherent muscle pathology and should be able to undergo therapeutic inclusion of exercise strategies to improve muscle mass and ultimately bone strength.

Using random forest for multi-marker predictive pharmacogenetics study. *N. Bing, P. St. Jean, I. Grossman, M. Mosteller* Genetics, GlaxoSmithKline, Research Triangle Park, NC.

The clinical goal of a pharmacogenetics (PGx) study is to enable the prospective identification of individual variations in drug response using a genetic marker, or a set of genetic markers. Predictive models can be used to provide rules for combining a series of genetic markers that best predict the phenotype of response to treatment. Random Forest (RF) is one such predictive modeling method, which has recently attracted much attention in genetics investigations due to its ability to (1) explore high order marker interactions; (2) handle genetic heterogeneity; (3) rank markers by importance when they are being incorporated into the multivariate prediction process; and (4) exhibit excellent performance in prediction accuracy. However, there is no clear criterion for marker selection within the RF modeling process. We therefore explored the usefulness of cross-validation (CV) as a method for marker selection in RF within the context of PGx studies. We evaluated CV in RF using both simulated and real clinical PGx data, where phenotypes are defined from adverse drug events as case or control status and genotypes are examined from more than 7000 single nucleotide polymorphisms in a panel of 120 candidate genes. Within simulation, case-control status is determined by underlying causal genetic variants and their interactions; in the meanwhile, the sample size, case event rate and genotype linkage disequilibrium relations are kept intact to mimic realistic PGx data. Simulations under various genetic interaction models indicate that CV can be used to identify correct combinations of sets of markers for RF model construction; and that marker selection by CV increases RF prediction accuracy. By contrast, marker selection via either sample fitness criteria or out of bag (OBB) error results in over-fitted models and incorrect or unnecessarily large sets of markers in the RF model. Results of applying CV for marker selection in RF to real clinical PGx data will also be discussed. Overall, we recommend that CV for marker selection be included as an essential step when using RF for building multi-marker predictive models for PGx studies.

A novel algorithm and software for evaluation of population level linkage disequilibrium (LD) patterns based on r^2. *K. K. Nicodemus[1,2], W. F. Bodmer[3]* 1) Centre for Human Genetics, Wellcome Trust, University of Oxford, Oxford, United Kingdom; 2) Department of Clinical Pharmacology, University of Oxford, Oxford, United Kingdom; 3) Cancer and Immunogenetics Laboratory, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, United Kingdom.

Linkage disequilibrium patterns vary between populations due to genetic drift, natural selection and admixture; metrics have been derived to measure LD including D and r^2. Additional methods have been developed to describe blocks of correlated SNPs based on D e.g., HAPLOVIEW. Clusters of correlated SNPs are commonly-used in association studies for selection of tagSNPs, defining haplotypes for association analysis and fine-mapping of putative causal loci; the use of haplotypes in detection of population substructure has not been fully explored. D is known to show a ceiling effect when only 3 of the 4 possible 2-SNP haplotypes are observed and thus is less informative than r^2 in tight-LD regions.

We present a set of new algorithms for clustering correlated SNPs based on the LD metric r^2; the 1st-level clustering algorithm accepts genotype-level data or phased haplotypes as input and allows users to impute missing genotypes, set an r^2 threshold for block definitions and set the windowsize for growing blocks, removing SNPs within the window not passing the threshold. The 1st-level algorithm may be used alone for defining haplotype blocks or users may pass the results of the algorithm to a 2nd-level meta-blocking algorithm which clusters correlated haplotype blocks and/or singleton SNPs, allowing for in-depth description of LD structure and facilitating fine-mapping. In addition, the meta-blocking algorithm may be used to detect population substructure by using meta-blocks as input to e.g., principal components analyses; differences in haplotypic LD structure are more informative than that of single SNPs. The **r2blocks** and **metablocks** functions are implemented in a freely-available package for the R statistical computing environment and we showcase its functionality on data simulated under the coalescent and on genomewide data from the HGDP-CEPH Human Genome Diversity Panel in multiple worldwide populations.

Screening of 144 patients with mental retardation and /or developmental delay by array-CGH. *F. Bena[1], S. Gimelli[1], S. Dahoun[1], N. Brun[1], S. Fokstuen[1], A. Giacobino[1], B. Conrad[2], M. A. Morris[1], A. Bottani[1], S. E. Antonarakis[1]* 1) Dept Medical Genetics, Univ Medical School and Hospital, Geneva, Geneva 4, Switzerland; 2) Dept Medical Genetics, Inselspital, Berne, Switzerland.

Array-Comparative Genomic Hybridization (aCGH) allows a high resolution whole genome analysis of copy number changes and can reveal submicroscopic deletions and duplications. We present the results of aCGH analysis in 144 probands with mental retardation, developmental delay, and/or congenital malformations. An oligo aCGH with an average coverage of 40 kb (Agilent 244K) was used. De novo Copy Number Variants were identified in 11.1% of the cases including 9 deletions (15q25.3q26.1, 22q13.3,6q13q14.1, 14q32.2q32.31, 5q14.3, 12q13.11, 10q11.22q11.23, 12p11.23, 1q21.11, 5 duplications (16p13.3, 5q14.3q15, 15q11q13, 16p12.3, Xq27.3q28), 2 deletions associated with duplications (6p25p24.3 and 6p24.3p24.1, 14q32.3 and 14q32.3), and one case with more complex rearrangement, ranging from 0.007 Mb to 13.3 Mb. aCGH analysis of patientss parents was required in 20% of these cases. Additionally, the analysis revealed 16 cases patients with novel Copy Number Variants inherited from a healthy parent ranging between 30 kb and 1.2 Mb. Our cohort also includes four cases of de novo apparently balanced translocations in which aCGH did not detect cryptic genomic unbalances at the breakpoints. As positive control, five cases of unbalanced karyotypes were analysed and revealed large deletions and duplications. We conclude that aCGH substantially contributes to the diagnostic evaluation of patients, but the interpretation of the results requires the collective effort of many laboratories and large numbers of cases and controls examined.

Vitamin D pathway gene polymorphisms and risk of breast cancer in Cyprus. *A. Hadjisavvas, M. Loizidou, A. Takousi, T. Michael, K. Kyriacou* Department of EM/Molecular Pathology, The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus.

Vitamin D plays a key role in cell proliferation, differentiation, and apoptosis in both normal and malignant breast cells. Studies have hypothesized that the active form of vitamin D has anti-proliferative effects in breast cells. This hypothesis is supported by the reduced breast cancer risk observed among women with high vitamin D intake. The involvement of vitamin D pathway gene polymorphisms (SNPs) and more specifically vitamin D receptor (VDR) SNPs in breast cancer etiology has long been of interest. In the present study we explored the implication of vitamin D pathway gene polymorphisms in breast cancer in the Cypriot population. A total of 2286 DNA samples from Cypriot women (1109 breast cancer patients and 1177 age-matched healthy controls) were genotyped for 8 SNPs in genes involved in the vitamin D pathway. Four SNPs located near the VDR 3 region have been examined; these SNPs are identified by their restriction endonuclease cleavage sites (TaqI, BsmI, ApaI and FokI). In addition, a poly(A) microsatellite repeat in the 3' untranslated region which may influence VDR mRNA stability was assessed. We also genotyped common SNPs in vitamin D pathway genes and more specifically T432G (rs7041) and A436C (rs4588), both in exon 11 of the GC gene, which codes for the vitamin D-binding protein (DBP) and rs2296241 in exon 4 of the CYP24A1 gene, which encodes 24(OH)ase, which initiates degradation of 1,25(OH)2D. The prevalence of the 8 SNPs was compared between cases and controls. Genotype frequencies were compared across groups using the chi square test and the Mantel-Haenzel test for linear trend. The association between breast cancer and each SNP was examined using logistic regression with the SNP genotype tested under models of complete dominance and recessive inheritance. Statistically significant results were observed for one of the SNPs under study. We are currently expanding our analysis to study haplotypes and their association with breast cancer.

Global microRNA analysis in human skin reveals post-transcriptional regulatory networks involved in psoriasis susceptibility and pathogenesis. *C. Joyce, A. Bowcock* Dept of Genetics, Washington Univ, Saint Louis, MO.

Psoriasis is a chronic inflammatory skin disease affecting 2-3% of the European population. Hallmarks of the disease include poorly differentiated, hyperoliferative keratinocytes, and infiltration of activated immune cells into the dermis and epidermis. In addition to these histological changes, our laboratory and others have identified many mRNAs that are misexpressed in psoriasis. MicroRNAs (miRNAs) are endogenous, small RNA molecules that post-transcriptionally regulate gene expression. Recent studies have demonstrated the importance of miRNAs in skin development and the ongoing program of terminal keratinocyte differentiation. Hence, dysregulation of miRNAs may be involved in psoriasis susceptibility and pathogenesis. To investigate this hypothesis, miRNA profiling of psoriatic lesions, matched uninvolved skin, and non-diseased controls was performed by hybridization of RNAs to Exiqon microarrays. Differentially expressed miRNAs were validated by qRT-PCR. We identified five microRNAs that were differentially expressed in psoriatic lesions and, to a lesser extent, matched uninvolved skin compared to non-diseased controls: miRs -133a/b were downregulated while miRs -21, -31, and -223 were upregulated. We also confirmed altered regulation of miR-203 which has been shown to play a role in terminal differentiation of keratinocytes and to be highly upregulated in psoriasis by Sonkoly *et al.* (2007). To determine which cell types express our novel miRNAs, we performed qRT-PCR in cell lines derived from keratinocytes, T and B cells. miR-31 was primarily expressed in keratinocytes, miR-223 was primarily expressed in T cells and B cells, and miRs-21 and 133a/b were expressed in all cell lines at high and low levels, respectively. Knockdown of miR-31 and miR-203 was successfully achieved in keratinocytes using locked nucleic acid knockdown probes. Peptide targets of these miRNAs are being identified by *in silico* approaches and by global protein analyses in wild-type and knockdown strains. These findings have implications for psoriasis pathogenesis and may provide novel methods of therapeutic intervention.

Complementing Mutation-Driven Databases with Phenotype-Rich Repositories: The Clinical and Functional TRanslation of CFTR (CFTR2) Project. *P. R. Sosnay[1], C. Castellani[2], C. Penland[3], J. Zielenski[4], G. R. Cutting[1]* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Cystic Fibrosis Centre, Ospedale Civile Maggiore, Verona, Italy; 3) Cystic Fibrosis Foundation, Bethesda, MD; 4) Hospital for Sick Children, Toronto, Canada.

Locus-specific mutation databases (LSDBs) are populated by alleles discovered in research and diagnostic laboratories but frequently contain insufficient data to interpret the phenotypic consequences of each variant. Enhancing the accuracy and depth of clinical or functional information in existing LSDBs by retrospective data collection is expensive and inefficient. Cystic fibrosis (CF) provides an example of the challenges posed by translation of genetic variation to medical practice. The CF Mutation Database contains over 1500 disease-associated CFTR mutations, but the functional and clinical consequences have only been well characterized for about thirty mutations. The Clinical and Functional TRanslation of CFTR (CFTR2 Project) proposes to annotate all reported CFTR mutation using rigorously vetted clinical data. The curators of the CF Mutation database are performing an extensive international survey of academic and commercial laboratories that scan or sequence the CFTR gene to create a comprehensive catalogue of variations in CFTR. Clinical information agreed upon by a panel of CF experts is being extracted from Patient Registries and from major CF Care Centers from around the world and entered into the CFTR2 database. CFTR mutations with inadequate or inconsistent clinical information will be evaluated in vivo for putative RNA processing defects or in cell-based systems for putative deleterious amino acid substitutions. These functional studies will be incorporated into the assessment of disease-liability and the potential for mutation specific therapeutics. The CFTR2 project presents a novel approach to clinical and functional annotation of mutations identified in disease-causing genes. Creation of separate phenotype-driven databases for single gene disorders allows preservation of established mutation-driven LSDBs while providing expert clinical assessment for medically significant alleles.

A Single Nucleotide Polymorphism (SNP) at DBH is associated with Alzheimer Disease in European-American Subjects. *Y. Tang[1], J. Lah[3], A. Rosen[3], A. Levey[3], J. F. Cubells[1,2]* 1) Dept of Human Genetics, Emory University, Atlanta, GA; 2) Dept of Psychiatry and Behavioral Sciences, Emory University, Atlanta, GA; 3) Dept of Neurology, Emory University, Atlanta, GA.

Background: Degeneration of the locus coeruleus (LC), the largest nucleus of norepinephrine (NE)-producing neurons innervating virtually all cortical and subcortical areas, is a well described yet under-studied neuro-pathological feature of Alzheimer disease (AD). Dopamine -hydroxylase (DH), encoded by the locus DBH on human chromosome 9q34, catalyzes the conversion of dopamine (DA) to NE and is expressed specifically in the LC and other NE-containing nuclei. We hypothesized that DBH sequence variation associates with AD or AD-related behavioral phenotypes. **Method:** Nine SNPs at DBH were selected based on assay availability, inter-marker distance and linkage disequilibrium (LD) relationships. Genotypes were determined using the Taqman platform in 295 samples from AD cases and 305 healthy elderly controls of self-reported European-American ancestry. Association data were analyzed in SPSS, haplotype frequencies were calculated using WHAP, and LD structure was examined using Haploview. **Results:** One SNP, rs2519148, located approximately 7 kilobases upstream of the translation-initiation codon of DBH, associated with the diagnosis of AD in EA samples (permutation p=0.002, significant at = .05 after correction for multiple testing), with allele G and genotype GG being over represented in cases. The SNP is not in LD with either of two known putatively functional SNPs, rs1611115 and rs6271. Binary logistic regression analysis showed that genotype at rs2519148 remained significantly associated with AD after controlling for age and gender (p=0.004). **Conclusions:** The results provide preliminary support for an association between sequence variation at DBH and AD diagnosis in EA subjects. **Support:** Alzheimer Disease Research Center grant P50 AG025688 to AL.

Interaction of the cilia-centrosomal protein Retinitis Pigmentosa GTPase Regulator (RPGR) with specific Bardet Biedl Syndrome (BBS) proteins implicates RPGR-BBS complex integrity in the pathogenesis of ciliopathies. *H. Khanna[1], S. He[1], N. Katsanis[2], A. Swaroop[1,3]* 1) Ophthalmology & Visual Science, University of Michigan, Ann Arbor, MI; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Neurobiology Neurodegeneration & Repair Laboratory, National Eye Institute, MD.

The dynamic behavior of cellular processes (such as ciliary transport) is mediated by distinct protein complexes that function as part of intricate networks or pathways. Mutations in Retinitis Pigmentosa GTPase Regulator (RPGR), a ciliary protein, are associated with a majority of XLRP cases and with hearing disorders. However, the function of RPGR in cilia-mediated regulatory pathways is poorly understood. Since retinal degeneration is a typical feature in Bardet-Biedl Syndrome (BBS), a syndromic ciliopathy, we hypothesized that RPGR associates with BBS proteins in the retina and that disruption of such interactions underlies the associated retinal degeneration in XLRP as well as BBS patients. Here we show that RPGR interacts directly with BBS4 and not with BBS2, BBS5, BBS6 or BBS8. Full-length BBS4 interacts with the amino-terminal RCC1-like domain of RPGR. Co-immunoprecipitation studies using bovine retinal extracts demonstrate that RPGR exists in complex with BBS2, BBS4, BBS6, and CEP290/BBS12. We predict the stability of RPGR-BBS complex(es) is critical for normal ciliary transport cascades and that RPGR mutations may act as modifiers of the penetrance and severity of the retinal degeneration phenotype in BBS patients.

SNP-based determination of 22q11 copy number variants in a schizophrenia trial. *P. Oeth[3], J. Crowley[1], T. Shi[3], J. Olson[3], J. Sebat[2], P. Sullivan[1]* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Cold Spring Harbor Laboratory, Cold Spring Harbor, New York; 3) Research & Development, Sequenom, Inc, San Diego, CA.

Deletion of 22q11 represents the most frequent deletion syndrome in humans, occurring in approximately 1 in 4000 live births. This deletion is currently believed to be the most common genetic risk factor for psychosis, but its prevalence in schizophrenia is unclear. To address this issue, we have examined copy number status at 22q11 in 741 individuals with schizophrenia from the CATIE clinical trial along with 733 matched controls. We first analyzed probe intensity data from a genome-wide association study of these samples using a Hidden Markov Model (HMM) for CNV prediction. We identified 2 schizophrenia cases and 0 controls with deletions >1 Mb on 22q11 (confirmed by Q-PCR), yielding a deletion prevalence in cases of 0.27% (95% CI, 0-0.64%). There were also a number of smaller predicted CNVs requiring confirmation. For this process, we employed a quantitative MassARRAY SNP-based CNV detection methodology. For an initial follow-up of the region, 109 SNPs with a HapMap minor allele frequency of 0.30 or higher were selected and multiplexed with 8 non-variant control SNPs from 4 genes located outside of the 22q11 region. Forty-eight samples, consisting of 24 cases, 18 matched controls, and 6 samples with known copy numbers for this region (CNV controls) were quantitatively genotyped. The results showed 39 SNPs deviating from the 1:1 ratio of a normal heterozygote in at least 1 or more clinical samples but showing no deviation in control SNPs for the same samples. The correlation between the HMM predictions and these results were promising with confirmation in 17 out of 41 individuals, with 12 individuals exhibiting multiple confirmatory loci. Clear allele-specific CNV status was resolved for duplications in these individuals. For example, an A/G SNP in the COMT gene exhibits a clear duplication of the A allele in two schizophrenia samples. Current work is focused on converting informative assays to resolve absolute copy numbers and expand the sample set to the entire CATIE cohort.

BRACHYOLMIA WITH AMELOGENESIS IMPERFECTA: FURTHER EVIDENCE OF A SINGLE ENTITY.

D. Bertola[1], R. Antequera[2], M. J. Rodovalho[1], R. S. Honjo[1], L. M. J. Albano[1], I. M. Furquim[1], L. A. Oliveira[3], C. A. Kim[1] 1) Pediatrics, Instituto da Criança, São Paulo, Brazil; 2) Dentistry Division, University of São Paulo, São Paulo, Brazil; 3) Radiology, University of São Paulo, São Paulo, Brazil.

Brachyolmia is a heterogeneous group of skeletal dysplasia characterized by generalized platyspondyly without significant epiphyseal or metaphyseal involvement. Several types of brachyolmia were described: (1) Hobaek and Toledo types, (2) Maroteaux type, and (3) an autosomal dominant type, in contrast to the inheritance of the others, all considered autosomal recessive (Shohat et al., 1989). In 1996, Verloes et al. described a further type of brachyolmia associated with amelogenesis imperfecta in two siblings born to a consanguineous Moroccan couple. The molecular basis of these different types of brachyolmia remains unknown. We evaluated three cases, two siblings and an isolated case also from consanguineous matings. The three affected patients presented with short stature, platyspondyly, oligodontia and enamel dysplasia. In the two siblings (ages 26 and 17) the skeletal findings were more striking with scoliosis, more pronounced in the older patient, narrow intervertebral distance, short pedicles, posterior scalloping and herniation of the nuclei; short ilia and broad femoral necks. Neither metaphyseal nor epiphyseal involvements were observed. Orthopantographic study disclosed agenesis of teeth in the three affected patients. Ophthalmologic evaluation and urinary excretion of mucopolysaccharides were normal. Our two families showing involvement of the spine and teeth give further support to the fact that skeletal and dental findings are part of the spectrum of one single entity and not a co-occurrence of two separate disorders, brachyolmia and amelogenesis imperfecta. Within the group of brachyolmia, the complete revealing of the molecular mechanisms underlying the different clinical forms of brachyolmia will help elucidate if these conditions are due to genetic heterogeneity or simply variable expressivity of the same disorder.

Generation and characterization of brain-targeted lysosomal -galactosidase for expression in microencapsulation therapy for GM1 gangliosidosis. *M. D. Lambourne, M. A. Potter* Medical Sciences, McMaster University, Hamilton, ON, Canada.

GM1 gangliosidosis is a neurodegenerative lysosomal storage disorder caused by an inherited deficiency of the enzyme -galactosidase (GLB1). Reduced catalytic activity of GLB1 results in the abnormal storage of glycoconjugates such as GM1 ganglioside, a major functional component of neuronal cell membranes, and typically leads to developmental arrest and death within the first few years of life. Microencapsulation therapy may provide an effective long-term treatment for GM1 gangliosidosis, whereby recombinant cells secreting a desired protein are implanted within a biocompatible polymer, but like other attempts to treat this disorder would be futile since the blood-brain barrier (BBB) obstructs the delivery of most therapeutics to the central nervous system (CNS). A 29 amino acid peptide derived from the rabies virus glycoprotein (RVG) can mediate transcytosis of small molecules across the BBB, and thus reveals a potential mechanism to safely target the CNS via the intravascular route. To determine whether a GLB1-RVG fusion protein would retain its enzymatic properties, the human GLB1 cDNA was cloned into an expression vector and modified to encode the RVG peptide sequence, and an Au1 epitope tag to facilitate detection. The Au1GLB1 and Au1GLB1-RVG constructs expressed in GM1 fibroblasts showed a GLB1 specific enzyme activity that was not abrogated when compared to cells expressing unmodified GLB1, and was able to restore GLB1 activity to greater than normal levels in these deficient cells. Enzyme secreted into the medium from microencapsulated cells was able to cross-correct the enzyme deficiency of cultured GM1 fibroblasts in a mannose-6-phosphate (M-6-P) dependant manner, while only the RVG peptide could facilitate M-6-P independent uptake by a neuronal cell line. Correct processing and routing of the protein from the supernatant to the lysosomes was verified for RVG-fused and unfused GLB1. These results indicate that GLB1-RVG fusion protein retains its lysosomal enzymatic properties when secreted by microencapsulated cells, and will serve as a good model to elucidate the ability of RVG peptide to allow transcytosis of large molecules across the BBB.

A flexible and powerful statistical method for evaluating genetic associations in families or unrelated subjects. *S. R. Diehl*[1, 2], *A. L. Maes*[1, 2, 3], *F. Kuo*[1] 1) Center for Pharmacogenomics and Complex Disease Research, New Jersey Dental School, University of Medicine and Dentistry of NJ, Newark, NJ; 2) Dept of Health Informatics, SHRP, University of Medicine and Dentistry of NJ, Newark, NJ; 3) Early Development Statistics, Merck & Co. Inc., Rahway, NJ.

Whole-genome and candidate-gene association studies of complex disease require very large numbers of subjects. Careful consideration of alternative study designs and the statistical tests is needed to maximize chances of success. As genotyping costs have decreased immensely, a studys power now often depends primarily on the cases and controls available. Investigators often have a mixture of unrelated subjects as well as small and larger families with one or more members affected by the disease of interest. Here, we present a flexible statistical method that accommodates both families and unrelated subjects, or combinations of both, and that provides power equal to or greater than existing methods. Using simulation, we compared the statistical power of our adjusted Armitage trend test (ATT) that accounts for family relatedness to existing family-based tests of association. We employed permutation-based adjustments to the Armitage ^{2} so the test could be applied to family data with unbiased results. Power was compared to that obtained using FBAT, PDT, and LAMP tests of association. Various nuclear family pedigree structures were studied. A disease gene along with SNPs in high, moderate and low LD to the disease gene were simulated following multiplicative, dominant and recessive models with prevalence ranging from 1% to 25%. For all pedigree structures and disease models we examined, the ATT was valid for family data (had nominal Type I error), and it very substantially outperformed both the FBAT and PDT in statistical power. The LAMP test had slightly higher statistical power than the ATT. However, the LAMP is limited to simple nuclear families while the ATT can accommodate large and complex pedigree structures with missing data. A computer program for implementing the test is available. The ATT is a powerful and flexible test of genetic association suitable for case-control and family data.

Sequence variants in the 3UTR of MECP2 gene and their potential effects on putative MicroRNA target sites. *Y. Yang, P. Fang, P. Ward* Dept Molec & Human Gen, Baylor Col Med, Houston, TX.

MicroRNAs (miRNA) are small non-coding RNAs of 18-24nt which can repress post-transcriptional gene expressions by binding to the 3UTR of targeted genes. Deregulations of miRNAs are associated with human diseases such as cancer and heart disease, and sequence variations in miRNA target sites in 3UTR can affect phenotypes. *In Silico* predictions showed that many genes, including the gene of our interest, MECP2, are abundant in putative miRNA target sites in their 3UTR regions. Sequence changes in 3 UTR of the MECP2 gene have been reported but their effects are mostly unknown. Those variants, if in the right locations, may potentially strengthen or weaken miRNA target sites, leading to increased or decreased MECP2 expression levels respectively and resulting in disease.

Our laboratory offers clinical tests for MECP2 gene sequencing, which covers the entire coding region of the MECP2 as well as a small portion of the 3UTR sequence. Seven sequence variants have been detected in the 3 UTR of the MECP2 gene by our routine sequencing analysis. While three out of the seven 3UTR changes are polymorphisms, the other four changes are unclassified variants. Using the TargetScan program, two unclassified variants, *13CT and *14GA, are ruled out as potential miRNA target sites because the variants are in proximity to the open reading frame of the MECP2 gene. The third unclassified variant, *93GA, is predicted to result in mismatches in the sites matching the seed region of a miRNA by TargetScan. The fourth unclassified variant, *55CG, is predicted to be outside miRNA target site by TargetScan. However, another *in Silico* program (www.microrna.org) predicted that *55C is located in a miRNA target site and *55CG results in a mismatch between the miRNA and its putative binding site. The possibility that the 3 UTR variants may strengthen or create miRNA binding site will also be explored. It should be noted that *in vitro* studies such as luciferase reporter assay are necessary to determine if a putative miRNA target sites is indeed a functional miRNA binding site and if a sequence variant in the target site may affect miRNA function.

Prader-Willi like phenotype in a boy with homozygous 1p31.3 microdeletion. *S. Jaillard[1,2], H. Journel[3], S. Odent[1,4], V. David[1,5], L. Pasquier[1,4], C. Bendavid[1], J. Mosser[1], C. Henry[2], J. Lucas[2], C. Dubourg[1,5]* 1) Faculty Medicine, CS34317, UMR 6061, Rennes, France; 2) Histology Cytogenetics department, Pontchaillou University Hospital, Rennes, France; 3) Genetics department, CHBA Vannes, France; 4) Genetics department, Hopital Sud University Hospital, Rennes, France; 5) Molecular Genetics department, Pontchaillou University Hospital, Rennes, France.

We report a case of homozygous 1p31.3 microdeletion, identified by CGH-array (Agilent 4x44K), in a boy with early-onset severe hyperphagia, mental retardation and some dysmorphic features. The microdeletion has a minimal size of 80 kb and includes 3 genes *(DNAJC6, LEPROT, LEPR)*. The deletion homozygosity could be explained by uniparental disomy (isodisomy) or heterozygous deletion in both parents. The latter hypothesis was confirmed by multiplex PCR method although pedigree of the family apparently didnt show consanguinity. *LEPR* gene encodes the leptin receptor, which allows leptin to regulate adipose-tissue mass through hypothalamic effects on satiety and energy expenditure. Deleterious mutations of *LEPR* have been reported in subjects with early-onset severe obesity, hyperphagia, hypogonadotrophic hypogonadism, but without mental retardation and dysmorphic features. Heterozygous subjects do not present with obesity and have normal sexual development. *LEPROT* is linked to *LEPR* as it negatively controls *LEPR* function. Finally, *DNAJC6* could possibly explain mental retardation and dysmorphic features in our patient since this gene has a strong cerebral expression.

Combining information from candidate genes for autism in a risk score model improves predictive power: Statistical assessment of 15 genes and potential clinical applications. *J. Hager, M. Letexier, F. Rousseau, F. Tores*
Res & Development, IntegraGen SA, Evry, France.

Autism is a complex disorder with a strong genetic etiology. Although association with many genes has been reported, the modest increase in risk for each gene individually has hampered replication of association and renders the clinical use as a risk assessment tool ineffective. However, a multigene risk assessment model might provide more useful risk prediction information. We explored the impact on disease risk of 15 genes previously shown to be associated with autism: ASMT, ATP2B2, CNTNAP2, EN2, ITGB3, MARK1, MET, OXTR, PITX1, PRKCB1, SLC6A1, SLC6A11, SLC6A4, SLC6A7 and SLC25A12. To enhance chances for replication for single genes we genotyped tagSNPs at r2= 1.0 including SNPs reported associated previously. The 15 genes were genotyped in 493 families from AGRE (858 affecteds; male/female ratio 4:1). FBAT analysis was used to assess single gene associations for all families combined or for families with female affecteds and male affecteds only. After correction for multiple testing only ATP2B2, CNTNAP2, EN2, MARK1, PITX1, PRKCB1, SLC6A7 and SLC6A11 remained positive (p-value range p= 4.2x10-3 to p= 5.6x10-5). Sub-group analysis in families by sex of the affected children increased the evidence for association for some of these genes significantly. The average odds ratios for single genes were ~1.4. We then combined positive genes in a risk score to determine if this would increase predictive values for autism. Logistic regression adjusting for gender was used to determine odds ratios associated with increasing numbers of risk alleles. The risk for autism increased with the number of risk alleles in the combined genes (increase per risk allele app. 1.35). A ROC curve was constructed and the area under the curve (AUC) was tested for significance to describe the overall performance of the combined genes. The AUC of the corresponding ROC curve was approximately 0.7. Thus we demonstrate that combining information from several autism-related genes significantly increases the odds ratios and the power to assess the risk to develop autism in these families.

Development of psoriasiform skin lesions under anti-TNF therapy: a genetic link? *I. Cleynen[1], B. Claes[2], H. Nuytten[3], K. Van Steen[4], L. Henckaerts[1], M. Noman[1], H. Fidder[5], H. Cuppens[3], D. Lambrechts[2], P. Rutgeerts[1], S. Vermeire[1]* 1) Gastroenterology, KU & UZ Leuven, Belgium; 2) Transgenic Technology and Gene Therapy, KU Leuven, Belgium; 3) Center of Human Genetics, KU Leuven, Belgium; 4) Inst.Montefiore & Bioinformatique, ULG, Liège, Belgium; 5) Gastroenterology, Leiden University Medical Center, Netherlands.

Anti-TNF therapy is very efficacious for patients with inflammatory bowel disease (IBD). Despite an overall favorable safety profile, 21.7% of IBD patients treated with infliximab (IFX) in our hospital develop skin lesions, including psoriasiform dermatitis. Since there is no clear association between occurrence of skin lesions and cumulative dose of IFX, we hypothesized that certain genetic risk factors, described for both IBD and psoriasis (*IL23R* and *IL12B* variants, *Beta-defensin* (*DEFB4*) copy number (CN)) predispose to the occurrence of skin lesions in IFX-IBD patients. IFX-IBD patients (n=714) and healthy controls (n=342) were genotyped for 22 *IL23R* and 10 *IL12B* markers using the Sequenom platform. A subset of patients (n=258) was also tested for the number of *DEFB4* repeats, using qRT-PCR. All IFX-IBD patients were reviewed for occurrence of skin lesions. Analysis of genotype frequency differences between patients and controls could confirm *IL23R*, but not *IL12B* as a susceptibility gene for IBD. Multifactor Dimensionality Reduction, to test single and multilocus genetic combinations for the ability to predict the development of skin lesions, suggested that the best multilocus model consisted of 4 loci, with balanced accuracy of 63.1% and cross-validation consistency of 70%. Of the patients tested for the number of *DEFB4* copies, 27.5% developed skin lesions. The distribution of the CN was significantly different between patients who developed skin lesions compared to those who do not (Chi^2 p=0.03). Presence of 4 copies was associated with a significantly higher risk of developing skin lesions (Chi^2 p=0.01). The results of our study suggest that a common genetic predisposition may trigger the development of (psoriasiform) skin lesions in IBD patients treated with IFX.

Polymorphisms in the vesicle-associated membrane protein-associated protein A (VAPA) gene on chromosome 18p and bipolar disorder. *F. W. Lohoff, A. E. Weller, P. J. Bloch, A. H. Nall, T. N. Ferraro, W. H. Berrettini* Dept Psychiatry, Univ Pennsylvania, Philadelphia, PA.

Objectives: Linkage studies in bipolar disorder (BPD) suggest that a susceptibility locus exists on chromosome 18p11. The vesicle-associated membrane protein-associated protein A (VAPA) gene maps to this region. VAPA interacts with presynaptic proteins and is necessary for vesicular neurotransmission. Dysregulation of synaptic neurotransmission might contribute to the pathophysiology of BPD. In this study, we hypothesize that genetic variations in the VAPA gene contribute to BPD. Methods: Genotyping of 6 SNPs (rs494015; rs29193; rs29162; rs29145; rs29067; rs29066) was carried out in BPD patients (n=570) and healthy controls (n=730). Genotypes and allele frequencies were compared between groups using Chi square contingency analysis. Linkage disequilibrium (LD) between markers was calculated and estimated haplotype frequencies were compared between groups. Results: Single marker analysis revealed an association of rs29067 and rs29066 with BPD; however, after permutation correction, only rs29066 showed a trend towards an allelic association (p=0.066). Haplotype analysis did not show any significant association with disease after permutation correction. Conclusion: Our results provide suggestive evidence of an association between SNPs in the 3UTR of the VAPA gene and BPD. Interestingly, these SNPs are in close proximity to the microsatellite marker D18S464, which showed significant signals in previous linkage studies of BPD. Additional studies are necessary to confirm and elucidate the role of VAPA as a susceptibility gene for BPD on chromosome 18p.

Significant Results of CNV Analysis of Myopia in Schoolchildren. *A. Dellinger[1], T. L. Young[1,3], M. Seielstad[2], L. K. Goh[3], S. M. Saw[4,5], Y. J. Li[1]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Genome Inst. of Singapore; 3) Duke Singapore Graduate Med School; 4) Dept of Community, Occupational, and Family Med, Nat. Univ. of Singapore; 5) Singapore Eye Research Institute.

The Singapore Cohort study Of the Risk factors for Myopia (SCORM) followed the ocular development of over 1000 Singapore schoolchildren over several years. Illumina 550K SNP arrays were used to analyze the copy number variation (CNV) content of 1027 SCORM samples, of which 123 were normal, 109 were hyperopic, 730 were myopic, and 65 had unknown phenotype. We classified phenotype as: hyperopia (>0.50 diopters (D)), normal (-0.5 < D <= 0.5), low myopia (-3.00 < D <= -0.5), medium myopia (-6.0 < D <= -3.0), and high myopia (D <= -6.0) at the most recent visit. Nexus CGH was used to detect CNVs in the samples. Plink was used to perform tests of association. There is a trend of increasing numbers of CNVs per individual with increase in myopia severity- 33.9, 36.7, 37.8 for low, medium and high myopia cases, respectively, compared with 28.3 for controls (normal vision). Searching for CNVs of greater frequency in high myopia cases (n=93) than in controls (n=123) at uncorrected $p < 0.05$ showed: CNVs, including a gene, in MYP4 and MYP10 myopia loci; a CNV in a region implicated in glaucoma; and four genes involved in neurological diseases. Comparing all myopia cases to controls, CNVs were overrepresented ($p < 0.05$) in controls in myopia loci MYP3, MYP5, MYP6, MYP10, and MYP14. Genes in these CNVs primarily have neurological and developmental roles. Another gene involved in retinitis pigmentosa and retinal degeneration is significant in myopia when comparing high myopia vs. controls and medium+high myopia vs. controls. Deletion CNVs cover 156Kb of this gene. The region of the CNV with the most significant p-value ($p < 0.004$) is present in 7.5% of high myopia cases, 3% of both medium and low myopia cases, and 0% in controls. Use of additional CNV detection methods and qPCR to confirm these CNVs are warranted.

Combined malonic and methylmalonic aciduria (CMAMMA) with normal malonyl-CoA decarboxylase (MCD) activity detected by newborn screening (NBS). *R. Gavrilova[1], S. Tortorelli[2], K. Schoonderwoerd[3], D. Matern[2], P. Rinaldo[2], D. Gavrilov[2]* 1) Dept Medical Genetics, Mayo Clinic, Rochester, MN; 2) Biochemical Genetics Laboratory, Mayo Clinic, Rochester, MN; 3) Dept Clin Genet, Erasmus MC, Rotterdam, Netherlands.

Background: Malonic aciduria has been reported in <30 patients, most with deficiency of MCD. Few patients have been categorized as CMAMMA with normal MCD activity. Both conditions are associated with variable phenotypes ranging from severe neonatal crisis to developmental delays/neurologic abnormalities. No cases thus far are reported with persistent CMAMMA and no associated symptoms. Case report: We present a case of CMAMMA. Patient was detected by NBS showing elevated malonylcarnitine (0.97 mol/L; cutoff 0.20, 99%ile of normal population 0.09). Accumulation of 3-OH octanoylcarnitine was unlikely because follow up testing revealed malonic aciduria (>500 mmol/mol Cr; reference <5) combined with mild methylmalonic aciduria (21-197 mmol/mol Cr; reference <3.6). In vitro MCD activity was normal (13 nmol/hr/mg protein; reference >5.7). MLYCD gene sequencing encoding MCD revealed no mutations in patient or parents. Patient on treatment from birth with MCT oil, cholesterol,avoiding fasting, remains asymptomatic at age 12 months. Mother has elevated plasma malonyl carnitine (0.29 mmol/L, controls <0.13), but no elevated urine malonic/methylmalonic acid excretion. Conclusions: This is the first case of CMAMMA identified by NBS. Like most acylcarnitine species, malonylcarnitine is not specific marker for single condition, but requires at least differential diagnosis between two conditions. In contrast to published cases, our patient has no symptoms at 12 months. Patients mother is also asymptomatic with elevated malonyl carnitine in plasma. These findings suggest asymptomatic individuals with malonic aciduria caused by mutations in yet unidentified gene(s) can be detected by NBS. Clinical significance of CMAMMA and its underlying defect remain to be elucidated.

MicroRNAs affect mRNA expression in a range of cells during retinal development. *D. A. C. Simpson, A. Arora, J. Guduric-Fuchs* Centre for Vision Science, Queen's University Belfast, Belfast, Northern Ireland, United Kingdom.

MicroRNAs (miRNAs) are small RNA molecules (22 nucleotides) which have been shown to play an important role in both development and in maintenance of adult tissue. Conditional inactivation of miRNAs in the eye causes loss of visual function and progressive retinal degeneration. In addition to inhibiting translation, miRNAs can mediate degradation of targeted mRNAs. We have previously shown that the resulting signature of those miRNAs which are active in a tissue can be detected within mRNA expression profiles detected by microarray analysis. The purpose of this study was to predict which miRNAs are active during retinal development and in the adult retina and to confirm their expression.

Microarray expression data from the retinal stem cells (RSCs), developing and adult retina were generated or downloaded from public repositories. Analysis of gene expression profiles detected the effects of multiple miRNAs at each time point. The expression of all 20 selected miRNAs was confirmed by RT-PCR and the cellular distribution of representative candidates analyzed by in situ hybridization. Highly expressed miRNAs (eg. miR-124, miR-204, let-7, miR-9) showed strongest correlation with the predicted effects upon gene expression.

This study has detected the effect of miRNAs upon mRNA expression within the developing and adult retina. The validity of these observations is supported by the experimental confirmation of candidate miRNA expression. Identified miRNAs are likely to be important in retinal development and function. Sequence variants which caused misregulation of these miRNAs would be likely to contribute to retinal degeneration and disease. Conversely, manipulation of the expression of these miRNAs could potentially be used as a therapeutic tool in the future.

Duplication of Xq28 including the *MECP2* gene in a female with mental retardation and seizures. *D. N. Abuelo[1,4], N. Shur[1,4], S. R. Gunn[2], D. Mandelbaum[3,4]* 1) Dept Pediatrics, Rhode Island Hosp, Providence, RI; 2) Combimatrix Molecular Diagnostics, Irvine, CA; 3) Dept Neurology, Rhode Island Hosp, Providence, RI; 4) Warren Alpert School of Medicine at Brown University, Providence, RI.

MECP2 duplications have been associated with an X-linked syndrome characterized by severe mental retardation, progressive neurological symptoms and recurrent respiratory infections in males. Phenotypic features are nonspecific except for hypotonic, open mouth facies. Neurologic examination often shows axial hypotonia and spastic diplegia. Many of these patients die of pulmonary infections in infancy or early childhood. Our patient was born after a pregnancy complicated by a flu-like illness during the first trimester. Labor and delivery were unremarkable and she was thought to be a normal newborn. However psychomotor development was delayed from infancy. At age 1, she developed hemophagocytic lymphohistiocytosis and was treated with chemotherapy. Sequencing of the perforin gene did not reveal abnormalities. Head measurements stayed on the 10th percentile until 6 months of age, decreased to the 5th percentile at 12 months and subsequently have been in the microcephalic range. A Nissen fundoplication was done because of reflux and she received nutrition by gastrostomy tube from age 18 months to 3 years. Myoclonic seizures began at age 6 1/2. MRI showed white matter atrophy. Physical examination at age 7 showed severe microcephaly, no definite dysmorphism, axial hypotonia and lower extremity spasticity. Evidence of neurologic regression includes loss of a few words spoken at age 6 and loss of ability to walk with a walker that had been accomplished at age 3. Seizure frequency has been increasing and together with a higher dose of antiepileptic drugs, may contribute to the apparent regression. Array CGH showed a 4.0 Mb duplication of Xq28, including the *MECP2* gene. Previous reports of *MECP2* duplications have only involved male patients. Female carriers have been normal due to highly skewed X-inactivation. Our patient's X inactivation studies were normal, which correlates with her clinical findings. The reason for her random inactivation is not clear and is being investigated.

Partial rescue of the Kit-deficient testicular phenotype in *TSPY*-W^v/W^v mice. *S. Schubert[1], A. Schöner[1], I. Adham[2], W. Engel[2], J. Schmidtke[1]* 1) Institute of Human Genetics, Hannover Medical School, D-30625 Hannover, Germany; 2) Institute of Human Genetics, University of Göttingen, D-37073 Göttingen, Germany.

Human TSPY (**t**estis-**s**pecific **p**rotein, **Y**-encoded) is the product of a Y-chromosome-specific gene family located within the male specific region of the Y chromosome (MSY). *TSPY* expression is restricted to the testis where expression is limited to spermatogonia, spermatocytes and round spermatids. The *TSPY* expression pattern in germ cells and its homology to members of the TTSN-family indicate that TSPY functions as a proliferation factor of germ cells. In contrast to bovines and primates, where *TSPY* is organized as a repetitive gene family, the laboratory mouse harbours a single-copy pseudogene. We restored Tspy activity in a *TSPY* transgenic NMRI mouse line that carries a human *TSPY* transgene of approximately 50 copies on the mouse Y chromosome. In this study, we generated *TSPY* transgenic W^v/W^v mice and analyzed the histology of their testes and epididymides in order to contribute to understanding TSPY function in spermatogenesis. The Kit receptor, and its ligand stem cell factor (SCF) play a fundamental role in hematopoiesis, melanogenesis and gametogenesis. Homozygous W^v mutant male mice on a C57BL/6 background with a mutation on c-kit are infertile because of the almost total loss of germ cells in testes. We examined the testes of 58 adult *TSPY*-W^v/W^v males and 38 age-matched controls (NMRI-W^v/W^v) histologically. Round and/or elongated spermatids were observed in the testes of 35 out of 58 *TSPY*-W^v/W^v males and in 18 out of 38 NMRI-W^v/W^v mice. Sperms were identified in the epididymides of 23 out of 58 *TSPY*-W^v/W^v mice and in 3 out of 38 investigated NMRI-W^v/W^v males ($P<0.01$). We observed fertility in 4 out of 28 *TSPY*-W^v/W^v male mice mating with wild-type females, whereas none of the controls (18 NMRI-W^v/W^v males) produced offspring. Taken together our findings show that TSPY is able to partially rescue spermatogenesis in W^v/W^v mutants, an effect that is influenced to some extent by the NMRI genetic background.

Greater Burden of Rare Copy Number Variants in Schizophrenia. *J. Stone[1], Int. Schizophrenia Consortium[1,2,3,4,5,6,7,8,9]* 1) Psych & Neurodev Gen, Ctr Human Gen Res/MGH, Boston, MA.; The Stanley Center, The Broad Inst. of Harvard and MIT, Cambridge, MA, USA; 2) Inst. of Med. Sci., Univ. of Aberdeen, Aberdeen, UK; 3) Inst. of Molec. Med., TCD, Dublin, Ireland; 4) Dept. of Psychol. Med., Cardiff Univ., Cardiff, UK; 5) Windeyer Inst. of Med. Sci., UCL, London, UK; 6) Div. of Psych., Univ. of Edinburgh, Edinburgh, UK; 7) Dept. of Med. Epidemiology and Biostat., Karolinska Inst., Stockholm, Sweden; Dept. of Psych., UNC, Chapel Hill, NC; 8) Dep. of Psych. and Behavioral Sci., USC, Los Angeles, CA; 9) Queensland Inst. of Med. Res., Brisbane, Australia.

Schizophrenia (SCZ) is a severe mental disorder marked by hallucinations, delusions, cognitive deficits and apathy with heritability estimated at 73-90%. Inheritance patterns are complex and the number and type of genetic variants involved are not understood. Copy number variants (CNVs) have been identified in individual SCZ patients and in other neurodevelopmental disorders, but large-scale genome-wide surveys have not been performed. We report such a genome-wide survey of rare CNVs in 3,391 patients with SCZ and 3,181 ancestrally-matched controls using high-density microarrays. For CNVs that were observed in less than ~1% of the sample and greater than 100kb in length, the total burden is increased in SCZ patients compared to controls (P=3x10^{-5}; 1.151 fold increase). This effect was more pronounced for rarer, single-occurrence CNVs and for those that involved genes (P=5x10^{-6}) as opposed to those that did not (P=0.16). As expected, deletions were found within the region critical for velo-cardio-facial syndrome (P=0.0017, odds ratio (OR) =21.6), which includes psychotic symptoms in 30% of patients. Associations with SCZ were also found for large deletions on chromosome 15q13.2 (P = 0.0029, OR =17.9) and 1q21.1 (P = 0.0076, OR =6.6). These associations were not previously reported in the literature and remained significant after genome-wide correction. Overall, our results provide strong support for a model of SCZ pathogenesis that includes the effects of multiple rare structural variants, both genome-wide and at specific loci.

Symmetry of metabolic network. *Y. Xiao[1], H. Dong[2,3], W. Wang[1], L. Jin[2,4], M. Xiong[2,3]* 1) Department of Computing and Information Technology, Fudan University,ShangHai 200433, China; 2) School of Life Science, Fudan University, Shanghai 200433, China; 3) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77225, USA; 4) Chinese Academy of Science-Max-Planck-Gesellschaft Partner Institute for Computational Biology, Shanghai Institutes for Biological Science, CAS, Shanghai, 200433, China;.

Previous studies on metabolic works mainly focus on the statistic properties of networks, including.the small world, power-law distribution of vertex degree, bow-tie model, building block of network motifs and hierarchical structure of the network topology. Symmetry has been shown to be universal across various empirical network systems, however rarely been studied so far. In this paper, we systematically investigate the symmetry in metabolic networks. Symmetry in directed graph is introduced and an algorithm to calculate symmetry in directed graphs is proposed. Several symmetry based indices are used to measure the degree of symmetry and heterogeneity of metabolic networks. We found that metabolic network is strong locally symmetric and weakly globally symmetric; and that the more advanced the species; the lower the degree of symmetry is and the larger the network heterogeneity is. We also calculate all the automorphism partitions and analyze the functional similarity among vertices in the same orbits. We found that compounds in the same orbit, i.e. vertices that are automorphic equivalent to each other, show much more similarity in function than compounds belongs to different orbits. Our study suggests that symmetry play an important role in the function and evolution of metabolic networks.

TMEM70 is a novel factor of mitochondrial ATPase biogenesis and its mutations cause isolated enzyme deficiency and neonatal encephalo-cardiomyopathy. *A. Čížková[1,2], V. Stránecký[1], J. A. Mayr[3], M. Tesařová[4], V. Havlíčková[2], J. Paul[2], R. Ivánek[1], AW. Kuss[5], H. Hansíková[4], V. kaplanová[2], M. Vrbacký[2], H. Hartmannová[1], L. Nosková[1], T. Honzík[4], Z. Drahota[2], M. Magner[4], W. Sperl[3], J. Zeman[4], J. Houštěk[2], S. Kmoch[1]* 1) Institute of Inherited Metabolic Disorders, Prague; 2) Institute of Physiology, ASCR, Prague; 3) Department of Pediatrics, Paracelsus Medical University, Salzburg; 4) Department of Pediatrics, 1st Faculty of Medicine, Prague; 5) Max Planck Institute for Molecular Genetics, Berlin.

ATP synthase defects of the nuclear genetic origin are characterized by selective decrease of the ATP synthase complex and a profound loss of both, synthetic and hydrolytic activities. With an exception of one case with ATP12 mutation no other affected nuclear genes have been identified yet. To identify the genetic defect in other patients we used Affymetrix 250K arrays, genotyped 8 index patients, their healthy siblings and parents from 6 families and intersected the mapping information with gene expression changes observed in patient fibroblasts (Agilent 44kArrays). The analysis illuminated a single gene, TMEM70, as it has been localized in a shared homozygosity region on chromosome 8, showed reduced transcript amount in patient fibroblasts and was characterized as a putative mitochondrial protein. Sequence analysis identified in patients a homozygous substitution c.317-2AG, located in the splice site of intron 2 of the TMEM70 which leads to aberrant splicing and loss of TMEM70 transcript. Screening of other suspected cases investigated in our institutions revealed 23 homozygous patients. In a single heterozygous patient a mutation c.118_119insGT encoding a truncated TMEM70 protein - p.Ser40CysfsX11 was identified on the second allele. Complementation of patient cell lines with TMEM70 restored biogenesis and metabolic function of the enzyme complex. Phylogenetic analysis revealed TMEM70 homologues in genomes of multicellular eukaryotes and plants, but not in yeast and fungi. We conclude, that TMEM70 is a novel factor of the ATPase biogenesis in higher eukaryotes and its defect is frequent among patients, particularly gypsies, with isolated ATPase deficiency.

Polymorphisms in Oxytocin Receptor and CD38 genes and Autism: Association and Functional Studies. *K. E. Tansey, M. J. Hill, R. J. L. Anney, M. Gill, L. Gallagher* Neuropsychiatric Genetics, Trinity College Dublin, Dublin, Ireland.

The neuropeptide oxytocin has recently been implicated in the aetiology of autism. It has effects on behaviour in relation to social cognition, compassing social memory formation, social recognition, and social motivation. Oxytocin is modulated by the oestrogen sex hormones, which heightens its candidacy for a role in autism where the ratio of affected males to affected females is highly skewed (4:1). CD38 plays a critical role in maternal nurturing behaviour and social recognition by regulating oxytocin secretion; implicating this gene in the aetiology of autism via the oxytocin system. We tested for association of oxytocin receptor (OXTR) using 20 tagging SNPs and 14 tagging SNPs for CD38 in 179 simplex families from the Irish Autism Study. We followed up genetic association studies with allelic expression imbalance (AEI) testing for alterations in expression of the OXTR and CD38 genes. Using lymphoblast cell lines from the CEU HapMap collection, we examined the influence of common variation and different levels of -Estradiol and Progesterone on AEI. Associations between OXTR and autism were found with 3 markers (rs11720238 p=0.031; rs7632287 p=0.0076; rs4564970 p=0.0091). Two SNPs showed association with a high functioning subset after multiple permutation testing (rs11720238 corrected p= 0.025; rs7632287 corrected p=0.0042). Associations between CD38 and autism were found with rs7655635 (corrected p=0.017). We observed AEI of OXTR and CD38 transcripts. The variation in OXTR was driven, in part, by a SNP in intron 3 (rs237897; p=0.0265). rs237897 was not associated with autism in our sample. The addition of hormones did not appear to alter AEI significantly from the baseline. These results confirm the importance of the oxytocin system in the aetiology of autism and identified SNPs involved in differential allelic expression.

Functional interactions of conserved non-coding (CNCs) sequences using circular chromosome conformation capture (4C). *D. Robyr, M. Friedli, G. Duriaux-Sail, S. E. Antonarakis* Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland.

The comparison of human chromosome 21 (Hsa21) sequences with the mouse syntenic regions led to the identification of roughly 3500 regions displaying an identity of >70% over a length of a least 100 nucleotides of ungaped alignment. About 65% (~ 2300) of these are conserved non-coding sequences (CNCs). Very little is known about the function of most CNCs. We speculated that a functional CNC might interact with its genomic target (i.e. an enhancer would bind to its cognate gene promoter). Thus, the identification of any part of the genome that interacts directly with a CNC could provide clues on the function of the latter. We have generated libraries of CNC-interacting DpnII fragments by chromosome conformation capture (4C) whose identity is determined by subsequent high-throughput sequencing. As proof of principle we have generated interacting maps between the human -globin locus control region (Dnase I hypersensitive sites 5, HS5) and the rest of the genome in the erithroïd K562 cell line. We have confirmed previous observations showing an interaction between HS5 and the promoter region of the gamma globin genes HBG1 as well as with the 3HS. Moreover, additional interactions were mapped to various Dnase I hypersensitive sites surrounding the -globin gene locus. We are currently screening for the interactions of 10 CNCs located in the two ENCODE regions of HSA21 in different cell lines. Preliminary results in K562 cells indicate that CNCs are capable of interactions with loci not only in cis and over several Mb, but also in trans with loci located on other chromosomes (between 1.2% and 82.2% of the sequenced tags are associated in trans depending of the CNC analysed). Interestingly, 4 CNCs located over the span of 250 kb show interactions with the CNS specific genes Olig1 and Olig2. Injection in fertilized mouse oocytes of two of these CNCs using a lentiviral vector drives the expression of a lacZ reporter gene in the somites and brain at E11 in embryos, reminiscent of olig expression.

Establishment of the Undiagnosed Diseases Program at the National Institutes of Health. *C. E. Wahl, M. E. Nehrebecky, W. Gahl* Office of Rare Diseases, NHGRI/NIH, Bethesda, MD.

The National Institutes of Health, through the National Human Genome Research Institute and the NIH Office of Rare Diseases announces the establishment of the Undiagnosed Diseases Program (UDP). Referrals are accepted from medical providers with patients deemed undiagnosed after an adequate workup. The NIH UDP screens arriving referrals to generate a subset of patients to be invited to the NIH for further workup and evaluation. The stated goals of the UDP include providing answers to patients with mysterious conditions that have long eluded diagnosis and advancing medical knowledge about rare and common diseases. Each patient visiting the NIH is evaluated by a custom-designed multidisciplinary team based on their presenting illness and the results of prior medical evaluation. Participating specialists span the expertise of the NIH community including rheumatology,oncology, mental health, nephrology, hematology, ophthalmology, neurology, laboratory medicine, pain and palliative care, bone disorders, endocrinology, oncology, immunology, dermatology, primary immunodeficiency, dentistry, genetics, pathology, pulmonology, cardiology, primary immunodeficiency, internal medicine, pediatrics and hepatology. Medical data collected during the evaluation is returned to the referring provider regardless of whether a definitive diagnosis was achieved during the visit. In addition to the potential for diagnosis, participating patients may benefit from additional ideas for treatment of ongoing medical problems. Data from the patient evaluations is be used to generate ideas and hypothesis for continuing medical research. Since the announcement of the program on May 19, 2008, approximately 400 inquires have been received regarding potential participation. Interested medical providers and their patients may obtain more information from the program by visiting http://rarediseases.info.nih.gov/UndiagnosedDiseases/FAQ.aspx.

Massive Parallel DNA (re)Sequencing in Hypertrophic Cardiomyopathy: a powerful approach to detect substitutions and indels. *J.-L. Blouin[1], C. Iseli[2,3], D. Robyr[4], A. Munoz[4], S. E. Antonarakis[1,4], S. Fokstuen[1]* 1) Dept Genetic Medicine, Univ Hosps Geneva, Geneva, Switzerland; 2) Ludwig Institute for Cancer Research, Lausanne, Switzerland; 3) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 4) Genetic Medicine and Development, University of Geneva School of Medicine, Switzerland.

With the prevalence of 1/500, Hypertrophic Cardiomyopathy (HCM) represents the most common inherited cardiovascular disorder, also considered as the primary cause of sudden cardiac death in young adults. More than 450 different pathogenic mutations in at least 16 genes have been identified. In order to overcome this extensive genetic heterogeneity we had developed a 30 Kbp HCM-custom-DNA-resequencing-array (HCM-RA) comprising all exons (n=160), splice-sites and 5-UTR of 12 HCM genes (Fokstuen et al, 2008). Although very efficient, this approach did not detect small indels, accounting for 14% of known HCM mutations. Moreover, the HCM-RA lacks flexibility since gene additions require a new design. In order to solve these shortcomings we assessed the performance of the developing Massive Parallel DNA Sequencing (MPS) technology. We reanalysed these regions (PCR amplified) of 12 genes in a total of 19 patients, previously hybridized on the HCM-RA (11 without known mutations, 8 positive-controls as a composite-pool), in a single channel of a Illumina-Solexa sequencer. Every single base (27070 bases, 570 fold coverage) was analyzed using a newly developed data analysis pipeline on the Vital-IT HPC platform. All the 8 known pathogenic mutations and the 18 SNPs previously identified by HCM-RA were also observed in MPS. Furthermore we found new indels (c.1028delC/p.Thr343fsX349, c.506-12delC in MYBPC3; c.53-15_-11delTTCTC in TNNT2) which were confirmed by classical sequencing. Interestingly we observed a complex nucleotide change altering the acceptor splice site of intron 20 of MYBPC3 [c.2146-9C>A+c.2146-2delA]. Although there is still a need for improvement in target enrichment, and data analysis, MPS hold considerable promises in DNA mutation/variant analysis underlying highly heterogeneous or multigenic genetic disorders in clinical practice.

Ephrin B4 Receptor (*EPHB4*) gene polymorphisms and risk of intracranial hemorrhage in patients with brain arteriovenous malformations (BAVM). *S. Weinsheimer[1], H. Kim[1,2,3], L. Pawlikowska[1,2], P.-Y. Kwok[2], C. E. McCulloch[3], W. L. Young[1,4]* 1) Center for Cerebrovascular Research, Dept Anesthesia; 2) Institute for Human Genetics; 3) Dept Epidemiology and Biostatistics; 4) Dept Neurology and Neurological Surgery; Univ. California, San Francisco, CA.

Background: BAVM are a tangle of abnormal vessels directly shunting blood from the arterial to venous circulation and an important cause of intracranial hemorrhage (ICH). EPHB4 is involved in arterial-venous determination during embryogenesis; altered signaling could lead to vascular instability resulting in ICH. We investigated the association of single-nucleotide polymorphisms (SNPs) and haplotypes in *EPHB4* with risk of ICH at clinical presentation in BAVM patients. **Methods**: Eight haplotype-tagging SNPs (2 exonic, 4 intronic, and 2 intergenic) spanning 28kb were tested in 146 Caucasian BAVM patients (56 ICH and 90 non-ICH) using allelic, haplotypic, and principal components analysis (PCA). Associated SNPs were then genotyped in a second set of 102 cases (37 ICH and 65 non-ICH) and data combined for multivariable logistic regression. **Results**: The minor alleles of 2 intronic SNPs were associated with reduced risk of ICH presentation (rs314313 C, P=0.005; rs314308 T, P=0.0004). Haplotype analysis revealed a significant overall association (^{2}=17.24, 6 df, P=0.008), and 2 haplotypes containing the minor allele of rs314308 (GCCTGGGT, P=0.003; and GTCTGGGC, P=0.036) were also associated with reduced risk. Sliding windows of 3-SNP haplotypes excluded 2 SNPs at the 3 end. PCA results retaining 2 components explained 91% of the total variance (P=0.003), and complemented haplotype results by implicating the 4 SNPs at the 5 end, including rs314308 and rs314313. These 2 SNPs were validated in a second set, and the combined data resulted in greater significance (rs314313, P=0.0007; rs314308, P=0.00008); the SNP association persisted after adjusting for age, gender, BAVM size, deep venous drainage and eloquent location. **Conclusions**: *EPHB4* polymorphisms at the 5 end of the gene are associated with risk of ICH presentation in Caucasian BAVM patients warranting further study.

Genetic Characterization of Zimmerman Laband syndrome. *T. S. Han[1], P. S. Hart[2], P. Sulima[1], C. Turner[2], S. I. Jang[1], T. C. Hart[1]* 1) NIDCR, NIH, Bethesda, MD; 2) NHGRI, NIH, Bethesda, MD.

A 7 y.o. African American male with extensive gingival overgrowth and minor dysmorphic features, including shortened nasal columella, posteriorly rotated ears, and large patulous lips, was ascertained. Family history was negative for gingival overgrowth. Because of the dysmorphisms and maternal history of pregnancy loss, karyotype analysis was conducted, revealing 46, XY, t(3;17) (p21.1;q23.3. 3). Haplotype analysis demonstrated the translocation arose on the paternal homologues. The father does not have gingival overgrowth, indicating a de novo event. The clinical features in this patient are most consistent with Zimmermann-Laband syndrome (ZLS), a rare autosomal dominant disorder of unknown etiology. The most penetrant finding in ZLS is gingival overgrowth. Breakpoint mapping demonstrated the break on chromosome 3 occurred in intron 3 of the CACNA2D3 gene. The chromosome 17 break did not occur within a gene or highly conserved region. The der 17 revealed 21 nucleotides that could not be assigned to either breakpoint region and did not map with 100% homology to any chromosomal segment. Within this 21 bp is a 9 bp sequence that is present on chromosome 17 at the location of the breakpoint and may represent a duplication. Expression of genes flanking translocation breakpoints were evaluated in gingiva from the patient and controls. HESRG, MAP2K6 and ACTR8 expression were not found to be different by quantitative PCR. LRTM1 and KCNJ16 were not expressed in gingiva. RT- PCR using a Taqman probe spanning the exon 3-4 junction of CACNA2D3 demonstrated significantly decreased expression in patient gingiva. Decreased expression of CACNA2D3 appears to result in gingival overgrowth. This conclusion is supported by the observation of another patient with gingival overgrowth with a break in this same gene, (3 to the break in our patient) and by a mother/daughter with a break approximately 0.1 Mb 3 of CACNA2D3. These results implicate CACNA2D3 in gingival overgrowth and may provide clues into the drug-induced forms which also center around calcium metabolism.

Identification of the gene responsible for a congenital muscular dystrophy with hyperlaxity (CMDH) in a French-Canadian cohort. *M. Tetreault[1], I. Thiffault[1], L. Loisel[1], J. Mathieu[2], Y. Robitaille[3], M. Vanasse[4], B. Brais[1]* 1) Neuromics Center for Excellence of Université de Montréal, Université de Montréal, CR-CHUM Hôpital Notre-Dame, Montreal, QC, Canada;; 2) Carrefour de la Santé de Jonquière, Saguenay, QC, Canada; 3) Département de pathologie, Hôpital Sainte-Justine, Montreal, QC, Canada; 4) Clinique des maladies neuromusculaires, Centre de réadaptation Marie-Enfant, Hôpital Sainte-Justine Hospital, Montréal, QC, Canada.

Congenital muscular dystrophies (CMD) are a heterogeneous group of disorders. A growing number of CMD have been found to be associated with joint hyperlaxicity. We recruited 16 French-Canadian cases belonging to 13 families from Southwestern Quebec affected by a novel autosomal recessive congenital muscular dystrophy with hyperlaxicity (CMDH). All patients present muscle weakness, proximal contractures coexisting with distal joint hyperlaxicity. They have a more benign course than most described CMD, with preservation of walking into adult age in most cases. A genome wide scan of 500 microsatellites markers, allowed us to identify the chromosomal locus responsible for CMDH on chromosome 3 at position 3p23-21.3. Fine mapping to a 0.11Kb interval was performed by SNPs genotyping using the Sequenom iPlex platform. We uncovered complex sequence insertion mutations, including an Alu insertion, in the CMDH causative gene. The mutations lead to abnormal molecular weight CMDH mRNA and protein. The identification of mutations in a gene coding for a transmembrane protein suggest that as in other muscular dystrophies the integrity of the interactions between the extracellular matrix and the membrane are likely disturbed in this CMD with hyperlaxicity.

The influence of metabolic polymorphisms and smoking during pregnancy on fetal growth and preterm delivery.

C. L. Relton[1], R. M. Freathy[2], S. M. Ring[3], A. Groom[1], R. Gray[4], A. T. Hattersley[2], T. M. Frayling[2], G. Davey Smith[3] 1) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, United Kingdom; 2) Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, United Kingdom; 3) Department of Social Medicine, Bristol University, United Kingdom; 4) National Perinatal Epidemiology Unit, Oxford University, Oxford, United Kingdom.

Exposure of the developing fetus to cigarette smoke is believed to compromise fetal growth and may trigger premature delivery. Evidence suggests that fetal growth and preterm delivery are influenced by the ability to detoxify the products of cigarette smoke and this in turn is influenced by genetic variation in the detoxification pathway. We performed a large association study using the Avon Longitudinal Study of Parents and Children (ALSPAC), genotyping 8,499 mothers and 8,617 children. The cohort included 1,660 children born small for gestational age (SGA;<10th centile birth weight) and 928 children born preterm (<37 weeks gestation). 30.7% of mothers smoked during pregnancy and 69.3% were non-smokers. We analysed common variants in 4 genes selected to tag known common functional and copy number variation; GSTM1 deletion, CYP1a1_2a (rs4646903), CYP1a1_2c (rs1048943) and UGT2b28 (rs11249532). A maternal copy of the UGT2b28 variant modestly increases risk of delivering a SGA infant in non-smokers (OR 1.26 [95%CI 1.04, 1.53] p=0.021) and this effect is exacerbated in smokers (OR 2.05 [95% CI 1.59, 2.64] p<0.001). A maternal copy of the UGT2b28 variant was associated with an increased risk of preterm delivery in non-smokers (OR 1.47 [95%CI 1.15, 1.87] p=0.002) but not in smokers. Smoking during pregnancy was associated with a small increase in risk of preterm delivery (OR 1.21 [95%CI 1.05, 1.39] p=0.01). None of the other variants studied influenced the risk of delivering a SGA or preterm infant in excess of that expected by smoking alone. Fetal development and gestation length are influenced by the presence of a common polymorphism in UGT2b28. This may be due to its function in detoxification or its role in androgen and estrogen metabolism.

