A pharmacogenetic model of alcohol consumption and metabolism. *L. Mustavich[1], P. Miller[1,2], H. Zhao[3,4], K. Kidd[4]* 1) Interdepartmental Program in Computational Biology and Bioinformatics, Yale University; 2) Center for Medical Informatics, Yale University, New Haven, CT 06520; 3) Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT 06520; 4) Department of Genetics, Yale University School of Medicine, New Haven, CT 06520.

Several classes of alcohol dehydrogenase and aldehyde dehydrogenase genes, which act in the primary ethanol metabolism pathway, have repeatedly been implicated in alcohol dependence. Certain isoforms are believed to protect against alcohol dependence by causing buildup of the toxic intermediate acetaldehyde, deterring further alcohol consumption. Bitter taste receptor genes also appear to affect ethanol intake, but their combinatorial effect on alcohol dependence, together with the metabolic genes, remains unclear.

We present a compartmental model to explore possible mechanisms underlying the development of alcohol dependence, with the primary aim of determining the extent to which variation in certain genes impacts variation in quantitative traits which may underlie the disease. Previous pharmacokinetic models have studied the time-course of blood ethanol levels, following a single dose of alcohol. We expand upon these models by including acetaldehyde levels, allowing the prediction of further alcohol consumption behavior. Genetics is incorporated into the model through kinetic parameters corresponding to different allelic variants. The result is a theoretical profile for each multi-locus genotype, consisting of a time-course of ethanol and acetaldehyde levels throughout the body, the area under the blood ethanol curve, and other endophenotypes. The model explains known in vivo metabolic measurements and makes testable predictions. Simulations of the current model reveal epistatic interactions among genetic variants of the metabolic and bitter taste receptor genes.

Variation in the 4q25 Chromosomal Locus Predicts New-onset Atrial Fibrillation after Cardiac Surgery. *S. C. Body[1], C. D. Collard[3], S. K. Shernan[1], A. A. Fox[1], K.-Y. Liu[1], M. D. Ritchie[6], T. E. Perry[1], J. D. Muehlschlegel[1], B. S. Donahue[4], M. Pretorius[4], P. T. Ellinor[8], C. Newton-Cheh[8], C. E. Seidman[2, 7], J. G. Seidman[7], D. S. Herman[7], P. Lichtner[9], T. Meitinger[9], N. J. Brown[5, 6], D. M. Roden[5, 6], D. Darbar[5,6]* 1) Dept Anesthesia, Brigham & Women's Hosp, Boston, MA; 2) Howard Hughes Medical Institute, Brigham and Womens Hospital, Harvard Medical School, Boston, MA; 3) Texas Heart Institute, Saint Lukes Episcopal Hospital, Houston, TX; 4) Department of Anesthesiology, Vanderbilt University School of Medicine, Nashville, TN; 5) Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 6) Department of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN; 7) Department of Genetics, Harvard Medical School, Boston, MA; 8) Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA; 9) Institute of Human Genetics, Helmholtz Zentrum München, Munich, Germany.

Atrial fibrillation (AF) is the most common adverse event following cardiac surgery. We used clinical and genomic data from 3 major cardiovascular surgical programs to determine the role of recently described 4q25 variants in new-onset postoperative AF (PoAF). In a discovery cohort of 566 patients, previously identified 4q25 SNPs were associated with PoAF, accounting for clinical covariates. Haplotype tagging SNPs encompassing ~300kbp of 4q25 were genotyped in a validation cohort of 940 patients. Multivariable logistic model of the occurrence of postoperative AF confirmed older age and prior AF to be risk factors for the development of PoAF. 4q25 SNPs previously associated with ambulatory AF, and other SNPs in linkage disequilibrium with those, described a haplotype that was significantly associated with new-onset PoAF, accounting for family-wise error. Odds ratio for the associated SNPs ranged between 1.61 and 2.26 ($P<10-6$) in the validation cohort, after accounting for clinical covariates. rs2200733 and rs2220427 were the most highly associated SNPs. We have shown in discovery and validation cohorts that non-coding 4q25 SNPs associated with ambulatory AF are also strongly associated with PoAF.

Clinical evaluation of a custom genome-wide microarray for the copy number changes in hematologic neoplasmas. *L. Shao, S. Kang, S. W. Cheung, A. Patel* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Conventional chromosome analysis in leukemic cells is of intrinsically low resolution. Emerging evidence suggests that chromosomal copy number changes are important predictors of disease progression and prognosis in hematological diseases. The most recent innovation in whole genome analysis, namely aCGH, offers a high resolution view of the leukemic cell genome. We present a custom genome-wide oligonucleotide array which is also targeted for genes involved in carcinogenesis for use in all hematological disorders characterized by copy number changes. We analyzed 21 patients with different hematologic neoplasms using this chip. The indications included chronic lymphocytic leukemia (N=11), myelodysplasia (N=3), acute myeloid leukemia (N=2), multiple myeloma (N=2), amyloidosis, eosinophila, and Burkitt lymphoma. All patients had concurrent karyotype and/or FISH analysis. At least one copy number change was detected in 10 out of 21 patients. Four of them were consistent with chromosome and/or FISH analysis while 6 of them had additional findings of cryptic deletions or duplications. The cryptic findings included a loss of 0.8 Mb in 1q25 including the ABL2 oncogene, a gain of 5 Mb in 2p16 including REL and BCL11A oncogenes, a loss of 0.9 Mb in 8q24 including the metastasis suppressing gene MTSS1, a loss of 5.5 Mb in 9p21 including the CDKN2A tumor suppressor gene, a loss of 2.5 Mb in 11q25, and a loss of 2.1 Mb in 17q12 including the NF1 gene. In addition, partial trisomies of chromosome 2p, 4q, 11q, and 15q, and der(8) were also observed. In a patient with a marker chromosome, aCGH revealed the marker to be of chromosome 7 origin. As expected, an apparently balanced inversion on 3q was not detected by aCGH. In total, 60% of patients with abnormal chromosome and/or FISH analysis displayed at least one additional cryptic change by aCGH. Our results suggest that a subset of potentially significant genomic alterations may be missed by the current available cytogenetic techniques. Furthermore, this pilot study clearly shows high sensitivity and specificity for whole genome microarray analysis for potential use in routine screening in hematological neoplasms.

Data coordinating infrastructure for the Autism Genome Project. *O. Stein, Autism Genome Project* Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital, Columbus, OH.

The Autism Genome Project is an international collaboration dedicated to gene discovery in Autism (AD). Due to the large quantities of clinical and molecular data, and the distribution of the project across many clinical groups and laboratories, the AGP has established a Data Coordinating Center (DCC) which houses a state-of-the-art infrastructure for data input, data cleaning and curation, data output, and large-scale data archiving. The core DCC infrastructure includes two 64 bit MySQL Linux database servers, and a webserver (LAMP) which is used by collaborators for uploads/downloads. The servers are configured as master and slave, which sit in different locations as a disaster recovery precaution: the master acts as the sole data input entity, and is automatically replicated to the slave. Both master and slave can be used to retrieve data, balancing the load each server has to carry; administrative tasks such as backups are also done on the slave. The system capacity can be extended by additional cloning of slave machines. The main interface for data submission is the web application, which automatically vets item-level clinical data (ADI, ADOS, etc), uploaded over a secure channel in simple csv (comma separated value) format, upon input, checking for illegal variable values and logical errors (eg age of onset prior to current age) with immediate feedback given to user if problems are detected. Molecular data ranging from 10k to 1M SNP chip data are imported and cleaned through a semi-automated process, in which files are output from the database, run through error-detection programs that write output directly in SQL command format for execution in the database, with iterative processing until all errors are removed from output files. AGP participants can download raw and cleaned data via the same web server. All raw data, including images from the large SNP experiments, are stored either within the database or (in the case of images) in an automated terabyte tape storage facility. The current footprint of the database is ~400GB and ~10 TB raw images on tape. This includes over 19000 samples, over 1M phenotypic datapoints, and ~2.5B genotypes.

Correlation of *HMGA2* gene variation with height in specific pediatric age categories. *J. P. Bradfield[1], M. Li[2], C. E. Kim[1], K. Annaiah[1], E. Santa[1], J. T. Glessner[1], E. C. Frackelton[1], F. G. Otieno[1], J. L. Shaner[1], R. M. Smith[1], A. W. Eckert[1], M. Imielinski[1], R. M. Chiavacci[1], R. L. Berkowitz[3], H. Hakonarson[1,4,5], S. F. A. Grant[1,4,5]* 1) Center for Applied Genomics, Abramson Research Center, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 3) Weight and Eating Disorders Program, Department of Psychiatry, University of Pennsylvania School of Medicine, 3535 Market Street, Philadelphia, PA; 4) Division of Human Genetics, Abramson Research Center, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pediatrics, University of Pennsylvania School of Medicine Philadelphia, PA.

Recently an association was demonstrated between the single nucleotide polymorphism (SNP), rs1042725, within the *HMGA2* locus and height as a consequence of a genome wide association (GWA) study of this trait in adults; this observation was also reported in children aged 7-11 years old. We examined in our Caucasian childhood cohort the effects of two strong surrogates for this SNP at this locus with height, rs8756 and rs7968902, with respect to the same pediatric age category but also in children grouped separately as younger and older. Utilizing data from an ongoing GWA study in our cohort of 2,619 Caucasian children with measurements for height, we investigated the association of the previously reported variation at the *HMGA2* locus with this height treated as a quantitative trait (age and sex corrected) in childhood in the 2-6 (n=706), 7-11 (n=617) and 12-18 (n=1293) years old categories. The minor alleles of rs8756 and rs7968902 respectively (strong surrogates for rs1042725 i.e. r^2= 0.873 and 0.761 in the CEU HapMap respectively) were significantly correlated with height in the 7-11 years old age group (P = 3.53×10^{-3} and 2.82×10^{-4}, respectively). However in the 2-6 and 12-18 years old age groups, no correlation was observed. In summary, we observe a strong correlation with height in same age group of 7-11 years old as has been previously reported. However, in the under 7s and the over 11s, no such association was observed.

Follow up analysis of genome-wide association data and replication identifies novel loci for type 1 diabetes. *S. F. A. Grant[1,2,3], H. Q. Qu[4], J. P. Bradfield[1], L. Marchand[4], M. Imielinski[1], C. E. Kim[1], J. T. Glessner[1], R. Grabs[4], S. P. Taback[5], E. C. Frackelton[1], K. Annaiah[1], M. L. Lawson[6], R. W. Grundmeier[7,8], C. A. Stanley[9], S. E. Kirsch[10], D. Waggott[11], A. D. Paterson[12], D. S. Monos[3,13], C. Polychronakos[4], H. Hakonarson[1,2,3]* 1) Center for Applied Genomics, Abramson Research Center, Children's Hospital of Philadelphia (CHOP), PA; 2) Division of Human Genetics, Abramson Research Center, CHOP, PA; 3) Dept of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Depts of Pediatrics and Human Genetics, McGill University, Montreal, Canada; 5) Dept Pediatrics and Child Health, University of Manitoba, Winnipeg, Canada; 6) Division of Endocrinology, Childrens Hospital of Eastern Ontario, University of Ottawa, Canada; 7) Pediatric Research Consortium, CHOP, PA; 8) Dept of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, PA; 9) Division of Endocrinology, CHOP, PA; 10) Markham-Stouffville Hospital, Markham, Canada; 11) Samuel Lunenfeld Research Institute of Mount Sinai Hospital, Toronto, Canada; 12) Dept of Public Health Sciences, Hospital for Sick Kids, Toronto, Canada; 13) Dept of Pathology and Laboratory Medicine, Abramson Research Center, CHOP, PA.

Two recent genome wide association (GWA) studies have revealed novel loci for type 1 diabetes (T1D). To fully utilize the GWA data we had obtained by genotyping 563 T1D probands and 1,146 controls, as well as 483 case-parent trios, using the Illumina HH550 BeadChip, we selected 982 markers with $P<0.05$ in both GWA cohorts. Genotyping these in an independent set of 636 nuclear families with 974 affected offspring revealed 75 markers that also had $P<0.05$ in this third cohort. Among these, 6 SNPs in 5 novel loci also had P<0.05 in the WTCCC dataset and were further tested in 1,303 T1D probands from DCCT/EDIC plus 1,673 controls. Two markers (rs9976767 and rs3757247) remained significant after adjusting for the number of tests in this last cohort; they reside in *UBASH3A* (OR=1.16; combined $P=2.33\text{x}10^{-8}$) and *BACH2* (OR=1.13; combined $P=1.25\text{x}10^{-6}$). The two genes are both biologically relevant to autoimmunity.

Genetic Variation in Late Preterm and Term Infants with Respiratory Distress. *K. Borowski[1], J. M. Dagle[2], J. C. Murray[2]* 1) Dept OB & GYN, Univ Iowa, Iowa City, IA; 2) Dept Pediatrics, Univ Iowa, Iowa City, IA.

BACKGROUND AND OBJECTIVE: Respiratory distress is a common morbidity in the late preterm infant. Single gene mutations in *SFTPB* and *ABCA3* as well as an increased risk for siblings suggest a genetic component to respiratory distress. The objective of this study is to evaluate genetic variants in fetal and maternal steroid metabolism genes and key pulmonary function genes in cases of late preterm and term respiratory distress. DESIGN: Utilizing a candidate gene approach, we analyzed 43 tagged SNPs in 15 genes within the following categories: glucocorticoid metabolism pathway, electrolyte/fluid balance, surfactant proteins and nitric oxide. Inclusion criteria included: respiratory distress with at least 24 hours of oxygen requirement, respiratory symptoms, abnormal xray findings and gestational age 33-41 weeks. Exclusion criteria included: multiple congenital anomalies, meconium aspiration syndrome, culture proven sepsis and surgery requiring ventilation. DNA was isolated from blood leukocytes and saliva/buccal swabs using Qiagen kits. Allelic discrimination was then performed using TaqMan genotyping assays from ABI. Analysis was performed using family based analysis/tranmission disequilibrium test (TDT). RESULTS: 92 probands and their families were included in the analysis. 23 probands met more stringent requirements with surfactant administration. Replication was then performed in 34 families. In the initial analysis four genes suggested association: *CRHR1* p=0.029, *SFTPB* p=0.013, *SCNN1A* p=0.035 and *SCNN1G* p=0.015. These did not meet a Bonferroni correction significance of p=0.0011. In replication *SCNN1A* and *CRHR1* had a p value of 0.02. A haplotype analysis of *SCNN1A*, *SCNN1B* and *SCNN1G* suggested a significant overtransmission with a Z score of 3.39 and p value of 0.0007. CONCLUSION: There is a suggestive association with SCNN1A and CRHR1 and respiratory distress in the late preterm and term neonate. These genes may play modifier roles in the development of respiratory distress in the late preterm and term infant. Furthermore, the SCNN1 gene family may act together to influence respiratory distress in the neonate.

Genetic Effects in the Leukotriene Biosynthesis Pathway and Association with Atherosclerosis. *D. Crosslin[1], S. Shah[1,2], S. Nelson[1], C. Haynes[1], J. Connelly[1], S. Gadson[1], P. Goldschmidt-Clermont[3], J. Vance[4], C. Granger[2], D. Seo[3], S. Gregory[1], W. Kraus[2], E. Hauser[1]* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Division of Cardiovascular Medicine, Duke University Medical Center, Durham, NC; 3) Miller School of Medicine, University of Miami, Miami, FL; 4) Institute of Human Genomics, University of Miami, Miami, FL.

To understand the role of the leukotriene (LKT) pathway in atherosclerosis pathophysiology, we analyzed genotype, expression and clinical data from 78 human aortas to evaluate correlations in the LKT biosynthetic cascade. We also evaluated the association between cardiovascular disease (CVD) phenotypes, expression and previously reported *ALOX5AP* and *LTA4* haplotypes. We analyzed SNPs found in HapA, HapB (*ALOX5AP*) and HapK (*LTA4H*) as well as SNPs found in the *ALOX5* gene. We also used Gene Set Enrichment Analysis (GSEA) to test correlation between expression and the phenotypes raised lesion mapping (RL) and Sudan IV staining (S4). Our results suggest the importance of using pathway-based modeling for evaluating the genomics of atherosclerosis susceptibility. All three genes had at least one SNP with a *cis* and *trans* effect and all effects for a given gene had a single target. Our results suggest that HapA and the relationship to expression levels for *ALOX5AP* ($p = 0.03$) and *ALOX5* ($p = 0.06$) may be an important feature that links the genetic and genomic results. Neither HapK nor HapB were associated with any of the expression values. For GSEA, the custom LKT biosynthesis gene set for RL had an enrichment score (ES) of 0.6897 ($p = 0.004$) and the S4 produced an ES of 0.6349 ($p = 0.009$). Our results support previous association studies; however, the relationship between genetic variation and CVD outcomes is not driven by a single gene or SNP. By exploring the pathway in terms of risk for atherosclerosis, coronary artery disease and myocardial infarction along with genotypic effects on expression, rather than the looking at each component in isolation, we observe significant complexity in the interactions that may alter risk profiles related to genetic variation.

GWAS identifies genes affecting quantitative variation of white blood cell count in African-American children on 1q23. *M. Imielinski[1,2], J. P. Bradfield[1], K. Annaiah[1], C. E. Kim[1], A. W. Eckert[1], J. T. Glessner[1], K. Thomas[1], G. Otieno[1], E. Santa[1], E. Frackleton[1], R. M. Chiavacci[1], S. F. A. Grant[1,3,4], H. Hakonarson[1,3,4]* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA; 2) Department of Pathology, Massachusetts General Hospital, Boston, MA. 02114; 3) Department of Pediatrics and Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA; 4) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA, 19104, USA;.

White blood cells (WBC) mediate immunity and inflammation in normal healthy individuals. WBC count elevation has also been identified as an independent risk factor for acute myocardial infarction, cerebrovascular accident, and all-cause mortality. A recent admixture mapping study found that the Duffy antigen locus on 1q23 associated with WBC count in African American adults. To further gain insight into the genetic basis of WBC regulation in health and disease, we conducted a genome-wide association study of WBC count in a cohort of 2275 Caucasian and 2734 African-American children genotyped on Illumina 550K SNP arrays. In the African-American cohort, we found normal variation in WBC count and absolute neutrophil count associated to a genome-wide significant level (<9E-8) with 65 SNPs spanning an 8 MB region on chromosome 1q23. This association replicated robustly in an independent cohort of 500 African American children. No similar or genome-wide significant associated signal was found in the Caucasian cohort. The region of association includes the Duffy antigen locus, as well as numerous genes involved in WBC development and inflammation. These results point to novel mechanisms underlying the regulation of hematopoiesis in healthy African American individuals. They also support a link between the selective pressure imposed by the malaria parasite Plasmodium vivax and immune system evolution. Further investigation is warranted to determine whether these genes confer clinically significant risk or protection to disease in African Americans.

Association of the *BANK1* R61H variant with systemic lupus erythematosus in Americans of European and African ancestry. *K. Sullivan[1,2], S. F. A. Grant[1,3,4], M. A. Petri[5], J. P. Bradfield[3], C. E. Kim[3], E. Santa[3], K. Annaiah[3], E. C. Frackelton[3], J. T. Glessner[3], F. G. Otieno[3], J. L. Shaner[3], R. M. Smith[3], A. W. Eckert[3], R. M. Chiavacci[3], M. Imielinski[3], H. Hakonarson[1,3,4]* 1) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Division of Allergy and Immunology, Abramson Research Center, Children's Hospital of Philadelphia, Philadelphia,; 3) Center for Applied Genomics, Abramson Research Center, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Human Genetics, Abramson Research Center, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Division of Rheumatology, Johns Hopkins School of Medicine, Baltimore, MD.

Recently an association was demonstrated between a common coding variant, rs10516487 (R61H), within the B-cell gene *BANK1* and systemic lupus erythematosus (SLE) as a consequence of a genome wide association (GWA) study of this disease in European and Argentinean populations. In a bid for replication, we examined the effects of the R61H variant with respect to SLE in our genotyped American cohorts of European and African ancestry. Utilizing data from our ongoing GWA study in our cohort of 178 Caucasian SLE cases and 1808 Caucasian population-based controls plus 148 African American (AA) SLE cases and 1894 AA population-based controls we investigated the association of the previously non-synonymous SNP at the *BANK1* locus with the disease in the two ethnicities separately. The minor allele frequency (MAF) of rs10516487 in the Caucasian cases was 22.6% while it was 31.2% in Caucasian controls, yielding a protective odds ratio (OR) of 0.64 (95% CI 0.49-0.85; one-sided $P=7.07 \times 10^{-4}$). Furthermore, the MAF of rs10516487 in the AA cases was 18.7% while it was 23.3% in AA controls, yielding a protective OR of 0.75 (95% CI 0.55-1.034; one-sided *P*=0.039). The OR of the *BANK1* variant in our study cohorts is highly comparable with that reported previously in a South American/European SLE case-control cohort (OR=0.72). As such, R61H in the *BANK1* gene confers a similar magnitude of SLE protection, not only in European Americans, but also in African Americans.

Genome Wide Association of Copy Number Variations (CNVs) in Type 1 Diabetes (T1D) Identifies Novel Genes in Previously Associated T1D Pathways. *H. Hakonarson[1], J. T. Glessner[1], H. Q. Qu[2], K. Wang[1], J. P. Bradfield[1], C. E. Kim[1], L. Marchand[2], S. F. A. Grant[1], C. Polychronakos[2]* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Departments of Pediatrics and Human Genetics, McGill University, Montreal H3H 1P3, Que'bec, Canada.

T1D is an autoimmune disease with permanent destruction of the insulin producing beta cells. To determine if CNVs contribute to T1D, we performed extensive Quality Control (QC) measures on our Illumina550 GWAS data, including call rate > 98%, SD of normalized intensity (LRR) < 0.35, low wave artifact correlating with GC content due to hybridization bias of low full length DNA quant -0.2X0.4, and proper balance of B-Allele Frequency (BAF). The samples that passed QC for association included 504 Caucasian children with T1D including 292 complete trios in comparison with 3979 controls. Key performance features of the Illumina array for CNV include random placement of SNP specific beads on each array, 18 fold assay redundancy, and confirmatory expected genotype color contrast to supplement intensity data. PennCNV (Wang et al, 2007) was used to call CNVs applying a Hidden Markov Model and Viterbi Algorithm. Observance of CNV at each SNP was evaluated genome wide with chi square significance testing. Here we report statistical local minimums in reference to a region of nominal significance including SNPs residing within 1MB. After review, 47 CNV regions (29 resided on genes) with at least 2 cases each were associated with T1D. Genes with direct functional relevance to T1D impacted by CNVs included IGFBP4, SORBS1, SCG, NGFR, PTPRT, MAML2, CCND1, BCMO1, EPX, and KCNK2. Functional clustering of independently associated results using Fisher's combined probability test provided: Immune system (3 loci, 7 CNVs p= 1.9E-4), Insulin (2 loci, 4 CNVs p= 1.6E-3), Pancreas or liver expression (4 loci, 8 CNVs p= 2.3E-3), CNS development (5 loci,16 CNVs, p= 1.0E-6), Vitamin A (1 locus, 3 CNVs 5.2E-3), Cell cycle signaling (10 loci, 29 CNVs p= 8.0E-7), and Membrane channels (4 loci,13 CNVs p= 1.6E-5). We conclude that 29 genes harboring 80 CNVs in previously associated T1D pathways affecting 70 T1D cases account for up to 14% of cases.

Genome Wide Association of Copy Number Variations (CNVs) in Schizophrenia Identifies Novel Genes in Glutamate Receptor Networks. *J. T. Glessner[1], K. Wang[1], O. Krastoshevsky[2], J. P. Bradfield[1], C. E. Kim[1], S. Shin[3], N. R. Mendell[3], S. F. A. Grant[1], J. Sebat[4], D. L. Levy[2], H. Hakonarson[1]* 1) Center for Applied Genomics, The Childrens Hospital of Philadelphia, Philadelphia, PA; 2) Psychology Research Laboratory, McLean Hospital, Belmont, MA; 3) Department of Applied Mathematics and Statistics, State University of New York at Stony Brook, Stony Brook, NY; 4) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Schizophrenia is a late adolescent-onset psychiatric disease typically characterized by delusions, hallucinations and thought disturbances. We have confirmed association of DISC1, GRIA4, and CHN2 with schizophrenia. To determine if CNVs contribute to the development of schizophrenia, we performed extensive QC on Illumina550 data including call rate > 98%, SD of normalized intensity (LRR) < 0.35, low wave artifact correlating with GC content due to hybridization bias of low full length DNA quant -0.2X0.4, and proper balance of B-Allele Frequency (BAF). Following QC, 136 Caucasian individuals with schizophrenia including 36 trios were analyzed with 1,338 controls. Key Illumina array features for CNV include random placement of SNP specific beads on each array, 18 fold assay redundancy, and expected genotype color contrast to supplement intensity data. PennCNV (Wang et al, 2007) was used to call CNVs applying a Hidden Markov Model. CNV at each SNP was evaluated genome wide with chi square testing. Statistical local minimums were reported in reference to a region of nominal significance of SNPs residing within 1MB. Associated regions were reviewed for call accuracy, lack of peninsulas created by boundary truncation, continuity of coverage, and compared with the Database for Genomic Variants. After review, 11 CNV regions (7 resided on genes) remained with at least 2 CNV cases. Genes with functional relevance to schizophrenia included NTS, GRIK5, and GRM5 (All p=8.5E-3). Functional clustering of independently associated results provided: ionotropic glutamate receptor activity (p= 5.8E-4 GRIK1, GRIA4, GRIN3A, and GRIK5). We conclude that 6 genes harboring 9 CNVs (in 9 cases) in neurotransmission may account for a significant number of schizophrenia cases.

A Genome Wide Association Study Identifies Novel Inflammatory Bowel Disease Susceptibility Loci on 20q13 and 21q22 in Patients with Pediatric Onset IBD. *R. N. Baldassano[1,2], S. Kugathasan[3], J. P. Bradfield[4], P. M. A. Sleiman[4], M. Imielinski[4], S. L. Guthery[5], S. Cucchiara[6], T. Willson[7], E. Bonkowski[7], N. Peterson[3], D. J. Abrams[2], R. Grundmeier[4], P. Mamula[3], G. Tomer[7], D. A. Piccoli[2], D. S. Monos[8], V. Annese[9], L. A. Denson[7], S. F. A. Grant[1,4,10], H. Hakonarson[1,4,10]* 1) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA; 2) Division of Gastroenterology, Childrens Hospital of Philadelphia (CHOP), Philadelphia, PA; 3) Department of Pediatrics, Childrens Research Institute & Medical College of Wisconsin, Milwaukee, WI; 4) Center for Applied Genomics, Abramson Research Center, CHOP, PA; 5) Department of Pediatrics, University of Utah School of Medicine and Primary Childrens Medical Center, Salt Lake City, UT; 6) Pediatric Gastroenterology & Liver Unit, Sapienza University of Rome, Italy; 7) Division of Gastroenterology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 8) Divisions of Immunology and Pathology, CHOP, Philadelphia, PA; 9) Units of Gastroenterology & Endoscopy, IRCCS, Casa Sollievo della Sofferenza Hospital, San Giovanni Rotondo, Italy; 10) Division of Human Genetics, Abramson Research Center, CHOP, PA.

Inflammatory bowel disease (IBD) is a common inflammatory disorder with complex etiology. It is characterized by two distinct phenotypes: Crohns disease (CD) and ulcerative colitis (UC). Previously reported GWA studies have identified genetic variation accounting for a small portion of the overall genetic susceptibility to CD and an even smaller contribution to UC pathogenesis. We hypothesized that stratification of IBD by age of onset may identify new IBD genes. To that end, we performed a GWA analysis in a cohort of 1,011 pediatric onset IBD cases and 4,250 matched controls. We identified, and replicated, significantly associated novel loci on chromosomes 20q13 (rs2315008 allele T and rs4809330 allele A; $P = 6.30 \times 10^{-8}$ and 6.95×10^{-8}, respectively; odds ratio (OR) = 0.74 for both) and 21q22 (rs2836878 allele A; $P = 6.01 \times 10^{-8}$; OR = 0.73) located close to the *TNFRSF6B* and *PSMG1* genes, respectively.

ORMDL3 variants associated with asthma susceptibility in North Americans of European ancestry. *K. Annaiah[1], P. M. A. Sleiman[1], M. Imielinski[1], J. P. Bradfield[1], C. E. Kim[1], E. C. Frackelton[1], J. T. Glessner[1], F. G. Otieno[1], E. Santa[1], W. Glaberson[1], M. Garris[1], R. Chiavacci[1], J. Allen[2], J. Spergel[3], R. Grundmeier[4], M. M. Grunstein[2], M. Magnusson[5], H. Bisgaard[6], S. F. A. Grant[1,5], H. Hakonarson[1,2,5]* 1) Center for Applied Genomics, The Childrens Hospital of Philadelphia; 2) Division of Pulmonary Medicine, The Childrens Hospital of Philadelphia; 3) Division of Allergy and Immunology, The Childrens Hospital of Philadelphia; 4) Department of Bioinformatics, The Childrens Hospital of Philadelphia; 5) Department of Pediatrics, The Childrens Hospital of Philadelphia; 6) Department of Health Sciences, University of Copenhagen.

Asthma is the most common chronic disease in children across all developed countries. The first GWA study of asthma predisposition was recently published by Moffatt et al. In that study 317,000 SNPs were typed in 994 patients with childhood-onset asthma, resulting in the identification of a novel locus on chromosome 17q12 containing multiple genes and associated markers. To determine if ORMDL3 is a genetic risk factor for asthma in North American Caucasians and African Americans we sought to replicate the association with the 10 most significantly associated SNPs in the study by Moffatt et al, in a large pediatric asthma cohort collected at the Childrens Hospital of Philadelphia. The study included 3390 North Americans of European ancestry; 807 patients with physician-diagnosed asthma and 2583 disease-free controls and 3429 African American samples, 1456 asthma patients and 1973 controls. High throughput genome wide SNP genotyping was carried out at the center for applied genomics on the HumanHap550 BeadChip. This study has replicated the reported association between asthma and variants in and around ORMDL3 in a cohort of North American Caucasian asthmatics. Seven of the nine SNPs that were tested showed significant association (P-value range 0.004-0.037 OR range 1.1-0.84). However, the odds ratios obtained in our cohort are significantly lower than those reported by Moffatt et al., which may be a case of the winners curse. In contrast, no association was detected between these markers and asthma in African-Americans.

Genome-wide analysis of structural variation by pair-end mapping. *V. Kumar[1], J. H. H. Tan[1], Y. Zhu[1], F. Yao[2], Y. Ruan[2], M. Seielstad[1]* 1) HUMAN GENETICS, GENOME INSTITUTE OF SINGAPORE, SINGAPORE; 2) GENOME TECHNOLOGY AND BIOLOGY, GENOME INSTITUTE OF SINGAPORE, SINGAPORE.

Structural variation (SV) can be defined as all genomic changes that are not single base-pair substitutions. Such variation includes insertions, deletions, inversions, duplications and translocations of DNA sequences, and encompasses copy-number differences. A number of studies have shown that SV is highly variable within the normal human population. Systematic analysis of these variations will provide fundamental knowledge to understand the normal human genetic diversity and to distinguish from pathogenic alterations. However, identifying them still remains a technical challenge. We use high-throughput and massive paired-end mapping (PEM), to identify SVs. PEM involves shearing and purifying of intact genomic DNA to yield DNA fragment of ~10 kb. Following this, the DNA fragments were methylated with EcoP15I, circularized, digested with EcoP15I and subsequently fragments containing the paired ends were isolated by streptavidin-affinity purifications. This was followed by massive parallel sequencing and mapping of paired ends to identify SVs, both, reported and novel. Since the fragment size was ~10 kb, it also enabled us to identify fine-scale SVs along with the precise mapping of the break points.

Developmental delay and late onset myoclonus in a patient with interstitial deletion of chr 6q21q22.31. *E. Andermann[1,2,3], J. Lavoie[4,5], F. Andermann[2,6]* 1) Neurogenetics Unit, Montreal Neurological Hospital and Institute, Montreal, Quebec, Canada; 2) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; 3) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 4) Department of Pathology, Montreal Children's Hospital, Montreal, Quebec, Canada; 5) Department of Pathology, McGill University, Montreal, Quebec, Canada; 6) Department of Paediatrics, McGill University, Montreal, Quebec, Canada.

Rationale: Chromosomal abnormalities are often associated with mental retardation, dysmorphic features and seizures. Interstitial deletions of chr 6q are relatively rare and usually not associated with epilepsy. Methods: A 30-year-old patient had a history of a single febrile seizure at the age of 8 months, mild to moderate developmental delay, and dysmorphic features. In his late twenties, he developed myoclonic jerks. Detailed examination and family history was performed. The patient had prolonged day and night telemetry recording, as well as MRI studies. Karyotype was performed, as well as FISH studies and array CGH. Results: On examination, the patient has mild dysmetria and frequent myoclonic jerks involving the upper extremities. There is no evidence of recent cognitive deterioration. Prolonged video-telemetry revealed extremely frequent myoclonic jerks arising from the right or left upper extremity. No epileptiform abnormality was noted during the jerks or interictally. MRI showed mild cerebellar vermian atrophy or hypoplasia. Karyotype revealed a subtle interstitial deletion of chr 6q. Array CGH employing an oligonucleotide array confirmed a deletion of chr 6q at 6q21-6q22.31. The extent of the deletion is estimated to be 7.6 Mb. Conclusions: Although deletions of chr 6q are usually not associated with epilepsy, the exact deletion described in our patient has not been reported previously, to our knowledge. Phenotypic variation is in large part due to differences in size and location of the segmental aneuploidy. The patient does not have evidence for progressive myoclonus epilepsy, although Kufs disease cannot be entirely ruled out.

13q14 Tumor Suppressor Candidate KCNRG Promotes Apoptosis and Arrests Division of the Tumor Cell Lines.

A. Birerdinc[1], E. Nohelty[1], J. Baughman[1], G. Manyam[1], A. Marakhonov[2], E. Nikitin[2,3], M. Skoblov[2], V. Chandhoke[1], A. Baranova[1,2] 1) Molecular and Microbiology, George Mason University, Fairfax, VA; 2) Research Center for Medical Genetics, RAMS, Moskvorechie Str., 1, Moscow, Russian Federation; 3) Hematology Research Center of Russia , Moscow , Russian Federation.

Deletions of 13q14 have been shown to play a role in the development of chronic lymphocytic leukemia (CLL) and the progression of multiple myeloma (MM). We created a detailed map of transcripts located in 13q14 area and pinpointed the KCNRG gene encoding a potassium channel inhibitor protein as a primary candidate for MM/CLL TSG. KCNRG encodes a protein with a strong homology to the tetramerization domain of voltage-gated K+ channels. This protein may interfere with the normal assembly of the K+ channel proteins, thereby suppressing the potassium currents. Experiments producing stable overexpression of KCNRG-L and KCNRG-S protein isoforms in the model cell lines LNCaP, HL60 and RPMI8226 demonstrated significant suppression of proliferation rates. Both stably and transiently KCNRG-transfected LNCaP and RPMI8226 cells demonstrated drastic phenotype changes, notably the presence of cells with lobular nuclei. In LnCaP cells, an isoform KCNRG-L has been shown to influence the processes of cell adhesion and contact inhibition. Caspase-Glo apoptosis assays showed a significant 26% increase in apoptosis for transfected cells of RPMI8226 line. Chemiluminescent apoptosis and proliferation assays were independently confirmed by FACS analysis using PI and annexin V. RealTime PCR analysis revealed that KCNRG mRNA levels are significantly decreased ($P < 0.02$) in the excised lymphoid tissue of the diffuse large B-cell lymphoma patients (DLBL, $N = 11$) as compared to the lymphoid samples of normal controls ($N = 6$). In stage I and II B-cell lymphoma samples ($N= 34$) KCNRG mRNA levels were higher compared to stage IV lymphomas ($N=4$). These data point to KCNRG as a strong candidate TSG for CLL, MM and other human tumors with 13q14 rearrangements. Supported by NIH R1R15CA113331-01 and Russian Fund for Basic Research RFFI No 07-04-12232 (ofi-a).

Small molecular inhibitors of the potassium channels as potential therapeutic agents for chronic lymphocytic leukemia. *A. Baranova[1,2], M. Skoblov[2], A. Marakhonov[2], B. Biderman[3], A. Birerdinc[2], V. Chandhoke[1], E. Nikitin[3], A. Sudarikov[3]* 1) Molecular and Microbiology, George Mason University, Fairfax, VA; 2) Research Center for Medical Genetics RAMS, Moscow, Russian Federation; 3) Hematology Research Center of Russia, Moscow, Russian Federation.

Region q14 of human chromosome 13 harbors a critical tumor suppressor gene (TSG) for Chronic Lymphocytic Leukemia and some other malignancies. Recently, we described CLL gene candidate KCNRG (K+ Channel Negatively Regulating Gene). KCNRG is significantly similar to the tetramerization domain of voltage-gated K+ channels (Kv channels) and is capable of the suppression of Kv currents. Studies of the proliferation and apoptosis of the cell lines strongly suggest that KCNRG may act as a tumor suppressor gene for the development or progression of various types of cancers, including CLL. If KCNRG indeed plays a role in CLL tumorigenesis, it might define a novel class of human tumor suppressor genes with a mechanism of action that can be relatively easily reproduced by pharmacological means. We hypothesized that K+ channel inhibitors could be used to make up for a loss of KCNRG activity in CLL. The excellent records for nanomolar concentrations of K+ channel blockers used in the management of epilepsy, stroke, and cardiac arrhythmias enhances the attractiveness of this therapeutic approach. Therefore, we started an initial evaluation of the known non-protein K+ channel blockers as apoptotic inducers in primary CLL cells using Chemiluminescent CaspaseGlo assays. For 9 out of 24 tested K+ channel inhibitors, including anti-hypertensive agent verapamil, CLL specific cytotoxic action has been demonstrated. Additionally, it has been noted that one of the control compounds, linoleic acid, possesses specific activities extending survival of the primary CLL cells in vitro. Supported by NIH R1R15CA113331-01 KCNRG gene as candidate tumor suppressor for CLL and MM (2005-2009) and Russian Fund for Basic Research RFFI No 07-04-12232 (ofi-a).