Several microRNAs are involved in the susceptibility to eating disorders as detected by association studies using a comprehensive miRNA-targeted genotyping platform. *Y. Espinosa-Parrilla[1,2], M. Muiños-Gimeno[1,2], J. M. Mercader[1,3], M. Montfort[1,3], M. Bayés[1,3], M. Gratacòs[1,2], F. Fernández-Aranda[4], X. Estivill[1,2,3,5]* 1) Genes & Disease Program, Centre de Regulació Genòmica, Barcelona; 2) CIBERESP, CRG, Barcelona; 3) CeGen, CRG, Barcelona; 4) CIBEROBN, Psychiatric Service, Ciutat Sanitaria Bellvitge, LHospitalet; 5) Pompeu Fabra University, Barcelona, Spain.

Involvement of microRNAs (miRNAs) in the control of neuronal differentiation and synaptic plasticity suggests a role for these molecules in the aetiology of psychiatric disorders. In order to evaluate this hypothesis we performed association studies in eating disorders (ED) using SNPs in miRNA regions. We analysed the organization of 326 human miRNAs (MiRBase 7.1) and defined 164 regions (2Mb of genomic DNA) including miRNA sequences as well as their 5kb flanking regions. Exploration of the SNP coverage (dbSNP128) revealed a statistically significant lower SNP density in miRNAs than in their flanking regions (1.8 versus 3.4SNPs/kb, p0.005, F test). Further, we constructed a panel of 768 SNPs covering miRNA regions and performed association analysis after genotyping 340 Spanish controls and 294 patients with different types of ED (custom Golden Gate assay, Illumina). We found strong associations ($p8x10^{-4}$) for one miRNA with EDNOS (ED non Otherwise Specified), two other miRNAs with Bulimia Nervosa and a miRNA cluster with Anorexia Nervosa. To identify common genetic factors for ED we studied the intersections of nominal associations among the three sub-phenotypes and found 10 shared associations. Seven of these miRNAs were also associated with Minimum Body Mass Index and one brain expressed miRNA with age at onset ($p=8.0x10^{-5}$, significant after correction for multiple testing). TargetScan predictions indicated 101 genes to be potentially regulated by this miRNA. Interestingly, Ingenuity Pathways Analysis revealed an enrichment of genes involved in development and function of the endocrine as well as nervous system ($p=1.09E^{-5}$-$p=6.49E^{-3}$). All together indicates that miRNA mediated regulation could underlie the genetic susceptibility to these complex disorders.

A new locus for recessive autosomal arthrogryposis multiplex congenita. *R. Attali[1], N. Warwar[1], A. Israel[1], A. Laquerriere[2], H. Topaloglu[3], Y. Nevo[4], Z. Ben Neriah[1], J. Melki[1]* 1) Dept. of Human Genetics, Hadassah University Hospital, Jerusalem, Israel; 2) Dept. of Pathology, CHU de Rouen, France; 3) Dept. of Child Neurology, Hacettepe Children's Hospital, Ankara, Turkey; 4) NeuroPediatric Unit, Dept of Pediatry, Hadassah University Hospital, Jerusalem, Israel.

Arthrogryposis multiplex congenita (AMC) is clinically and genetically heterogeneous. AMC with hypokinesia or akinesia may be isolated or associated with additional features. AMC can be secondary to a myopathic or a neurogenic process, a connective tissue disorder, a mechanical cause or a maternal illness. The neurogenic forms characterized by the paucity of motor neurons associated with muscular atrophy are considered to be the most common form. In order to elucidate the genetic basis of recessive autosomal AMC (RA-AMC) of neurogenic origin, patients were recruited through the geneticists, neuropediatricans or fetopathologists based on strict clinical inclusion criteria. A total of 7 families were selected, 4 of them were consanguineous and/or with at least two affected children. No homozygous or heterozygous deletion of SMN1 exon 7 was found in the index cases excluding this locus. Whole genome analysis was performed using 250K snp microarray (Affymetrix). In a large consanguineous pedigree, linkage analysis revealed a highly candidate region of 6 Mb with a positive lod score of 2.85, the other regions of the genome giving a lod score below -2. In the linked region, the affected patients and obligate carriers were homozygous and heterozygous, respectively. Several genes have been recently identified as responsible for RA-AMC of neurogenic origin including SMN1, GLE1, ERBB3, PIP5K1C and UBE1. This region of Chromosome 6 linked to the disease locus in our family does not contain a gene known to be involved in arthrogryposis or in motor neuron diseases indicating that we found a new locus. Other families from the same geographic origin or with similar phenotype will be tested for this new locus. Sequence analysis of the most candidate genes found in this region should allow the identification of the gene responsible for this very severe disease.

Fine mapping an Autism Susceptibility locus on chromosome 1q23-24. *P. Garavito[1], N. Gharani[1], M. Azaro[1], CW. Bartlett[2], O. Stein[2], R. Goedken[2], J. Millonig[1,3,4], E. DiCicco-Bloom[4], VJ. Vieland[2], LM. Brzustowicz[1]* 1) Dept Genetics, Rutgers University, Piscataway, NJ; 2) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital & The Ohio State University, Columbus, OH; 3) Center for Advanced Biotechnology and Medicine; 4) Dept Neuroscience & Cell Biology, UMDNJ-RWJMS, Piscataway, NJ.

Multiple linkage and association studies in autism have suggested several loci that may harbor autism susceptibility genes but no universally accepted gene has emerged. One possible explanation for the lack of consistency of these studies is genetic heterogeneity. To address this issue, phenotypic subsetting of family data and the Posterior Probability of Linkage (PPL) statistic have been used by different studies. Previously, PPL analysis of the Autism Genome Resource Exchange (AGRE) genome scan data for 303 families identified a 30cM linkage region on chromosome 1q23-24, in a subset of 46 families with broad diagnosis and negative for Phrase Speech Delay (PSD-). Here we have fine mapped the 30cM linkage region through high density microsatellite genotyping. Multipoint PPL analysis of the genotype data narrowed the 30cM linkage interval to 5cM. Currently we are conducting a high density SNP genotyping and Linkage Disequilibrium (LD) mapping of this interval. We initially focused on a central region of 335kb that encompassed two evolutionarily ultra conserved regions. Data from the International HapMap Project was used to select 76 tagSNPs for this region. The posterior probability of linkage disequilibrium (PPLD) which directly measures the probability of association was used to evaluate LD between the SNPs and the disease locus. PPLD scores > 0.02 indicates evidence in favor of LD. So far PPLD data for 44 tagSNPs have not provided evidence for association. In addition, we analyzed 254 SNPs from the recently released AGRE Affymetrix 500K SNP array data from the chromosome 1 interval. 13 SNPs show PPLD values greater than 0.02 indicating possible association of these markers with the trait locus. rs2800785 provided the highest PPLD score of 0.13 and is in intron 2 of PBX1 suggesting PBX1 as a potential candidate gene for autism.

Diagnosis of neuronal ceroid lipofuscinoses. *N. Abdelmoula[1], S. Zekri[2], H. Jaafoura[2], A. Amouri[3], R. Louati[1], T. Rebai[1]* 1) Lab Histology, Univ Medicine, Sfax, Tunisia; 2) Lab electronic microscopy, Univ Medecine, Tunis, Tunisia; 3) Lab Histomogy and cytogenetics, Univ Medecine, Tunis, Tunisia.

The NCLs are a family of genetically inherited metabolic storage diseases that exhibit a common pathology, lysosomal accumulation of autofluorescent lipopigment, neurodegeneration and premature death. NCL is inherited in an autosomal recessive manner and mutations in at least seven genes, CLN1, CLN2, CLN3, CLN5, CLN6, CLN8 and CTSD (cathepsin D) are known to result in human disease. Infantile neuronal ceroid lipofuscinosis is caused by mutations in CLN1 at 1p32 chromosome, the gene encoding the enzyme palmitoyl protein thioesterase 1 (PPT1). The clinical course and age of onset of the disease vary much due to the different mutations in CLN1 ranging from infantile-onset devastating disease to an adult-onset form with symptoms presenting in the fourth decade. For the majority of families affected by one of the neuronal ceroid lipofuscinoses (NCLs), a biochemical and/or genetic diagnosis can be achieved. We report the observation of a child in whom diagnosis of CLN1 was difficult to confirm at the clinical level: age at onset of symptoms at 12 months, developmental delay, visual impairment, attention deficit, central hypotonia, seizures, jerks, motor dysfunction with spasticity of the limbs and progressive diffuse brain atrophy on MRI. Ultrastructural analysis performed in skin punch biopsy permit to show granular osmiophilic deposits (GROD) in the secretory eccrine sweat gland epithelial cells. Molecular screening of CLN1 and CLN2 is conducted but biochemical testing to study PPT1 activity was difficult to consider. We show through this observation and review of literature current methods available to achieve clinical, pathological, biochemical and genetic diagnosis in children presenting with symptoms suggestive of one of the NCLs and interest of such diagnosis for therapeutic options and genetic counselling with prenatal diagnosis.

Identification of the LGMD2M gene by SNP homozygosity mapping in a French-Canadian cohort. *V. Bolduc[1], J. Jarry[1], MF. Rioux[2], Y. Robitaille[3], I. Thiffault[1], M. Tetreault[1], MJ. Dicaire[1], L. Loisel[1], JP. Bouchard[4], B. Brais[1]* 1) CENUM, CRCHUM Notre-Dame, Universite de Montreal, Montreal, Quebec, Canada; 2) CHUS, Universite de Sherbrooke, Sherbrooke, Quebec, Canada; 3) Hopital Ste-Justine, Montreal, Quebec, Canada; 4) CHA-Hopital Enfant-Jesus, Universite Laval, Quebec, Canada.

Limb-girdle muscular dystrophies (LGMD) represent a heterogeneous group of disorders characterized by progressive proximal weakness and atrophy. We have identified French-Canadian patients displaying a new form of LGMD associated with prominent quadriceps atrophy and myalgia (LGMD2M). To identify the mutated gene, we took advantage of high-density single nucleotide polymorphism (SNP) microarrays and genotyped three affected sibs of a first-degree consanguineous family, using the Illumina HumanHap300 (9 kb resolution). Homozygosity analysis revealed a 4.5 Mb region on chromosome 11, located next to the chromosome 11p13-p12 interval previously identified by microsatellite linkage analysis. The lower resolution obtained with the microsatellite genotyping (8 cM) precluded the identification of this homozygous region. Genomic and cDNA sequencing of the genes lying in the 4.5 Mb interval uncovered an illegitimate exonic splice site mutation within the LGMD2M gene, producing a 38pb-deletion in the cDNA sequence predicted to lead to a premature stop codon. The function of the mutated protein is unknown but it is highly expressed in muscle. This study identified a new LGMD gene belonging to a protein family not previously identified to be mutated in a neuromuscular disorder.

Extended Fisher-Yates Haplotype Exact Tests to Detect Genetic Disequilibrium for Genome-wide Scans of Human Genome. *R. Fan[1], K. Lange[2], M. Zhong[1]* 1) Dept Statistics, Texas A&M Univ, College Station, TX; 2) Department of Human Genetics, David Geffen School of Medicine,University of California, Los Angeles, CA.

The concepts of Hardy-Weinberg equilibrium and linkage equilibrium are central in population genetics theory. Departure from the Hardy-Weinberg equilibrium and linkage equilibrium leads to genetic disequilibrium, which can be very useful. For instance, it can point to the association of particular alleles with an increased risk of disease, can reveal population evolution and population substructure, and can indicate positive selection. Thus, tests of genetic equilibrium are of fundamental importance in population genetics and in mapping genes of complex diseases that continues to plague us. With the advent of dense maps of human genetic variations, it is possible to test genetic equilibrium across the human genome. In this research, we develop a novel statistical method to perform genome-wide test of genetic equilibrium and local fine mapping of candidate gene regions. Extended haplotype exact tests based on multivariate Fisher-Yates distribution are developed to provide insights about structure of human genome. Robustness of the proposed methods is evaluated via type I error calculation and comparison. The methods are applied to the HAPMAP phase II haplotype data for both genome-wide scans and fine mapping of local candidate gene regions.

The contribution of common and rare Copy Number Variants to disease risk in seven common diseases. *M. Hurles on behalf of the Wellcome Trust Case Control Consortium* Wellcome Trust Sanger Inst, Cambridge, United Kingdom.

Recent SNP-based genome-wide association studies have confirmed that the majority of the heritability of most common diseases does not reside in common SNPs with large effect sizes. One source of the remaining genetic risk could be common CNVs whose effects are poorly captured by genotyped SNPs. Another potential source could be rare alleles of relative large effect sizes. Such rare alleles are likely to be drawn from all forms of genetic variation in the human genome, including SNPs, indels and structural variants. Efficiently identifying such rare alleles requires large sample sizes, and ascertainment of variation unbiased to allele frequency. The identification of CNV from the Affymetrix 500k SNP genotyping data in the ~17,000 individuals studied by the Wellcome Trust Case Control consortium provides an opportunity to assess the impact of both common and rare CNVs on disease risk. We identified over 200,000 CNVs in the seven disease collections and two case collections, which reside in ~9,000 non-redundant locations in the human genome. We will report the results from our association testing of 100 common CNVs against these seven diseases. We also sought genes, pathways and genomic locations enriched for rare CNVs in each disease, and identified many disease-specific CNVs with 0.25-0.5% frequency There are compelling biological interpretations for many of the genes enriched for CNVs in these diseases. We will raise issues about the prospects for validation and the level of evidence required for inference with rare variants.

CYP7B1 in non-consanguineous hereditary spastic paraplegia. *C. Beetz[1], R. Schule[2], E. Brandt[1], M. Khundadse[1], K. Karle[2], M. Synofzik[2], M. Auer-Grumbach[3], A. Crosby[4], C. Hubner[1], L. Schols[2], T. Deufel[1]* 1) Institute of Clinical Chemistry, University Hospital Jena, Germany; 2) Herthie Institute for Clinical Brain Research Tübingen, Germany; 3) Centre for Medical Research, Medical University Graz, Austria; 4) Department of Medical Genetics, St. Georgess University London, UK.

Hereditary spastic paraplegia (HSP) is a neurodegenerative condition affecting lower limb movement. Homozygous mutations in CYP7B1 have been identified in several consanguineous families that represented HSP type 5 (SPG5), i.e. one of the many genetic forms of the disease. We used direct sequencing and multiplex ligation-dependent probe amplification (MLPA) to screen apparently sporadic HSP patients (n=12) as well as index patients from non-consanguineous recessive (n=8) and from dominant families (n=8) for mutations in CYP7B1. MLPA indicated absence of copy number aberrations in all samples. One sporadic patient showing HSP as well as optic atrophy carried a homozygous nonsense mutation, whereas compound heterozygosity (frameshift + missense) was observed in a recessive family with a clinically pure phenotype. We also found a heterozygous missense alteration to segregate in a small dominant family and a novel coding SNP to be significantly associated with the presence of cerebellar signs. The unexpectedly high frequency of 10% (2 of 20) SPG5 in our cohort of recessive and apparently sporadic HSP patients as well as a potentially modifying role for CYP7B1 variants need to be confirmed by larger studies.

Dinucleotide repeat tracts in human gene promoters. *A. Jasinska[1], M. Mason[1], C. Sabatti[2], N. Freimer[1]* 1) Dept Psychiatry; 2) Dept Statistics and Dept Human Genetics, Univ California, Los Angeles, CA.

The widespread occurrence of polymorphic short tandem repeats (STRs) in the human genome make them an important source of inter-individual variation. STR polymorphism is involved in abnormal gene regulation in several human disorders. As intergenic regions are enriched in dinucleotide (DINT) repeats - known to be a highly polymorphic class of STRs and shown to have gene regulation potential - we investigated their divergence between human and chimpanzee as well as their co-localization with genomic features, to identify STRs potentially involved in human-specific traits. We searched human and chimpanzee genomic sequences for DINT tracts 12 repeats. We focused on tracts located in a core promoter region of human genes up to 1500 bp upstream and 500 bp downstream of genes. We analyzed altogether 37.2 Mb of human promoter sequence, identifying 649 distinct DINTs distributed at 4 times lower density compared to total genome sequence. Almost all tract types are significantly longer in human compared to their chimpanzee orthologs. Some repeat tracts with increased length might exceed a length threshold triggering higher mutability, length polymorphism, and possible gain of a regulatory role. The length of numerous DINT tracts oscillates close to the length predicting no or low length polymorphism in one species while in the other species the tract expanded and most likely exists as multiple alleles. Excessive tract length divergence (>15 units) was found in 9 human and 1 chimpanzee expanded tracts, with extreme examples being the FLJ10374 and C8orf31 human tracts which are more than 25 units longer than their chimpanzee orthologs. The most interesting tracts show putative polymorphism which could influence gene activity e.g. by affecting CpG islands (CpGIs), such as the long FCHSD2 and HMGA2 tracts completely contained within CpGIs. More than 40 DINTs considerably overlap CpGIs and at least two of them (SLC6A9 and HHIP) are highly polymorphic STRs. The promoter DINT tracts showing greatest divergence, polymorphism potential and localization in gene regulatory regions could be interesting candidate loci for individual variation in transcript levels.

Joint hypermobility, skin hyperelasticity and microcephaly: Ehlers-Danlos syndrome type VI, VII C or a new syndrome? *A. Perez, T. ZANOLLA, N. SOBREIRA, M. CERNACH* Centro de Genetica Medica, Unifesp - EPM, Sao Paulo, Brazil.

The Ehlers-Danlos syndromes (EDS) are a group of heritable connective tissue disorders characterized by joint hypermobility, skin extensibility, and tissue fragility. Genetic heterogeneity is a characteristic of EDS type VI and type VII C. EDS type VI (OMIM 225400) is an autosomal recessive disease caused by a deficiency of lysil hydroxylase (PLOD), characterized for generalized joint laxity, progressive scoliosis, scleral fragility and rupture of the ocular globe. EDS type VII (OMIM 225410), is also an autosomal recessive disease but caused by deficiency of procollagen I N-terminal peptidase, characterized for severe skin fragility. Both types may courses with microcephaly (Beighton et al., 1998). We describe a 4 years-old male born from a non consanguineous young couple. Delivery was pos-term by cesarean section. His examination showed microcephaly, triangular face, epicanthal folds, telecantus, large, cup shaped and hyperextensible ears, flat nasal bridge, thin superior lip, short neck, pterigium colli, pectus escavatum, generalized joint hypermobility, syndactyly of fingers, medial deviation of both halux, hyperlordosis, hip luxation, smooth, velvety and redundant skin and left criptorquia. He presents hypotonia and mild developmental delay. G-banding karyotype from lymphocytes cells was 46, XY, echocardiography and audiometry are normal, and microcitic hypochromic anemia. Skeletal survey documented bilateral hip luxation. Skin biopsy will be done. The most significant clinical characteristics of this patient are psychomotor retardation, microcephaly, joint hyperlaxity and hip luxation suggesting a connective tissue disorder like EDS type VI and type VII C but the presence of mental retardation, syndactyly of fingers, facial signs and speech abnormalities may rule it out. Nevertheless this patient resembles two brothers described by Mégarbané et al. at 2001 whose phenotype is characterized by microcephaly, rudimentary language, and syndactyly of fingers, hip dislocation and similar facial appearance and brain MRI abnormalities. We believe that this case is the third of the literature and can help on delineation of a new syndrome.

Genome-wide association study (GWAS) identifies novel SNPs associated with autism. *D. Q. Ma[1], I. Konidari[1], J. Jaworski[1], D. Salyakina[1], P. Whitehead[1], S. Slifer[1], J. Hoffman[1], A. Andersen[1], H. H. Wright[2], R. K. Abramson[2], J. L. Haines[3], M. L. Cuccaro[1], J. R. Gilbert[1], M. A. Pericak-Vance[1]* 1) Miami Institute for Human Genomics, University of Miami, Miami, FL; 2) University of South Carolina, Columbia, SC; 3) Center for Human Genetic Research, Vanderbilt University, Nashville, TN.

Autism is one of the most heritable neuropsychiatric disorders. No single major gene has been identified conclusively suggesting a complex genetic etiology. We performed a GWAS to help dissect its genetic complexity. 1497 samples from 488 nuclear families in our Collaborative Autism Project (CAP) database were genotyped using the Illumina Human 1M beadchip. All genotypes were called in Beadstudio and the Pedigree Disequilibrium Test (PDT) was used for association analysis. 480 trios (passing mendelian error checking) and 773,149 SNPs (Quality Control (QC): call frequency > 95% MAF > 0.05; HWE > 0.00001) were included in the analysis. For validation, we examined the AGRE 550K SNP dataset. Using the same QC thresholds, 3304 samples from 630 autism families remained in the final AGRE dataset. 74 SNPs scattered across the genome showed strong association with autism risk (PDT-P < 0.0001) in the CAP dataset, but none reached genome-wide significance. 6 of the 8 most significant SNPs were found within genes and several of these genes are expressed in brain. Five SNPs are close to previous reported candidate gene regions (2q37.1, 3p26.2, 6q15, 11p15.3, 20q13.13). Our most significant SNP is located in a novel region on chromosome 5 (25,900kb-26,100kb) in an LD block where 38 out of 52 genotyped SNPs had p-values < 0.05 and the most significant SNPs are all located in a highly evolutionarily conserved region. Among the 34 genotyped SNPs in the 550K AGRE dataset within this region, 9 replicated our result (p < 0.05) including rs4701259 and rs1428665. Analysis of copy number variants (CNVs) is underway. These data further suggest that the genetic etiology of autism is complex and that no single polymorphism carries a large effect. The replicated result on 5p14.1 strongly implicates this novel region in autism risk.

Genome-wide association scan for serum bilirubin levels in a Sardinian cohort. *M. Uda[1], S. Sanna[1], F. Busonero[1], M. G. Piras[1], G. Usala[1], A. Maschio[1], A. Mulas[1], M. Dei[1], S. Lai[1], N. Sestu[1], S. Naitza[1], L. Crisponi[1], M. Masala[1], G. Cuccuru[1], M. Marongiu[1], L. Perseu[1], R. Galanello[2], G. R. Abecasis[3], S. Schlessinger[4], A. Cao[1]* 1) INN, CNR, Monserrato, Cagliari, Italy; 2) Clinica Pediatrica, Ospedale Microcitemico, Università degli Studi di Cagliari, Italy; 3) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, MI, USA; 4) Gereontology Research Center, NIA, Baltimore, MD, USA.

Bilirubin is the main bile pigment formed from the breakdown of heme in red blood cells. Serum bilirubin is considered a reliable test of liver function, as it reflects the liver's ability to take up, process, and secrete bilirubin into the bile. Within the SardiNIA population study we conducted a genome-wide association analysis in 6,148 Sardinians to identify genetic factors affecting a series of quantitative traits, including bilirubin levels. Analysis was performed in 4,305 individuals genotyped with either 10K or 500K Affymetrix GeneChip arrays. Prior to the analysis, to avoid inflation of type I error, the trait was normalized using quantile transformation. We confirmed the association of bilirubin levels with two known loci, the *UGT1A* gene ($p=6.2*10^{-62}$), and the *G6PD* gene ($p=2.5*10^{-8}$). Mutations in the *UGT1A* gene are responsible for the Crigler-Najjar syndromes as well as the more common mild hyperbilirubinemia of Gilbert syndrome, whereas deficiency in G6PD is correlated with a shorter life span of red blood cells, resulting in a modest increase in bilirubin levels. We also identified a novel association on chromosome 12 ($p=4.1*10^{-9}$). Preliminary analysis in an independent cohort of 1,862 Sardinians confirmed the association with the same direction of the effect, leading to a combined p-value of ($p=9.8*10^{-12}$). Our results suggest that other genes may be important for the regulation of serum bilirubin levels, and thus for the etiology of bilirubin- related disorders that are only partially explained by the known gene variants.

A genome-wide association study of body mass index (BMI) in African-origin samples. *S. J. Kang[1], B. Tayo[2], C. Chiang[3], T. Feng[1], A. Luke[2], R. Cooper[2], J. Hirschhorn[3,4], X. Zhu[1], H. Lyon[3]* 1) Case Western Reserve Univ, Cleveland, OH; 2) University Chicago Stritch School of Medicine, Maywood, IL; 3) Childrens Hospital Boston and Harvard Medical School, MA; 4) Broad Institute of Harvard and MIT, Cambridge, MA.

Obesity is a serious health problem that is associated with an increased risk of several common diseases. To identify genetic variants associated with obesity, we performed a genome-wide association study (GWAS) with an obesity related trait (BMI) using the Affymetrix 6.0 platform in 743 African Americans and 909 Nigerians. After quality control to remove individuals and SNPs with low quality data, we performed linear regression analysis using the residual obtained by regressing log(BMI) on age in each gender. In African-Americans, we observed 95 SNPs with P 1e-4 after correcting for population stratification (86 expected) and one SNP with p 5e-7 (0.4 expected). Among the 95 SNPs, 9 SNPs have P 0.05 in Nigerians (4.8 expected). Similarly, in the Nigerian GWAS, 112 SNPs had P 1e-4 (79 expected) and one SNP had p 5e-7 (0.4 expected). Among the 112 SNPs, 5 SNPs have P 0.05 in African-Americans (5.6 expected). To increase power, we pooled the data from African-American and Nigerian samples, correcting for population stratification. We observed 122 SNPs with P 1e-4 (79 expected), with the most significant SNP rs472039 (in a gene desert on chromosome 8; p = 3.27e-7). The SNP rs17700633 near MC4R previously found to be associated with BMI (Loos et.al. Nat. Gen., 2008) was also associated with BMI in African-Americans (p = 0.02), but not in Nigerians (p = 0.32). A pooled association test indicated a possible association (p = 0.03). Our genome-wide analysis did not yield any conclusive associations, indicating that there are not any variants of that are represented on the Affymetrix 6.0 and have large enough effects on BMI in African-ancestry populations. Our sample size may be too small to detect associations reaching genome-wide significance. However, among the list of SNPs with suggestive P values, there are likely to be valid associations that will only be detected by replication in further samples.

Pilot Newborn Screening Study for Pompe Disease in Taiwan involving 132,538 infants. Confirmation of 4 at-risk infants. *P. Labrousse[1], Y. Chein[3], R. Pomponio[2], J. Keutzer[1], N. Lee[3], S. Mann[1], C. Donohoe[1], B. Hendrickson[1], V. Akmaev[1], W. Hwu[3], T. Scholl[1]* 1) Dept Research & Development, Genzyme Genetics, Westborough, MA; 2) Molecular Genetic Analysis Group, Genzyme, Framingham, MA; 3) 2Department of Pediatrics, and Medical Genetics, National Taiwan University Hospital and National Taiwan University School of Medicine, Taipei, Taiwan.

Pompe disease is an autosomal recessive lysosomal storage disorder caused by a deficiency of lysosomal acid -glucosidase. We conducted a large Newborn Screening (NBS) pilot study in which dried blood spots from 132,538 newborns were screened for enzyme deficiency. Of the 121 newborns recalled for further testing due to reduced enzyme activity, 101 were sequenced to determine their genotypes and haplotypes. The majority of the subjects (65/101, 64.4%) were carriers of either a known deleterious mutation (38/101) or contained sequence variants of unknown significance (26/101). Ninety-nine infants carried at least one copy of the [p.G576S + p.E689K] pseudodeficient allele (GAA*03 Hap), and 35 (34.6%) were found to be homozygous for this allele only, providing evidence that this haplotype is a pseudodeficient allele. Pompe disease was confirmed by genotyping in 4 of the newborns. Overall, 15 novel variants and 6 distinct haplotypes, along with the allelic frequencies, were identified in this population. Additionally, we have characterized one new haplotype and found the frequencies to be different from those found in Caucasian and European studies. Homozygosity for the pseudodeficient allele appears to result in enzyme activity below the normal cut off for this assay in this population in the absence of any other mutations. This study shows that the NBS assay is effective in identifying infants with low GAA activity.

Genotype/Phenotype correlation in patients with Crisponi and Cold-Induced Sweating syndrome. *L. Crisponi[1], A. Meloni[1], M. Marongiu[1], F. Chiappe[1,2], M. Deiana[1], G. Zampino[3], I. Okur[4], S. Danda[5], C. Roche Herrero[6], G. Crisponi[7], F. Rutsch[8]* 1) Istituto di Neurogenetica e Neurofarmacologia, Consiglio Nazionale delle Ricerche, Cagliari, Italy; 2) University of Cagliari, Italy; 3) Departments of Paediatrics, Catholic University, Rome, Italy; 4) Gazi University Medical School, Ankara, Turkey; 5) Clinical Genetics Unit, Christian Medical College, Vellore, India; 6) Hospital Infantil La Paz, Madrid, Spain; 7) Casa di cura Sant Anna, Cagliari, Italy; 8) Department of General Pediatrics, University Childrens Hospital, Muenster, Germany.

Crisponi syndrome (CS) is a severe autosomal recessive disorder manifesting in infancy, characterized by contractions of facial muscles, dysmorphic features, camptodactyly, feeding and respiratory difficulties. Characteristic hyperthermic crisis frequently lead to death within the first months of life. Surviving patients usually develop a severe progressive kyphoscoliosis along with a paradoxical sweating after exposure to low ambient temperature. We found that mutations in the CRLF1 gene are associated with CS, showing allelism with Cold Induced Sweating syndrome type 1 (CISS1). CS and CISS1 present overlapping phenotypes, but the reason for phenotypic variation is unknown. To elucidate a genotype/phenotype correlation for both CS and CISS1, we performed functional studies on CRLF1 constructs reproducing 4 mutations found in CS and 5 mutations found in CISS1. Transfection of these mutated constructs in COS-1 cell lines revealed that all the CS mutations lead to a loss of secretion of the mutated protein; on the other hand, 3 of the 5 CISS1 mutations did not affect the secretion of the protein. Reviewing the published data on the CISS1 patients carrying the two mutations affecting secretion, we found that these patients developed a more severe phenotype than other CISS1 patients. We propose to classify the patients with CS and CISS1 as CRLF1 secreters versus non-secreters based on the effect of the mutation, and this might reflect the severity of the phenotype The continuing expansion of the mutational spectrum of CRLF1 on more cases will help us to better define this genotype/phenotype correlation.

The Coriell Personalized Medicine Collaborative- a Model for the Ethical, Legal and Responsible Implementation of Genome-Informed Medicine. *M. Christman* Coriell Institute for Medical Research, Camden, NJ.

The Coriell Personalized Medicine Collaboratives (CPMC) goal is to better understand the coming impact of genome-informed medical practice and guide its ethical, legal and responsible implementation. Coriell has formed close partnerships with several hospital partners including Cooper University Hospital, Virtua Health and Fox Chase Cancer Center - to enroll volunteers in a study that will correlate individual genome profiles of 1 million SNPs with disease course, treatment outcomes and drug responses. There is no charge to study participants. Participants control access to their genetic profiles through a secure web portal and will be able to determine whether they wish the information to become part of their medical records in the future. Participants who wish to will be able to view medically relevant information about their genomic profiles through a secure web-browser-based system. Educational material on genomics and medicine is also provided through streaming video, downloads and seminars. One goal of the CPMC is to facilitate the education of medical professionals regarding genome-derived information. To this end, many medical professionals from the hospital partners have enrolled in the study. The project has enrolled over 3,000 participants to date and will enroll ~10,000 participants in the first two to three years through the Coriell Institute and its hospital partners. There are two arms to the study: i) cancer, primarily breast and prostate cancer patients and ii) wellness, apparently healthy individuals. Only genetic variants that are deemed potentially medically actionable will be made available to participants. An Informed Cohort Oversight Board of outside scientists, physicians and ethicists will decide which risk variants will be revealed through a review of material submitted by scientists. The board (modeled after Kohane et al. (2007) Science 316, 836-837) will meet bi-anually to reevaluate and update the list of medically actionable variants. Participants may then choose to view their status for these new variants. Genetic counseling is provided at no cost to participants. Genome-informed medicine will be a national reality soon and the complex issues associated with its adoption must be addressed.

Genomewide linkage scan for split-hand/foot malformation with long-bone deficiency in a large family identifies two novel susceptibility loci on chromosome 4q21 and 9q21.2-q22.32. *M. Naveed[1], M. T. Al-Ali[1], N. Al-Khaja[1], U. Ratnamala[2], A. K. Maiti[3], C. Sun[4], M. Gains[4], K. Holden[5], D. Everman[5], CE. Schwartz[5], SE. Antonarakis[6], S. K. Nath[4], U. Radhakrishna[1,2,6]* 1) Center for Arab Genomic studies (CAGS), Dubai, United Arab Emirates; 2) Green Cross Blood Bank & Genetic Res Centre, Ahmedabad, India; 3) Sealy Center for Molecular Medicine, Univ of Texas Med Branch, Galveston, TX; 4) Arthritis and Immunology Res Program, Oklahoma Med Res Foundation, Oklahoma City, OK; 5) Center for Molecular Studies, J.C. Self Res Institute, Greenwood Genetic Center, Greenwood, SC USA; 6) Dept. of Genetic Medicine and Devp. Univ. of Geneva Medical School, Geneva, Switzerland.

Split-hand/foot malformation with long bone deficiency (SHFLD) is a rare severe limb deformity characterized by tibia abnormality with or without split-hand/split-foot deformity. Families with SHFLD have been reported with autosomal dominant and recessive inheritance, however sporadic cases exist. We recently reported large UAE family that gave significant evidence of linkage to 1q42.2-q43 and 6q14.1 (Am J Hum Genet. 80:105-11, 2007). We have recently analyzed another large multigenerational white SHFLD family (UR080) with autosomal dominant mode of inheritance and reduced penetrance. The family consists of 38 individuals including 8 affecteds (5 males and 3 females). Gnome-wide linkage analysis done on 15 members (7 affecteds) using the GeneChip Mapping EA 10K Array (Affymetrix) identified two novel loci on 4q21 and 9q21.2-q22.32. Multipoint non-parametric linkage yielded a significant evidence of linkage for several SNPs at 4q21 (NPL= 6.41, P= 0.003) and at 9q21.2-q22.32 (NPL=6.61, P=0.00098), suggests linkage at these regions. Subsequent parametric analysis also yielded a LOD score of 2.0 for each locus under an autosomal dominant with reduced penetrance model. Haplotype analysis with informative crossovers enabled the mapping of the SHFLD locus to a region of ~21.0Mb and ~26.3Mb on 4q21 and 9q21.2-q22.32 respectively. These results suggest the existence of genetic heterogeneity and suggestive evidence of two potential susceptibility loci at 4q21 and 9q21.2-q22.32 for SHFLD.

Genome-wide association analyses of composite variables identify genetic loci with pleiotropic effects on Metabolic Syndrome-related traits in GEMS Study. *H. Ling[1], D. M. Waterworth[2], K. Song[2], V. E. Moose[2], B. D. Mitchell[3], GEMS. Investigators[4]* 1) Dept Epidemiology, Univ Maryland Baltimore, MD; 2) Genetic Division, GlaxoSmithKline, King of Prussia, PA; 3) Department of Medicine, Univ Maryland Baltimore, MD; 4) GEMS Investigators.

Metabolic Syndrome (MetS) is characterized by clustering of CVD and T2DM-related risk factors, which co-occur more frequently than expected by chance. To identify genes having pleiotropic effects across multiple traits, we combined phenotype information across a set of MetS-related traits into composite variables using two different dimension-reduction approaches, a principal component analysis (PCA) and a variable cluster analysis (VCA), and then performed GWA analysis on the two sets of composite scores. Data for this study came from 1,800 subjects enrolled in the Genetics Epidemiology of Metabolic Syndrome (GEMS) Study, in whom 13 different MetS-related traits were measured. Approximate 475,000 SNPs were included after QC. Both the PCA and VCA generated a four-factor structure as their optimal solutions. Following GWA of composite traits from VCA produced no associations exceeding a genome-wide significance ($p < 1.25 \times 10^{-7}$). In contrast, 3 SNPs were significantly associated ($p < 1.25 \times 10^{-7}$) with the composite scores of PCA. These 3 SNPs were located within genes (*APOA5-APOA4-APOC3* cluster & *PSRC1*) that are widely regarded as strong candidates for CVD. Overall, the associations with the individual traits tended to be a little stronger than the associations with composite scores, although peak associations for PCA were stronger than those for VCA. Combining information across correlated traits is a commonly used data reduction approach. However, generating composite MetS-related traits from the GEMS Study using PCA and VCA did not lead to stronger associations being observed in the GWA compared to analysis of the individual constituent traits. In these data, the strongest SNP associations were observed in PCs, with SNPs in the *APOA5-APOA4-APOC3* gene cluster being associated with TG, HDL and LDLsize. SNPs in *MYBPC1* and *AGT* were associated with BP while SNPs in *TRIB1* and *PSRC1* were associated with lipids.

Distal gene expression associations in human populations. *S. B. Montgomery, B. E. Stranger, C. Ingle, C. Beazley, E. T. Dermitzakis* Population and Comparative Genomics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Gene expression is the product of both proximal and distal protein-DNA and protein-protein interactions. We have compared the genomic organization and relative effect of these types of interactions by quantifying gene expression and performing subsequent genome-wide association analyses in individuals derived from lymphoblast cells of the HapMap3 project (830 unrelated individuals; 1.6 million SNPs). We have identified relationships between proximal and distal associations by categorizing pathway-based interactions at different levels of association strength. Furthermore, we have hypothesized that evidence of nuclear organization should be present in genome-wide association studies of gene expression data as variation in spatially proximal regions may confer properties influencing neighbouring gene regulatory dynamics. To assess this, we have investigated the distribution of distal-associations between individual chromosomes and we have identified a unique signature of abundance of distal associations for each chromosome. We have further performed a Monte-Carlo analysis of the distribution of reciprocal distal associations and identified a window size and strength of association that is strongly overrepresented in reciprocal distal associations suggestive of direct interchromosomal interactions. We will also present analyses of distal associations within chromosomes that may be indicative of chromosome architecture within a chromosome territory, the effects of gene expression variation of CTCF, a known mediator of long-range interactions. These analyses provide evidence for distal interactions driven both by pathway effects as well as direct interchromosomal interactions. We have further dissected the distal interactions by various biological pathways and processes. This analysis has provided us with a biological framework to dissect complex biological interactions within the cell and allows for dissection of higher order effects of genetic variation.

Development of a new predictive algorithm for drug response. *S. Lupoli[1,2], F. Torri[2], L. Citterio[3], C. Barlassina[2], A. Orro[4], F. Martinelli Boneschi[1], L. Milanesi[4], D. Cusi[5,6], G. Bianchi[3], F. Macciardi[2]* 1) INSPE, San Raffaele Scientific Institute, Milan, Italy; 2) University of Milan, Milan, Italy; 3) San Raffaele Hospital, Milan, Italy; 4) ITB, CNR, Milan, Italy; 5) San Carlo Borromeo Hospital, Milan, Italy; 6) GENOPOLIS, University of Milan, Milan, Italy.

Pharmacogenetics (PGx) i.e the use of genetic analysis to predict drug response, efficacy and toxicity, is becoming the first pipeline technology to address new drug discovery. There is strong evidence that both genetic heterogeneity and genetic complexity are to be expected in drug response. Therefore, much attention has been placed on association / Linkage Disequilibrium methods, even across the entire human genome, since they can deal more appropriately with the issues of complexities. Technically, the recent improvement in the technology of high-throughput SNP genotyping and the availability of a large number of SNP databases make association studies and fine mapping of disease loci more convenient using a Genome-wide Association Study (GWAS) framework. The next critical issue relates to the definition of the phenotype and to the use of bioinformatics to build a predictive model based on the genetic profile. We performed a GWAS and we identified the genes that control for the drug effect. We adopted a quantitative genetic association design, where the factors affecting the distribution of the phenotype are the SNPs, the therapy group and the SNP*therapy interaction. Thus, for each SNP that we investigate, the following linear model is built: Phenotype = SNP + therapy + SNP*therapy. Once we identified the genes that control for the drug effect, we developed an algorithm to detect the genotypic profiles that discriminate responders from non-responders using the minimal set of significant SNPs. It is in fact highly desirable both clinically and economically to establish models to distinguish responders from non-responders and to predict possible outcomes of treatment. We present an example of this approach, with an algorithm that has the ability to predict outcomes when the relationships between the variables are multidimensional and nonlinear as found in complex medical applications.

The Kinesin Family Member 6 Trp719Arg variant does not associate with coronary artery disease in the Ottawa Heart Genomics Study. *A. F. R. Stewart, S. Dandona, O. Assogba, M. Belanger, L. Chen, G. A. Wells, R. McPherson, R. Roberts* Univ Ottawa Heart Inst, Ottawa, ON, Canada.

Background: Several recent reports have identified an association between the 719Arg variant of KIF6 and incident coronary events. In some instances, this association has been extended to include coronary artery disease (CAD). **Methods**: Here, we tested whether the KIF6 719Arg variant is associated with CAD in early onset cases (average age 49 years) defined by coronary angiography as having greater than 50% stenosis of any coronary artery versus asymptomatic elderly (average age 75 years) controls. 1540 cases (45.8% with myocardial infarction) and 1455 controls were genotyped on the Affymetrix 500K or 6.0 SNP microarrays. High resolution melting curve genotyping of rs20455 was also carried out in 957 cases and 1004 controls. **Results**: KIF6 Trp719Arg variant showed no association with coronary artery disease (p=0.523 for trend test). Moreover, among 706 cases with myocardial infarction, no association with coronary events was detected when compared to 756 non-MI CAD cases (p=0.588). Concordance between Affymetrix array and high resolution melting curve genotyping data was 98%, confirming the accuracy of genotypes. Data from the Wellcome Trust Case Control Consortium (WTCCC) also showed no significant association with CAD (p=0.897). **Conclusion**: The KIF6 Trp719Arg variant does not associate with myocardial infarction or with coronary artery disease in the Ottawa Heart Genomics Study.

A Genome Wide Linkage Study of Endophenotypes for Schizophrenia in Extended Families. *M. F. Aukes[1], B. Z. Alizadeh[2], M. M. Sitskoorn[1,3], C. Kemner[1], R. van 't Slot[2], B. P. C. Koeleman[2], R. A. Ophoff[2,4], R. S. Kahn[1]* 1) Rudolf Magnus Institute of Neuroscience, Psychiatry Dept, UMC, Utrecht, Netherlands; 2) Complex Genetics Section, Medical Genetics Dept, UMC, Utrecht, Netherlands; 3) CoRPS, Tilburg University, Tilburg, Netherlands; 4) UCLA Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA.

Genetic studies of schizophrenia have not resulted so far in the detection of causal variants for the disorder. Linkage analysis of endophenotypes for schizophrenia may aid in finding loci that contain genes affecting the disorder. Both the use of quantitative traits and extended families can improve power in a linkage design. First we performed heritability, segregation and bivariate heritability analyses to select six promising endophenotypes for schizophrenia: sensorimotor gating, openness, verbal fluency, early visual perception, spatial working memory, and IQ. Then, we performed a genome-wide high-density linkage scan in 7 extended multiple affected Dutch pedigrees (n=125, including 174 parent-offspring pairs, 141 sibling pairs, 110 grandparent-grandchild pairs, and 207 avuncular pairs), using 6090 single nucleotide polymorphism markers (SNPs) (Illumina Infinium Humanlinkage-12), with a mean interval of 0.441 Mb. We removed SNPs showing ambiguous clustering (n=80), and checked for Mendelian inconsistencies (using Pedcheck, n=2), allelic frequencies and gender errors (using PLINK, n=0). Variance-component based linkage analysis was performed in SOLAR and MERLIN. Our preliminary results show suggestive linkage (LOD1.7) for openness on 2p24 (LOD=2.02) and 2q31 (2.17), sensorimotor gating on 5q33 (2.3), spatial working memory on 2q33 (1.71) and 15q13 (2.15), and for IQ on 12p13 (2.29). Peaks overlapped among traits on 2p24, 2q31-33, 3p22-21, 11q14-22, 12p13, 15q13 and 17q25. Moreover, several peaks were detected in regions associated in previous linkage studies with schizophrenia and/or endophenotypes (e.g. 5q33, 3p22-21, 15q13). This study provides the first genome wide scan for several candidate endophenotypes for schizophrenia. This approach may thus enhance the detection of loci associated with schizophrenia.

Role of *PRKRA* in the development of isolated microtia. *J. S. Guimbellot[1], L. C. Pyle[1], E. G. Spencer[1], D. Hurtado[2], K. Johnson[1], T. Callens[1], L. O. Vasconez[3], H. C. Vasconez[3], B. Engels[3], R. J. Fix[3], N. H. Robin[1], L. Messiaen[1]* 1) Dept Genetics, UAB, Birmingham, AL; 2) Pontificia Universidad Católica, Quito, Ecuador; 3) Dept Surgery, UAB, Birmingham, AL.

Microtia is a developmental abnormality of the ear, resulting in significant malformation of the middle and outer ear.Recent studies have suggested a link between several loci and microtia, including mutations in *FGF3*, *HOXA2*, and a copy-number variation (CNV) at chromosome 4p16.In addition to microtia, other anomalies were also found in these patients.Another candidate gene was suggested by a mouse model with a non-functional *PRKRA*, which has a similar phenotype to that of humans with isolated microtia.We hypothesized that mutations in the *PRKRA* gene may play a role in the development of isolated microtia.We collected 52 saliva samples from microtia patients, non-affected family members, and unrelated controls in Ecuador, where a high incidence of microtia is found.The study was approved by the UAB IRB and the Ecuador Ministry of Health.We conducted a thorough history and physical assessment of congenital anomalies and asymmetry.DNA was extracted from all samples using a salting-out method, followed by amplification and sequencing of all eight exons of *PRKRA* and the 5UTR.

Our results revealed no association with any historical factors.Asymmetry of the ears, maxilla and mandible, but of no other features, was found in the case group and not the control group.The most common variant, c.236-130_236-128dupGTA, was found in both groups and is likely a normal variant among this population.No clearly pathogenic mutations that could account for the development of microtia were found.While our study is limited by the number of enrolled individuals, it suggests mutations in the coding region of *PRKRA* are not responsible for the development of isolated microtia as seen in the mouse model, although we did not assess the presence of dosage alterations.It will be of interest to evaluate our patient population for mutations in *FGF3*, *HOXA2*, and the CNV on 4p16 to assess whether these loci play a role in the development of microtia in the absence of other anomalies.

Clinical effects of nonadherent cells on children with osteogenesis imperfecta. *R. Jethva[1], M. Dominici[2], P. Gordon[3], T. J. Hofmann[1], E. M. Horwitz[1,4]* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Modena and Reggio Emilia, Modena, Reggio Emilia, Italy; 3) Penn State Milton S. Hershey Medical Center, Hershey, PA; 4) The University of Pennsylvania, Philadelphia, PA.

Bone marrow transplantation (BMT) is an effective therapeutic modality for many genetic and acquired diseases of the hematopoietic system. Recently, it has been shown that hematopoietic cells in the marrow are capable of both blood and bone cell differentiation. Allogeneic BMT in children with severe osteogenesis imperfecta (OI) resulted in engraftment of donor-derived cells with both hematopoietic and osteopoietic differentiation. Clinical outcomes included improvements in growth, bone histomorphometry, fracture rate and bone mineral content. Subsequent adherent mesenchymal stromal cell (MSC) transplantations were performed in the same OI patients, which also resulted in improvements in growth. Murine studies with nonadherent cells (NAC) have shown that NACs are capable of significantly greater engraftment in bone than MSCs and are likely to harbor stem cells capable of dual potential. To investigate their clinical impact, NACs were harvested from the donors of the original studies. Cells were CD3-depleted and had low MSC counts prior to transplantation. In two 3-month periods following transplant, growth was documented. Patients 1 and 2 were considered non-responders with no more than 1cm growth. Patients 3, 4 and 5 were considered responders, with a maximum growth of 3.3cm. No correlation was found between responders and the absolute number of MSCs or CD34+ cells transplanted (Pearsons test). It was noted that the same two patients who were non-responders had responded the least in the prior allogeneic BMT trial whereas there was no difference in their growth patterns compared to other patients during the MSC trials. Each child had a different mutation, suggesting the possibility that the effects of NACs and MSCs may work based on mutation-dependent and independent mechanisms, respectively. Further study is necessary to characterize these possible associations, which could have implications on cell therapy for OI.

Using principal components analysis to identify candidate genes for natural selection. *P. Paschou[1], J. Lewis[2], P. Drineas[2]* 1) Dept of Molecular Biology & Genetics, Democritus University of Thrace, Greece; 2) Dept of Computer Science, RPI, USA.

Genetic markers that differentiate populations are excellent candidates for natural selection due to local adaptation, and may shed light into physiological pathways that underlie disorders with varying frequencies around the world. Principal Components Analysis (PCA) has emerged as a powerful tool for the characterization and analysis of the structure of genomewide datasets. In prior work, we described an algorithm that can be used to select small subsets of genetic markers (SNPs) that correlate well with population structure, as captured by PCA. Our method can be used to detect SNPs that differentiate individuals from different geographic regions, or even neighboring subpopulations. We set out to explore the nature and properties of the genes where population-differentiating SNPs reside, by analyzing the publicly available Human Genome Diversity Panel dataset (650,000 SNPs for 1,043 individuals, 51 populations). Applying our SNP selection algorithms, we chose small subsets of SNPs that almost perfectly reproduce worldwide population structure as identified by PCA. We determined SNP panels both for population differentiation within seven geographic regions, as well as around the globe. We then explored the hypothesis that the selected SNPs attained their current worldwide allele frequency patterns as a response to the pressure of natural selection. Comparing our lists to recently published reports, we found a significant overlap with other genomewide scans for selection, thus validating our hypothesis. For example, EDAR (involved in the development of hair follicles) harbors the most differentiating SNPs in our world-wide panels. SNPs located in genes that are involved in skin and eye pigmentation (OCA2, MYO5C, HERC1, HERC2) are also among the top population differentiating markers. In East Asia, SNPs residing at the ADH cluster appear among the most important SNPs for population structure, while, in Europe, the same is true for genes that are involved in immune response to pathogens (CR1, DUOX2, TLR, and HLA). Finally, a comprehensive gene ontology analysis is presented.

GENOME-WIDE PROFILES OF SNP AND COPY NUMBER VARIATION IN 1,260 HAPMAP INDIVIDUALS FROM MULTIPLE GLOBAL POPULATIONS. *E. Dermitzakis*[1], . *BI*[2], . *BCM*[3], . *WTSI*[1] 1) Wellcome Trust Sanger Inst, Cambridge, United Kingdom; 2) Broad Institute of Harvard and MIT, Boston, USA; 3) Baylor College of Medicine, Texas, USA.

Efforts to understand the genetic basis of disease increasingly analyze copy-number variation and SNPs, in large diverse sample sets. The International HapMap Consortium described an initial map of 3.1 million SNPs in 270 individuals from 4 population samples, enabling a first generation of genome-wide association studies. To enable next-generation investigations and to better understand patterns of global human genetic variation, we set out to make an even, dense map of SNPs and CNVs across 1,260 individuals from 11 population samples, (African Ancestry in SW USA; Chinese in Metropolitan Denver, CO, USA; Gujarati Indians in Houston, TX, USA; Luhya in Webuye, Kenya; Maasai in Kinyawa, Kenya; Mexican Ancestry in LA, CA, USA; Toscani in Italy; and additional samples from the 4 populations sampled in HapMap. Both the Affymetrix SNP 6.0 and the Illumina Infinium 1M SNP Arrays were used to measure SNP and CNVs in these individuals. In addition, 10 genomic regions (total size 1 Mbp) were sequenced in more than 800 samples. Using data from both platforms, we constructed a relatively even and dense SNP map and a high-quality CNV map, providing estimates of allele frequencies in different populations, and distinguishing among rare, common, and de novo CNVs. We will present comparison of the newly generated data with previous datasets, analysis of linkage disequilibrium, haplotype structure, and population differentiation across these 1,260 samples and how the estimates compare to those inferred from smaller sample sizes. We will also present evaluations of SNP ascertainment and coverage through imputations for both common and rare variants. Based on combined SNP and CNV data we will present the genomic and population-genetic properties of CNVs and tagging provided by SNPs in these population samples. Finally, we will describe genome-wide inference of recent natural selection. These public datasets provide a high-resolution framework for genome-wide association studies and populations not previously represented in HapMap, and integrate SNP and copy number variation with high accuracy.

Association analysis of 42 hereditary prostate cancer (HPC) families using segregating risk haplotypes identifies a 20Kb region on chromosome 22q12.3. *B. Johanneson[1], SK. McDonnell[2], JL. Stanford[3], DM. Karyadi[1], DJ. Schaid[2], L. Wang[2], K. Deutsch[4], L. McIntosh[3], JR. Cerhan[2], JL. St. Sauver[2], SN. Thibodeau[2], EA. Ostrander[1]* 1) NHGRI, National Institutes of Health, Bethesda, MD; 2) Department of Health Sciences, Mayo Clinic, Rochester, MN; 3) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Institute for Systems Biology, Seattle, WA.

Multiple studies of HPC families identify a susceptibility locus at chromosome 22q12. In this study, a set of 24 families from the Mayo Clinic and 18 from the Seattle-based PROGRESS study, each with family-based LOD scores 0.58 at 22q12 were initially used for fine mapping and mutation scanning. Fourteen families with 5 affected men highlight a 2.53 Mb minimal recombination interval. A set of 202 SNPs were genotyped in the 18 PROGRESS families. Markers were selected from among 670 SNPs previously genotyped in 498 Mayo family-based cases and 533 population-based controls which yielded a p-value 0.05 in a family-based association study. Fifty-two of these SNPs are located inside the 2.53 Mb recombination interval described above. We then used the pedGenie software to test all 202 SNPs in the 18 PROGRESS families and the 24 Mayo families as well as the 533 population-based controls. Monte Carlo simulation compensated for related individuals. By assessing haplotype sharing between affected family members, unassigned individuals were defined as likely carriers of the at risk haplotype or not. This allowed us to exclude potential phenocopies and healthy carriers, increasing the power and accuracy of the overall data set. Preliminary results highlight a 20 Kb region within the 2.53 Kb minimal recombinant interval indicated by 3 SNPs that includes 1 or 2 candidate genes. The association is observed independently in both the Mayo and PROGRESS data sets, as well as the combined set of 42 families. We are currently sequencing within and surrounding the candidate gene/s to identify putative causative SNPs which will be assessed in a larger population-based, case control study of 2800 individuals.

Multi-population HLA allele prediction from SNP data. *S. Leslie[1], L. Ohm-Laursen[2], R. Bowden[1], J. Frater[2], D. Goedhals[3], C. van Vuuren[3], C. Seebregts[4], P. Donnelly[1], R. Phillips[2], G. McVean[1]* 1) Department of Statistics, University of Oxford, 1 South Parks Road Oxford, OX1 3TG, UK; 2) The Peter Medawar Building for Pathogen Research, University of Oxford; 3) University of Free State, Bloemfontein, South Africa; 4) Medical Research Council (South Africa).

Genetic variation at classical HLA alleles is a crucial determinant of transplant success and susceptibility to a large number of infectious and autoimmune diseases. Large-scale studies involving classical type I and type II HLA alleles are currently limited by the cost of allele typing technologies. Recently we developed a statistical method using SNP variation within the MHC region to predict alleles at key class I (HLA-A, HLA-B and HLA-C) and class II (HLA-DRB1, HLA-DQA1, HLA-DQB1) loci (Leslie et al. 2008. Am. J. Hum. Genet. 82: 48 - 56). This uses a population genetic approach, combined with a database of individuals with known HLA and SNP alleles within the MHC region, to predict HLA alleles for individuals for which only SNP information is known. The method promises to facilitate large-scale experiments, including disease-association studies and vaccine trials, where detailed information about HLA type is valuable. We present two further studies of the efficacy of this method. Firstly we study the effect of increasing the database size on the accuracy of predictions and report results for populations of European ancestry. Secondly, we present the results of a pilot study testing the efficacy of the method in samples of African origin. It is known that there is a high degree of human genetic variation in Africa and that there are considerable differences between populations of different origin. To study the effect of these factors on the HLA allele prediction method we obtained approximately 350 samples from South Africa, determined their HLA and SNP allelic types, and compared the accuracy of predictions using different training data sets: The HapMap Yoruba samples, subsets of the South Africa samples and samples of European origin.

c.1392+2TC mutation in MFN2 gene affects splicing in Charcot-Marie-Tooth (CMT) 2A family. *A. Vettori[1], F. Boaretto[1], G. Vazza[1], M. Muglia[2], A. Martinuzzi[3], A. Paticucci[2], C. Bertolin[1], G. Bergamin[1], A. Quattrone[2], M. L. Mostacciuolo[1]* 1) Dept. Biology, University of Padova, Padova, Italy; 2) Institute of Neurological Sciences, National Research Council, Mangone, Cosenza, Italy; 3) IRCCS E. Medea, Conegliano Research Center, Italy.

Mutations in the MFN2 gene have been reported as the primary cause of the axonal form of Charcot-Marie-Tooth disease (CMT type 2A), a peripheral neuropathy characterized by axonal degeneration. The MFN2 gene maps in the 1p36 and codes for mitofusin 2 (mfn2) protein that belongs to a class of highly conserved mitochondrial transmembrane GTPases. By a functional point of view, mfn2 is an essential component of the mitochondrial fusion machinery and thus involved in the regulation of mitochondrial dynamics. In addition, recent reports shed new light on the physiological importance of mfn2 function suggesting a role in mitochondrial metabolism, apoptosis as well as cellular signalling. Despite these knowledge gains, several issues regarding mfn2 function and its relation to the neurodegenerative disease remain poorly understood. Here we preset the genetic study in a two-generation family in which three affected members developed CMT2 symptoms in the fifth decade of life (late onset). All patients experienced a rapid worsening of clinical features and became dependent on wheelchair in only two years. Moreover, few years after the onset of symptoms all affected subjects suddenly died for encephalopathy. Conversely to the majority of mutations detected so far, that are clustered in the GTPase domain, we identified a point mutation in intron 13 affecting the conserved consensus sequence of the donor splice site (c.1392+2T>C). Lymphocytes and in vitro transcript analysis reveled that the mutated allele generates four different aberrant transcripts with partial or total intron-13 retention. If translated, these mRNA give raise to either C-truncated, shorter or longer mfn2 proteins compared to the wild type. The functional study of each one of these protein isoforms may help explain the unusual phenotype we observed in this family and contribute to elucidate the potential pathogenic mechanisms involved in CMT2A neurophaty.

Association of a common *G6PC2* variant with fasting plasma glucose levels. *F. Y. Demirci[1], A. S. Dressen[1], R. F. Hamman[2], C. M. Kammerer[1], M. I. Kamboh[1]* 1) Dept. of Human Genetics, GSPH, Univ. of Pittsburgh, Pittsburgh, PA; 2) Dept. of Preventive Medicine and Biometrics, Univ. of Colorado Denver, Aurora, CO.

Fasting plasma glucose (FPG) levels are genetically influenced (heritability estimates; 25-40%) and correlate with mortality and cardiovascular disease in both diabetic and non-diabetic subjects. *G6PC2* encodes a pancreatic islet-specific glucose-6-phosphatase-related protein and *G6pc2*-null mice were reported to exhibit a mild metabolic phenotype with decreased FPG levels. Two recent genome-wide association studies (Bouatia-Naji et al. *Science* 2008 & Chen et al. *J Clin Invest* 2008) have implicated a role for *G6PC2* in contributing to inter-individual variation in blood glucose levels in the general population. The rs560887 SNP [minor allele frequency (MAF) = 0.30] was reported to be associated with FPG levels in normoglycemic subjects but not with type 2 diabetes (T2D). This observation led to the hypothesis that the genetic determinants of FPG levels in physiological states may be different than those associated with overall T2D risk. The rs560887 SNP is located in intron 3 of *G6PC2* close to acceptor splice-site and is predicted to affect alternative RNA splicing. The purpose of this study was to replicate the association of the rs560887 SNP in our independent epidemiological sample of American non-Hispanic Whites. DNA samples from a total of 623 non-diabetic individuals (328 women and 295 men) were genotyped using the TaqMan SNP genotyping assay for rs560887. The genotype frequencies were in Hardy-Weinberg equilibrium and the allele frequencies (MAF = 0.33) were similar to those previously published or reported in public databases. The rs560887 SNP was significantly associated with FPG levels in our sample after adjusting for gender, age, and BMI (p=0.003 under the additive model). Consistent with recent reports, no association was detected with fasting insulin levels, BMI, or lipid measurements. Our results in an independent sample confirm the robust association of the *G6PC2*/rs560887 SNP with FPG levels in non-diabetic individuals and further supports the relevance of the glucose phosphorylation pathway to glucoregulation in the general Caucasian population.

Genome wide analysis and heritability estimation of intelligence in the International Multi-centre ADHD Genetics (IMAGE) study. *A. Arias-Vasquez[1,2], T. Sampaio Rizzi[3], N. Lambregts-Rommelse[1], K. Zhou[4], P. Asherson[4], E. Sonuga-Barke[5], M. Gill[6], J. Sergeant[7], R. Ebstein[8], A. Rothenberger[9], H. C. Steinhausen[10], T. Banaschewski[11], R. Oades[12], A. Miranda[13], F. Mulas[13], H. Roeyers[14], J. Buitelaar[1], D. Posthuma[3], B. Franke[2,1], S. Faraone[15] for The IMAGE Group* 1) Psychiatry, UMC St. Radboud, Nijmegen, NL; 2) Human Genetics, Nijmegen, NL; 3) Biological Psychology, Vrije Universiteit, Amsterdam, NL; 4) London, UK; 5) Southampton, UK; 6) Dublin, Ireland; 7) Amsterdam, NL; 8) Jerusalem, Israel; 9) Göttingen, Germany; 10) Zurich, Switzerland; 11) Mannheim, Germany; 12) Essen, Germany; 13) Valencia, Spain; 14) Ghent, Belgium; 15) SUNY, Upstate Medical University, Syracuse, NY, USA.

Attention-Deficit/Hyperactivity Disorder (ADHD) is a neurodevelopmental disorder characterised by symptoms of inattention, hyperactivity and impulsivity. There is growing evidence of heterogeneity in its etiology, pathophysiology and clinical expression. One approach to resolving heterogeneity involves the identification of endophenotypes, intervening variables that might mediate pathways between specific genes and clinical phenotype. IQ is a candidate endophenotype for ADHD. Genome-wide linkage analyses of full scale IQ and IQ subscales were performed in the International Multi-centre ADHD Genetics (IMAGE) study including 1094 families with 1094 DSM-IV combined type ADHD probands and their 1441 siblings (unselected for ADHD status). IQ was measured using five subscales of the WISC-IIIR scale. The full scale prorated IQ score and the five subscales were used as quantitative traits for linkage analysis. 5,407 autosomal SNPs were used to run multipoint regression-based linkage analyses using MERLIN. The h^2 estimates from the IQ subscales and the full IQ score ranged from 31% to 100%. Three suggestive linkage signals were found (LOD scores 2, p values 0.001) on chromosomes 7, 9 and 14 for three different subscales. Previously, two regions on chromosomes 7 and 14 were reported as being associated or linked to IQ. Our results, though only suggestive, suggest the presence of additional genetic variants contributing to the variance of IQ in ADHD.

Fine mapping of multiple causal MHC variants using imputation and shrinkage regression. *C. Vignal*[1,2], *A. Bansal*[2], *D. Balding*[1] 1) Imperial College, UK; 2) GlaxoSmithKline, UK.

Risk of rheumatoid arthritis (RA) is associated with the MHC region, most notably with a group of alleles termed the shared epitope (SE) at HLA-DRB1. Additional MHC loci may also play a role but inference is hampered by the presence of high linkage disequilibrium (LD) and differences in SNP coverage across studies. We investigate genotype imputation at untyped and typed markers as a means to jointly analyse correlated SNPs from multiple studies.

Genotype imputation was applied, using MACH, to data from the Wellcome Trust Case Control Consortium (WTCCC), HapMap (Caucasian parents) and 977 RA cases and 855 controls from the GoRA study, whose subjects had been genotyped for 2,302 SNPs, together with HLA-DRB1 locus. After imputation, the combined dataset comprised 6,647 subjects and 9,990 genetic markers from the MHC region. Uncertainty in imputation was taken into account in the association analyses by using the estimated minor allele count, averaged across MACH iterations. We adopted a Bayesian-inspired penalised logistic regression approach for variable selection, adjusting for the effect of the SE at HLA-DRB1. We investigated a range of prior (penalty) functions, including the Laplace (double exponential). Parameter inference was based on the posterior mode, with non-zero values indicating marker-disease associations.

Careful choice of burn-in improved the performance of MACH. After controlling for type-I error, univariate association tests identified many positive associations in the combined GoRA-WTCCC dataset, most of them likely to be spurious. Shrinkage regression better handled the correlation between predictors and greatly reduced the number of positive signals. Moreover the positive signals identified were not strongly correlated with each other or with SE. Thus imputation and shrinkage regression have identified a number of independent candidates associated with RA in the MHC region, and these are being further investigated.

Somatic events in retinoma and retinoblastoma. *M. Amenduni[1], K. Sampieri[1], F. Ariani[1], F. T. Papa[1], M. Bruttini[1], M. A. Mencarelli[1], M. C. Epistolato[2], P. Toti[2], S. Lazzi[2], A. Marozza[1], F. Mari[1], T. Hadjistilianou[3], S. De Francesco[3], A. Acquaviva[4], A. Renieri[1]* 1) Medical Genetics, Univ of Siena, Italy; 2) Human Pathology and Oncology Dept, Univ of Siena, Italy; 3) Ophtalmology Dept, Univ of Siena, Italy; 4) Pediatrics Dept, Univ of Siena, Italy.

To characterize somatic events leading from normal retina (Rt) to retinoma (Rn) and from Rn to retinoblastoma (Rb), we used 3 different approaches on two eye samples showing areas of Rn adjacent to Rb: i) RB1 mutational analysis; ii) qPCR at 4 genes involved in Rb pathogenesis (MDM4, MYCN , E2F3 and CDH11); iii) array-CGH. We demonstrated that 2 RB1 mutational hits are already present in Rn. In contrast with the previous model, qPCR showed that MYCN and E2F3 amplifications are already present in Rn tissue. The level of amplification is increased in Rb cells. Array CGH revealed interesting and different results in the two cases. In Case#1, Rn was documented by ophthalmoscopic examination as a lesion stable for 11 months before Rb transformation. In this case, no genomic rearragements are present in Rn. In Case#2, belonging to a patient diagnosed with advanced Rb, Rn tissue was observed by retrospective histopathological examination. In this case, Rn shares 3 genomic rearrangements with Rb (dup5q13.2, dup6p, dup8p23.1). Two other rearrangements without any known gene are Rn specific (dup1q32.2 and dup13q31.2). One rearrangement (dup5p) is present only in Rb and contains several candidate genes for malignant transformation, including SKP2 (p45), essential for S-phase entry of cell cycle. These results suggest that the two lesions named retinomas are different in nature. The first is a pretumoral lesion, while the second represents a clone of cells that presents benign rearrangements different from those acquired by another clone generating Rb. To characterize recurrent genomic rearrangements in Rb tissues, we analysed 18 tumor eye samples by array CGH. We detected 7 common rearrangements including dup6p (E2F3), dup2p24.1 (MYCN), dup1q (MDM4), del13q13.2-22.3 (RB1) and del16q12.1-12 (RBL2 encoding p130). Overall, these results emphasize the role of these oncogenes/oncosuppressors in Rb tumor progression.