Novel *GNE* mutations in patients of non-Middle Eastern descent with autosomal recessive hereditary inclusion body myopathy. *C. Saechao[1], Y. Valles-Ayoub[1], A. Haghighatgoo[1], S. Esfandiarifard[1], C. Riley[1], M. Pietruszka[1], D. Darvish[1,2]* 1) HIBM Research Group, Encino, Ca; 2) VA Greater Los Angeles (VA-GLA/UCLA), Los Angeles, CA.

The most prevalent form of autosomal recessive (AR) hereditary inclusion-body myopathy (HIBM) is originally described in Iranian-Jewish families. AR HIBM is a progressive muscle wasting disease characterized by early adult onset degeneration of proximal and distal muscles, often sparing the quadriceps. Mutations in the UDP- N-acetylglucosamine 2-epimerase/ N-acetylmannosamine kinase gene (*GNE*) on chromosome 9p12-13 are associated with AR HIBM. In the present study, we have identified the nucleotide sequence of the *GNE* coding region for twenty patients, and noted nine novel mutations. Of these twenty patients, one is homozygous for the M712T founder Middle-Eastern mutation, and one is homozygous for the V572L founder Asian mutation. Thirteen patients, eight of whom are compound heterozygotes, carry the novel mutations. These *GNE* mutations should be considered in clinical and research testing protocols along with previously reported mutations related to HIBM.

Plastin 3 protects against spinal muscular atrophy (SMA) - the first fully protective modifier of a Mendelian disorder. *B. Wirth[1,2], S. Kröber[1,2], M. L. McWhorter[3], W. Rossoll[4], S. Müller[2], M. Krawczak[5], G. J. Bassell[4], C. E. Beattie[3], G. E. Oprea[1,2]* 1) Inst. of Human Genetics, Univ. of Cologne, Cologne, Germany; 2) Center for Molecular Medicine Cologne, Univ. of Cologne, D-Cologne; 3) Centre for Molecular Neurobiology, The Ohio State Univ., Columbus, OH; 4) Emory Univ. School of Medicine, Dept.of Cell Biology, Atlanta, GA; 5) Inst. of Medical Informatics and Statistics, Christian-Albrechts Univ. of Kiel, D-Kiel.

Homozygous deletion of SMN1 causes spinal muscular atrophy (SMA), the most frequent genetic cause of early childhood lethality. In rare instances, however, individuals are fully asymptomatic despite carrying the same SMN1 mutations and the same number of SMN2 copies as their affected siblings, thereby suggesting the influence of modifier genes. By comparing the transcriptom from lymphoblastoid cell lines between unaffected and affected SMN1-deleted siblings, we identified plastin 3 (PLS3; Xq23) to be highly expressed in all unaffected but not in the affected counterparts. PLS3 expression in blood turned out to be a rare variant, occurring only in 5% of controls. We found that PLS3 is highly expressed in spinal cord, associates with SMN, and together are part of a large multiprotein complex in spinal cord. The two proteins are present at similar subcellular locations in primary motor neurons and increase in expression during neuronal differentiation. PLS3, as an actin bundling protein, influenced the F-actin levels known to be involved in axonal outgrowth and guidance. PLS3 knock-down severely affected axonal growth, whereas its overexpression induced axonal growth. Most importantly, over-expression of PLS3 rescued the axonal growth defects caused by reduced SMN levels in neuronal differentiated PC12 cells, in primary motor neurons of SMA mouse embryos and in an in vivo zebrafish SMA-model. Our data strongly support the view that the involvement of SMN in axonal outgrowth and pathfinding is the major pathogenic defect in SMA. The results may help to identify novel targets for SMA therapy. This discovery signifies a major breakthrough in medical genetics in that it represents the first report ever of a fully protective modifier for a Mendelian disorder in humans.

Associated malformations in cases with congenital diaphragmatic hernia. *C. Stoll, Y. Alembik, B. Dott, M. P. Roth*
Genetique Medicale,Faculte de Medecine,Strasbourg, France.

The etiology of congenital diaphragmatic hernia (CDH) is unclear and its pathogenesis is controversial. Because previous reports have inconsistently noted the type and frequency of malformations associated with CDH, we assessed these associated malformations ascertained between 1979 and 2003 in 334,262 consecutive births. Of the 115 patients with the most common type of CDH , the posterolateral, or Bochdalek-type, hernia , 70 (60.8%) had associated malformations. These included patients with chromosomal abnormalities (21, 30.0%); non-chromosomal syndromes including Fryns syndrome, fetal alcoholism syndrome, De Lange syndrome, CHARGE syndrome, Fraser syndrome, Goldenhar syndrome, Smith-Lemli-Opitz syndrome, multiple pterygium syndrome, Noonan syndrome, and spondylocostal dysostosis; malformation sequences including laterality sequence, and ectopia cordis; malformation complexes including limb body wall complex and non syndromic multiple congenital anomalies (MCA) (30, 42.9%). Malformations of the cardiovascular system (42, 27.5%), urogenital system (27, 17.7%), musculoskeletal system (24, 15.7%), and central nervous system (15, 9.8%) were the most common other congenital malformations. We observed specific patterns of malformations associated with CDH which emphasizes the need to evaluate all patients with CDH for possible associated malformations. Geneticists and pediatricians should be aware that the malformations associated with CDH can be often classified into a recognizable malformation syndrome or pattern (57.1%).

Systematic resequencing of the coding exons of the X chromosome in X-linked Mental Retardation. *M. Stratton*
Cancer Genome Project, Wellcome Trust Sanger Inst, Hinxton, Cambs, United Kingdom.

Mental retardation (MR) affects 1-3% live births and has both genetic and non-genetic causes. A proportion of cases with genetic abnormalities are attributable to mutations of genes on the X chromosome. Although several X-linked MR (XLMR) genes have been reported, identification of more by conventional approaches is problematic because mutations of many genes cause MR and their associated phenotypes are similar. Here, we have implemented a new strategy in which the coding exons of most X chromosome genes (720/850, ~1Mb DNA per sample) have been systematically resequenced for disease-causing variants in individuals from more than 200 XLMR families. The strategy has yielded several new XLMR genes. However, many families remain to be explained. The study also indicates that loss of function of ~1% of X-genes is compatible with apparently normal existence. To our knowledge, this is the largest resequencing study to identify human disease genes thus far conducted. The results highlight issues that will be faced in the future by whole genome screens for rare disease-causing variants.

Mosaicism for a structural abnormality with 12p duplication. *S. Wenger[1], C. Cutenese[1], M. Hummel[2]* 1) Dept Pathology, West Virginia Univ, Morgantown, WV; 2) Dept Pediatrics, West Virginia Univ, Morgantown, WV.

At 38 weeks gestation, a female infant was delivered to a 19 year old mother with a history of polyhydramnios and gestational diabetes. The infant had a VSD, anal fistula, hypertension and mild hypotonia. She was hospitalized for 3 ½ weeks due to breathing problems. She was seen at 6 months of age by genetics and was noted to have minor dysmorphic features and developmental delays. She showed significant developmental delay and hypotonia at 10 months of age. Her karyotype was 46,XX,dup(12) (p12.2p13.3)[5]/46,XX[15]. The additional material on 12p was confirmed to be a duplication using TEL and subtelomere FISH probes. The patient has facial features similar to tetrasomy 12p, or Pallister-Killian syndrome, including the sparse temporal hair. Only about two dozen cases with mosaicism involving an autosomal structural abnormality have been reported in the literature, which have included duplications, deletions, insertions, isochromosomes and derivative chromosomes. The presence of both a normal cell line and structural abnormality indicates a mitotic error. The phenotype of 12p duplication is similar to that seen for tetrasomy 12p. Since our patient has significant developmental delay, most likely the mitotic duplication error occurred early during development. One of the characteristics of tetrasomy 12p is loss of the abnormal cell line in peripheral blood. Since the clinical consequences of duplication 12p are not as dramatic as tetrasomy 12p, the structurally abnormal cell line in our patient may not have as great of a growth disadvantage, resulting in the presence of the abnormal cell line in peripheral blood. We would suspect that the structurally abnormal cell line in our patient, similar to tetrasomy 21p, is more prevalent in fibroblasts, and will completely disappear from peripheral blood over time.

Reproductive Genetic Counseling in Patients with Complex Chromosomal Rearrangement. *N. Takeshita[1,2,3], Y. Katagiri[1,2,3], Y. Fukuda[1,3], M. Kitamura[1,3], Y. Iizuka[1], H. Takano[1], Y. Ishihara[1], T. Taniguchi[1], A. Oji[1], M. Saigusa[1], H. Hayashi[1], Y. Sasaki[1,3], S. Watanabe[1,3], Y. Matsue[1,3], A. So[1,3], C. Aoki[1], Y. Yao[1], T. Maemura[1], M. Tanaka[1], M. Morita[1]* 1) Department Obstetrics and Gynecology, Toho University, School of Medicine, 6-11-1 Omori Nishi, Ota-Ku, 143-8541, Tokyo, Japan; 2) Division forClinical Genetics, Toho University, School of Medicine, 6-11-1 Omori Nishi, Ota-Ku, 143-8541, Tokyo, Japan; 3) Center for Reproductive Medicine and Infertility, Toho University, School of Medicine, 6-11-1 Omori Nishi, Ota-Ku, 143-8541, Tokyo, Japan.

IntroductionThe first birth of a child by in vitro fertilization (IVF) in 1978 was a landmark event in the field of medicine. In the three decades since, there has been remarkable progress in assisted reproductive technology (ART). In the three decades since, there has been remarkable progress in assisted reproductive technology (ART). Recently, we conducted reproductive genetic counseling for a couple with a complex chromosomal rearrangement (CCR) that had five cleavage points involving four chromosomes 1, 6, 9 and 14. Here we present this case with some discussion regarding key points and matters to be considered for such counseling.This is a case report of reproductive genetic counseling for a couple with a CCR. The patient was a man aged 34 who was diagnosed with oligozoospermia. **Results** The results of chromosome analysis revealed that the chromosomal karyotype of the CCR in this patient was found to be 46, XY, der (1) (1qter1p13.3::9q22.19qter), der (6) (6pter6q15::?1p13.3?1p31.2::14q3114qter), der (9) (9pter9q22.1::6q156qter), der (14) (14pter14q31::1p31.21pter). **Conclusions** In patients with CCR, it is important to provide the patient with sufficient information and gain understanding of the pathogentic mechanism that underlies this genetic error. Pregnancy is dependent on the presence of phenotypic aberration. It is not infrequent that miscarriage occurs due to a high probability of unbalanced chromosome constitution even if pregnancy is confirmed. Furthermore, it may be difficult to establish an accurate preimplantation genetic diagnosis (PGD) in CCR patients.

An Integration of Genome-Wide Association (GWA) and Microarray Expression Profile to Accelerate the Discovery of New Candidate Genes. The Framingham Osteoporosis Study. *Y. Hsu[1], S. Demissie[2], K. Cho[2], Y. Zhou[2], E. Bianchi[3], SL. Ferrari[3], LA. Cupples[2], D. Karasik[1], DP. Kiel[1]* 1) Hebrew SeniorLife and Harvard Med. Sch., Boston, MA; 2) Biostat., BU, Sch Public Health, Boston, MA; 3) Div. of Bone Dis., Geneva Univ. Hosp., Geneva, Switzerland.

GWA approach is a powerful tool for identifying susceptibility genes of common diseases and providing novel targets for potential therapies. While a powerful method, GWA is not without challenges. Critical to success is to minimize the false association signals due to testing large number of markers. To overcome the challenge, we integrated mouse gene expression atlas with GWA study to identify and prioritize subsets of novel candidate genes for further evaluation. We conducted a GWA study using the Affymetrix 550K SNP chips to localize susceptibility genes for bone health phenotypes (bone density and hip geometric indices) in 2073 women and 1554 men (677 extended pedigrees) from Framingham cohorts. Family-based association test weighted by rank order of population-based linear mixed effect model statistics was used to estimate the genome-wide significance. The 3000 most significant SNPs from each trait were further evaluated in 2650 men and 5850 women from 2 independent studies (Rotterdam and the UK Twins Studies). To test whether associated genes were expressed in bone, we measured mRNA of PTH-differentiated primary osteoblasts, profiled bone cell expression from aging mice, and examined an embryonic mouse microarray database for in situ localization. Several novel candidate genes were found to be expressed in osteoblasts and genome-wide significantly associated with bone traits (i.e. PTPRD, SLC16A4, and PRKG1 genes). In addition, a gene-set enrichment analysis by Gene Ontology for the genes selected from the most significant SNPs suggested significant clustering of genes involved in CNS (nervous) development. In conclusion, our results reveal novel candidate genes and pathways to further elucidate the etiology of osteoporosis. To complement the leads from GWA studies, integration of expression profile allow effectively exploring the underlying mechanisms by which gene products act to alter disease susceptibility.

Association of Angiotensin-converting enzyme (ACE) gene insertion-deletion polymorphism with spondylarthropathies. *M. Z. Haider[1], D. K. Shehab[2], K. Al-Jarallah[2], A. M. Al-Awadhi[2], A. Al-Herz[3], I. Nahar[4]* 1) Pediatrics, Fac. of Medicine, Kuwait University, Safat, Kuwait; 2) Medicine, Fac. of Medicine, Kuwait University, Safat, Kuwait; 3) Medicine, Amiri Hospital, Kuwait; 4) Medicine, Mubarak Al-Kabeer Hospital, Kuwait.

Low back pain (LBP) is a common medical problem in which an interaction between genetic and environmental factors predisposes individuals even at an early age. Inflammatory back pain or spondylarthropathies include ankylosing spondylitis (AS), psoriatic arthritis(PSA), reactive arthritis enteropathic and undifferentiated arthropathies. Angiotensin-converting enzyme (ACE) plays an important role in circulatory homeostasis, physiology of vasculature and inflammation. The insertion-deletion (I/D) polymorphism of the ACE gene determines the plasma and tissue levels of ACE especially in the synovial fluid. The aim of this study was to investigate an association between ACE gene I/D polymorphism and inflammatory back pain (spondylarthropathies) secondary to ankylosing spondylitis (AS), psoriatic arthritis, inflammatory bowel disease and undifferentiated spondylarthropathies. The prevalence of ACE gene I/D polymorphism genotypes was determined in 63 patients with inflammatory back pain by polymerase chain reaction (PCR) and compared with that in 111 healthy controls. Of the 63 patients studied, 45 (71.4%) were with AS. 13 (20.6%) were with PSA, 4 (6.3%) were with reactive arthropathy and 1 (1.6%) manifested undifferentiated arthropathy. There were 43 males and 20 females. Mean age of patients was 39.0 11.36 years, age at onset of spondylarthropathy was 27.7 7.49 years and disease duration was 10.3 7.74 months. The ACE gene polymorphism showed an overall significant difference between patients and controls ($p = 0.05$). The incidence of heterozygous ID genotype was significantly higher in patients than in the controls 30.2% vs. 16.2% ($p = 0.01$), and DD genotype was more prevalent in controls 66.7% vs. 49.2% ($p = 0.01$). This study showed a significant association of the ACE gene I/D polymorphism with spondylarthropathy.

A large-scale survey of genetic copy number variations among Han Chinese residing in Taiwan. *C.-H. Lin[1], L.-H. Li[2], S.-F. Ho[2], T.-P. Chuang[2], J.-Y. Wu[2], Y.-T. Chen[2], C. S.-J. Fann[1,2]* 1) Department of Life Sciences and Institute of Genome Sciences, National Yang-Ming University, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Copy number variations (CNVs) have recently been recognized as an important structural variation in the human genome. CNVs affect expression of corresponding genes, and thus may contribute to certain phenotypic differences. The copy number inferring tool (CNIT) is an effective hidden Markov model-based algorithm for estimating allele-specific gene copy number and predicting chromosomal alterations from single nucleotide polymorphism microarrays. Using HapMap, we analyzed CNV information from 270 multi-ethnic individuals to determine the parameters of the CNIT algorithm and then applied the parameters to 300 unrelated Han Chinese residing in Taiwan. Under very restricted selection criteria, 230 regions having CNVs were identified in the Han Chinese population; 64 displayed greater than 1% minor allele frequency. The average size of the CNV regions was 322 kb (ranging from 1.48 kb to 5.68 Mb) and covered a total of 2.47% of the human genome. One hundred ninety-six of the CNVs were simple deletions and 27 were simple amplifications; 130 of the CNVs (56.52%) were reported previously. There were 449 genes and 5 microRNAs within these CNV regions and some of these genes are known to be associated with diseases. These CNVs are characteristic of Han Chinese populations and should be taken into consideration when genetic studies are conducted.

Possible implication of mRNA folding on the translation of FMR1 transcript on FMRP levels among normal and premutation carriers. *E. Peprah, W. He, E. Allen, T. Oliver, S. Sherman* Human Genetics, Emory University, ATLANTA, GA.

Fragile X syndrome (FXS) is the most common form of inherited mental retardation. FXS is caused by a trinucleotide repeat expansion in the 5 untranslated region (UTR) of the Fragile X mental retardation-1 (FMR1) gene. The expansion of CGG repeats can be grouped into categories based on the CGG repeat length and stability of the sequence. Normal individuals (6-44 repeats), intermediates (45-54 repeats), premutation carriers (55-199 repeats) and full mutations (>200 repeats). Alleles with >200 repeats lead to methylation of the regulatory region of FMR1, which induces transcriptional silencing. The absence of the FMR1 protein (FMRP) leads to FXS. Intriguingly, previous data have shown that FMR1 premutation carriers have increased FMR1 mRNA levels with decreased FMRP levels. The decreased levels of FMRP are thought to be due to translational inefficiency of the FMR1 transcript due to mRNA folding of the 5 UTR which contains the CGG repeats. To determine if there is a repeat length threshold for this effect we examined 31 males with repeats ranging from 29 to 110. For transcript and protein analysis, buffy coat samples were collected from fresh venous blood samples. Using quantitative protein assay, we confirmed the significant negative association between repeat length and FMRP. This association appeared to be linear, however we observed an increase in FMRP among repeat size ranges of 80-89. We conducted MFOLD analysis to better elucidate 5 UTR folding structures within each repeat size range. This increase could possibly be explained via the folding of the 5 UTR of the transcript. These data support a model of increasing inefficiency of protein translation based on increasing repeat size.

Stroke in Fabry Disease Frequently Occurs Before Diagnosis and in the Absence of Other Clinical Events: Natural History Data from the Fabry Registry. *K. Sims[1], J. Politei[2], M. Banikazemi[3], P. Lee[4]* 1) Center for Human Genetic Research and the Department of Neurology, Massachusetts General Hosp, Boston, MA; 2) Neurology Service, Juan Fernandez Hospital, Buenos Aires, Argentina; 3) Departments of Neurology and Pediatrics, New York University School of Medicine, New York, NY; 4) Charles Dent Metabolic Unit, National Hospital for Neurology & Neurosurgery, Queen Square, London, UK.