Promoter region in the ARG1 gene is involved in the genetic risk for asthma in Puerto Rican patients. *M. Via[1], C. Eng[1], S. Choudhry[1], H. Corvol[1], M. A. Seibold[1], R. Chapela[2], J. R. Rodríguez-Santana[3], W. Rodríguez-Cintron[4], P. C. Ávila[5], E. G. Burchard[1]* 1) Dept Medicine, Univ California, San Francisco, San Francisco, CA; 2) Instituto Nacional de Enfermedades Respiratorias, Mexico City, Mexico; 3) Centro de Pneumología Pediátrica, San Juan, Puerto Rico; 4) Veteran Affairs Medical Center, San Juan, Puerto Rico; 5) Northwestern University School of Medicine, Chicago, IL.

Arginase-1 (ARG1) gene has been identified as a candidate gene for asthma in animal models. Moreover, a recent study has established an association between variants in ARG1 gene and atopy among Latino subjects with asthma. In this study we have analyzed five SNPs in the ARG1 gene region in a family-based association study of Mexican and Puerto Rican asthmatic patients (N=687 families). An association was found between allele C of SNP rs2781664 located in the promoter region and an increased risk for asthma only among Puerto Rican families (OR=1.38; 95%CI 1.08-1.77; P=0.009). In these patients, this variant was also associated with higher levels or increased risk for all recorded allergy-related phenotypes such as IgE levels (P=0.018), number of factors causing runny/stuffy nose or cough (P=0.006), eczema (P=0.033) and hay fever (P=0.023). The same results were obtained for the most common haplotype in the promoter region (C-T-T-T), and partially for other SNPs in tight linkage disequilibrium. Luciferase expression assays were performed to assess the potential functional role underlying the observed associations. Haplotype C-T-T-T showed higher levels of expression at the basal transcription level, but differences were not statistically significant. Although not conclusive, this trend towards higher transcription levels could imply a more severe allergic asthmatic response and be the causative factor for the associations found.

Identification of SNPs underlying parental preferential effects on gene expression levels. *C. A. Anderson, B. M. Herrera, M. Jain, A. P. Morris, C. M. Lindgren* Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom.

Recently, many studies have attempted to correlate gene expression levels to genotypic variation. Such studies have followed similar paradigms to traditional association and linkage analyses. Thus far, the identification of SNPs which underlie parental preferential gene-expression effects has been neglected. The identification of such SNPs, where the effect of the inherited allele differs depending from which parent it was inherited, would reveal an as yet uncharacterised mechanism underlying human phenotypic variation. Here, we use publicly available gene-expression data obtained from the CEU HapMap samples in an attempt to identify such variants. Only expression traits with a standard deviation 0.5 were taken forward. We identified all SNPs 500kb downstream and 50kb upstream of each gene transcript (i.e. our analysis was restricted to the identification of SNPs with cis-acting effects on parental preferential gene-expression). The list of SNPs under analysis was further reduced so that no pair of SNPs had an r^2 0.99. In total, 173,527 SNPs and 1,327 gene-expression traits were analysed and 212,933 tests were performed. 4 SNPs (from 3 unique transcripts) were identified showing significant evidence (p2.3×10^{-7}) of parental preferential effects on gene expression. We attempted replication using gene-expression and genotypic data from the Yoruban HapMap individuals and saw nominal evidence of parental preferential effects (p0.05) for 1 SNP. Permutation analysis is planned to better define significance thresholds and replication will be attempted in a large independent cohort of European descent.

Confirmation of novel prostate cancer susceptibility loci in men with early-onset prostate cancer. *K. Zuhlke[1], A. Ray[1], S. Walters[1], E. Lange[3,4], K. Cooney[1,2]* 1) Dept Internal Medicine, Univ Michigan, Ann Arbor, MI; 2) Dept of Urology, Univ Michigan, Ann Arbor, MI; 3) Dept of Genetics, Univ North Carolina, Chapel Hill, NC; 4) Dept of Biostatistics, Univ North Carolina, Chapel Hill, NC.

Large genome-wide association studies (GWASs) continue to emerge as a powerful approach for identifying common disease alleles associated with complex human diseases. A recent publication by Eeles et al. (2008) performed a two-stage GWAS with familial and early-onset prostate cancer cases from the UK and Australia that confirmed the association between prostate cancer and SNPs in previously reported regions on chromosomes 8 and 17. In addition, Eeles et al. identified seven new prostate cancer susceptibility loci on chromosomes 3 (rs2660753), 6, (rs9364554), 7 (rs6465657), 10 (rs10993994), 11 (rs7931342), 19 (rs2735839), and X (rs5945619), that reached global statistical significance ($p < 2.7x10-8$). In this study, we genotyped these seven newly identified SNPs in 750 unrelated Caucasian prostate cancer cases diagnosed at or before the age of 55 (avg. age dx = 49.8 yrs 3.9) from the University of Michigan Prostate Cancer Genetics Project (PCGP) and compared their genotype frequencies to 3,085 self-reported Caucasian controls from Illuminas iControlDB database. Unconditional logistic regression models were used to evaluate the association between prostate cancer and each SNP. We found confirmatory evidence ($p < 0.05$ and the association in the same direction as in Eeles et al.) to support an association for six of the seven novel SNPs and early-onset prostate cancer. Only rs2660753 on chromosome 3 was not significantly associated with prostate cancer, despite our sample having a higher frequency of the risk allele than that reported in both Stage 1 and Stage 2 samples reported by Eeles et al. We believe that early-onset prostate cancer is an important public health problem and that studies using early-onset prostate cancer cases will have the greatest power to detect genetic variants associated with the disease.

Single nucleotide polymorphisms in the BDNF gene affect cognitive measures shortly after traumatic brain injury. *T. W. McAllister[1], A. L. Tyler[1], L. A. Flashman[1], C. H. Rhodes[1], A. J. Saykin[2], B. C. McDonald[2], T. D. Tosteson[1], G. J. Tsongalis[1], L. L. Hoskins[1], J. H. Moore[1]* 1) Dartmouth Medical School, Dartmouth College, Lebanon, NH; 2) Indiana University School of Medicine, Indianapolis, IN.

Different functional outcomes are often reported in individuals with similar degrees of traumatic brain injury (TBI) suggesting that environment and genotype play important roles in outcome. Polymorphisms in genes responding to neurotrauma or modulating cognition-associated neurotransmitter systems may influence either the acute response to trauma or adaptation to injury. Brain Derived Neurotrophic Factor (BDNF) plays a role in neural survival, repair, and plasticity, and facilitates both early and late long-term potentiation. A non-synonymous SNP (rs6265) in BDNF has been shown to affect human memory function. We hypothesized that this SNP and neighboring SNPs would affect cognitive function shortly after MTBI. 75 consecutive patients with mild-moderate TBI (MTBI) were recruited from a Level-1 trauma center emergency department, studied approximately one month after injury and compared to 38 healthy subjects. Written informed consent was obtained from all participating subjects. Participants were tested in areas of learning and reaction time and genotyped across 9 SNPs within the BDNF using a custom made 3600 SNP microarray gene chip (Affymetrix, Inc., Santa Clara, CA). Adjusting for age and education, and using an FDR of 0.1, we found a significant main effect of three on measures of processing speed (p0.005). Within the MTBI group, there were significant effects of genotype on processing speed and memory. Cognitive effects were most prominent in male participants. A six SNP haploblock in male MTBI patients was most predictive of outcome. This study provides support for the hypothesis that polymorphisms in the BDNF gene may influence cognitive performance shortly after MTBI, particularly in males. The mechanism is unclear but may be related to alterations in BDNF expression or function in the hippocampus.

Adenylosuccinate lyase (ADSL) deficiency. *M. Zikanova, V. Skopova, L. Dvorakova, J. Krijt, S. Kmoch* Charles University, 1st Faculty of Medicine, IIMD, Prague, Czech Republic.

Adenylosuccinate lyase deficiency is a rare autosomal recessive disease of purine metabolism affecting predominantly central nervous system. Although spectrum and severity of clinical symptoms overlaps, three forms of ADSL deficiency - severe neonatal, severe childhood and mild myopathic - can be distinguished clinically based on onset and severity of symptoms and biochemically on diverse ratios of accumulating succinylpurines in body fluids (SAdo/SAICAr ratio). The pathogenic mechanisms leading to the development of symptoms and underlying the phenotypic and biochemical heterogeneity remain unknown. We introduced a complex diagnostic system for ADSL deficiency based on metabolite profiling, enzyme activity measurements, mutation analysis and recombinant protein characterisation. So far we have analysed 22 patients from 18 families (8 Czech, 7 Poland, 5 Germany and 2 US), identified 16 ADSL mutations and cloned, expressed, purified and characterized catalytic properties of corresponding recombinant wild type and mutant ADSL proteins. We found evidence that residual enzyme activity, calculated as a mean of homoallelic activities, correlates with severity of phenotype. However, all the active mutant enzymes displayed proportional decrease in activity towards both substrates and no ground for the varied SAdo/SAICAr ratio was found. Based on these molecular data, prenatal diagnosis of 5 embryos was performed on genomic DNA isolated from chorionic villi. The analyses showed that 2 fetuses were heterozygotes for one mutation inherited from one parent and 3 fetuses inherited both mutations from their parents. We also investigated expression patterns of ADSL protein in available tissues from three deceased patients with R426H/Y114H, E376D/Y114H and R396H/Y114H genotypes. Compared to age matched controls, Western blot analysis showed in patients reduced amounts of ADSL in brain, heart, kidney and liver, but elevated amounts of ADSL in muscle. Based on these observations we hypothesize, that selective affection of central nervous system can be attributed rather to the toxic effects of accumulating succinylpurines then tissue specific involvement of ADSL function.

Analysis of Holoprosencephaly syndrome using array CGH indicates 32% of genomic rearrangements. *V. David[1,2], L. Rochard[1], C. Dubourg[1,2], I. Gicquel[1], MR. Durou[2], S. Jaillard[3], J. Mosser[1], V. Dupe[1], L. Pasquier[1,4], S. Odent[1,4], C. Bendavid[1]* 1) Fac de Medicine, UMR 6061 CNRS/Univ Rennes, Rennes, France; 2) Molecular Genetics, CHU Pontchaillou, Rennes, France; 3) Cytogenetics, CHU Pontchaillou, Rennes, France; 4) Medical Genetics, Hopital Sud, Rennes, France.

Holoprosencephaly (HPE) is the most common developmental brain anomaly in humans, usually associated with facial features. Our group focuses on patients with HPE and normal karyotype. Genetics of holoprosencephaly is complex: in our experience, mutations (18%) or deletions (8%) in the four main genes (SHH, ZIC2, SIX3 and TGIF) can explain about 26% of HPE cases. MLPA subtelomeric screening revealed 4% of additional complex rearrangements. In order to identify new candidate loci and thus novel candidate genes, we decided to screen HPE patients using Agilent CGH-array technology. 117 samples (68 fetuses and 49 live-borns children), with no karyotype alterations were tested using a unique male or female DNA as control. Out of these 117 samples, 37 presented with new rearrangements involving known or new potential HPE loci located on different chromosomes with 2 redundant regions. In a total of 117 patients, 37 chromosomal imbalances were detected (32%). These included 23 deletions, 9 duplications and 5 associated gains and losses. Detected alterations ranged from less than 1 gene to 17 Mb and were not further considered if they involved less than 3 consecutive spots on the array. None of these regions matched against copy number variations described in databases (TCAG database). Frequencies of alterations were higher in foetuses (70%) than in live-borns (30%). Thus, it appears that loss of genetic material represent severe alterations leading to more severe phenotypes. We are focusing on redundant rearrangements in order to identify new HPE genes; the prioritization of these genes is made using bioinformatics, expression in animal models during development and sequencing in patients.

A study of the frequency and haplotypes of SMA carrier alleles in the Ashkenazi Jewish population. *L. Liu, A. A. Mitchell, N. Cohen, R. J. Desnick, R. Kornreich, L. Edelmann* Dept Genetics/Genomic Sciences, Mount Sinai Sch Medicine, New York, NY.

Spinal muscular atrophy (SMA) is a common autosomal recessive neuromuscular disorder and has been reported to occur at a frequency of about 1 in 6000 liveborns. Mutations in the SMN1 gene on 5q13 are identified in the great majority of SMA patients. SMN1 resides in a region of the genome which has complex repetitive architecture and a highly homologous copy, SMN2, is located 1.4 Mb proximally on 5q13. Most mutations involve SMN1 copy number loss by either deletion or gene conversion events with SMN2 and consequently, carrier testing is performed using dosage sensitive methods. Approximately 1 in 40 individuals is a carrier for SMA; however, no data exists specifically for the Ashkenazi Jewish (AJ) population for which the frequencies of a number of disorders are high due to founder mutations. To determine the frequency of SMA carriers, we screened 692 individuals of AJ ancestry using MLPA. Fifteen SMN1 mutation carriers (1 in 46) were identified, and three major mutation groups were encountered; (1)SMN1 deletion, (2)SMN1 and SMN2 deletion (3)SMN1 exon 7/8 deletion. To determine whether these mutation groups represented founder alleles, we genotyped all 15 carriers and 25 AJ controls with 11 microsatellite markers that span 4.7 Mb on 5q13. In all three groups, a conserved haplotype of at least four consecutive alleles was identified. Haplotype A was found at estimated frequencies of 13% in Group 1, 8% in Group 2 and 2% in controls. Haplotype B, the most commonly identified haplotype in all groups, was found at estimated frequencies of 25% in Group 1, 36% in Group 2 and 12% in controls. Haplotypes A and B were not seen in Group 3. Haplotype C was found at estimated frequencies of 30% in Group 3, 14% in Group 2 and 5% in controls, but absent from Group 1. Interestingly, 4 of the 15 carriers did not fit into one of the three haplotype groups, which is likely to reflect the high denovo mutation rate at this locus. Our data support the existence of SMA founder alleles and represent the first rearrangement disorder for which AJ founder mutations have been identified.

Prioritization of Candidate Genes for Retinitis Pigmentosa. *K. F. Cribben[1], T. A. Braun[1], J. H. Fingert[1], V. C. Sheffield[1,2], E. M. Stone[1,2], T. L. Casavant[1], T. E. Scheetz[1]* 1) University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, Chevy Chase, MD.

We have previously developed a method for prioritizing gene candidates (NPCE) and utilized that method to successfully identify two novel genes for Bardet-Biedl syndrome. This method calculates a significance score for a set of genes based upon the network of pairwise correlations among the genes. This NPCE strategy provides a single representative value for a given network of gene correlations. The relative benefit for adding a gene to an existing network is then evaluated by assessing the significance score of that new network versus those networks derived from adding any other single gene. Each gene may then be prioritized based upon its relative contribution to the significance score. Our ability to prioritize the set of retinitis pigmentosa (RP) genes, however, varies greatly. This is due to the variable structure in the network of expression correlations among the RP genes, likely representing the increased complexity of RP. To address this lack of consistent structure, we iteratively reduced the RP network to the size of the BBS network (12 genes). The NPCE method was used to prioritize these 12 genes using a leave-one-out strategy. This resulted in a median prioritization in 11^{th} percentile of all genes, ranging from the 1^{st} to the 27^{th} percentile. This technique was applied to the set of linked RP intervals in human for which the disease gene is unknown, and identified several interesting candidates. We expect that the performance of the NPCE method can be increased significantly, particularly for the case of complex diseases. Several other expression data sets have yielded very promising preliminary results. The NPCE method is being extended to incorporate: (i) multiple expression data sets simultaneously, (ii) graph-theoretic approaches, and (iii) comparative genomic methods to utilized data sets from multiple species. The diffuse network structure of RP will be an excellent test-bed in developing the next generation of candidate gene prioritization methods needed to address the needs of truly complex diseases (diabetes, macular degeneration, etc).

Inherited abnormalities of unknown significance detected by aCGH and their implication in prenatal decisions, experience from an Israeli hospital. *H. Yonath[1,2], M. Berkenstadt[1], M. Frydman[1,2], B. Ghidoni- Ben-Zeev[1,2], E. Praas[1,2]* 1) Sheba Medical Ctr, Ramat Gan, Israel; 2) Sackler, TAU, Israel.

The increasing use of array CGH (aCGH) has refined our knowledge of chromosomal aberrations. In some of the cases the significance of the findings is unknown, especially when familial and rare. Many Israeli couples elect to perform invasive prenatal testing in order to assure a normal offspring. The indications include: advanced maternal age, abnormal US findings, previous abnormal child and parental concern. Increasing numbers of these samples are sent for aCGH analysis. When known deletion or duplication syndromes are detected by aCGH, the couples often elect to terminate the pregnancy. It is problematic when the significance is unknown. We present here four such families: Family #1: A young boy suffers from seizures, speech delay and compromised fine-motor skills. His brain MRI showed partial agenesis of the corpus callosum (CC). aCGH revealed a gain on 9p24.3. His healthy father has the same gain, and a normal brain MRI. The paternal grandfather, a normal male, had a single seizure at 63 years. Brain MRI revealed complete agenesis of the CC, and the same gain on chromosome 9. Family #2: An aCGH on a normal female fetus revealed a maternally inherited copy gain in Xp11.22. The first pregnancy was terminated due to a male fetus that had severe hydrops, DNA was extracted and saved. The girl is now 6 months old and developing well. Family #3: An aCGH preformed on a female fetus due to parental concern, revealed a maternally inherited 18p11.32 duplication. The mother is normal and healthy. Family #4: A female fetus' aCGH revealed deletions on 7p21.3 and 13q12.11. It was sent due to a previous son with cerebello-cerebral progressive atrophy, which has a deletion at 7p21.3. The father, who is healthy, has both deletions. Even after an in depth literature and database search, the clinical significance of these abnormalities is difficult to determine. These cases illustrate the problems encountered when interpreting certain familial aCGH abnormalities, especially when these cases are performed prenataly and the results are needed within a short time.

Dopamine Polymorphisms and Depressive Symptoms Predict Intake of Salty and Sweet Foods in a US Nationally Representative Sample of Adolescents and Young Adults. *TD. Agurs-Collins[1], BF. Fuemmeler[2]* 1) Health Promotion Research Branch, National Cancer Institute, Bethesda, MD; 2) Department of Community and Family Medicine, Duke University Medical Center.

Background: The brain mesolimbic dopaminergic system may play an important role in sensory pleasure of food, drugs and other rewards. Evidence suggests gene expression alterations in this system may mediate some of the rewarding effects of sucrose. Depression and emotional eating are associated with increased intake of sweet high energy-dense foods and salty high energy-dense foods. We examined the association between genotypes linked to dopaminergic pathways and depressive symptoms on predicting consumption of salty and sweet snack foods. **Methods:** A subsample of participants in Wave III of the National Longitudinal Study of Adolescent Health (n=1551) who provided DNA, an in-home 24-recall, and a measure of depressive symptoms were included in the analysis. Salty/high fat snack and sweet food indices were developed from the 24-hour recall. Depressive symptoms were measured using the Center of Epidemiologic Studies-Depression Scale (CES-D). Polymorphisms analyzed were dopamine transporter (DAT) and dopamine D2 receptor (DRD2). Multivariate linear regression analyses for genotype and depressive symptoms predicted consumption of sweet and salty snack foods. Models were stratified by gender and adjusted for age, parental education, race and body mass index (zBMI). Interactions between genotype*depressive symptoms were explored. **Results:** Significant main effects were observed for depressive symptoms among males consuming salty/high fat snack foods (p=0.01)and among females with the 10/10 allele relative to any 9 allele on salty/high fat snack foods (p=0.03). Significant DAT gene*depressive symptoms interaction was observed for females predicting consumption of sweet snack foods (p<.001)and a significant DRD2 gene*depressive symptoms interaction for males consuming salty/high fat snack foods (p=0.03). **Conclusions:** These findings suggest that genes associated with the dopaminergic system and depressive symptoms may play an important role in consumption of snack foods with possible gender differences.

Bayesian Algorithm for scoring polymorphic deletions from SNP data and genomewide scan for common CNVs.

S. Zollner[1,2], W. C. L. Stewart[1], K. Stephenson[1], P. Zhang[1], M. Mcinnis[2] 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Psychiatry, Univ Michigan, Ann Arbor, MI.

Copy Number variations (CNVs) in the human genome provide exciting candidates for functional polymorphisms affecting complex trait phenotypes. Efforts are underway to generate a CNV-map by identifying and cataloging all common CNVs in the human genome. Thus, association of CNV carrier status and diseases status in case-control studies can be assessed. One approach to score such common CNVs is to evaluate the signal intensity of SNP genotyping assays. However, such analyses are hampered by a lack of appropriate statistical methods. Here we present a novel statistical method that is designed to perform such inference, assess this method using a known CNV and apply it to a large sample of genomewide SNP genotyping data. Using a bayesian algorithm we calculate the posterior probability for the carrier status, jointly analyzing genotype information and hybridization intensity. We model the signal intensity as a mixture of normal distributions, allowing for locus-specific and allele-specific distributions estimated using an EM algorithm. Our model accounts for genotyping error and uncertainty about the boundaries of an assessed CNV. We test the method using a previously described common deletion on 8q24 in a sample of 3512 individuals. We unambiguously inferred 172 heterozygous and 1 homozygous deletion carrier. We assessed the power of this algorithm to detect shorter CNVs by sub-sampling from the SNPs covered by this deletion, We demonstrate that our EM algorithm produces precise estimates for CNVs covering 7 or more SNPs, thus providing a better resolution than commonly used hidden Markov models. We apply the method to a population sample of 1600 individuals sequenced with the Affymetrix 6.0 chip to assess carrier status for 15466 CNVs collected in the database of genomic variants. In our analysis we use both the genotype probes and the CNV probes on the Affy 6.0 chip. We thus describe the utility of large collections of CNVs for association mapping.

***CFTR* screening in infertile couples candidate for Assisted Reproductive Techniques (ART).** *A. Saluto, A. Murro, A. Celeste, A. Marongiu, G. Voglino* Laboratory of Molecular Genetics - PROMEA S.p.A - Turin, Italy.

Cystic Fibrosis (CF) is a multi-system autosomal recessive genetic disorder caused by mutations in the Cystic Fibrosis Transmembrane Regulator *(CFTR)* gene primarily affecting Caucasian populations. With an incidence of about 1 in 2500 live births it is the most common life-shortening disease. Thus far, more than 1600 mutations in the *CFTR* gene have been identified; the great majority are rare and present in only one or a few CF patients. The most common mutation is F508, whose prevalence varies among populations of different geographical and ethnic backgrounds, accounting approximately for the 70% of the mutations in European patients. Our aim was to evaluate the frequency of *CFTR* mutations in infertile couples referred to our center for Assisted Reproductive Techniques (ART) (either IVF-ICSI or IUI). *CFTR* gene screening was performed according to Italian guidelines for genetic tests in infertile couples (C. Foresta et al, 2002). We analysed 2888 infertile couples in the last five years; molecular analysis of the *CFTR* gene was performed on genomic DNA extracted from peripheral blood lymphocytes by using OLA assay (Cystic Fibrosis Genotyping Assay, Abbott Laboratories, Germany). The 3.6% (208/5776) of the tested patients showed the presence of a *CFTR* gene mutation; these patients underwent a genetic counseling to inform the couple of the genetic risk for having a baby with CF. The prevalence of 1/28 cystic fibrosis heterozygous carriers we detected is in agreement with previous studies for the Italian population. 131/208 mutations (63%) were F508 that was confirmed using a rapid test developed in our laboratory based on fluorescent fragment analysis of *CFTR* exon 10; the same test is utilized for particular PGS (Prenatal Genetic Screening) cases using QF-PCR technique. To our knowledge this is one of the largest screening of *CFTR* gene in Italian infertile couples and we do not show higher prevalence of mutations in infertile cases compared with the general Caucasian population.

Genetics of VEGF serum level variation in human: importance of VEGF gene polymorphisms. *D. Ruggiero[1], R. Sorice[1], C. Bellenguez[2], T. Nutile[1], G. Fardella[1], M. Aversano[1], C. Bourgain[2], M. Ciullo[1]* 1) Institute of Genetics and Biophysics - CNR, Naples, Italy; 2) INSERM U535, Villejuif, France.

Vascular Endothelial Growth Factor (VEGF) is a potent mediator of angiogenesis and vascular permeability, having a key role in both physiological and pathological angiogenesis. In order to identify QTLs influencing VEGF serum levels, we performed a genome wide linkage analysis using a sample of individuals randomly chosen in Campora, an isolated population in South Italy. VEGF serum levels were measured using the ELISA method in a sample of 656 individuals. 627 individuals out of the 656 were all related through a 3049-member pedigree and genotyped for 1122 microsatellites on the genome (average marker spacing of 3.6cM). The heritability for VEGF serum levels was estimated to be 0.86 after adjusting for age. To perform linkage analysis we broke the large genealogy using the GREFFA method through a multiple splitting approach recently proposed by Bellenguez and coll. With the regression-based linkage statistics proposed by Sham and collaborators (2002), we detected a strong linkage on chromosome 6p12.3 (LOD=10.07) at marker D6S459. This linkage signal exactly corresponds to the location of the VEGF gene. Next, the coding and regulatory regions of the VEGF gene were sequenced in a sample of 42 individuals. 33 polymorphisms were identified, 24 of which having a MAF>0.05. The association between these 24 SNPs and VEGF levels was tested using the GTAM test, that also corrects for relatedness between individuals through the genealogical information. After correction for the number of independent tests performed, a significant association was detected between three of the 24 SNPs ($p<0.001$) and VEGF serum levels. To assess if the linkage signal detected on chromosome 6 could be explained by these associations, linkage analysis was carried out taking into account the effect of the SNPs on the trait. A lower linkage peak (LOD=6.457) was obtained, showing that 35% of the linkage is explained by the identified variants. With this work therefore, we show that isolated populations, allowing both linkage and association analyses, could be a powerful approach in complex trait studies.

Validation Study of Candidate Gene SNP Genotyping Protocol. *A. Kureichyk, S. Wendell, ML. Marazita* School of Dental Medicine, University of Pittsburgh.

The single nucleotide polymorphism (SNP) genotyping of candidate genes using commercial fluorescent PCR assay systems is utilized to investigate genetic associations. We sought to validate a SNP genotyping protocol, adapting the recent advances in saliva DNA extraction, PCR based human DNA quantification, sample handling, and PCR based genotyping. Methods Human DNA from saliva was extracted and handled under separate PCR hoods. Barcode labels and electronic file conversions were used for sample handling and software analysis. The RNaseP Taqman assay from Applied Biosystems, (ABI) was used to quantify the human component of the saliva DNA. Genotyping with five SNP assays was conducted on three concentrations (0.45, 4.5, and 22.5ng) of 15 individual DNA samples in 5ul reactions. This was done in triplicate on separate days totaling 9 genotype calls per sample between three concentrations and 675 accumulative genotype calls. PCR quantification and genotyping were analyzed on the ABI 7900 using SDS software in absolute quantification or allelic discrimination mode respectively. Genotype calls were assessed using SDS software in a variety of settings including manually adjusted autocalls. Restriction enzyme digests were conducted on two SNP assays to confirm fluorescent PCR based genotype calls. Results Tight genotype clustering was seen using DNA normalized by RNaseP assay. The level of undetermined genotypes (45/675, 6.7%) was minimal with successful genotyping in at least one replicate at the same DNA concentration. Two incorrect genotypes (2/675, 0.3%) were seen in the same SNP and represented the only homozygous minor allele genotypes for this SNP, ruling out cross contamination. The 4.5ng DNA concentration was optimal with 4 out of 225 (<2%) undetermined genotypes. Independent PCR and restriction enzyme digest in two SNP regions confirmed accurate genotyping. Conclusions The assessed protocol for candidate gene genotyping indicated a low level of undetermined genotypes (6.7%) and incorrect genotypes (<0.3%). The 0.45ng/5ul DNA concentration was optimal for genotype clustering and successful calls (>98%). All genotypes for two SNPs were confirmed by independent restriction enzyme digest. NIH Grant # DE014899.

Association of Sporadic ALS with Candidate Genes and Environmental Risk Factors: The Genes and Environmental Exposures in Veterans with ALS (GENEVA) Study. *S. Schmidt[1], K. Allen[1,2], J. Rimmler[1], V. Loiacono[1], C. Stanwyck[1], C. Williams[1], H. Munger[1], M. Hauser[1], E. Oddone[1,2]* 1) Dept Medicine, Duke Univ Med Center, Durham, NC; 2) VA Medical Center, Durham, NC.

An increased risk of amyotrophic lateral sclerosis (ALS) has been reported for US military veterans. Head injury and cigarette smoking have been implicated as risk factors for developing ALS, and both are more common in military personnel, compared to civilians. Recent genome-wide association studies have proposed DPP6 and ITPR2 as potential ALS susceptibility genes, but the respective SNPs (rs10260404, rs2306677) have not yet been examined in a veteran study population. In conjunction with the National Registry of Veterans with ALS, we have enrolled 617 patients with motor neuron disease (85% ALS, 98% male, 93% white) and 445 controls (94% male, 91% white) into the GENEVA case-control study to date. DNA samples from 852 cases and 202 controls have been genotyped thus far; results will be updated by adding 280 case and 190 control samples. We analyzed the association between head injury, cigarette smoking, SNP genotypes and ALS risk in the entire study population and the subset of incident cases. While the number of head injuries requiring medical attention was not significantly associated with ALS risk, an older age at the time of the last head injury conferred an increased risk. Relative to veterans without any head injuries, those with an age at last injury below 30 years, 30-40 years and >40 years, respectively, had an odds ratio (OR) for ALS of 0.99 (95% CI 0.64-1.56), 1.78 (0.84-3.80) and 2.44 (1.20-4.93) (p(trend)=0.01, 204 incident cases, 410 controls). There was no significant association between cigarette smoking and ALS risk. The minor allele frequencies of rs10260404 and rs2306677 in veteran controls were similar to those reported for civilian populations, but these SNPs were not associated with ALS risk in our sample. We conclude that head injuries may make a moderate contribution to the increased risk of ALS in US veterans, and will examine if coding variants in the apolipoprotein E (APOE) gene modify this relationship.

Left ventricular noncompaction is frequently associated with sarcomere protein gene mutations. *S. Klaassen[1], S. Probst[1], E. Oechslin[2], B. Gerull[1], F. Berger[3,4], R. Jenni[5], L. Thierfelder[1]* 1) Max-Delbrueck-Center for Molecular Medicine, Berlin, Germany; 2) Toronto General Hospital, Toronto, Canada; 3) German Heart Institute Berlin, Berlin, Germany; 4) Pediatric Cardiology, Charité, Berlin, Germany; 5) University Hospital Zürich, Zürich, Switzerland.

Introduction- Left ventricular noncompaction (LVNC) has recently been recognized as a primary cardiomyopathy. It is characterized by a severely thickened, two-layered myocardium, numerous prominent trabeculations, and deep intertrabecular recesses. Recently, mutations in genes encoding sarcomere proteins -myosin heavy chain (MYH7), -cardiac actin (ACTC), and cardiac troponin T (TNNT2) were shown to be associated with LVNC. We report on the frequency of mutations in sarcomere protein genes in a cohort of patients with isolated LVNC. Methods and Results- Mutational analysis of 8 sarcomere protein genes was carried out in a cohort of 63 unrelated Caucasian adult probands (mean age, 40 years) with LVNC and absence of other congenital heart anomalies. Denaturing high performance liquid chromatography (DHPLC) analysis and direct DNA sequencing were performed. Heterozygous mutations were identified in 18 of 63 samples (29%). Two new disease-genes were identified: cardiac myosin-binding protein C (MYBPC3) and -tropomyosin (TPM1). 5 mutations were found in MYBPC3, and 2 in TPM1. The LVNC phenotype was characterized by a variable adult-onset of symptoms such as heart failure and systemic emboli. Younger affected individuals were diagnosed because of family screening and were usually clinically asymptomatic. MYH7 was the most prevalent disease gene and accounts for 13% of cases followed by MYBPC3 as the second most frequent disease gene (8%). Conclusions- Mutations in sarcomere protein genes account for a significant proportion of cases of isolated LVNC in this cohort (29%). We describe the first mutations in MYBPC3 and TPM1 associated with isolated LVNC. These findings confirm that LVNC belongs to the spectrum of cardiomyopathies caused by molecular defects of the sarcomere and open new perspectives for genetic investigations and counseling.

An Overview of the Literature on Genetic Epidemiology of Infectious Disease. *R. Waltenburg[1,2], W. Yu[1], M. Gwinn[1], M. Khoury[1]* 1) National Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA; 2) Epidemiology Department, Rollins School of Public Health, Emory University, Atlanta, GA.

Background: Increasingly, host genomics has been explored to explain heterogeneity in susceptibility, severity and treatment response to infection. The Human Genome Epidemiology (HuGE) Published Literature database is a searchable online knowledge base comprised of population-based epidemiology studies of human genes. The database has been curated by the National Office of Public Health Genomics at the Centers for Disease Control and Prevention since October, 2000. The objective of this study was to characterize the HuGE infectious disease literature. **Methods:** On May 21, 2007 the HuGE Literature Finder was queried to identify studies of infectious disease with a publication date between 2001 and 2006. A 20% simple random sample by year was obtained (n=328) and 284 articles met inclusion criteria. **Results:** The number of publications increased each year from 2001 through 2006. Most studies were observational, with 93% exploring gene-disease associations and 23% examining gene-environment interactions. 69% examined disease susceptibility, while 29% examined disease severity. Forty-five percent of all studies incorporated some type of chronic outcome (i.e., chronic infection, chronic sequelae, carcinoma), with 14% of all articles studying cancer as an outcome. The mean number of genes per article was 2.1 (range 1-45). *TNF*, *IL10*, *HLA-DRB1*, *IL1B*, *CCR5*, *HLA-DQB1*, *IL6*, *IL1RN* and *IFNG* were the most commonly referenced genes. Twenty percent of all studies performed haplotype analyses of which half examined non-HLA genes. The most frequently studied pathogens were human immunodeficiency virus, hepatitis C virus, *Helicobacter pylori*, *Mycobacterium tuberculosis* and hepatitis B virus. Only 5% of studies incorporated pathogen characteristics into the analysis. **Conclusion:** Research into the contribution of human genomics in the study of host-pathogen interactions is becoming increasingly common, but much work remains to be done.

Genomic deletions/duplications in patients with esophageal atresia/tracheoesophageal fistula and VACTERL association. *B. J. Kim[1], H. Zaveri[1], E. M. de Jong[6], J. F. Felix[6], C. J. Fernandes[2], A. Johnson[3], K. P. Lally[4], D. Tibboel[6], A. de Klein[5], B. Lee[1,7], D. A. Scott[1]* 1) Mol & Hum Gen; 2) Pediatrics; 3) OB & Gyn, Baylor College of Medicine, Houston, TX; 4) Ped Surg, U of Texas Med School, Houston Texas; 5) Clin Genet; 6) Paed Surg Erasmus M.C. Retterdam, Netherlands; 7) Howard Hughes Med Ins.

Esophageal atresia/tracheoesophageal fistula (EA/TEF) is a life-thretening birth defect that affects 1:3,500 live births. Although EA/TEF can occur in isolation, approximately 50% of cases occur with additional anomalies. VACTERL (Vertebral, Anal, Cardiac, Tracheo-Esophageal Fistula, Renal, Limb) association is found in approximately 10% cases and is defined by the presence of at least three anomalies. The sporadic nature of EA/TEF makes a linkage-based approach to gene identification impractical. In an alternative approach, we are using a positional candidate approach based on chromosomal data to localize and identify the genes that cause or predispose to the development of EA/TEF. A review of published cases revealed 10 chromosomal regions that are recurrently deleted/duplicated in EA/TEF. We hypothesize that each of these regions harbors one or more EA/TEF-related genes. To identify new chromosomal regionsand refine those previously reportedwe screened a cohort of 75 patients with EA/TEF for cryptic deletions/duplication in affected individuals using high density genome-wide array comparative genome hybridization. Although the majority of deletions/duplication had been previously identified in normal controls, over 100 rare genomic variants were identified. These rare variants affect a variety of genes that play important roles in cell migration, adhesion, differentiation, proliferation, and signaling. We are presently using quantitative PCR to determine the inheritance pattern of these deletions/duplication within families. Although de novo changes are considered more likely to be causative, the 2% recurrence risk seen in EA/TEF and VACTERL suggests that the majority of cases may result from a combination of inherited changes affecting important developmental pathways combined with environmental stressors such as maternal diabetes.

Pharmacogenetics of low dose naltrexone treatment in primary progressive multiple sclerosis. *F. Martinelli Boneschi[1], M. Gironi[1,2], P. Sacerdote[3], F. Esposito[1], S. Lupoli[1], C. Solaro[4], M. Zaffaroni[5], R. Cavarretta[2], L. Moiola[1], S. Bucello[1], M. Radaelli[1], S. Franchi[3], V. Martinelli[1], R. Nemni[2], G. Martino[1], G. Comi[1]* 1) Institute of Experimental Neurology (INSPE), and Department of Neurology, San Raffaele Scientific Institute, Via Olgettina 58, 20132, Milan; 2) Fondazione Don Carlo Gnocchi, Milan; 3) Department of Pharmacology, University of Milan, Milan, Italy; 4) Department of Neurology, ASL 3 genovese, Genoa, Italy; 5) Multiple Sclerosis Study Center, Hospital of Gallarate, Gallarate (VA), Italy.

Primary progressive multiple sclerosis (PPMS) represents a rare variant of disease, characterized by a progression of neurological symptoms from the beginning, for which no treatment is available. We performed a sixth-month phase-II multicentre pilot trial with low dose Naltrexone (LDN) in 40 patients with PPMS. The primary end points of the study were safety and tolerability, while secondary outcomes were its efficacy on spasticity, pain, fatigue, depression, and quality of life. Since the rationale of the treatment is related to an increase in beta-endorphins, intracellular protein levels of beta-endorphins (BE) in PBMC using a radioimmunoassay procedure and mRNA levels and allelic variants of the Mu-opiod-receptor gene (OPRM1) were analysed in all patients at differen follow-up. At the end of the trial, we measured a significant reduction of spasticity which was paralleled by a significant increase in beta-endorphin levels. However, no association was found between *OPRM1* variant (Asn40Asp SNP) and mRNA levels of beta-endorphins and response to treatment, defined as an amelioration in spasticity. Thirty-one patients (79.5%) were homozygous, while 8 (20.5%) heterozygous for the more common A variant of *OPRM1* gene, and no association was found between allelic variants and symptomatic responsiveness (p:ns; OR and 95% C.I. of G carriers and efficacy on spasticity: 3.11; 0.6-16.8). A larger study including more patients is ongoing.

DNA Methylation Profiles in Monozygotic and Dizygotic Twins. *Z. Kaminsky[1,6], T. Tang[1,6], S.-C. Wang[1,8], C. Ptak[1,6], G. Oh[1,6], S. Ziegler[1,6], A. Wong[1,6], L. A. Feldcamp[1,6], C. Virtanen[2], J. Halfvarson[3,7], C. Tysk[3,7], A. F. McRae[4], P. M. Visscher[4], G. W. Montgomery[4], I. I. Gottesman[5], N. G. Martin[4], A. Petronis[1,6]* 1) Ctr Addiction & Mental Health, Toronto, ON, Canada; 2) University Health Network Microarray Centre, Toronto, Ontario, Canada 4. 5; 3) Division of Gastroenterology, Department of Medicine, Örebro University Hospital, Örebro, Sweden; 4) Queensland Institute of Medical Research, Brisbane, Australia; 5) University of Minnesota, Minneapolis, Minnesota, USA; 6) University of Toronto, Toronto, Ontario, Canada; 7) School of Health and Medical Sciences, Örebro University, Örebro, Sweden; 8) Institute of Systems Biology and Bioinformatics, National Central University, Chungli, Taiwan.

Comparison of phenotypic similarities and differences in monozygotic (MZ) and dizygotic (DZ) twins has provided the basis for molecular genetic and epidemiological studies in human diseases and normal traits. In the wake of increasing evidence that epigenetic factors can contribute to phenotypic outcomes, we performed a DNA methylome analysis of MZ twins in white blood cells (WBC), buccal epithelial cells, and gut (rectum) biopsies (N=57 pairs in total) using 12K CpG island microarrays. The detected DNA methylation differences provided the basis for the first annotation of epigenetic metastability of ~6,000 unique genomic regions in MZ twins. We also compared the degree of DNA methylation difference in WBC and buccal epithelial cells from 39 pairs of MZ twins to 40 pairs of DZ twins. DZ co-twins exhibited significantly higher epigenetic difference compared to the MZ co-twins in buccal cells ($p=1.2x10^{-294}$). While such higher epigenetic discordance in DZ twins can result from DNA sequence differences, our in silico SNP analyses and comparison of methylomes in inbred vs. outbred mice favour the hypothesis that this is due to epigenomic differences in the zygotes. This study suggests that molecular mechanisms of heritability may not be limited to DNA sequence differences.

Natural Selection Targets Innate Immunity Genes: the Paradigm of the Human Toll-Like Receptor Family. *L. B. Barreiro[1,2], H. Quach[1], E. Patin[1], G. Laval[1], C. Bouchier[3], M. Tichit[3], O. Neyrolles[4], B. Gicquel[4], J. R. Kidd[5], K. K. Kidd[5], A. Alcais[6,7], L. Abel[6,7], J. L. Casanova[6,7], L. Quintana-Murci[1]* 1) Institut Pasteur, Human Evolutionary Genetics, CNRS, URA3012, Paris, France; 2) University of Chicago, Department of Human Genetics, Chicago, USA; 3) Plate-forme Génomique, Pasteur Genopole, Institut Pasteur, Paris, France; 4) Unité de Génétique Mycobactérienne, Institut Pasteur, Paris, France; 5) Department of Genetics, Yale University School of Medicine, New Haven, USA; 6) Laboratory of Human Genetics of Infectious Diseases, Necker Medical School, Paris, France; 7) University Paris René Descartes, Necker Medical School, Paris, France.

Toll-like receptors (TLRs) are thought to be essential for host defense by sensing and initiating innate and adaptive immune responses against microbes. Here, we characterized the levels of genetic variation in the ten human TLRs in a natural ecosystem governed by natural selection, namely in a panel of healthy individuals representative of the general population worldwide. We found that the nucleic acid sensors TLR3, TLR7, TLR8 and TLR9, which are principally involved in viral recognition, have evolved under strong purifying selection, with mutations altering the encoded proteins proscribed. Conversely, selective constraints on the remaining six TLRs, which detect non nucleic acid microbial products on the cell surface, have been much more relaxed, with higher rates of missense and nonsense mutations tolerated. However, although amino acid-altering variants of these genes may be tolerated, weak negative selection precludes increases in the frequency of these variants in the general population. Finally, we identified two haplotypic backgrounds in the region encompassing TLR10-TLR1-TLR6 showing clear signs of positive selection in Europeans and East-Asians, indicating the presence of variants conferring a selective advantage to host survival. Our evolutionary data indicate that the different members of TLR family differ in their ecological relevance and increase our understanding of how variation in these genes results in different contributions to the outcome of infectious diseases.

A new wide-genome and high resolution approach for detecting methylation profiles through simulations and modeling. *L. Pantano[1,2,3], R. Rabionet[2], X. Estivill[2,3], C. Notredame[1]* 1) Comparative bioinformatics, CRG, Barcelona, Spain; 2) Genes and Diseases, CRG, Barcelona, Spain; 3) Universidad Pompeu Fabra, UPF, Barcelona, Spain.

Epigenetics refers to heritable phenotypic alterations in the absence of DNA sequence changes, and DNA methylation is one of the extensively studied epigenetic alterations. Genomic DNA methylation profiles exhibit substantial variation within the human population, with important functional implications for gene regulation through its ability to induce locally condensed chromatin structure. Promoter hypermethylation is known to cause stable silencing of associated genes and plays an important role for both normal and disease development. We model and simulate in order to benchmark a novel wide-genome and high-resolution approach for detecting the genome methylation profile assuming an open/close model for CpG Island. Based on our finding, we propose a cost-optimized strategy for mammalian methylome projects.

Inferring human admixture history using a copying model. *G. Hellenthal[1], D. Falush[2], S. Myers[1]* 1) Dept Statistics, Univ Oxford, Oxford, United Kingdom; 2) Microbiology, University College Cork, Cork, Ireland.

We have developed a novel statistical method to characterize the admixture events by which individual populations were formed. The method is applied to recently published genome-wide SNP data for the Human Genome Diversity Panel (Science 319, 1100-1104). We show that it is possible to date admixture events that took place between 5 and 500 generations ago. We are able to reconstruct a number of events supported by strong historical evidence, including the wave of Bantu admixture, ancient African admixture into middle eastern populations, and ancient secondary East Asian migrations into Melanesia. We also analyze signals relating to more ancient and historically less well understood events, several of which are relevant to major anthropological controversies.

Genome-Wide Linkage Analysis of Platelet Phenotypes in White and African American Families with Coronary Artery Disease. *R. A. Mathias[1], Y. Kim[1], L. Yanek[2], J. E. Herrera-Galeano[2], L. C. Becker[2], D. M. Becker[2], A. F. Wilson[1]* 1) IDRB/NHGRI/NIH, Genometrics Section, Baltimore, MD; 2) Johns Hopkins Medical Institutions, Baltimore, MD.

Background: The inability of aspirin (ASA) to adequately suppress platelet aggregation is associated with future risk of myocardial infarction, stroke, and cardiovascular death; and genetic variation may be responsible for ASA responsiveness. In this study, we performed a genome-wide linkage scan for platelet phenotypes before and after ASA treatment (i.e. pre-ASA, post-ASA or change-after-ASA). Methods: Clinical data on 37 agonist-induced platelet function phenotypes were evaluated in 1231 white and 846 black healthy subjects with a family history of premature CAD before and after a 2-week trial of ASA (81 mg/day). There were 243 black and 398 white pedigrees, respectively. Principal components analyses were run separately for whites and blacks on the phenotypes adjusted for age, sex, diabetes, hypertension, smoking, LDL cholesterol, fibrinogen, and body mass index. Nine factors were identified for the pre-ASA variables, and 8 factors each were identified for the post-ASA and change-after-ASA variables. Genotyping was performed at deCODE Genetics with the standard deCODE 550 STR marker set (average spacing= 8cM). Linkage analysis was performed with the Hasemen-Elston regression approach in SAGE (v 5.1.0) for each factor and each STR within race. Results: Three loci in blacks and one in whites were significant at the 0.0001 level. A 5cM region in blacks on 1q41-42 had a pleiotropic effect (i.e. linkage to 5 platelet-rich plasma [PRP] or whole blood aggregation factors to different doses of collagen, all either post-ASA or change-after-ASA); and a 5cM region in whites on 4p12 had significant linkage to PRP aggregation to high doses of collagen post-ASA. Conclusion: Several genomic regions show significant evidence for linkage to agonist-induced platelet function phenotypes in the context of aspirin response. The strongest evidence appears to be for post-ASA or change-after-ASA aggregation to collagen as an agonist in both blacks and whites, although in different regions for the two races.

Transglutaminase-1 mutations and genotype-phenotype investigations of 104 patients with ARCI in the USA. *S. Farasat[1], M. H. Wei[1, 2], O. Toure[1], M. L. Herman[1], D. J. Liewehr[3], S. M. Steinberg[3], S. J. Bale[4], P. Fleckman[5], J. R. Toro[1]* 1) Genetic Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Rockville, MD 20892, USA; 2) Basic Research Program, SAIC-Frederick Inc., Frederick, MD 21702, USA; 3) Biostatistics and Data Management Section, Center for Cancer Research, National Cancer Institute, NIH, Bethesda, MD 20852, USA; 4) GeneDx, Inc, Gaithersburg, MD 20877, USA; 5) Division of Dermatology, University of Washington, Seattle, WA 98195, USA.

Autosomal recessive congenital ichthyosis (ARCI) is a rare hereditary disorder of keratinization. Mutations in the transglutaminase-1 (TGM1) gene, which encodes for the transglutaminase-1 (TGase-1) enzyme, are one of the causes of ARCI. We characterized the TGM1 mutation spectrum, and investigated genotype-phenotype correlations in 104 patients with ARCI ascertained through the USA National Registry for Ichthyosis. Germline mutations in TGM1 were identified in 55% (57/104) of ARCI patients. Arginine residues were mutated in 39% (22/57) of all patients and 54% (20/37) of patients with missense mutations. Fifty-five percent (12/22) of missense mutations were within CpG dinucleotides. Our genotype-phenotype investigation found that ARCI patients with TGM1 mutations were significantly associated with presence of collodion membrane at birth (p=0.006), ectropion (p=0.001), plate-like scales (p=0.005), and alopecia (p=0.001). Patients with at least one mutation predicted to truncate TGase-1 were associated with severity of hypohidrosis (p=0.001) and overheating (p=0.0007) at onset of symptoms compared with patients with only TGM1 missense mutations. Patients with missense mutations in the catalytic core were associated with eclabium compared with patients with mutations predicting to truncate TGase-1 (p=0.003). We developed a model predicting that patients with collodion membrane, alopecia, and/or eye problems were about four times more likely to have TGM1 mutations than patients without these findings. This study expands the TGM1 mutation spectrum and shows that TGM1 is the main causative gene for ARCI. There is a high frequency of mutated arginines in TGase-1 associated with ARCI.

Associations and interactions between a network of dopaminergic gene polymorphisms in schizophrenia: a follow-up in an Indian sample. *V. Kodavali[1], P. Semwal[4], M. E. Talkowski[1], J. Wood[1], S. Deshpande[3], B. K. Thelma[4], V. L. Nimgaonkar[1,2]* 1) Dept Psychiatry, Univ Pittsburgh, Pittsburgh, PA; 2) Dept of Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 3) Dept of Psychiatry, Dr. RML Hospital, New Delhi, India; 4) Dept of Genetics, Univ of Delhi, South Campus, New Delhi, India.

We have earlier evaluated the hypothesis that dopaminergic polymorphisms are risk factors for schizophrenia (SZ) in Caucasian samples from the USA and Bulgaria (Talkowski, et al, Hum. Mol. Genet. 2008). The most promising associations are detected with SLC6A3 (alias DAT), DRD3, COMT and SLC18A2 (alias VMAT2). Here we present the follow-up analyses in the collaborative Indian trio sample (n=601 families). Unscreened cord blood samples (n= 520) were collected from live birth at Lok Nayak Hospital, New Delhi. The SZ diagnoses were based on DSM IV criteria, similar to the US sample. Informed consent was obtained from the probands and family members at Ram Manohar Lohia Hospital, New Delhi. Snplex and SnapSHOT assay methods were employed for SNP genotyping. Our goals were, a) to seek replication at SNP level based on our earlier work in the US and Bulgarian sample, b) to understand the linkage disequilibrium (LD) patterns in the Indian sub-population and c) to test the epistatic interactions reported. We have evaluated a total of 41 SNPs. Suggestive associations were detected in the same direction reported earlier at SLC18A2 (rs363338, trends test p = 0.075). At DRD3 and SLC6A3, trends were noted with the opposite alleles (respectively, rs324030, p = 0.084; rs403636, p = 0.058).We also observed additional SNPs with suggestive associations at SLC18A2 (rs363399, rs10082463 and rs363285, p 0.1). The LD patterns were similar to the US and Bulgarian samples. Earlier reported epistatic SNP interactions at all four genes between seven locus pairs (p0.05), were not noted. However, we observed other epistatic interactions, the majority being between SNPs at SLC6A3 and COMT. They need to be explored further at a functional level. Overall, we suggest the importance of DA genes and their interaction, as risk factors for SZ in the Indian sample.

Co-regulation of ancestral pseudoautosomal genes in the mouse. *M. A. Levy[1,4], A. D. Fernandes[1,2], D. C. Tremblay[1,4], C. Seah[3,4], N. G. Bérubé[1,3,4]* 1) Department of Biochemistry, University of Western Ontario, London, Canada; 2) Department of Applied Mathematics, University of Western Ontario, London, Canada; 3) Department of Paediatrics, University of Western Ontario, London, Canada; 4) Children's Health Research Institute, Lawson Health Research Institute, London, Canada.

The X and Y chromosomes in mammals are morphologically distinct. However, eutherians retain homologous regions at the tips of the X and Y referred to as pseudoautosomal regions (PARs). The PARs play a critical role in the obligatory X-Y crossover during male meiosis. Genes that reside in the PAR are exceptional in that they are rich in repetitive sequences and undergo a very high rate of recombination. Murines lack the large PAR regions seen in other eutherians. Remarkably, murine PAR1 homologs have translocated to various autosomes, reflecting the complex recombination history during the evolution of the mammalian X chromosome. Here we show that the SWI/SNF chromatin remodeling protein ATRX controls the expression pattern of ancestral PAR genes that have translocated to autosomes in the mouse. We propose that the ancestral PAR genes share a common epigenetic environment, originating from their ancestral location in the PAR, which allows ATRX to control their expression.

Genome wide association study for Fibromuscular Dysplasia(FMD). *J. Yang[1], M. Nalls[2], B. Traynor[2], D. Hernandez[2], N. Washecka[2], B. Griswold[1], L. Sloper[1], A. Singleton[2], N. B. McDonnell[1]* 1) LCI, NIA/NIH, Baltimore, MD; 2) LNG,NIA/NIH,Bethesda,MD.

Fibromuscular dysplasia is a heterogeneous disorder characterized by angiopathy of the arteries, which predominantly affects women in mid-life, resulting in stenosis, dissection or aneurysm. It may involve renal arteries, carotid, vertebral, coronary and abdominal vessels. Autosomal dominant inheritance has been suggested, however no genes have been identified to date. On detailed clinical examination of a cohort of 69 patients seen at the National Institute on Aging, features of connective tissue dysplasia as exemplified by joint hypermobility, scoliosis, pectus deformity, pes planus and high myopia were frequently noted, suggesting a defect in the extracellular matrix pathways. In order to elucidate the genetic factors underlying this disorder, we performed genome wide association study in 46 sporadic cases and 540 controls utilizing the Illumina HumanCNV370-Duo BeadChip and HumanHap550 Beadchip. By permutation analysis, we have identified a number of marker SNPs with significant differences between cases and controls. The candidate genes include CDH12, EXOC2, PACRG, HECW1, ZAN, CSMD1, SRA and DIP2B with p scores <10-6. Although the disorders has been suggested to be dominant, we did homozygosity analyses for our samples, our results show chromosome 4, 5, 12 could include some specific overlapping homozygous runs in FMD patients.

Delineating Williams-Beuren Syndrome Chromosomal Region Using High-density Targeted Array CGH. *X. Hu[1,2], D. Mercer[2], T. Narumanchi[2,3], H. Andersson[2,3], M. Li[1,2,3]* 1) Louisiana Cancer Research Cons, Tulane Univ Sch Medicine, New Orleans, LA; 2) Hayward Genetics Center,Tulane Univ Sch Medicine, New Orleans, LA; 3) Dept. of Pediatrics; Tulane Univ. Sch. Med, New Orleans, LA.

Williams-Beuren syndrome (WBS) is caused by a heterozygous deletion of contiguous genes at 7q11.2. Three large region-specific low copy repeat elements (LCRs A, B, and C) located in the proximal region of chromosome 7q are thought to be responsible for the high frequency of deletions in this region. These LCRs also hinder the molecular characterization of deletions in different WBS patients and the phenotype/genotype correlation of the syndrome. We attempt to use a novel technology, high density targeted array CGH, to delineate the deletions in 6 patients with WBS. In this study, we constructed a custom designed targeted array that covers the commonly deleted chromosomal region and flanking regions of WBS. A total of 36,400 genomic probes spanning a 10 Mb region with 200 bp - 500 bp intervals were selected for the Agilent 4x44K array format. Patients were initially diagnosed with standard Agilent 4x44K arrays and confirmed by FISH. The detailed deletion breakpoint junctions were determined by the high density targeted array CGH study. Five out of six patients showed a deletion of approximately 1,398 Kb with only 100 bp differences at distal and/or proximal breakpoints, indicating non-random recombination between LCRs. One case that showed a ~4,000 Kb deletion from 7q11.22 to 7q11.23 with the standard array displayed two adjacent deletions of 1,693 Kb and 1,390 Kb separated by an 897 Kb undeleted region. The 1,390 Kb deletion corresponds well with the WBS commonly deleted region and shares the same distal breakpoint as in the deletions of the other 5 cases. The 1,696 Kb deletion is centromeric to the common WBS deletion. The deletions in most of our cases occurred between centromeric and medial B block LCRs (Bc and Bm).The detailed mapping of WBS deletion breakpoints has not been possible before the use of the high density targeted arrays and the mapping data is of great significance in exploring the pathogenesis and phenotype/genotype correlations of the disease.

Chondrodysplasia: An example of fixed trait mapping in the domestic dog. *H. G. Parker[1], P. Quignon[1], B. VonHoldt[2], T. Spady[1], D. S. Mosher[1], E. Margulies[3], C. D. Bustamante[4], R. K. Wayne[2], E. A. Ostrander[1]* 1) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Dept of Ecology and Environmental Biology, UCLA, Los Angeles, CA; 3) Genome Technology Branch, NHGRI, NIH, Rockville, MD; 4) Dept of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Dog breeds are isolated populations created through application of strict breeding practices aimed at maintaining a set of characteristics deemed ideal for the breed. While the combination of traits is unique in each breed, the individual traits are not. This population architecture can be used to find the genes responsible for traits that have been bred to fixation in multiple breeds. As a first example of fixed-trait mapping we examined the phenotype of asymmetrical dwarfism or chondrodysplasia. Archetypal chondrodyplastic breeds such as Basset hounds and Dachshunds are characterized by very short legs with normal sized heads and bodies. Many of these breeds share little in common outside of the short-legged phenotype: they fall into different breed clusters in phylogenetic studies, display a variety of coat types, cranial morphologies, and behaviors, and originate from different geographic regions. A search for selected regions in all of these breeds that are not found in proportionate breeds should produce a genetic mutation responsible for chondrodysplasia. To investigate this hypothesis we have run 835 dogs from 75 different breeds including seven chondrodysplastic breeds on the Affymetrix 127K canine SNP chip. After removing SNPs with greater than 10% missing data, 60% heterozygous calls and minor allele frequency of less than 1%, a set of 41635 informative SNPs remained. Analyses from these data identified a single locus spanning 500 Kb associated with chondrodysplasia (p=10-104). Fine mapping using 70 documented SNPs, 170 newly discovered SNPs and indels, and genotypes from additional chondrodysplastic breeds revealed a region of 35 Kb that is homozygous in all chondrodysplastic breeds. Here we discuss the results from this study including the content and significance of a 10 Kb insert in a highly conserved regulatory region.

CAPL: An association test combining nuclear family and case-control data. *R.-H. Chung, R. W. Morris, M. A. Schmidt, E. R. Martin* Miami Inst Human Genomics, Miami, FL.

Family-based and case-control are commonly used designs for complex disease-gene mapping. It has become increasingly important that statistical tests for association be able to accommodate both types of data in a single analysis. We have developed a method, CAPL, for combining family and case-control data based on the Association in the Presence of Linkage (APL) procedure (Martin et al. 2003). Case-control data are integrated into a family-based framework by treating cases and controls as triad families with missing parents. CAPL infers missing parental genotypes based on offspring genotypes, thereby estimating parental genotypes for cases and controls jointly with family data. The APL statistic, which is based on the difference between the observed number of alleles in affected siblings and the expected number of alleles conditional on observed or inferred parental genotypes, is calculated for the combined data. A bootstrap procedure is used to estimate the variance of the APL statistic. We use simulations to demonstrate that CAPL has correct type I error rates under the null hypothesis of no linkage or no association between disease and marker loci. Other association tests that combine nuclear family and case-control data include SCOUT (Epstein et al. 2005) and UNPHASED (Dudbridge 2008). Since CAPL uses families with missing parents and multiple affected siblings, it is more flexible than SCOUT. Using simulated triad family and case-control data, we find that SCOUT can have more power than CAPL and UNPHASED. Under a recessive genetic model, we find that CAPL can have more power than UNPHASED when multiplex families with missing parents and case-control data are combined.

***PIK3CA* mutations are frequent in clinically aggressive forms of endometrial cancer.** *D. Bell[1], M. Rudd[1], S. Fogoros[1], A. Godwin[2], M. Merino[3]* 1) NHGRI/NIH, Bethesda, MD; 2) Fox Chase Cancer Center, Philadelphia, PA; 3) NCI/NIH, Bethesda, MD.

Endometrial cancer is the 8th leading cause of cancer death among women in the United States. Tumors are classified as either type I or type II based on differences in histology, epidemiological risk factors and molecular characteristics. Type I tumors have an endometrioid histology whereas type tumors consist of serous and clear cell histologies. Although type II tumors comprise only 1 in 7 cases at diagnosis they are clinically aggressive and contribute to approximately half of all endometrial cancer related deaths. Currently, the molecular alterations underlying type II tumorigenesis are poorly understood. The *PIK3CA* gene encodes a lipid kinase that activates the AKT signal transduction pathway, which controls cell proliferation and survival. Although *PIK3CA* is one of the most frequently activated oncogenes in human cancer, and represents an attractive therapeutic target, the incidence of *PIK3CA* mutations in type II endometrial tumors has not been defined. We used nucleotide sequencing to search for mutations within all coding exons of *PIK3CA*, and quantitative real-time PCR to evaluate gene copy number, among 69 primary type II endometrial tumors. We detected 27 somatic *PIK3CA* mutations among 20 of 69 (28%) tumors. Six cases had two or more mutations. Most variants (19 of 27, 70%) affected codons that undergo mutation in other tumor types suggesting they are likely to be functionally significant. Increased *PIK3CA* copy number was rare, being detected in a single tumor that had a concomitant *PIK3CA* mutation. In contrast to tumors from other tissue types, in which *PIK3CA* mutations occur predominantly within exons encoding the helical and kinase domains, mutations within our series were dispersed throughout the coding region. In conclusion, our findings indicate that *PIK3CA* is mutated at an appreciable frequency in type II endometrial cancer, and with a unique mutation spectrum. Thus, therapeutic agents that disrupt the PIK3CA-AKT signal transduction pathway may merit future consideration in the clinical management of patients with serous or clear endometrial cancer.

Mapping of Vascular Calcified Plaque Loci on Chromosome 16p in the Diabetes Heart Study. *A. B. Lehtinen[1], V. S. Voruganti[2], M. E. Rudock[1], J. T. Ziegler[1], B. I. Freedman[1], J. J. Carr[1], A. G. Comuzzie[2], C. D. Langefeld[1], D. W. Bowden[1]* 1) Wake Forest Univ Sch of Medicine, Winston-Salem, NC; 2) SW Foundation Biomedical Res, San Antonio, TX.

Cardiovascular Disease(CVD) is the leading cause of death among Americans and is the most common cause of death in type 2 diabetes(T2D).All manifestations of CVD are more common in diabetic than non-diabetic patients.Vascular calcification is a subclinical measure and independent risk factor for CVD.We have reported evidence for a carotid artery calcified plaque(CarCP) locus on chromosome 16p(LOD 4.39 @ 8.4cM) in European Americans(EA) with T2D from the Diabetes Heart Study(DHS).We performed fine-mapping of 16p and evaluated candidate genes and SNPs to ascertain their contribution to the variation in measures of subclinical CVD.69 HapMap SNPs were chosen for fine-mapping and an additional 58 SNPs were genotyped in 6 genes(CACNA1H, SEPX1, ABCA3, IL32, SOCS1, KIAA0350) in the EA DHS subjects consisting of 937 subjects from 315 pedigrees with at least two individuals with T2D.Linkage mapping data were analyzed using SOLAR adjusting for age, gender, BMI, and T2D status.SNP association analysis was also performed using SOLAR with the same covariates.Fine mapping resolved the CarCP linkage peak into 2 distinct linkage regions with maxLOD of 3.89 at 6.9cM and 4.86 at 16.0cM in EA T2D individuals.When all EA subjects were included, the maxLODs were 3.72 at 9.8cM and 2.61 at 16.0cM.Evidence of linkage for coronary calcified plaque(CCP; LOD 2.27 @ 19cM) and a vascular calcification principle component(LOD 3.71 @ 16.0cM) was also observed.The strongest evidence for association with CarCP was observed in and near A2BP1(rs4337300 p=0.005).Furthermore, there was modest evidence of association between CCP and CarCP with SNPs in CACNA1H(p=0.010-0.033) but no single locus explains the evidence for linkage.SNP data was further analyzed using Bayesian Quantitative Trait Nucleotide analysis which identified a SNP, rs1358489, which has either a functional effect on CarCP or is in LD with a functional SNP.This study has substantially refined the 16p region through complementary fine-mapping and candidate gene analysis.

Ordered Subset Analysis for Case-Control Association Mapping (OSACC). *X. Qin, E. Hauser, S. Schmidt* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Genetic heterogeneity can reduce the power for complex disease gene mapping since only a fraction of the cases in the collected dataset may carry a specific disease susceptibility allele. Ordered subset analysis (OSA) was originally designed as a linkage test that identifies a subset of families with the strongest linkage signal based on the ranking of family-specific continuous covariate values. The same strategy can be applied to association analysis to identify a subset of cases that provides the strongest association evidence. The OSACC algorithm adds one or more cases at a time on the basis of their ranked covariate values and re-calculates the contingency table chi-square statistic. The subset of cases that generates the largest chi-square statistic is identified. A permutation procedure is used to approximate the distribution of the maximized chi-square statistics under the null hypothesis that the covariate is uncorrelated with disease risk and marker genotypes; this generates an empirical p-value for evaluating whether the observed association evidence in the subset of cases is greater than expected by random case selection. We performed a comprehensive simulation study under different disease-generating models, including gene-environment interaction, genetic heterogeneity, presence of a quantitative trait locus (QTL) and population stratification. We found that the type I error rate of OSACC can be inflated in the presence of population stratification when only covariate information from cases, not controls, is used. OSACC has higher power to detect a disease susceptibility allele in the presence of extensive genetic heterogeneity, compared to standard tests that either ignore covariates (trend test) or test the relationship between covariate values and marker genotypes directly (ANOVA). We distribute novel software implementing OSACC, in which the user may choose to use covariate data from either cases only, or from cases and controls. In the former case, the software implements a method very similar to the one proposed by Macgregor et al. (2006).

Familial aggregation of common sequence variants on 15q24-25.1 in lung cancer. *P. Liu[1,2], H. Vikis[1,2], D. L. Wang[1,2], Y. Lu[1,2], Y. Wang[1,2], M. You[1,2], Genetic Epidemiology of Lung Cancer Consortium* 1) Dept of Surgery, Washington Univ, St Louis, St Louis, MO; 2) The Alvin J. Siteman Cancer Center, Washington Univ, St Louis, St Louis, MO.