Strokes are a common and serious clinical manifestation of Fabry disease, an X-linked lysosomal storage disorder caused by deficiency of alpha-galactosidase A activity. A total of 138 patients of 2446 in the Fabry Registry (86 of 1243 males [6.9%] and 52 of 1203 females [4.3%]) experienced a stroke before starting enzyme replacement therapy. The median age at first stroke was 39.0 years in males and 45.7 years in females. The majority of patients (70.9% of males and 76.9% of females) had not experienced a renal or cardiac event before their first stroke. Fifty percent of males and 38.3% of females experienced their first stroke before they were diagnosed with Fabry disease. Thirty patients (21 males and 9 females) had strokes at age <30 years with a median age of 25.8 years in males (N=21) and 24.1 years in females (N=9). Two patients had strokes during their teenage years (a 13.8 year-old male and a 19.8 year-old females). 86.8% had ischemic strokes, but 13 of 77 males (16.9%) and 3 of 44 females (6.9%) had hemorrhagic strokes, among those for whom a stroke type was reported. Sixty percent of males and 25.5% of females exhibited stage 3-5 chronic kidney disease after their first stroke, based on the most recent eGFR data. 66.1% of males and 59.5% of females had left ventricular hypertrophy at some point after their first stroke. Compared to non-stroke patients, those who had strokes were more likely to have had a TIA (36.2% versus 5.4%), an arrhythmia (32.6% versus 12.7%) or hypertension (52.9% versus 20.5%). All patients with Fabry disease, regardless of age or gender, should be monitored closely for possible cerebrovascular complications, as stroke can occur in the absence of other key signs of the disease.

Syndrome Association with Cleft Lip/Palate in Center West of Brazil Region. *R. L. L. Séllos* dentistry, Hospital Materno Infantil, Goiania, GO., Goiania, Brazil.

The Cleft lip and palate (CLP) are frequent congenital malformations. Its happens in the 1st quarter of gestation, for flaw in the development of the lateral and medium nasal processes with the processes maxillaries. Studies show that 70% of CLP happen in subjects no syndromics, while the remaining 30% are frequently associated to the syndromes and sequence, existing about 350 of these: syndrome Pierre Robin, syndrome of Van der Woude, syndrome Treacher Collins... In Brazil, is considered 280.000 bearers of FLP, appearing 5.800 new cases/year, with tax of 1:650 new born. In Goiânia - Goiás, there is the Center of Rehabilitation of Cleft Lip and Palate (CERFIS), reference of the State, about 3.000 registered patients. Objective:, The objectives of the study went to describe the population assisted in this center in the period 1998-2004, and to identify the occurrence of syndromes associated with CLP. Methodology :, The sample totaled 1257 handbooks of patient with of CLP in the period. The studied variables were gender, hereditary, consanguinity, occurrence of syndromes associated to the cleft and classification of the cleft. The project was approved by the Committee of Ethics in Research of Hospital Materno Infantil. Results:, Of the 1.257 patients of CLP of the study, (46,7%) they were female and (53,3%) of the male. The family history of CLP was registered in 227 handbooks, 41 registrations referred consanguineous marriages,. Syndromes and/or sequences associated to CLP happened in 51 cases. Being the larger frequency of cases with Pierre Robin's sequence (60,8%). The classification of the clefttt: Cleft Lip 27%, Cleft Lip an Palate 43%, Cleft palate 27,7% and Rare fissures of the face 2.2% Conclusions:, The present study has shown that it would be appropriate to continue the investigation of patients attending CERFIS in order to characterize the environmental and genetic factors associated with the etiology of cleft Such information could be employed to improve the assistance given to patients and consequently the treatment applied.

Haploinsufficiency of FOXP1 is associated with Chiari I malformation and speech/language disorder. *O. Abdul-Rahman[1], H. Zimmerman[1], N. Justice[2], C. Lese-Martin[2]* 1) Dept Pediatrics, Univ Mississippi, Jackson, MS; 2) Dept Human Genetics, Emory University, Atlanta, GA.

We report on the first case of a patient with haploinsufficiency of FOXP1. The patient did not walk until 16 months of age. He was able to imitate sounds, but had no words. Hearing was normal. He uses sign language. Physical exam at age 3 showed normal growth. He had a broad forehead, hypertelorism, downslanting palpebral fissures, ptosis, short nose, full nasal tip, smooth philtrum, and down-turned mouth. MRI showed a Chiari I malformation. CGH detected a 1Mb deletion at 3p13. Parental analysis confirmed the deletion was de novo. The deletion involved 70,549,922 bp to 71,570,262 bp (hg 17) and FOXP1 is the only known gene in this region. FOXP1 is a transcriptional regulator that binds DNA through a winged-helix domain and influences gene expression through a zinc-finger and leucine zipper motif. This feature identifies it as a member of the forkhead family that include four members, FOXP1-4. Mutations in FOXP2 have been associated with speech-language disorder 1. Mutations in FOXP3 cause X-linked immunodysregulation, polyendocrinopathy, and enteropathy. In humans, FOXP4 expression is noted to be reduced in some tumors. Studies of FOXP1 expression suggest tumor suppressor activity and roles during embryonic expression in the nervous system. Abnormalities in FOXP1 expression are seen in colon, stomach, and prostate tumors in addition to B-cell lymphomas. Developmental expression studies of FOXP1 in zebrafish demonstrate increased signals in the midbrain, hindbrain, and anterior spinal cord. The presence of a Chiari I malformation in our patient, believed to be caused by dysgenesis of para-axial mesoderm in the developing hindbrain, is likely related to deficient FOXP1 expression during embryogenesis. Additionally, SPCH1 is a result of reduced FOXP2 expression in the perisylvian frontal and temporal regions important for auditory vocal learning and speech development. Songbird and human fetal brain analysis supports overlapping expression of both FOXP1 and FOXP2 in structures important for learned articulation, which may explain the speech/language phenotype in this patient.

Cellular impact of *RAI1* haploinsufficiency: *RAI1* functions through specific pathways to regulate growth, metabolism, and circadian rhythm. *S. Girirajan[1,2], H. T. Truong[3], C. L. Blanchard[3], S. H. Elsea[2]* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Depts. of Human and Molecular Genetics and Pediatrics, Virginia Commonwealth University, Richmond, VA; 3) School of Biomedical Sciences, Charles Sturt University, Wagga Wagga, NSW, Australia.

Smith-Magenis syndrome (SMS) is a complex syndrome characterized by a constellation of ~30 features that include sleep disturbance, craniofacial defects, neurological and behavioral anomalies, and variable systemic features. SMS is caused by a 17p11.2 deletion encompassing the retinoic acid induced 1 (*RAI1*) gene or by mutation of *RAI1*. While haploinsufficiency of *RAI1*, a known transcription factor, is the major cause of SMS, its exact functional pathways are not known. We hypothesized that *RAI1* acts through specific cellular pathways involving several downstream targets which are altered by *RAI1* haploinsufficiency. To identify genes in these *RAI1*-mediated pathways, we performed genome-wide gene expression analysis on cells haploinsufficient for *RAI1*. Human embryonic kidney (HEK293T) cells with RNA-interference-based ~50% knockdown of *RAI1* and lymphoblastoid cell lines created from SMS patients were utilized. Genome-wide gene expression profiling using microarrays showed that ~60 genes were upregulated and ~200 genes were downregulated due to *RAI1* haploinsufficiency. Real-time qRT-PCR confirmed the gene expression profile in knockdown HEK293T cells. Lymphoblastoid cell lines obtained from SMS patients confirmed the altered expression pattern in downstream genes that are involved in growth signaling and insulin sensitivity (*INSIG1, PIK3R1, ZNF236*), circadian activity (*NR1D2*), neuronal differentiation (*ZIC1, PSEN2, RXRb, SMA4, CLN8, NF1, MLL*), lipid biosynthesis and fat mobilization (*LIPE, HMGCS1*), skeletal development (*GLI3, PSTPIP2, ANKH*), behavior (*SCN12A*), gene expression (*SPTBN1, POLDIP3, PPP1R14D, ADD3*), cell cycle regulation (*RUNX1T1, AKR7A3, FBLN1, ZNF236*), and recombination (*RAD51*). Our study suggests that *RAI1* functions through several genes in specific pathways regulating various biological processes, that when disrupted result in the phenotypic effects observed in Smith-Magenis syndrome.

Health Technology Assessment of Gene Expression Profiles for the Prognosis of Recurrence of Primary Breast Cancer. *A. P. Lea, T. L. Rogstad, S. Levine* Hayes Inc., Lansdale, PA.

Objectives: A number of prognostic gene expression profiles (GEPs) have been developed to help identify patients most likely to benefit from systemic adjuvant chemotherapy following surgery for the treatment of early-stage breast cancer. A comparative evidence-based health technology assessment of 5 GEPs was performed focusing on their use to estimate the risk of recurrence of primary unilateral breast cancer in women. **Methods:** The ACCE model that was developed by the Centers for Disease Control and Prevention (CDC) was utilized for the assessment of genetic tests. A strict definition of clinical validation was also used: the assay methods to perform the test had to be the same as used in the study that derived the gene expression test, and also the tumor samples used for validation had to be independent of those included in the study that derived the test. The tests included in this assessment were the 2-gene ratio, the 5-gene panel, the 21-gene panel, the 70-gene panel and the 76-gene panel. Conclusions were based only on published data. **Results:** For most of the 5 GEPs, there were little analytical validity data available. Most of the research into these 5 GEPs focused on establishing clinical validity. Using conservative criteria, clinical validity was found to have been demonstrated for the 21-gene, 70-gene and 76-gene panels, but not the two-gene ratio or the 5-gene panel. No published prospective studies examining the clinical utility of any of the 5 GEPs were identified. **Conclusions:** Given the lack of published prospective studies on the clinical utility of any of the 5 GEPs, a clinical benefit of using these gene expression tests has yet to be established. Accordingly, despite the widespread use of some of these tests, from an evidence-based medicine perspective, none of these tests can be unequivocally recommended for clinical use. Results of ongoing major studies (MINDACT and TAILORx) will be essential in determining the clinical utility of these gene expression tests and defining any impact on patient outcomes.

Congenital Inborn Errors of Metabolism. 15 Years Experience at the Hospital Para el Niño Poblano(HNP), Mexico. *J. M. Aparicio[1,7], M. L. Hurtado[2], M. P. Barrientos[3], V. H. A. Leon[4], M. S. R. Gutierrez[5], M. P. A. Gallegos[6], H. O. Chavez[7], J. G. Vega[7], S. M. Chatelain[1]* 1) Dept Genetics; 2) Cytogenetics; 3) Endocrinology; 4) Pediatrics; 5) Clinical Laboratory, Hospital para el Nino Poblano, Puebla,; 6) Molecular Genetics, CIBO IMSS Guadalajara Jalisco,; 7) Estomatology Faculty, Benemerita Universidad Autonoma de Puebla, Mexico.

INTRODUCTION. Inborn errors of metabolism (IEM) comprise a large class of genetic diseases involving disorders of metabolism. Most of them are due to defects of single genes that code for enzymes that facilitate conversion of various substances called substrates. In most of the disorders, problems arise due to accumulation of substances which are toxic or interfere with normal function, or reduced ability to synthesize essential compounds. Inborn errors of metabolism are now often referred to as congenital metabolic diseases or inherited metabolic diseases, being both terms considered similar. The IEM are clinical identificables diseases mentioned by Garrod in 1908. Consanguinity was an importan issue if inheritance background was observed. CASES REPORTED. 2 370 patients were studied at the hospital during a 15 years period. All clinical patients with polymalformed muscle esqueletal and skull dismorfies were included in the study. 102 patients (4%) were found to be positive for IEM. RESULTS. From these 102 patients with IEM, 42 patients had amino acid, 2 mitochondrial and 43 carbohydrates alterations. 15 of these patients had mucopolysaccharidosis, from these 10 were diagnosed as Hurler, 2 as Hunter and 3 as Morquio syndromesFigure 1. CONCLUSIONS. The congenital Inborn Errors of Metabolism (IEM) are inherited diseases with a Mendelian autosomic recessive inheritance risk. A gen alteration produces an enzymatic defect with a unique biochemical alteration. Most of these genetic defects clinical manifestations are observed in children, were neonatal metabolic test are important. Actually, the IEM are defined as monogenic inherited diseases or mendelians, due to a metabolic error for a protein or enzime absence. It might be incompatible with the patient life and some times if the patient lives it will modify its quality life (Fenilketonuria).

Freeman Sheldon syndrome. A case report from the Hospital Para el Niño Poblano, Mexico. *M. Barrientos[1], J. M. Aparicio[2,5], N. C. O. Gil[3,5], W. B. San Martin[3], R. A. E. Garcia[3], E. M. Landini[4], S. M. Chatelain[2]* 1) Endocrinology; 2) Genetics; 3) Estomatology; 4) Orthopedics, Hospital para el Niño Poblano, Puebla, puebla, Mexico; 5) Estomatology Faculty, Benemerita Universidad Autonoma de Puebla.

INTRODUCTION. Freeman Sheldon syndrome (FSS) is characterized by talipes equinovarus, camptodactyly, scoliosis, abnormalities of the muscles of the eye, microstomia, high-arched palate, attenuated movement of the muscles of facial expression and other primary anomalies involving the musculoskeletal system. On the whole, DA1 is the least severe; DA2B is more severe with additional features that respond less favourably to therapy. DA2A (FSS) is the most severe of the three, with more abnormalities and greater resistance to therapy. FSS has been described as a type of congenital myopathy. In March 2006, Stevenson et al. published strict diagnostic criteria for distal arthrogryposis type 2A (DA2A) or Freeman-Sheldon syndrome. These included two or more features of distal arthrogryposis: microstomia, whistling-face, nasolabial creases, and 'H-shaped' chin dimple. CASE REPORTED. A 3 years old female patient, was diagnosed as FSS, due to her clinical phenotype, short stature, whistling-face, nasolabial creases, 'H-shaped' chin dimple, microstomia, high-arched palate, attenuated movement of the muscles of facial expression. Distal arthrogryposis, and camptodactyly. Congenital cardiopaty, auricular communication, was also observed. CONCLUSIONS. Patients with FSS must have early craniofacial and orthopedic evaluation since tey have craniofacial and musculoesqueletic malformations. Correction is indicated to improve function or aesthetics. Although some surgical procedures have suboptimal outcomes, due to the muscular pathology of FSS. Genetic counseling is also important, since FSS has been associated to either autosomal dominant, most often demonstrated or autosomal recessive inheritance. FSS is caused by genetic changes. Krakowiak mapped the distal arthrogryposis multiplex congenital (DA2B) gene, a syndrome very similar in phenotypic expression to classic FSS, to 11p15.5-pter.Early intervention leads the possibility to minimize developmental delays and improve basic functions.

Genetic counseling in carriers of reciprocal chromosomal translocations involving two autosomes. *H. Pour-Jafari[1,2], M. Farimani[2], S. Ghahramani[3], M. Hashemzadeh Chaleshtori[4], B. Pour-Jafari[2]* 1) Molecular Medicine & Genetics, School of Med., Hamadan Univ Med Sciences, Hamadan, Hamadan, Iran; 2) Research Centre for Molecular Medicine, Hamadan University of Medical Sciences, Hamadan, Iran; 3) Genetic Laboratory, Sh. Beheshti Hospital, Hamadan, Iran; 4) Molecular Genetic Research Center, Shahre Kord, Iran.

One of the main genetic causes involve in the pathogenesis of recurrent abortion is parental chromosomal abnormalities. The central concept in genetic counseling with such families is to estimate the probability of recurrence of unfavorable pregnancy outcomes. The main questions that consultants usually ask are: why this happened? What is the risk to be done again? Our cases were two families with repeated miscarriage. The pedigrees were drawn, the chromosomes of couples were studied and estimation for recurrent risk was done. We tried to answer those two main questions and clear the results for them. Parental chromosome abnormalities were found after karyotyping with GTG technique at 450 band resolution, revealing 46 chromosomes with balanced translocation of autosomes in one of the partner in both families. Recurrent risk was estimated as 1/6 for their future pregnancies in each family. Couples in which one partner is the carrier of such balanced translocation have increased risks of infertility, recurrent abortion, and delivery of chromosomally abnormal offspring. Genetic counseling of such couples therefore presents a unique challenge and should be considered in dealing with such families.

A Survey of (CAG)n Repeats Causing the Juvenile Huntington Disease in an Iranian Family with Four Affected Members. *B. Pour-Jafari[4], M. Mazdeh[2], A. Ghaleiha[3], H. Pour-Jafari[1,6], M. Houshmand[5], F. Talebzadeh[6], M. Rostami[5]* 1) Mol Med & Genetics, School of Medicine, Hamadan Univ Med Sciences, Hamadan, Iran; 2) Neurology Dept, School of Medicine, Hamadan University of Medical Sciences, Hamadan, Iran; 3) Psychiatry Dept, School of Medicine, Hamadan University of Medical Sciences, Hamadan, Iran; 4) SKG Heart Center, Houston, TX; 5) Special Medical Center, Enghelab Ave., Ostad Nejat Allahi, #1, Tehran, Iran; 6) Research Center for Molecular Medicine, Hamadan University of Medical Sciences, Hamadan, Iran.

Huntington's disease is a rare inherited neurological disorder. HD is caused by a trinucleotide repeat expansion (CAG)n in the gene coding for Huntingtin (Htt) and is one of several polyglutamine diseases. Huntington's disease's most obvious symptoms are abnormal body movements called chorea and a lack of coordination, but it also affects a number of mental abilities and some aspects of personality. These physical symptoms occur in a large range of ages, with a mean occurrence in a person's late forties/early fifties. If the age of onset is below 20 years then it is known as Juvenile HD. Huntington's disease is autosomal dominant, needing only one affected allele from either parent to inherit the disease. Although this generally means there is a one in two chance of inheriting the disorder from an affected parent, the inheritance of HD and other trinucleotide repeat disorders is more complex. Our case was an Iranian family with four affected sibs (2 daughters and 2 brother). They had 4 affected and 5 normal male children. There was no any other case in their family history. The onset age of the disease in our case family was 20 to 25 years. Their parents were unaffected and nonconsanguineous. Analysis of pathogenic (CAG)n repeat region of the HD gene for the affected members have showed an expansion allele with 46, 50, 46 and 44 repeats in four affected sibs. These results indicate that molecular analysis after clinical diagnosis for HD inclusions facilitates the pathological evaluation of HD and enhances its accuracy.

Differential response to Galsulfase therapy in brothers with mucopolysaccharidosis VI (Maroteaux-Lamy). *A. Scheuerle* Tesserae Genetics, Dallas, TX.

Mucopolysaccharidosis VI (MPSVI; Maroteaux-Lamy) is a recessive lysosomal storage disease due to mutations in arylsulfatase B (ARSB). Galsulfase enzyme therapy (ERT) was made available in 2005. Two brothers who began ERT at different ages and stages of disease demonstrate the advantages of early treatment. Case 1: 30 m/o BM. He delivered by caesarean section due to macrocephaly. Motor development was delayed. Language and cognitive development were normal. He had frontal bossing, chronic rhinorrhea, corneal clouding, decreased use of his left arm, and an unusual gait. Enzyme diagnosis of MPSVI was made (ASRB = 0.0 nmol/min/mg protein). He was begun on ERT at 33 months of age. A fall at home resulted in C3/C4 subluxation and spinal cord injury. He had cervical spine fusion, recovering well. He regained much of his motor function. At one year of therapy there was no measurable progression of disease and no adverse reaction to infusion. At 4.5 y/o he had physical features of severe MPS VI, but was cognitively normal. Urine glycosaminoglycans (GAG) went from 617.9g/mg creatinine to 200 without proteinuria. He has had an antibody response to the enzyme. Case 2: Newborn BM. Postnatal enzyme analysis confirmed ASRB = 0.0 nmol/min/mg protein. He began ERT at 5 weeks of age. At one year of therapy he had normal growth and development. Physical exam was normal except for scaphocephaly. Skeletal survey, head magnetic resonance imaging and echocardiogram were normal. At 20 m/o his weight was 30th centile, length 20th centile and head circumference 50th centile. His physical exam was normal except for mild frontal bossing. Urine GAG went from 214g/mg creatinine to 120.5 without proteinuria. At a year of treatment he had not mounted an antibody response to the enzyme. The cases show: 1) normal cognition even with severe physical disease, 2) efficacy of galsulfase to stabilize the phenotype, and 3) efficacy of galsulfase to prevent physical involvement when started presymptomaticly. It is likely that the younger brother would have had a more involved course if ERT had not been started early. This experience also supports the observation that younger children have a lower risk of anaphylactoid events and may tolerate the enzyme.

Genome wide admixture mapping identifies MYH9 as a major effect risk gene for focal segmental glomerulosclerosis. *C. Winkler[1], M. Smith[1], G. Nelson[1], D. Vlahov[2], B. Freedman[3], D. Vlahov[3], T. Olelsyk[1], J. Kopp[4], NIH Kidney Genetic Study and the Wake Forest ESRD Study* 1) Dept Molec Gen Epidemiology, SAIC, NCI-Frederick, Frederick, MD; 2) New York Academy of Medicine, New York, NY; 3) Section of Nephrology, Wake Forest School of Medicine; 4) Kidney Disease Section, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD.

The increased burden of chronic kidney disease and end stage kidney disease (ESKD) in populations of West African ancestry is only partially explained by socioeconomic status; the genetic basis remains unexplained. African Americans are at a 4-fold and 18-50-fold increased risk for idiopathic focal segmental glomerulosclerosis (FSGS) and HIV-1-associated nephropathies, respectively, compared to European Americans. Approximately 20 percent of ESKD is attributable to FSGS. To identify genetic variants predisposing to idiopathic and HIV-1 associated FSGS, we used a mapping by admixture linkage disequilibrium genome scan on 190 African American FSGS cases and 222 controls that identified a region of chromosome 22 with a significant genome-wide logarithm of the odds (LOD) score of 9.2 and a peak LOD of 13.6 that centers on *MYH9*. *MYH9* is both a positional and functional candidate gene as it is expressed in kidney podocytes, critical cells required for glomerular filtration. Three *MYH9* SNPs ($P=2x10^{-18}$ - $1x10^{-20}$ and OR=4.5 - 4.8, recessive) were most strongly associated with FSGS in African Americans (n=852); the *MYH9* association was confirmed in Europeans (346) for FSGS (OR=9, P=0.02, recessive), for all three SNPs. In an extension study, the same SNPs were also associated with hypertensive ESKD (n=433) (OR=2.2, $P=7x10^{-5}$, recessive for SNP rs4821481), but not with diabetic ESKD (n=476) in African Americans. The increased risk for FSGS and hypertensive ESKD among African Americans is substantially due to one or more *MHY9* genetic risk alleles frequent on African-origin haplotypes (frequency60%) but much less frequent on European-origin haplotypes (4%).

Current depression in LGI1 mutation carriers. *G. Heiman[1], R. Ottman[2]* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) G.H. Sergievsky Center, Columbia Univ, NY, NY.

Depression is the most common comorbid psychiatric condition in individuals with epilepsy, but the cause is unknown. Explanations include an emotional reaction to a physical disorder, effects of seizures on the brain, and a shared genetic susceptibility. We addressed this problem by investigating depression in families with a known genetic cause of epilepsy, i.e., families with autosomal dominant partial epilepsy with auditory features (ADPEAF) with mutations in the leucine-rich, glioma inactivated 1 gene (LGI1). We administered a depression interview to 70 members of 8 families, each of which had a different mutation in LGI1. We classified family members into three groups: mutation carriers with epilepsy (n=25), mutation carriers without epilepsy (n=9), and non-carriers (n=36). Only two subjects, both of whom were mutation carriers with epilepsy (8%), met criteria for current *major depressive disorder*. Nine subjects met criteria for current *other depressive disorder*. The risk for current *other depressive disorder* was increased non-significantly in both mutation carriers with epilepsy (OR=2.10, 95% CI=0.42-10.51) and mutation carriers without epilepsy (OR=3.14, 95% CI=0.37-26.37), compared with non-carriers. Current depression symptom scores were significantly higher in mutation carriers with epilepsy than non-carriers (mean = 5.4 vs. 1.9, p=0.003). However, current depression symptom scores were not higher in mutation carriers without epilepsy than non-carriers (mean = 2.3 vs. 1.9, p=0.71). In this small study, current other depressive disorder (i.e., previous 2 weeks) was elevated in LGI1 mutation carriers both with and without epilepsy whereas current depressive symptoms were only increased in LGI1 mutation carriers with epilepsy. While the results for other depressive disorder are suggestive of a shared genetic susceptibility, analyses of current depressive symptoms suggest that the comorbidity of depression and epilepsy is related to having epilepsy. Future studies, using a larger sample and assessing lifetime rather than current depression, could help to clarify whether or not depression is an alternative manifestation of LGI1 mutations.

Novel Methods for Detecting Associations with Rare Variants for Common Diseases: Application to Analysis of Sequence Data. *B. Li, S. M. Leal* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Although whole genome association studies using tagSNPs are a powerful approach for detecting common variants, they are underpowered to detect associations with rare variants. Recent studies have demonstrated that common diseases can be due to functional variants with a wide spectrum of allele frequencies ranging from rare to common. An effective way to identify rare variants is through direct sequencing. The development of cost-effective sequencing technologies enables association studies to use sequence data from candidate genes and in the future from the entire genome. Although methods used for analysis of common variants are applicable to sequence data, their performance may not be optimal. In this study it is shown analytically that the collapsing method, which involves collapsing genotypes across variants and applying a univariate test, is powerful for analyzing rare variants, while multivariate analysis is robust against inclusion of non-causal variants. Both methods are superior to analyzing each variant individually using univariate tests. In order to unify the advantages of both collapsing and multi-marker tests, we developed the Combined Multivariate and Collapsing (CMC) method and it is demonstrated analytically that the CMC method is both powerful and robust. The CMC method can be applied to either candidate gene or whole genome sequence data.

Identification of Skin Abnormalities in Osteogenesis Imperfecta Patients by Magnetic Resonance ImagingA Pilot Study. *E. M. Carter[1], C. L. Raggio[2], K. W. Fishbein[3], M. Kim[5], N. Pleshko[4], R. G. Spencer[6]* 1) Center for Skeletal Dysplasias, Hospital for Special Surgery, New York City, NY; 2) Pediatric Orthopaedics, Hospital for Special Surgery, New York City, NY; 3) National Institutes on Aging, NIH, Baltimore, MD; 4) Biomechanics, Exponent, Philadelphia, PA; 5) Mineralized Tissue Laboratory, Hospital for Special Surery, New York City, NY; 6) Nuclear Magnetic Resonance Unit, National Institute on Aging, NIH, Baltimore, MD.

Osteogenesis imperfecta (OI) is a genetic disorder characterized by bone fragility and frequent fractures. Diagnosis is based on clinical and radiological criteria and increasingly by genetic test results. We tested the hypothesis that magnetic resonance imaging (MRI) can detect skin abnormalities that correlate with OI genotype and phenotype. Our primary research objectives were to determine: 1. whether MRI can differentiate between skin from OI and control subjects; 2. whether nondestructive MRI analysis is supported by invasive but highly specific Fourier transform infrared spectroscopic imaging (FT-IRIS); and 3. whether there is a relationship between genotype, skeletal phenotype, and skin phenotype across patients of all ages. MRI analysis of 3-mm full-thickness forearm skin biopsies from OI (n=6) and non-OI control (n=2) subjects was performed, followed by FT-IRIS. MRI parameters, including T1, T2, and magnetization transfer (MT), were compared to FT-IRIS parameters characterizing dermal collagen. Initial findings showed clear differences in both MRI and FT-IRIS parameters between patients with OI and controls. Findings within the OI group correlated with the severity of clinical phenotype; epidermal and dermal layers were thinner in OI patients compared to controls with the degree of thinning correlating with the severity of OI phenotype. MRI revealed fat deposits within the dermis of OI skin only. FT-IRIS revealed differences in collagen orientation in the dermis of OI skin compared to controls. We conclude that MRI is sensitive to presence and severity of OI in human skin, as confirmed by FT-IRIS analysis. This supports the potential for developing an MRI approach for rapid non-invasive diagnosis of children with OI.

Treatment and Prevention of SMA through Newborn and Population Carrier Screening. *T. W. Prior[1], R. E. Pyatt[1], D. C. Mihal[1], T. Conlan[1], P. J. Snyder[1], B. Schmalz[1], L. Montgomery[1], K. Ziegler[1], S. Hashimoto[2], S. Garner[2], C. Noonan[2]* 1) Ohio State University; 2) Riverside Methodist Hospital, Columbus, Ohio.

The identification of SMA in newborns will allow these children enrollment into current clinical trials earlier, before irreversible motor neuron death, and allow for an accurate diagnosis, genetic counseling and family planning. A new chemistry for the detection of the common SMN1 deletion from newborn blood spots using a microbead array luminex platform was developed. We have currently completed the screening of 40,130 bloodspots (from the Ohio Department of Health) and 4 homozygous SMN1 deletions have been detected. SMN2 copy numbers were determined and indicated that 2 of the spots had 2 SMN2 (most consistent with type I SMA) and 2 had 3 SMN2 (most consistent with type II or III SMA). Our pilot study has demonstrated that screening for SMA can be technically accomplished on a large-scale newborn population basis. Currently, individuals with a family history of SMA are most often offered carrier testing. However, more broad-based population carrier screening is currently recommended for a number of genetic disorders. The goal of the Claire Altman Heine Foundation SMA population carrier screening pilot program is to identify couples at risk for having a child with SMA, to gain a better estimate of the carrier frequency, to determine the allele frequencies of the two copy SMN1 chromosomes and to study the practical, technical, cost effectiveness, and feasibility of large-scale screening for SMA carrier status. Formal genetic counseling services have been made available to everyone requesting this testing at the Ohio State University and Riverside Methodist Perinatal Centers. 187 individuals have currently been screened and 7 carriers have been identified. Six of the seven carrier spouses were tested and all exhibited noncarrier status. Our survey results indicate that although there is a general lack of familiarity with SMA, there is general interest in carrier screening and therefore population screening may be a means of reducing the prevalence of SMA. The findings of our work have significant implications for risk assessment and genetic counseling of SMA.

Comparison of BAC array-CGH data using formalin-fixed paraffin-embedded versus fresh frozen specimens in multiple myeloma and follow-up FISH. *P. Lennon[1], C. Perez[1], D. Sebastian[1], J. Abraham[1], P. Hu[1], D. Pierson[3], C. Williams[2], X. Zhang[3], P. Lin[3]* 1) Sch Health Sci, UT-MD Anderson Cancer Ctr, Houston, TX 77030; 2) Perkin Elmer BAC Array-CGH Core, UT-MD Anderson Cancer Ctr, Houston TX 77030; 3) Dept Hematopathology, UT-MD Anderson Cancer Ctr, Houston, TX 77030.

Introduction: Multiple Myeloma is an incurable disease involving neoplastic plasma cells, often harboring chromosomal aberrations. Some aberrations are implicated in neoplastic transformation, disease progression, and prognosis. Fresh bone marrow (FT) aspirates are considered most reliable for molecular genetic analysis; however, formalin fixed paraffin-embedded (FFPE) tissues are easily retrievable. Compared to conventional cytogenetics, array-CGH allows more sensitive detection of chromosomal abnormalities. Method: We analyzed seven paired samples of (FT) and (FFPE) bone marrow aspirate samples obtained from MM patients to determine the efficacy of aCGH using FFPE. Results: A total of 34 aberrations were identified of which 29/34 were found in both sample types, yielding 85% concordance. Nonrandom anomalies were observed including 7q+, 15q+, 19p+, 8p-, and 13q- of paired samples of at least 2 cases. We verified these results performing fluorescent in situ hybridization on FFPE and bone marrow smears using Williams probe for 7q+, and a home-brewed overlapping probe created with BACs (RP11-119K8 and RP11-61M22) to target 15q+. In addition, we analyzed FFPE samples of 3 cases of Monoclonal Gammopathy of Undetermined Significance (MGUS) by FISH to determine if 7q+ might be an early, possibly transforming event, and found that 1 of 3 cases did in fact carry 7q+. Conclusions: We conclude that array-CGH analysis can be effective using FFPE samples and is a sensitive method for identification of chromosomal aberrations. The non-random chromosomal anomalies found via array-CGH and validated via FISH are authentic, and some may represent early transforming events that affect disease progression in multiple myeloma. The other non-random changes detected by array-CGH should also be validated via FISH and examined in MGUS patients as well to determine their possible early arrival in this disease process.

Identification of multiple novel prostate cancer predisposition loci. *R. Eeles[1], Z. Kote-Jarai[1], D. Easton[2], J. Stanford[3], E. Ostrander[4], J. Schleutker[5], S. Ingles[6], D. Schaid[7], S. Thibodeau[7], T. Dork[8], D. Neal[9], W. Vogel[10], M. A. Kedda[11], E. John[12], G. Giles[13], W. Foulkes[14], P. Chappuis[15], K. Muir[16, 17], M. Guy[1], A. A genome wide association study in prostate cancer (PC)involving analysis of over 500 000 SNPs in 3748 blood samples from men with prostate cancer has found genetic variants on chromosomes 3, 6, 7, 10, 11, 19 and X are associated with PC risk. Blood DNA from 7370 PC cases and 5742 control men was analysed in a follow up study in 13 groups worldwide (The PRACTICAL Group). The per allele OR was 1.12 to 1.29 and combined risks were consistent with a multiplicative risk model. These and previous loci explain 16 per cent of familial risk of PC, and men in the top 10 per cent of the risk distribution have a 2.1 fold risk relative to general population rates. Genetic profiling of such variants will enable research studies in targeted PC screening.

Clinical spectrum of patients with SOS1 mutations ranges from Noonan syndrome to cardio-facio-cutaneous syndrome. *Y. Narumi[1,2], Y. Aoki[1], T. Niihori[1], M. Sakurai[3], H. Cavé[4], A. Verloes[4], K. Nishio[5], H. Ohashi[6], K. Kurosawa[7], N. Okamoto[8], H. Kawame[9], M. C. Addor[10], C. Vincent-Delorme[11], A. Coeslier-Dieux[12], M. Aoki[13], A. Guliyeva[1], T. Kobayashi[1], S. Noonan syndrome (NS) and cardio-facio-cutaneous (CFC) syndrome are characterized by cardiac defects, facial dysmorphism, ectodermal abnormalities and mental retardation. Mutations in PTPN11 and KRAS have been identified in patients with NS and those in KRAS, BRAF and MAP2K1/2 have been identified in patients with CFC syndrome. Recently, mutations in the son of sevenless gene (SOS1) have been also identified in patients with NS. To clarify the clinical spectrum of patients with SOS1 mutations, we analyzed 24 patients with NS, including three patients in a three-generation family and 30 patients with a CFC phenotype without PTPN11, KRAS, HRAS, BRAF and MAP2K1/2 mutations. We identified two SOS1 mutations in four NS patients, including three patients in the above mentioned three-generation family. In the patients with a CFC phenotype, three mutations, including a novel three amino-acid insertion, were identified in one CFC patient and two patients with both NS and CFC phenotypes. These three patients exhibited ectodermal abnormalities such as curly hair, sparse eyebrows and dry skin, and two of them showed mental retardation. Our results suggest that clinical manifestations in patients with SOS1 mutations range from NS to CFC syndrome.

Genome-wide association study identifies susceptibility loci for biliary atresia. *M. Garcia-Barcelo[1], MY. Yeung[2], C. Tang[2], PC. Sham[2,3], S. Cherny[2,3], PK. Tam[1]* 1) Department of Surgery; 2) Department of Psychiatry; 3) Genome Research Centre of the Li Ka Shing Faculty of Medicine of The University of Hong Kong, Hong Kong, China.

Biliary atresia (BA) is characterized by the progressive fibrosclerosing obliteration of the extrahepatic biliary system during the first weeks of life. The incidence of BA ranges from 1 in 5000 to 1 in 18,000 in different populations, the highest being found in Chinese. Despite early diagnosis and prompt surgical intervention, the disease progresses to cirrhosis in many patients. Reported cases of familial BA, together with immunochemistry and gene expression studies on liver tissues, suggest that the immunogenetic vulnerability of the patients to the precipitating factors is likely to play a role in the susceptibility to develop BA. To find susceptibility loci for BA, we conducted genome-wide SNP association study using Affymetrix SNP arrays assaying approximately 500,000 markers on 150 patients and 351 controls. Genotype calling was done using the Birdseed V2 algorithm, yielding an average call rate of 96%. As a preliminary control for stratification, samples were clustered using Multidimensional Scaling (MDS) and the nearest neighbor analysis implemented in PLINK. Samples with evidence of admixture were consequently excluded. To further ensure the accuracy of the study, samples were subjected to biological relationship and cross-examination verification by using the GRR program. SNPs with minor allele frequency less than 5% and call rate lower than 93% were filtered out to produce a panel of around 290K high quality SNPs for genome wide association tests. After stringent quality control, the association tests were conducted on 142 BA patients and 322 controls. Initial data revealed suggestive susceptibility loci on 10q24.2, 5q31.5, and 12q13.3 chromosomal regions.

microRNA regulation of chemoresistance in NSCLC. *A. Pertsemlidis[1], L. Du[1], R. Greer[1], A. Gazdar[1], S. Hammond[2], M. White[1], J. Minna[1]* 1) The University of Texas Southwestern Medical Center, Dallas, TX; 2) University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, NC.

We are trying to determine whether microRNA expression profiles correlate with chemotherapy sensitivity/resistance in lung cancers, whether microRNAs play a functional role in drug sensitivity/resistance of lung cancer cells and whether microRNA expression levels can be manipulated to increase drug sensitivity in cultured lung cancer cells. We have developed a panel of lung cancer and immortalized normal lung epithelial lines for which we have in vitro sensitivity profiles to drugs commonly used in the treatment of lung cancer which can show variations of >1,000 fold, as well as Affymetrix mRNA expression profiles (providing gene expression signatures for sensitivity/resistance). We profiled miRNA expression in a subset of 20 lung cancer lines, and identified miRNAs that that are differentially expressed between cancer and normal and between drug sensitive and resistant NSCLCs. We have identified several miRNAs with expression profiles that are inversely correlated with response to drug treatment in cultured cells. We have transfected chemoresistant NSCLCs with stabilized mimics of these miRNAs and observed a 200- to 300-fold increase in sensitivity to paclitaxel. We also developed a computational method to predict interactions between miRNAs and mRNAs. Based on this method, we predicted that a number of genes potentially related to drug resistance are regulatory targets of miRNAs, including tubulin- and microtubule-associated protein kinases. Combining the predictions with a high-throughput siRNA screen, we identified 20 candidate regulatory targets of microRNAs relevant to chemosensitivity. Several of these predicted targets have been shown to increase cellular sensitivity to paclitaxel when silenced. These data suggest that miRNAs can be both diagnostic of and modulate the response of lung cancers to chemotherapy.