Three recent genome-wide association studies identified association of markers on chromosome 15q24-25.1 with lung cancer risk (1-3). We conducted a genome-wide SNP association analysis in 194 familial lung cases and 219 cancer-free controls and identified several regions of association. Common sequence variants on 15q24-25.1, spanning LOC123688, PSMA4, CHRNA3, CHRNA5 and CHRNB4, were shown to be associated with lung cancer in the current study. The 15q24-25.1 variants appear to contribute to familial aggregation of lung cancer. Risk of lung cancer is increased over five fold among those subjects having family history of lung cancer and taking two copies of risk alleles of the 15q24-25.1 locus.

NPY and ADORA2a Genes, Incidence and Prevalence of Proliferative Diabetic Retinopathy. *B. A. Charles[1], T. J. Orchard[2], S. M. Sereika[3], M. B. Gorin[4], R. E. Ferrell[5], Y. P. Conley[1,5]* 1) University of Pittsburgh, SON, Dept. HP&D, Pittsburgh, PA. 15261; 2) University of Pittsburgh, Dept. Epidemiology GSPH, Pittsburgh, PA 15213; 3) University of Pittsburgh, SON, Dept. H & CS, Pittsburgh, PA 15261; 4) The Jules Stein Eye Institute, David Geffen School of Medicine, UCLA, CA; 5) University of Pittsburgh, Dept. Genetics, GSPH , Pittsburgh, PA 15213.

Diabetic retinopathy (DR) is a microvascular complication of diabetes marked by micro-aneurysms, retinal hemorrhages, exudates; capillary nonperfusion; retinal edema, ischemia and neovascularization. Proliferative diabetic retinopathy(PD)the most severe form of DR is the leading cause of new cases of blindness in individuals between 20 and 70 yrs old, up to 24,000 new cases annually.

Neuropeptide Y (NPY) plays a role in wound healing, diabetes severity, vasoconstriction, and angiogenesis. The Adenosine A2 receptor (ADORA2A) tissue impairment caused by, inflammation, hypoxia, and oxidative stress. Our aim was to determine if the NPY gene or the ADORA2A gene play a role in PD. Two tagging single nucleotide polymorphisms (tSNPs) of the ADORA2A (rs2236624 and rs4822489) and 2 tSNPs of the NPY genes (rs16143 and rs16145) were selected via HapMap. We genotyped (TaqMan allelic discrimination assays) participants (n=496) of the Pittsburgh Epidemiology of Diabetes Complications (EDC) prospective study of childhood onset type 1 diabetes (baseline mean age 28 yrs and mean diabetes duration 19 yrs) for whom banked DNA was available. Stereoscopic images were obtained at baseline (1986-1988) and biennially for 18 yrs. PD was defined as grade 60 in one eye or < 60 but with panretinal scars consistent with laser therapy, according to the Arlie House system.

Univariate analysis showed rs2236624 was associated with prevalence of PD (OR=1.68; 95%CI=1.11-2.54; p=0.03) at baseline and the prospective incidence of PD (HR=0.17; 95%CI=0.042-0.69; p=0.01).

No association was found between the 2 tSNPs of the NPY gene or the rs4822489 tSNP of the ADORA2 gene and prevalence of PD at baseline or prospective incidence of PD.

Fx-1006A: A Novel Small Molecule Stabilizer of Tetrameric Wild-Type and Variant Transthyretin (TTR). *J. Fleming[1], C. E. Bulawa[1], J. Packman[1], R. Labaudiniere[1], T. Coelho[2], J. Kelly[3], L. Wang[4]* 1) FoldRx Pharmaceuticals, Cambridge, MA; 2) FAP Clinical Unit and Neurophysiology Department, Hospital San Antonio, Portugal; 3) Scripps Research Institute; 4) Novartis Institutes for Biomedical Research.

Background: TTR amyloidosis (ATTR) is caused by dissociation of tetrameric TTR (due to genetic mutations or aging) and formation of amyloid deposits. The autosomal dominant disease has >80 known TTR mutations and presents primarily with neuropathy or cardiomyopathy. Fx-1006A, a novel small molecule that binds to the thyroxine binding site of tetrameric TTR, is a potent inhibitor of TTR dissociation, the critical step in TTR amyloid formation. Methods: An immunoturbidimetric assay was developed to determine Fx-1006A stabilization of tetrameric TTR in plasma. Human plasma samples are incubated under denaturing conditions for 48 hours and the fraction of remaining tetrameric TTR is determined. Data is expressed as fold stabilization compared to an untreated control plasma pool. Plasma from healthy volunteers given qd Fx-1006A 15, 30, 60 mg or placebo x 14 days in a Phase I study and V30M ATTR patients given qd Fx-1006A 20 mg or placebo x 8 weeks in a Phase II/III study were assayed. Results: In volunteers (N=24), TTR levels 24 hrs post last dose were 23-42 mg/dL, with stabilization achieved at Fx-1006A concentrations of 0.9-1.2g/mL (15mg) and 1.3-4.2g/mL (30mg), (fold stabilization vs placebo of 2.040.44 and 3.570.92, respectively; $p<0.05$). Saturation of stabilization occurred at or before 30mg, with no significant difference between 30 and 60mg ($p=0.46$). Saturation is observed when Fx-1006A:TTR stoichiometry reaches 1, achieved with Fx-1006A levels of ~1-2g/mL. TTR stabilization was also achieved in V30M ATTR patients at 8 weeks (2.660.7 fold stabilization for treated (n=6) vs placebo (n=4); $p=0.0019$); TTR levels were 20-33mg/dL, Fx-1006A concentrations were 0.7-2.8g/mL. Conclusions: Fx-1006A stabilizes both wild-type and variant TTR in vivo, and should provide disease modification and halt disease progression in ATTR. A Phase II/III study in V30M ATTR patients is ongoing, with final results expected in mid 2009.

Characterization of an ENU-induced mutant mouse uncovers a novel gene, *Thm1 (Ttc21b)*, important for Sonic hedgehog (SHH) signaling and cilial function. *P. V. Tran[1], T. Y. Besschetnova[2], J. V. Shah[2], D. R. Beier[1]* 1) Genetics Division, Brigham and Women's Hospital/Harvard Medical School, Boston, MA; 2) Renal Division, Brigham and Women's Hospital/Harvard Medical School, Boston, MA.

We have recently described the characterization of an ENU-induced mutant mouse, *alien (aln)*, which displays preaxial polydactyly, craniofacial abnormalities and neural tube defects, characteristic of inappropriate activation of SHH signaling (Tran et al., Nature Genetics, 40: 403-10, 2008). Positional cloning revealed a missense mutation in a novel gene, *Thm1* (Tetratricopeptide repeat -containing Hedgehog modulator 1, also called *Ttc21b*), an orthologue of *Flagellar Associated Protein 60/IFT139* in *Chlamydomonas*. Vertebrate cilia, synonymous to flagella of *Chlamydomonas*, are microtubule-based extensions of the plasma membrane in which proteins are transported bidirectionally in intraflagellar transport (IFT). Defects in cilial physiology underlie an increasing number of human diseases or ciliopathies. In *aln* mutants, cilia are shortened and have bulb-like structures at their tips in which IFT proteins are sequestered. RNAi knock-down of *Thm1* in mouse inner medullary collecting duct (IMCD) cells recapitulated the *aln* cilial phenotype and live imaging of IFT88-EYFP in these cells revealed a defect in trafficking proteins away from the cilial tip toward the base. We propose that this retrograde IFT defect causes sequestration of IFT proteins in *aln* cilia and leads to the hyper-activated SHH signaling phenotype. Importantly, *aln* is the first cilial mutant which separates the components of IFT and their roles in SHH signaling. To explore this in more detail, we have adapted the IMCD cells so that SHH signaling can be directly measured in this *in vitro* system. We are using live cell imaging of GFP- and RFP-tagged GLI2 to investigate the processing events that mediate the activation of this transcription factor, which are as yet unknown. Finally, since perturbations of *Wnt* signaling have been reported in cilial mutants that show defective SHH signaling, we are exploring whether the *Wnt* pathway is affected in *aln* mutant cells and mice.

Chromosome abnormalities associated with features of Pervasive Developmental Disorder. *A. D. Rasalam, J. C. Dean* University of Aberdeen, Scotland.

Autistic disorder is a neurodevelopmental disorder charcterised by three core symptom domains: impaired social communication and language, impaired social interaction and repetitive and stereotyped behaviours. Autism spectrum disorders or Pervasive Developmental Disorders have been estimated to occur at a prevalence of approximately 60 per 10,000 school age children. They are associated with speech or general developmental delay and other features such as epilepsy, facial dysmorphology and malformations in a proportion of cases. We report on the chromosome anomalies identified in six patients who also fulfilled the Diagnostic and Statistical Manual of Mental Disorders IV (DSM IV) criteria for diagnosis of Autistic Disorder. The abnormalities identified involved chromosomes 1q, 9q, 11q, 15q, 18p, 18q, 20q and Xp. Three of the anomalies were identified using MLPA analysis and are in subtelomeric regions, two were identified by FISH and one was identified by karyotyping. In five cases, the abnormalities were de novo while in one case it was maternal in origin. All these patients had a degree of developmental delay. Only 2 patients had major malformations. One patient who did not have malformations had poor growth (2nd centile), one was obese and another had growth parameters above the 97th centile. One patient also has epilepsy. These six cases are selected from a larger group of patients with chromosome abnormalities who also have developmental delay and one or more of the features of a pervasive developmental disorder, but who did not fulfil the DSM IV criteria for diagnosis of Autistic Disorder. The features present in this larger group of cases and the chromosome anomalies that were identified in them are also described.

Procedure for detecting genes and environmental factors for common diseases dealing with competing risks and comorbidity. *N. Tanaka[1], M. Muramatsu[2], T. Yamaguchi[3], M. Sawabe[4]* 1) Dept Biostatistics, Harvard Sch of Public Health, Boston, MA; 2) Dept Molecular Epidemiology, Medical Research Institute, Tokyo Medical and Dental Univ, Tokyo, Japan; 3) Dept Clinical Trial Data Management, Grad Sch of Medicine, Univ Tokyo, Tokyo, Japan; 4) Dept Pathology, Tokyo Metropolitan Geriatric Hospital, Tokyo, Japan.

In the previous decade, genetic association studies have generated many data concerning the genetic basis of common multifactorial diseases. Several genetic polymorphisms have been linked to more than one disease, for example, polymorphisms in the ACE, APOE, and TGF- gene, which suggest that there should be competing risk factors for a multifactorial disease. However, we would or could not collect the data on other diseases that could be competing risks when we conduct a case-control study. It has been well established that the proportion of people with multiple diseases may vary from 30% in the general population to over 50% in people aged 60 years and older. If people die with other than a primary disease of interest, the other diseases is defined as competing risks and it is difficult to evaluate true effect of genes on development of the diseases. Co-morbid status would extract useful information about competing risks and genetic risk factors which are shared with some diseases. We present a procedure to investigate whether a specific combination of genes and environmental risk factors results in a specific combination disorders using a consecutive autopsy study data. Considering combination-combination association, we found APOE had no marginal effect on Ischemic Heart Disease (IHD) but was associated with higher risk of co-occurring IHD and Alzheimer's disease (AD) than of developing only AD. Some other potential interaction effects on a specific disease and combination of diseases are presented. Furthermore, we can infer whether the marginal effect from the standard multiple regression models might be biased due to potential competing risks. The results from this study will be useful for designing of whole genome studies for discovering novel susceptible genes as well as of candidate gene studies.

Hypo-functional *SLC26A4* variants associated with nonsyndromic hearing loss and enlargement of the vestibular aqueduct: genotype-phenotype correlation or coincidental polymorphisms? *B. Y. Choi[1], A. Stewart[2], A. Madeo[1], S. Pryor[1], S. Lenhard[1], R. Kittles[3], K. Arnos[4], W. Nance[5], K. King[1], C. Zalewski[1], C. Brewer[1], L. Karniski[6], S. Alper[2], A. Griffith[1]* 1) NIDCD/NIH, Rockville, MD; 2) Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA; 3) University of Chicago, Chicago, IL; 4) Gallaudet University, Washington, DC; 5) Medical College of Virginia, Richmond, VA; 6) Veterans Affairs Medical Center and University of Iowa College of Medicine, Iowa City, IA.

Hearing loss with enlargement of the vestibular aqueduct (EVA) can be associated with mutations of the *SLC26A4* gene encoding pendrin, a transmembrane $Cl^-/I^-/HCO_3^-$ exchanger. Pendrins critical transport substrates are thought to be I^- in the thyroid gland and HCO_3^- in the inner ear. We previously reported that bi-allelic *SLC26A4* mutations are associated with Pendred syndromic EVA whereas one or zero mutant alleles are associated with nonsyndromic EVA. Scott et al. (HMG, 2000) proposed a correlation of nonsyndromic EVA with *SLC26A4* alleles encoding pendrin with residual transport activity. Here we describe the phenotypes and *SLC26A4* genotypes of 47 EVA patients ascertained since our first report of 39 patients. We sought to determine the pathogenic potential of each variant in our full cohort of 86 patients. We evaluated the trafficking of 11 missense pendrin products expressed in COS-7 cells. Products that targeted to the plasma membrane were expressed in Xenopus oocytes for measurement of anion exchange activity. p.F335L, p.C565Y, p.L597S, p.M775T, and p.R776C had Cl^-/I^- and Cl^-/HCO_3^- exchange rate constants that ranged from 13 to 93% of wild type values. p.F335L, p.L597S, p.M775T and p.R776C are typically found as mono-allelic variants in nonsyndromic EVA. The high normal control carrier rate for p.L597S indicates it is a coincidentally detected nonpathogenic variant in this context. We observed moderate differential effects of hypo-functional variants upon exchange of HCO_3^- versus I^- but their magnitude does not support a causal association with nonsyndromic EVA. However, these alleles could be pathogenic in trans configuration with a mutant allele in Pendred syndrome.

Sample Size Calculations in Multiple Matched Case-Control Studies with Binary Exposure Levels. *M. Rao, R. Chakraborty, X. Liu* Ctr Genome Information, Univ Cincinnati, Cincinnati, OH.

The focus of this research is on 1:M matched case-control studies. For each case (the one with the disease under scrutiny), M (1) controls (those who do not have the disease) are chosen from the same population matched on a number of variables such as age, gender, race, etc. A matched set will thus have (M+1) subjects. Each subject is either exposed or not. The goal is to examine association between the disease and exposure. The null hypothesis of interest is that the population odds ratio ; is unity. We propose Raos score statistic for this problem. We work out a sample size formula for a given level, size, and alternative value of ;. The formula involves a nuisance parameter. We compare the performance of out test with the one proposed by Ejigou (Biometrics, 52, 1996). We show that our method is more cost-effective. For example, when M = 2, =1.5, level = 0.05, power = 0.80, nuisance parameter = 0.45, our sample size is 165 and Ejigou's sample size is 174. Simulations with our sample size yields observed power 0.7924 and with Ejigou's sample size 0.8195. The difference between the sample sizes is much more pronounced with other choices of the inputs with our sample size being lower.

A novel genomic (CGH) microarray abnormality in a patient with clinical features of KBG syndrome - a case report. *S. Ahmed, K. Wendt, C. Spring, M. Jamehdor* Regional Genetic Service, SCPMG, Kaiser Permanente.

INTRODUCTION: Comparative genomic hybridization (CGH) has become a commonly ordered test in Medical Genetics practice. However, the interpretation of abnormal CGH results is complicated by the limited number of mutation databases providing genotype phenotype correlation. We report a case of an 11 yr old girl with an abnormal CGH microarray result and clinical features of KBG syndrome, a clinical syndrome characterized by macrodontia, costovertebral anomalies and mental retardation. The genetic basis of KBG syndrome is currently unknown. CASE REPORT: Our patient is an 11 yr old girl referred to genetics clinic for evaluation of her dysmorphic facial features, behavioral problems and severe delays. Pregnancy history was essentially unremarkable. Dysmorphic facial features and hypotonia were noted at birth. During childhood, short stature, severe developmental delay and self-mutilating behavioral abnormalities including hand-biting and head-banging were noted.Dysmorphic features include mild hypertelorism, a large mouth with large prominent incisors and short stubby hands. Family history was unremarkable. Brain MRI, chromosome analysis and FISH for Smith Magenis were negative. Imaging showed delayed bone age.A clinical diagnosis of probable KBG syndrome was made. CGH microarray demonstrated a deletion on chromosome 4 involving 2 BAC clones within the 4q21.21 region, suggesting partial monosomy for this region of chromosome 4. FISH using a BAC within the abnormal region confirmed the microarray findings. Mother tested negative for the deletion. The patients father is deceased. Close paternal relatives could not be tested. DISCUSSION: With the increasing use of CGH, the novel genetic changes that are being reported may elucidate the molecular etiology of various clinical dysmorphology syndromes. Our patient has some features of KBG syndrome. Self-mutilation has not been described with this syndrome. Whether or not our patient has a variation of KBG syndrome, or another distinct clinical syndrome, remains unclear. Individual case reports may help define these CGH abnormalities and aid in clinical correlation.

E297K Mutation of Calcium-sensing Receptor (CASR) Gene is Associated with Short Stature and Impaired Growth Hormone Response. *W. Chen[1], A. Bos[2], L. Sloper[2], E. R. Miller[2], S. Basaria[2], N. B. McDonnell[1,2]* 1) Lab Clinical Investigation, NIA/NIH, Baltimore, MD; 2) Clinical Research Branch, NIA/NIH, Baltimore, MD.

The calcium-sensing receptor (CASR) is a plasma membrane G protein-coupled receptor that is expressed in the parathyroid hormone (PTH)-producing chief cells of the parathyroid gland and the cells lining the kidney tubule. By virtue of its ability to sense small changes in circulating calcium concentration and to couple this information to intracellular signaling pathways that modify PTH secretion or renal cation handling, CASR plays an essential role in maintaining mineral ion homeostasis. Mutations in the CASR gene have resulted in different human diseases. E297K, a loss of function mutation in the CASR, is associated with familial hypocalciuric hypercalcemia (FHH) and neonatal severe hyperparathyroidism (NSHPT). Here we report a dominant E297K mutation that is transmitted in a three-generation Brasilian family with short stature and variable hypercalcemia. The arginine/growth hormone challenge test in the proband, an adult male with short stature, showed an impaired growth hormone response, despite normal serum IGF-1 level. Prior studies have shown that in patients with primary hyperparathyroidism, growth hormone response can be blunted similar to our patients. Correction of serum calcium in these patients resulted in normalization of growth hormone secretion. We propose that elevated serum calcium is responsible for the short stature and blunted growth hormone secretion in our patients. FHH may not be as benign as previously thought and should be considered in the differential diagnosis of short stature. Familial short stature may in fact be familial hypocalciuric hypercalcemia in some cases.

High-resolution analysis of subtelomeric breakpoints. *J. Jackson, K. Rudd* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Between 3-6% of patients with idiopathic mental retardation have a detectable subtelomeric rearrangement, a genomic change in the end of the chromosome. Subtelomeric rearrangements occur on all chromosome ends, and are a major cause of birth defects, mental retardation, and developmental delay. Despite the frequency of double-strand breaks at chromosome ends, the mechanisms of subtelomeric breakage and repair remain unknown. To elucidate this process, we have performed the first high-resolution analysis of subtelomeric breaks via a combination of high-density array CGH, breakpoint cloning, and comprehensive sequence analysis. Using a custom oligonucleotide array, we have mapped 18 subtelomeric rearrangements at a resolution previously unattainable. We have analyzed 12 terminal deletions, 2 terminal duplications, and 4 unbalanced translocations, resolving breakpoints to a few hundred basepairs at each site. To isolate the repaired genomic structure and identify sites of double-strand breaks we are cloning breakpoint junctions. We have cloned one junction created by an unbalanced translocation between the X chromosome and chromosome 16. Breakpoint cloning and sequence analysis of breakpoint regions at other sites is ongoing. We postulate that subtelomeric sequences are predisposed to breakage, as subtelomeres are enriched in certain types of repeats known to cause genomic instability at other loci. Subtelomeres are incredibly variable and a major source of polymorphism in the human genome. We predict that particular subtelomeric sequence variants are more likely to rearrange in meiosis, thereby affecting the risk of having a child with a subtelomeric rearrangement. Based on the prevalence of subtelomeric rearrangements, the enrichment of subtelomeric breaks in mitosis and meiosis, and the repetitive sequences at subtelomeres, we hypothesize that subtelomeres are particularly susceptible to breakage. We present our initial results detailing the mechanisms of human subtelomeric breaks, with broader implications for the factors mediating other chromosome rearrangements.

Identification of a Novel Chromosome 11 Locus from Murine Strain 129 that Protects from Sex Reversal in the B6 XYPOS Mice. *V. Arboleda, E. Vilain* UCLA Department of Human Genetics.

Disorders of sexual development (DSD) encompass a vast spectrum of phenotypes ranging from minor malformations of genitalia (hypospadias cryporchidism, clitoral hypertrophy) to sexual ambiguity. Together, these anomalies have a frequency estimated at 0.5 % to 1% of live births. Despite the prevalence of these malformations, the genetic etiology a majority of DSDs remain unexplained. Mouse models of disorders of sex development are invaluable. The presence of the Mus domesticus poschiavinus Y chromosome, YPOS on the C57Bl/6J (B6) genetic background results in the development of ovarian tissue (i.e. sex reversal) in all genotypic XY animals. The same YPOS chromosome on the 129S1/SviMJ (129) background results only in the development of testicular tissue in XY mice. We have previously reported the existence of a congenic region of 129 origin, on chromosome 11, conferring protection from XY sex reversal. In nineteen B6-XYPOS animals, investigation of the gonads (testis, ovary or ovotestis) revealed 10 XY-females, 7 XY-males, and 2 hermaphrodites, consistent with susceptibility to XY sex reversal. However, in the B6.129-YPOS congenic animals, of 20 animals analyzed, 18 XY-males, 2 XY-females, and no hermaphrodites were identified, showing significant protection against sex reversal. In addition, we generated, by backcrossing to B6, a line carrying a subset of the congenic region. 15 genotypic males homozygous for a subcongenic fragment between position 0 and 20Mb on chromosome 11 were analyzed at 4-6 weeks of age. 8 XY mice had 2 ovaries, 1 was classified as a hermaphrodite, with both an ovary and a testis, and 6 were phenotypic males with two testes. These results suggest protection from XY sex reversal by the whole congenic region, but absence of protection by the 0-20Mb subcongenic region. Marker analysis localizes the congenic fragment protecting against XY sex reversal between position 60Mb and 95Mb on chromosome 11. This new locus contains several genes expressed in the developing gonads that are proposed to account for the sex-reversal phenotype in the B6-YPOS as well as the unexplained genetic etiology of the majority of XY DSDs.

The mitochondrial DNA landscape of modern Mexico. *A. Achilli[1,2], U. A. Perego[2,3], J. E. Gomez-Palmieri[3], R. M. Cerda-Flores[4], K. H. Ritchie[3], A. Pollock[3], N. Angerhofer[3], A. Escobar-Mesa[5], A. Torroni[2], N. M. Myres[3], S. R. Woodward[3], Sorenson Molecular Genealogy Foundation, SLC, Utah (USA)* 1) Dip. di Biologia Cellulare e Ambientale, Universita' di Perugia, Perugia, Italy; 2) Dip. di Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 3) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah, USA; 4) Genetics Division, Northeast Biomedical Research Center, Instituto Mexicano del Seguro Social, Monterrey, Nuevo Leon, Mexico; 5) Secretaria de Salud, Veracruz, Mexico.

With more than 180 ethnic and linguistics groups, Mexico is a rich source for anthropological and population studies. This country witnessed the rise and fall of major civilizations, including the well-known Maya and Aztec civilizations, but as a result of heavy European colonization and influx, the population landscape has dramatically changed over the past five centuries. Today less than 30% of modern Mexicans identify themselves as being fully or partly Amerindians and the remaining population seems to have very little in common with their pre-Columbian ancestors. However, this is not the case when the maternal genetic component is evaluated in detail. Analysis of the mitochondrial DNA (mtDNA) control region sequences, including HVS-I, HVS-II and HVS-III, from more than 2,000 subjects revealed an overwhelming Native American legacy in the modern Mexican population, with ~90% of mtDNAs belonging to the four major pan-American haplogroups A2, B2, C1 and D1. This finding supports a European contribution to the Mexican gene pool primarily by male settlers and confirms the effectiveness of employing the uniparentally-transmitted mtDNA as a tool to reconstruct a countrys history.

A genome-wide association study identifies new susceptibility variants for male pattern baldness on chromosome 20. *F. F. Brockschmidt[1], A. M. Hillmer[1], S. Hanneken[2], S. Eigelshoven[2], M. Steffens[3], A. Flaquer[3], S. Herms[1], T. Becker[3], D. R. Nyholt[4], Z. Z. Zhao[4], N. G. Martin[4], T. W. Mühleisen[1], S. Moebus[5], M. Bröcker-Preuss[6], R. Erbel[7], R. C. Betz[8], M. P. Baur[3], T. F. Wienker[3], R. Kruse[2], M. M. Nöthen[1,8]* 1) Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 2) Department of Dermatology, University of Düsseldorf, Düsseldorf, Germany; 3) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany; 4) Genetic Epidemiology, Queensland Institute of Medical Research, Brisbane, Australia; 5) Institute for Medical Informatics, Biometry and Epidemiology, University Duisburg-Essen, Germany; 6) Clinic of Endocrinology, Central Laboratory Unit Research and Education, University Hospital of Essen, University Duisburg-Essen; 7) Clinic of Cardiology, West-German Heart Center Essen, University Duisburg-Essen, Germany; 8) Institute of Human Genetics, University of Bonn, Bonn, Germany.

We performed a genome-wide association study in 296 individuals with male pattern baldness (androgenetic alopecia) and 347 controls, all of German descent. We found highly significant association at the previously described androgen receptor locus. The best SNP located outside this locus was on chromosome 20 with P=1.3x10-7 (OR=1.90, CI 1.50-2.41). We then investigated the 30 best autosomal SNPs in an independent replication sample of 319 affected and 234 unaffected German individuals and found highly significant association for five SNPs at the chromosome 20 locus. No interaction was detected with the X-chromosomal androgen receptor locus suggesting a role of the chromosome 20 locus in a yet to be identified androgen independent pathway.

CAG repeat instability and gender of the transmitting parent in Huntington disease: a large maternally-derived expansion. *E. M. Ramos[1], J. Cerqueira[2], C. Lemos[1,2], J. Pinto-Basto[1,2], I. Alonso[1.2], J. Sequeiros[1,2,3]* 1) UnIGENe, IBMC, Porto, Porto, Portugal; 2) CGPP, IBMC, Univ. Porto, Portugal; 3) ICBAS, Univ. Porto, Portugal.

Huntington disease (HD) is an autosomal dominant disorder of adulthood, characterized by motor impairment, chorea, behavioural symptoms and dementia. It is caused by the expansion of an unstable $(CAG)_n$, in the first exon of the HD gene, on 4p16.3, resulting in an expanded polyglutamine tract in huntingtin. Alleles below 35 CAGs produce no symptoms, those with 35-39 repeats show incomplete penetrance, and those with 40 CAGs or more are fully penetrant. The CAG repeat is unstable when transmitted to offspring. We now assessed meiotic instability in 53 paternal and 50 maternal transmissions (79 parents). Instability occurred in 71/103 transmissions (69%), and was more frequent when the transmitting parent was the father (t_{101}=2.485, p=0.015). Mean change was +2.11 CAGs for all male (-2 to +30) and +0.02 CAGs for all female transmissions (-5 to 20). Male and female transmissions differed also regarding the proportion of expansions and contractions (X^2_2=11.077, p=0.004). More expansions and fewer contractions occurred in male transmissions, whereas the opposite was observed with transmitting mothers. Interestingly, a patient with onset at age 8 years inherited a large expansion from her mother (who had symptoms at age 18). The mother had a 75 CAGs allele, whereas her daughter had ~95 CAGs. This large expansion through the maternal lineage is uncommon and increased the mean change for female transmissions (excluding it, the range would be -5 to 4 CAGs, and the mean -0.39). There was no difference with gender of the offspring: sons and daughters had a similar proportion of expansions and contractions, either when the CAG repeat was transmitted from the father (X^2_2=0.807) or the mother (X^2_2=0.954). In conclusion, repeat-length changes were dependent on the gender of the transmitting parent, but not on that of the offspring. Of note, was one maternally inherited infantile-onset case; this was due to the additional expansion of about 20 repeats, of an already large repeat in a mother with juvenile-onset.

Development and characterization of Fmr1 and Fmr2 double knockout mice. *Y. Gu, R. Paylor, D. Nelson* Dept Molec & Human Genetics, Baylor Col Medicine, Houston, TX.

X-linked mental retardation is a common inherited disorder and mutations in over 20 genes have been identified to date. Of these, FMR1 is the most common single gene causing mental retardation and is responsible for Fragile X syndrome. Some 600 kb distal to FMR1 lies another gene that can cause mental retardation (MR) or FRAXE disease when mutated: FMR2. A small number of patients have been found to carry deletions of the region spanning FMR1 to FMR2; these individuals have much more severe MR when compared to patients with Fragile X syndrome or FRAXE disease. We created a mouse model carrying both Fmr1 and Fmr2 mutations through meiotic recombination between previously characterized knockout alleles at Fmr1 and Fmr2. This model carries mutations at both Fmr1 and Fmr2 on the same X chromosome, but importantly, has no other mutations for genes in the vicinity. Thus, it will provide the opportunity to explore whether FMR1 and FMR2 have synergistic effects in the cognitive problems seen in humans lacking both genes or whether other genes that may also be deleted in patients play a significant role. Fmr1/Fmr2 double knockout mice were characterized for general and behavioral phenotypes. They showed reduced brain weight, especially in the cerebra, which was not observed in either Fmr1 or Fmr2 single knockout mice. The increased weight of testis (macroorchidism) resulting from Fmr1 mutation was also observed. Behavioral tests showed additional abnormalities, including a defect in the Rotarod test of motor learning in double knockout mice, while both Fmr1 and Fmr2 single knockout models were unchanged from wild type animals. These results demonstrate for the first time that Fmr1 and Fmr2 play synergistic roles in neural development and function. Ongoing efforts to characterize this model for finer scale neuro-anatomy and for electrophysiology will allow improved understanding of the interaction between these genes. Molecular analysis to determine the mechanisms of interaction will also provide insight into the functions of each of these X-linked MR genes, and may offer insight into the severe MR found in patients lacking both FMR1 and FMR2.

The Human Phenotype Ontology. *P. N. Robinson, S. Köhler, S. Bauer, D. Seelow, D. Horn, S. Mundlos* Institute for Medical Genetics, Charité-Universitätsmedizin, Berlin, Germany.

There are many thousands of hereditary diseases in humans, each of which has a specific combination of phenotypic features. Although humans are particularly good at recognizing human phenotypic anomalies, research employing a systematic approach to the relationships of phenotypes to human cellular biology is still in its infancy. A number of considerations suggest that an ontological description of human phenotypes has distinct advantages over hierarchical systems, including the ability to relate concepts (terms) to multiple parents, to allow descriptions and queries at different levels of granularity and completeness, and also to take advantage of algorithms that have been developed for ontological analysis following the success of the Gene Ontology. These considerations prompted us to develop an ontology with currently over 8000 terms to describe human phenotypic abnormalities. Each term in the HPO describes a phenotypic abnormality such as Atrial septum defect. Terms are related to parent terms by is a relationships. We used an ontological similarity measure between the diseases listed in OMIM in order to visualize and cluster the human phenome. We compared the observed clustering to 21 predefined physiological disorder classes to clusterings obtained from 10,000 networks in which edges were randomly rewired 2,000 times. The actual network score was 47.2 standard deviations above the mean random score. We will demonstrate that searches for clinical diagnoses using the HPO achieve a high degree of accuracy that is not overly sensitive to noise, completeness, or specificity of the set of phenotypic terms used for the search. We will demonstrate the use of the HPO to generalize our method for prioritizing candidate disease genes from disease families using random walk analysis (Köhler et al., Am J Hum Genet, 2008). The HPO is freely available under an open-source license, and we are actively seeking the involvement of the community to refine and extend the ontology and disease annotations. Downloads and project information are available at the project hompeage, http://www.human-phenotype-ontology.org.

Functional analysis of the rheumatoid arthritis associated 6q23 region; regulation of TNFAIP3. *L. Elsby[1], T. Eastell[1], J. Worthington[1], D. Ray[2], R. Donn[1]* 1) arc Epidemiology Unit, University of Manchester, Manchester, United Kingdom, M13 9PT; 2) Centre for Molecular Medicine, Faculty of Medicine, University of manchester, Manchester, United Kingdom, M13 9PT.

Recently, two independent studies have shown association of the 6q23 region with rheumatoid arthritis (RA). The WTCCC genome wide association study of RA found association with a SNP in the 6q23 region (rs6920220); this has since been replicated in a cohort of 5063 UK RA cases and 3849 controls. This SNP lies in an intergenic region between Oligodendrocyte Lineage Transcription Factor 3 (OLIG3) and Tumour Necrosis Factor Alpha-Induced Protein 3 (TNFAIP3) and is in complete LD (r^2=1) with 4 other SNPs (rs6933404, rs2327832, rs6927172 & rs17264332). TNFAIP3 is a candidate gene for investigation in RA as it is a negative regulator of TNFa signalling. To determine the transcriptional regulatory capacity of the 6q23 SNPs on TNFAIP3, 1Kb DNA sequences encompassing the SNPs were cloned into the reporter plasmid pGL3 in both the sense and antisense orientation, with the TNFAIP3 promoter driving reporter gene expression. Site directed mutagenesis was used to alter the SNP alleles. Transfection of the constructs into a T lymphoblast cell line, CEMC7A, demonstrated three of the five SNP sequences (rs 6920220, rs6933404 & rs6927172) were able to repress the activity of the TNFAIP3 promoter in an orientation independent manner, suggesting that these sequences are capable of binding transcription factors that can regulate TNFAIP3 gene expression. The rs6927172 SNP lies in a highly conserved region of homology. Bioinformatic analysis of this sequence showed that the C allele is a consensus ets-1 binding site, and that the G allele disrupts this. Examination of the rs6927172 SNP by electrophoretic mobility shift assay has shown differential protein binding to the allele variants. Further studies will aim to characterise this transcription factor binding and also to determine transcription factor binding to the rs6933404 and rs6920220 SNPs. This data represents novel evaluation of the 6q23 intergenic SNPs associated with RA and suggests a relevant role of altered TNFAIP3 expression with RA pathogenesis.

The shared genetic architecture of common autoimmune diseases. *C. Cotsapas[1,2,3], M. Daly[1,2,3], Network of Consortia, Federation of Clinical Immunology Societies* 1) CHGR, Massachusetts General Hospital, Boston, MA; 2) Dept of Medicine, Harvard Medical School, Boston MA; 3) Broad Institute of MIT and Harvard, Cambridge MA.

There is abundant evidence that complex autoimmune/inflammatory (AI) diseases may have overlapping etiologies, shown both by the aggregation of these disorders within families and by the efficacy of common therapies. Genetic evidence such as the association of the PTPN22 R620W polymorphism to type I diabetes, SLE, and rheumatoid arthritis, suggests that this is at least partly due to shared genetic susceptibility to autoimmunity and inflammation. Recent genome-wide association (GWA) studies for several AI diseases have implicated tens of loci in at least one such disorder, with some of these loci harboring associations to more than one disease. We therefore investigated the commonality of susceptibility architecture by conducting a meta-analysis of selected loci in approximately 14,000 cases and 13,000 controls genotyped in GWA studies of six diseases. We have assembled a list of 51 non-MHC loci unequivocally associated to at least one of ankylosing spondylitis, coeliac disease, crohn's disease, multiple sclerosis, psoriasis, rheumatoid arthritis, systemic lupus erythematosus and type I diabetes. Our inclusion criteria are that association in a genome-wide scan and replicated in independent samples at a cumulative significance level of $P < 5e-8$. We have meta-analyzed data for these loci, excluding the ascertainment disease. We find that >25% of loci may be implicated in multiple diseases: for example, 9/11 type 1 diabetes loci are shared with at least one other disease. We also find evidence that some loci may have opposite effects: the PTPN22 R620W polymorphism, for example, appears protective for Crohn's disease. We will replicate these and other discoveries in independent sample collections. We believe that these results will help to differentiate between common mechanisms of autoimmunity and disease- or tissue-specific factors. This research should lead to greater mechanistic understanding of the underlying processes and ultimately to better treatments and therapies.

Life threatening menorrhagia in patients with Glycogen Storage Disease Type I- An unrecognized complication?

S. Austin, P. Kishnani, A. James, M. Spencer-Manzon Duke University Medical Center, Durham, NC.

Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, Von Gierke Disease) is caused by a defect in the glucose-6-phosphate system. The biochemical defect results in hypoglycemia, hyperlipidemia, hyperuricemia, and a prolonged bleeding time. The prolonged bleeding time is due to a von Willebrand disease like defect which has been described as an acquired platelet abnormality related to chronic hypoglycemia. Recurrent/severe epistaxis is often reported. As patients age, complications such as gout, pancreatitis, hepatic adenomas with risk for progression to hepatocellular carcinoma, pulmonary hypertension, osteoporosis, and renal disease are being recognized. Menorrhagia, defined as greater than 80mL of blood loss per cycle, appears to be a problem in reproductive aged females with GSD I. In our cohort of 15 reproductive aged females (ages 12-46 years), five (33%) developed menorrhagia. Initially, four required hospitalization and blood transfusion and one required hormonal treatment. All five were in inadequate metabolic control. The menorrhagia has subsequently been managed by a gynecologist with experience in GSD I. Interventions included hormonal and non-hormonal treatments: endometrial ablation in conjunction with Micronor (norethindrone) as well as Provera (medroxyprogesterone acetate). Alternatives to oral hormonal treatment have included the Mirena intrauterine system, endometrial ablation, and hysterectomy. Before treatment, the gynecologist discussed these options with the treating team. Neutropenia and risk for infection should be considered in GSD Ib. Additional risk factors for menorrhagia, such as anovulation (as a result of thyroid disease or polycystic ovarian disease) and exogenous hormones were also present in some of the patients. Other risk factors for menorrhagia, such as fibroid polyps, endometrial hyperplasia, and cancer, were not noted in any of the patients. This case series will describe each patients course related to the treatment of menorrhagia. This newly recognized complication should be considered when reviewing the history of patients with GSD I and in the management of these cases.

Autistic features with speech delay in a girl with an ~1.5 Mb deletion in 6q16.1, including *GPR63* and *FUT9*. *E. Bocian[1], K. Derwinska[1,2], J. Bernaciak[1], E. Obersztyn[1], P. Stankiewicz[1,2]* 1) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston TX, USA.

Recent studies have shown that up to 40% of the apparently balanced reciprocal chromosome translocations in patients with abnormal phenotype can be accompanied by a chromosome imbalance. We present a 10-year-old girl with mild mental retardation, language delay, and autistic behavior. She had no dysmorphic features and her brain MRI was normal. Karyotype analysis revealed a de novo apparently balanced translocation t(6;14)(q16;q22). Interestingly, autism, schizophrenia, and bipolar disorder have been linked previously to chromosome 6q16q21. Whole genome array CGH analysis with ~385,000 oligonucleotide probes (NimbleGen) identified an ~1.5 Mb deletion in 6q16.1. FISH with BAC clones mapping within and directly flanking the deleted segment showed that the deletion arose at the translocation breakpoint. The deleted segment harbors *FUT9, GPR63, FHL5, KLHL32, c6orf66*, and *AK091365*, but does not involve *GRIK2*, previously linked and associated with autism and schizophrenia. *GPR63* (*G-protein-coupled receptor 63*) is expressed in the frontal cortex, with lower levels in the thalamus, caudate, hypothalamus and midbrain and encodes a G-protein-coupled receptor for sphingosine 1-phosphate. The *fucosyltransferase 9* (*FUT9*) gene, is highly conserved among humans, mice, rats, and hamsters and is strongly expressed in brain during embryogenesis. *FUT9* is considered to be involved in cell-cell interactions, differentiation, and neurodevelopmental processes. We propose that haploinsufficiency of *GPR63* or *FUT9* may be responsible for the austistic spectrum features present in our patient. Our data confirm previous observations that copy-number variation is a significant factor responsible for autistic spectrum behavior and speech delay.

Familial Aneurysm Syndrome Associated With COL5A1 Mutation. *H. Zhang[1], J. Yang[2], W. Chen[2], F. Cancellario[3], G. Maritati[3], N. McDonnell[1]* 1) CRB, NIA/NIH, Baltimore, MD; 2) LCI, NIA/NIH, Baltimore, MD; 3) San Camillo Hospital, Rome.

We examine here a North American family with a strong history of arterial aneurysms, dissections, and ruptures associated with a premature termination codon in procollagen V(1). The proband, a 32 year old woman, presented features consistent with the classical form of EDS such as joint hypermobility, epicanthal folds, and abnormal scars; however, family history revealed that her father died of a thoracic aorta rupture at age 48 and a paternal aunt developed a 4.1 cm renal aneurysm in her 50s. The probands brother, born with a club foot, was also hypermobile. Protein analysis of procollagen III and I did not reveal any abnormalities. Research based sequence analysis of COL3A1, TGFBR1, and TGFBR2 genes revealed neither pathological mutations nor SNP homozygosity suggesting a deletion.

Imaging showed that the patient had a 1.8 cm ectatic left iliac artery with no perceived immediate risk of rupture. Aggressive blood pressure control was initiated. Two months later, while on vacation in Italy, the patient experienced severe lower quadrant pain and lost consciousness. Rupture of the left iliac was diagnosed, and an emergent repair with Dacron bypass from the right common iliac to her left external iliac artery was performed. Approximately one year later, a new 2.4 cm aneurysm in the right common iliac artery was detected via MRI.

The patients brother with a similar phenotype underwent research imaging studies, and ectasia of the celiac and mesenteric axes were identified.

Due to the phenotypes similarity to classical EDS, a research based sequence analysis of the COL5A1 gene was performed. A premature termination codon in exon 3 was identified in the proband, her brother, and her aunt. Haploinsufficiency mutations in COL5A1 have been previously associated with the classical and hypermobile forms of EDS, but aggressive vascular complications as seen in this family have not been described. COL5A1 mutations should be considered in families with strong histories of vascular complications and features suggestive of classical EDS.

SNP detection algorithm for next generation sequencing technologies. *S. Gopalakrishnan, Z. S. Qin* Biostatistics, University of Michigan, Ann Arbor, MI.

As we move forward with next generation sequencing technologies, we have the opportunity to identify low frequency mutations within each individuals including de novo ones that cannot be detected using SNP panels designed based on common mutations. To avoid ambiguity, most of the current methods only utilize uniquely mapped reads to identify polymorphic loci. This is undesirable since mapping ambiguity may be caused by polymorphisms. In this work we present a Bayesian approach to identify polymorphic loci using short reads including those that are not uniquely mappable. Our method attempts to align the ambiguous reads to their true genomic locations and performs polymorphism detection at the same time. This is achieved by reconciling among observed read sequences, reference genome and the possibility of polymorphic sites. Simulation studies using real sequence trace data showed favorable performance in terms of sensitivity and specificity compared to the method using only uniquely mapped reads. We tried our method on a real dataset generated from Illumina Genome Analyzer. The reads were generated using a 1.8 Mb region on the q arm of chromosome 7 near the CFTR gene. Using one million reads mappings covering a 300 kb region, our method identifies 94 previously known SNP loci. In contrast, using only uniquely mapped reads identifies only 59 previously known sites. Upon increasing the number of mappings to 5 million, covering a 900 kb region, the numbers increases to 189 and 152 respectively.

The XLMR gene *ACSL4* plays a role in dendritic spine architecture. *I. Meloni[1], V. Parri[1], R. De Filippis[1], F. Ariani[1], R. Artuso[1], M. Bruttini[1], E. Katzaki[1], I. Longo[1], F. Mari[1], C. G. Dotti[2,3], A. Renieri[1]* 1) Department of Molecular Biology, Medical Genetics, University of Siena, Siena, Italy; 2) Department of Human Genetics, University of Leuven Medical School, Leuven, Belgium; 3) Department of Molecular and Developmental Genetics, Flanders Institute of Biotechnology (VIB 11) Leuven, Belgium.

ACSL4 is a gene involved in non-syndromic X-linked mental retardation. It encodes for a ubiquitous protein that adds Coenzyme-A to long-chain fatty acids, with a high substrate preference for arachidonic acid; it presents a brain-specific isoform deriving from alternative splicing and containing 41 additional N-terminal aminoacids. To start unravel the link between *ACSL4* and mental retardation, we have characterized the protein and analyzed the consequences of its absence in rat primary hippocampal neurons. By RT-PCR analyses we identified a new transcript with a shorter 5-UTR region and showed that *ACSL4* is expressed at higher levels in fetal than in adult brain. Differential expression of the alternative transcripts in different adult brain regions was also observed. By immunofluorescence microscopy we report that ACSL4 is located preferentially in endoplasmic reticulum. To characterize ACSL4 function in rat hippocampal neurons we silenced the gene by siRNA technology. These experiments suggest that ACSL4 might be dispensable for neurites formation and final length but it is required for the presence of normal dendritic spines. In fact, reduced ACSL4 levels led to a significant reduction in dendritic spine density and an alteration in spine/filopodia ratio and in spine distribution among different morphological categories (stubby, thin and mushroom spines). It has been reported that arachidonic acid, ACSL4 substrate, is involved in the regulation of actin cytoskeleton. These data suggest that ACSL4 might directly or indirectly influence actin cytoskeleton organization; the observed spine anomalies might thus be a secondary effect of an abnormal actin organization due to ACSL4 absence.

Quantifying and correcting for the winner's curse in genome-wide association studies for quantitative traits. *R. Xiao, M. Boehnke* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Genetic association mapping is a powerful method to detect genetic variants that influence quantitative traits. As a consequence of winners curse, initial estimates of genetic effect sizes for quantitative trait loci (QTL) tend to be upwardly biased. In this paper, we parameterize the genetic effect of the QTL as the linear regression coefficient of the genotype. In the context of genome-wide association studies or large-scale candidate-gene studies, we analytically quantify the impact of the winners curse on the uncorrected estimator of QTL effect size under different genetic models. We then propose an ascertainment-corrected maximum likelihood method to improve the QTL effect estimate. Simulation results indicate that the proposed method reduces the overestimation by different degrees, depending on study power, consistent with findings from us and others for dichotomous traits.

Novel genetic associations of the antioxidative enzyme glutathione peroxidase 1 with low total bone mineral density in postmenopausal women. *S. Jurkovic[1], J. Osredkar[1], J. Prezelj[2], J. Marc[3]* 1) KIKKB, University Medical Centre Ljubljana, Njegoseva 4, Ljubljana, Slovenia; 2) Department of Endocrinology, Diabetes and Metabolic Diseases, University Medical Centre Ljubljana, Slovenia; 3) Department for Clinical Biochemistry, Faculty of Pharmacy, Ljubljana, Slovenia.

Osteoporosis, a systemic bone disease with low bone mass, affects every second women at the age of 65 years or later. Recently, oxidative stress has been suggested to participate in the development of osteoporosis. Osteoblasts can produce antioxidants such as glutathione peroxidase 1 (GPX1) to protect against reactive oxygen species. The aim of this study was to determine whether the polymorphisms in GPX1 are associated with low bone mineral density (BMD), 1-year BMD changes and biochemical bone turnover markers, such as sBALP, RANKL, ALP, pOC, sOPG and DPyr. The study included 535 postmenopausal women, aged 45-92 years. Each patient was examined for BMD and biochemical bone turnover markers. After a year, BMD was measured again in 160 of the postmenopausal women involved in the study. All subjects were genotyped for polyalanine repeats in the first exon and Pro198Leu variation in the second exon of the GPX1 gene using the non-denaturing DHPLC and RFLP, respectively. The frequencies of genotypes in the control group of 190 subjects were as follows: 5/5 (24.4%), 5/6 (30.7%), 5/7 (18.2%), 6/6 (6.3%), 6/7 (14.2%), 7/7 (6.3%) for the polyalanine repeats and CC (51.1%), CT (44.1%), TT (4.8%) for the Pro198Leu polymorphism. Significant associations between both GPX1 polymorphisms and total BMD values in postmenopausal osteoporotic women were found (p0.005). The genotype 6/6 is strongly associated with a lower total BMD value than the 5/7 genotype (p=0.003). A similar decrease of total BMD was observed in genotypes TT in comparison with the genotype CC (p=0.026). Moreover, no significant associations with the biochemical bone turnover markers were determined. The results show for the first time significant associations between polymorphisms of the GPX1 gene and BMD values and thus the connection of the antioxidative genetic polymorphisms with the osteoporosis.

Extreme short stature resulting from mutation of the C-type lectin domain of aggrecan. *S. W. Tompson[1], B. Merriman[2], V. A. Funari[1], M. Fresquet[3], D. L. Rimoin[1], R. S. Lachman[1], S. F. Nelson[2], M. D. Briggs[3], D. H. Cohn[1,2], D. Krakow[1,2]* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA, USA; 2) Human Genetics Department, University of California at Los Angeles, Los Angeles, CA, USA; 3) Wellcome Trust Centre for Cell-Matrix Research, University of Manchester, Manchester, UK.

A novel approach combining homozygosity mapping with cartilage-specific gene expression analysis was used to identify the disease gene in a family with a unique form of extreme short stature. The 3 affected individuals showed a distinctive form of autosomal recessive spondyloepimetaphyseal dysplasia, characterized by severe short stature (22-24), flattened midface, prognathism, brachydactyly with joint laxity, and lumbar lordosis. Carriers had proportionate mild short stature. SNP array-based homozygosity mapping identified a 17Mb disease gene interval on chromosome 15, a region containing 296 genes. The genes were assessed and ranked by cartilage-selectivity using whole genome expression microarray data, revealing only 2 genes that were selectively expressed in cartilage: aggrecan (ACAN) and chondroitin sulfate proteoglycan 4 (CSPG4). Sequence analysis revealed homozygosity for a missense mutation (6793G>A) that predicts a D2265N amino acid substitution in the C-type lectin domain (CLD) within the G3 domain of ACAN. This residue is highly conserved among ACAN orthologues as well as paralogous lectican proteins. Expression of the normal and mutant G3 domains in mammalian cells showed that the mutation created a functional N-glycosylation site but did not adversely affect protein trafficking and secretion. The D2265 residue coordinates binding of a calcium ion which influences the conformational binding loops of the CLD, a domain known to mediate interactions with tenascins and other extracellular matrix proteins. Surface plasmon resonance studies showed that the mutant form of the ACAN G3 domain bound tenascin-C similar to the wild type protein, but dissociated slowly. These findings identify a new autosomal recessive skeletal dysplasia and a significant role for the aggrecan C-type lectin domain in regulating endochondral ossification.

Von Hippel-Lindau disease gene mutations in South African families : Identification of a founder mutation. *E. J. van Rensburg, C. M. Dorfling, M. de la Rey* Dept Human Genetics, Univ Pretoria, Pretoria, South Africa.

Von Hippel-Lindau (VHL) disease is a dominantly inherited familial cancer syndrome characterized by retinal and central nervous system haemangioblastomas, renal cell carcinomas, phaeochromocytomas, pancreatic endocrine tumours and endolymphatic sac tumours. In addition epididymal, pancreatic, and renal cysts are common. Since the *VHL* gene, located on chromosome 3p25, was cloned many inactivating mutations have been identified in VHL families. In two thirds of the families, missense, nonsense and splice site mutations as well as micro-deletions and micro-insertions have been identified. Large deletions involving part of or the entire gene, account for one third of the families. Thirteen South African families diagnosed on the basis of clinical criteria, were tested for *VHL* mutations in order to determine the frequency and spectrum of germ-line mutations. Following informed consent and extraction of DNA from peripheral blood, the coding exons and exon-intron boundaries were directly sequenced. Screening for large deletions was carried out using long-range PCR in which three overlapping fragments of 8.7Kb, 12.5Kb and 16Kb were amplified. Germ-line mutations were detected in all of the families; two missense (p.R167Q and p.C162F), one splice-site (c.463+1G>C), one novel in-frame insertion (c.591insGAT, p.197insD) and two novel large deletions of 5Kb and 6.3Kb, that both result in the in-frame deletion of exon 2, were detected. The breakpoints were sequenced and narrowed to homologous sequences of 7bp and 17bp respectively. With the exception of the 6.3Kb deletion that was detected in eight Afrikaner families, all other mutations were detected in one family each. Genealogical investigation of the eight families dating back to the 16th century have identified the founding couple for this mutation. To our knowledge, this is only the second founder mutation to be detected. A founder mutation (c.292C>T ; p.Y98H) has once before been described in families from Germany. These results now allow for presymptomatic testing of family members who can benefit from early diagnosis and treatment of VHL associated tumours.

Folinic acid-responsive seizures is identical to pyridoxine-dependent epilepsy. *R. Gallagher[1], J. Van Hove[1], G. Scharer[1], K. Hyland[2], B. Plecko[3,6], P. Waters[4], S. Mahmutoglu[3], S. Stockler-Ipsiroglu[3], G. Salomons[5], E. Rosenberg[5], E. Struys[5], C. Jakobs[5]* 1) Clinical Genetics and Metabolism, University of Colorado at Denver and Health Sciences Center, Denver, Colorado, USA; 2) Horizon Molecular Medicine, Atlanta, Georgia, USA; 3) Division of Biochemical Diseases, University of British Columbia, Vancouver, British Columbia, Canada; 4) Biochemical Genetics Laboratory, University of British Columbia, Vancouver, British Columbia, Canada; 5) Metabolic Unit, Department of Clinical Chemistry, VU University Medical Centre, Amsterdam, The Netherlands; 6) Department of Pediatrics, Medical University Graz, Austria.

Folinic acid-responsive seizures and pyridoxine-dependent epilepsy are two treatable causes of neonatal epileptic encephalopathy. The former is diagnosed by characteristic peaks on CSF monoamine metabolite analysis, its genetic basis has remained elusive. The latter is due to -aminoadipic semialdehyde dehydrogenase deficiency, due to mutations in the *ALDH7A1* (antiquitin) gene. We report two patients whose CSF showed the marker of folinic acid-responsive seizures, but who responded clinically to pyridoxine. We performed genetic and biochemical testing of samples from these individuals, and seven others, in order to determine the relationship between these two disorders. CSF was analyzed for -aminoadipic semialdehyde and pipecolic acid. DNA sequencing of the A*LDH7A1* gene was performed. Both patients had mutations in the *ALDH7A1* gene consistent with pyridoxine-dependent epilepsy due to -aminoadipic semialdehyde dehydrogenase deficiency. CSF samples from seven others, also diagnosed with folinic acid-responsive seizures because of characteristic CSF peaks, were identified to have elevated -aminoadipic semialdehyde, and sequencing of the *ALDH7A1* gene also revealed disease-causing mutations in these. These findings identify the cause of folinic acid-responsive seizures as -aminoadipic semialdehyde dehydrogenase deficiency due to mutations in the *ALDH7A1* gene, and demonstrate that folinic acid-responsive seizures is identical to the major form of pyridoxine-dependent epilepsy.

Automated Sequence Analysis Pipeline (ASAP) for Clinical Genetic Testing. *A. P. DeLuca[1], D. J. Wilder-Tack[1], N. E. Stone[1], K. R. Taylor[1], J. D. Bogaard[1], T. E. Scheetz[1], T. L. Casavant[1], V. C. Sheffield[1,2], E. M. Stone[1,2], T. A. Braun[1]*
1) University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, Chevy Chase, MD.

The Carver Non-profit Genetic Testing Laboratory (CNGTL) provides genetic testing to patients with inherited eye disorders. To minimize errors, genetic testing currently uses experienced personnel to manually read chromatograms to find and annotate mutations. As the volume of patients for genetic testing at the CNGTL has grown we have developed a system to augment the manual reading to improve workflow, laboratory information management, and add software-based mutation identification in addition to human sequence reading. This system detects mutations by leveraging existing bioinformatic software. The end result will be an increase in our capacity to perform genetic testing. Additionally patients will receive timely status updates on their tests and observed allelic variation frequencies will be made available to the community. Existing tools to detect variations in Sanger sequencing have either focused on large-scale variation discovery projects where the contents of a single chromatogram are not as important as finding a novel variant (PolyPhred, PolyScan), or tools that analyze datasets interactively (MutationSurveyor, InSNP). ASAP consists of a user interface that allows clients to view and transfer data, a database that acts as a central repository for the chromatograms as well as all associated annotation, and a series of servers that handle mutation detection (using PolyPhred), annotation (using BLAT and the UCSC annotation database), and integration with laboratory information management systems. It also improves the ability to evaluate sequence quality and identify sequencing problems more rapidly. ASAP is designed to analyze a continuous flow of chromatograms from genetic testing, and identify and annotate mutations. It generates mutations annotated in standard format defined by the Human Genome Variation Society (HGVS). In summary, ASAP enables clinical genetic testing to be performed more efficiently by reducing the burden of manual sequence reading.

A comparison of genome-wide imputation methods using the WTCCC control datasets. *B. Neale[1,2,3], Genetic Analysis Information Network(GAIN) Imputation Workgroup* 1) Richard Simches Bldg CPZN 6818, Ctr Human Gen Res, Massachusetts General Hospital, Boston, MA; 2) 7 Cambridge Center, Broad Institute of Harvard and MIT, Cambridge MA; 3) Institute of Psychiatry, Kings College London, De Crespigny Park, London, United Kingdom.

Imputation methodology has become pervasive in genome-wide association studies as a tool for checking data quality, increasing power, and facilitating meta-analysis by allowing cross-chip comparisons. However a rigorous comparison of the strengths and weaknesses of available methods using empirical data has not been performed. Generally, these methods utilize linkage disequilibrium patterns in the human genome to predict genotypes at untyped loci. Essential to the integrity of such efforts is the accuracy of the imputation algorithm. Given this wide array of applications, many groups have developed and implemented imputation methods. As part of the GAIN initiative, we have attempted to determine the relative merits of a majority of these methods. To do so, we are using the WTCCC 1958 birth cohort data, which has genotypes on the Affymetrix 5.0 and Illumina 550K platforms. Each of the ten enrolled groups run their respective imputation software on the Affymetrix 5.0 data to impute the Illumina 550K SNPs in HapMap. As outcome metrics, we use the accuracy of the posterior probabilities and allele frequencies estimated by the imputation methods. We also determine the number of individuals with posterior probabilities above thresholds for an assessment of the 'certainty' of each method. These three considerations are calculated for all SNPs and then broken down by minor allele frequency to shed light on the efficacy of imputation across the frequency range of human diversity. Additionally, we assess the relative computational requirements for each of these packages by running each method on a central computational system. In summation, we provide here insight into the general performance of imputation in different frequency and LD scenarios; the relative strengths of various methods in those scenarios; and introduce correction factors/recommendations for incorporating post-imputation uncertainty in meta-analysis.

Maternal germline mosaicism and somatic mosaicism in NF1. *M. R. Wallace[1], R. Loda[1], S. A. Rasmussen[1], K. Stephens[2], V. M. Riccardi[3]* 1) Molec Genetics & Microbiol, Univ Florida, Gainesville, FL; 2) Laboratory Medicine, Univ Washington, Seattle, WA; 3) The Neurofibromatosis Institute, La Crescenta, CA.

NF1 is an autosomal dominant condition present in 1/3000 - 1/4000 worldwide, characterized primarily by the presence of neurofibromas and café-au-lait spots, with an increased risk of learning disabilities and certain malignancies. Approximately half of newly-diagnosed cases of neurofibromatosis 1 (NF1) represent the first case in the family due to a new mutation in the NF1 gene. Although new-mutation cases are thought to have a constitutional NF1 mutation, an unknown percentage is actually mosaic for a somatic mutation that occurred early in development. There is a wide spectrum of NF1 mutations, with only one (microdeletion spanning NF1 and flanking genes) representing more than 1-2% of alleles. We present a unique family with an unaffected mother (without findings of NF1) with two affected children who are half-siblings. Both affected individuals have a novel Q2319X nonsense mutation in exon 38, but are highly discordant for NF1 features, particularly cutaneous neurofibroma burden. The mutation was not evident in the mothers blood by sequence analysis. Furthermore, a third child, an unaffected half-sib of one of the affected children, shares the same maternal allele, but lacks the Q2319X mutation, confirming that the mothers germline is truly mosaic with gametes representing 3 different NF1 alleles. We also describe somatic mosaicism in relatively mildly-affected new-mutation cases, including a novel frameshift in exon 29 (c.5382insG), and discuss the implications of mutation mechanism, effect on phenotype, and modifier loci.

Molecular Studies on FUNDC2 a candidate gene for mitochondrial diseases. *C. Laperuta, J. Monfregola, D. Esibizione, C. Carbone, M. V. Ursini, M. G. Miano* Institute of Genetics and Biophysics Adriano Buzzati Traverso CNR, Naples, Italy.

Human chromosome Xq28 is a gene-rich region, which lies within the critical linkage interval for many human diseases and characterized by an unusual degree of genomic instability. Here we report the structural/functional analysis of a new Xq28 gene FUNDC2 that encodes for a small mitochondrial protein with unknown function. The gene maps approximately 4,1 kb centromeric to F8 and 6,5 kb telomeric to MTCP1. Comparative and chromosomal mapping indicates that FUNDC2 has duplicated to specific locations near the pericentromeric region of human chromosomes highlighting a phenomenon for paralogous genome evolution common to other Xq28 genes. FUNDC2 has ubiquitously expression in human embryos and adult tissues with high level in the heart and skeletal muscle. Its predicted protein shows high conservation from Archeabacteria to Human suggesting that it could be a member of a new family of functionally related genes. Its 189-amino-acid sequence appears rich of hydrophobic residues and lacks a signal-sequence for protein sorting or target membrane. In HeLa and COS cells, confocal immuno-fluorescence studies co-localized FUNDC2 protein to the mitochondria stained by anti-HSP60 antibody and pECFP-mito. We also performed subcellular fractionation by differential centrifugation and alkali treatment establishing that FUNDC2 is located in the mitochondria inner membrane. Based on a high-throughput yeast 2-hybrid screen, we found that Drosophila FUNDC2 orthologue interacts with mtacp1 (mitochondrial acyl carrier protein 1). Its human counterpart is NDUFAB1, a subunit of the mitochondrial respiratory Complex I that is the entry point for electrons donated from NADH. Mutations in the structural building blocks of Complex I have been detected in 40 percentage of patients with Complex I deficiencies. Further investigation of FUNDC2 will contribute to understanding of its function as well as provide a new candidate for mitochondrial pathogenesis including those associated to Complex I deficiency.

Mitochondrial DNA footprints in modern Mongolia. *S. R. Woodward[1], A. Achilli[2,3], U. A. Perego[1,3], J. E. Gomez-Palmieri[1], D. Tumen[4], E. Myagmar[4], D. Bayarlhagva[4], K. H. Ritchie[1], A. Pollock[1], N. Angerhofer[1], A. Torroni[3], N. M. Myres[1], Sorenson Molecular Genealogy Foundation, SLC, UT (USA)* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT, USA; 2) Dip. di Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy; 3) Dip. di Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 4) National University of Mongolia, Ulan Bator, Mongolia.

Although Mongolia is one of the most sparsely populated countries in the world, it is located at a pivotal crossroad between the four corners of Asia (including the well-known Silk Road) and has been characterized throughout history by events that greatly added to its current cultural and ethnic diversity. Among these, perhaps one of the most significant happening was the ambitious expansion strategy employed by Mongolias most prominent personality, Genghis Khan, whose empire eventually stretched across all of modern-day China, a portion of modern Russia, Southern Asia, Eastern Europe and the Middle East. In 2007, through a well-planned collection effort, researchers at the Sorenson Molecular Genealogy Foundation and the National University of Mongolia were able to gather over 3,000 DNA samples, informed consents, and genealogical data throughout the country of Mongolia, including samples from 21 distinct tribal or ethnic populations. All the samples were sequenced for the three hypervariable segments of the mitochondrial DNA (mtDNA) control region to assess the genetic composition of modern Mongolia. The most common mtDNA haplotypes are typical of haplogroup C, which is frequent throughout Eastern Asia. However, nearly 40% of the observed mtDNA lineages are of Western Eurasian origin, including a significant frequency (~7%) of haplogroup H - the most common in Europe. The high prevalence of Western Eurasian lineages could be a remnant from Genghis Khans conquering efforts, trade and cultural exchanges along the Silk Route. To assess the extent of recent gene flow that could account for the elevated levels of Eurasian haplogroups within Mongolian populations, we have examined genealogical data of samples representative of Western Eurasian haplogroups.

Incontinentia pigmenti caused by NAHR in NEMO locus: a case report. *F. Fusco[1], A. Pescatore[1], M. Paciolla[1,2], MB. Lioi[2], MG. Miano[1], MV. Ursini[1]* 1) Institute of Genetics and Biophysics ;Adriano Buzzati-Traverso; (IGB-CNR), Naples, Italy; 2) University of Basilicata, Potenza, Italy.

Incontinentia Pigmenti (IP) is an X-linked dominant disease caused by mutation in the NEMO gene located in the Xq28 chromosomal region. NEMO encodes for a key subunit of the crucial IKK regulatory complex required for the activation of NF-kB pathway. Therefore, the remarkably heterogeneous and often severe clinical presentation reported for IP is due to the pleiotropic role of this transcriptional signalling pathway. Previous reports from us and from others have demonstrated that 70 percentage of the IP cases are due to a recurrent exon 4-10 genomic rearrangement in the NEMO gene. We report on a case of Incontinentia Pigmenti in an 8 months old girl who presented the classical dermatological four signs of the disease associated to neonatal seizures. The analysis of the NEMO gene responsible for IP in the patient DNA revealed the presence of a common exon4-10 deletion which was not present in the unaffected mother of the girl who was instead carrier of an exon4-10 deletion in the closely located non-functional NEMO pseudogene. Haplotype analysis of the NEMO/pseudoNEMO region in the mother of the proband, the grandmother and other unaffected members of the family revealed that a homologous non-allelic recombination between the NEMO gene and pseudogene mediated the relocation of the exon4-10 deletion from the pseudogene to the gene. This is the first case of a genomic IP rearrangement caused by nonallelic homologous recombination (NAHR) between gene-pseudogene pair in the NEMO locus and enrols IP among the very few disease caused by gene conversion between gene-pseudogene pair. It also represents a significant contribution to highlight how unaffected individuals carrying deletions in the pseudoNEMO may be at risk to have descendants with IP.