Pre-implantation Genetic Diagnosis (PGD) vs Pre-implantation Genetic Screening (PGS): *A study to determine the acceptance rate of these procedures after genetic counseling during the years 2004 and 2007.* *J. Santolaya-Forgas, C. Jabbour, S. L. McElhinney, M. Hornstein, L. Wilkins-Haug* Ob & Gyn, Brigham & Women's Hospital, Boston, MA.

Objective: PGD and PGS are offered in various centers across the world. Our aim was to determine the rate of acceptance for PGD and PGS after genetic counseling in our center. **Material and Methods:** Our reproductive genetics counseling database was reviewed to obtain information concerning the acceptance rate for pre-implantation genetic testing between the years 2004 and 2007. Patients were divided in 2 groups based on indication for referral. Patients from the PGD group were referred because one member of the couple was a carrier of a disease causing mutation or chromosomal rearrangement. Patients from the PGS group were referred for aneuploidy screening due to advance maternal age, recurrent miscarriages, unsuccessful IVF cycle, previous pregnancy with chromosomal abnormality, or sex selection. All patients were informed about the benefits, limitations and the increased risks for adverse pregnancy outcome associated with assisted reproductive technologies (ART) and pre-implantation genetic testing. Chi-sq test was used to compare the acceptance rate from the PGD and PGS groups. **Results:** Two hundred and seventy one patients received genetic counseling prior to genetic testing during the study period. Overall, 31.3% (85 out of 271) declined pre-implantation genetic testing. Of the 108 patients from the PGD group, 76 (70.4%) accepted pre-implantation genetic testing. Of the 183 patients from the PGS group, 110 (68%) accepted pre-implantation genetic testing (N.S.). **In conclusion:** Our data suggests that during the study period the acceptance rate for PGD and PGS was similar. Studies are know required to determine the impact of recent reports questioning the utility of PGS to improve the rate of take-home baby. Further studies of this type are also recommended to better understand patient's expectations from pre-implantaion genetic testing.

Ethical Aspects of Rare Diseases in Clinical Trials: Gaucher Disease as a Model. *D. Elstein, A. Zimran* Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Albert Einstein has been quoted (1950) to say Morality is not a fixed and stark system. It is a task never finished, something that is always present to guide our judgment and inspire our conduct. Actually Einstein is describing Ethics: whereas Morality is an immutable standard for behavior, Ethics is a resultant of societal mores that accommodates a range of standards based on extant norms. Society may therefore impose constraints that dictate acceptable practice at the expense of some individuals. Meta-ethics is the resultant of this interactive interplay between the individual and society when both sides of the equation cannot be completely satisfied; when this happens society determines what is normative. Thus, in dealing with patients with rare diseases but expensive therapies, some balance must be achieved that serves societal interests because of the issue of limited financial resources. The rare lysosomal disorder, Gaucher disease, albeit the most prevalent storage disorder, serves as a model for these ethical dilemmas because standard enzyme replacement therapy that is both safe and effective is available, yet national health systems must grapple with the ethical equation of the extraordinary expense of this treatment for a relatively small number of citizens with what in most instances is not life-threatening disorder. Recently, new modalities such as substrate reduction therapy, pharmacological chaperones, as well as biosimilar enzyme products, have entered into clinical trials raising new ethical issues such as enrollment in trials when standard therapy is excellent, placebo arms, early-access to investigational drugs, and the critical issues of transparency of data reporting and full disclosure by investigators regarding funding. Finally, one ramification of these ethical concerns is that comparable therapies are being brought to trial for even more rare diseases and for some of these, the clinical efficacy is not as acceptable as for Gaucher disease despite the equally extraordinary cost.

Prevalence of the *MTHFR* C677T polymorphism in patients of Middle Eastern descent. *A. Haghighatgoo[1], Y. Valles-Ayoub[1], C. Saechao[1], S. Esfandiarifard[1], S. Martinez[1], M. Pietruszka[1], D. Darvish[1,2]* 1) HIBM Research Group, Encino, CA; 2) VA Greater Los Angeles (VA-GLA/UCLA), Los Angeles, CA.

The methylenetetrahydrofolate reductase gene (*MTHFR*) 677 C>T polymorphism produces an elevation in plasma homocysteine concentrations. Increased homocysteine levels have been associated with a greater risk for vascular diseases, including cardiovascular disease and ischemic stroke. In this study, we randomly selected and genotyped nucleic acid samples for the C677T allele from our database of Middle Eastern patients, namely Iranian Jews. Results show 52% of patients to be wild-type, 35% to be heterozygous, and 13% to be homozygous for the C677T mutation. This data suggests that the prevalence of the C677T allele in Iranian Jews is slightly higher than what has been reported in populations from varying regions in Iran.

Validation studies on a multiplex quantitative PCR assay for large rearrangements in the *MLH1* and *MSH2* genes for HNPCC. *B. Roa[1], T. Judkins[1], B. Hendrickson[2], K. Bowles[1], K. Eliason[1], J. Schoenberger[1], S. Rajamani[1], J. Trost[1], S. Chen[1], M. Frost[1], G. Rao[1], T. Scholl[2], C. Colvin[1]* 1) Myriad Genetic Laboratories, Inc., Salt Lake City, UT; 2) Genzyme Corporation, Cambridge, MA.

Hereditary non-polyposis colon cancer (HNPCC) is caused by germline mutations in the mismatch repair genes *MLH1*, *MSH2*, *MSH6* and *PMS2*. Approximately 90% of cases are reportedly due to mutations in *MLH1* and *MSH2*, 7-10% to *MSH6*, and <5% to *PMS2*. Clinical testing in our laboratory has shown that 45% of Lynch mutations are due to *MLH1*, 41% from *MSH2*, and 14% from *MSH6*. Mutations in these genes result in an ~80% increased risk of colon cancer and a higher risk for a variety of other cancers. Approximately 5% and 20% of mutations in *MLH1* and *MSH2*, respectively, are large rearrangements that can not be detected by sequencing and require other methods of detection like Southern blot or multiplex ligation-dependent probe amplification (MLPA). We developed and validated the COLARIS Rearrangement Test (CART), that uses quantitative multiplex endpoint PCR analysis and confirmatory testing to detect rearrangements in *MLH1* and *MSH2*. CART uses less DNA and significantly decreases the turnaround time, as compared to Southern blots, while still providing consistent, accurate results. CART consists of 11 multiplexes of 6-12 amplicons each and targets each exon, promoter, and 3UTR of both genes with at least 2 amplicons. Proprietary software normalizes copy numbers for *MLH1* against *MSH2*, and two unlinked control genes. Statistical confidence values are calculated for the presence or absence of duplications or deletions. During a two-phase validation, CART was performed on 130 positive and 541 negative DNA samples in a blinded manner. CART was successful in producing results that were concordant with previous data from routine Southern blots and confirmatory testing. CART will be performed on all patients referred to our laboratory for comprehensive HNPCC testing, along with sequencing of *MLH1* and *MSH2* and/or *MSH6*. The CART assay will facilitate molecular diagnostic testing and will greatly benefit individuals at risk for HNPCC.

Reasons for GJB2/GJB6 testing vary by cultural affiliation: Preliminary data from a collaborative research project on the impact of genetic information on deaf individuals. *C. Palmer[1], P. Boudreault[2], E. Baldwin[1], A. Martinez[1], M. Fox[1], J. Linden[2], R. Trank[1], L. Dutton[1], L. Tullis[1], D. Kovacs[2], L. Perez[2], Y. Kobayashi[2], J. Sinsheimer[1], Y. Sininger[1], W. Grody[1]* 1) UCLA, CA; 2) California State University, Northridge, CA.

Genetic testing for deafness (GTD) is a reality; however, deafness is viewed as a linguistic and cultural trait by many individuals rather than a medical condition. Empirical studies are needed to grasp the ramifications of genetic counseling and testing for deafness. Here we describe a collaborative research model and preliminary data assessing impact of GJB2/GJB6 testing and counseling on deaf adults and the Deaf community using a prospective, longitudinal design. The collaborative model was designed by a hearing, deaf, and hard of hearing research team from diverse disciplines. To include a broad segment of the deaf population, various communication technologies are used and sign language interpreters are provided. Questionnaires (English, Spanish, ASL) assess deaf identity, attitudes, beliefs, testing motivations, knowledge, behaviors, and psychosocial outcomes at four stages. Preliminary data on motivations for GTD at baseline on the first 92 subjects are described. Subjects are 60% female, 86% Caucasian, average age 43y, and 41% ASL-users. Subjects vary in cultural affiliation, with 46%, 15%, 37%, 1% identifying with the Deaf, Hearing, Both, or Neither community, resp. On average, subjects most strongly agreed that learning the cause of deafness and helping research were reasons for GTD, and were neutral or disagreed that GTD would be used to choose a mate. Reasons regarding self, children, family, and deaf community varied by cultural affiliation. These are the first prospectively collected empirical data to examine the relationship between cultural affiliation and GTD. Findings suggest that there is great interest in GTD and cultural factors play a significant role in why deaf adults seek GTD. The results of this culturally sensitive collaborative project provide broader insight into the views of individuals targeted for GTD, and are relevant for deaf individuals, Deaf communities, and genetics services.

A Morpho-Etiological Desription of Congenital Limb Anomalies. *S. M. Tayel[1], F. M. Al Kandary[2], N. A. Al Naqeeb[3], S. Gouda[4], S. A. Al Awadi[4], K. K. Naguib[4]* 1) Anatomy Dept, Genetics Unit, Alexandria Faculty of Medicine, University of Alexandria, Alexandria, Egypt; 2) Faculty of Allied Health Sciences, Kuwait; 3) Neonatology Dep., Adan Hospital, Kuwait; 4) Kuwait Medical Genetics Centre, Maternity Hospital, Kuwait.

BACKGROUND: Limb anomalies rank behind congenital heart disease as the most common birth defects observed in infants. More than 50 classifications for limb anomalies based on morphology and osseous anatomy have been drafted over the past 150 years. The present work aims to provide a concise summary of the most common congenital limb anomalies on a morpho-etiological basis. PATIENTS AND METHODS: In a retrospective study, 70 newborns with anomalies of the upper and/or lower limbs were ascertained through clinical examination, chromosomal analysis, skeletal surveys and other relevant investigations. RESULTS: Fetal causes of limb anomalies represented 55.8% of the cases in the form of 9 cases (12.9%) with chromosomal aberrations (trisomy 13, 18 and 21, duplication 13q and deletion 22q) and 30 cases (42.9%) with single gene disorders. An environmental etiology for limb anomalies was diagnosed in 11 cases (15.7%) as amniotic band disrup¬tion, monozygotic twin with abnormal circulation, vascular disruption (Poland sequence, sirenomelia and general vascular disruption) and an infant with a diabetic mother, Twenty cases (28.5%) had limb anomalies as part of sporadic syndromes of unknown etiology. CONCLUSIONS: The morpho-etiological work-up of limb anomalies adopted in the present study is valuable for detecting the cause of the anomaly and is crucial for its prevention. Prevention can be achieved by proper genetic counseling, which includes recurrence risk estimation and prenatal diagnosis.

Functional analysis of a human *ATPAF2* gene mutation in yeast S.cerevisiae. *S. Seneca[1], A. Meulemans[2], J. Smet[3], R. Van Coster[3], W. Lissens[1], L. De Meirleir[4], I. Liebaers[1], S. Ackerman[5]* 1) Center for Medical Genetics, UZ Brussel, Brussels, Belgium; 2) Laboratory of Pediatrics, ULB, Brussels, Belgium; 3) Department of Pediatrics and Metabolism, UGent, Ghent, Belgium; 4) Department of Pediatric Neurology, UZ Brussel, Brussels, Belgium; 5) Department of Surgery, Biochemistry and Molecular Biology, Wayne State University School of Medicine, Detroit, Michigan, USA.

Aims : Mitochondrial ATP synthase or complex V couples the proton gradient, generated by the respiratory chain, to ATP synthesis. Assembly of this enzyme requires the activities of several accessory proteins. Here, we report on the functional effect of a p.W94R mutation, present in the ATPAF2 gene of an infant with a complex V decreased activity. The ATPAF2 gene is the human (Hu) orthologue of the yeast (y) ATP12 gene. Methods : Multi and single copy plasmid constructs containing the wild type ATPAF2 or ATP12 gene, as well as the Hu mutant p.W94R or the y mutant counterpart p.W103R were generated. These constructs were introduced in an ATP12 respiratory deficient yeast strain. ATP synthase activity of individual yeast transformants was assayed by growth studies on a non-fermentable carbon source and by Blue Native Polyacrylamide Gel Electrophoresis (BN-PAGE) stained for ATP synthase catalytic activity. Plasmid constructs carrying a wt ATP12 or ATPAF2 gene rescue the respiratory defect of a y atp12 mutant strain. Results : Growth on a non-fermentable carbon source was strongly impaired for the Hu W94R mutant, while the growth of the y W103R mutant strain was normal. These results were confirmed by BN-PAGE studies and measurements of the enzymatic complex V activity of the plasmid constructs in yeast cells. Conclusions : Our yeast complementation studies showed clearly that the p.W94R mutant of the huATPAF2p does not confer respiratory competence to an atp12 yeast strain and is most probably the cause of the complex V dysfunction and early death of a 14 months-old patient. In additional studies with atp12fmc1 double mutants, and at 37C, the altered yeast protein was no longer able to rescue the respiratory deficient phenotype of the S.cerevisiae host strain.

Whom Recommended For Screening of The BRCA1 and BRCA2 Mutations? *R. Habibi* Genetics, Royan , Tehran, Tehran, Iran.

Background Only small proportion of breast cancer cases to be due to an inherited predisposition .This condition is increased if there are any susceptibility such as positive family history ,early onset ,involvement before menopause ,bilateral breast cancer and male breast cancer .In this situation , screening for germline mutation in BRCA1 or BRCA2 is important for genetic counseling and cancer risk management . Materials & Methods We studied 104 breast cancer females who were between 25 and 80 years old . Results We found a female case of invasive carcinoma who had 37-year-old ,and positive family history with paternal and maternal involvement .She had involvement in right breast that negative for malignancy and also invasive carcinoma in left breast . Conclusion If the parent /parents are carrier of the mutation , the outcome for the offspring in the generation and family member could be diagnosed and provided the preventive genetic test of the defective gene in the healthy and affected family members . Key words :hereditary ,breast , cancer ,BRCA1 ,BRCA2 ,mutation ,Iranian.

Polymorphisms in immune response and inflammation genes are associated with chronic kidney disease in the U.S. population: data from NHANES III. *R. M. Ned[1,2], A. Yesupriya[1,2], G. Imperatore[3], D. T. Smelser[2,4], R. Moonesinghe[2], M. Chang[2], N. F. Dowling[2], CDC/NCI NHANES III Genomics Working Group* 1) McKing Consulting Corporation; 2) National Office of Public Health Genomics, Centers for Disease Control and Prevention (CDC), Atlanta, GA; 3) National Center for Chronic Disease Prevention and Health Promotion, CDC, Atlanta, GA; 4) ASHG Fellow.

Patients with chronic kidney disease manifest a higher inflammatory state relative to healthy individuals, and therefore, genetic variation in cytokines and other molecules that mediate inflammation or the immune response may play an important role in the pathogenesis of the disease. We studied 34 polymorphisms in 14 genes (*CCR2*, *CRP*, *FCGR2A*, *IL10*, *IL1B*, *IL4*, *IL4R*, *MBL2*, *B9D2/TGFB1*, *NOS2A*, *PPARG*, *TLR4*, *TNF*, and *VDR*) in DNA samples collected from participants in the second phase (1991-1994) of the Third National Health and Nutrition Examination Survey (NHANES III), a population-based, nationally-representative survey of the civilian, non-institutionalized population of the United States. Chronic kidney disease was evaluated in 5,446 participants aged 20 years or older from the three main race/ethnic groups in the U.S. (non-Hispanic white, non-Hispanic black, and Mexican-American). Additive and co-dominant genetic models were tested in both crude and age-sex adjusted analyses. The estimated prevalence of chronic kidney disease was 12.5% in the adult U.S. population, with differences by gender, age, and race/ethnic group. For non-Hispanic whites, variants in *IL10*, *MBL2*, *TLR4*, *TNF*, and *VDR* were associated with chronic kidney disease ($p < 0.05$), as were *CRP*, *MBL2*, *B9D2/TGFB1*, and *VDR* polymorphisms in non-Hispanic blacks and *FCGR2A*, *IL1B*, *B9D2/TGFB1*, and *TNF* variants in Mexican-Americans. This work is the first to investigate the association of genetic polymorphisms with kidney function or chronic kidney disease in a nationally representative sample of the U.S. population.

Evidence for a rheumatoid arthritis protective variant independent of R620W within the PTPN22 locus. *W. R. Wan Taib[1], C. McKinney[1], J. Highton[2], N. Dalbeth[3], L. Stamp[4], P. J. Gow[5], P. B. B. Jones[3], A. A. Harrison[6], S. Steer[7], T. R. Merriman[1]* 1) Department of Biochemistry, University of Otago, Dunedin, New Zealand; 2) Department of Medicine, University of Otago, Dunedin, New Zealand; 3) Department of Medicine, University of Auckland, Auckland, New Zealand; 4) Department of Medicine, University of Otago, Christchurch, New Zealand; 5) Department of Rheumatology, Middlemore Hospital, Auckland, New Zealand; 6) Department of Medicine, University of Otago, Wellington, New Zealand; 7) Department of Rheumatology, Kings College London School of Medicine at Guy's , King's and St. Thomas', London, UK.

Rheumatoid arthritis (RA) is a complex autoimmune disease with a strong genetic contribution to its pathogenesis. The first non-Major Histocompatibility Complex (MHC) gene discovered to be reproducibly associated with RA is the protein tyrosine phosphatase non-receptor 22 (PTPN22) gene in the Caucasian population. The PTPN22 functional variant, R620W, has been associated with RA in many studies in different populations. Carlton et al (Carlton et al, AJHG 77: 567-581, 2005) successfully identified and defined Haplotype 2 that was tagged by R620W and conferred susceptibility effect, whilst haplotypes 5 and 6 conferred protection to RA. We further analysed the two protective haplotypes using three Caucasian case-control cohorts; New Zealand, Wellcome Trust Case Control Consortium (WTCCC) and UK (London). We replicated association with RA using rs3789607 that tags haplotype 5 in 2,717 RA cases and 3,665 controls (OR=0.89, P=0.009). Using rs12144309, which tags haplotype group 6-10 we also replicated this protective effect (OR=0.88, P=0.004) . Within the PTPN22 haplotype block, haplotype 5 and 6-10 coalesced with the major allele of a group of markers within the neighbouring Bfk (B-cell lymphoma 2 family kin) gene. We tested one of the markers, rs12566340, in the New Zealand and WTCCC cohorts for association with RA conditional on rs2476601 (R620W) yielding P=0.13 and P=0.03, respectively. These data provide evidence for a RA protective effect at PTPN22 independent of R620W, mapping outside of PTPN22.

A Systematic Prenatal Diagnosis of a Small Supernumerary Marker Chromosome. *D. Cha[1,2], S. Shim[2], S. Bai[2]* 1) Dept OB/GYN, Kangnam CHA Hosp, Seoul, Korea; 2) Genetic Laboratory, Fertility Center of CHA General Hospital, Pochon CHA University.

A 37-year-old female referred for prenatal chromosome analysis. In previous study of the fetus in other institute, the fetal karyotype was 46,XY,+mar. The marker chromosome was revealed as a de novo from chromosome analyses of parental blood samples. To identify the origin of the marker chromosome, array-CGH was carried out but no informative results were obtained. We re-established the amniotic fluid culture for fetal chromosome analysis. The marker chromosome was a typical small supernumerary marker chromosome apparently originating from an acrocentric chromosome. NOR-staining and FISH analyses with CEP15 and CEP13/21 probes showed the marker chromosome was a biosatellite (NOR-positive in both arms) and CEP 13/21 positive. With careful ultrasound examination, we concluded that the marker chromosome was originated from an inverted duplication of the short arm of chromosome 13 or 21 and the fetal risk with abnormal phenotype was as low as background risk. In this report, we would like to suggest a systematic flow for identification of marker chromosome.

Allele-specific expression due to mutations in the chromatin-associated factor ATRX. *R. J. Gibbons[1], K. M. Lower[1], M. J. Law[1], V. Viprakasit[2], I. Ragoussis[3], A. Morris[3], J. Cross[1], H. Ayyub[1], D. R. Higgs[1]* 1) MRC Molecular Hematology Unit, John Radcliffe Hosp, WIMM, Oxford, OX3 9DS, UK; 2) Division of Medical Genetics and Molecular Medicine, Department of Medicine, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 3) The Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, OX3 7BN, UK.

Genetically determined patterns of gene expression underlie much of the phenotypic variation found in both normal individuals and those with inherited and acquired diseases. Whole genome association studies have shown that levels of expression for many genes are associated with polymorphic *cis* and *trans* acting elements called expression quantitative trait loci (eQTLs) although the identities of the true regulatory polymorphisms are largely unknown. As might be expected *cis* eQTLs are associated with unequal allelic expression. The X linked gene *ATRX* encodes a SWI/SNF-like chromatin associated factor and transacting mutations give rise to ATR-X syndrome. The condition is associated with variable levels of thalassemia due to downregulation of globin gene expression. The severity of thalassemia may be treated as a quantitative trait.

Here we show that mutations in ATRX (acting as a *trans* eQTL) may downregulate globin and a closely linked, newly identified, target gene (called *NME4*) in an allele-specific manner, producing allele-specific differences in gene expression. Often but not invariably, the downregulation is associated with CpG island methylation. In each case there is compelling evidence that the associated *cis* eQTLs are G-rich variable number tandem repeats (VNTRs). Not only are these VNTRs the sites of peak ATRX binding but in cases which are heterozygous for the VNTR, the larger allele of the VNTR at *NME4* is always preferentially downregulated and methylated (n=55). These observations demonstrate that, contrary to expectations, *trans* eQTLs may be restricted by the regulatory haplotypes containing their target genes. This adds important new insights to the nature of interactions between *trans* and *cis* eQTLs, the phenotypic variability to which these give rise and the function of the ATRX protein.

Confounded by association: A general principle for the identification of causal genetic effects in association studies. *C. Lange* Dept Biostatistics, Harvard Sch Public Health, Boston, MA.

In genetic association studies, different complex phenotypes are often associated with the same marker. Such associations can be indicative of common genetic causes, of indirect genetic effects via one of these phenotypes, or can be solely attributable to non-genetic/environmental links between the traits. In the analysis, the multiple associations disguise the causative genetic effect and aggravate its identification. To identify the phenotypes with the inducing genetic association, statistical methodology is needed to distinguish between the different origins of the associations. We propose a simple, general adjustment principle that can be incorporated into virtually all standard genetic association tests which are then able to infer whether a SNP has a direct biological influence on a given trait other than through the SNPs influence on another correlated phenotype. The proposed adjustment is straightforward to compute and is robust against population admixture. It is particularly relevant for genome-wide association studies, pathway analysis, and association studies with an integrative genomic component. Using simulation studies, we show that, in the presence of a non-marker related link between phenotypes, standard association tests without the proposed adjustment can be biased. In contrast to that, the proposed methodology remains unbiased and has sufficient power to infer causal genetic effects for realistic sample sizes. Its achieved power levels are identical to those of standard methodology, making the adjustment principle universally applicable in genetic association studies. The principle is illustrated by an application to three genome-wide association studies.

A novel multi-loci Bayesian approach to genome-wide association studies with family-based designs. *M. Naylor, C. Paciorek, C. Lange* Dept of Biostatistics, Harvard University, Boston, MA.

For genome-wide association studies with family-based designs, we propose a multi-loci Bayesian approach. We show that standard TDT/FBAT statistics can naturally be implemented in a Bayesian framework and that informative priors can be constructed for each marker based on the actual data. In contrast to Bayesian approaches that have recently been proposed for genome-wide association studies, our approach does not require prior assumptions about the genetic effect size; this makes the proposed method entirely data-driven. For the construction of the priors, the evidence for association for a single marker is obtained at the population-level by estimating the posterior distribution of the genetic effect sizes in the conditional mean model. Since such genetic effect size estimates are statistically independent of the effect size estimation within the families, the actual data set can inform the construction of the priors without any statistical penalty. The power of the approach is assessed through simulation studies.

IL23R in the Swedish, Finnish, Hungarian and Italian populations: Association with inflammatory bowel disease and psoriasis, and linkage to celiac disease. *E. Einarsdottir[1], L. L. E. Koskinen[1], E. Dukes[1], K. Kainu[2], F. Ziberna[3], I. R. Korponay-Szabo[4], K. Kurppa[5], K. Kaukinen[5], R. Ádány[4], T. Not[3], A. Ventura[3], R. Löfberg[6], L. Torkvist[6], F. Bresso[6], J. Halfvarson[7], M. Mäki[5], U. Saarialho-Kere[2], J. Kere[1,6], M. DAmato[6], P. Saavalainen[1]* 1) University of Helsinki, Helsinki, Finland; 2) Helsinki University Hospital, Helsinki, Finland; 3) University of Trieste, Trieste, Italy; 4) University of Debrecen, Debrecen, Hungary; 5) Tampere University Hospital, Tampere, Finland; 6) Karolinska Institutet, Huddinge, Sweden; 7) Örebro University Hospital, Örebro, Sweden.

Background: The recently reported association of interleukin 23 receptor (IL23R) with inflammatory bowel disease (IBD) has been confirmed in several populations. The IL23R gene also associates with psoriasis and ankylosing spondylitis, making it an interesting candidate for many immunological diseases. **Materials and methods:** We studied association of single-nucleotide variants in IL23R with IBD in Swedish patients with Crohns disease (CD) and ulcerative colitis (UC), the two major forms of IBD. The same variants were studied in Finnish psoriasis patients and in Finnish, Hungarian and Italian patients with celiac disease. In total, 2924 cases and 1030 controls were studied. **Results:** We replicated the association of IL23R with IBD in Swedish IBD patients, and found linkage and association of IL23R with psoriasis in the Finnish population. IL23R was linked to celiac disease in Finnish, but not Hungarian families. No significant association was seen with IL23R in the celiac datasets. Western blot analysis suggests that the genetic variants analyzed in this study do not directly affect levels of IL23R protein. **Conclusions:** Our study further supports the involvement of IL23R in IBD in Swedish patients, and the linkage and association of IL23R with psoriasis in the Finnish population. We also found linkage of IL23R to celiac disease in the Finnish population, and postulate that other variants in IL23R or in a nearby gene may be associated with celiac disease.

Association study of *IL18RAP* in three European populations with celiac disease. *L. L. E. Koskinen[1], E. Einarsdottir[1], E. Dukes[1], G. A. R. Heap[2], P. Dubois[2], I. R. Korponay-Szabo[3,4], K. Kaukinen[5], K. Kurppa[5], F. Ziberna[6], S. Vatta[6], T. Not[6], A. Ventura[6], R. Ádány[4], Z. Pocsai[4], G. Széles[4], M. Mäki[5], J. Kere[1,7], C. Wijmenga[8], D. A. van Heel[2], P. Saavalainen[1]* 1) University of Helsinki, Helsinki, Finland; 2) Queen Mary University of London, London, UK; 3) Heim Pal Childrens Hospital, Budapest, Hungary; 4) University of Debrecen, Debrecen, Hungary; 5) University of Tampere and Tampere University Hospital, Tampere, Finland; 6) University of Trieste, Trieste, Italy; 7) Karolinska Institutet, Huddinge, Sweden; 8) University Medical Center Groningen and University of Groningen, Groningen, Netherlands.

Background: Celiac disease is caused by dietary gluten, which triggers chronic inflammation of the small intestine in genetically predisposed individuals. Recently, a novel risk locus on chromosome 2q11-q12, harboring *IL18RAP*, was identified for celiac disease. IL18 has been shown to play an important role in Th1 activity in celiac disease, making IL18RAP a highly interesting candidate gene.

Materials and methods: In this study, two previously indicated risk variants at the *IL18RAP* locus were tested for association in 1210 cases with celiac disease and 1033 controls from the Finnish, Hungarian, and Italian populations. The protein expression of IL18RAP was compared between risk allele carriers and non-carriers.

Results and conclusions: We confirmed genetic association, and in addition found a dose effect of *IL18RAP* genotypes with celiac disease in the Hungarian population. The GA haplotype of the two markers showed the strongest association (P=0.0001, OR=1.5) in the Hungarian, as well as in the combined material (P=0.0002, OR=1.3). Putative isoforms of IL18RAP were detected and cells with risk background showed higher levels of protein expression than cells with protective background. Our study supports IL18RAP as a novel predisposing gene for celiac disease and highlights the need for further functional studies on this relatively unknown gene in celiac disease pathogenesis.

Matrilin-3 - an essential protein in the normal development of cartilage and bones. Progress in structure determination. *V. Adir[1], A. Shahar[2], N. Adir[2], Z. U. Borochowitz[1]* 1) The Simon Winter Institute for Human Genetics, Bnai-Zion Medical Center, Rappaport Faculty of Medicine,Technion, Haifa, Israel; 2) Schulich Faculty of Chemistry, Technion, Haifa, Israel.

Matrilin-3 (MATN3) belongs to the matrilin family of extracellular matrix proteins and is primarily expressed in cartilage. Mutations in the gene encoding human MATN3 lead to skeletal disorders, such as Spondylo-Epi-Metaphyseal dysplasias (SMED). A novel form of SMED that was report by us, is caused by a homozygote substitution 973TA in the MATN3 gene. The defect is characterized by short stature and early-onset osteoarthritis. The majority of disease-causing mutations are located within the predicted -sheet of the single von Willebrand Factor A (vWFA) domain of MATN3, suggesting that they disrupt the structure and/or function of this important domain. Structural insights into this protein family's function have not yet been achieved. In order to obtain such insights, the gene encoding for the MATN3 from Mus musculus was cloned and overexpressed in E.coli. In addition, the vWFA domain was also cloned into an expression vector. In both cases the protein was expressed as insoluble inclusion bodies which were recovered by the use of 1% SDS and urea. We are currently working on modifications of the purification process of the MATN3 protein and the vWFA domain in order to obtain large amounts of pure and soluble protein. This will then be used for crystallization and structure determination.

Association in the 15q13-14 Schizophrenia Linkage Region. *S. H. Stephens[1], A. L. Franks[2], R. Berger[2], S. Leonard[2]*
1) Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 2) Dept of Psychiatry, University of Colorado Health Sciences Center, Aurora, CO.

Schizophrenia has been linked to the 15q13-14 locus in multiple independent studies and across ethnicities. The 7 neuronal nicotinic acetylcholine receptor subunit gene (*CHRNA7*) maps to this chromosomal region and was selected as the best candidate gene for an endophenotype of schizophrenia, the P50 sensory processing deficit, based on genetic linkage to the locus and human and animal studies. Mutation screening of *CHRNA7* gene identified functional polymorphisms in the upstream regulatory region. However, the mutations isolated thus far do not account for linkage to the 15q13-14 locus. The current study addresses this issue by fine mapping genes in the 15q13-14 linkage peak region to determine if genetic variance in the *CHRNA7* gene accounts for the linkage to schizophrenia. Family-based and case-control association was performed on samples from 120 families as well as 468 schizophrenic patients and 144 controls. 1217 Single Nucleotide Polymorphism (SNP) markers and three informative microsatellite markers were utilized. Association with the outcomes of schizophrenia, smoking, smoking in schizophrenia, and the P50 deficit in controls were performed. Three genes were associated with schizophrenia in both ethnic populations, after correction for multiple testing: *TRPM1*, *KLF13*, and *RYR3*. One SNP in *CHRNA7* (rs8028396) was significant for an association with smoking and smoking in schizophrenia in Caucasians. A SNP in *RYR3* (rs8035184) was associated with smoking in African-Americans. Association studies with the P50 deficit in controls found significant P-values for SNPs in genes *CHRNA7*, *RYR3*, *SGNE1*, and *AVEN*. These studies continue to support *CHRNA7* as a candidate gene for schizophrenia and introduce three new genes in the 15q13-14 linkage region as additional candidate genes for the disorder.

Nav1.7 channel mutations cause two different clinical phenotypes. *T. Fischer[1,2,3], E. Gilmore[1,2,3], M. Estacion[1,2,3], B. W. Jarecki[4], L. Tyrrell[1,2,3], S. Taylor[5], M. Melanson[5], M. Lawden[4], T. R. Cummins[6], S. D. Dib-Hajj[1,2,3], S. G. Waxman[1,2,3]* 1) Dept Neurology, Yale Univ, New Haven, CT; 2) Center for Neuroscience & Regeneration Research, Yale Univ, New Haven, CT; 3) Rehabilitation Research Center, VA CT Healthcare System, West Haven, CT; 4) Dept Neurology, Leicester General Hospital, Leicester UK; 5) Dept Neurology, Kingston General Hospital, Ontario, Canada; 6) Dept Pharmacology & Toxicology, Stark Neurosciences Institute, Indiana Univ School of Medicine, Indianapolis, IN.

Human and animal studies have shown that the Nav1.7 sodium channels play a major role in inflammatory and neuropathic pain. Early-onset inherited erythromelalgia (IEM) is the first known human pain syndrome to be examined at a molecular level, and has been linked to gain-of-function mutations in the Nav1.7 sodium channel. A different set of mutations in Nav1.7 underlie another Nav1.7-related painful neuropathy, paroxysmal extreme pain disorder (PEPD). In contrast to IEM, PEPD has been effectively treated with the sodium channel blocker carbamazepine. We now report a novel mutation (V400M) in a three-generation Canadian family with early-onset IEM located within domain I/S6 in Nav1.7. Interestingly, the pain symptoms in these patients respond favorably to treatment with carbamazepine. Furthermore, we have identified a mutation (M1627K) in a two-generation English family with PEPD located within domain IV/S4-5. The proband and her sister from this family also respond favorably to treatment with carbamazepine. The biophysical properties of the mutant channels were evaluated using whole-cell patch clamp studies in stably-transfected HEK293 cells. Boltzman fits of activation and fast-inactivation curves show a hyperpolarizing shift in activation and a depolarizing shift in fast-inactivation for V400M channels as compared to wild-type channels. Electrophysiologic studies on cells containing the M1627K mutation show a shift in voltage-dependence of fast-inactivation and inactivation from the open state with slower kinetics. Using current-clamp methodology, both mutations have been shown to render DRG neurons hyperexcitable, yet they underlie different clinical phenotypes.

Autism and Cognitive-Behavioral Features Of Children With Subtelomeric Deletions. *G. Fisch[1], J. Carey[2], J. Youngblom[3], R. Simensen[4], A. Battaglia[5]* 1) NYU, New York, NY; 2) University of Utah, Salt Lake City, UT; 3) California State University, Turlock, CA; 4) Greenwood Genetics Center, Greenwood, SC; 5) University of Pisa, Pisa, Italy.

Cognitive-behavioral features of children with subtelomeric deletions have not been systematically evaluated. The aim of our study was to assess cognitive-behavioral features of children with 4 different subtelomeric deletions, using a comprehensive neuropsychological battery. Our assessment battery consisted of 5 standardized measures of cognitive ability, adaptive behavior, emotionality and temperament, attentiveness/ hyperactivity, and autism. We examined 29 children, ages 4-17 years, with del2q37 [n=7], del8p23 [n=7], del11q25 n=3], or 4p16 [n=12], from 9 sites in the US and Europe. We found 10/29 (34%) of our sample who had CARS scores 30. That is, more than a third of the sample could be diagnosed as autistic. In addition, each disorder was associated with a distinct cognitive-behavioral profile. Children with de11q25 had significantly higher cognitive abilities, while those with del4p16 were significantly lower. Adaptive behavior was significantly higher among children with 11q25. Cognitive ability and adaptive behavior profiles were also statistically significantly different among the groups. Attention deficits and hyperactivity were also noted in 18/29 [62%] of children assessed.

HRAS mutations and 11p allelic imbalance in a rare case of agminated Spitz nevus in a giant nevus spilus. *K. Sol-Church[1], D. L. Stabley[1], S. Catalano[1], J. Holbrook[1], J. B. Lee[2], K. Conard[3], P. Hyde[2], D. Shurman[2]* 1) Dept Biomedical Research, Alfred I duPont Hosp Children, Wilmington, DE; 2) Department of Dermatology and Dermatopathology, Thomas Jefferson University, Philadelphia, PA; 3) Dept Pathology, Alfred I duPont Hosp Children, Wilmington, DE.

Background: Differentiating a Spitz nevus from a Spitzoid melanoma is often a challenging task faced by dermatopathologists. While the dysplastic nevus theory supports the notion that a Spitz nevus can progress to a melanoma, there is molecular evidence that refutes this possibility. Namely, Spitz nevi can carry unique mutations found in the mitogen-activated protein kinase pathway that are not found in melanomas. Thus it would be extremely unlikely that a Spitz nevus could lose a unique mutation to transform into melanoma. **Methods**: In this report, the cytogenetics and detailed molecular analysis was performed on a rare and fascinating case of agminated Spitz nevus in a giant nevus spilus. We used DNA sequencing as well as STR-PCR and real time PCR for genotyping and copy number evaluation. **Findings**: The analysis revealed two *HRAS* mutations located on the maternally inherited allele. The *HRAS* mutations observed in the patients Spitz nevi, result in A11S and G13R amino acid substitutions in the ras protein. *HRAS* copy number increase, as well as allelic imbalance at 11p with gain of the maternal allele, was also observed in tissue containing the mutated gene. **Interpretations**: Differential gene dosage effect of important imprinted genes located on the short arm of chromosome 11 may counteract the effects of *HRAS* activation in Spitz nevi, and prevent malignant transformation and may explain why no case of conversion of multiple Spitz nevi to malignant melanoma has ever been reported.