Multi-ethnic Genome-wide Alterations in Breast Cancer using Paraffin Embedded Samples. *M. E. Ahearn[1], C. Gomez[1], M. Jorda[1], T. Halsey[2], J. Yan[2], A. Mejias[1], K. Ellison[2], K. Mulligan[2], M. Pegram[1], S. Gluck[1], L. Baumbach[1]* 1) Univ Miami, Miami, FL; 2) Almac Diagnostics, Durham, NC.

Ethnic-specific disparities in breast cancer (BC) stage of presentation and survival rates are well documented. To investigate possible ethnic-specific genetic contributions to disparity, we are completing gene expression profiling of a multi-ethnic cohort consisting of 30 Triple Negative BC patients [10 each African-American (AA), Hispanic (His) and non-Hispanic white (Cauc) women] matched for age of diagnosis. The overall aim is to increase understanding of the biological basis of ethnic-specific BC disparities, leading ultimately to ethnic-specific diagnostic and therapeutic approaches. Immediate goals are to demonstrate utility of FFPE samples in obtaining consistent, reproducible data from gene expression arrays, and to identify differentially expressed genes between tumor and normal tissue common or unique to the ethnic groups. Specimens from FFPE blocks were marked by pathology as to normal vs. tumor tissue. RNA isolation, cDNA preparation, and hybridization of tumor/normal cDNAs to a breast cancer focused gene expression microarray (*Breast Cancer DSA Research Tool*) was performed by *Almac Diagnostics*. Using self matched tumor and normal FFPE samples from 18 patients, over 17516 transcripts were detected on the *Breast Cancer DSA* with intensity significantly greater than background. For normal and tumor tissue, 9399 and 10,296 transcripts respectively, were detected in all three groups. Importantly, a subset of transcripts was detected in only one or two ethnic groups allowing identification of ethnic-specific expression patterns in the matched normal/tumor tissue samples. We are completing this study by increasing sample size, matching for stage, mapping clusters of differentially-expressed genes in pathway analysis, and validation by real-time PCR. DNA copy number variation (CNV) will be investigated by high density SNP arrays. This preliminary analysis shows that: high quality gene expression data can be generated from FFPE samples, and ethnic specific gene expression differences can be detected in tumor and matched normal breast tissue samples across ethnic groups.

Questions raised by molecular genetic testing for Huntington disease: 10 years-experience of a reference diagnostic laboratory in Portugal. *I. Alonso[1,2], J. Cerqueira[2], E. M. Ramos[1], P. Magalhães[2], M. C. Costa[1], J. Pinto-basto[1,2], J. Sequeiros[1,2,3]* 1) Unigene, IBMC - Univ Porto, Porto, Portugal; 2) CGPP, IBMC, Univ. Porto, Portugal; 3) ICBAS, Univ. Porto, Portugal.

Huntington disease (HD) is a degenerative neurological disease, with autosomal dominant transmission, with onset usually in adulthood. It is clinically characterized by involuntary choreic movements, motor and cognitive impairment and behavioural changes. Its molecular defect is a $(CAG)_n$ expansion in the coding region of the HD gene, on 4p16.3. CGPP is the reference laboratory for routine testing of HD in Portugal, since 1998. We have performed 1,084 molecular tests for HD, over the last 10 years: 737 were requests for confirmation or exclusion of a clinical diagnosis; 320 were presymptomatic, and 16 were prenatal diagnostic tests. Proficiency testing has been evaluated every year, through the external quality assessment schemes of the European Molecular Genetics Network (www.emqn.org). Only 58.4% of all diagnostic requests were confirmed, as many came just for exclusion, in the differential diagnosis of HD. Among all presymptomatic tests, 40.3% of the subjects were found to be carriers; an excess of female consultands (65.3%) was observed. In the 16 prenatal tests performed, seven foetuses carried the mutation (one couple abandoned the counselling process, just before delivery of the test result). We found a full homozygote (with 41 and 51 CAGs), as well as three cases compound by one reduced-penetrance and one fully-mutated allele. Alleles of reduced penetrance (36-39 CAGs) were found in 24 cases. Normal homoallelism (two wild-type alleles of the same size) was seen in approximately 6% of all cases, and represents a major concern particularly in presymptomatic and prenatal testing. It requires the use of additional testing and techniques for the exclusion of a large expansion, which are continuously under development. Other important concerns, regarding genetic counselling, are the finding of large normal alleles, reduced-penetrance alleles, or a compound of these or of these with full expansions, as well as the presence of two expansions, particularly in patients already with offspring.

Molecular basis of Y-linked hearing impairment (DFNY1) in a Chinese pedigree. *C. Tyler-Smith[1], Y. Xue[1], -. Asan[1], Q. Long[1], D. J. Turner[1], F. Yang[1], M. Quail[1], B. L. Ng[1], N. P. Carter[1], H. Yang[2], Q. Wang[3]* 1) The Wellcome Trust Sanger Institute, Hinxton, UK; 2) Beijing Genomics Institute, Beijing, China; 3) Department of Otolaryngology, Head and Neck Surgery, Chinese PLA Institute of Otolaryngology, Beijing, 100853, China.

Y-linked hearing impairment has previously been described in a large Chinese family (Wang et al. (2004) J. Med. Genet. 41 e80). We have now investigated the molecular basis of this phenotype. We discovered an unaffected branch of the pedigree and used 67 Y-STRs to verify that it carried the same Y-chromosomal lineage, then set out to find mutational differences between affected and unaffected Y chromosomes. The two Y chromosomes were flow-sorted and completely resequenced using Solexa/Illumina paired-end reads. No sequence differences in protein-coding genes were found, but read-depth measurement indicated duplication of two discontinuous regions (adding up to about 0.5 Mb) in proximal Yp. Duplication was confirmed by high-resolution oligonucleotide array CGH, quantitative PCR, pulsed-field gel electrophoresis and fibre-FISH. The duplication has not been reported in individuals with normal hearing and maps to the same position on the pedigree as the hearing-impairment phenotype, so is likely to be causal. The only annotated protein-coding genes included in the duplicated region are part of the TSPY1 gene cluster.

Epigenetic changes in Friedreich ataxia are associated with altered CTCF binding in the FXN gene promoter. *I. De Biase, P. Rindler, Y. Chutake, S. I. Bidichandani* Biochemistry & Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Friedreich ataxia (FRDA) patients are homozygous for large expansions of a GAA triplet-repeat (GAA-TR) sequence in the FXN gene. The expanded alleles severely reduce FXN gene transcription, resulting in deficiency of the mitochondrial protein frataxin. The repeat induces heterochromatin formation in vivo. Hallmarks of silenced genes have been described in FRDA patient cells and transgenic mouse models, including increased DNA methylation and histone hypoacetylation and trimethylation. Pharmacological reversal of heterochromatin changes increases frataxin mRNA and protein levels. We show that the FXN gene promoter is a target for epigenetic changes that may allow the spreading of heterochromatin within this region. We identified a binding site for CCCTC-Binding Factor (CTCF), an established vertebrate genomic insulator, in the minimal promoter region of the human FXN gene, which is also conserved in P. troglodytes. CTCF acts as transcriptional insulator, organizing eukaryotic genes into domains. We confirmed the binding of CTCF to the frataxin promoter in vitro and in vivo using electrophoretic gel mobility shift assay, and chromatin immunoprecipitation (ChIP) followed by real-time PCR, respectively. Furthermore, CTCF binding to the FXN gene promoter was significantly reduced in two FRDA fibroblast cell lines versus two healthy control cell lines. There was no difference in the promoter methylation status between patients and controls, and in vitro methylation of the binding site did not alter CTCF binding, excluding this mechanism as responsible for the reduced CTCF binding. Furthermore, using ChIP analysis we found an increase in the trimethylation of histone H3 at lysine 9 and 27 specifically in the FXN gene promoter of FRDA patients, which strongly correlates with silenced chromatin. Our results indicate that the GAA expansion in FRDA alters CTCF binding in the FXN gene promoter, and a potential role for CTCF in regulating FXN transcription and local chromatin organization.

The ITMAT-Broad-CARE (IBC) array: a 50K candidate gene SNP array for large-scale CVD association studies. *B. J. Keating[1], S. Tischfield[2], T. Bhangale[3], S. S. Murray[4], T. S. Price[1], J. Barrett[5], M. I. McCarthy[5], M. R. Reilly[1], J. C. Engert[6], D. J. Rader[1], D. A. Nickerson[3], J. N. Hirschhorn[2], G. A. FitzGerald[1]* 1) Inst Translational Med/Therap, Univ Pennsylvania, Philadelphia, PA; 2) Broad Institute of Harvard & MIT, Cambridge, MA 02142, USA; 3) Dept of Genome Sciences, Uni. of Washington, Seattle, WA 98195, USA; 4) Scripps Genomic Medicine, 10550 North Torrey Pines Road, La Jolla, CA 92037, USA; 5) The Wellcome Trust Centre for Human Genetics, Uni. of Oxford, OX3 7BN, UK; 6) Dept of Medicine & Human Genetics, McGill Uni., Montréal, Québec, Canada.

A wealth of associations for CVD phenotypes has been accumulating, in particular a large number of loci derived from recent GWAS.True complex disease-associated loci often exert modest effects, so their delineation requires integration of diverse phenotypic data from large studies to ensure robust meta-analyses.We have designed a ~50K SNP array (Infinium, Illumina) to assess potentially relevant loci across a range of CVD syndromes.The array utilizes a cosmopolitan tagging approach to capture genetic diversity in ~2,100 loci in populations represented in HapMap & SeattleSNPs. The array content is informed by vascular & inflammatory disease GWAS, CVD implicated eQTLs & comprehensive literature searching.The custom flexibility of the array platform facilitated interrogation of loci at differing stringencies allowing saturation of higher priority loci with denser markers than existing GWAS tools.We demonstrate that the array can be used effectively in complementation with GWAS to increase coverage in high priority loci.Recent efforts show that CNVs can be accurately mapped on the platform using signal intensity metrics.Over 1500 loci are tagged at denser coverage than most commercial GWAS tools & we demonstrate multiple novel CNVs in these loci at high resolution using CNV calling algorithms including PennCNV. DNA from >200K extensively phenotyped individuals are being genotyped on the array (80K at time of press) with significant portions of data being released into the academic domain in 2008 facilitating in silico replication, analyses of rare variants, meta-analyses in diverse populations & epistasis.

Newborn Screening for Fragile X Syndrome and Sex Chromosome Aneuploidies by FMR1 DNA Methylation. *B. Coffee, T. Malone, K. Keith, J. Mowrey, S. T. Warren* Department of Human Genetics, Emory University, Atlanta, GA.

The vast majority of fragile X syndrome is due to aberrant changes in chromatin structure, as a consequence of CGG repeat expansion, resulting in the silencing of the FMR1 gene. One epigenetic change concomitant with CGG repeat expansion is DNA methylation of FMR1. We have developed a rapid, high-throughput and quantitative methylation-sensitive PCR method (Q-MSP) to assess FMR1 methylation in DNA from dried blood spots from newborn boys to screen for fragile X syndrome. An additional benefit of this method is that it will also detect numerical and structural sex chromosome aneuploidies, such as Klinefelter syndrome (47,XXY). The sensitivity of the Q-MSP method allows for the pooling of male samples, permitting the simultaneous screening of 44 males in a single experiment. Given the incidence of these abnormalities, the majority of these pools will screen negative requiring no further analysis, reducing the cost of screening substantially. Positive pools are then rescreened to identify the positive individual who is then verified, using PCR and Southern analyses on fresh DNA extracted from the original dried blood spot. An advantage of this approach is that Q-MSP directly detects abnormal FMR1 DNA and circumvents the problems with long CGG-repeat amplification. In addition, this approach specifically will not detect newborn males who are premutation carriers, and potentially at risk for fragile X associated tremor ataxia syndrome, as we consider it inappropriate to identify newborns at risk for adult neurodegenerative disease. To test the feasibility of his methodology for population screening, we have collected and are screening a cohort, currently consisting of 40,000 deidentified male blood spots, collected from the Georgia Public Health Laboratory. Using this approach we have identified positive individuals who were verified by secondary analysis to have fragile X syndrome or sex chromosome abnormalities. Preliminary prevalence estimates will be presented using the latest completed dataset.

Determination of Airway Epithelium Expression Levels of Glutathione S-transferase Subtype M by Copy Number Variation Polymorphisms. *N. Hackett, T. O'Connor, J. Salit, Y. Strulovici-Barel, R. Crystal* Dept Gen Med, Weill Cornell Med Col, New York, NY.

Smoking is the major risk factor for chronic obstructive pulmonary disease (COPD), but only 15-20% of chronic smokers develop the disease. Given that the initial manifestations of COPD occur in the small airway, we hypothesize that the gene expression patterns for protective and susceptibility genes in the small airway epithelium of smokers determines risk for COPD. Further, we propose that the gene expression level for these genes is genetically determined by polymorphisms including copy number variation in the vicinity of the gene. Glutathione is proposed to play a critical role in protection of the airway epithelium from oxidant damage and glutathione S-transferase polymorphisms have been reported to increase risk for COPD (J Zidzik et al, Croat. Med J 2008; 49:182). Genomic copy numbers in the vicinity of the glutathione S-transferase M gene cluster in chromosome 1 (nucleotides 110,000 - 110,085 kb) were determined using the Affymetrix Genome-Wide Human SNP Array 5.0. Gene expression levels were determined by analysis of airway epithelium mRNA levels on the Affymetrix Human Genome U133 Plus 2.0 microarray. Of our population of 86 smokers, 21% were observed to have deletions of both alleles encompassing approximately 30 kilobasepairs within the GSTM gene cluster. Expression levels for GSTM1 and GSTM3 in these subjects were significantly lower ($p<0.01$ both genes) than in subjects with at least 1 copy of the gene. By contrast, the expression level for flanking genes (GNAI3 and AHCYL1) were the same ($p>0.5$) for subjects with and without the GSTM deletions. Therefore, high frequency copy number variation polymorphism can dictate the expression levels of genes critical to the protection of the airway from smoking-induced oxidant damage. This suggests the link between GSTM polymorphisms and COPD is mediated by airway epithelial GSTM expression levels.

A novel 1p32 microdeletion in patients with abnormalities of the corpus callosum. *C. Haldeman-Englert[1], D. M. McDonald-McGinn[1], J. Coppinger[2], L. G. Shaffer[2], S. Kubendran[3], S. G. Kahler[3], P. L. Brock[4], G. C. Gowans[4], R. P. Matthews[5], E. H. Zackai[1], T. H. Shaikh[1]* 1) Human Genetics, Children's Hosp of Philadelphia, Philadelphia, PA; 2) Signature Genomics Laboratories, LLC, Spokane, WA; 3) Pediatrics, Univ of Arkansas for Medical Sciences, Little Rock, AR; 4) Univ of Louisville, Louisville, KY; 5) Gastroenterology, Children's Hosp of Philadelphia, Philadelphia, PA.

The introduction of microarray-based DNA analysis has greatly accelerated the discovery of many novel genomic syndromes. These rearrangements frequently lead to congenital anomalies and/or mental retardation by presumably altering the dosage of one or more genes. Using high-density oligonucleotide microarrays, we have identified overlapping *de novo* deletions of 1p32.2-p31.3 in three patients, each with micrognathia and a corpus callosum (CC) abnormality. Patients 1 and 3 have an absent CC, a cleft palate, and a structural cardiac defect. Patient 2 has thinning of the posterior CC, and also has a 15q11.2-q13.1 microdeletion of the Prader-Willi/Angelman syndrome region. The smallest overlapping deleted region is 371 kb and includes only one known transcript, *FGGY*. The function of this gene is unknown, but protein homology suggests that it may be involved in carbohydrate metabolism. To elucidate the function of this gene in normal development, we used the zebrafish as an animal model. Preliminary results using two morpholinos against *FGGY* show a similar abnormal phenotype, and studies are ongoing to further characterize these morphans. Another gene, *NFIA*, is also deleted in Patients 1 and 2. Haploinsufficiency of this gene has been previously reported in two patients with similar deletions and CNS abnormalities. After review of the literature, a total of 8 patients (including 3 patients from the present study) have been identified with deletions of this region. They appear to have variable clinical phenotypes but share similar CNS malformations with the CC commonly involved. Additional investigation of the genes in this region may provide further insight into these patients phenotypes as well as their role in early brain development.

Limb and craniofacial abnormalities and a patient with chromosome 1q21.2-21.3 deletion. *H. Vernon[1, 2], K. Johnson[2], V. Kottoor[1], E. Lisi[1], G. Cutting[1], D. A. S. Batista[3,4]* 1) Institute of Genetic Medicine; 2) Department of Pediatrics; 3) Department of Pathology, Johns Hopkins Hospital; 4) Kennedy Krieger Institue, Baltimore, MD.

We report a patient with multiple congenital anomalies and an interstitial deletion of chromosome 1q. The patient was born to a nonconsanguineous couple after an uneventful full term pregnancy. She was noted to have multiple dysmorphic features at birth. After further clinical investigation she was found to have multisystem organ dysfunction including: congenital heart defect (ventricular septal defect), craniofacial abnormalities (severe micrognathia and retrognathia, malar hypoplasia), renal abnormalities (multicystic dysplastic kidney), hematologic abnormalities (anemia) and skeletal abnormalities (bilateral small radii and ulnae, fused radius and ulna, unilateral absent thumb on left, fused on right, unilateral missing digit). A karyotype was performed and initially described as normal, 46, XX. A 4,200 BAC array-CGH was performed because an underlying genetic defect was strongly suspected. The patient was found to have a deletion of chromosome 1at bands q21.2-21.3. The size of the deletion was estimated to be between 2.3 and 5.6 Mb. After this deletion was found, chromosome 1 was re-examined in the karyotype, and in some elongated chromosomes a deletion could be suspected. Parental chromosome analysis is pending. A patient with similar clinical features and deletion of chromosome 1q12-1q21.3 was described previously (Waggoner et. al, 1999, Am J Med Genet 82:301-4). This patient had radial ray abnormalities, similar craniofacial abnormalities, and a cardiac defect. This region is also of particular interest because the suspected critical region for susceptibility for TAR (thrombocytopenia absent radius) syndrome is located on 1q21.1, which either overlaps or is immediately proximal to the centromeric area of the common region of these patients deletions. The discovery of a discrete deletion in our patient provides new evidence that the 1q21 region harbors genes responsible for radial limb development.

ALFRED: a resource for research and teaching. *K. K. Kidd[1], H. Rajeevan[1], K.-H. Cheung[2], U. Soundararajan[1], S. Stein[1], A. J. Pakstis[1], J. R. Kidd[1]* 1) Dept Genetics, Sch Med, Yale U, New Haven, CT; 2) Ctr Med Informatics, Sch Med, Yale U, New Haven, CT.

ALFRED (http://alfred.med.yale.edu) is a unique resource for research and teaching in human genetics and related areas. ALFRED is free, web-accessible, actively curated and GIS-enabled with links to ethnographic and molecular databases, and to the relevant literature. As of June 2008 ALFRED has data on 14,617 polymorphisms and 653 different populations(with multiple samples for 359 populations), a total of 277,127 frequency tables(one population sample typed for one site). 22 markers in ALFRED have frequency data on over 100 population samples; the 32bp Ins/Del in coding region of gene CCR5 has data on 226 different population samples. In the past year data from high throughput datasets have been added to ALFRED increasing the type and quantity of data considerably. This unique collection of allele frequencies has been integrated with other genetic databases by reciprocal URL links to and from PharmGKB, dbSNP and Genopedia HuGE Navigator. ALFRED description pages can be accessed from these resources. Mapping tables for gene identifiers (Entrez Gene ID, ALFRED UID) and polymorphism identifiers (dbSNP rsnumber, ALFRED UID) have been provided for ease of linking to ALFRED pages from other resources. This mapping information offers an immensely useful tool for researchers and bio-informaticists to map SNP/gene information obtained from NCBI to frequency data downloaded from ALFRED. Because earlier literature may have a SNP associated with a gene due to proximity but now is known to be in an adjacent gene, a polymorphism can be associated with a gene in many ways: as the primary locus, as also associated with, or as previously associated with. Fst and avg heterozygosity values for bi-allelic SNPs are pre-calculated and displayed in tables organized by chromosome. Individual locus values can also be viewed from each Polymorphism Description page. In addition to providing genotype summary data ALFRED now has a link to individual genotype data for several hundred SNPs on ~2000 individuals in 43 populations typed at Kidd Laboratory, Yale U. Support: US NSF BCS-0725180.

Folic acid supplementation during pregnancy in MTHFR c.1298CC homozygote mothers associates with an increased the risk of cleft lip and palate in the offspring. *M. Rubini[1], C. Baluardo[1], M. Ferrian[1], E. Calzolari[1], A. Franchella[3], M. Accordi[4], G. Garattini[2], R. Brusati[2]* 1) Eperimental and Diagnostic Medicine Dept. Medical Genetics Unit, University of Ferrara, Ferrara, Italy; 2) Maxillo-facial Surgery Dept., University of Milan, Milan, Italy; 3) Surgical Pediatrics Unit, Sant'Anna Hosp., Ferrara, Italy; 4) Phoniatric Center, Padova, Italy.

Folate metabolism plays a critical role in embryonic development, and folic acid (FA) supplementation during early pregnancy has been reported to reduce the risk for isolated cleft lip with/without cleft palate (CL/P) by a third. We used a case-parent triad design to determine if common variants in genes encoding folate enzymes were risk factors for CL/P and explore if folate supplementation during pregnancy interacts with mothers or childs genotype to modify the risk for CL/P. We analyzed 163 complete CL/P triads collected in Italy in the 1999-2002 period. All individuals were genotyped for MTHFR c.677C>T and c.1298A>C, MTR c.2756A>G, and MTRR c.66A>G variants. Association was assessed using transmission disequilibrium test (TDT) and relative risks of variant alleles in mother or child were calculated by log-linear Poisson regression model. Periconceptional supplementation with FA (alone or in multivitamins) was observed in only 8.6% of mothers, while in 27.6% cases FA administration begun after pregnancy ascertainment. None of the studied polymorphisms significantly associated with CL/P risk, but in MTHFR c.1298CC homozygote mothers the relative risk for CL/P was significantly increased ($p<0.0001$) when FA was administered at time of pregnancy ascertainment, while FA had no significant effect when supplementation begun before conception. In c.1298CC mothers FA administration during pregnancy was associated with a eight-fold increased relative risk for CL/P (RR = 7.98, 95%C.I. 3.45-18.4). Although FA supplementation in general reduces the risk of CL/P, this evidence suggests that in subgroup of cases beginning FA administration after pregnancy ascertainment might have opposite effect, and suggest that MTHFR c.1298A>C genotyping of mothers could be considered before administration of FA during pregnancy.

Prevalance of Slow Metablizing Cytochrome P450 CYP2C9*2 Allele in the Qatari Population may Impact Dosage of Warfarin. *T. O'Connor[1], N. Pereira[2], L. Chouchane[2], H. Sattar[3], M. Allangawi[3], A. Al-Mohammed[3], W. Ibrahim[3], T. Raza[3], M. Hamza[3], A. Al-Mulla[3], M. Al-Merri[3], A. Al-Hashemi[3], M. Al-Nesf[3], J. Geraghty[2], R. Mathew[2], A. Maayah[2], A. Gohar[2], N. Hackett[1], R. Crystal[1]* 1) Department of Genetic Medicine, Weill Cornell Med Col, New York, NY; 2) Weill Cornell Medical College-Qatar, Doha, Qatar; 3) Hamad Medical Corporation, Doha, Qatar.

Warfarin is a commonly prescribed anticoagulant drug that is used as a treatment for deep vein thrombosis and pulmonary embolism, and is also used prophylactically for the prevention of thromboembolic events that could arise following surgical procedures. Despite warfarins low cost and proven efficacy, there is considerable morbidity from warfarin therapy because of wide variation in the rates of metabolism of the drug. Based on the knowledge that the CYP2C9*2 and *3 alleles are poor metabolizers of warfarin (necessitating 15-30% lower dosage), and the knowledge that there are ancestral differences in prevalence (<1% Asians, 1-3% African-Americans, and 8-12% Europeans) of the CYP2C9*2 and *3 alleles, we asked: what is the prevalence of these alleles in the Qatari population, a population with a high rate of consanguinity that evolved from Arab, Persian and African populations? DNA extracted from blood samples of n=42 self-reported Qataris was assessed by TaqMan allelic discrimination assays (Applied Biosystems) for the CYP2C9*2 and CYP2C9*3 alleles. The analysis revealed a high prevalence of the CYP2C9*2 allele (frequency 0.16), compared to the prevalence of that allele in HapMap populations (frequency of 0.10 in European and absent in Chinese, Japanese and African). For the CYPC9*3 allele, the prevalence in the Qataris was 0.05, which is within the range of prevalence frequency in the HapMap populations (frequency of 0.04, 0.06, 0.03 and 0.00 in European, Chinese, Japanese, and African respectively). In neither case did the population genotype frequencies differ significantly from Hardy-Weinberg equilibrium ($p>0.2$). The Qatari population genotyped has a relatively high frequency of the CYP2C9*2 allele, an observation with clinical relevance to the use of warfarin in thromboses and in prophylactic applications in this population.

Method to Measure Global DNA Methylation. *D. Vassar* R&D, Genomics, Sigma-Aldrich Research Biotech, St Louis, MO.

It has been well demonstrated that DNA methylation plays an important role in the regulation of gene expression. Shifts away from normal global DNA methylation levels have been observed in various cancers, neurological disorders, autoimmune diseases, and aging. Several methods exist to measure global methylation levels but each have drawbacks including the cost of required equipment [i.e. mass spec methods], lengthy protocols [i.e. enzymatic degradation and analysis] and/or radioactive components. We have developed a new method, similar to a sandwich ELISA, which allows fast measurement of overall DNA methylation status. We utilize two models separately and in combination to demonstrate the utility of this new technique for global DNA methylation measurement. The first example employs representatives of the MicroRNA-29 family, which have been shown to decrease global DNA methylation in lung cancer cell lines. In addition, we have used decitabine, a well-known demethylating agent, to measure its effects on total DNA methylation in A549 cells. Both systems afford the expected levels of demethylation, and show the utility of this new, four-hour global methylation measurement method.

Association of CD14 Promoter Polymorphism with prostate cancer in men of African descent. *T. E. Mason[1], L. Ricks-Santi[1,6], V. Apprey[1], W. Chen[1], J. Joykutty[1], C. Ahaghotu[1,2], R. A. Kittles[3], G. Bonney[1,4], G. M. Dunston[1,5]* 1) National Human Genome Center at Howard University, Washington, DC; 2) Division of Urology, Howard University Hospital, Washington, DC; 3) Department of Medicine, University of Chicago, Chicago, IL; 4) Department of Community Health and Family Medicine, Howard University, Washington, DC; 5) Department of Microbiology, Howard University College of Medicine, Washington, DC; 6) Howard University Cancer Center, Washington, DC.

African American men have the highest rates of prostate cancer worldwide and immunogenetic studies suggest that people of African descent have increased susceptibility to diseases of inflammation. We hypothesize that sequence variants in the promoter region of the CD14 gene that regulate inflammation may modify individual susceptibility to prostate cancer. The CD14 promoter region was screened for SNPs using dHPLC. One variant, -260 C>T (rs2569190), was genotyped via restriction digest in all study participants (264 cases and 188 controls). Eleven variants (4 novel) were identified in the promoter region of CD14. A marginal association between the C allele and prostate cancer was found ($p=0.07$). When stratified by age, among men 55 years of age, the C allele was significantly associated with prostate cancer ($p=0.03$). When stratified by self-reported ethnicity, African-American men with the C allele were at a higher risk for Prostate Cancer ($p<0.05$) compared to those of African ancestry (Afro-Caribbean, Afro-Latino, East and West Africans). Here is the first study to show an association between the C allele in CD14 -260 variant and prostate cancer and supports the hypothesis that genetic variation in the inflammatory process can contribute to prostate cancer susceptibility. Our findings have interesting implications for the evolution of PRRs and regulation of the inflammatory response in health disparities. With the advent of genome-wide variation resources such as Hap Map offers unprecedented opportunities to investigate evolutionary forces that have shaped inherited variation in natural populations.

Microsatellite instability is not present in endometrial carcinoma cell lines after 2 and 4 Gy gamma irradiation.

Endometrial cancer (EC) is the commonest gynecological cancer in Europe and North America. Radiotherapy is the most effective conservative treatment for EC in women with high risk of surgery, though its efficiency is limited, as tumors exhibit different behavior and the appearance of resistant subpopulations upon relapse of an originally responsive malignancy can occur. In previous studies with lymphoblastoid cell lines [LB705 (normal), WI-L2-NS (TP53-/-) and LB463(XPG)] treated with ionizing radiation (), our group observed novel length alleles (microssatelite instability - MSI) in a TP53 *locus* marker and a decrease in the principal alleles height in the normal cell line. As these results suggest the emergence of radiation resistant neoplastic MSI+ mutant clones, we decided to investigate whether or not this phenomenon could be involved in the resistance to ionizing radiation in EC. So, matched tumoral and non-tumoral endometrial cells from 4 patients submitted to hysterectomy were established in culture. These cell lines were irradiated with the technetium isotope ^{99m}Tc at an effective dose of 2Gy and 4Gy. At days 0, 4, 8 and 12 post-irradiation the viability of the cells was determined with trypan blue and their MSI profile determined by amplification and fragment analysis of 5 mononucleotide repeats (NR-21, NR-24, NR-27, BAT-25 and BAT-26). A parallel control group of non-irradiated cell lines was also studied. The 4 tumors studied were all MSI- and no MSI was detected at any time post-irradiation, which contrasts with the results we found in XPG cell lines. Nevertheless, more cell lines are being irradiated in order to have a more representative picture of this carcinoma and to elucidate the mechanisms of its resistance to radiation. The generated results may allow the prediction of tumor responsiveness to radiotherapy and the adjustment of therapeutic protocols. M Alves is a post-doctoral fellowship from FCT.

Identification of GATA3 Regulated Transcription Factors in the Inner Ear. *D. Alvarado, R. Veile, M. Warchol, M. Lovett* Washington Univ, St Louis, MO.

The inner ear utilizes sensory hair cells as mechano-electric transducers for sensing sound and balance. In mammals, these hair cells lack the capacity for regeneration. However, hair cells from non-mammalian vertebrates, such as birds, can be regenerated throughout the life of the organism. Mutations in the zinc finger transcription factor GATA3 are known to cause sensory neural deafness in humans and we previously identified GATA3 expression differences in the cochlea and utricle. In the avian cochlea GATA3 is expressed throughout the sensory epithelia [SE]. However, expression is limited to the striola of the utricle. The striola corresponds to an abrupt change in morphologically distinct hair cell types and a 180 shift in hair cell orientation. To identify genes co-expressed with GATA3 in the utricle striola, we compared gene expression differences between the SE of the striola and the surrounding region of the extra-striola on a custom transcription factor microarray. We also gene expression profiled GATA3 siRNA knockdowns and GATA3 over-expression in avian utricle SE and confirmed several of the observed gene expression differences by RNA *in-situ*. We identified 27 known modulators of Wnt signaling, specifically numerous inhibitors of Wnt signaling were up-regulated in the striola and when GATA3 was over-expressed. These were down-regulated in GATA3 knockdowns. We also identified 12 FGF signaling genes and many known regulators of axonal guidance/ neurogenesis that are specific to the striola region and differentially regulated in response to GATA3 expression levels. To determine if the differentially expressed genes are directly regulated by GATA3, we performed ChIP in dissociated SE primary cells and identified GATA3 binding sites upstream of the LMO4 and muscleblind like 2 (MBNL2) genes. Together this evidence suggests that GATA3 plays an important role in local inhibition of Wnt signaling at the striola and that this process may be involved in specifying distinct sensory hair cell types. These observations will play an important role in understanding GATA3 regulation in the inner ear and its affects on human hearing disorders.

Individuation of new mutations in L1CAM gene in patients with L1 diseases. *F. Boaretto[1], C. Bertolin[1], G. Vazza[1], L. Garavelli[4], E. Della Giustina[2], M. T. Divizia[3], A. Vettori[1], M. L. Mostacciuolo[1]* 1) Dept. Biology, University of Padova, Italy; 2) Dept. of Neuropsychiatry, Hospital of Reggio Emilia, Reggio Emilia, Italy; 3) Gaslini Institute, University of Genova, Genova, Italy; 4) Dept. of Pediatrics, Hospital of Reggio Emilia, Reggio Emilia, Italy.

Backgroung: L1CAM (Neural cell adhesion molecule L1) is a gene highly conserved in mammals and in other species, suggesting an important functional role for this adhesion molecule. Mutations of L1CAM are responsible for X-linked syndromes, including different diseases that can be associated with CNS malformations. The most frequent is the Hydrocephalus secondary to Stenosis of the Aqueduct of Sylvius (HSAS, MIM 307000) but also a severe condition such as MASA (Mental retardation, Aphasia, Shuffling gait, and Adducted thumbs. MIM 307000) has been described. Materials and methods: We identified a sample of subjects with specific severe phenotype characterized by following major features: hydrocephalus, mental retardation, spasticity of the legs, and adducted thumbs. By direct sequencing, these patients have been investigated for mutations in the coding regions of the L1CAM gene. Results: Three new mutations have been detected in three uncorrelated patients. The first one is a novel missense mutation within exon 1 (c.25T_A), leading to an amino acid substitution (p.W9R) in codon 9. The other two nucleotidic changes are frameshift mutations (c.670delC, c.2410insA) resulting in premature stop codons respectively in exons 6 (codon 224) and exon 18 (codon 804). Interestingly both the identified mutations are located in the extracellular portion of the mature protein, which is involved in homo- and heterophilic protein-protein interactions. Conclusions: MASA syndrome is an extremely rare, severe condition associated with both missense and frameshift mutations of L1CAM gene.

Characterization of Neuronal Storage in the Mucolipidosis Type IV Murine Model. *C. Curcio-Morelli[1], B. Venugopal[1], M. F. Browning[1], J. Pickel[2], S. U. Walkley[3], S. A. Slaugenhaupt[1]* 1) Center for Human Genetic Research, Harvard Medical School, Boston, MA; 2) NIMH Transgenic Core, National Institutes of Health, Bethesda, MD; 3) Dominck P. Purpura, Albert Einstein College of Medicine, Bronx, NY.

We have recently reported the first murine model for MLIV, which accurately models most phenotypes seen in MLIV patients. Here we characterized the cellular storage phenotype in Mcoln1-/- mice in both fibroblasts and embryonic neuronal primary cultures. Fibroblasts established from both Mcoln1-/- embryos and post-natal day four pups showed a defect in trafficking after incubation with BODIPY- FL ceramide, as previously described in human MLIV fibroblasts. Analysis of fluid-phase endocytosis showed an increase in the number and size of FITC-dextran-labeled structures in Mcoln1-/- fibroblasts when compared with Mcoln1+/+, suggesting that the endocytosed material is accumulated and/or fluid phase endocytosis is increased in MLIV. The availability of the Mcoln1-/- mouse model allows, for the first time, characterization of cellular phenotypes in neurons. The Mcoln1-/- mice present with numerous dense inclusion bodies in all cell types in brain and particularly in neurons. Mcoln1-/- embryonic E15 neuronal primary cultures (E15NPC) revealed intense staining of acidic vesicles after lysotracker staining. Electron microscopy of E15NPC showed the presence of several concentric membranes in the cytoplasm (zebra bodies). Recently it was suggested that the storage in human MLIV fibroblasts could be rescued with low-dose chloroquine treatment, and therefore we investigated the effects of chloroquine on Mcoln1-/- neuronal cells. E15NPC were treated with 10 nM chloroquine for 4 days and lysotracker staining showed an increased number of acidic vesicles in Mcoln1-/- after treatment. Electron microscopy revealed enlarged, multi-vesiculated storage bodies, suggesting that chloroquine is unlikely to resolve neuronal storage. The presence of storage bodies in neurons established from embryonic stages of MLIV mice provides us with an excellent tool to test strategies and potential drugs aimed at ameliorating this neurological disorder.

The mitochondrial protease AFG3L2, a key player in axonal development and cerebellar degeneration. *G. Casari[1], F. Maltecca[1], L. Cassina[1], G. A. Cox[2], J. L. Guenet[3], A. Quattrini[1]* 1) Dept Dibit, Vita-Salute San Raffaele Univ, Milan, Italy; 2) The Jackson Laboratory, 600 Main Street, Bar Harbor, ME 04609, USA; 3) Institut Pasteur, 25 Rue Du Docteur Roux, 75724 Paris CEDEX 15, France.

Axonal degeneration of the longest motor and sensory axons is the main pathological feature of hereditary spastic paraplegia (HSP). Mutations of paraplegin, a nuclear-encoded mitochondrial metalloprotease, cause a recessive form of HSP. We showed that paraplegin co-assembles with a highly homologous protein, AFG3L2, to form a functional complex (the m-AAA protease) in the inner mitochondrial membrane. Lack of this complex in HSP primary fibroblasts causes a reduced complex I activity and an increased sensitivity to oxidative stress. The paraplegin mouse model partially recapitulates what observed in patients, showing a slowly progressive axonal degeneration. We are characterizing two different mutant mouse models defective in Afg3l2. In spite of the close functional association of AFG3L2 with paraplegin, either Afg3l2 mutation leads to a more severe neurological syndrome. Actually, both Afg3l2 mutants show a dramatic neuromuscular phenotype beginning at P7 with hindlimbs paraparesis which progresses until complete tetraparesis and death, generally at P16-18. Morphological analysis shows a marked impairment of axonal development with delayed myelination and poor axonal radial growth. The presence of morphologically altered mitochondria and the highly reduced enzymatic activities of the respiratory chain denote the mitochondrial origin of the disease. Moreover, Afg3l2 mutation severely affects cerebellum, which is spared in paraplegin-deficient mouse. Interestingly, the critical region associated to the recently reported spinocerebellar ataxia type 28 locus (SCA28) includes few neural genes and, among these, AFG3L2. This evidence, together with the cerebellar phenotype of the Afg3l2 mutant mice, points to AFG3L2 as the excellent candidate for this disease.

Genome-wide association for cognitive ability and overlap with results from Alzheimers disease. *Q.-R. Liu[1], T. Drgon[1], C. Johnson[1], P.-W. Zhang[1], D. Walther[1], J. Hess[2], K. Bolla[3], J. L. Cadet[4], C.-Y. Li[1,5], M. Nino[1], G. R. Uhl[1]* 1) Molecular Neurobiology Branch, NIDA/NIH, Baltimore, MD; 2) Office of the Clinical Director, NIH-IRP (NIDA), 333 Cassell Drive, Suite 3510, Baltimore MD 21224; 3) Department of Neurology, Johns Hopkins Bayview Medical Center, Baltimore MD 21224; 4) Molecular Neuropsychiatry Branch, NIH-IRP (NIDA), Baltimore MD 21224; 5) Center for Bioinformatics, National Laboratory of Protein Engineering and Plant Genetic Engineering, College of Life Sciences, Peking University. Beijing, China 100871.

Classical genetics documents substantial heritable components that underlie individual differences in human cognitive abilities. However, only little information documents which gene variants are likely to contribute to these individual differences or the ways in which these differences could contribute to interactions between cognitive abilities and vulnerabilities to Alzheimers disease (AD). We have used genome-wide association (GWA) with 1M SNP arrays to seek haplotypes that could contribute to individual differences in an assessment of general cognitive ability in each of three samples of research volunteers. We have also sought convergence of these results with data from two previously reported GWA studies of AD. We have identified replicable results from the three cognitive function samples that converge much more than expected by chance. These results identify cognitive function genes in a number of classes, including many whose allelic variants are likely to influence neuronal connectivities. Results from each of two reported AD GWA studies also converge much more than expected by chance. Findings are generalizable, since the cognitive function results fit remarkably well with those for AD. Effects at each individual gene locus are modest. Nevertheless, the data provide strong molecular genetic support for classical genetic results concerning the heritabilities of cognitive abilities and AD and novel support for shared genetic influences on both phenotypes. The data add to evidence that variants in genes that alter neuronal connectivities influence a number of brain phenotypes and disorders.

Pharmacological chaperone treatment for Pompe disease. *J. J. Flanagan, H. V. Do, X. Wu, A. C. Powe, R. Khanna, B. Ranes, K. Tang, C. Pine, H. Williams, R. Soska, L. Pellegrino, J. Feng, M. Zdancewicz, E. R. Benjamin, B. A. Wustman, K. J. Valenzano, D. J. Lockhart* Amicus Therapeutics, Cranbury, NJ.

Pompe disease is caused by deficient acid alpha glucosidase (GAA) activity which impairs lysosomal glycogen metabolism. The enzyme deficiency leads to lysosomal glycogen accumulation and results in progressive skeletal muscle weakness, reduced cardiac function, respiratory insufficiency, and CNS impairment at late stages of disease. Genetic mutations in the GAA gene result in either lower expression or produce mutant forms of the enzyme with altered stability, and/or biological activity ultimately leading to disease. Pharmacological chaperones represent a promising new therapeutic approach for the treatment of genetic diseases. In this study, we show that the pharmacological chaperone AT2220 (1-deoxynojirimycin-HCl) binds to mutant GAA and increases its stability. In Pompe patient-derived fibroblasts and in transiently transfected COS-7 cells expressing certain GAA missense mutations, AT2220 significantly increases GAA levels. AT2220 also increased GAA levels in disease-relevant tissues of wild-type mice, rats and monkeys suggesting that AT2220 may be appropriate for Pompe patients with the common IVS 1 (-13 T>G) splicing defect which produces low levels of wild-type GAA. In cell lines derived from late-onset Pompe patients with this common splicing mutation, AT2220 increased GAA levels. We are also investigating the ability of AT2220 to improve the biological properties of enzyme replacement therapy. In rats, the plasma half-life of recombinant human GAA (rhGAA) increased 2-fold when AT2220 (30 mg/kg p.o.) was administered 30 minutes prior to rhGAA injection. In GAA KO mice, the uptake of rhGAA was increased approximately 2-fold in heart and diaphragm when AT2220 (100 mg/kg p.o.) was administered prior to rhGAA injection. These data indicate that co-administration of a pharmacological chaperone with rhGAA may increase the enzymes exposure and tissue uptake in vivo.

Genome-wide association scan for genetic determinants of warfarin dose. *R. McGinnis[1], F. Takeuchi[1], S. Bourgeois[1], N. Soranzo[1], V. Ranganath[1], N. Eriksson[2], J. Lindh[3], A. Rane[3], M. Wadelius[2], P. Deloukas[1]* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Department of Medical Sciences, Clinical Pharmacology, University Hospital, Uppsala, Sweden; 3) Clinical Pharmacology, Karolinska Institute, Campus Huddinge, Stockholm, Sweden.

Warfarin is an anticoagulant that is the most widely prescribed therapy for reducing thromboembolic events that often give rise to stroke, deep vein thrombosis, pulmonary embolism or serious coronary malfunctions. A combination of genetic and non-genetic factors cause Caucasians to exhibit 10-fold interindividual variation in required dose (RD) needed for the usual therapeutic level of anticoagulation (2.0-3.0 PT INR). Thus, in the absence of information (genotypic, clinical, etc.) for predicting each patient's RD, initial prescribed doses may be too low (risking failure to protect the patient) or too high (risking over-anticoagulation and severe bleeding). We were among the first to show that polymorphism in the warfarin drug target (VKORC1) accounts for a major portion (~30%) of the variance in RD and have recently evaluated 1523 Swedish patients from the Warfarin Genetics (WARG) cohort in the largest study to date showing likely patient benefit from genetic forecasting of RD (Wadelius et al. Blood, in press). This study confirmed that SNPs in VKORC1 and CYP2C9 predict at least 40% of RD variance while non-genetic factors (age, gender, etc.) jointly account for another ~15%. We are now searching for additional genetic predictors of RD in a large-scale genome-wide association study (GWAS) of 370,000 SNPs (Illumina 370K) genotyped in >1,000 WARG patients. Our initial GWAS results based on both single marker and haplotype analysis identified CYP4F2 as at least one additional genetic predictor of RD and we have replicated this finding in a further 600 samples (combined p-value of 8.9×10^{-10}). We will show that detection of additional genetic predictors critically depends on the statistical technique applied, and will also report on the analysis of CNVs and on additional warfarin-related phenotypes (e.g. over-anticoagulation).

Variants in Neuroligin Pathway Genes and Autism Spectrum Disorder. *K. Steinberg[1,2], M. Zwick[1]* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Graduate Program in Population Biology, Ecology and Evolution, Emory University, Atlanta, GA.

Neuroligins are cell adhesion molecules important in the post-synaptic density. Recent studies demonstrate that mutations in the X linked genes neuroligin 3 (NLGN3) and 4X (NLGN4X) contribute to autism spectrum disorder (ASD). However other studies failed to find these associations in individuals with ASD. To comprehensively survey the common and rare variation in these regions, we are resequencing NLGN3 and NLGN4X in individuals from families with two or more affected male sibpairs from the Autism Genetic Resource Exchange (AGRE). Affected male sibpairs were chosen based upon sharing identical markers near NLGN4X (DXS9895 and 9902). One male from each sibpair was selected for resequencing. The fathers of the affected sibpair were selected as unaffected controls. Sequence data from the 101 affected males and their matched controls will be presented. Target DNA, isolated with Microarray-based Genomic Selection (MGS), was hybridized to a custom designed high density resequencing array containing unique coding and non-coding sequences from NLGN3 and NLGN4X, and coding sequences from neurexin-1beta (NRXN1b) and SHANK3. A total of 59.5 Mb of sequence was generated with an average conformance of 92.6% and average call rate of 90.9%. SNPs identified in our study are partitioned into functional classes (UTR, silent, replacement, intron, intergenic) and compared within and between these classes. We have identified 136 replacement SNPs that have been evaluated for evolutionary conservation using the phastCon program, severity of functional mutations using the SIFT program and presence or absence from dbSNP. We are currently in the process of validating these SNPs using traditional Sanger sequencing and will present the results of our analysis.

Clinical, Biochemical and Molecular Characterization of a Family with Hepatoerythropoetic Porphyria. *J. L. Cohen[1], L. Liu[1], D. Doheny[1], J. L. Cantatore-Francis[2], J. V. Schaffer[2], R. J. Desnick[1], M. Balwani[1]* 1) Dept. Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York; 2) Dept. Dermatology, NYU School of Medicine, New York.

Porphyria Cutanea Tarda (PCT) is an autosomal dominant inborn error of heme biosynthesis which results from decreased hepatic uroporphyrin decarboxylase (UROD) activity (<30% of nl). A familial form is caused by heterozygous mutations in UROD, while Hepatoerythropoietic Porphyria (HEP) is the very rare autosomal recessive form of PCT. We report a non-consanguineous family of Puerto Rican/Dominican descent, in which both parents and two children have PCT, and three have HEP of varying severity. The proband, a 7 year old girl, presented with photosensitivity and blistering/scarring lesions on the dorsum of hands, skin fragility, hypertrichosis of the face, and onycholysis. She had anemia and dark colored urine, but denied abdominal pain or neurologic symptoms. Two symptomatic siblings had similar manifestations. Lab studies showed normocytic anemia, increased urine total porphyrins >6,000 (nl 0-300) nmol/24h (primarily uroporphyrin and heptacarboxylporphyrin), and normal ALA and PBG levels. Plasma total porphyrins and protoporphyrins were elevated with fluorescence at 619 nm, suggestive of HEP. Erythrocyte UROD activity was markedly decreased. Similar, but milder findings were noted in the other affected siblings. UROD sequencing of the probands genomic DNA revealed a deletion, 645del1053ins10, and a novel missense mutation, V166A. The mother had the deletion, the father the missense mutation. The two asymptomatic siblings were heterozygous for V166A. HEP has clinical manifestations similar to Congenital Erythropoetic Porphyria, including skin lesions, splenomegaly, and hemolytic anemia. Sun protection is the key to avoidance of severe scarring. Therapeutic options are limited and the long term natural history of this rare disorder is unknown. The three affected HEP children with the same genotype varied phenotypically, having mild to severe cutaneous involvement, anemia, and accumulated porphyrin levels, emphasizing the variable intra-familial expression in this rare disorder.

Polymorphisms in the promoter region of Nrf2 and association with systemic lupus erythematosus, juvenile, rheumatoid arthritis and asthma. *E. J. Cordova[1], V. Baca[2], J. Ramírez[1], S. Jiménez[1], R. Velázquez[1], F. Centeno[1], L. Orozco[1]* 1) Investigación, Instituto Nacional de Medicina Genómica, Mexico D.F; 2) Centro Médico Nacional, Siglo XXI, IMSS.

The Nrf2-Keap1 pathway is one of the main mechanisms against xenobiotics and oxidative stress. The Nrf2 transcription factor is required for both basal and inducible expression of a number of genes encoding antioxidant, detoxificant and immune associated enzymes. Expression of Nrf2-dependent genes confers cellular protection from different environmental insults. Murine models have highlighted the participation of Nrf2 in systemic lupus erythematosus and asthma. The -653G/A and -617C/A SNPs, in the 5' regulatory region of NRF2 gene, have been associated with an increased risk for gastric mucosal inflammation, acute lung injury and aberrant DNA methylation in gastric epithelium. The aim of this study is to determine whether NRF2 SNPs are associated with systemic lupus erythematosus (SLE), juvenile rheumatoid arthritis (JRA) and asthma. Three hundred patients with SLE, 250 with asthma and 129 with JRA were enrolled into the study. In addition 300 unrelated healthy subjects without immune and inflammatory diseases were also included. All the subjects were recruited from four tertiary level Institutions from Mexico City. Allelic discrimination was performed by TaqMan assay and Fluorescent Fragment Analysis. The association test, Hardy-Weinberg equilibrium (H-WE) and haplotypes were determined using EPIDAT, FINETTI and Haploview softwares, respectively. Genotype distribution in cases and controls were in H-WE. Our results did no show evidence of association of NRF2 gene with any of the three studied diseases. However, when we explored the possible association between these SNPs with lupus nephritis, we could observe that the frequency of heterocygote -650C/A SNP was significantly lower in SLE female cases without nephritis than those with nephritis. Interestingly, our results suggest that in Mexican population this gene confers suceptibility to develop lupus nephritis and it seems that it is in a gender-dependent manner.

Outcome of genetic test result review in the DuchenneConnect Registry. *V. Rangel Miller[1], W. A. Faucett[1], K. Loud[1], M. Hegde[1], G. Spinella[2], P. Furlong[2]* 1) Dept of Human Genetics, Emory University, Decatur, GA; 2) Parent Project Muscular Dystrophy, Middletown, OH.

Purpose: In Duchenne/Becker muscular dystrophy (DBMD), well-characterized mutations are necessary to evaluate eligibility for therapeutic trials using molecular genetic corrective approaches. Despite advances in genetic testing, many patients do not have results that provide adequate mutation information. DuchenneConnect is a self-report patient registry, developed to connect the patient, provider and research communities and to facilitate participation in research opportunities. We present the frequencies of genetic testing, informative test results and the need for further testing among registry participants. We emphasize the availability of registry data to researchers for use in prospective study design, feasibility planning and patient recruitment. **Methods:** We developed a web-based survey stored in a HIPAA-compliant database to capture patients clinical presentation and *DMD* mutation. Molecular test results are reviewed by trained genetic counselors and geneticists and compared to the Leiden database. Design of the survey and review of the data follows guidelines employed by other North American DBMD registries and the TREAT-NMD Neuromuscular Network. **Results:** Of 970 participants to date, 507 completed a survey of which 84% had genetic testing, 8% had a muscle biopsy alone, 6% did not have testing and 2% did not know. From preliminary test result curation, 69% were informative, 20% warranted further mutation characterization and 11% had research results that needed clinical laboratory confirmation. In total, 42% of participants were eligible for additional testing. **Conclusion:** New therapies are being developed utilizing specific molecular genetic corrective approaches. A substantial number of participants do not have well characterized mutations and will need additional molecular testing to determine their eligibility for clinical trials. The improved mutation characterization of participants in the registry will provide critical data for researchers to identify potential participants and obtain data for study design and planning.

A submicroscopic tandem duplication in 6p21.2, including *KCNK16* and *KCNK17*, in a 10-month-old girl with an intractable epilepsy. *M. Nesteruk[1,2], B. C. Lanpher[3], Z. Xia[1], S. W. Cheung[1], P. Stankiewicz[1]* 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 3) Vanderbilt Children's Hospital, Nashville TN.

Recent studies have indicated a genetic contribution to epilepsy in ~40% patients. Seizures can be inherited in a Mendelian, non-Mendelian, or complex trait fashion. In the majority of identified cases, the pathogenic mutations have been found in genes encoding subunits of ion channels. We present a 10-month-old girl with intractable epilepsy, including infantile spasms, in whom, using a clinical targeted oligonucleotide array-CGH V6.5 (Agilent, 44K), we identified a submicroscopic duplication in 6p21.2, involving three potassium channel genes: *KCNK5*, *KCNK16*, and *KCNK17*. The same duplication was detected in the patients mother, who as a child had delayed motor development with no episodes of epilepsy. Interestingly, Sáez-Hernández et al. (2003) reported a balanced translocation t(4;6)(q35;p21) with a 6p21 breakpoint mapping 3.5 kb upstream to *KCNK16* in two sisters and their mother, wherein only the sisters manifested the idiopathic generalized epilepsy. Whole-genome array CGH analysis with ~385,000 oligonucleotide probes (NimbleGen) allowed breakpoint sequencing with help of long range PCR. The duplication is 280,796 bp in size, tandem in orientation, and contains entire *KCNK16* and *KCNK17* and exon 1 of *KCNK5*. We found a 5.6 kb LINE-1 retrotransposon element L1PA11 and six nucleotide insertion at the junction fragment, indicating a nonhomologous end joining (NHEJ) mechanism of formation. Supporting this, recently, Korbel et al. (2007) and Kidd et al. (2008) identified retrotransposons in one third of the CNV breakpoints. We suggest that the epilepsy in our patient is due to an increased dosage of *KCNK16* that could be imprinted, similarly as another recently reported member of the potassium channel family, *KCNK9*.

Identification of copy number variants implicated in the development of neural tube defects. *K. Soldano[1], A. Dellinger[1], D. S. Stamm[2], A. Trott[1], N. Ellis[1], D. G. Siegel[1], H. Cope[1], P. Xu[1], C. F. Potocky[1], C. S. Haynes[1], T. M. George[3], A. E. Ashley-Koch[1], S. G. Gregory[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) University of California, Davis School of Medicine, Sacramento, CA; 3) Dell Children's Medical Center of Central Texas, Austin, TX.

Neural tube defects (NTDs) are among the most serious congenital birth defects and result from the neural tube failing to close during the first three to four weeks of fetal development. NTDs are a phenotypically heterogeneous group of disorders with a large spectrum of clinical presentation and degree of impairment. The most common NTD presentations are lumbosacral myelomenginocele (also known as spina bifida) and anencephaly. In the US, spina bifida and anencephaly occurs in 19.6 per 100,000 live births and 10.4 per 100,000 live births, respectively. Non-syndromic NTDs comprise the majority of NTDs, and are thought to have a multifactorial etiology with a complex interplay of genetic and environmental factors. We recently completed a genome wide association screen (GWAS) of 50 families affected with cranial NTDs using the Illumina Infinium HumanHap300 genotyping microarray. As part of this analysis we used the GWAS data to identify copy number variants (CNVs), genomic deletions or duplications, which may harbor genes that contribute to NTDs. This was achieved using Nexus Copy Number software (BioDiscovery, Inc.). The most interesting findings amongst the detailed analysis, consisting of 49 anencephaly affected individuals, 2 affected siblings, 36 unaffected siblings and 50 parents, were de novo rearrangements containing ERBB4 and CNTNAP2, and familial CNVs that were independent of known CNVs in the AKT3 gene. Genomic rearrangements were also detected in HDAC9, FRG2C, and the KIR gene cluster although those genomic regions contain known CNVs. AKT3, CNTNAP2, HDAC9 and ERBB4 could be relevant to the etiology of NTDs because they are expressed in the fetal brain and may play a role in the developing neural tube.

Association between GP6 polymorphisms and coronary heart disease in a community-based population: The Western New York Acute Myocardial Infarction Study. *J. Shaffer[1], C. Kammerer[1], L. Iacoviello[2], M. Trevisan[2], R. Ferrell[1], R. Donahue[2]* 1) U Pittsburgh, Pittsburgh, PA; 2) U Buffalo, Buffalo, NY.

Chronic inflammation, collagen-induced platelet aggration, and endothelial dysfunction are risk factors for acute myocardial infarction (MI). The genetic contributions to cardiac disease that involve these and other pathways have been understudied, especially in community-based samples. From 1995-2001, The Western New York Acute MI Study identified survivors of acute MI from hospitals in Erie and Niagara Counties and matched them with an equal number of apparently healthy community-based controls on sex and age (1 year). 756 cases and 751 controls (comprising 1168 men aged 35-70 and 339 post-menopausal women) were genotyped for 31 functional single nucleotide polymorphisms (SNPs) in 24 loci involved in inflammation, collagen content, and endothelial function pathways. Using logistic regression, while simultaneously adjusting for several covariates (age, sex, body mass index, hypertension, high cholesterol, smoking status, diabetes, and family history of heart disease), we tested for an association between each SNP and MI status. A missense SNP (minor allele frequency [MAF]=0.16) in GP6, a glycoprotein receptor for collagen found in platelets, was associated with MI after permutation-based adjustment for multiple testing (OR=0.70; p=0.002; adjusted p=0.068). We further investigated the role of GP6 in risk for MI by genotyping and testing 4 additional intronic SNPs spanning the GP6 gene, all of which are in low linkage disequilibrium (r^2=0.00 to 0.51) with the missense SNP and with each other. One of these additional GP6 SNPs was also associated with MI (OR=0.75; p=0.004; MAF=0.22). Haplotype analysis of GP6, while confirming the SNP-wise associations, did not yield evidence that any specific haplotype(s) accounts for the observed associations. Overall, these findings suggest genetic variants in GP6 may predispose for MI through its activating role in platelet aggregation. Identification of the genetic risk factors for MI may lead to a better understanding of disease etiology and possible therapeutic interventions for cardiac disease.

Kinetin treatment in transgenic mice carrying mutant human *IKBKAP*: A model for treating human splicing disease. *R. S. Shetty[1, 2], Y. T. Chen[1, 2], M. M. Hims[1, 2], J. Mull[1, 2], M. Leyne[1, 2], L. Liu[1, 2], J. Pickel[3], S. A. Slaugenhaupt[1, 2]* 1) Center for Human Genetic Research, MGH , Boston, MA; 2) Harvard Medical School, Boston, MA; 3) National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

The study of human genetic disease highlights the importance of mRNA splicing, as 20-30% of all disease causing mutations result in splicing defects. The plasticity of the splicing reaction has made these mutations attractive candidates for the development of therapeutics, since a slight shift in isoform ratios can lead to dramatic phenotypic improvement. In Familial Dysautonomia (FD), a severe neurodegenerative disorder, all patients have an intronic splice site mutation (IVS20+6T>C) in the *IKBKAP* gene (FD *IKBKAP*), which results in tissue-specific skipping of exon 20. Although FD is a recessive disease, homozygous mutant cells express wild-type *IKBKAP* transcripts, and produce normal IKAP protein. The relative amount of wild-type and mutant *IKBKAP* mRNAs varies between tissues, with the lowest levels of wild-type *IKBKAP* production in tissues from the nervous system. Recently, we created transgenic mouse lines using BACs containing human *IKBKAP* carrying the same intronic splice mutation present in all FD patients. These humanized FD *IKBKAP* transgenic mice exhibit the same tissue-specific aberrant splicing pattern of as the FD patients. We have previously shown that plant cytokinin kinetin can significantly improve the production of normal *IKBKAP* transcripts in FD lymphoblast cell lines. In this study we tested the ability of kinetin to alter *IKBKAP* splicing in vivo by treating transgenic mice by oral gavage or dietary supplementation. Treatment with kinetin modifies splicing in all tissues assayed in the FD *IKBKAP* transgenic mice, including brain. These exciting results prove that dietary supplementation with kinetin holds great promise as a potential therapeutic for FD.

Exhaustive search for two-locus interactions in genome-wide association study of Crohns disease. *T. Bhangale, L. Cardon* Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA.

Simulation studies suggest that searches for two locus interactions (TLI) using regression models are computationally feasible for the large-scale datasets involved in genome-wide association studies (GWAS) and can be more powerful than single locus approaches. While an exhaustive search for TLI using a genome-wide dataset is possible, it involves several computational challenges: the time required to perform billions of tests and memory and storage requirements. Results of such an analysis have so far not been reported. We developed a computer program that uses parallel computing and data compression methods to overcome these difficulties to analyze GWAS datasets for all TLI by performing a likelihood ratio test for the fit of the full logistic regression model (up to 9 parameters). We apply the method to Wellcome Trust Case Control Consortiums Crohns disease data. Since the test will detect main and/or interaction effects, even after applying the conservative Bonferroni correction, 3983679 pairs showed significant association. We analyzed these pairs further to find those that showed interactions over and above the main effects and discovered 17 new such potential TLI. We verify the previous simulation-based findings that two-stage approaches that only test for interactions among the SNPs with large marginal effects, are not as powerful as an exhaustive search. We find that an association study for TLI faces new difficulties e. g. possible failure of imputation methods at interacting loci due to their reliance on reference haplotypes (similar to control haplotypes) as TLI imply a difference in LD between the interacting loci in cases and controls; poorly understood genotyping artifacts that lead to false positive TLI despite clear clusters on the scatter plots of signal intensities for the two alleles; and difficulties in performing permutation tests. It is likely that current GWAS, which are mainly focused on the marginal effects of SNPs, will soon be followed by scans for TLI. In this work we provide one possible framework for doing such analysis and illustrate the type of results and quality control issues that are likely to be encountered.

Trisomy X in dogs, humans, and other species. *U. Prociuk[1], V. Meyers-Wallen[2], M. E. Haskins[1,3], M. L. Casal[1]* 1) Section of Medical Genetics, Veterinary Hospital Univ of PA, Philadelphia, PA; 2) Dept. of Biomedical Sciences, College of Veterinary Medicine, Cornell University, Ithaca, NY; 3) Dept.of Pathobiology, School of Veterinary Medicine Univ of PA, Philadelphia, PA.

First described as a super female Trisomy-X is one of the most common chromosomal sex abnormalities seen in humans. This syndrome is a form of chromosomal variation characterized by the presence of an extra X chromosome which occurs in one of every 1002 newborn girls. Most women with Trisomy X are asymptomatic and thus indistinguishable from normal XX females unless karyotyping is performed. While this syndrome rarely causes any unusual physical features or medical problems in humans, females with trisomy X may have low birth weight, menstrual irregularities, are taller than average and rarely exhibit severe mental impairments with an increased risk of learning disabilities, delayed speech and language skills. Trisomy X females have normal sexual development and are able to conceive children. Trisomy X has been recognized in a variety of other species animals such as dog, cat, cattle and horse, mice and river buffalo. As in humans, most animal species presented here were essentially normal on physical examination with the exception of abnormal external genitalia in one dog and small stature in a cat and one cow. Delayed puberty, primary amenorrhea/primary anestrus, and irregular cycles have been described in all affected species including humans. A common finding in both humans and animals is the presence of ovarian dysgenesis and infertility, which was the main reason for cytogenetic studies. Previously, only three cases of trisomy X have been described in dogs with persistent anoestrus. We have identified and present here two cycling dogs that were examined for infertility in which karyotyping revealed trisomy X. Many women and some animals with trisomy X cycle and can conceive. As the incidence of trisomy X is fairly high in humans, it is likely underdiagnosed in animals underscoring the value of karyotyping in companion animals.

Polymorphisms in the MYH9 gene are associated with non-diabetic ESRD in African Americans. *M. A. Bostrom[1], P. J. Hicks[1], M. E. Cunningham[2], J. Divers[2], J. B. Kopp[3], C. A. Winkler[4], G. W. Nelson[4], C. D. Langefeld[2], D. W. Bowden[1,5,6], B. I. Freedman[5]* 1) Dept Biochemistry, Wake Forest Univ, Winston-Salem, NC; 2) Biostatistical Sciences, Wake Forest Univ, Winston-Salem, NC; 3) Kidney Disease Section of the NIDDK, Bethesda, MD; 4) SAIC National Cancer Institute-Frederick, Frederick, MD; 5) Internal Medicine/Nephrology, Wake Forest Univ, Winston-Salem, NC; 6) Center for Human Genomics, Wake Forest Univ, Winston-Salem, NC.

African Americans (AA) have increased susceptibility to non-diabetic etiologies of end-stage renal disease (ESRD), particularly attributed to hypertension and glomerular disease, relative to European Americans. In AA the non-muscle myosin heavy chain 9 (MYH9) gene is strongly associated with focal and segmental glomerulosclerosis and HIV-associated nephropathy using Mapping by Admixture Linkage Disequilibrium (MALD); and a four SNP haplotype (E1) in this gene (3224; rs4821480, rs2032487, rs4821481, and rs3752462) is significantly associated with both kidney diseases. This haplotype has also been shown to be associated with non-diabetic etiologies of ESRD (not diabetic ESRD) in limited numbers of AA patients. We attempted to replicate this genetic association in 1817 AA born in the southeastern U.S. (871 with non-diabetic ESRD and 946 controls lacking nephropathy). Fifteen SNPs were genotyped and a single SNP (rs2187776) deviated from Hardy-Weinberg Equilibrium in controls and was excluded. Thirteen remaining SNPs were significantly associated with non-diabetic ESRD (recessive model; $p = 0.01 - 4.0 \times 10^{-22}$; odds ratio (OR) = 1.38-2.96). The four SNP E1 haplotype (3224) was associated with non-diabetic ESRD under the recessive model ($p = 1.56 \times 10^{-20}$; OR = 2.2; confidence interval (CI) = 1.82 - 2.68). After adjusting for this haplotype, logistic regression analysis showed that 5 SNPs remained associated with non-diabetic ESRD, rs12107, rs5756152, rs1005570, rs16996674, and rs16996677 (additive model; $p = 0.02 - 9.08 \times 10^{-7}$; OR = 1.22-1.50). We conclude that the 4 SNP E1 haplotype is associated with increased risk of non-diabetic ESRD among AA and potentially additional variants in MYH9 contribute to non-diabetic etiologies of ESRD.

Population-Based GWAS Reveals Four Novel Trans-Acting Loci Influencing Plasma Levels of Liver Enzymes. *X. Yuan[1], D. Waterworth[1], J. Perry[2], N. Lim[1], K. Song[1], J. Chambers[3], W. Zhang[3], P. Vollenweider[4], G. Waeber[4], L. Cardon[1], T. Frayling[2], J. Kooner[5], V. Mooser[1]* 1) Genetics Division, GlaxoSmithKline, Collegeville, PA; 2) Genetics of Complex Traits, Institute of Biomedical and Clinical Sciences, Peninsula College of Medicine and Dentistry, University of Exeter, UK; 3) Department of Epidemiology and Public Health, Imperial College London, UK; 4) Department of Medicine and 5National Heart and Lung Institute, Imperial College London, UK; 5) National Heart and Lung Institute, Imperial College London, UK.

BACKGROUND : Plasma levels of liver enzymes (PLEs) are widely used for the diagnosis of liver diseases and to follow the response to treatments. PLEs levels are known to be heritable. An understanding of the molecular determinants of PLEs is of paramount importance for a proper interpretation of liver laboratory tests and to expand our knowledge of liver diseases. METHOD : We conducted a GWAS analysis on Alanine-Aminotransaminase (ALT), Alkaline phosphatase (ALP), Gamma glutaryl transferase (GGT) and Aspartate aminotransferase (AST) considered as quantitative traits in three discovery and three replication cohorts with up to 12,419 individuals. Meta-analysis was conducted on the summary results from both genotyped and imputed SNPs. RESULTS : 10, 6 and 18 genotyped SNPs were replicated at genome-wide significant level ($p\ 10^{-7}$) for plasma ALT, GGT and ALP levels, respectively, whereas none was associated with AST level. Among the four newly identified trans-acting loci, the lead SNPs in PNPLA3 were strongly associated with levels of ALT ($p=8.4\times10^{-16}$) and AST ($p=5.7\times 10^{-6}$). A strong interaction with obesity was observed, suggesting that PNPLA3 might predispose to liver fat accumulation. Robust associations with cis-acting SNPs were identified for plasma GGT and ALP levels. CONCLUSION : We have discovered novel loci that influence the plasma liver enzymes levels. These discoveries shall assist in the interpretation of PLEs and may point to new mechanisms, and potentially new targets for liver diseases.

Mosaic trisomy 9: Three new cases with variations in phenotype. *B. A. Kozel[1], D. K. Grange[1], S. Kulkarni[2], T. Reimschisel[3]* 1) Genetics and Genomic Medicine, Washington Univ. School of Med., St. Louis, MO; 2) Clinical and Molecular Cytogenetics, Washington Univ. School of Med., St. Louis, MO; 3) Developmental Medicine and Cognition, Vanderbilt Univ. School of Med., Nashville, TN.

The phenotype associated with mosaic trisomy 9 is highly variable. We present 3 new patients with phenotypes of varying degrees of severity. Case 1 exhibited a more classic presentation. The phenotype included IUGR, congenital heart defect with PFO, hypoplastic aortic arch and large PDA, micropenis, respiratory failure, and hypotonia. Facial features, including hypotelorism and microophthalmia, were suggestive of holoprosencephaly, although head ultrasound was normal. Abdominal ultrasound was also normal. Amniocentesis showed 80% 47,XY,+9 cells and 20% 46,XY cells. Postnatal FISH studies of buccal cells showed 685/1000 (68.5%) trisomy 9 cells. Case 2 showed more subtle features. The infant presented at 4 months of age due to global developmental delay, bilateral congenital hip dysplasia, and Duane syndrome of the left eye. Microarray analysis of peripheral blood with confirmatory FISH revealed 26% 47,XX,+9 cells and 74% 46,XX cells. Her facial dysmorphisms include thick hair, micrognathia, and bulbous nose. She has had persistent gastroesophageal reflux and difficulty gaining weight. Echocardiogram and abdominal ultrasounds were normal. Case 3 is a boy who is now 10 years old. His peripheral blood shows 24% 47,XY,+9 cells and 76% 46,XY cells. He has mental retardation, CP, and seizures, as well as Duane syndrome. His facial features include bilateral preauricular pits, small palpebral fissures, and mild facial asymmetry. These cases demonstrate two points. First, although the degree of mosaicism is not completely predictive of phenotype, a higher percentage of trisomy 9 cells generally correlates with more severe features. Second, distinctive features in cytogenetic syndromes may point investigators to the discovery of new disease causing loci, possibly unmasked by uniparental disomy. Of note, at least one other patient with Duane syndrome, not linked to trisomy 9, has been found to have an alteration of the NELF gene on 9q34.3.

Association mapping of expression trait loci from peripheral blood CD4+ lymphocytes. *B. A. Raby[1], A. Murphy[1], J. Chu[1], V. Carey[1], B. J. Klanderman[1], S. Sylvia-Senter[1], J. Ziniti[1], C. Lange[2], S. T. Weiss[1]* 1) Channing Laboratory, Brigham & Women's Hospital, Harvard Medical School, Boston, MA; 2) Harvard School of Public Health, Boston MA.

Association studies of human gene expression promise to identify regulatory genetic variation that contributes to phenotypic diversity. Such studies performed to date have largely relied on expression data from immortalized cell lines. Herein we demonstrate the feasibility of expression-trait association testing using RNA derived from freshly harvested peripheral blood CD4+ lymphocytes from 154 asthmatics. We generated quantile-normalized gene expression profiles using Illumina HumanRef8 arrays that survey 20,589 RefSeq-curated mRNA transcripts. Genome-wide genotype data (534,290 autosomal SNP, Illumina Infinium 550K array) were available for these subjects and their parents. Family-based association testing was performed (additive model) using PBAT. We screened for cis-acting variants (within 50kb of transcripts), resulting in 511K comparisons. Significant associations for 405 genes were observed using a false discovery rate of 0.05 (corresponding to p-values ranging from 10^{-15} to 10^{-4}). Sizable SNP-specific genetic effects were observed (median locus-specific heritability of 0.171), with variants explaining more than 50% of expression trait variability in 16 genes. 18.35% of associations were also observed in a prior expression trait association study of immortalized cell lines from asthmatics (Dixon 2007), suggesting only modest generalizability of results from immortalized cells. These results highlight the feasibility of expression-trait association mapping in human populations for the identification of functional expression-related polymorphisms. Proteomic Analysis of Platelet -Granules Using Mass Spectrometry: An Application to Gray Platelet Syndrome.

D. M. Maynard[1], M. Gunay-Aygun[1, 2], H. F. G. Heijnen[3], H. Edwards[1], J. G. White[4], W. A. Gahl[1] 1) MGB, NHGRI, NIH, Bethesda, MD, USA; 2) ORD, NIH, Bethesda, MD, USA; 3) Laboratory of Clinical Chemistry and Haematology and Cell Microscopy Centre, Univ Medical Centre, Utrecht, The Netherlands; 4) Depts of Laboratory Medicine and Pathology and Pediatrics, Univ of MN, Minneapolis, MN, USA.

A deficiency in granule-bound substances in platelets causes a group of congenital bleeding disorders known as storage pool deficiencies (SPDs). For disorders such as Gray Platelet syndrome (GPS), only the clinical and histological states have been defined. In order to understand the basic defect in this disorder, we are using proteomics and mass spectrometry (MS). Platelet -granules contain several adhesive proteins involved in hemostasis, and glycoproteins involved in inflammation, wound healing, and cell-matrix interactions. Our research represents the first effort to define the normal platelet -granule proteome using MS. We prepared a subcellular fraction (fr. 6) enriched in intact -granules from human platelet lysates using sucrose gradient ultracentrifugation. Fraction 6 proteins were separated and identified using SDS-PAGE and LC-MS/MS. We identified 219 non-redundant proteins, 44 of which appear to be newly described -granule proteins. Immuno-electron microscopy confirmed the presence of Scamp2, APLP2, ESAM and LAMA5 in platelet -granules for the first time. Recently, we analyzed fraction 6 proteins from two GPS patients and two controls. The number of peptides from soluble proteins synthesized in the megakaryocyte was markedly decreased or undetected in GPS fraction 6 compared to normal. The number of peptides from soluble proteins endocytosed into alpha granules was slightly decreased in GPS platelets compared to normal. The number of peptides from some membrane proteins was decreased in GPS while the number was approximately the same for others compared to normal. These results support the existence of ghost granules in GPS. This proteomic technology can be employed to characterize the intracellular vesicles of patients with other SPDs and other genetic disorders of organelle formation and trafficking.

Does dysregulation of the PDGFRA gene cause anomalies of the human pulmonary veins? Combining evidence from TAPVR genetics and model organisms. *S. B. Bleyl[1], Y. Saijoh[2], K. Shiota[3], S. Klewer[4], G. C. Schoenwolf[2]* 1) Dept Pediatrics, Univ Utah, Salt Lake City, UT; 2) Dept Neurobiology Anatomy,Univ Utah, Salt Lake City, UT; 3) Dept Anatomy Dev Biol, Kyoto Univ, Kyoto, Japan; 4) Dept Pediatric Cardiology, Univ Arizona, Tucson, AZ.

Total anomalous pulmonary venous return (TAPVR), is a life-threatening congenital heart defect inherited as a multifactorial trait via complex genetic and/or environmental factors. We mapped the first locus for isolated TAPVR to a 2.4 Mb interval of chromosome 4q12 by linkage and founder effect mapping, but a causative gene could not be identified by mutation analysis. While the embryology of normal heart stalk and pulmonary vein is well described, little is known about the embryogenesis or molecular pathogenesis of TAPVR. Indeed, no animal models for TAPVR have previously been reported. Here we report further mapping in the original TAPVR founder kindreds and several new extended TAPVR kindreds using 40 tag SNPs spanning a region of shared STR haplotypes. Alignment of phased haplotypes between kindreds implicates a narrow interval within the *PDGFRA-KIT* intragenic region, suggesting defective regulation of a neighboring gene(s) in the development of TAPVR. Using *in situ* hybridization in mouse and chick embryos, we found that *PDGFRA* and its ligand *PDGFA* are expressed in a temporal and spatial pattern consistent with a role heart stalk remodeling. We then used an *in ovo* function blocking assay in chick and a conditional knockout approach in mouse to knock down PDGFRA expression in the developing heart stalk and compared the morphology of the heart stalk and pulmonary veins using histological sections and 3D reconstruction. We observed that loss of PDGFRA function in both organisms can cause TAPVR, but with low penetrance (~10%) reminiscent of that observed in our human TAPVR kindreds. These animal models of TAPVR, the first reported, provide important insight into the pathogenesis of anomalous pulmonary vein development. Taken together, these data from human mapping and animal models support a role for PDGF-signaling in the normal development of the pulmonary veins, and in the pathogenesis of TAPVR.

Multi-dimensional analyses of genetic alterations in glioblastomas implicate three critical signaling pathways. *B. A. Santillan[1], L. A. Donehower[1], N. Schultz[2], J. N. Weinstein[3], L. Bull[1], C. Sander[2], D. Wheeler[1]* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Computational Biology Center, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Department of Bioinformatics and Computational Biology, MD Anderson Cancer Center, Houston, TX.

Glioblastoma multiforme (GBM) is a grade 4 cancer arising from brain astrocytes. It is the most common and the most aggressive of the gliomas. As part of The Cancer Genome Atlas (TCGA) Project 94 tumor and matched normal samples have undergone exon sequencing (603 genes), RNA expression, and copy number analysis. Following a large-scale analysis of nonsynonymous point mutations, indels, and copy number variations in each tumor, three major pathways have arisen as significant in the genesis of GBM in humans. The observed activation of the RTK/Ras/PI-3K growth signaling pathway and the inactivation of the p53 and Rb signaling pathways suggest that the genes within these three pathways are key to oncogenesis of GBM. Of the tumors analyzed, 87% contain genomic alterations in at least one of four genes in the p53 signaling pathway. 77% of tumors contain alterations within at least one of five Rb signaling pathway genes, and 85% of tumors contain alterations in at least one of ten RTK/Ras/PI-3K pathway genes. Approximately 70% of the tumors analyzed contain an alteration in all three pathways. Consistent observation of copy number deletions and mutations in oncogenesis-inhibiting genes and copy number amplifications of oncogenenesis-promoting genes are consistent with expected oncogenic patterns. In addition, alterations within each of the p53 and Rb pathways are generally anti-correlated within each sample, suggesting that one alteration is sufficient to inactivate a pathway. These results demonstrate the efficacy of the TCGA Project in generating a more comprehensive picture of the molecular events associated with the development of an important human cancer.

Genome-Wide Association Study Identifies APOE, RELN and Other Loci Associated with Longevity. *R. Little[1], S. Kebache[1], J. Raelson[1], P. Van Eerdewegh[1], Q. Nguyen-Huu[1], G. Lepage[1], T. Fülöp[2], M. Dugas[3], H. Fournier[1], B. Paquin[1], J. Hooper[1], A. Belouchi[1], T. Keith[1]* 1) Dept Computational Biology, Genizon BioSciences, St Laurent, PQ, Canada; 2) University of Sherbrooke, Sherbrooke, QC, Canada; 3) Université Laval, Centre de recherche du CHUQ, Quebec, QC, Canada.

We recently completed a GWAS of longevity resulting in clinically relevant discoveries relating to protection against several common diseases of aging such as cardio-metabolic diseases, Alzheimers disease and cancer. The GWAS was performed using 520 cases (94 years of age or older) and 520 matched controls (18-65 years of age) from the Quebec Founder Population (QFP). Cases and controls were individually genotyped using the HumanHap 550 chip (Illumina). Regions with p-values that met the criteria for genome-wide significance based on permutation studies were identified both with the haplotype and single marker association tests, indicating that a well-powered GWAS using the QFP can be achieved with a relatively small sample size. The scope of the study was expanded through further GWA studies based on phenotypic and genetic stratification of the original patient population. The former identifies genes relevant for subsets of patients based on clinical features and the latter discovers genetic interactions, both epistatic and independent risk factors. Top candidate loci include APOE, an important regulator of lipoproteins that has consistently been associated with longevity, and the extracellular matrix protein RELN. APOE and RELN belong to the same canonical pathway. Both bind lipoprotein receptors to regulate the lamination of the neocortex and the foliation of the cerebellum. APOE has repeatedly been associated with increased risk of both cardiovascular disease and Alzheimers disease. Other loci, including centenarian-specific genes and genes epistastic to and/or independent of APOE and RELN, were discovered. Genes identified from these analyses have been used to build a GeneMap, consisting of networks of disease susceptibility genes and their biological pathways.

Meta-analyses of over 36,000 genome-wide association scans for fasting glucose and related glycaemic traits. *I. Prokopenko[1], C. Langenberg[2], J. Florez[3,4], R. Saxena[3,4], G. Thorleifsson[5], N. Soranzo[6,7] for MAGIC* 1) Oxford, UK; 2) Cambridge, UK; 3) Cambridge, MA; 4) Boston, MA; 5) Reykjavik, Iceland; 6) Hinxton, UK; 7) London, UK.

MAGIC (Meta-Analyses of Glucose and Insulin-related traits Consortium) represents a collaborative effort to identify genetic loci associated with fasting glucose (FG), insulin (FI) and related traits. We conducted a genome-wide association meta-analysis in European descent populations from the GEM, DFS, ENGAGE and Framingham groups, combining data from 10 individual studies (deCODE, NFBC66, NTR/NESDA, Rotterdam, CoLaus, TwinsUK, DGI, FUSION, SardiNIA and FHS), comprising a total of 36,610 individuals for FG and ~26,800 individuals for FI and indices of beta-cell function (HOMA-B) and insulin sensitivity (HOMA-IR). We tested for trait associations under an additive model for a total of ~2.5 million common HapMap SNPs (directly genotyped and imputed). In the FG meta-analysis, we observed a marked excess of signals exceeding stringent significance threshold. Three of them were at the previously-reported signals at *GCK* ($p=4.8x10^{-20}$), *GCKR* ($p=1.2x10^{-8}$) and *G6PC2* ($p=7.1x10^{-49}$). We also detected a novel signal at *MTNR1B* ($p=1.1x10^{-41}$). All of these (except *GCKR*) were detected in the HOMA-B meta-analysis with the glucose-raising allele indicative of reduced beta cell function (e.g. *MTNR1B*, $p=1.0x10^{-15}$, see abstract Langenberg C. et al.) In addition to these four, there were 8 additional independent signals for FG ($p<10^{-5}$). Two of these coincided with known Type 2 Diabetes susceptibility genes (*TCF7L2* $p=2.8x10^{-11}$, *SLC30A8* $p=1.1x10^{-7}$), the strongest other signal being associated with a novel locus on chr7p ($p=3.7x10^{-12}$). These FG signals dominated the HOMA-B meta-analysis, though a slight excess of additional significant signals ($p <7.9x10^{-6}$) was observed, two of which were also detectable from the insulin and HOMA-IR meta-analyses ($p<10^{-5}$). Large-scale replication efforts currently underway should extend the list of loci with a robust effect on glycaemic traits in adults. Both physiological (homeostatic) and pathological (diabetes-related) mechanisms seem to be implicated in the regulation of these traits.

Fibulin polymorphisms and subclinical atherosclerosis, blood pressure and arterial stiffness: The Multi-Ethnic Study of Atherosclerosis (MESA). *J. D. Vargas[1], K. Musunuru[1], M. F. Cotch[2], S. D. Adar[3], D. A. Bluemke[1], L. J. Raffel[4], X. Guo[4], B. Fang[4], W. S. Post[1]* 1) Jonhs Hopkins Hospital, Baltimore, MD; 2) National Eye Institute, NIH, Bethesda, MD; 3) University of Washington, Seattle, WA; 4) Cedars-Sinai Medical Center, Los Angeles, CA.

The fibulins, a family of proteins involved in the development of the extracellular matrix, are determinants of normal arterial morphology. Single nucleotide polymorphisms (SNPs) in fibulin-3 (EFEMP1), fibulin-5 (FBLN5), fibulin-6 (HMCN1) and fibulin-3 associated protein, matrix metalloproteinase-3 (MMP-3), may play a role in the development of atherosclerosis and blood pressure homeostasis. 2,847 participants without known cardiovascular disease in the Multi-Ethnic Study of Atherosclerosis (MESA) from 4 racial/ethnic groups [African-American (AFA), Chinese (CHN), White (EUA), and Hispanic (HIS)] were genotyped. Single SNP analyses were performed to determine the associations between genotypes and arterial phenotypes, including coronary artery calcium (CAC), carotid intima-media thickness (IMT), carotid artery distensibility (CD), systolic blood pressure (SBP), diastolic blood pressure (DBP) and pulse pressure (PP). Multivariate regression analyses were used adjusting for age and gender, stratified by racial/ethnic group. An additive model was used to analyze SNP-phenotype associations with a p-value of < 0.05 in two ethnic groups indicating significance. 95 SNPs were genotyped [FBLN5 (32), EFEMP1 (25), HMCN1 (27), MMP-3 (11)]. FBLN5 rs929608 was associated with IMT in AFA and EUA (p=0.03 and p=0.01), rs7143288 with IMT in HIS and EUA (both p=0.02) and rs6575221 with CD in CHN and EUA (both p=0.03). EFEMP1 rs7589466 was associated with CAC in HIS and EUA (p=0.01 and p=0.001), rs727877 with IMT in HIS and EUA (p=0.04 and p=0.02), rs727878 with CD in AFA and EUA (both p=0.03) and rs7573078 with DBP in CHN and HIS (p=0.04 and p=0.01). HMCN1 rs10127540 was associated with CAC in AFA and EUA (p=0.006 and p=0.03) and rs1407136 with CAC in AFA and EUA (p=0.002 and p=0.01); these two SNPs are in LD (r2>0.94). There were no significant associations with MMP-3. Fibulin genes may influence blood pressure and atherosclerosis.

Novel Association of HK1 with Glycated Hemoglobin in a Non-Diabetic Population: A Genome Wide Evaluation of 14,618 Participants in the Womens Genome Health Study. *G. Pare[1], D. Chasman[1], A. N. Parker[2], J. P. Miletich[2], R. Y. L. Zee[1], P. M. Ridker[1]* 1) Center for Cardiovascular Disease Prevention, Brigham and Womens Hospital, Harvard Medical School, Boston, MA; 2) Amgen, Inc., Cambridge, MA.

Type 2 diabetes is a leading cause of morbidity and mortality. While genetic variants have been found to impact on the risk of type II diabetes mellitus, relatively few studies have focused on glycated hemoglobin, a marker of the mean blood glucose concentration of the preceding 8-12 weeks formed through non-enzymatic glycation of hemoglobin. Prospective randomized clinical trials have documented the relationship between glycated hemoglobin and the development of chronic complications in diabetics, and higher glycated hemoglobin levels, even within reference intervals, have been shown to predict type 2 diabetes risk and cardiovascular disease in healthy individuals. To comprehensively address the issue of common genetic determinants of glycated hemoglobin, we report the results from a genome wide association study of glycated hemoglobin, evaluating 337,343 SNPs in 14,618 apparently healthy Caucasian women. We demonstrate that glycated hemoglobin is associated with genetic variation at the GCK (rs730497; P=5.7 x 10-12), SLC30A8 (rs13266634; P=5.4 x 10-8), G6PC2 (rs1402837; P=4.7 x 10-10), and HK1 (rs7072268 and rs2305198; 1.8 x 10-25 and 4.3 x 10-19, respectively) loci. While associations at the GCK, SLC30A8 and G6PC2 loci confirm or extend previous work done on the genetic basis of diabetes or fasting glucose, the findings at HK1 are novel. Moreover, we were able to replicate this novel association in an independent validation sample. HK1 encodes for the enzyme hexokinase, the entry point of glucose in glycolysis and a likely candidate for glucose metabolism and diabetes. This genetic observation therefore paves the way for further studies of the biology of HK1 in hemoglobin glycation, glucose metabolism and diabetes.

Modifier genes analysis in mexican cystic fibrosis patients. *C. N. Sanchez Dominguez[1,2], M. A. Reyes Lopez[1], A. E. Bustamante Saenz[2], M. C. Villalobos Torres[2], R. Ortiz Lopez[2]* 1) Centro de Biotecnologia Genomica, Instituto Politecnico Nacional. Tamaulipas, Mexico; 2) Biochemistry Department, School of Medicine, Universidad Autonoma de Nuevo Leon. Nuevo Leon, Mexico.

Introduction: Cystic fibrosis (CF) is the most common monogenic disease in Caucasian population, its frequency is about 1/2500 live born. The estimated frequency in Hispanic population is about 1/8500. The detection rate among Hispanic CFTR mutation carriers is about 52% compared to 70 to 97% in all other Caucasians. The phenotype of CF, specially in the pulmonary disease, range from very mild symptoms reaching adult age to a fulminant course resulting in death within the first year of life. Recent studies are focused on modifier genes. These are genes that could influence the CF phenotype, acting trough inflammation, repair and remodeling, protease- anti protease balance, innate immune response, among others mechanisms. This work shows results in CF diagnosis and modifier genes analysis in Mexican population. Methods: We included 76 CF patients analyzed for CFTR mutations by PCR and reverse hybridization with allele specific oligonucleotides probes or multiplex PCR. For frequency analysis of modifier genes, we tested Alpha 1 Antitrypsin (AAT) Z and S alleles, Tumor Necrosis Factor Alpha (TNF) -308, and Interleukine 8 (IL8)-251A/T polymorphisms. Results: F508 allele was present in one or both alleles in 86.8% of the CF patients. Allele frequency of F508 was 61.8% followed by 6542X, 2789 +5G/A, S549N and 3849+10kb (ranking from 5.3 to 2.6%). 21.1% of the mutant alleles remain undetected. Preliminary results in modifier genes showed low frequency for AATS mutant allele (1%) whereas Z allele was not detected. Allele frequency for TNF -308 was higher in patients than controls (8.7% vs 2.5%). For IL8, both alleles are represented in both groups, being higher the heterozygote genotype in patients (53% vs 38%). Conclusions: F508 was present in 82.5% of the CF patients, with an allele frequency of 61.8%. TNF mutant allele had higher tendency in patients, as well as heterozygote -251A/T IL8 polymorphism.

Association of Preanalytical Variation with DNA Quality in the Prostate, Lung, Colorectal and Ovarian (PLCO) Cohort. *L. E. Mechanic[1], T. Sheehy[2], D. Carrick[1], A. Varanasi[1], K. Pettit[1], A. Khan[1], M. Cosentino[2], B. O'Brien[1]* 1) Health Studies, Westat, Rockville, MD; 2) SAIC-Frederick, Inc., Frederick, MD.

The field of genetic epidemiology has witnessed a revolution due to the launch of the International HapMap project describing the linkage disequilibrium of the human genome and the advent of high density genotyping platforms. These platforms enable genotyping of millions of single nucleotide polymorphisms (SNPs) in a single individual. Despite such marked success, the majority of statistically significant SNPs identified in genome wide association or candidate gene studies fail to replicate. The quality of DNA used in genotyping assays influences genotyping success and may influence the results. We hypothesized that the quality of DNA used in genomic assays was modulated by the type of biological specimen, method of DNA extraction, and variation in collection and storage. We investigated this hypothesis using data obtained from specimens selected for a case-control study nested within the Prostate Lung Colorectal and Ovarian (PLCO) screening trial examining association of genetic variation with breast cancer. DNA quantity and quality was assessed using Nanodrop assays. Specimens with concentrations greater than 25 ng/l and total yields of at least 20 g were considered high quality DNA for genotyping based on standards established by the NCI Core Genotyping Facility (http://cgf.nci.nih.gov/). The number of high quality DNA samples for genotyping purposes and average DNA amounts per volume of starting specimen obtained after DNA extraction were compared for each method of DNA extraction and type of biological specimen. The association of DNA quality with time between blood collection and freezing and storage time was also examined. Overall, all specimen types and methods of DNA extraction yielded DNA of sufficient quality and quantity for genotyping. Determining how DNA quantity and quality are affected by preanalytic variables will enable investigators to optimize the design and implementation of genetic association and candidate gene studies.

The origin of Native Americans from a mitochondrial DNA viewpoint. *U. A. Perego[1,2], A. Achilli[2,3], L. Milani[4], M. Lari[4], M. Pala[2], A. Olivieri[2], B. Hooshiar Kashani[2], J. E. Gomez-Palmieri[1], N. Angerhofer[1], A. Pollock[1], K. H. Ritchie[1], N. M. Myres[1], S. R. Woodward[1], D. Caramelli[4], A. Torroni[2]* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, UT, USA; 2) Dip. di Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 3) Dip. di Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy; 4) Dip. di Biologia Evolutiva, Università di Firenze, Firenze, Italy.

America, the last continent to be colonized by modern humans, is characterized by an extraordinary linguistic and cultural diversity. Until recently, it was generally believed that starting around 13,500 years ago, the first Paleo-Indians arrived from Beringia, passing through an interior ice-free corridor in western North America, and spread rapidly all the way to Tierra del Fuego. Today, we realize that the peopling of the Americas involved a much more complex process. As for the maternally transmitted mitochondrial DNA (mtDNA), it has been clear since the early nineties that Native Americans could be traced back to four major maternal lineages (haplogroups) of Asian affinity. These were initially named A, B, C and D, and are now termed A2, B2, C1 and D1. More than 95% of living Native Americans belong to these four haplogroups, which can be considered pan-American, because they are shared by North, Central and South American populations. Later, five additional maternal lineages were discovered and named X2a, D2, D3, C4c, and D4h3. These less common or rare haplogroups are restricted only to some Native American populations or geographic areas and bring the overall number of Native American mtDNA lineages to nine. Our comprehensive overview of the four pan-American branches of the mtDNA tree suggests a scenario with a human entry and spread into the Americas from Beringia about 20,000 years ago, and preliminary data raise the possibility that the uncommon five Native American haplogroups might have marked additional migratory events from Asia or Beringia. Overall, through a combined analysis of modern and ancient Native American mtDNA, we are making an effort for reconstructing the complex pre-Columbian history at both macro- and micro-geographic levels.

***PTCH1* duplication in a family with microcephaly and mild developmental delay.** *K. Derwinska[1,2], M. Smyk[1,2], M. L. Cooper[1], P. Bader[3], S. W. Cheung[1], P. Stankiewicz[1,2]* 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; USA; 2) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 3) Cytogenetics, Parkview Memorial Hospital, Ft Wayne, IN, USA.

With the exception of the X chromosome, genomic deletions are more prevalent than duplications. Due to a lack of accurate diagnostic methods, submicroscopic duplications have been under-ascertained. The development of array CGH has enabled detection of chromosomal microduplications with nearly the same sensitivity as deletions, leading to the discovery of previously unrecognized syndromes. Using a clinical targeted oligonucleotide array (CMA-V6.3 OLIGO), we identified an ~360 kb duplication in 9q22.32 in a 21-month-old boy with developmental delay, failure to thrive, and microcephaly. The same duplication was identified in the patients mother who has also microcephaly. We have sequenced the chromosomal breakpoints and determined the duplication as tandem in orientation and 363,599 bp in size. The proximal duplication breakpoint mapped within a unique sequence, 229 bp from a 6421 bp LINE1 retrotransposon element L1PA7 and the distal breakpoint mapped within a 492 bp DNA/MER1_type element Charlie2a. The duplicated segment harbors only the entire *PTCH1* gene and a non-coding exon 1 of the *FANCC* gene. To date, over 160 mutations (loss-of-function, mostly truncating) and more than 20 constitutional deletions of entire *PTCH1* have been reported in patients with Nevoid Basal Cell Carcinoma syndrome, or Gorlin syndrome. In contrast, gain-of-function mutations in *PTCH1* lead to holoprosencephaly 7 (HPE7). *PTCH1* encodes a receptor for SHH and suppresses the SHH signaling pathway. Mutations in *SHH* are the most common identified cause of both autosomal dominant and sporadic HPE; however, they have been found also in patients with microcephaly without holoprosencephaly. Furthermore, up to 50% of children with HPE have been found microcephalic at birth. We suggest that gain-of-function mutations or duplication of *PTCH1* may result in microcephaly with or without holoprosencephaly. We propose that patients with microcephaly or holoprosencephaly of unknown origin should also be screen for *PTCH1* duplication.

Investigation of the role of the PRKAR1A gene and protein kinase A enzymatic activity in endometrial tumors.

E. I. BIMPAKI[1], A. M. TSIGGINOU[2], S. A. BOIKOS[1], M. NESTEROVA[1], C. PAPAGEORGIOU[2], C. A. STRATAKIS[1] 1) Section on Endocrinology and Genetics, Program on Developmental Endocrinology & Genetics (PDEGEN), NIH, Bethesda, MD; 2) 1st Obstetrical and Gynecological clinic, 'Alexandra' Hospital, Athens, Greece.

The PRKAR1A gene is coding for the type 1a regulatory subunit of the cAMP-dependent protein kinase A (PKA), an enzyme with an important role in cell cycle regulation and proliferation. Alterations in RIA protein levels were detected in various tumors and PRKAR1A inactivating mutations lead to Carney complex (CNC), a multiple endocrine neoplasia syndrome. In this study, we investigated the role of PRKAR1A in endometrium tumors. Specimens were collected from 31 patients with endometrial cancer. In 26 of these patients, a sample from the surrounding normal tissues was also collected; in addition, 15 samples of endometrium were collected from normal controls that underwent gynecological operations for other reasons. In all samples, we 1) sequenced the PRKAR1A coding sequence; 2) determined the PKA activity and cAMP binding capacity; and 3) studied the PKA subunit expression by protein studies (immunoblotting, immunohistochemistry). There were no PRKAR1A mutations. In 5 controls and in 9 tumor samples we found the previously described polymorphism IVS3-5dupT (p value not statistically important); in 6 samples it could be determined that this was germline. Also, in the germline state, one synonymous polymorphism (c.87G>A/p.Ala29Ala) was found. cAMP binding was lower in tumor tissue compared to normal endometrium both within the same samples and normal samples from controls (12 samples/group were tested, p value<0.05).This finding was in agreement with the observation that free PKA activity was higher in tumor samples compared with control tissue (12 samples/group were tested, p value<0.05). Accordingly, PKA regulatory subunit protein levels,both RIA and RIIB were lower in tumor samples. We conclude that despite the apparent lack of frequent PRKAR1A mutations in endometrial cancer, there are widespread changes of the PKA system that suggest an involvement of cAMP signaling in this tissues malignant transformation.

Variation in *GIGYF2* is not associated with Parkinson disease. *W. Nichols[1,2], D. Kissell[1], N. Pankratz[3], M. Pauciulo[1], V. Elsaesser[1], K. Clark[1], C. Halter[3], A. Rudolph[4], J. Wojcieszek[3], R. Pfeiffer[5], T. Foroud[3], PSG-PROGENI Investigators* 1) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) University of Cincinnati School of Medicine, Cincinnati, OH; 3) Indiana University Medical Center, Indianapolis, IN; 4) University of Rochester, Rochester, NY; 5) University of Tennessee Health Science Center, Memphis, TN.

Parkinson disease (PD) affects nearly one million Americans and is the second most common neurodegenerative disorder. We have previously reported linkage to chromosome 2q36-37 in a sample of multiplex PD families, with the strongest evidence of linkage obtained using the subset of the sample having the strongest family history of disease and meeting the strictest diagnostic criteria. A recent study reported that mutations in *GIGYF2* result in PD and may account for the previously observed linkage finding. We sequenced 96 unrelated PD patients used in our original study that contributed to the chromosome 2q36-37 linkage signal and have subsequently genotyped our entire sample of 566 multiplex PD kindreds as well as 359 controls to test whether variants in *GIGYF2* are causative or increase susceptibility for PD. We detected three novel variants as well as one of the seven previously reported variants, but did not detect consistent evidence that these variants segregated with PD in the families. We also did not find a significant increase in risk for PD among those inheriting variants in *GIGYF2*. With the identification of so few potential *GIGYF2* mutations in these families, it is very unlikely that these few variants, observed in only a total of five families, could have accounted for the substantial linkage evidence (LOD=5.1) reported in our sample. Therefore, we do not believe that variation in *GIGYF2* accounts for the previously reported linkage finding on chromosome 2q36-37. We hypothesize that there is another gene within this chromosome 2q region which when mutated results in familial PD. Studies are ongoing to identify this gene(s). This project was supported by NS37167.

Assessing the contribution of genomic rearrangements to X-linked mental retardation: high resolution arrayCGH analysis of the IGOLD cohort. *F. L. Raymond[1], A. Whibley[1], P. S. Tarpey[2], V. Plagnol[1], R. Francis[1], R. Smith[2], P. A. Futreal[2], M. R. Stratton[2], i. GOLD consortium[1,2,3,4,5]* 1) Medical Genetics, University of Cambridge, Cambridge, United Kingdom; 2) Sanger Institute, Hinxton, Cambridge UK; 3) Greenwood Genetics Centre, South Carolina USA; 4) University of Adelaide, Australia; 5) Hunter Genetics, Newcastle, Australia.

We have previously described the systematic resequencing of >700 X chromosome genes in the IGOLD cohort of >200 males with mental retardation (MR) and transmission compatible with X-linked inheritance. We have identified sequence variants in several novel MR genes and attributed pathogenicity in a significant proportion of the cohort families. However, the cause of MR in the majority of these families remains unidentified. To address the contribution of genomic rearrangements, a mutational class inefficiently detected by capillary resequencing, we designed an X-chromosome-specific Nimblegen 385K format microarray to interrogate copy number variation by comparative genomic hybridization (CGH). Our array design targeted coding regions and evolutionarily conserved elements but also maintained high density coverage across non-coding regions. The IGOLD cohort previously screened by resequencing was investigated with this high resolution array. Pathogenic variants have been identified in >10% of cohort families, with aberrations ranging from 2kb to >3Mb in size. Most pathogenic deletions and duplications occur in only a single family, although duplications of MECP2 or HSD17B10 /HUWE1 were detected recurrently, albeit with unique breakpoints. Junction fragments have been obtained where possible, providing insight into the mutational mechanism underlying these genomic imbalances. The challenges of analysing and interpreting data generated using oligo-based arrayCGH are also discussed.

Enhanced activation of p97.ARSA fusion enzyme by sulfatase-modifying factor I for brain targeted therapy of Metachromatic leukodystrophy. *D. Y. Hou[1], M. A. Potter[2]* 1) Medical Sciences, McMaster University, Hamilton, Canada; 2) Pathology and Molecular Medicine, McMaster University, Hamilton, Canada.

Metachromatic leukodystrophy (MLD) is a neurodegenerative lysosomal storage disorder that arises from the deficiency of the lysosomal enzyme Arylsulfatase A (ARSA). ARSA undergoes post-translational activation via conversion of a conserved active site cysteine residue into a C-formylglycine residue. This modification is executed by sulfatase-modifying factor I (SUMF1). Severe deficiency of ARSA leads to lysosomal accumulation of sulfatide, progressive demyelination and neurodegeneration. The challenge facing gene therapy for MLD is the delivery of active ARSA across the blood-brain barrier (BBB) at levels sufficient for correction of sulfatide storage. P97 is a cell-surface glycoprotein for which BBB transcytosis has previously been demonstrated. To circumvent the BBB for MLD therapy, we have developed an expression vector fusing p97 and human ARSA to deliver enzyme across the BBB. MDCK cells were transfected with unmodified ARSA and p97.ARSA. We investigated whether co-transfection of MDCK cells with expression vectors for SUMF1 and either p97.ARSA fusion enzyme or unmodified ARSA resulted in an increase in secretion of active enzyme compared to cells without added SUMF1. Transfected MDCK cells expressed and secreted intact fusion proteins as confirmed by immunoblot using antibodies against p97 and ARSA. Enzyme activity assays with artificial substrate P-Nitrocatechol sulfate demonstrated that ARSA activity was not impaired after p97 fusion. The maximal secretion of unmodified ARSA and p97.ARSA from transfected MDCK cells were 290 and 600 nmoles/hr/10^6 cells respectively. Following SUMF1 co-transfection, secretion of activated unmodified ARSA was increased 7-fold to 2130 nmoles/hr/10^6 cells. Secretion of activated p97.ARSA increased 4-fold to a maximum of 2245 nmoles/hr/10^6 cells. The similar maximal secretion of active enzyme for both ARSA and p97.ARSA transfected cells after SUMF1 co-transfection suggests complete activation of produced enzyme. These results demonstrate the importance of SUMF1 in enhancing activation of p97.ARSA for brain targeted gene therapy for MLD.

Microdeletion at 9q33.3q34.11 encompassing the LMX1B and ENG genes: a case report. *P. Trapane[2], J. Jarzembowski[2,1], D. Bick[2], W. Rhead[2], D. Wargowski[4], S. Aradhya[3], A. Mitchell[3], R. Veith[1]* 1) Children's Hospital of Wisconsin; 2) Medical College of Wisconsin; 3) GeneDx; 4) University of Wisconsin School of Medicine.

We report a male neonate with multiple congenital anomalies including coarctation of the aorta, tortuous aorta, hypoplastic left ventricle, mild aortic valve stenosis, cleft palate, alveolar ridge cleft, hypospadias, midline sternal skin tag, widening of the cranial vault sutures, hypertelorism, low set ears, epicanthic folds, short and broad nose, cerebral arteriovenous malformation, broad hands, short first and fifth metacarpals, underdeveloped middle phalanx of the 5th rays bilaterally, hypoplasia of nails bilaterally, absent patellae, hindfoot deformity and widely spaced first and second digits on the feet. Prior to death at one month of age the patient developed cholestatic jaundice and hapatomegaly. No other individuals within this pedigree demonstrate the phenotype.

Utilizing oligonucleotide array CGH we identified a genomic microdeletion at 9q33.3q34.11. The deleted segment is approximately 3.7 Mb and involves a contiguous region of single copy loss of over 40 genes including LMX1B and ENG. Quantitative PCR analysis of the CRAT gene in the deleted interval confirmed a heterozygous deletion of this region. Haploinsufficiency of LMX1B causes nail-patella syndrome (OMIM 161200), a syndrome characterized by aplastic/hypoplastic nails, small or absent patellae, elbow abnormalities, and the presence of iliac horns. Approximately 15% of cases involve a deletion of a part or of the entire gene. Haploinsufficiency for ENG is associated with Hereditary Hemorrhagic Telangiectasia type I (HHT type 1, OMIM 187300). HHT type 1 is an autosomal dominant, highly penetrant vascular dysplasia leading to telangiectases and arteriovenous malformations of the skin, mucosa and viscera typically affecting the brain, liver and lung tissues. Other genes in the deleted interval include AK1 and LRRC8A. The phenotype of the patient demonstrates the utility of oligonucleotide array CGH as a tool to diagnose contiguous gene deletion syndromes unable to be detected by standard cytogenetics.

Placebo-Controlled Study of Alglucosidase Alfa in Adults with Pompe Disease. *A. Skriner[1], P. R. Clemens[2], D. Corzo[1], D. Escolar[3], J. Florence[4], P. Laforet[5], S. Lake[1], J. Mayhew[3], A. Pestronk[4], R. Rosenbloom[6], M. Wasserstein[7], A. van der Ploeg[8]* 1) Genzyme Corporation, Cambridge, MA; 2) University of Pittsburgh, Pittsburgh, PA; 3) Children's National Medical Center, Washington, DC; 4) Washington University School of Medicine, St. Louis, MO; 5) Institut de Myologie, Groupe Hospitalier Pitie-Salpetriere, Paris, France; 6) Tower Hematology Oncology, Beverly Hills, CA; 7) Mount Sinai School of Medicine, New York, NY; 8) Erasmus Medical Center, Rotterdam, The Netherlands.

Background: Pompe disease (also known as acid maltase deficiency) is a rare, metabolic myopathy caused by a deficiency of acid -glucosidase (GAA). In juveniles and adults, the disease is relentlessly progressive, leading to wheelchair dependency and respiratory failure. Methods: Patients were 8 years old, ambulatory, free of invasive ventilation, and had quantifiable respiratory and lower extremity muscle weakness. Patients (randomized 2:1) received biweekly alglucosidase alfa (Myozyme) 20 mg/kg IV or placebo for 78 weeks. Distance walked in the six minute walk test (6MWT) and % predicted forced vital capacity (FVC) were co-primary endpoints. Results: 90 patients (45 male, 45 female; 93% Caucasian; age range 10-70 years) were randomized. Baseline mean 6MWT distance was 327.4128.0 meters (50.1% predicted) and mean FVC was 54.614.8% predicted, indicating considerable disease burden at baseline. By last evaluation, estimated mean absolute differences of 28.113.1 meters in 6MWT distance (p=.03) and 3.41.2% in % predicted FVC (p=.003) were observed in favor of Myozyme vs. placebo. The frequency of adverse events and infusion associated reactions were comparable between groups. Three patients in the Myozyme group experienced hypersensitivity reactions and discontinued treatment. One patient in the Myozyme group died from causes unrelated to treatment. All evaluable patients in the Myozyme group (n=59) developed IgG antibodies to rhGAA. A trend toward decreasing IgG titers was observed. Conclusions: In this first placebo-controlled study of rhGAA in juveniles and adults with Pompe disease, Myozyme was shown to improve walking and pulmonary outcomes compared to placebo.

Sex differences in repetitive stereotyped behaviours in autism: implications for genetic liability. *P. Szatmari[1], X.-Q. Liu[2], A. D. Paterson[2,3], The Autism Genome Project Consortium* 1) Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, Ontario, Canada; 2) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Departments of Public Health Sciences, Psychiatry and the Institute of Medical Sciences, University of Toronto, Toronto, Ontario, Canada.

Background: The specific mechanisms underlying male predominance in autism remain a mystery. One hypothesis is that the genetic liability for autism is normally distributed in the population, and males and females have different genetic thresholds. As a consequence, we would expect that male siblings of the female probands will possess a similarly high genetic load as their sisters, and they might show greater severity or more symptoms than affected males from sibships with no affected females. Methods: Families with at least two individuals diagnosed with autism spectrum disorders (ASD) were collected from ten Autism Genome Project (AGP) sites in North America and Europe. Of the 970 families selected for the analysis, there were 631 male-only families (MO), 51 female-only families (FO) and 288 female-containing families (FC). Four gender categories were used in a mixed linear model with family as a random effect: male ASDs from MO, male ASDs from FC, female ASDs from FO and female ASDs from FC. In addition, we added covariates such as AGP site, verbal/non-verbal status and the age at ADI-R completion to the model. Results: After the adjustment for covariate effects, the repetitive stereotyped behaviour (RSB) domain total scores were significantly different across the four gender groups ($p < 0.0001$). In general, the female ASDs had lower RSB scores than the male ASDs ($p < 0.0001$). The largest RSB score difference was observed between the female and male ASDs from FC ($p < 0.0001$). Besides the differences between the male and female ASDs, the male ASDs from FC had significantly higher RSB scores than the male ASDs from the MO ($p = 0.01$). Conclusion: These results suggest important phenotypic differences in RSB across gender in ASD families and provide support for a gender-specific threshold model of genetic liability in autism.

Deletions in 15q13.3 and 16p11.2: Genomic Disorders exhibiting Incomplete Penetrance and Variable Expressivity. *T. H. Shaikh, C. Haldeman-Englert, E. Geiger, B. Connor, J. Morrissette, K. Gripp, K. Jenny, L. Medne, D. McDonald-McGinn, J. Ganesh, M. Deardorff, N. B. Spinner, E. H. Zackai* The Childrens Hospital of Philadelphia, Phila., PA.

Genomic Disorders (GDs) can arise due to copy number alterations (CNAs) of genomic fragments containing dosage-sensitive gene(s). Many GDs result from non-allelic homologous recombination (NAHR) between segmental duplications (SDs). We have analyzed 500 patients with multiple congenital anomalies (MCA) using microarray-based analysis. We identified 5 patients with a 1.5 Mb deletion in 15q13.3 and 3 with a 550 Kb deletion in 16p11.2. Both of these recently discovered, recurrent CNAs, have been associated with abnormal phenotypes and appear to result from NAHR mediated by SDs. The 15q13.3 deletion has been associated with mental retardation and seizure disorder, whereas the 16p11.2 deletion was found to be associated with autism. Of the four 15q13.3 deletions for which parental analysis was possible, 2 were found to be de novo and 2 were inherited from a phenotypically normal mother. The observed phenotypes in our patients included developmental delay, facial dysmorphia, palatal defects, cardiac defects and obesity. None of our patients have seizures or abnormal EEGs reported previously. Of the two 16p11.2 deletions for which parental analysis was possible both were found to be de novo. The observed phenotype in our patients includes developmental and language delays, seizures, facial dysmorphia, palatal defects and cardiac defects. The more severely affected patient has hemifacial microsomia and autistic-like behavior. Current data suggests that both the 15q13.3 and 16p11.2 microdeletions may exhibit incomplete penetrance and/or variable expressivity. Our ongoing analysis includes testing for recessive mutations on the non-deleted allele of genes, other modifying gene mutations or CNAs and imprinting, especially in the 15q13.3 region. We are beginning to address these questions by collecting and characterizing more patients with these CNAs. Further elucidation of genotype-phenotype correlations in these GDs will have significant implications for clinical diagnostics and genetic counseling.

Premature NRXN1 truncations due to intragenic genomic rearrangements in two families with autism, Asperger syndrome, anxiety, depression, ADHD, developmental delay, and speech delay. *B. Wisniowiecka-Kowalnik[1,2], M. Nesteruk[1,2], S. U. Peters[1], Z. Xia[1], M. L. Cooper[1], S. Savage[3], R. S. Amato[3], P. Bader[4], S. W. Cheung[1], P. Stankiewicz[1]*
1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 3) Eastern Maine Medical Center, Bangor, ME; 4) Cytogenetics, Parkview Memorial Hospital, Ft Wayne, IN.

In addition to copy-number-variation, mutations in syndromic and non-syndromic genes have been found in patients with autism or autistic spectrum disorder (ASD). Several studies reported mutations in genes encoding neurexins in a small percentage of ASD patients. These proteins are transmembrane molecules which are essential for efficient neurotransmission. and isoforms of *NRXN1* are highly expressed in the brain and have been shown to be associated with autism, ASD, schizophrenia, cognitive and behavioral abnormalities, and alcohol and nicotine dependence. We present two families, in whom we identified an intragenic deletion and a duplication within *NRXN1* using a clinical targeted oligonucleotide array-CGH V6.5 (Agilent, 44K). Whole-genome array CGH analysis with 385,000 oligonucleotide probes (NimbleGen) narrowed the breakpoints and allowed their sequencing by long range PCR. The 378,996 bp deletion was found in a pregnant woman with Asperger syndrome, anxiety and depression and three out of her four children with autism, anxiety, developmental delay, ADHD, and speech delay. The 184,260 bp tandem duplication was found in a patient with a diagnosis of autism (by ADOS and ADI-R), speech/language delays, and cognitive delays. The evaluation of parents is pending. In both cases, we found LINE-1 retrotransposon element L1PA at one of the breakpoints, suggesting its causative role. The deletion removed exons 2-4 (isoform) and the duplication copied exons 3-5 (isoform), resulting in premature truncation of NRXN1. Our data confirm previous observations that *NRXN1* may be pathogenic in a wide variety of psychiatric diseases, including autism, Asperger syndrome, anxiety, depression, ADHD, developmental delay, and speech delay.

A novel CYBB mutation causing X-linked chronic granulomatous disease in a family with primary biliary cirrhosis and granulomatous colitis. *A. Psychogios[1], A. Maddalena[2], D. Pardi[3], NM. Lindor[1], KD. Lindor[3], KN. Lazaridis[3]* 1) Medical Genetics, Mayo Clinic, Rochester, MN, USA; 2) GeneDx, USA; 3) Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, USA.

Primary biliary cirrhosis (PBC) is an idiopathic cholestatic liver disease typically affecting middle-aged women. PBC causes florid intrahepatic bile duct lesions and loss of bile ducts resulting in cirrhosis and liver failure. Patients are often asymptomatic and 90 % test positive for serum antimitochondrial antibodies (AMA). Chronic granulomatous disease (CGD) is a rare immunodeficiency disorder caused by neutrophil bactericidal defect of the NADPH oxidase enzyme complex. 70% of patients have X-linked recessive CGD caused by mutation of the p91-phox-beta polypeptide gene (CYBB). We report a Caucasian family with PBC, CGD and granulomatous colitis. The proband is a 23-year-old female with a family history of two maternal great-uncles who died in infancy of CGD. She was presented with Crohns disease and CGD retinopathy. She had functional absence of NADPH oxidase, positive AMA and a novel heterozygous deletion of 16 nucleotides in exon 5 of the CYBB gene. This mutation, c.360_375del16 (p.Phe121ValfsX2), causes a frameshift starting with codon 121 changing this amino acid to a Val residue, creating a premature Stop codon at position 2 of the new reading frame F121VfsX2, and is predicted to result in nonsense-mediated mRNA decay or premature protein truncation. The patients mother has psoriasis, decreased NADPH oxidase, negative AMA and is heterozygous carrier of the CYBB deletion. A maternal aunt has history of resected granulomatous colitis, positive AMA, liver biopsy diagnostic for PBC and is heterozygous carrier of the CYBB deletion. Conclusion: We report for the first time a clinical association of a novel disease-associated CYBB mutation with CGD, granulomatous colitis and PBC. We hypothesize that the three granulomatous disorders may represent a spectrum of a common X-linked disorder related to deficient NADPH oxidase complex. Further research is needed to clarify the pathogenetic role of CYBB mutations in females with PBC and granulomatous colitis.

The use of genome-wide eQTL associations to identify novel genetic pathways involved in complex traits. *J. L. Min[1], J. M. Taylor[1], J. B. Richards[2], T. Watts[3], J. Broxholme[1], F. Pettersson[1], K. R. Ahmadi[2], I. Ragoussis[3], A. P. Morris[1], T. D. Spector[2], L. R. Cardon[4], K. T. Zondervan[1]* 1) Bioinformatics and Statistical Genetics, Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 2) Twin Research Unit, King's College London,London, United Kingdom; 3) Genomics Laboratory, Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 4) Pharmacogenetics and Medical Genetics, GlaxoSmithKline, USA.

Despite recent successes of genome-wide association studies in complex traits, many associations between clinical phenotypes and genetic variants will remain difficult to uncover because of phenotypic heterogeneity. The use of downstream biological phenotypes may provide a more powerful approach. Gene expression levels are highly variable and heritable, and are known to be strongly associated with genetic variants. This study investigates the association between 44 quantitative metabolic phenotypes and 19,828 gene expression levels in 299 twins, followed up by targeted SNP association analysis in a replication set of 2,277 female twins. Expression profiling was conducted in lymphoblastoid cell lines from 154 female twin pairs from the St. Thomas UK adult twin registry, and 57 unrelated CEU HapMap individuals, using the Illumina Sentrix Human-6 version 2 BeadChip. We found 956 probes correlating with one or multiple traits. Genome wide association analysis between 900,651 non-redundant SNPs and these probes in HapMap individuals identified 5 probes with association signals in cis and 314 probes in trans. Replication of these signals in other eQTL studies was obtained for 20% of cis signals and 8% of the trans signals. We tested 1050 SNPs associated with any of the 319 probes for a SNP-clinical phenotype association in 2,277 twins and we are currently following up significant associations. This study suggests that SNPs associated with expression levels in trans may be more clinically relevant than those in cis.

Identifying genotype-phenotype signatures in genome-wide data sets using market-basket-analysis. *T. G. Schulze[1], L. Kassem[1], E.-H. Han[2], F. J. McMahon[1], G. Karypis[2]* 1) NIMH, Bethesda, MD; 2) U of Minnesota, Minneapolis, MN.

There is a lack of methods that can model gene-gene interactions and identify robust genotype-phenotype signatures in complex disorders. We propose to use market-basket-analysis, a standard tool in retail business. This technique can discover relationships between pairs of products purchased together and can be used to uncover cross-sells and related products. In contrast to many traditional clustering methods, this approach is not hampered by the presence of missing phenotypic data, typical for collections of complex disease phenotypes. We recently published the first genome-wide association study on bipolar disorder (Baum et al. 2008) using a replication design. Here, we study these 409 US and 675 German cases. The study is based on 47 phenotypic variables and 45 SNPs replicating across the samples and representing 39 genes. We then: (1) mine the US genotype (GT) data to find a frequent GT itemset (T, I), where T is the set of cases in the US dataset that contain the itemset denoted by I. (2) Look at the phenotypic (PT) signature of the US dataset for T and determine the PT variables that are at least present in 70% of the cases and their occurrence frequency within the set T is at least 1.3 times higher than the occurrence frequency in the entire US PT dataset. (3) Using the same itemset I of GT markers, look at the German dataset to find its set of cases that contain it. Call this set T_D. (4) Finally, we look at the PT variables of the German dataset for the set of cases in T_D and find its PT signature. We identify 16 GT combinations, the PT signatures of which show a degree of similarity of 85 to 99 % between the two samples. The phenotypic signatures are made up of combinations of a limited numbers of phenotypes, such as psychosis, suicidal behavior, psychomotor agitation and retardation, as well as dysregulation of sleep, appetite, and weight. Most of these variables are highly familial and have thus long been considered important delineators of genetic homogeneity. In a next step, we will apply this method to whole 500K and 1000K chip data. Using market-basket-analysis may prove to be a powerful fresh look at genotype-phenotype dissection.

Genome-wide association scan of psoriasis implicates genes associated with T cell differentiation. *A. M. Bowcock[1], J. Ding[2], K. Callis Duffin[3], R. P. Nair[4], P. E. Stuart[4], D. Goldgar[3], C. Helms[1], T. Tejasvi[4], J. E. Gudjonsson[4], A. Menter[5], J. J. Voorhees[4], G. G. Krueger[3], J. T. Elder[4,6], G. R. Abecasis[3], Collaborative Association Study of Psoriasis*
1) Dept Genetics, Washington Univ, St Louis, MO; 2) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 3) Dept Dermatology, Univ of Utah, Salt Lake City, UT; 4) Dept Dermatology, Univ of Michigan, Ann Arbor, MI; 5) Dept Dermatology, Baylor Univ Medical Center, Dallas, TX; 6) Ann Arbor Vetrans Affairs Hospital, Ann Arbor, MI.

Psoriasis is a chronic inflammatory skin disease affecting 2-3% of the European population. T cells in psoriasis lesions belong to the Th1 (CD4+) and Tc1 (CD8+) subsets, and may include a separate population of Th17 cells. To obtain insight into the genetic basis of psoriasis, a genome-wide association scan of 1,384 Caucasian psoriasis cases and 1,414 Caucasian controls on 451,724 SNPs was performed. Highly significant signals mapped to the MHC, with the most significant signals found in the immediate vicinity of HLA-C ($p = 8.36 \times 10^{-54}$). Seventeen signals were subjected to confirmation in an independent sample of 5,048 psoriasis cases and 5,041 controls of Northern European origin. 7 loci reached genome-wide significance and genes in several different associated regions encode proteins in the same biological pathway. Strong replicated association signals implicate the IL-23 signaling pathway in psoriasis, providing significant evidence for the first time of involvement of IL23A (combined $p = 9 \times 10^{-10}$) which encodes the p19 subunit of IL23, and replicating previously reported associations with IL23R (combined $p = 3 \times 10^{-8}$) and IL12B (combined $p = 10^{-28}$) which encodes the p40 subunit of IL23. IL23 signaling has been implicated in the development of Th17 cells and both IL23A and IL12B are upregulated in psoriatic lesions. Another association was to the vicinity of the tightly clustered IL4 and IL13 genes (combined $p = 3 \times 10^{-15}$) whose products are involved in the regulation of Th2 versus Th1 differentiation. These results indicate that genetic factors contribute to the altered balance of T-cell differentiation in psoriasis.

Patterns of diversity of NADPH Oxidase genes (*CYBB, CYBA, NCF2* and *NCF4*) in human populations. *E. Tarazona-Santos[1,2], F. Lyon-Freire[1], M. Machado[1], L. Burdette[3], R. Cheen[2,4], A. Crenshaw[3], C. Fabbri[5], L. Pinto[1], B. Sestanovich[2], M. Yeager[3], S. J. Chanock[2,4]* 1) Departamento de Biologia Geral, Universidade Federal de Minas Gerais, Brazil; 2) Section on Genomic Variation, Pediatric Oncology Branch, National Cancer Institute (NCI), National Institutes of Health (NIH), USA; 3) Intramural Research Support Program, NCI-FCRDC and Core Genotype Facility, NCI, NIH, USA; 4) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, NCI, NIH, USA; 5) Dipartimento di Biologia Evoluzionistica e Sperimentale, Università di Bologna, Italy.

The phagocyte NADPH oxidase is an enzymatic complex that catalyzes the reduction of oxygen to O^{2-} and generates reactive oxygen species (ROS), a critical reaction for the microbicidal activity of phagocytes. In non-phagocyte cells, NADPH oxidase produces a lower amount of O^{2-}, which overproduction is associated with neurodegenerative disorders and cardiovascular impairment. The NADPH oxidase includes two membrane-spanning polypeptide subunits, gp91-phox and p22-phox (encoded by *CYBB* and *CYBA*) and three cytoplasmic polypeptide subunits, p40-phox, p47-phox and p67-phox (encoded by *NCF4*, *NCF1* and *NCF2*). Mutations in *CYBB*, *CYBA*, *NCF1* or *NCF2* can result in Chronic Granulomatous Disease, a primary immunodeficiency. We have resequenced 35524bp including the exons, UTRs, promoters and intronic regions of *CYBB*, *CYBA*, *NCF2* and *NCF4* in 102 ethnically diverse healthy individuals. For the four genes, diversity and the recombination parameter are higher in Africans than in non-Africans, consistently with the demographic history of human populations. Although most of the patterns of diversity are compatible with the mutation-drift equilibrium model in the four studied populations, we observed an exception for *NCF2* in Asia, with a particularly differentiated haplotype structure, a modal haplotype that is rare elsewhere, low diversity and an excess of rare segregating sites ($D_{Fu\text{-}Li} = -2.67$, $p = 0.007$). This pattern of diversity is compatible with the action of positive natural selection acting on *NCF2* in Asian populations.

Segmental duplications mediate novel chromosome rearrangements. *K. Rudd, B. Bunke, J. Keene, M. Adam, D. H. Ledbetter, C. L. Martin* Dept Human Gen, Emory Univ Sch Med, Atlanta, GA.

Segmental duplications (SDs) are substrates for unequal crossing-over, mediating gains and losses of genomic intervals between highly paralogous regions. This mechanism generates recurrent chromosome rearrangements that may be associated with a clinical phenotype or normal copy number variation. "Genomic disorders" generated by unequal crossing-over have been described previously; however, given the concentration of SDs in the human genome many more remain to be discovered. We identified five novel copy number changes (CNCs) in samples from 8 individuals ascertained in our clinical cytogenetics lab using a custom whole-genome oligonucleotide array. CNCs were confirmed by FISH and inheritance testing in parents is ongoing. We have mapped the breakpoints of CNCs in 2q11.2, 2q13, 7q11.21, 7q36.1 and 16p12.1 to flanking SDs, consistent with rearrangement via unequal crossing-over. Like previously described SD-mediated rearrangements, flanking SDs are >40 kb, >98% identical, and separated by 450 kb to 2.7 Mb. The 2q11.2 *de novo* gain is 1.6 Mb and contains 16 genes. Three out of four reciprocal gains or losses in 2q13 were paternally inherited; the inheritance of one loss remains to be determined. The 2q13 CNC is 2.1 Mb and includes 6 genes. The 450 kb 7q11.21 loss includes only one gene. Inheritance is unknown, and gain of an overlapping region has been reported as a CNC in control populations. The 2.7 Mb 7q36.1 loss includes 37 genes; inheritance is unknown. The 630 kb loss at 16p12.1 is of unknown inheritance and partially overlaps with a previously reported microdeletion; however, it is flanked by different SDs, producing a smaller genomic change encompassing 5 genes. Though the mechanism of rearrangement is the same, some SD-mediated copy number changes are pathogenic while others are tolerated as benign variants. Consideration of dosage-sensitive genes, comparison to CNCs in normal populations, and parental studies inform clinical interpretation. The collection of SD-mediated rearrangements reported in this study is relevant to other clinical labs diagnosing causative genomic changes and highlights the incredible plasticity of the human genome.

TSPY and its X-encoded Homologue Interact with Cyclin B and Exert Contrasting Functions on Cyclin Dependent Kinase 1 Activity and Cell Cycle Progression. *Y.-F. C. Lau, Y. Li* Dept Medicine, University of California, San Francisco, San Francisco, CA.

Testis-specific protein Y-encoded (TSPY) gene is the putative gene for the gonadoblastoma locus on the human Y chromosome (GBY). Gonadoblastoma develop most frequently in dysgenetic gonads of XY sex-reversed individuals and intersex patients. TSPY is abundantly expressed in tumor cells of gonadoblastoma, premalignant carcinoma-in-situ precursors and testicular seminoma, as well various somatic tumors, including hepatocellular carcinoma, melanoma and prostate cancer. TSPY and an X-homologue, TSPX, harbor a conserved domain, designated as SET/NAP domain, but differ at their carboxyl termini. Ectopic expression of TSPY accelerates cell proliferation by abbreviating the G2/M stage while over-expression of TSPX retards cells at the same stage of the cell cycle. Previous studies demonstrated that the SET oncoprotein is capable of binding to cyclin B. Using various protein interaction techniques, we demonstrated that TSPY and TSPX indeed bind competitively to cyclin B at their SET/NAP domains in vitro and in vivo. TSPY colocalizes with cyclin B1 during the cell cycle, particularly on the mitotic spindles at metaphase. TSPY enhances while TSPX represses the cyclin B1-CDK1 phosphorylation activity. The inhibitory effect of TSPX on the cyclin B1-CDK1 complex has been mapped to its carboxyl acidic domain that is absent in TSPY, suggesting that TSPX could serve a normal or tumor suppressor function(s) in modulating cell cycle progression at the G2/M stage while TSPY has acquired a specialized function(s) in germ cell proliferation and meiotic division. Epigenetic dysregulation of TSPY in incompatible germ or somatic cells could promote cell proliferation and predispose susceptible cells to tumorigenesis. The present findings strongly support TSPY to be the gene for GBY, a germ cell tumor predisposition locus on the Y chromosome.

Rapid generation of conditional and null mutant alleles in the mouse using targeted trapping. *B. C. Bjork[1], F. Schnütgen[2], H. von Melchner[2], D. R. Beier[1]* 1) Div Genetics, Brigham & Women's Hospital, Boston, MA; 2) Dept Molecular Hematology, Univ of Frankfurt Med Sch, Germany.

Our ongoing recessive ENU mutagenesis screen generates phenotypes that model human birth defects, such as clefting. The *cleft secondary palate 1 (csp1)* mutation is an excellent model of nonsyndromic clefting. We are developing strategies to rapidly validate such positionally-cloned mutations. The rapid generation of multi-purpose targeted mouse alleles is an attractive approach to take to accomplish this goal. The *csp1* mutant is a hypomorphic allele caused by a splice-site mutation in the zinc finger transcription factor, *Prdm16*. Mutant palate shelves fail to elevate likely due to extrinsic defects affecting mandible and/or tongue development. *Prdm16* expression in the palate shelves and other craniofacial structures is consistent with it playing a critical role during palatogenesis.

In order to validate our hypothesis that *Prdm16* is the causal gene in the *csp1* mutant, we developed a strategy to rapidly generate targeted trapping constructs for targeted trapping (Friedel et al., 2005). This approach employs a multi-fragment gateway site-specific recombination system, and requires only the PCR-amplification of two genomic fragments flanking the integration targeting site. From a single targeting of the *rsFlpROSAbgeo** gene trap cassette (Schnütgen et al. 2005) into a *Prdm16* intron, we generated a novel multi-purpose allele of *Prdm16* that can be analyzed as 1) a functional null, 2) a reporter of endogenous gene expression and 3) a conditional null allele that employs the FLEx recombination system (Schnütgen et al., 2003). Our analysis demonstrates that this allele recapitulates the *csp1* phenotype and accurately reports the endogenous *Prdm16* expression pattern.

By crossing these trapped mice to ubiquitous *FLPe*-expressing *FLPer* transgenic mice, we generated homozygous viable mice carrying the inverted, inactive gene trap cassette. We are currently breeding these mice to various *Cre*-expressing transgenic mice to study the tissue-specific *Prdm16* loss of function.

Genome-wide analyses of gene expression in Williams syndrome. *L. Dai[2], T. Tirosh-Wagner[1], R. Weiss[2], M. Gao[1], D. Mills[3], A. Reiss[4], U. Bellugi[5], J. Korenberg[2]* 1) Dept Medical Genetics, Cedar Sinai Medical Ctr, Los Angeles, CA; 2) The Brain Institute, University of Utah, Salt Lake City, UT; 3) Dept. of Psychology, Emory University, Atlanta, GA; 4) Dept. of Psychiatry and Behavioral Sciences, Stanford University, Palo Alto, CA; 5) Laboratory of Cognitive Neuroscience, The Salk Institute for Biological Studies, La Jolla, CA.

Williams syndrome is a neurodevelopmental disorder due to the deletion of a ~1.5 Mb region of chromosome band 7q11.23. Although the features of WS are ultimately due to the decreased copy number of the ~25 genes, the critical downstream biological pathways that alter development and adult function are unknown. WS provides a unique human model in which to combine high resolution array analyses to determine the components of these pathways. In this study, we determined the deletion in a cohort of 21 subjects with WS and asked whether genome-wide approaches querying 22,000 genes at the single exon level, were capable of sensitively measuring alterations of two fold reduction in single gene transcripts. Whole genome gene expression analysis was performed on total RNA samples from 21 WS DNAs with the common deletion and 6 normal controls. RNAs were labeled using a whole transcript sense target labeling assay after an rRNA reduction. Biotinylated target was hybridized to the Affymetrix GeneChip Exon 1.0 ST (sense target) arrays containing 6.5 million probe features. Probe level data was processed with RMA analysis (Robust Multiarray Analysis) for 22,000 RefSeq supported genes, and for exon-level results. Unexpectedly, rank products analysis (RP) revealed a 25-50% (1-2 fold) reduction in expression levels across chromosome 7 Williams region transcripts as the most significant genome-wide reduction observed between normal and affected groups. Of 22,000 gene transcripts queried, WS genes represented 10 of the top 11 transcripts with reduced expression. These data indicate that genome wide analyses can be used to establish both deleted genes and non-deleted genes whose transcription is altered, providing the opportunity to identify genetic networks that mediate the features of WS.

Posterior probability of linkage genome scan in NIMH Chinese schizophrenia sample. *V. Saviouk[1], Y. H. Huang[2], M. A. Azaro[1], A. S. Bassett[3], V. J. Vieland[2], L. M. Brzustowicz[1]* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Childrens Hospital, Columbus, Ohio; 3) Dept of Psychiatry, Univ of Toronto, ON, Canada.

The results of a genome linkage scan for schizophrenia (SZ) in the NIMH HGI Chinese family collection were reported by Faraone et al (Am J Psychiatry 163:10) with the largest nonparametric linkage z score of 2.88 for D10S2327. We have reanalyzed the autosomal genome using the posterior probability of linkage (PPL). We reviewed the clinical information and classified as phenotypically unknown all individuals with organic mental syndromes and active substance dependence. Some 4.6% of families were excluded from the PPL analysis due to lack of informativeness after these diagnostic changes. We split the sample into two subsets: those without any family members with affective diagnoses (SZ group); and those with SZ, schizoaffective disorder (SA), and bipolar disorder (BP) (heterogeneous [HET] group). Subjects with SZ (1207), SA (14) and BP (5) were all considered affected. The SZ group (558 of 578 families) had 1160 subjects affected exclusively with schizophrenia; the HET group (20 families) had 47 affected subjects (28 with SZ). Genotypes were cleaned using PEDCHECK and multiple SIMWALK runs. Sample specific genetic maps were constructed using KELVINs mapping function; SZ and HET groups were analyzed by four-point analysis using KELVIN at 2 cM resolution, and the results from each group were combined via sequential updating. The results confirmed the linkage peak on 10q22 between D10S2327 and D10S2470 with a PPL of 29% after updating (SZ 29%, HET 2%). In addition we observed a peak of 30% over D3S1311 on 3q29 coming primarily from the HET group (SZ 2%, HET 30%). Two additional regions reached PPL of 10% each: 13q32 over D13S793 (SZ 12%, HET 2%) and 19q13 between D19S178 and D19S246 (SZ 9%, HET 2%). Our results demonstrated that a conservative approach to diagnostic classification and sample stratification based on observed psychopathology in families, thorough error checking of genotypes, ethnic specific genetic maps, and use of the PPL can yield novel linkage findings for complex phenotypes.

Encephalopathic ApoCII Deficiency- A Case Report. *M. Niell, M. A. Abbott* Clinical Genetics, Baystate Medical Center, Springfield, MA.

A now 6 year old girl was noted to have severe hyperlipidemia at 1.5 months of age after her eye color changed from blue to an orange/pink color. On ophthalmoscopy, she had evidence of lipemia retinalis (elevated retinas with sub-retinal yellowish exudates, dilated vessels and distortion of retinal anatomy). Brain CT showed hypodense lipid-type deposits mostly in the right hemisphere, but deposits were also apparent in the left. Upon initial hospital admission at 1.5 months of age, her blood was found to be pink and creamy in nature. Her initial triglyceride count was 3,736 mg/dL and rose to 24,540 mg/dL and her cholesterol rose from 608 mg/dL to 2,265 mg/dL over the course of two weeks. Abdominal ultrasound revealed hepatomegaly and fatty infiltration of the liver, and echocardiogram identified interventricular septal hypertrophy and right ventricular hypertrophy. Two exchange transfusions were successful in decreasing her triglyceride and cholesterol levels to 356 mg/dL and 950 mg/dL respectively. Nonetheless she had her first seizure at 2 months of age. She has been following a strict low-fat diet since 2 months of age and is receiving additional treatment with lovastatin. She currently has significant developmental delays, visual impairment due to bilateral retinal detachments, seizures controlled by anti-epileptics, and spastic quadriparesis. She has exhibited a non-progressive course with strong developmental gains. A brain MRI at 3.5 years of age showed extensive encephalomalacia and mild-to-moderate enlargement of the ventricles with areas of hemosiderin deposition and abnormal globes. Analysis of the *APOC2* gene revealed a previously unreported homozygous deletion, c.196-197delGC, in exon 3. This deletion results in a premature termination codon and presumably a truncated ApoCII protein lacking its C-terminus, which is necessary for functional interaction with lipoprotein lipase. Although ApoCII deficiency is typically diagnosed later in life, between the second and fifth decades, following episodes of recurring abdominal pain caused by pancreatitis, there have been reports of an early onset severe form. Ours is an additional description of this dramatic encephalopathic presentation of ApoCII deficiency.

Brain mitochondrial dysfunction may contribute to phenotypes of Angelman syndrome in the Ube3a deficient mice. *H. Su[1], W. Fan[2,3], J. Vesa[1], E. P. Coskun[2,3], J.-A. Gold[1], Y.-H. Jiang[4], A. Acab[5], J. H. Weiss[5], D. C. Wallace[2,3,6], V. E. Kimonis[1]* 1) Dept of Pediatrics, University of California, Irvine, Irvine, CA; 2) Center for Molecular and Mitochondrial Medicine and Genetics, University of California, Irvine, CA; 3) Dept of Biological Chemistry, University of California, Irvine, CA; 4) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Dept of Anatomy and Neurobiology, University of California, Irvine, CA; 6) Dept of Ecology and Evolutionary Biology and Pediatrics, University of California, Irvine, CA.

Angelman syndrome (AS) is a severe neurological disorder caused by deficiency of the ubiquitin protein ligase Ube3a. It is as yet unknown if mitochondrial functions are related to phenotypes of AS. We found that the Ube3a deficiency results in mitochondria that are smaller in size. There is disturbance of mitochondrial inner membranes and reduction of synaptic vesicle density in the Ube3a deficient mice when compared to wild-type by using electron microscopy. We measured the enzyme activities of mitochondrial complexes in the brain, liver, heart and muscle by using oxidative phosphorylation (OXPHOS) enzyme assays. Consistently, enzyme activities of the brain mitochondrial complexes II+III were significantly reduced ($p<0.05$, Student t test, n=5/group) in the Ube3a deficient mice when compared to the wild-type mice, which could contribute to pathophysiology of AS. Muscle mitochondrial complex IV is elevated ($p=0.05$, Student t test, n=5/group) in the Ube3a deficient mice when compared to the wild-type mice, which may represent the Ube3 deficient mices attempt to compensate cumulative energetic deficiency of the brain by upregulating skeletal muscle mitochondrial enzyme activity to increase ATP production. The observed differences in the different tissue may be related to observed imprinting of Ube3a expression in the brain. These findings may help in understanding the pathogenesis and offers a new opportunity to develop treatment that could prevent the symptoms and phenotype of AS.

Cumulative effects of risk alleles on systemic lupus erythematosus susceptibility and subphenotypes. *K. E. Taylor[1], R. R. Graham[2], G. Hom[2], S. A. Chung[1], W. Ortmann[2], A. T. Lee[3], M. Petri[4], S. Manzi[5], P. K. Gregersen[3], T. W. Behrens[2], L. A. Criswell[1]* 1) Univ. California San Francisco Div. Rheumatology, San Francisco, CA; 2) Genentech Inc., South San Francisco, CA; 3) Feinstein Inst. for Medical Research, North Shore L.I.J. Health System, Manhasset, N.Y; 4) Johns Hopkins Univ. School of Medicine, Baltimore, MD; 5) Univ. Pittsburgh, Pittsburgh, PA.

Systemic lupus erythematosus (SLE) is a genetically complex disease with heterogeneous clinical manifestations. Recent whole-genome scans have greatly expanded the number of known SLE risk alleles, but the distribution of multiple risk alleles in cases versus controls and their relationship to SLE subphenotypes has not been studied. We analyzed 10 established SLE risk alleles from the Illumina 550K array in 4 independent Caucasian SLE case series (n=1310) and independent sets of controls (n=7859). We also studied associations with clinical manifestations for the cases, namely the 11 ACR criteria, anti-double-stranded DNA (anti-dsDNA) autoantibodies, and age of onset. The mean number of SLE risk alleles was 5.91 (SD 1.91) for cases versus 4.95 (SD 1.77) for controls, linear trend in log odds $p_{trend}=3x10^{-54}$. The odds ratio for SLE risk comparing 7 or greater (24%) versus 4 or less (36%) risk alleles was 3.3 (95% CI 2.8-4.0). The number of SLE risk alleles was most strongly associated with anti-dsDNA autoantibodies ($p_{trend}=3x10^{-6}$), earlier age of onset ($p_{corr} = 0.0003$), and inversely with oral ulcers ($p_{trend} = 2x10^{-5}$), and was more significant than individual SNPs in multivariate regressions for these subphenotypes. Similar results omitting HLA-DR3 and HLA-DR2 tagging SNPs ($p_{trend}=0.0004$, $p_{corr} = 0.0003$, and $p_{trend} = 10^{-5}$, respectively) indicate that these are not due simply to the HLA. In contrast, a borderline association with renal disease (p=0.03) was more strongly associated with HLA-DR3 alone, p=0.004. We conclude that SLE risk increases approximately linearly with the number of risk alleles, which is also strongly associated with the specific subphenotypes of increased anti-dsDNA autoantibodies, earlier age of onset, and decreased risk of oral ulcers.

TUBA1A mutations are a rare cause of posterior predominant lissencephaly that resembles the LIS1-associated pattern. *R. A. Kumar[1], R. J. Harvey[3], T. D. Babatz[1], W. B. Dobyns[1, 2]* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Depts Pediatrics and Neurology, Univ Chicago, IL; 3) Dept Pharmacology, The School of Pharmacy, London, UK.

Lissencephaly (LIS) is a severe cortical malformation characterized by abnormally broad gyri and a thick cortex, and by histological evidence of deficient neuronal migration. It results in severe mental retardation and epilepsy, and typically shortened postnatal survival. Our past studies have detected mutations of *LIS1* or *DCX* in 85% of children with the common classic type of LIS, leaving only 15% unexplained. Recently, mutations in the tubulin alpha 1A gene (*TUBA1A*) were associated with LIS that is more severe in posterior than anterior brain regions, resembling the LIS1 pattern. We have used direct DNA sequencing to screen for *TUBA1A* coding mutations in 66 individuals with posterior predominant LIS who were negative for mutations in *DCX* and *LIS1*. We identified two missense mutations in exon 4 in 4/66 patients (6%), which suggests that *TUBA1A* mutations will account for ~1% of classic LIS (0.06 x 15% = 0.9%). The first mutation, p.R402C, was reported previously in a 35-week gestation fetus with severe grade 1 LIS and identified here in three unrelated patients with grade 2 or 3 posterior predominant LIS. The apparently greater severity in the fetus may be accounted for by developmental considerations. The second mutation, p.G143W, is novel and was found in a child with LIS who had more severe hypogenesis of the corpus callosum and cerebellar vermis than found in most children with LIS1 mutations. We used structural modeling to predict the functional impact of p.G143W on protein function. The p.G143W substitution results in a tryptophan side chain that projects into the GTP binding site, resulting in several predicted clashes and/or contacts between atoms, thereby perturbing GTP binding. G143W is the first report of a human mutation affecting the TUBA1A GTP-binding site. In conclusion, our results indicate that *TUBA1A* mutations account for ~1% of posterior-anterior LIS. Functional analysis of G143W is underway to assess whether this mutation disrupts incorporation of TUBA1A into microtubules.

Eight new cases plus review of literature supports U-type exchange as the most frequent mechanism for inverted duplication with terminal deletion rearrangements involving most chromosomal arms. *L. R. Rowe[1], L. Rector[1], J. C. Carey[2], D. Viskochil[2], A. F. Rope[2], A. R. Brothman[1,2], S. T. South[1,2]* 1) Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Division of Medical Genetics, Department of Pediatrics, University of Utah, Salt Lake City, UT.

Chromosomal rearrangements resulting in an inverted duplication with concomitant terminal deletion were first described for the short arm of chromosome 8 in 1976. Since then, this type of alteration has been identified and characterized for most chromosome arms. Three mechanisms are commonly proposed to explain the origin of this type of rearrangement. All 3 mechanisms involve formation of a dicentric chromosome that then breaks in a subsequent meiotic division to produce a monocentric duplicated and deleted chromosome. However, the events leading to the formation of the dicentric chromosome differ between the mechanisms. In one mechanism, either parent carries a paracentric inversion. This results in formation of a loop during meiotic pairing with a recombination event occurring in the loop. In the second mechanism, inverted low-copy repeats in the same chromosome arm allow partial folding of one homolog onto itself with a recombination event between the inverted repeats. The third mechanism involves a pre-meiotic double-strand break with subsequent fusion, or U-type exchange, between the sister chromatids. The first two mechanisms require a single-copy region to exist between the duplicated and deleted regions, therefore high-resolution analysis of the rearrangement can be used to distinguish between these mechanisms. Using G-banded chromosome analysis, FISH and array CGH, we describe 8 new cases of inverted duplication with terminal deletion of 2q, 8p, 9p, 10q, 15q, 18p, 18q, and 22q. These new cases combined with previously described cases demonstrate that U-type exchange is the most frequent mechanism for this type of rearrangement involving most chromosome arms.

High-density linkage screen identifies potential dementia loci in the Amish. *A. C. Davis[1], J. L. Haines[1], L. Jiang[1], P. J. Gallins[2], N. Schnetz-Boutaud[1], L. L. McFarland[1], D. Fuzzle[1], C. Knebusch[1], M. Creason[2], L. Caywood[2], C. E. Jackson[3], W. K. Scott[2], M. A. Pericak-Vance[2], J. L. McCauley[2]* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Miami Institute for Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 3) Scott & White, Temple, TX.

While APOE has replicated numerous times as an Alzheimer Disease (AD) susceptibility gene, it explains less than half of the genetic risk for AD, leaving more than half of the risk unsolved. Genetic heterogeneity complicates the identification of the remaining genetic risk factors. However, using a genetically isolated, and therefore relatively homogenous, population can minimize heterogeneity. We have assessed over 1700 (132 with AD) individuals from the genetically isolated Amish populations in Ohio and Indiana. Using the Anabaptist Genealogy Database (AGDB) and its query software PedHunter, we determined kinship coefficients and the family structure of our sample. We used the GREFFA program to cluster individuals, based on kinship scores 0.0156 (second-cousins), to create sub-pedigrees from our complex multi-generational extended Amish pedigree (n>4,300 over 11 generations). We performed a genome-wide SNP linkage screen (Illumina Linkage Panel IVb) using 672 Amish individuals (103 with AD) in 21 sub-pedigrees. Suggestive linkage to AD was found for 18 SNPs across 16 independent loci (2-pt lod scores >2.0: 1q, 2p, 2q, 3q22, 3q26, 4q, 5q, 7q, 8p, 13q, 14q23, 14q24, 16p, 18q, 20q, 21q). The MQLS test of linkage and association also identified 284 SNPs with nominally significant p-values (p0.05). Subsequently, we utilized the Simwalk program to perform multipoint linkage analysis for multiple 3-SNP sliding windows across each of the regions identified by the 2-pt analysis. Five of these regions continued to demonstrate strong evidence for linkage (mpt lod >1.8: 1q, 3q22, 5q, 18q, and 21q), with three of these also demonstrating MQLS p-values 0.05 (1q, 3q22, 18q). We are currently genotyping 100 SNPs across these regions in an extended set of Amish samples to confirm and refine these results.

Association analysis of SNPs located in regions linked to enuresis in children with ADHD and enuresis. *F. Lantieri[1], T. Takeda[1], R. Deberardinis[2], J. Accardo[1], P. J. Ambrosini[3], N. J. Blum[1,2], L. W. Brown[1,2], W. Berrettini[2], J. Glessner[1], C. Kim[1], M. Devoto[1,2,4], H. Hakonarson[1,2], J. Elia[1,2]* 1) The Childrens Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA; 3) Drexel University, Philadelphia, PA; 4) University of Rome La Sapienza, Roma, Italy.

ADHD and enuresis co-occur at higher rates than expected. Genetic factors are thought to play an important role in both nocturnal enuresis and ADHD. Several studies have reported linkage of enuresis to four chromosomal regions including 8q, 12q, 13q and 22q. We carried out a family-based association study on 51 ADHD children that were also affected by enuresis and their parents for SNPs located in these loci to address their potential role in the co-morbidity of enuresis and ADHD. TDT analysis was applied to a total of 24,945 SNPs located on chromosome 13 (3179 SNPs), 12 (6602), 8 (12817), and 22 (2347) in the 51 family trios. Several of these regional SNPs showed p-value below 0.01. However, no SNP remained significant after correction for the number of test performed. Among SNPs with p0.001 the majority clustered to specific regions less than 1 Mb in size. Moreover, none of these SNPs showed a TDT p-value lower than 0.01 in a set of ADHD trios not presenting enuresis that was used as a control sample. Thus, we cannot exclude that these loci may contribute to both enuresis and ADHD, or be involved in enuresis or ADHD independently. Since ADHD had been reported to coexist in 30-40% of enuretic children, and since these children are more likely to have the inattentive symptoms of ADHD, we are currently analyzing this subset of ADHD cases only, regardless of the enuresis trait, to determine if these loci may be related to a deficits in arousal and therefore be associated to both enuresis and the inattentive symptoms of ADHD.

Evidence for current co-evolution of fertilization genes in humans. *R. V. Rohlfs*[1], *W. J. Swanson*[1], *B. S. Weir*[1,2] 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA.

Coevolving genes must undergo complementary mutations to maintain the fitness of their interaction. If a pair of coevolving genes have multiple functionally distinct alleles, matching alleles will be selected across loci. Selection for allele matching may be detectable as allelic correlation between physically unlinked loci. This sort of selection has generally been dismissed as biologically improbable due to the extremely intense selective pressure required.

Using the test statistic for composite linkage disequilibrium (CLD), we have found evidence for allelic association between genes mediating sperm-egg binding in humans. We tested candidate genes for association using 1408 members of the 1958 Birth Cohort typed with Affy 500K SNP chips. Genes proposed to encode receptors in sperm cell membrane and egg zona pellucida which allow sperm-egg recognition, ZP3 and ZP3R, show an unusual degree of correlation using a standard CLD test. We are in the process of refining a novel test for general genotypic association to confirm or refute this finding.

Our results support the hypothesis of allele matching selection, even across physically unlinked loci. It is not surprising that this sort of selection is found in fertilization since this process is known to be subject to intense selection.

Functional dissection of ARMS2/LOC387715 protein, associated with susceptibility to age-related macular degeneration. *A. Kanda[1,2], A. Estrada-Cuzcano[2], A. Swaroop[1,2,3]* 1) Neurobiology-Neurodegeneration, National Eye Institute, Bethesda, MD; 2) The Departments of Ophthalmology and Visual Sciences , University of Michigan, Ann Arbor, MI; 3) The Departments of Human Genetics, University of Michigan, Ann Arbor, MI.

We previously reported that SNP rs10490924 at 10q26 within the ARMS2/LOC387715 gene is strongly associated with susceptibility to age-related macular degeneration (AMD) and that ARMS2 encodes a 12 kDa protein which localizes to or associates with mitochondrial outer membrane in transfected cells (Kanda et al. 2007 PNAS). These results have been validated recently (Fritsche et al 2880 Nature Genetics). To further dissect its function, we generated multiple missense and deletion mutations in the ARMS2 protein by site-directed mutagenesis. Our data demonstrate that C-terminal 10 amino acids are required for mitochondrial localization/association of the ARMS2 protein. We also performed yeast two-hybrid screening using human retina cDNA library to identify ARMS2-interactive proteins; the analysis of interacting proteins is in progress. We propose that C-terminal region of ARMS2 and its mitochondrial localization/association are necessary for physiological function.

Underprovision of guideline-recommended advice regarding genetic risk assessment for hereditary breast and ovarian cancer among U.S. women. *D. E. Levy[1,2], A. E. Shields[1,2], J. E. Garber[2,3]* 1) Center on Genomics, Vulnerable Populations, and Health Disparities; Massachusetts General Hospital; Boston, MA; 2) Dept of Medicine; Harvard Medical School; Boston, MA; 3) Division of Population Science; Dana-Farber Cancer Institute; Boston, MA.

Context BRCA1/2 testing is the most commonly used genetic test to predict cancer risk. Guidelines are available to help clinicians determine who will benefit most from testing. **Objective** To identify women at high risk of hereditary breast/ovarian cancer and develop national estimates of the proportion of high-risk women who have discussed genetic testing for cancer risk with a health professional. **Methods** We identified women aged 18 and older with no personal history of breast or ovarian cancer participating in the 2000 and 2005 National Health Interview Survey Cancer Control Supplements (n=35,116). Respondents were labeled as being at high risk of hereditary breast/ovarian cancer using one of three national guidelines and self-reported family history of cancer. Main outcomes were self-reported awareness of genetic testing for cancer risk, discussion of genetic testing for cancer risk with a health professional, and having undergone genetic testing for breast/ovarian cancer risk. We compared these outcomes across women at high vs. average risk levels. **Results** 0.92% of women met at least one guideline criterion indicating high risk of hereditary breast/ovarian cancer. Among high-risk women, 55.5% were aware of genetic testing for cancer risk, 10.8% had discussed genetic testing for cancer risk with a health professional, and 1.5%; had actually undergone such testing. Adjusting for survey year, high-risk women were more likely than average risk women to have heard of genetic testing for cancer risk (RR, 1.3, 95% CI 1.2-1.5), to have discussed genetic testing for cancer risk with a health professional (RR 5.3, 95% CI 3.8-7.6), and to have undergone genetic testing for breast/ovarian cancer risk (RR 7.1, 95% CI 2.7-18.6). **Conclusions** We find few women at high risk for hereditary breast/ovarian cancer discuss genetic testing with a health professional. Thousands of women are not receiving clinically valuable information.

Genotoxicity assessment of two mouthwashes by means of micronuclei assay in buccal mucosa cells. *A. L. Zamora-Perez[1], M. Fuentes-Lerma[1,2], C. Guerrero-Velázquez[1], R. Brihuega-Velázquez[1], B. Gómez-Meda[3], G. Zúñiga-González[4], R. Researchs in the dentistry fields has allowed the knowledge of the structure and biology of dental tissues, as well as technological development, resulted in new materials, tools and techniques which indicated the need to apply methods or models to evaluate the possible genotoxic properties of it. There are many different tests for the detection of genotoxic effects, as is the micronuclei assay (MN). Mouthwashes components may vary and some contain high levels of alcohol. This produces a burning sensation caused by the chelating action in the basal layer of the exfoliated cells and this direct stimulus to the epithelium, might causes increase in the rate of cell renewal. The aim of the present work was to assess the genotoxicity of two mouthwashes by means of the MN assay in buccal mucosa cells. Twenty healthy adults volunteered to participate in the study and were divided into two groups (10 each). Samples were taken from buccal mucosa before starting treatment and 30 days after treatment. A marked increased in MNC was seen in subjects that rinse their mouth with mouthwash with alcohol compared with those without that used mouthwash without alcohol (mean (SD) 2.6 (1.0) MNC/2000 cells vs 1.3 (0.6) MNC/2000 cells, respectively. Intragroup comparisons showed no differences in the MNC frequencies in group 1, whereas the MNC frequency in group 2 varied significantly (before: 1.0 (0.6) MNC/2000 cells; after: 2.6 (1.0) MNC/2000 cells. In the present study, the frequency of MNC from buccal mucosa increased significantly in those subjects who rinse their mouth with mouthwashes who contain alcohol compared with those without alcohol.

Accommodating Population Structure in the APL Test. *M. Schmidt, E. R. Martin, R. Chung* Ctr Human Genomics, Univ Miami, Miami, FL.

APL (Martin et al. AJHG 2003) is a powerful test for association based on general nuclear family structures, allowing for multiple affected offspring and missing parental genotypes. The APL statistic is based on the difference between the observed number of alleles in affected siblings and the expected number of alleles conditional on parental genotypes. In a single population, APL correctly computes the expected number of alleles by inferring missing parental genotypes based on siblings genotypes while properly accounting for identity-by-descent (IBD). In the presence of population stratification, however, the expected number of alleles can be biased away from the null hypothesis, resulting in excess type I error. Here we propose a modification of the APL test that accommodates population structure by incorporating a population clustering algorithm based on information from non-candidate markers. The expected value in the APL statistic is calculated conditional on parental genotypes and cluster information. Variability due to clustering is accommodated in the bootstrap procedure currently used by APL. Due to efficiency considerations the bootstrap requires an algorithm that is not too computationally intensive. Preferably the algorithm is robust to outliers and LD between markers. The methods investigated include complete linkage hierarchical clustering as implemented in PLINK and Wards clustering algorithm as implemented in AWclust. The outlier problem is addressed via the gap statistic or nearest neighbor analysis. We demonstrate validity of the modified APL incorporating population stratification algorithms using HapMap data originating from distinct populations as well as simulated data with known outliers or LD. We compare the power of the APL test using different clustering algorithms under a variety of population models and different sets of genetic markers to provide practical guidelines for applying APL in stratified populations.

A genome-wide association study of attempted suicide in the GAIN bipolar study. *V. Willour[1], P. Belmonte[1], P. Zandi[2], F. McMahon[3], J. Kelsoe[4], J. Potash[1], BiGS Consortium and Bipolar Phenome Group* 1) Dept Psychiatry, Johns Hopkins Univ, Baltimore, MD; 2) Dept Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) National Institute of Mental Health, Bethesda, MD; 4) Dept Psychiatry, University of California, San Diego, CA.

Family, twin, and adoption studies provide strong evidence for a heritable component to attempted and completed suicide. The heritability of suicidal behavior appears to depend in part on psychiatric disorders and, importantly, to also be partly independent of them (Brent and Mann 2005). Linkage regions related to attempted suicide in bipolar disorder (BP) have been identified on 2p12 and 6q25-26. We conducted a secondary analysis of genome-wide association data from the Genetic Association Information Network (GAIN) BP sample using attempted suicide as the phenotype. This sample consists of 1034 controls and 1001 BP cases, of whom 553 had a history of attempted suicide and 427 had no history of attempted suicide (21 were unknown). Genotyping was performed using Affymetrix Genome-Wide Human SNP Array 6.0 and 729,779 SNPs passing QC were examined for association with attempted suicide in BP. We analyzed the data using polytomous logistic regression with three outcome groups: BP suicide attempters, BP non-attempters, and controls. There were 649 loci with a difference in association for BP suicide attempters vs. BP non-attempters at $p<0.001$. One of the top findings (rs10269703; p=3.01 x10-7) was in muskelin (MKLN1), a mediator of cell spreading and cytoskeletal responses to the extracellular matrix component thrombospondin I. Muskelin is expressed in rodent neurons and may be involved in synaptogenesis. The odds ratio for association of rs10269703 in MKLN1 with BP suicide attempters vs. controls was 1.3 (p= 0.002), while association with BP non-attempters vs. controls was 0.8 (p=0.003). There was no evidence for association at this locus in BP when attempted suicide was not included in the analysis. We identified several interesting candidate genes for attempted suicide in BP, including MKLN1. These findings will need further follow-up for relevance to attempted suicide and replication in other samples.

MP-CBS: a new method for multi-platform integrated analysis of copy number variation (CNV). *Y. Senbabaoglu[1], N. Zhang[3], D. Absher[5], G. Sherlock[4], R. M. Myers[5], J. Li[2]* 1) Bioinformatics Graduate Program; 2) Dept of Human Genetics, University of Michigan, Ann Arbor, MI, USA; 3) Dept of Statistics; 4) Genetics, Stanford Univ, Palo Alto, CA, USA; 5) HudsonAlpha Institute for Biotechnology, Huntsville, AL, USA.

Recent advances in high-throughput data collection have dramatically improved our ability to study gene expression changes, DNA variants, and their impact to disease risks. In many studies, multiple technical platforms were used to interrogate the same samples; and it became necessary to pool information across platforms to derive a consensus molecular profile for each sample. A motivating example is The Cancer Genome Atlas (TCGA) project, a recent, NIH-funded initiative to characterize DNA, RNA, and epigenetic abnormalities in tumors. For studying CNVs it adopted three independent platforms: Affymetrix SNP 6.0 arrays, Illumina HumanHap 550K SNP arrays, and Agilent CGH 244K arrays. An integrated analysis is expected to maximize resolution and accuracy, yet currently there is no statistically well formulated method to address the between-platform differences in probe design, assay methods, sensitivity, and analytical complexity. An initial approach is to apply the circular binary segmentation (CBS) algorithm, which iteratively searches for DNA segments of altered signal intensity. The results from three platforms are combined after segmentation. Here we propose a new method, multi-platform CBS (MP-CBS), which extends CBS by relying on a generalization of the -square statistic used in the original CBS. MP-CBS does not require standardization of data, sums statistical evidence across platforms, and makes use of the integrated statistics during segmentation. It achieves improved spatial resolution, detection power, and provides a natural consensus. We will discuss data preprocessing issues, computation efficiency, as well as efforts to independently evaluate the performance of MP-CBS by comparing the integrated analysis of Affymetrix and Illumina SNP array data on HapMap samples with fosmid library-sequencing results on the same samples.

***AGTR2* is a genetic and therapeutic modifier of Marfan syndrome.** *J. P. Habashi[1,2], J. J. Doyle[2], D. Bedja[2], H. C. Dietz[2]* 1) Div Ped Cardiol; 2) Institute of Genetic Medicine and HHMI, Johns Hopkins Univ, Baltimore, MD.

Marfan syndrome(MFS), a disorder that includes aortic aneurysm, is caused by mutations in the fibrillin-1 gene(*FBN1*). Murine models demonstrated that excess activation of and signaling by TGF causes many of the manifestations of MFS. We have shown that antagonizing TGF signaling with TGF neutralizing antibody or the angiotensin II(AngII) type 1(AT1) receptor blocker losartan attenuates aneurysm formation in MFS mice. Signaling of AngII through AT1 increases the expression of TGF ligands, receptors and activators such as thrombospondin-1, while signaling through the AT2 receptor is thought to antagonize these events in some cell types. In theory, induction of AT2 signaling by AT1 blockade may contribute to the protective effect of losartan. This position is controversial because AT2 signaling can also induce apoptosis, leading to the proposal that the dual AT1/AT2 blockade achieved by limiting the production of AngII with angiotensin converting enzyme inhibitors(ACEi) is preferable. To address this, we disrupted the *Agtr2* gene (encoding AT2; AT2KO) in fibrillin-1 targeted mice(Fbn1+/-) and followed the progression of aortic aneurysms by echocardiography. AT2KO:Fbn1+/- mice showed a larger aortic dimension than Fbn1+/- mice at 8 weeks (p0.0008), and this difference was maintained at each time point until the mice were sacrificed at 1 year of age. Both were significantly worse than wild-type mice at all time points(p0.0001), while isolated disruption of AT2 did not induce aortic enlargement. AT2KO:Fbn1+/- mice had significantly worse aortic wall architecture as compared to Fbn1+/- alone (p0.0009). We then compared losartan to the ACEi enalapril in MFS mice using hemodynamically equivalent doses. While aortic growth during the 5 months of treatment was reduced in both the losartan (p0.00003) and enalapril (p0.001) groups when compared to placebo, the growth in the losartan group was less than that seen with enalapril (p0.0002). We conclude that AT2 signaling protectively modifies MFS, that the therapeutic effect of ACEi relates strictly to AT1 blockade, and that the selective AT1 antagonist losartan results in a superior clinical outcome.

A Haplotype Spanning the SREBF1 Gene is Associated with BMI and Varies in Frequency Worldwide. *S. D. Bailey[1], G. Pare[2], A. Montpetit[2], N. Rudzicz[3], R. Do[1], D. Gaudet[4], C. Bouchard[5], L. Perusse[6], M.-C. Vohl[6], B. Keavney[7], T. J. Hudson[2], S. Yusuf[8], S. S. Anand[8], J. C. Engert[1]* 1) Dept. of Human Genetics,McGill Univ.,Montreal,QC; 2) McGill Univ. & Genome Quebec Innovation Centre, Montreal,QC; 3) McGill Univ. Health Centre,Montreal,QC; 4) Dept. of Medicine,Univ. of Montreal,Chicoutimi,QC; 5) Pennington Biomedical Res. Centre,Baton Rouge,LA; 6) Lipid Res. Centre,Laval Univ. Hospital Res. Centre, Ste-Foy,QC; 7) Univ. of Newcastle,Newcastle,UK; 8) Dept. of Medicine,McMaster Univ.,Hamilton,ON.

Significant differences in cardiovascular disease (CVD) risk exist between populations. Therefore identifying genetic variants that display differences in allele frequencies between populations may help elucidate the etiology of these population differences, as well as identify genes that have undergone recent selection. We analyzed 1536 SNPs, from 103 CVD candidate genes, for differences in derived allele frequency (DAF) in 38 populations. One gene was the sterol regulatory element-binding transcription factor 1 (SREBF1), which plays a role in lipid metabolism. Eight SNPs encompassing SREBF1 had large and similar differences in DAF between populations. This pattern was caused by two common haplotypes that accounted for 65% of all haplotypes in non-African populations. One haplotype (HapA) was found to be most common among Europeans (freq=0.37-0.68). The second most frequent haplotype in Europeans (HapB) had the opposite allele at every SNP. Individuals homozygous for HapA were found to be significantly heavier than those homozygous for HapB in the entire INTERHEART sample (p=0.007). HapA was associated with BMI in the three largest ethnic groups examined (p0.05). The frequency of HapA is highly correlated with the mean BMI for each country (r^2=0.66,p=3.8x10-5;r^2=0.2,p=0.025 for men and women respectively). We replicated the association with BMI in Quebec family-based samples, using 2 SNPs that captured the Haplotype (p0.05). Additional associations were found with total abdominal adipose tissue (AT) and subcutaneous AT assessed by CT at the L4L5 level (p0.05). Thus, this locus may explain a portion of the between population differences in BMI and adipose tissue distribution.

SNPs into the NFE2L2 regulatory region and arsenic susceptibility. *F. Centeno[1], E. Cordova[1], C. Rangel[1], K. Carrillo[1], O. Valenzuela[2], L. M. Del Razo[2], L. Orozco[1]* 1) Investigación, Instituto Nacional de Medicina Genómica, SS; 2) Centro de Investifación y de Estudios Avanzados, IPN.

Arsenic contaminated ground water is the main source of human exposure worldwide and it represents an important health issue. Arsenic exposure has been associated with skin cancer and non-cancerous skin lesion as hyperkeratosis, hyperpigmentation and acanthosis. The Nrf2 transcription factor (nuclear factor erythroid 2-related factor 2) regulates the expression of a battery of genes encoding antioxidant and phase II detoxification enzymes. Nrf2 activation has been proposed as an important mechanism against arsenic exposure in different cellular types. Thus, the aim of this study was to determine whether the association between NFE2L2 gene variants and the occurrence of skin lesions by exposure to arsenic-contaminated water. Initially, we sequence 1000 Kb of the Nrf2 regulatory region and its first non-conding exon from 120 Mexican-Mestizo healthy donors to identify novel NFE2L2 SNPs. We found three out of six (-653G/A, -651G/A and -617C/A) previously described polymorphisms in the promoter and one (12delGCC) at the 5 untranslated region sequence. Additionally, we found a novel variation in only one subject (). We also identify a new allele comprised by only two repetitions of the CCG triplet, instead of the previously reported four or five-time triplet repeat alleles. It was found in two unrelated heterozygous subjects, The -617C/A and -653G/A SNPs were genotyped by the 5'nuclease assay (TaqMan), and the 12delCCG polymorphism by Gene Scan Analysis in 117 subjects with (cases) or without (controls) arsenic-related skin lesions. Total arsenic levels was determined in urine and drinking water. Genotypic and allelic frecuencies from the analyzed polymorphisms did not show significant differences between cases and controls. Haplotype analysis showed a higher frecuency of the CA haplotype in controls with low levels of arsenic, than in cases. Our results, suggest a protective role of the Nrf2 CA haplotype against low exposure to arsenic. Increasing the sample size will allow us to confirme this data.

Efficient Reconstruction of Whole Genomes Using Massively Parallel Shotgun Sequence Data. *Y. Li, G. R. Abecasis* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Tremendous advances in shotgun sequencing technologies make it feasible to rapidly generate gigabases of sequence data in hundreds or thousands of individuals. These new technologies represent an important advance over conventional genotyping approaches because they allow for more comprehensive assessments not only of SNP variation but also of other polymorphisms, including many types of copy number variants. To date, these technologies have been used to sample and reconstruct whole genomes for a small number of individuals by sampling non-repetitive regions of the genome high redundancy (20-30x coverage). We show that, when many individuals are examined, it is possible to use relatively modest amounts of sequence data for each individual (2-4x coverage) to reconstruct high-quality whole genome sequences. The savings is possible because, typically, short stretches of chromosome are shared between many individuals in each sample and information can be combined across these to achieve high-quality sequence. We describe a Hidden Markov Model for rapid reconstruction of whole genome sequences from shotgun resequencing data. By simulating shotgun sequence data consisting of 30bp reads with a 0.5% error rate per base-pair, we show that, using our approach, analyzing sequence data for 400 - 1,000 individuals sequenced at depth 8 achieves comparable accuracy (< 1 error / 10,000 bp at polymorphic sites) as analysis of deep 20-30x coverage using conventional approaches that don't integrate data across individuals. To illustrate the practical utility of our approach, we also analyze publicly available sequence data on ~180 individuals examined by the 1000 Genomes Project. We expect that our method will allow for the cost-effective utilization of new sequencing technologies, either for targeted analysis of specific regions or for whole genome resequencing. We expect that both these approaches will be important for identifying causal variants and for mapping rare variants that are not adequately captured by current whole genome genotyping approaches.

First neuronally expressed gene associated with multiple sclerosis. *Y. S. Aulchenko[1], I. A. Hoppenbrouwers[2], S. V. Ramagopalan[3], L. Broer[1,2], N. Jafari[2], J. Hillert[4], J. Link[4], W. Lundström[4], E. Greiner[4], A. D. Sadovnick[5], D. Goossens[6], C. van Broeckhoven[6], J. del Favero[6], G. C. Ebers[3], B. A. Oostra[1], C. M. van Duijn[1], R. Q. Hintzen[2]* 1) Epidemiology & Biostatistics and Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 2) Department of Neurology, Erasmus MC, Rotterdam, The Netherlands; 3) Wellcome Trust Centre for Human Genetics and Department of Clinical Neurology, University of Oxford, Oxford, UK; 4) Department of Neurology, Karolinska Institute, Stockholm, Sweden; 5) Department of Medical Genetics, Division of Neurology, University of British Columbia, Vancouver, Canada; 6) Department for Molecular Genetics, Antwerp Univerity, Antwerp, Belgium.

Multiple sclerosis (MS) is a complex disease resulting from genetic and environmental factors. The genetic influence on MS susceptibility is substantial, as evidenced by the 20-fold increase in risk for siblings of MS patients. Until recently, the MHC class II locus has been the only one consistently associated with MS. Given the strong evidence for an autoimmune origin of MS, it is not surprising that the major MS genes discovered by genome wide association (GWA) analysis were these related to T-cell function (*IL2R* and *IL7R*). We here report a GWA study in 45 MS cases and 195 controls in a genetically isolated population. The study has identified a new MS susceptibility locus on chromosome 1. This locus was confirmed in a replication set of 2,679 cases and 3,125 controls derived from four independent populations. A single nucleotide polymorphism, located in this newly identified gene, was significantly and consistently associated to MS in each of the four populations (combined allelic odds ratio 1.35, 95% confidence interval from 1.23 to 1.48, $p = 2.5\ 10^{-10}$). The gene identified is neuronally expressed and is involved in axonal function and thus can be directly linked to recent data on axonal suffering in MS. This risk gene for the first time draws genetic attention to the central nervous system, the target organ in this disease.

Popular representations of genetics research: Recommendations for journalist-researcher relationships. *C. Ouellette[1], T. Bubela[2], T. Caulfield[1]* 1) Health Law Institute, University of Alberta, Edmonton, AB, Canada; 2) School of Public Health, University of Alberta, Edmonton, AB, Canada.

Human genetics research receives a lot of attention from the media and the public. The media have been criticized for hype with coverage generally falling into two categories: great promise or concern. To add to concerns, new media are now a major source of information for the public. These range from news sites, allowing for expanded coverage of scientific and social issues, to corporate advertising aimed at providing genetic testing services. Providers are concerned that media coverage is inadequate; it influences the tests and treatments requested by patients and is often misinterpreted.

Our study asks whether the media coverage evidence of genomics is as bleak as it appears. We synthesize the evidence on media portrayals of genetics and genomics. Are the media overly deterministic in representing genetic causation for phenotypes and prone to error and hype? Second, we summarize communication recommendations between researchers and journalists from journal articles, commentaries and policy reports. Do these recommendations hold for new media? Are they based on a 'deficit model' of science communication, where the public would be more supportive of genetic research if only they understood the science and issues?

Evidence shows that print media accurately reflect genetic research. However, hype may be initiated by researchers quoted by journalists; coverage is generally uncritical and framed to promote economic interests and scientific progress. The majority of errors are omissions of risk factors, timelines for benefits, conflicts of interest, funding, and the rise of commercial interests in biomedical research. Omissions may contribute to the sense of hype and may decrease public trust. In the face of these issues, the internet is both a blessing and a curse. For high quality sites, the absence of space constraints and the ability to link to sources may correct the omission problem of print media. For industry representations, there is likely a need for tighter regulation of health claims and information.

PHYLOGENY OF THE PROLYL-3 HYDROXYLASE FAMILY COMPARED TO EXPRESSION. *J. Lennington[1], D. Baldridge[1], R. Morello[1], B. Lee[1,2]* 1) Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Howard Hughes Medical Institute.

The family of prolyl-3 hydroxylase related proteins is required for evolutionarily conserved post-translational modification of collagens. Mutations in two of its members cause a form of OI, and dysregulation may contribute to a broader range of connective tissue diseases. The family is made up of 5 homologues: CRTAP, No55, P3H1, P3H2, and P3H3. The P3Hs all have dioxygenase domains and hydroxylate collagen prolines in the 3-trans position of Gly-X-4Hyp. CRTAP and No55 lack the functional dioxygenase domain; however, CRTAP is required for P3H1 function in a tertiary complex with cyclophilin B. All family members share a predicted common ancestor, at which point a duplication event lead to a common CRTAP/No55 branch, and common P3H branch. CRTAP is the most highly conserved family, with average of 75.8% homology to the human ortholog in vertebrates, possibly as it is required for the function of other family members. No55 has the lowest homology among vertebrates, 63.2%, and greatest number of duplication events during evolution, suggesting a less essential role. There is a separate branch initially for a P3H1 and common P3H2/P3H3 ancestor. Homology among vertebrates for P3H1, P3H2, and P3H3 is 65.2%, 74.6%, and 66.4% respectively. P3H1 and P3H3 have many overlapping regions of expression such as cortical bone and craniofacial mesenchyme. P3H2 expression is unique and includes hypertrophic chondrocytes, skeletal muscle, glomeruli, and heart. P3H3 has the largest distance between avian and mammalian ancestors, 4.7-5.9 fold greater than P3H2 and P3H1. P3H3 may be required for mammalian specific development, such as viviparous nature or more developed medulla and urinary concentrating ability. P3H3 is expressed most strongly in early murine kidney development (E13.5), and has strong expression in the medulla and interstitium of the kidney. The mammal with lowest homology to human P3H3, the armadillo, has acute interstitial nephritis and thickened tubular basement membranes in as high as 70% of animals. Examining the phylogeny of this group integral to collagen modification may further aid in understanding each members differential function.

***AFG3L2* mutations cause autosomal dominant ataxia SCA28 and reveal an essential role of the *m*-AAA AFG3L2 homocomplex in the cerebellum.** *D. DiBella[1], F. Lazzaro[2], A. Brusco[3], G. Battaglia[1], A. Pastore[4], A. Finardi[1], V. Fracasso[1], M. Plumari[1], C. Cagnoli[3], F. Tempia[3], A. Brussino[3], C. Gellera[1], C. Mariotti[1], P. Plevani[2], S. DiDonato[1], T. Langer[5], M. Muzi-Falconi[2], F. Taroni[1]* 1) Fond IRCCS Ist Neurologico Carlo Besta, Milan, Italy; 2) Dept Biomol Sci Biotec, Univ of Milan, Italy; 3) Univ of Turin, Italy; 4) Nat.l Inst Med Res, London, UK; 5) Genetics Inst, Univ of Köln, Germany.

Autosomal dominant spinocerebellar ataxias (SCA) are a heterogeneous group of neurological disorders characterized by cerebellar dysfunction mostly due to Purkinje cell degeneration. We previously mapped SCA28 to chromosome 18p11 in a 4-generation Italian family. We have now discovered that *AFG3L2* (ATPase family gene 3-like 2) mutations cause SCA28. Along with paraplegin, which causes recessive spastic paraparesis SPG7, AFG3L2 is a component of the mitochondrial *m*-AAA complex, an evolutionarily conserved metalloprotease involved in protein quality control. We have identified 4 heterozygous *AFG3L2* missense mutations in the original kindred and in other 3/129 (~2%) unrelated SCA families. Interestingly, one index patient in this latter group was found to carry also a heterozygous SPG7 recessive mutation in the paraplegin gene. Segregation analysis of the *AFG3L2* and *SPG7* mutations in this family demonstrated a modulatory role of the *SPG7* mutation, with a full-blown phenotype in the *AFG3L2*/*SPG7* compound heterozygote and cerebellar atrophy in the *AFG3L2* heterozygotes. All the AFG3L2 mutations are located in the FtsH-like protease domain at highly conserved amino acids. Modeling on FtsH structure indicates that they may affect substrate interaction. AFG3L2 protein and transcript were found to be highly and selectively expressed in cerebellar Purkinje cells. Expression of normal and mutant AFG3L2 homocomplex in *m*-AAA-deficient yeast cells demonstrate that the mutations cause respiratory deficiency and proteolytic defect. This work identifies *AFG3L2* as a novel cause of dominant neurodegenerative disease and indicates an essential role of the AFG3L2 homocomplex in protecting the cerebellum against neurodegeneration [Italian Ministry of Health grant (ex art 56) to FT].

Investigation of Lipase Maturation Factor 1 in dyslipidemia. *D. Weissglas[1], M. Péterfy[2], M. Doolittle[2], O. Ben-Zeev[2], A. Huertas-Vazquez[1], B. Aouizerat[3], J. Kane[4], I. Cruz-Bautista[5], T. Tusie-Luna[5], C. Aguilar-Salinas[5], M.-R. Taskinen[6], P. Pajukanta[1]* 1) Dept. of Human Genetics, UCLA, Los Angeles, CA; 2) Dept. of Medicine, UCLA, Los Angeles, CA; 3) Dept. of Physiologic Nursing, UCSF, San Francisco, CA; 4) Dept. of Medicine, UCSF, San Francisco, CA; 5) INCMNSZ, Mexico City, Mexico; 6) Dept. of Medicine, University of Helsinki, Finland.

Mice carrying the combined lipase deficiency (cld) mutation exhibit hypertriglyceridemia (HTG) due to decreased activities of both lipoprotein lipase (LPL) and hepatic lipase (HL). The cld mutation that we recently identified resides in a novel gene, lipase maturation factor 1 (LMF1) (Péterfy et al. Nature Genetics 2007) that promotes maturation of nascent LPL and HL. To study the potential role of LMF1 in human dyslipidemia, we resequenced the coding regions of LMF1 in 42 Finnish and U.S. Caucasian HTG cases exhibiting combined lipase deficiency. We identified 19 DNA variants: 7 intronic, 7 synonymous, 4 nonsynonymous (ns) (G36D, M117L, R364Q, R451W) and a nonsense variant (Y439X). Of the 5 coding variants, 4 were novel, and 3 were highly conserved across species. To estimate the frequency of the coding variants we genotyped them in normolipidemic controls. The frequency of the mutations was lower or zero among the controls except for G36D. Therefore, we investigated the 4 rare mutations in the mouse cld model for functional significance. We introduced wildtype LMF1 and the mutations into an LMF1 cDNA expression construct in cld/cld cells to examine LPL specific activity. Although the ns cDNA constructs rescued the cld/cld cells, we observed a decrease in specific activity of LPL for two of these ns variants. Importantly, the Y439X cDNA construct was not able to rescue the cld/cld cells. Currently we are investigating the LMF1 gene in 38 Mexican individuals with severe HTG (TG > 1000 mg/ml), to search for shared and population-specific DNA variants. Thus far, we have identified 7 intronic, 7 synonymous and 4 ns variants, of which 7 were observed only in Mexicans. Furthermore, 30% of the Mexican HTG cases had a ns variant in LMF1. In conclusion, our data show that LMF1 variants are involved in human lipase deficiencies and dyslipidemia.

VKORC1 is associated with bone mineral density and osteoporosis risk in African-Americans from the Third National Health and Nutrition Examination Survey. *M. J. Rieder[1], C. L. Sanders[2], D. C. Crawford[3]* 1) Dept Genome Sciences, University of Washington; 2) Division of Health and Nutrition Examination Surveys, National Center for Health Statistics, Centers for Disease Control and Prevention; 3) Center for Human Genetics Research, Vanderbilt University.

Osteoporosis is a common disease in postmenopausal women defined by a low bone mineral density (BMD), with both environmental and genetic factors. We hypothesized that SNPs in the vitamin K epoxide reductase complex subunit 1 (*VKORC1*) gene are associated with BMD. VKORC1 generates vitamin K quinone, a cofactor for the gamma-carboxylation of bone-related proteins such as osteocalcin. We genotyped four *VKORC1* SNPs in 7157 individuals from the Third National Health and Nutrition Examination Survey (NHANES III). NHANES III is a nationally representative sample linked to health and lifestyle variables including BMD, which was measured using dual energy x-ray absorptiometry (DEXA) on four regions of the proximal femur. In a multivariate model stratified by race/ethnicity and sex, SNPs rs9923231 and rs9934438 were associated with decreased BMD in African-American (AA) adult females ($n=953$; $p<0.01$) and males ($n=671$; $p<0.005$) while rs8050894 was associated with decreased BMD in AA males only ($p<0.001$). In multivariate models with genetic interactions for SNP*serum calcium levels rs9923231 ($p=0.0175$) and rs9934438 ($p=0.0064$) serum calcium interactions were associated in AA females with increased BMD. All four SNP*serum calcium terms were significantly associated with decreased BMD in Mexican-American (MA) males ($n=834$; $p<0.05$). No significant associations or interaction terms were observed for European-American females or males or MA females. Osteoporosis risk was tested by defining cases as participants 2.5 SD below the reference BMD mean (at 20-29 yrs). Among AA female cases ($n=19$) and controls ($n=703$), rs9923231 and rs993438 ($OR_{adj}=0.20$; 95% CI: 0.07-0.58), and rs2359612 ($OR_{adj}=0.52$; 95% CI: 0.28-0.94) were significantly associated with decreased osteoporosis risk; rs8050894 was marginally associated ($OR_{adj}=0.27$; 95% CI:0.07-1.02). These data suggest *VKORC1* may be associated with BMD and osteoporosis in the AA population.

Integration of a novel medical genetics curriculum in the family medicine junior clerkship. *K. D. McKelvey[1], S. H. Prajapati[2], B. Bendure[4], C. Paniagua[3], R. M. Smith[5], V. A. Johnson[5]* 1) Division of Genetics and Department of Family and Preventive Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Department of Family and Preventive Medicine; 3) College of Nursing; 4) College of Medicine; 5) Office of Academic Affairs and Educational Development.

In recognition of the emerging importance of genetics in clinical medicine, we developed a novel curriculum to educate junior medical students regarding unique aspects of genetic tests. Implications for medical genetics include an ever-expanding role in preventive medicine, but responsible application requires critical thought into the ethical, legal, and social issues created by molecular genetics. Our interactive online curriculum is designed to accommodate students across multiple sites over a 4 week period. It uses topic-based asynchronous discussion to stimulate critical thinking during the process. Inclusion of this project into the required curriculum of the third year family medicine clerkship serves as a crucial step in the incorporation of genetics into preventive medicine. We will present data from a total of 69 students who have completed both the pre and post knowledge acquisition tests and evaluated the course to date. The mean, standard deviation, and overall change in scores will be discussed and illustrated. The primary purpose of the evaluation is continuous program improvement. Since this is a new curriculum, information that maximizes future student learning is particularly important. An examination of pre-post scores for specific course topics indicates a need for this type of curriculum as well as opportunities to improve learning. Open responses to the query Please give your suggestions for improving the material in the course will be discussed and provide valuable insight into where the content could be improved to increase the amount of learning change.

Fragile X allele frequency comparisons among different ethnicities. *A. Cronister, S. Bhatt, Y. Wang, L. Rosenblum-Vos* Genzyme Genetics, Westborough, MA.

Introduction: Carrier screening for fragile X requires complete information for genetic counseling, yet published studies comparing premutation and intermediate allele prevalence among different ethnicities are limited. Studies in Canada and Israel found a premutation frequency of 1/259 and 1/157 women, respectively. Variation in the modal distribution of allele sizes among ethnicities has also been documented. Here, we analyze Genzyme Genetics data from over 40,000 females who had fragile X carrier testing. Allele frequencies were compared among different populations. Methods: This study included >40,000 women referred for fragile X carrier testing between 1999 and 2008. Women with a family history of fragile X, MR, DD or autism were excluded. Ethnicity was self-reported by the patient. Ethnic groups were: Caucasian (n= 22655), African American (n= 3550), Asian (n= 5106), Hispanic (n= 7804) and Jewish (n= 1214). Results: Overall, the intermediate frequency was 1/45 and the premutation frequency was 1/227. The observed premutation frequency was 1/187 in Caucasians and significantly lower in Asians than in other groups (1/567; $p = 0.0013$). Intermediate frequencies were lowest in Asians (1/104) and African Americans (1/60) and differed significantly from other groups ($p < 0.0001$ and $p=0.0025$, respectively). Allelic distribution also varied among populations. The most common size allele in all groups was 30, but Asians showed minor populations at 36 and 37. Caucasians and Hispanics had sub-populations at 20-24 repeats. The percentage of women whose smallest allele was 33-44 repeats varied among populations (Asians: 2.41%, Caucasians: 1.28%, African Americans: 0.96%, Hispanics: 0.85%, Jews: 0.31%). Conclusions: Our study suggests variation in allelic distribution and intermediate and premutation frequencies in different ethnic groups. The lower premutation carrier frequency observed in Asians but higher frequency of allele pairs in the 33-44 range, is of interest considering the prevalence of fragile X syndrome is similar to other populations. Further studies within different ethnic groups are necessary to clarify the prevalence of fragile X as well as factors that may lead to instability and risk for fragile X expansion.

In depth association analysis of positional candidate region for bipolar disorder. *P. Zhang[1], S. Zöllner[1,2], Y. Chen[1], M. Burmeister[2,3], M. McInnis[2]* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Psychiatry, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Bipolar disorder (BP) is a highly heritable trait but identifying susceptibility genes has been challenging and no findings have been reliably confirmed. Previous meta-analysis by McQueen et al (2005) showed the strongest linkage peak with LOD=3.40 in chromosome 8q region. We use fine map association analysis to further explore the 8q region for underlying risk variants. A sample of 3,553 individuals from 737 families with bipolar disorder was collected and genotyped for 1,461 tag SNPs in a 16Mb region flanking the candidate loci identified by McQueen et al. We performed genetic association analysis using LAMP. Our preliminary analysis identified three SNPs that are significantly associated with BP after correction for multiple testing: rs7845065 (p =9.80E-06), rs2668096 (p =1.40E-05), and rs7825584 (p=7.00E-05). Two genes are located within 1 Mb of the most significant SNP rs7845065, the hyaluronan synthase 2 gene (HAS2) and the zinc fingers and homeoboxes 2 gene (ZHX2). We have genotyped an additional 1536 SNPs in the same region to get more complete coverage. Further investigation is needed to confirm these results and to identify candidate genes that play a role in the biological pathway of BP.

A novel *FGFR2* Deletion in Beare-Stevenson Syndrome. *A. Slavotinek[1], H. Crawford[2], H. Perry[3], C. Tao[3], C. Fitzgerald[1], S. Oberoi[3], K. Vargevik[3], M. Friez[2]* 1) Dept Pediatrics, U585P, Univ California, San Francisco, San Francisco, CA; 2) Greenwood Genetics Center, Greenwood, SC; 3) School of Dentistry, Univ California, San Francisco, San Francisco, CA.

Beare-Stevenson syndrome (BSS) is a rare craniosynostosis syndrome characterized by cutis gyrata, acanthosis nigricans, skin furrows and tags, anogenital anomalies and a prominent umbilical stump. We present a fraternal twin male who had cutis gyrata and acanthosis nigricans of the scalp, excess neck skin, proptosis with hypoplasia of the supraorbital ridges, hypertelorism, midface hypoplasia, narrowing of the external ear canals, skin tags at the corners of the mouth, neonatal teeth, a prominent umbilicus, broad halluces, excess palmar and plantar skin and a prominent scrotal raphé. Investigations revealed an Arnold-Chiari malformation, fusion of the superior sagittal suture and bilateral choanal stenosis. A clinical diagnosis of BSS was made shortly after birth, but sequencing of exon 11 of the *FGFR2* gene for the previously reported p.Y375C and p.S372C mutations in BSS was normal. These two mutations are likely to affect both the BEK and KGFR isoforms of FGFR2 and were hypothesized to cause disease by constitutive activation of these isoforms, although functional studies were not performed (Przylepa et al., Nat Genet 1996;13:492-494). Our patient was re-studied at age six years because of a diagnosis of rhabdomyosarcoma in his twin brother. A novel, *de novo* mutation in *FGFR2* was identified, with a deletion of 62 nucleotides starting in exon 8 (IgG IIIa domain) of the gene, c.859del62, a region in which missense mutations have been associated with Crouzon syndrome. This deletion predicts haploinsufficiency for *FGFR2*, a disease mechanism previously found in lacrimo-auriculo-dento-digital (LADD) syndrome, a condition very different from BSS. This deletion provides new information concerning the mutational spectrum of BSS, the phenotypic overlap between BSS and Crouzon syndrome, and broadens the phenotypes that arise from *FGFR2* deletions.

Genomics and doping control: The application of high-resolution expression profiling of whole blood to strategies to detect erythropoietin (EPO) abuse in athletes. *J. L. Rupert, M. E. Gallo, M. N. Fedoruk* Sch Human Kinetics, Univ British Columbia, Vancouver, BC, Canada.

BACKGROUND: Erythropoietin (EPO))is a glycoprotein hormone that stimulates the maturation of red blood cells, thereby increasing haematocrit and the oxygen carrying capacity of blood. Since the late 1980s, recombinant EPO (rhEPO) has become one of the most widely abused performance enhancing substances in endurance sports. Current anti-doping tests are based on differences in glycosylation patterns between the rhEPO and naturally occurring EPO; however, doping authorities are concerned that new variants of the drug or the use of EPO gene therapy (gene-doping) may render current testing stratagems obsolete. We are investigating transcription profiling as a potential method of detecting the abuse of rhEPO or EPO gene-doping. METHODS: Erythropoiesis was induced in mice by hypoxia (13% O2) or rhEPO (10mg/kg SC). Conditions were designed to mimic the ~10% increase in haematocrit targeted by doping athletes. For each condition (and controls), blood was taken from 10 mice and pooled. LongSAGE libraries generated and sequenced using Illumina 1G technology by the Genome Science Center in Vancouver. The libraries were compared and transcripts significantly over-represented in the EPO treated animals identified. RESULTS: The three libraries (control, hypoxia and rhEPO)contained 7.6, 8.1 and 7.1 million tags representing between 149,000 and 210,000 and 157,000 tag types (excluding singletons) respectively. Approximately 47,000 tag-types were unique to the EPO library. Most of these were at very low frequencies; however, 30 were present in at least 10 copies. DISCUSSION: We demonstrate that transcriptional signatures representing exposure to rhEPO can be characterized, and differentiated from the hypoxia response, in mouse blood, supporting the feasibility of using gene expression patterns in human blood as a basis for detection of EPO doping in athletes. Validation of these expression patterns in humans and analysis of inter-individual due to exercise, menstrual cycle, and time of blood draw is underway.

Sex, Aldosterone and Telomere Length in African American Adolescents. *H. Zhu, X. Wang, J. Thomas, K. Li, I. Stallmann-Jorgensen, G. A. Harshfield, Y. Dong* Dept Pediatrics, Med College Georgia, Augusta, GA.

Background: Telomeres are tandem repeats of TTAGGG at the ends of chromosomes that protect genomic integrity and progressively shorten with each cell division. Age, sex, body mass index (BMI), and renin-angiotensin-aldosterone (RAAS) system have been shown to affect the rate of telomere attrition in adults. However their effects on telomere length in youth, especially in African American youth remain unknown. Objectives: To evaluate the roles of age, sex, BMI and markers of RAAS system on telomere length in African American adolescents. Methods: One hundred and fifty nine African American adolescents (aged 17.0 1.3, 59% females) participated in the study. Relative telomere length (T/S ratio) was determined in buffy coat DNA samples using a rapid, real-time quantitative PCR method, which normalized telomere extension product (T) to the amount of extension product of a single copy gene (S), and standardized the results to a reference DNA sample. The relative T/S ratio was dichotomized at the median into two groups (long telomere group vs. short telomere group). In a subset of the sample including 61 individuals (61% females), plasma renin activity, angiotensin II and aldosterone were measured by competitive enzyme methods. Results: The relative T/S ratio was not associated with age or BMI in this age group. However, the percentage of female in the long telomere group is higher than in the short telomere group (70.0% vs. 48.1%, p=0.004). Moreover, plasma aldosterone levels were higher in the long telomere group as compared to the short telomere group (125.8 62.4 pg/ml vs. 90.4 29.2 pg/ml, p=0.036). Further adjustment of age and sex did not change the results (p=0.003 for the difference in sex and p=0.052 for the difference in aldosterone levels). No associations were found between renin, renin/aldosterone ratio and the relative T/S ratio. Conclusion: This is the first study to show that in African American adolescents, females tend to have longer telomere than males. Aldosterone appears to be positively correlated with telomere length in this group. The mechanism is not clear and warrants further investigation.

Proximal symphalangism in a neonate with a 13q12q14.3 deletion. *J. Kaplan, G. Enns, L. Hudgins* Stanford University, Stanford, CA.

Purpose: Proximal symphalangism is a rare autosomal dominant disorder characterized by ankylosis of the proximal interphalangeal joints, carpal and tarsal bone fusion, and conductive deafness. Mutations in both *NOG* (17q22) and *GDF5* (20q11.2) have been identified in this disorder as well as in other disorders involving abnormalities in joint morphogenesis. We describe a neonate with proximal symphalangism and radiohumeral synostosis who was found to have a deletion involving 13q12q14.3 by high-resolution chromosome analysis. The novel findings in this case prompted us to examine this region for proximal symphalangism candidate genes.

Methods: Genes in the deleted region were identified using OMIMs gene map. We then concentrated on genes with the potential to affect joint morphogenesis. We reviewed the literature for cases with similar deletions causing symphalangism and for studies involving candidate genes.

Results: To our knowledge, there are no reported cases of symphalangism associated with a deletion in 13q12q14.3. Candidate genes in this region include *FLT1*, a VEGF receptor that may play a role in osteoclastogenesis; *TNFSF11*, which is involved in the differentiation of osteoclasts; and *CHM1*, which encodes chondromodulin 1, a cartilage-specific glycoprotein that stimulates chondrocyte growth.

Conclusions: Based on this intriguing case, it is clear that there are genetic causes of proximal symphalangism that remain to be identified. Whereas *NOG* and *GDF5* mutations can result in increased osteoblast activity, it is certainly possible that defects in osteoclast activity may result in a similar synostosis phenotype. Haploinsufficiency of a gene in this region may be responsible for proximal symphalangism.

Polymorphisms of *HIF-1alpha* gene in Mexican patients with preeclampsia. *S. Nava-Salazar[1], E. N. Sánchez-Rodríguez[1], C. A. Mendoza-Rodríguez[1], P. Cruz-Cruz[2], M. A. Cerbón[1]* 1) Departamento de Biología, Universidad Nacional Autónoma de México, Ciudad Universitaria. Ciudad de México, Mexico; 2) Instituto Mexicano del Seguro Social, Hospital de Ginecología y Obstetricia No. 3 La Raza, Ciudad de México, México.

Preeclampsia is a pregnancy-specific syndrome characterized by new onset hypertension, proteinuria and edema. This disease is a considerable obstetric problem and significant source of maternal and neonatal morbidity and mortality. Although the pathophysiology of preeclampsia remains undefined, placental ischemia/ hypoxia are widely regarded as a key factor. The hypoxia inducible transcription factor, HIF-1alpha, is overexpressed in placentae from women with preeclampsia and contributes to the dysregulation of numerous genes related with trophoblast invasion. P582S and A588T are variants of HIF-1alpha that have been associated to high transcriptional activity in some types of cancer and are used as risk factor markers of the disease. In the present study, we explore the association of the allelic polymorphism P582S and A588T of HIF-1alpha gene and the association with prevalence of preeclampsia in Mexican population. The molecular analysis of P582S and A588T alleles was performed by PCR and direct sequencing. A case - control study of risk factors is currently undertaken. The preliminary results suggest that the allelic variants, P582S and A588T, present a similar frequency, in Mexican than other populations in the exploratory study. However, we are increasing the size of the sample to establish the prevalence of these polymorphisms and its possible association with preeclampsia in our population.

Multiple source genetic heterogeneity and population- and intra-familial tests of association for quantitative traits. *Y. Kim, A. J. M. Sorant, A. F. Wilson* Genometrics Section, IDRB, NHGRI, NIH, Baltimore, MD.

The presence of undetected genetic heterogeneity produces a loss of power in association studies. In this study, computer simulation was used to determine the effect of genetic heterogeneity due to multiple sources on tests of association between a quantitative trait and a causal SNP in both population and intra-familial study designs (unrelated individuals, and nuclear and extended families). G.A.S.P. [v3.3] was used to simulate a single quantitative trait in 3 sub-populations. In the association subpopulations (populations 1 and 2), the trait was based on a different SNP marker in each subpopulation; in the non-association subpopulation (population 3), the trait was due to a random effect. The heritability of the trait in the combined sample was fixed to be 0.05, and the subpopulation with the causal SNP (population 1) had a constant heritability of 0.025. In each simulation experiment, different proportions (100%, 50%, 30%, and 10%) from the association subpopulations (half from population 1 and half from population 2) were combined with the non-association subpopulation to produce samples with various degrees of genetic heterogeneity. ANOVA [SAS] was used to test for association in population-based tests of unrelated individuals. ASSOC [S.A.G.E.], FBAT and ROMP were used to perform intra-familial tests. The proportion of samples with a significant result was used to estimate the power at the causal SNP. Of the models considered, the power of the test of association, regardless of the method used, decreased dramatically as the proportion of the non-association subpopulation increased. The intra-familial ASSOC analysis had the greatest power in each scenario, followed by the population-based test, and then the intra-familial based ROMP and FBAT tests. In general, it appears that the presence of even a modest amount of genetic heterogeneity within a sample, regardless of the source, can cause a substantial loss of power to detect an association. Of the methods considered, the likelihood based intra-familial ASSOC test was the most robust to the presence of genetic heterogeneity.

Phenotypic spectrum of Microcephalic osteodysplastic primordial dwarfism type Majewski II caused by mutations in the Pericentrin (PCNT) Gene. *A. Rauch[1], C. T. Thiel[1], Y. J. Crow[2], A. J. van Essen[3], T. O. Goecke[4], L. Al-Gazali[5], K. H. Chrzanowska[6], H. G. Brunner[7], C. J. Curry[8], B. Dallapiccola[9], K. Devriendt[10], E. Kinning[11], A. Megarbane[12], P. Meinecke[13], R. K. Semple[14], A. Toutain[15], R. C. Trembath[16], R. Hennekam[16], A. Reis[1], H. G. Dörr[1]* 1) Inst Hum Genet, Univ Erlangen, Germany; 2) Leeds; 3) Groningen; 4) Düsseldorf; 5) Al-Ain; 6) Warsaw; 7) Nijmegen; 8) Fresno; 9) Rome; 10) Leuven; 11) Leicester; 12) Beirut; 13) Hamburg; 14) Cambridge; 15) Tours; 16) London.

In his book bird-headed dwarfs (1960) Helmut Seckel described a heterogenous group of individuals with variable degrees of primordial short stature and microcephaly. In 1982 Majewski and colleagues reviewed cases reported as Seckel syndrome and distinguished three types of osteodysplastic primordial dwarfism from bona fide Seckel syndrome. Using positional cloning, we recently identified biallelic loss-of-function mutations in the pericentrin (PCNT) gene resulting in disorganized mitotic spindles, premature sister chromatid separation and missegregation of chromosomes to cause microcephalic osteodysplastic primordial dwarfism type Majewski II (MOPD II) (Rauch et al. 2008, Science 319:816-9). Since this distinct entity is commonly not well known we report here on the clinical spectrum and natural history of 26 MOPD II patients with biallelic pericentrin mutations in more detail. Adults with this condition belong to the shortest of the short having a height of about 100 centimeters. We observed that deviation from the mean increased with age, with average birth weight of -3.5 SDS, average height at last investigation of -9.6 SDS and average head circumference of -8.9 SDS. Although most of our patients had an IQ within the low-normal range, 6 of 26 were moderately to severely retarded, due to cerebral complications such as multiple infarctions or cerebral bleedings commonly associated with Moyamoya disease (10/26 patients). Despite the fact that only 3 of our patients were older than 12 years, 4 had already type 2 diabetes and dyslipidemia. Three patients died at age 9, 11 and 14 years from subarachnoid or aneurysm bleeding, and one died at age 3 years from cardiomyopathy.

Identification of six candidate long-range cis-regulatory elements upstream to *NR0B1* (*DAX1*) using 3C technique. *M. Nowak[1,2], P. Stankiewicz[1,2]* 1) Dept of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston TX.

Defects in long-range regulatory elements have been shown as a mechanism underlying genetic diseases, with most of them involving dosage-sensitive genes. NROB1, the nuclear receptor 0B1 (DAX1) is essential for the development and functioning of hypothalamus-pituitary-gonadal axis. Deletion of NR0B1 in Xp21.2 results in congenital adrenal hypoplasia (AHC), whereas NR0B1 duplication in 46,XY individuals leads to gonadal dysgenesis and a female phenotype (dosage sensitive sex reversal, DSS). We have reported recently a 257,782 bp deletion, 11 kb upstream to *NR0B1* in a 21-year-old 46,XY female manifesting primary amenorrhea, a small immature uterus, gonadal dysgenesis, and apparent normal adrenal function and suggested a loss of regulatory sequences resulting in position effect up-regulation of DAX1 expression. To verify this hypothesis, we have analyzed 300 kb region upstream to *NR0B1* using chromosome conformation capture (3C) technique in a lymphoblastoid and HeLa cell lines. In lymphoblasts, we have identified four sequences located ~81 kb, ~111 kb, ~121,5 kb, and ~176 kb 5 to *NR0B1*, showing high intensity physical interaction with *NR0B1*, and two sequences ~95.7 kb and ~187.4 kb 5 to *NR0B1* with weaker intensity interactions with the gene. Conversely, in HeLa cells, the ~95.7 kb and ~187.4 kb sequences showed the highest intensity, the ~111 kb, ~121,5 kb, and ~176 kb intermediate intensity, whereas the ~81 kb did not show physical proximity with NR0B1, indicating cell line dependent variety of interactions. All the identified elements correspond to, or are in close proximity to evolutionarily conserved nongenic sequences described previously. Our results confirm the hypothesis that these long-range upstream elements have regulatory impact on *NR0B1* expression.

Genetic association study of height growth and timing of puberty in the Northern Finland Birth Cohort 1966. *U. Sovio[1], A. J. Bennett[2], N. J. Timpson[2,3], J. Haukka[4], I. Millwood[1], J. Molitor[1], E. Widen[5], L. Peltonen[5,6], M. I. McCarthy[2], M.-R. Jarvelin[1,7]* 1) Imperial College London, UK; 2) University of Oxford, UK; 3) Bristol University, UK; 4) National Public Health Institute, Helsinki, Finland; 5) University of Helsinki, Finland; 6) Broad Institute of Harvard and MIT, Cambridge, USA; 7) University of Oulu, Finland.

Adult height is a complex, yet highly heritable trait. Recent findings from GWA studies suggest that many common variants are associated with this trait. However, it is unclear how these variants are involved in height growth throughout childhood. We derived peak height velocity (PHV) and pubertal timing parameters from longitudinal height growth data to test their association with known height variants. The study sample consisted of N=3,538 singletons from the Northern Finland Birth Cohort 1966 with genotype data and on average 20 height measurements/person at 0-20 years. PHV in infancy was derived from sex-specific 4-parameter Reed1 models and regressed on each SNP, weighted by the number of measurements, adjusted for sex and population structure. PHV in puberty, age at growth spurt take-off and age at PHV in puberty were derived from sex-specific 8-parameter JPA2 models and regressed on each SNP. We replicated 23 of the 43 signals found in GWA scans with adult height in this sample (p0.05). Seven SNPs in HHIP, DLEU7, GDF5, SF3B4, LCORL and HIST1H1D showed association with PHV in infancy. Five SNPs in SOCS2, SF3B4, C17orf67, CABLES1 and DOT1L were associated with PHV in puberty and two SNPs in SOCS2 and C6orf106 with timing of puberty. In this sample, few genetic variants associated with adult height had a measurable effect on PHV in infancy or puberty. However, statistical power was limited to 80% to detect a per allele effect size of 7% SD in infancy and 8% SD in puberty, whereas for adult height we had similar power to detect an effect size of 6% SD (0.6cm) at level p0.05. GWA studies on height growth parameters will help identify genomic regions affecting height growth velocities at different stages of growth and timing of puberty.

Follow-up of 22 Prader-Willi syndrome patients. *L. M. J. Albano[1], C. R. S. Silva[1], M. C. Varela[2], C. P. Koiffmann[2], D. Bertola[1], R. S. Honjo[1], I. M. Furquim[1], C. A. Kim[1]* 1) Pediatrics, Instituto da Criança, São Paulo, São Paulo, Brazil; 2) Insituto de Biociências, University of São Paulo, São Paulo, Brazil.

Prader-Willi syndrome (PWS) is a genetic disorder characterized by neonatal hypotonia, mental retardation, behavioral abnormalities, dysmorphic features, hyperphagia and progressive obesity. The expression of imprinted paternal genes is abolished, mainly due to a paternal deletion within 15q11-q13 (70-75%). Maternal uniparental disomy of this same region, a defect in the imprinting center, and translocations occur in 20-25%, 2-5%, and 1%, respectively. We studied 22 PWS cases (10F:12M) evaluated at our Unit since 1996 (12 years) that fulfilled the clinical criteria consensus, confirmed by methylation analysis. All of them were sporadic cases and the age at the diagnosis ranged from 7 days to 16 years. The molecular PWS diagnosis was established before 1 year of age in seven patients (32%). Low birth weight (<2,500g) was noticed in 7/21 (32%); hypotonia improved over time and was present at birth in all cases; reduced fetal movements were referred in 10/14 cases (71%); assisted delivery (cesarean section) was required in all of them. Hypogonadism and poor or absent sucking was observed in all patients and 7/16 (44%) required gavage feeding. In 4/11 (36%) temperature instability was referred and 2 presented hip dislocation. All patients referred some infectious disease, mainly respiratory. Obesity was noted in all patients older than 3 years of age and in two of them it was present in a more precocious age. Growth hormone therapy was performed in 7/13 patients (54%), all after 6 years of age but one, who started at 1 year of age. Mental retardation was referred in all patients. Six patients died at an age that ranged from 9 to 19y, due to cardio-respiratory problems. One patient was submitted to a bariatric surgery at 10 years of age. Dysmorphic features, as well as behavioral problems, were noticed in more than 75% of the patients. All G-banded karyotypes were normal. All cases presented a positive methylation test for PWS syndrome: 14 (64%) showed a microdeletion, 5 (23%) a maternal uniparental disomy and in 3 (13%) the genetic mechanism could not be established.

-Nicotinic Acetylcholine Receptor (CHRNA3/5) Polymorphisms Influence Risk of Chronic Obstructive Pulmonary Disease (COPD). *SG. Pillai[1], D. Ge[2], G. Zhu[1], X. Kong[1], KV. Shianna[2], A. Need[2], C. Hersh[3], P. Bakke[4], A. Gulsvik[4], A. Ruppert[5], K. Carlson[6], A. Roses[2], W. Anderson[1], S. Rennard[7], D. Lomas[8], EK. Silverman[3], DB. Goldstein[2], ICGN & ECLIPSE Investigators* 1) Genetics, GlaxoSmithKline, RTP, NC; 2) Duke University, Durham, NC; 3) Brigham and Women's Hospital, Boston, MA; 4) University of Bergen, Norway; 5) GRC, Munich, Germany; 6) University of Oslo, Norway; 7) University of Nebraska, Omaha, NE; 8) CIMR, Cambridge, UK.

Recent genome-wide association studies (GWAS) have identified the CHRNA3/5 locus on chromosome 15 as a major genetic risk factor for lung cancer. This GWAS and subsequent replication studies in four COPD populations found that the same locus associates with COPD, highlighting the public health importance of this locus in smoking related diseases. The GWAS was conducted in a case-control cohort from Bergen, Norway (823 cases and 810 controls) and evaluated the top 100 SNPs in a family-based study, the International COPD Genetics Network (ICGN, 1891 subjects from 606 pedigrees). The SNPs that showed replicated associations were further evaluated in 389 subjects from the National Emphysema Treatment Trial (NETT) and 472 controls from the Normative Aging Study (NAS). The SNPs with genome-wide significance were then evaluated in the ECLIPSE (Evaluation of COPD Longitudinally to Identify Predictive Surrogate End points) cohort to identify association with COPD-related phenotypes. In the Bergen cohort, 3 SNPs on chromosome 5 reached genome-wide significance, but showed only nominal association in the replication studies. Two SNPs in the CHRNA3/5 locus, rs8034191 and rs1051730, showed unambiguous replication in the ICGN and in the NETT/NAS studies with a combined p value of 8.31×10^{-13} and 1.93×10^{-11}. Analysis in the ECLIPSE COPD subjects showed association of the CHRNA3/5 SNP (rs1051730) with airflow obstruction (FEV1/FVC; $p=7 \times 10^{-4}$) and high resolution CT-defined emphysema ($p=1.3 \times 10^{-5}$). These results suggest the possibility of multiple functional polymorphisms in the region or a single polymorphism with wide phenotypic consequences, potentially mediated through an effect on smoking behavior.

Coronary Artery Disease Risk Locus at 9p21.3 Alters *ANRIL* Expression and Modulates Cell Proliferation Pathways. *O. Jarinova[1], A. Stewart[1], P. Lau[1], T. Naing[1], R. Roberts[1], G. Wells[1], C. Buerki[2], B. McLean[2], R. Cook[2,3], J. Parker[4], R. McPherson[1]* 1) University of Ottawa Heart Institute, Ottawa; 2) Med BioGene Inc., Vancouver; 3) University of British Columbia, Vancouver; 4) Expression Analysis, Durham, NC.

We and others recently identified a novel intergenic locus on chromosome 9p21, which remained robustly associated with coronary artery disease (CAD) risk upon replication in numerous independent samples. The risk locus spans 58 kb and encompasses multiple single nucleotide polymorphisms in tight linkage disequilibrium. Approximately 25% of Caucasians carry 2 copies of the risk allele and have a 1.5 fold increased risk for CAD, independently of all known risk factors, implying a novel biological pathway relevant to atherosclerosis. The risk locus lies centromeric to the alternatively spliced cyclin dependent kinase inhibitors, *CDKN2A* ($p14^{ARF}$, $p16^{INK4A}$) and *CDKN2B* ($p15^{INK4b}$) which function in cell proliferation, aging and apoptosis. We have determined the effects of genetic variation at the 9p21.3 locus on gene expression profiles in whole blood RNA. Since lymphocyte gene expression is altered in a number of disease states and in response to various medications, only healthy control subjects homozygous for the 9p21.3 reference or alternative alleles were studied. Pathway analysis revealed upregulation of gene sets regulating cell proliferation in carriers of the risk allele. It is notable that the 9p21 risk locus overlaps a newly annotated antisense non-coding RNA (*ANRIL*) which spans 126.3 kb and overlaps at its 5 end with *CDKN2B* ($p15^{INK4b}$). Quantitative real time PCR revealed that expression of the long variant of *ANRIL* was decreased by 1.3 fold whereas expression of the short *ANRIL* variants was increased by 2.2 fold in subjects homozygous for the risk allele and this difference was associated with a decrease in relative copy numbers of transcripts involved in cell proliferation, namely *CDKN2A*, *CDKN2B* and *GAPDH*. We hypothesize that the 9p21.3 risk allele promotes atherosclerosis by regulating the alternative splicing of *ANRIL*, which in turn alters the expression of genes controlling cell proliferation pathways.

Genome-Wide Association Study in Parkinsons Disease: Identification of Strong Associations with SNCA and MAPT. *S. Scholz[1,2], C. Schulte[3], P. D. Genetics Consortium[1,2,3,4,5,6,7]* 1) Laboratory of Neurogenetics, National Institute on Aging, Bethesda, MD, USA; 2) Department of Molecular Neuroscience, Institute of Neurology, Queen Square, London, UK; 3) Hertie Institute of Clinical Brain Research, Tuebingen, Germany; 4) Department of Medical Genetics, University of Tübingen, Tübingen, Germany; 5) Institute of Epidemiology, Neuherberg, Germany; 6) Institute of Medical Biometrics, Informatics and Genetics, University of Bonn, Bonn, Germany; 7) Department of Neurology, University of Lübeck, Lübeck, Germany.

Background: Parkinsons disease (PD) is the second most common neurodegenerative disorder. The etiology of PD is largely unknown. Methods: We performed a genome-wide association study in PD in 1713 cases and 3978 neurologically normal controls. We genotyped each individual on Illumina genotyping chips (Illumina humanhap550 or Illumina humanhap240S + Illumina humanhap317K) yielding over 550,000 genotypes/individual. SNPs with minor allele frequencies (MAF) 1%, Hardy-Weinberg Equilibrium $p > 0.001$ and genotype call rates 98% were included in the analysis (463,187 SNPs). We performed association tests using the additive model in PLINK software. Results: We identified clear association exceeding Bonferroni correction level for the following loci: SNCA (p=5.69E-9, OR=1.27) and MAPT (p=4.50E-8, OR=0.74). Conclusions: SNCA has previously been implicated with PD in familial forms of disease, whereas MAPT mutations are known to be involved in a number of neurodegenerative disorders. Our data suggest that genetic variants at the SNCA and MAPT locus play a critical role in the pathogenesis of PD. The PD Consortium consists of: D. Berg, M. Bonin, E. Caliskan-Erle, G. Deuschl, J.R. Gibbs, C. Gieger, J. Hardy, D. Hernandez, T. Illig, C. Klein, R. Krüger, P. Lichtner, C. Paisan-Ruiz, S. Poths, O. Riess, S. Scholz, C. Schulte, M. Sharma, J. Simon-Sanchez, H.E. Wiechmann, T. Wienker, T. Gasser, A.B. Singleton.

Allelic variations upstream of the T1R3 gene correlate with sucrose sensitivities in humans. *A. Fushan[1], J. Slack[2], C. Simons[2], A. Manichaikul[1], D. Drayna[1]* 1) NIDCD, National Institutes of Health, Rockville, MD; 2) Givaudan Flavors Corp., Cincinnati, OH.

Members of the human TAS1R class of taste-specific G protein-coupled receptors have been proposed to function in combination as heterodimeric sweet taste receptors. TAS1R2/TAS1R3 heterodimers recognize sweet taste stimuli. We hypothesized that allelic variation of the TAS1R3 receptor gene can be one of the mechanisms determining differences in individual sensitivities to sweet compounds. To test this hypothesis, we analyzed sucrose and sucralose sensitivities of 130 unrelated human volunteers aged 20 - 55 years, using a sorting test and subsequent cumulative R-index score. Then, we examined the genomic sequence of the T1R3 gene in these individuals including exons, introns, and upstream and downstream regions, to survey all polymorphisms that could affect amino acid composition, RNA splicing, or potential regulatory regions. Quantitative trait analysis revealed significant association (adjusted $p<0.01$) between phenotypes and SNPs located in the genomic region 2000 bp upstream of T1R3 coding sequence. Together the associated alleles account for approximately 8% of the total variation in sweet sensitivity in our subject population. Bioinformatic analysis predicts these polymorphism are located in the regions of transcription factor binding sites, suggesting that differences in expression levels of T1R3 are a significant factor determining human sweet sensitivity in vivo.

Candidate gene analysis reveals genetic pathways associated with a persistent pain disorder. *S. Smith[1], M. Siddiqi[1], V. Miller[1], D. Gibson[1], R. Arunasalam[1], P. Kasravi[1], G. Slade[2], A. Neely[1], E. Bair[1], W. Maixner[1], L. Diatchenko[1]* 1) Sch Dentistry, Univ North Carolina, Chapel Hill, NC; 2) Sch Dentistry, Univ Adelaide, Adelaide, Australia.

Although evidence supports a heritable basis for pain conditions such as temperomandibular joint disorders (TMJD) and fibromyalgia, few genetic determinants for persistent pain have been identified. To explore the genetic basis of chronic pain conditions, we have created a genotyping chip comprised of 3295 single nucleotide polymorphisms (SNPs), representing over 300 genes known to influence pain pathways. This panel was designed to assay SNPs most likely to regulate gene expression and function, employing Paralleles MIP technology. In the first use of this platform, 200 Caucasian females with a history of chronic TMJD were recruited as cases at a multidisciplinary pain clinic, with corresponding controls. Subjects underwent a comprehensive battery of nociceptive and psychosocial assessments. DNA from donated blood was genotyped using our pain candidate gene chip. Statistical associations between genetic markers and disease phenotypes were examined using PLINK software. Genotypic trend tests were employed to determine associations between candidate genes and disease status, and linear regression was used for quantitative sensory and affective traits. Numerous polymorphisms were significantly implicated in persistent TMJD or its putative mechanisms, such as stress modulation and nociceptive neurotransmission. Associated odds ratios for common (MAF>0.05) risk alleles for TMJD ranged up to 2.2. Haplotype analysis further revealed multilocus effects contributing to genetic variability in these traits. The results of this study were compared with associations previously revealed in a separate incidence sample of 186 initially disease-free subjects; Several risk genes, including genes for adrenergic and opioid receptors, were replicated in this study, supporting the likelihood that they are true associations. Using a candidate gene approach, we successfully implicated a number of pain-relevant genes and pathways in susceptibility to a persistent pain disease.

Mapping successful aging phenotypes to chromosome 2q14 in the Amish. *W. K. Scott[1], P. J. Gallins[1], J. L. McCauley[1], L. Jiang[2], M. Creason[1], L. Caywood[1], D. Fuzzell[2], C. Knebusch[2], C. E. Jackson[3], J. R. Gilbert[1], M. A. Pericak-Vance[1], J. L. Haines[2]* 1) University of Miami, Miami, FL; 2) Vanderbilt University, Nashville, TN; 3) Scott & White, Temple, TX.

Successful aging (SA) is a multi-dimensional phenotype involving preservation of cognitive ability, physical function, and social engagement throughout the lifespan. Several quantitative components of the SA phenotype (longevity, upper and lower extremity function, and cognitive ability) are heritable. The Indiana and Ohio Amish are genetically and socially isolated from the surrounding communities and maintain homogeneous lifestyles. These conditions make the Amish an optimal population for identifying loci associated with successful aging. We collected DNA along with subjective and objective measures of function, cognition, life satisfaction, and social support on more than 672 Amish individuals over age 65. Using the Anabaptist Genealogy Database (AGDB), we grouped all individuals into a single 11-generation pedigree. Subsequently, we performed a genome-wide linkage screen of 5,944 single nucleotide polymorphisms (SNPs). We utilized the GREFFA program to create 7 sub-pedigrees for linkage and association analysis. Analysis of the SA phenotype (48 individuals over age 80 who were cognitively intact, not depressed, satisfied with life, little self-reported limitation in activities of daily living or musculoskeletal function, in the top 1/3 of the sample in lower-extremity physical function, and having adequate social support) identified 11 SNPs with 2-point lod scores greater than 1.0 and association p-values less than 0.05. Analyses of quantitative measures of physical function (grip strength and lower extremity function) were also performed. Notably, the SNPs with the strongest evidence for linkage and association with both the overall SA phenotype (rs2056282: lod=2.6, p=0.026) and quantitative measure of lower extremity function (rs1712865: lod=2.4, p=0.05) co-localized to a 7 Mb region of chromosome 2q14. These results suggest that 2q14 harbors a locus promoting successful aging, whose effect may influence lower extremity function (balance, gait, and mobility) in older adults.

Elucidating a novel gene associated with Inherited Myoclonus Dystonia. *T. J. Read[1,2], D. A. Grimes[2,3], D. E. Bulman[1,2,3]* 1) Dept. of Biochemistry, Genetics, University of Ottawa, Ottawa, Ontario, Canada; 2) Ottawa Health Research Institute, Ottawa, Ontario, Canada; 3) Division of Neurology, Dept. of Medicine, University of Ottawa, Ottawa, Canada.

Inherited Myoclonus Dystonia (IMD) is an autosomal dominant disease with high but incomplete penetrance and is characterized by both involuntary myoclonic jerks and dystonic posturing. We have found that mutations within the epsilon sarcoglycan (SGCE) gene on chromosome 7q21 are associated with IMD in 30-40% of affected individuals in 31 families studied, supporting the basis for genetic heterogeneity. Novel mutations have been found in the SGCE gene by screening these families for point mutations and large deletions/duplications through the use of sequencing and MLPA exon dosage analysis, respectively. A 10cM genome wide linkage analysis of a large Canadian family provided significant LOD scores for microsatellite markers within the 18p11 region, now designated as the DYT 15 locus. Further haplotype analysis has narrowed a non-recombinant region associated with the disease phenotype to a 3.18 Mb region in this locus. Since the current understanding of Myoclonus Dystonia is poor, it is difficult to predict genes that could be responsible for IMD. Sarcoglycans are essential constituents of the dystrophin-glycoprotein complex and are involved in linking the extracellular lamanin matrix to the actin filaments within the cytoplasm, therefore focus is given to the examination of potentially related structural genes that are expressed in the brain. By analyzing such candidate genes in a panel of affected individuals, we believe that a novel gene will be elucidated and provide insight into the mechanism of Inherited Myoclonus Dystonia.

The evolutionary history of lactase persistence in Africa. *A. Ranciaro[1,2], F. Reed[3], J. Hirbo[1], K. Powell[4], M. Osman[5], H. Muntaser[5], O. Sabah[6], A. Fremont[7], S. A. Tishkoff[1,8]* 1) Dept Genetics, Univ Pennsylvania, Philadelphia, PA; 2) University of Ferrara, Italy; 3) Department of Evolutionary Ecology, Max Planck Institute for Evolutionary Biology, Plön, Germany; 4) University of Maryland, College Park, MD; 5) Institute of Endemic Diseases, University of Khartoum, Sudan; 6) Kenya Institute of Medical Research, Nairobi, Kenya; 7) Museum National d'Histoire Naturelle, Centre National de la Recherche Scientifique, Paris, France; 8) Department of Biology, University of Pennsylvania, Philadelphia, PA.

In most individuals, the ability to digest lactose, the sugar present in milk, declines rapidly after weaning because of decreasing levels of the enzyme lactase (lactase-phlorizine hydrolase, LPH) in the small intestine. However, there are individuals who maintain the ability to digest milk into adulthood due to a genetic adaptation in populations that have a history of pastoralism. In order to identify variants associated with the lactase persistence (LP) trait and to study the evolutionary history of LP in Africa, we resequenced 1.7 kb of intron 9 and 3.3 kb of intron 13 of the *MCM6* gene (associated with LP in Europeans), and 2.2 kb of the promoter region of the *LCT* gene in 821 Africans and a comparative sample of 138 Middle Easterners, 34 Europeans, and 23 Chinese. We analyzed genotype/phenotype associations in >500 individuals for which we measured lactase activity using a lactose tolerance test and identified three variants associated with the LP trait in Africans (G/C-14010, T/G-13915, and C/G-13907). We identify a strong signature of recent positive selection in several East African pastoralist groups. Microsatellite haplotype analysis was used to reconstruct the origin and spread of the LP associated variants in Africa. Our results indicate that mutations associated with LP arose independently in ethnically and geographically African populations. Additionally, we find evidence for an East African origin for the spread of pastoralism into South Africa.

Genome wide linkage analysis using SNPs in high performance distributed environments. *A. Calabria[1], D. Di Pasquale[1], A. Orro[1], G. Trombetti[1], E. Salvi[1,2], L. Milanesi[1]* 1) Institute for Biomedical Technologies, National Research Council, Segrate, Milano, Italy; 2) Dept of Science and Biomedical Technologies, Università degli Studi di Milano, Italy.

The problem of Linkage Analysis is NP-hard, and the computational cost and memory requirements of the major algorithms proposed in literature grows exponentially with pedigree size and markers' number. Implementations of these algorithms reflect such limitations, making analyses of medium/large data sets very hard on a single CPU. The aim of the present work is to enable the use of high performance computing infrastructures, such as clusters and grid infrastructures, for the execution of linkage analysis on large data sets, especially for the case of SNPs-based analysis, without the need to own dedicated HPC resources. The approach used relies on the EGEE grid framework and grants an easy web access to the GRID platform, hence requiring only very basic informatics knowledge. Some of the most used linkage analysis software have been ported to clusters and the gLite EGEE Grid environments, and a system has been designed and implemented in order to realize a parallel approach for the linkage analysis. The method adopts inputs' splitting to achieve the best balance for computational time/memory cost on the basis of the specific algorithm adopted by the linkage program, and subsequently runs the processes in parallel. The system provides a web user interface which allows an easier approach to linkage analysis softwares on grid and cluster environments. Below the interface, the workflow progress is supported by a reliable and scalable grid system facility called VNAS, which monitors and manages grid interactions (submission and job retrieving). Tests results show that when reaching the computational limits in data set size there is a real benefit in the use of our implementation: mean improvements of about 65% in computational time compared to a single computer execution was experienced adopting Genehunter with 26 individuals and 80 markers. Increasing the number of individuals some computations, still completed successfully on the Grid, but resulted infeasible on a desktop PC due to memory overflow.

Bone Density, Sex Hormone Levels and Spinal Abnormalities in Vascular Ehlers-Danlos Syndrome Patients. *N. L. Commins, N. Obeng-Adjei, B. F. Griswold, L. J. Sloper, N. B. McDonnell* National Institute on Aging, Baltimore, MD.

Vascular Ehlers-Danlos Syndrome (VEDS) is a hereditary disorder of connective tissue that arises from mutations in COL3A1 . Patients with VEDS are susceptible to bowel and arterial rupture, and joint laxity is seen. Bone density, sex hormone levels and spine abnormalities have not been studied systematically. We evaluated these features in twenty-four patients with genetically confirmed VEDS using dual energy x-ray scans and magnetic resonance imaging, and laboratory measurements of sex hormones. Osteopenia (17/24)and osteoporosis (6/24) were commonly seen in vascular EDS subjects, all affected were over 18 years of age. Spinal abnormalities including dural ectasia (18/24), disc desiccation (14/24), disc disease (12/24), disc protrusions or bulges (12/24) and facet arthrosis (4/24) were also common. Abnormal levels of testosterone (5/24) and sex hormone binding globulin (13/24) occurred frequently among the subjects. Patients with low testosterone levels showed a high occurrence rate of osteopenia and osteoporosis. It was noted that there were particular hot spots of spinal abnormalities including disc desiccation, disc protrusions and bulges at L1-L2 and L5-S1, and C3-C4 and C6-C7. It was also noted that dural ectasia and disc disease occurred with higher frequency among women and disc desiccation and disc protrusions/bulges occurred with higher frequency among men. Although patients with low testosterone levels had low bone densities as expected, many patients with normal testosterone or estrogen levels also showed low bone densities (11/24). Abnormalities of sex hormones, bone density, and frequent incidence of spine pathology are previously unrecognized complications of VEDS.

Convergent patterns of association between phenylalanine hydroxylase variants and schizophrenia in four independent samples. *L. McClain[1], M. Talkowski[1], T. Allen[3], D. Bradford[4], M. Calkins[5], N. Edwards[6], R. Go[8], R. Gur[5], R. Gur[5], G. Kirov[7], D. Toncheva[11], J. Kwentus[9], P. Lyons[2], H. Mansour[1], J. McEvoy[3], M. O'Donovan[7], J. O'Jile[9], M. Owen[7], A. Santos[10], V. L. Nimgaonkar[1]* 1) University of Pittsburgh, Psychiatry, Human Genetics, Pediatrics; 2) University of VA, Neurology; 3) Duke University Medical Center-John Umstead Hospital; 4) Morehouse School of Medicine, Psychiatry; 5) University of Pennsylvania, Psychiatry; 6) University of Tennessee, Psychiatry; 7) Cardiff University School of Medicine, Psychological Medicine; 8) University of Alabama Birmingham, Psychiatry, Behavorial Neurobiology, Epidemiology; 9) University of Mississippi, Psychiatry and Human Behavior; 10) Medical University of South Carolina, Psychiatry and Behavioral Sciences; 11) University Hospital, Maichin Dom, Medical Genetics.

Recessive mutations in phenylalanine hydroxylase (PAH) predispose to phenylketonuria (PKU) in conjunction with dietary exposure to phenylalanine. Previous linkage and association studies suggested PAH variations could confer risk for schizophrenia. We analyzed 15 PAH tag SNPs and 3 rare exonic variations among four independent samples from the US and Bulgaria (n=5,414), including three Caucasian cohorts (US: 1. 260 trios, 2. 230 cases/474 controls, Bulgaria: 3. 659 trios) and an African-American sample (464 families, 401 controls). Initial analyses of the US Caucasian samples revealed significant associations with 5 SNPs (uncorrected $p<0.05$); most notably allele (G) of rs1522305 ($p=0.006$). This SNP was independently replicated in 659 Bulgarian trios ($p=0.015$). A non-significant trend was also observed among the African American families. Combined analyses across samples were significant for this allele (2=23.28, 8 df, $p=0.003$). Case-control differences were also noted among African Americans with the common allele of L321L ($p=0.047$, OR=1.46). Our analyses suggest several PAH variations could be risk factors for SZ. Lineage-specific and acquired epigenetic changes in diffuse large B-cell lymphoma. *X. Wang[1], T. C. Greiner[2], B. L. Pike[1], D. J. Weisenberger[3], K. D. Siegmund[4], P. W. Laird[3], J.-B. Fan[5], J. G. Hacia[1]* 1) Department of Biochemistry and Molecular Biology, University of Southern California Los Angeles, CA, USA; 2) Departments of Pathology and Microbiology University of Nebraska Medical Center Omaha, NE, USA; 3) Department of Surgery University of Southern California Los Angeles, CA, USA; 4) Department of Preventive Medicine University of Southern California Los Angeles, CA, USA; 5) Illumina, Inc. San Diego, CA, USA.

In an initial epigenetic characterization of diffuse large B-cell lymphoma (DLBCL), we evaluated the DNA methylation levels of over 1,500 CpG islands using the Illumina GoldGate BeadArray methylation platform. Sixty-seven CpG islands showed significant methylation in over 85% of tumors. Interestingly, the methylation levels of CpG islands proximal to 31 genes differed between the activated B-cell-like (ABC-DLBCL) (10 cases) and germinal center B-cell-like (GCB-DLBCL) (14 cases) subtypes. In parallel, we conducted DNA methylation analyses on normal B-cell precursors of ABC-like and GCB-like tumors isolated from normal human plasma and lymph nodes by fluorescence-activated cell sorting (FACS). By comparing these methylation profiles to that of the corresponding tumors, we identified tumor-specific DNA methylation that was acquired during carcinogenesis and lineage-specific DNA methylation that is present in normal B-cell precursors. In addition, we compared the methylation and expression status of 161 genes proximal (within 500-bp) to the methylation assays. We frequently observed that hypermethylated CpG islands are proximal to genes that are expressed at low or undetectable levels in tumors. However, many of these same genes were also poorly expressed in DLBCL tumors where their cognate CpG islands were hypomethylated. Lastly, the moderate expression of several genes proximal to hypermethylated CpG tracts suggests that DNA methylation assays are not always accurate predictors of gene silencing. Overall, further investigation of the highlighted CpG islands as potential clinical biomarkers is warranted.

Cognitive Function in Autosomal Recessive Polycystic Kidney Disease. *E. J. Johnson[1], E. Wiggs[2], J. Bryant[1], A. Garcia[1], D. Adams[1], M. Tuchman[1], L. Guay-Woodford[3], W. A. Gahl[1,4], M. Gunay-Aygun[1,4]* 1) Medical Genetics Branch, National Human Genome Research Institute , Bethesda, MD; 2) National Institutes of Health, Clinical Center, Bethesda, MD; 3) University of Alabama, Birmingham, Al; 4) Office of Rare Disorders, DHHS, Washington, DC.

Autosomal Recessive Polycystic Kidney Disease/Congenital Hepatic Fibrosis (ARPKD/ CHF), the most common form of PKD in children, is characterized by progressive cystic degeneration of the kidneys resulting in chronic renal insufficiency and congenital hepatic fibrosis complicated by portal hypertension (PH). Although the central nervous system is not primarily involved, certain characteristics of ARPKD/CHF, might predispose affected children to developmental delay in early childhood and/or affect their cognitive function later in life. These complications include oligohydramnios, hypoplastic lungs requiring mechanical ventilation, severe systemic hypertension from birth, chronic renal insufficiency and portosystemic shunting. In our ongoing NIH study on ciliopathies (ClinicalTrials.gov, number, NCT00068224), we evaluated 60 ARPKD/CHF patients (age 12.3 + 11.9 years) with at least 1 pathogenic PKHD1 mutation. Developmental history was normal in 44 of 60 patients while 15 had mild to moderate delays in the areas of gross and/or fine motor and/or expressive speech. One patient, who required 17 amniotic fluid infusions, had severe global delays. Twenty-one of the 60 ARPKD/CHF patients (11 females, 10 males, mean age 10.1 + 5.7 years) underwent either the Wechsler Intelligence Scale for Children- Fourth Edition (WISC-IV) or the Wechsler Adult Intelligence Scale- Third Edition (WAIS-III) administered by a psychologist with extensive experience. Scores in the areas of verbal comprehension, perceptual reasoning/organization, working memory, and processing speed, were at the 65th + 15, 55th + 30, 51st + 30, and 43rd + 17 centiles, respectively. Mean full scale intelligence quotient (FSIQ) was 102 + 15 (at 58th + 28 centile). There was no correlation between FSIQ and creatinine clearance or platelet count as a measure of PH. Our results suggest that most ARPKD/CHF patients have normal cognitive development.

The NCBI dbGaP database of genotypes and phenotypes provides resources for genome-wide association studies.
S. Sherry, M. Feolo, Y. Jin, M. Kimura, K. Tryka, R. Bagoutdinov, J. Paschall, L. Hao, A. Kiang, L. Phan, N. Popova, S. Pretel, L. Ziyabari, M. Lee, Y. Shao, Z. Wang, M. Xu, M. Kholodov, S. Shevelev, J. Ostell NCBI, NIH, Bethesda, MD.

The National Center for Biotechnology Information (NCBI) offers investigators an unprecedented wealth of data for research through the dbGaP database of genotypes and phenotypes. Launched in December 2006, dbGaP (http://view.ncbi.nlm.nih.gov/dbGaP) assembles and redistributes comprehensive data sets from large scale association studies to support research problems in genome-wide disease association, population structure, haplotype analysis, and genetic epidemiology. dbGaP serves the research community in the dual roles of repository-of-record for published research, and as an information discovery space that provides summary reports, on-line documentation, browsers to explore association results on the genome, and connections to other information resources. For authorized investigators, dbGaP distributes de-identified, individual-level phenotype and genotype data for use in investigator-specified research projects in accordance with the NIH GWAS policy (http://grants.nih.gov/grants/gwas). dbGaP provides summary-level and individual-level data for 29 studies: longitudinal (including NHLBI Framingham SHARe, n=4), family-based not longitudinal (n=1), case-control (including Macular Degeneration and GAIN studies, n=16, association-results with no individual level data n=3), case-only (n=2), control-only (phenotyped normal controls n=1, genotyped HapMap samples n=2). In total, these studies provide individual-level data for over 30,000 phenotype measures and 22.4 billion genotypes across 55,109 study participants (mean participants per study = 2705). 188 investigators have been approved for access to dbGaP, and 146 of them have downloaded at least one study component with de-identified, individual-level data. The presentation will cover content submission, curation, accessioning, public summary-level measures, organization and request process for obtaining individual-level data, and a demonstration of the supporting tools and browsers that support exploration of submitted association results.

First Report of a Partial Duplication of Xp at prenatal Diagnosis. *R. Habibian[1], J. C. Wang[1], D. Liang[1], H. Makary[1], K. Troxell[2], A. Hajianpour[1]* 1) Cytogenetics Laboratory, Genzyme, Monrovia, CA; 2) University of Missouri Department of Child Health Mercy St. John's Hospital, Springfield, MO.

Duplication of Xp in conjunction with a normal Y chromosome has been rarely reported. It is characterized by a significant degree of phenotypic abnormalities including multiple congenital anomalies, short stature, and mental retardation. The external genitalia may be male or female, or ambiguous. We report what we believe is the first de novo Xp duplication detected at prenatal diagnosis. Cytogenetic analysis was performed on an amniotic fluid specimen from a 41 year-old female at 13.1 weeks gestation due to advanced maternal age. All cells showed a normal Y chromosome and an abnormal X chromosome with additional material on the short arm. This abnormality was determined to be a duplication of the short arm from band p21.2 to p22.3 by FISH using whole chromosome paint X probe, and probes specific for the steroid sulfatase (STS) gene, Kallmann (KAL) gene and Xp subtelomere (Vysis, Inc.). Maternal blood cytogenetic analysis revealed a normal karyotype. The fetal karyotype was therefore designated as: 46,Y,add(X)(p22.1)dn.ish dup(X)(p21.2p22.3)(wcpX+,Xpter+,STS++,KAL++). Duplications in Xp including the dosage sensitive sex reversal (DSS) region can cause male to female sex reversal. It has been shown that the gene NR0B1 (DAX-1) located at Xp21.2p21.3 is a dosage sensitive gene, preventing the formation of male reproductive tissues when duplicated. This gene encodes a protein containing a DNA-binding domain which functions as an anti-testis gene by acting antagonistically to SRY. The pregnancy is continuing and clinical outcome will be provided.

Overexpression of Wwp1 causes left ventricular hypertrophy and sudden death in a novel transgenic mouse model. *L. E. Matesic[1], J. B. Lea[1], W. Basheer[1], A. J. Dupuy[2], D. A. Swing[2], N. G. Copeland[2], N. A. Jenkins[2], R. L. Price[3]* 1) Department of Biological Sciences, University of South Carolina, Columbia, SC; 2) Mouse Cancer Genetics Program, National Cancer Institute at Frederick, Frederick, MD; 3) Department of Cell and Developmental Biology, University of South Carolina School of Medicine, Columbia, SC.

Familial hypertrophic cardiomyopathy (FHC) is the most common genetic myocardial disease and is the leading cause of sudden cardiac death in athletes and young people. FHC is characterized by left ventricular hypertrophy in the absence of hemodynamic stress with areas of myocyte disarray in the myocardium. Although most known FHC-causing mutations map to genes that encode sarcomeric proteins, recent findings indicate that the molecular mechanism underlying some of the more common mutations may be an impairment of the ubiquitin proteasome system (UPS). In order to test the contributions of the UPS to FHC, we created an inducible transgenic mouse that globally overexpresses the ubiquitin ligase Wwp1. Overexpression of Wwp1 contributes to epithelial hyperplasia and transformation in breast and prostate cancer but has not been previously associated with FHC. Mice globally overexpressing Wwp1 died very suddenly at 7-12 weeks of age. This phenotype was 100% penetrant in two independent transgenic lines. Examination of Wwp1 overexpressors by histology, by echocardiography, and by confocal measurement revealed concentric left ventricular hypertrophy. Further, transgenic animals displayed a significant increase in heart weight to body weight ratio, and myocyte disarray with disruption of intercalated discs was noted by confocal microscopy. The mammalian heart is known to undergo postnatal remodeling which establishes the intercalated disc structure and redistributes gap junctions. These changes underlie alterations in the rate and anisotropy of conduction during postnatal maturation. Our results are consistent with the assertion that hyperactivation of the UPS interferes with this remodeling, leading to electrical conduction defects and death, and suggest that the UPS may be a novel therapeutic target for FHC.

Empirical evaluation of genome-wide allelotyping on pooled DNA samples. *C. W. K. Chiang[1,2], Z. K. Z. Gajdos[1,2], F. G. Kuruvilla[2], J. M. Korn[2], R. Cooper[3], X. Zhu[4], H. N. Lyon[1,2], J. N. Hirschhorn[1,2]* 1) Harvard Med School & Childrens Hospital, Boston MA; 2) Broad Inst, Cambridge MA; 3) Loyola Univ Chicago, Chicago IL; 4) Case Western Reserve Univ, Cleveland OH.

Genome-wide association studies (GWAS) have recently proven successful in identifying common variants associated with complex diseases and quantitative traits, such as diabetes and height. A drawback to such studies is that a well-powered design is costly if each subject is genotyped individually, making GWAS less feasible for very large studies. The relatively high cost of custom genotyping prohibits extensive follow-up of potential signals using a staged design. GWAS conducted by allelotyping pooled DNA samples has been proposed as a cost-efficient alternative screening method to prioritize potential associations. However, a pooled GWAS design has not yet been evaluated on the Affymetrix 6.0 array, and few studies have compared results from pooled cases and controls to that from individual genotype data for the same individuals. We report the construction of five DNA pools composed of mixtures of the HapMap YRI and CEU individuals in varying proportions. DNA pools were made in triplicate, and allelotyped using the Affymetrix 6.0 array; for association testing, different pools designated cases and controls. Normalized polar transformations of SNP intensity readings were used to estimate allele frequencies. Informed by the actual allele frequencies from individual genotype data, we established quality control filters based on the radius of the average pool intensity in polar coordinates, separation of genotype clusters, and the spread in allele frequency estimate errors across pools. We also corrected for pool-specific experimental variation to avoid inflation of the ^{2} statistics. After QC filtering, we assayed approximately 450K autosomal SNPs. Among SNPs with a corrected $P<10^{-7}$, the QC filters lowered the proportion of false positives (defined as SNPs with an expected P value of greater than 10^{-4}) from 0.89 to 0.54. We have also allelotyped four pools of obese and lean African Americans for which we have the individual genotype data to further validate the effectiveness of our filters.

Blood pressure-related aminopeptidase genes show putative genetic association with preeclampsia. *M. P. Johnson[1], T. D. Dyer[1], K. A. Freed[1], C. E. East[2], J. Blangero[1], S. P. Brennecke[2], E. K. Moses[1]* 1) Deptartment of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX U.S.A; 2) Deptartment of Perinatal Medicine, Royal Women's Hospital & Deptartment of Obstetrics & Gynaecology, University of Melbourne, Melbourne, Australia.

We have previously reported strong evidence of a preeclampsia susceptibility locus on chromosome 5q in a cohort of Australian and New Zealand preeclampsia families. The resolution of this 5q locus posits the next challenge of positional candidate gene selection for more in depth genetic and (potential) functional examination. Initial molecular interrogation has to date incorporated the selection of publically available exon-centric and putative regulatory SNPs for evidence of association/linkage disequilibrium. Strong genetic associations with SNPs in two aminopeptidase genes, ERAP1 (rs3734016; $p=9\times10^{-3}$) and ERAP2 (rs2549782; $p=4\times10^{-3}$), were identified. The Endoplasmic Reticulum Aminopeptidase 1 and 2 genes encode enzymes belonging to an oxytocinase subfamily of M1 zinc-containing aminopeptidases. Contiguously located on chromosome 5q15 these genes are proposed to play an important role in the metabolism of peptides potentially involved in blood pressure and in the pathogenesis of essential hypertension. These are plausible candidates in the context that preeclampsia is characterized in part by new onset hypertension during pregnancy and that preeclamptic pregnancies are known to elevate the risk of women developing later life cardiovascular disease. These positional candidate genes are therefore of great interest in our current efforts to unravel the allelic architecture of preeclampsia.

Detection of population substructure among Jews and a north/south gradient within Ashkenazi Jews using 32 STR markers. *J. Listman[1], D. Hasin[2], H. R. Kranzler[3], A. Frisch[4], A. Weizman[4], E. Aharonovich[2], R. T. Malison[5], A. Mutirangura[6], A. Sughondhabirom[6], J. Gelernter[5]* 1) Dept Anthropology, New York U, New York, NY; 2) Dept Psychiatry, Columbia U College Physicians & Surgeons, NY, NY; 3) Dept Psychiatry, U CT Sch Med, Farmington, CT; 4) Sackler Faculty of Med, Tel Aviv U, Tel Aviv, Israel; 5) Dept Psychiatry Yale U Sch Med, New Haven, CT; 6) Chulalongkorn Faculty of Med, Bangkok, Thailand.

Understanding and detecting population substructure are critical issues. Using 32 autosomal STR markers and the program STRUCTURE we demonstrated differentiation between Ashkenazi (AJ) (N=135) and Sephardic (SJ) (N=226) Jewish populations in the form of Northern and Southern European genetic components (AJ north 73%, south 22%, SJ north 32%, south 61%) and a significant relationship between latitude of grandparental country of origin (GCO) and percent north/south genetic component in AJ. Notably, we revealed substructure among Jews (and among European Americans (EA)) using a small STR panel, only when additional samples representing major continental populations (African American, EA, Asian) were included in analyses. Further, negative R_{IS} (-0.035) indicates recent admixture in individuals with both SJ and AJ parents (N=38). R_{IS} is a measure of inbreeding adapted from F_{IS} for STR markers. Negative R_{IS} indicates allelic variation within individuals greater than expected under random mating, i.e., excess heterozygosity due to outbreeding. Although geographic patterns are seen in the average north/south percent assignment values between groups as defined by AJ or SJ, grandparental world region of origin, or GCO, within each group there is high variability among individual assignment values. Thus, even based on data from a small marker set, AJ is not a homogeneous population. The north/south gradient in AJ may be a reflection of the pre-existing north/south gradient in European host populations (recently shown in other studies using large numbers of SNPs) with which Jews admixed slowly. We also demonstrate the utility of including purported parental populations when attempting to detect population substructure within closely related populations.

RAAS and Inflammation Factors Regulate Telomerase Expression in the Mouse Cortical Collecting Duct Cells.
Y. Dong, K. Li, DH. Guo, J. Thomas, H. Zhu Georgia Prevention Inst, Medical Col Georgia, Augusta, GA.

Background: Telomerase complex consisting of a reverse transcriptase catalytic subunit (TERT) and an RNA component (TERC) is responsible for telomeric maintenance and extension. Oxidative stress, inflammation and renin-angiotensin-aldosterone (RAAS) system have been shown to increase the rate of telomere attrition in vitro and in vivo. However, their effects on renal distal tubular cells are not well understood. Aims: To elucidate the effects of markers of RAAS and inflammation on the regulation of telomerase expression in mouse cortical collecting duct cells. Methods: M-1 cortical collecting duct cells were cultured and serum-deprived for 24 hours, and cells then were treated with aldosterone (1M), angiotensin II (10M), IL-6 (100ng/mL), TGF-1 (20ng/mL) and TNF- (100ng/mL) for 24 hours. Total RNA was extracted, and real-time quantitative RT-PCR was conducted. The amount of TERT and TERC expressed were normalized to the endogenous control -actin. The relative quantification was determined by comparative CT method. Results: Both aldosterone and IL-6 decreased TERT expression by 38 5%, p=0.004 and 20 4%, p=0.008 respectively. Angiotensin II decreased TERT expression by 24 5%, p=0.009, whereas increased TERC expression by 73 11%, p=0.01. Both TERT and TERC expression did not change after 24 hour of treatment by TGF-1, however, TERT expression was reduced by 23 6%, p=0.018 after 12-hour treatment. TNF- slightly increased TERC expression by 18 4%, p=0.015. Conclusion: This is the first study to show that aldosterone, angiotensin II, IL-6 and TGF-1 inhibit mouse cortical collecting duct cell TERT expression. On the other hand, angiotensin II and TNF- stimulate mouse cortical collecting duct cell TERC expression. The mechanisms are not clear and warrant further investigation.

Using the mouse model to confirm genes identified by genome-wide association studies for the complex trait HDL cholesterol. *M. S. Leduc[1], R. Korstanje[1], M. Orho-Melander[2], S. Kathiresan[3], B. Paigen[1]* 1) The Jackson Laboratory, Bar Harbor, ME; 2) University Hospital Malmo, Lund University, Malmo, Sweden; 3) Massachusetts General Hospital, Boston, MA.

Plasma high density lipoprotein cholesterol (HDL) level is a complex trait associated with risk of cardiovascular events. Recently, a human genome wide association study (GWAS) involving 8,816 individuals (Kathiresan et al., Nat. Genet., 2008) identified putative new loci determining plasma HDL. However, due to the multiplicity of hypotheses tested in GWAS, validation of these putative loci is required. Traditionally, validation occurs through replication by association analysis in other human populations. However, we suggest that the mouse model may also by used to provide supportive evidence if the significant results is in a genomic region homologous to quantitative trait loci (QTL) in the mouse. We previously mapped all known mouse HDL QTLs on the mouse genome (Wang and Paigen, Circ. Res., 2005). From the GWAS, we reduced the 3382 significant SNPs (P<10-3) to 1121 bins based on linkage disequilibrium and selected 171 bins containing at least one highly significant SNP (P<10-4). The 171 bins from this human study were positioned to homologous regions in the mouse, leading to 98 genomic loci in the mouse genome. A total of 85% of these loci lay within 20 Mb of a HDL QTL peak in the mouse. Some of these confirmed major key players in HDL metabolism, already known from other human and mouse studies (*Lpl, Lcat, Lipc, Abca1, Lipg*). By comparing the strains that were used for the QTL studies using our bioinformatic tool, we were able to confirm several putative genes from the GWAS study as mouse QTL gene (*Tshr, Pcsk5, Galnt2, Ppara*). Evidences included haplotype differences, amino acid changes in the coding region, significant expression changes between the strains, and other bioinformatic tools. Finding that the same gene was responsible for the QTL in the mouse therefore adds confirmatory evidence to the human GWAS gene. We conclude that mouse-human genomic comparison is a powerful tool to identify and validate complex trait genes and will help decipher results from human GWAS.

Analysis of Kalirin Polymorphisms with Cardiovascular Risk, Type 2 Diabetes, Metabolic Syndrome in the Diabetes Heart Study. *M. E. Rudock, J. T. Ziegler, A. B. Lehtinen, B. I. Freedman, J. J. Carr, C. D. Langefeld, D. W. Bowden* Wake Forest Univ Sch Med, Winston-Salem, NC.

Coronary artery disease (CAD) is the most common cause of death in type 2 diabetes (T2D) and all manifestations of cardiovascular disease are substantially more common in diabetic than in non-diabetic patients. Following a genome wide linkage scan for CAD in the GENECARD population, peak wide mapping of the 3q13 region identified KALRN as a candidate gene for CAD (Wang et al., Am.J.Hum.Genet., 2007). KALRN is thought to play a role in the development of CVD and T2DM via binding to RAC1. The KALRN locus lies under a linkage peak for prevalent CVD previously identified in a genome wide scan of the Diabetes Heart Study, DHS (Bowden et al., Diabetes, 2006). In an attempt to replicate this association, we chose to evaluate the relationship of polymorphisms in KALRN with cardiovascular phenotypes of the DHS. 28 SNPs in KALRN were genotyped in 977 Caucasian siblings from 369 DHS families, as well as 724 controls. Primary discrete traits were: +/- T2D, +/- metabolic syndrome (MS), +/- prevalent CVD (self-reported history of clinical CVD) and +/- combined-phenotype (+T2D, +MS, +CVD, and +coronary calcified plaque; CCP), which were analyzed for association using GEE1. The strongest evidence of association among discrete traits was seen with rs4234218, which was associated with T2D, MS and the combined-phenotype with p-values of 0.008 (OR=0.863), 0.006 (OR=0.825), and 0.014 (OR=0.889), under the dominant genetic model. Tests for single SNP association with quantitative traits relating to cardiovascular disease, including C-reactive protein (CRP), were performed using SOLAR (age and gender adjusted). The strongest evidence of association within the quantitative traits was with 6 SNPs and CRP (p=0.003 to 0.04 under the dominant model). In order to examine our data for evidence that smoking modulates the genetic effects of KALRN, we stratified our population by smoking status. The association among quantitative traits is more pronounced (p=0.0001 to 0.049) in smokers rather than the non-smokers. We conclude that KALRN variants are associated with presence of T2D, MS and CVD risk factors.

Gene expression in muscle degeneration and regeneration pathways, in different mice models for muscular dystrophies. *P. C. G. Onofre-Oliveira, P. C. M. Martins, V. L. Ferreira, D. Ayub-Guerrieri, M. Vainzof* Human Genome Research Center, University of São Paulo, São Paulo, São Paulo, Brazil.

Muscular dystrophies (MD) are characterized by progressive and irreversible weakness. Muscle degradation is the consequence of disequilibrium between the degeneration and regeneration processes. In the dystrophic process, some cytokines such as TGF-b1, when in high concentrations, can activate the production of collagen, promoting tissue fibrosis. Regeneration is controlled mainly by the myogenic factors MyoD and Myf5 (activation and proliferation of the quiescent mesenchimal precursors), and Myf6 and Myogenin (differentiation and fusion of the activated myoblasts into the affected muscle). Several mice models for genetic MD are recognized, presenting variable histopathological and clinical findings. Mice MDX, SJL/J, and dy2J/dy2J are models for Duchenne, Limb-girdle-2B and congenital-1A MDs, respectively. Using Real-Time PCR, we have been studying the differential expression of genes TGF-b1 and PCOL1a2 (Pro-collagen) from the degeneration pathway, and MyoD, Myf5 and Myf6 from the regeneration pathway, in these adult mice models. Our preliminary results show some residual expression of TGF-b1 and PCOL1a2 in normal muscles, which are not sufficient to activate the regeneration pathway, as observed through the very low expression of MyoD and Myf5 genes. As expected, the more severely degenerated dy2J/dy2J muscles showed the highest levels of PCOL1a2 and TGF-b1. The regeneration process, however, was also very active, in spite of its significant clinical weakness. The mildly affected SJL/J mouse showed a very low expression of regeneration genes with some prevalence of Myf5. On the other hand, MDX mouse, whose muscle histology presents the highest regeneration pattern, showed similar levels of expression for all studied genes. Our results suggest there is no direct correlation between the muscle histological degeneration/regeneration patterns, and the expression of genes of the degeneration/regeneration pathways. More tests are being conducted on animals of different ages to better clarify these mechanisms. FAPESP-CEPID, CNPq, ABDIM-BR.

Combining two genome wide association scans for seven smoking related phenotypes replicates published associations in the CHRNA3/5 region. *F. Gu[1], A. Bergen[2], N. Chatterjee[3], J. Sheng-Shih[5], K. Yu[3], M. Yeager[4], D. H. Hunter[1], G. Thomas[4], K. Jacobs[4], M. T. Landi[3], S. Chanock[4], J. Chen[1], R. Ziegler[3], N. Caporaso[3], P. Kraft[1]* 1) Program in Molecular and Genetic Epidemiology, Harvard School of Public Health, Boston, MA; 2) Molecular Genetics Program, SRI International; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute; 4) Core Genotyping Facility, National Cancer Institute; 5) Johns Hopkins University.

Smoking is a risk factor for more than two dozen diseases and conditions and a leading contributor to mortality worldwide. We performed genome-wide association scans for seven smoking behavior phenotypes using data on 1,144 breast cancer cases and 1,138 controls from the Nurses' Health Study and 1,065 prostate cancer cases and 995 controls from the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial. We tested the association between these phenotypes and over 518,350 SNPs on the Illumina HumanHap 550k platform that passed quality control and had minor allele frequency >1% in both studies. We combined study-specific results using weighted Z scores. Although no SNPs achieved genome-wide significance ($p<10-7$) for any phenotype, we replicated published associations between SNPs in the CHRNA3/CHRNA5 region and cigarettes per day (CPD). We also found evidence that variation in the candidate genes MAOA, TRPV1, and FOSB was associated with CPD (gene-level $p<0.01$). Our study provides further evidence that SNPs in the CHRNA3/CHRNA5 region are associated with smoking behavior, and suggests several other regions for further study.

Identification and functional analysis of schizophrenia risk variants at the DTNBP1 locus. *N. Williams, L. Carroll, A. Gerrish, L. Elliston, G. Kirov, M. Owen, M. O'Donovan* Psychological Medicine, Cardiff University, Cardiff, United Kingdom.

A large volume of genetic association data from multiple populations now supports the locus encoding Dysbindin (DTNBP1) as a schizophrenia susceptibility gene. The source of the genetic association at DTNBP1 is equivocal, however studies to date show altered protein and mRNA levels in schizophrenic CNS. Furthermore, there is evidence to suggest that cis acting variation alters Dysbindin mRNA levels in post-mortem neural tissue and is correlated with a replicated schizophrenia at-risk haplotype. To identify the functional variation causing the association at DTNBP1 we have performed resequencing and high-density association mapping in case-control and familial schizophrenia samples from Europe. Refining the association signal in both samples has yielded intriguing evidence for allelic heterogeneity at this locus. Associated variants in both samples have been analysed to see whether they account for the changes in mRNA levels observed in post-mortem brain by both allelic expression analysis and also via luciferase reporter assay.

Determining the Genetic Architecture of Central Cornea Thickness (CCT) with GWAS using DNA Pooling. *A. B. Ekici[1], J. Etschel[1], S. Uebe[1], F. Pasutto[1], F. E. Kruse[2], C. Y. Mardin[2], A. Reis[1]* 1) Institute of Human Genetics, Friedrich-Alexander-University Erlangen-Nuremberg, Erlangen, Germany; 2) Department of Ophthalmology, Friedrich-Alexander-University Erlangen-Nuremberg, Erlangen, Germany.

Purpose: Our aim was to identify quantitative trait loci which influence central cornea thickness (CCT). Here, cornea thickness refers to the average of both eyes, since correlation of CCT in both eyes had been determined previously. CCT values from 600 individuals of German descent showed a normal distribution. **Methods:** We performed a genome-wide association analysis using SNP-MaP (SNP Microarray and DNA pooling) with 500,568 SNP Affymetrix arrays. We pooled DNA of 36 individuals from either extreme of the normal distribution in 3 replicates (n=12). Array analysis of pooled DNAs was done with a modified version of GenePool (Pearson et al., AJHG 2007; 80(1):126-39). For graphical visualization of GenePool data, we developed the software GPGraphics to facilitate analysis. **Results:** We correlated the difference in mean RAS values of both pools (RASmean) with GenePool ranks for each SNP. Distinct differences were only present among the first 2,000 SNPs. Accordingly, we defined clusters with at least 3 SNPs with a rank <1,000 as associated loci. Our analysis identified 40 loci with marked RASmean values as indication of differential allele frequencies between both extreme quantiles. We also reproduced the association by comparing the extreme groups with pools of population based controls. 34 of these SNP loci showed strong LD in HapMap data and 26 pointed to genes. We then verified pooling data at single genotype level for two selected loci using TaqMan assays in the complete cohort. htSNPs selected to contain at least 1 SNP with a rank <2,000 confirmed significant allele frequency differences (p=0.001), even after permutation correction (p=0.011). **Conclusion:** Our data show that hybridization intensities of pooled DNA correlate well with individual genotyping results. Thus DNA pooling is a useful strategy for GWAS, although loci with strong LD are preferentially detected on those arrays. Furthermore, the genetic architecture of CCT is extremely complex with at least 40 loci influencing this trait.

The importance of developing comprehensive mutation analysis in a clinical diagnostic setting. *L. Bean, B. Coffee, C. Alexander, E. Chin, M. Hegde* Dept Human Genetics, Emory Univ, Atlanta, GA.

Full gene sequence analysis to detect mutations in disease genes is common place in clinical diagnostic laboratories. Current technology allows rapid development and implementation of sequencing assays. Since mutation identification is of paramount importance for diagnosis confirmation, genetic counseling, risk assessment and carrier screening, efforts must be made to perform comprehensive mutation analysis. Although methods such as Southern blotting, quantitative PCR methods and MLPA are used in clinical laboratories, they can be time consuming, laborious, insensitive and even inaccurate. As we enter the era of rare disorder testing the true mutation spectrum for many rare disorders is not known. Comparative Genomic Hybridization (CGH), which has undergone rapid development in the last few years, offers is a powerful alternative to the current methods used for detecting large deletions and duplications. We have developed a single high resolution array to detect single and multi-exon deletion or duplication mutations in a large set of genes. Using this technology, we have detected novel copy number changes within several genes including, GALC (Krabbe disease) and BCKDHB (MSUD). In addition to a common 30kb GALC gene deletion we have identified 3 novel deletions and 1 novel duplication in the GALC gene. Molecular diagnostics for MSUD present several unique diagnostic challenges. Mutations in three unlinked genes (BCKDHA, BCKDHB, and DBT) in which few causative mutations have been reported cause an identical MSUD phenotype. Identification of missense changes can leave substantial doubt as to their causative nature. We have identified one novel duplication and one novel deletion within the BCKDHB gene in two patients with 1 mutation identified by sequencing. In these cases, carrier testing for family members at risk for carrying the mutations and prenatal testing could be offered following identification of a deletion or duplication. Despite the maturity of sequencing and CGH, an estimated 1-2% of mutations located deep within intronic or promoter regions cannot be identified. Future work will focus on accomplishing truly comprehensive mutation analysis.

A biochemical link between Gaucher and Parkinson's diseases suggests a potential approach to treating synucleinopathies. *S. Clark[1], Y. Sun[2], Y. H. Xu[2], G. A. Grabowski[2], B. A. Wustman[1]* 1) Amicus Therapeutics, Cranbury, NJ; 2) Children's Hospital Research Foundation, Cincinnati, OH.

Mutations in the GBA gene that encodes the lysosomal enzyme glucocerebrosidase (GCase) are a risk factor for Parkinsons disease and Dementia with Lewy Bodies. Homozygous mutations in GBA lead to Gaucher disease due to reduced enzyme activity and accumulation of glucosylceramide (GlcCer), and a 2-fold increase in -synuclein is sufficient for Parkinson's. We hypothesized that the decreased GCase activity of carriers and ensuing accumulation of GlcCer may interfere with the normal degradation of synuclein, increasing synuclein levels. We examined a Gaucher mouse model that combines a GBA mutation with reduced expression from the Prosaposin locus. Prosaposin is processed into Saposins including the GCase-activating protein Saposin C. Combining the GBA mutation with reduced Saposin expression results in the accumulation of GlcCer in the brain and viscera. These mice accumulate -synuclein in the cortex and hippocampus. Mice harboring the GBA mutation, but wild-type expression of Prosaposin, do not accumulate GlcCer or -synuclein. This suggests accumulation of -synuclein is correlated with increased GlcCer or a related sphingolipid. Exploring the GCase--synuclein relationship further, we utilized a mouse model moderately overproducing wild-type human -synuclein in the hippocampus, cortex, and olfactory bulb ([PDGF]pr-hSNCA). Unlike the Gaucher mouse model, these mice express endogenous, wild-type GCase. The pharmacological chaperone, AT2101 (isofagomine), has been shown to increase GCase activity in mice and humans. Treatment of these mice with AT2101 prevented the age-dependent accumulation of human -synuclein in neurons in the hippocampus and to a lesser extent in the cortex. We found that AT2101 also prevented an age-dependent increase in Campbell-Switzer-positive aggregates in the hippocampus. This suggests that increase of GCase activity by AT2101 reduces the steady-state level of -synuclein, leading to reduced accumulation of -synuclein aggregates in the brain.

Maternal Age and Risk for Trisomy 21 Assessed by the Origin of Chromosome Nondisjunction: A Report from the Atlanta and National Down Syndrome Projects. *S. Sherman[1], E. G. Allen[1], C.