***De novo* mutations in the gene encoding STXBP1 (MUNC18-1) cause early infantile epileptic encephalopathy with suppression-burst.** *H. Saitsu[1], M. Kato[2], T. Mizuguchi[1], K. Hamada[3], H. Osaka[4], J. Tohyama[5], K. Uruno[6], S. Kumada[7], K. Nishiyama[1], A. Nishimura[1], I. Okada[1], Y. Yoshimura[1], S. Hirai[8], T. Kumada[9], K. Hayasaka[2], A. Fukuda[9], K. Ogata[3], N. Matsumoto[1]* 1) Dept Human Gen, Grad Sch Med, Yokohama City Univ, Yokohama, Japan; 2) Dept Pediatrics, Yamagata Univ Sch Medicine, Yamagata, Japan; 3) Dept Biochemistry, Grad Sch Med, Yokohama City Univ, Yokohama, Japan; 4) Division of Neurology, Clin Res Ins, Kanagawa Children's Medical Center, Yokohama, Japan; 5) Dept Pediatrics, Epilepsy Center, Nishi-Niigata Chuo National Hospital, Niigata, Japan; 6) Epilepsy Center, Yamagata National Hospital, Yamagata, Japan; 7) Dept Neuropediatrics, Tokyo Metropolitan Neurological Hospital, Fuchu, Japan; 8) Dept Mol Biol, Grad Sch Med, Yokohama City Univ, Yokohama, Japan; 9) Dept Physiology, Hamamatsu Univ Sch Med, Handayama, Japan.

Early infantile epileptic encephalopathy with suppression-burst (EIEE), also known as Ohtahara syndrome, is one of the most severe and earliest forms of epilepsy. Using array-based comparative genomic hybridization, we found a *de novo* 2.0-Mb microdeletion at 9q33.3-q34.11 in a female EIEE patient. Mutation analysis of candidate genes mapped to the deletion revealed that four unrelated EIEE patients had heterozygous missense mutations in *syntaxin binding protein 1* (*STXBP1*). STXBP1 (also known as MUNC18-1) is an evolutionally conserved neuronal Sec1/Munc-18 protein, which plays an essential role for synaptic vesicle release in multiple species. Transient expression in Neuroblastoma 2A cells showed that all mutant STXBP1 proteins tend to aggregate. Circular dichroism melting experiments revealed that a mutant protein was significantly thermolabile compared to the wild type. Furthermore, binding of the mutant protein to syntaxin was impaired. These findings suggest that haploinsufficiency of STXBP1 causes EIEE.

Binding sites for ETS family of transcription factors dominate the promoter regions of differentially expressed genes in abdominal aortic aneurysms. *J. Nischan[1], Z. Gatalica[2], M. Curtis[2], G. M. Lenk[1], G. Tromp[1], H. Kuivaniemi[1]*
1) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI; 2) Department of Pathology, Creighton University School of Medicine, Omaha, NE.

Abdominal aortic aneurysm (AAA) is a life threatening disease affecting about 10% of the population over the age of 65 and causing over 15,000 deaths per year in the US. AAAs are characterized by local chronic inflammation of the aortic wall, decreased numbers of smooth muscle cells in the aortic media layer and fragmentation of the extracellular matrix. Our previous study identified 3,274 distinct differentially expressed genes in AAA compared to age, sex and ethnicity matched non-aneurysmal aortas. Using transcriptional genomics we investigated whether there were common transcriptional regulatory elements in the promoter regions of the differentially expressed genes. We used Whole Genome rVISTA to analyze the differentially expressed gene sets with increased and decreased expression to determine the transcription factor binding sites (TFBSs) overrepresented in the 5 kb promoter regions of these 3,274 genes. There were 144 transcription factors (TFs) whose TFBSs were overrepresented in the subset with decreased expression as compared to the entire genome. In contrast, there were only 13 overrepresented TFs in the set with increased expression. TRANSFAC classification showed 8/13 enriched TFs in the gene set with increased expression belonged to the ETS-type family of TFs. Additionally, NFKB and its heterodimeric subunits p65 and p50 showed enrichment in this subset. Both NFKB and many members of the ETS family of TFs have been previously implicated in vascular inflammation and remodeling and have been targets for investigation for their roles in AAA. By immunohistochemistry, 7 of 8 TFs were present in the adventitia and media of aneurysmal tissue. This is consistent with our microarray study, which showed that the same 7 TFs were expressed in aneurysmal tissue. Our results provide additional information on the role of the ETS family in the pathogenesis of AAA offering potential therapeutic targets for the management of this deadly disease.

MicroRNA Profiling of Human Lens Cell Lines HLE-B3 and SRA01/04. *L. Tian, K. Huang, D. Stambolian*
Department of Ophthalmology, University of Pennsylvania, Philadelphia, PA 19104, PA.

Many miRNAs are expressed in a developmentally regulated and tissue-specific manner making them crucial for tissue development in structures such as the eye. Most of the miRNA target function studies for the eye will need to be performed in ocular tissue culture cells. To date, miRNA profiles for the standard cell lines representative of the eye are nonexistent. We used miRNA microarrays to determine the relative level of miRNA expression in two human lens epithelial cell lines, HLE-B3 and SRA01/04. The Limma data analysis package was used to perform global loess normalization, and estimate fold changes. Multiple test adjusted p-values were obtained by the Benjamini and Hochbergs method with a false discovery rate below the threshold value of 1%. Four microRNAs showed more than 2-fold expression differences between SRA01/04 and HLE-B3. These miRNAs included mir-184, mir-31, mir-100 and mir-222. Differences in miRNA profiling were significant between the human cell lines and mouse lens. Comparison of the miRNA profile of either cell line to mouse lens miRNA demonstrated 70 miRNAs that had >2-fold relative expression change. A molecular function annotation was performed using DAVID to further characterize the pathways influenced by the 70 differentially expressed miRNAs. Grouping of target genes into pathways were significant for adhesion, cell death, cell cycle, post-translational protein modifications, transport and cell communication.

Why dont deaf people come for genetic counselling? Quantitative and qualitative findings from a UK study. *A. Middleton[1], S. Emery[2], G. H. Turner[2], A. Clarke[1], S. Sarangi[3], M. Bitner-Glindzicz[4], M. Richards[5], D. Stephens[6]* 1) Institute of Medical Genetics, Cardiff University, Cardiff, South Glamorgan, United Kingdom; 2) Department of Languages & Intercultural Studies, School of Management & Languages, Heriot-Watt University, Edinburgh, United Kingdom; 3) Health Communication Research Centre, School of English, Communication and Philosophy, Cardiff University, United Kingdom; 4) Clinical & Molecular Genetics, Institute of Child Health, London, United Kingdom; 5) Centre for Family Research, Cambridge University, United Kingdom; 6) Welsh Hearing Institute, School of Medicine, Cardiff University, United Kingdom.

Despite genetic deafness affecting more than 1 in 2000 people, deaf adults very rarely access genetic counselling in the UK, neither to discuss deafness nor other conditions that may be running through their family, e.g. cancer. Each genetics centre in the UK has several thousand deaf sign language users within their catchment area; however, referrals are likely to be received for fewer than 5 deaf adults per year. There may be many complex reasons behind this - e.g. lack of information, assumptions about inheritance or fears about being told not to have children. This project aims to gather the views of deaf and hard of hearing people, looking specifically at the above issues. 30 interviews have been conducted in sign language and qualitative analysis performed. A structured postal questionnaire has been completed by more than 1000 participants. The results indicate that most deaf people dont know how to get genetic counselling. Of those that are interested in having genetic counselling, most want to know about deafness rather than other conditions. Of those not interested in having genetic counselling, most assume that the deafness in their family is not inherited, even if they have a strong family history. Lack of information, assumptions about inheritance, negative attitudes towards genetics and communication difficulties all appear to play a part in preventing access to services. Once more is understood about these issues then steps can be taken to address them.

Timing of Imiglucerase Initiation and Other Risk Factors for Avascular Necrosis in Type 1 Gaucher Disease. *N. Weinreb[1], P. Deegan[2], A. Vellodi[3], J. A. Cole[4], M. Yeh[4], P. K. Mistry[5]* 1) Univ Research Foundation, Hollywood, FL; 2) Addenbrooke's Hospital, Cambridge, UK; 3) Great Ormond Street Children's Hospital NHS Trust, London, UK; 4) Genzyme Corporation, Cambridge, MA, USA; 5) Yale University School of Medicine, New Haven, CT.

OBJECTIVE: Treatment of type 1 GD (GD1) is initiated at varying intervals following diagnosis. This study assessed the effect of elapsed time from diagnosis to initiation of enzyme therapy with alglucerase or imiglucerase on the subsequent risk of developing avascular necrosis (AVN), the principal bone manifestation of GD1. The secondary aim was to identify other determinants of AVN. METHODS: All alglucerase/imiglucerase-treated patients with GD1 enrolled in the ICGG Gaucher Registry without documented AVN prior to initiation of therapy were included. Incidence rate for the first occurrence of AVN after starting therapy was calculated according to time intervals from diagnosis to initiation of therapy. Other risk factors investigated included spleen status, GBA genotype, age at therapy initiation and enzyme dose. RESULTS: 2,700 patients met the inclusion criteria. Among GD1 patients who began alglucerase/imiglucerase 2 or more years after diagnosis, the incidence rate of AVN was 16.6 per 1,000 person-years. Patients with an interval to start of treatment less than 2 years had a lower rate of AVN (incidence rate 8.1 per 1,000 person-years; adjusted incidence rate ratio <2 years vs. >2 years 0.58, 95% confidence interval 0.37 - 0.91). Patients with antecedent splenectomy (total or partial) had a higher incidence rate of AVN, regardless of the timing of treatment initiation (incidence rate 26.8 per 1,000 person-years; adjusted incidence rate ratio vs. non-splenectomized patients 2.35, 95% confidence interval 1.73-3.18) CONCLUSION: With an interval of more than 2 years between GD1 diagnosis and initiation of therapy, patients have increased risk of post-treatment osteonecrosis.

Genome-wide screen of late-onset Alzheimer's disease identifies TRPC4AP in two large pedigrees. *S. Poduslo*[1,2], *R. Huang*[1], *J. Huang*[1], *S. Smith*[1] 1) Inst Molec Medicine & Genetics, Medical Col Georgia, Augusta, GA; 2) VA Medical Center.

Alzheimer's disease is a complex disease with profound cognitive decline. Two extended pedigrees with many siblings affected with late-onset Alzheimer's disease were used in a genome-wide screen, using SNP microarrays, containing 500,000 SNPs. Significant SNPs were identified in one gene, after Bonferroni correction. Additional SNPs were analyzed in the extended families, with unaffected spouses as controls. All of the affected siblings had the same haplotype for ten SNPs in the gene, while the unaffected spouse controls had a different haplotype. TRPC4AP (transient receptor potential cation channel, subfamily C member 4 associated protein) on chromosome 20q11.22 is part of the TRP family which functions in regulating calcium. The gene has 19 exons and is 97,000 bp. The gene is being resequenced to identify the mutation. Supported by funds from a VA Merit award and MCG startup funds.

Defects in cell polarity underlie renal cystic disease in tuberous sclerosis. *C. S. Bonnet[1], C. von Ruhland[2], R. Harris[1], R. Sandford[3], J. P. Cheadle[1]* 1) Institute of Medical Genetics, Cardiff University, Cardiff, CF14 4XN, United Kingdom; 2) Medical Microscopy Sciences, Cardiff University, Cardiff, CF14 4XN, United Kingdom; 3) Department of Medical Genetics, University of Cambridge, Cambridge, CB2 0XY, United Kingdom.

Clinical trials are underway for the treatment of tuberous sclerosis (TSC)-associated tumours using mTOR inhibitors. Here, we show that many of the earliest renal lesions from *Tsc1*$^{+/-}$ and *Tsc2*$^{+/-}$ mice do not exhibit mTOR activation, suggesting that pharmacological targeting of an alternate pathway may be necessary to prevent tumour formation. Defects in the structure or function of primary cilia underlie numerous disorders associated with cystic kidneys such as autosomal dominant polycystic kidney disease (ADPKD). Given that patients with TSC often develop renal cysts, we tested for a functional interaction between the *TSC1* and *TSC2* gene products (hamartin and tuberin) and the *ADPKD1* gene product (polycystin-1), by crossing *Tsc1*$^{+/-}$ and *Tsc2*$^{+/-}$ mice with *Pkd1*$^{+/-}$ mice. We found that compound heterozygous mice had significantly more renal cysts as compared to single heterozygotes and that hamartin, tuberin and polycystin-1 helped maintain the length of primary cilia in pre-cystic renal tubule cells. Consistent with the observation that primary cilia modulate the planar cell polarity (PCP) pathway, we found that many dividing cells from *Tsc1*$^{+/-}$, *Tsc2*$^{+/-}$ and *Pkd1*$^{+/-}$ mice were highly misorientated along the tubule axis. We therefore propose that defects in cell polarity underlie both ADPKD and TSC-associated renal cystic disease and targeting of this pathway may be of key therapeutic benefit.

A case of Down syndrome with "mirror image" duplication of chromosome 21. *T. H. T. Minh[1], N. V. Nihan[1], N. M. Lindor[2], R. G. Meyer[3], R. Rai[3], G. V. N. Velagaleti[3]* 1) Dept. Medical Genetics, Hue College of Medicine & Pharmacy, Hue City, Viet Nam; 2) Dept. Medical Genetics, Mayo Clinic, Rochester, MN; 3) Dept. Laboratory Medicine & Pathology, Mayo Clinic, Rochester, MN.

A 12-year-old girl was referred for cytogenetic analysis because of moderate mental retardation and features typical of Down syndrome (DS). Family history is significant as two of her siblings with apparent DS died during infancy. The mother has two spontaneous abortions. The mother was 22 years old and the father was 34 at the time of proband's birth. Chromosome analysis showed a karyotype 46,XX,idic(21)(q22.3) in all the 100 metaphases analyzed. AgNOR staining on the abnormal chromosome showed satellites at both ends suggesting it is dicentric. Parental chromosome analyses from peripheral blood showed normal karyotypes. FISH analysis with chromosome 13/21 alpha satellite probes confirmed the presence of two centromeres on idic(21). FISH analysis with LSI 21, AML1 and subtelomere probes also showed duplication of signals, although the telomere signals showed overlapping signals making precise determination of telomere status difficult. FISH using LSI 21 probe on parents blood lymphocytes did not show mosaicism for a balanced rearrangement. Although trisomy 21 is one of the most common chromosome abnormality, DS due to mirror image duplication of chromosome 21 is extremely rare with fewer than 10 cases reported. The mechanism of these mirror image duplications is not clearly elucidated, but translocation between sister chromatids or intrachromosomal interchange has been suggested as one mechanism. The majority of the mirror image DS cases are reported as sporadic mutational events with no significant family history, unlike our case. The family history of 3 affected siblings and 2 spontaneous abortions and normal chromosome results from peripheral blood in parents suggests a strong possibility that there might be gonadal mosaicism in our family. Further FISH studies are in progress to analyze the sperm for idic(21) in the father. To the best of our knowledge, this is the first case of mirror image duplication of chromosome 21 leading to DS with a strong possibility of gonadal mosaicism.

The Genetic Information Nondiscrimination Act of 2008: Minimal Protections but Maximum Publicity. *J. Wagner* Dept Anthropology, Penn State Univ, University Park, PA.

For over a decade Congress has tinkered with legislation to prohibit genetic discrimination. Accumulating suspicions of misuse in employment and insurance contexts following the realization of the Human Genome Project and the growing popularity of genetic discoveries in the news sparked Congress into action. On May 21, 2008, the Genetic Information Nondiscrimination Act of 2008, known colloquially as GINA, was signed into law. Yet the practical impact of GINA is far from certain, as the bill neglects as much as it addresses. Geneticists must not only be aware of the state of the laws but also be aware of how laws are shaped and refined over time. This research analyzes the legislative history of GINA, its legislative precursors, and the framework within which it was constructed. The text and scope of genetic nondiscrimination laws at the state-level are analyzed in relation to GINA and the medias reporting of GINA is surveyed. GINA amends Employee Retirement Income Security Act, Public Health Service Act, and Internal Revenue Code. GINA neglects the use of genetic predispositions to limit damages or deny causality in medical tort cases. While defining genetic information broadly to include family history, GINAs applicability is narrow, giving a potential false sense of security. For example, while insurers are forbidden from increasing premiums for someone found to carry the BRCA1 mutation, the insurers are still permitted to use their business judgment to determine whether a double mastectomy is elective or medically necessary, subject only to an abuse of discretion review. GINA prohibits employment discrimination on the basis of genetic information yet intentionally fails to provide a cause of action to such a victim: The efficacy of such an empty threat is doubtful. Moreover, GINA does not apply to employers who have less than 15 employees. While the passage of GINA and the medias advertisements of its protections may alleviate the publics concerns for misuse of genetic information, GINA opens a new host of challenges and dangers to those seeking or receiving genetic testing.

***Sall1*, *Sall2*, and *Sall4* are required for neural tube closure in mice.** *J. Kohlhase[1], J. Böhm[2], A. Buck[3], W. Borozdin[1,2], A. U. Mannan[3], U. Matysiak-Scholze[2], I. Adham[3], W. Schulz-Schaeffer[4], T. Floss[5], W. Wurst[5], F. Barrionuevo[2]* 1) Dept Human Genetics, Ctr Human Genetics Freiburg, Freiburg, Germany; 2) Inst Human Genetics, University of Freiburg, Freiburg, Germany; 3) Inst Human Genetics, University of Goettingen, Goettingen, Germany; 4) Dept Neuropathology, University Clinic Goettingen, Goettingen, Germany; 5) GSF National Research Center for Environment and Health, Institute of Developmental Genetics, Neuherberg, Germany.

Four homologs to the Drosophila homeotic gene spalt (sal) exist in humans and mice (*SALL1-4*/*Sall1-4*). Mutations in *SALL1* and *SALL4* result in the autosomal-dominant developmental disorders Townes-Brocks and Okihiro syndrome, respectively. In contrast, to date, no human disease has been associated with *SALL2*, and *Sall2*-deficient mice showed no apparent abnormal phenotype. We have generated mice deficient in *Sall2*, and in contrast to previous reports, 11% of our *Sall2*-deficient mice showed background-specific neural tube defects. To investigate whether Sall4 may compensate for the absence of Sall2, we generated compound *Sall2* knockout/ *Sall4* genetrap mutant mice. In these mutants, the incidence of neural tube defects was significantly increased. Furthermore, we found a similar phenotype in compound *Sall1/4* mutant mice, and in vitro studies showed that SALL1, SALL2 and SALL4 co-localize in the nucleus. We therefore suggest a fundamental and redundant function of the SALL proteins in murine neurulation.

HIF-1a gene polymorphisms in thyroid cancer. *M. Lu, P. Hsiao, F. Chiang, S. Juo* Grad Inst Medical Genetics, Kaohsiung Medical Univ, Kaohsiung, Taiwan.

Thyroid cancer is the most common endocrine malignancy. Angiogenesis is important for the development of thyroid cancer. HIF-1a(hypoxia-inducible factor)is the headstream of angiogenic pathway. We conducted a case-control study to evaluate the genetic effect of HIF-1a and thyroid cancer. A total of 299 cases and 477 controls were recruited for this study. The genotypes were determined by the Taqman 5 nuclease assay. A total of six tagging SNPs and two non-synonymous SNPs were tested. Hardy-Weinberg equilibrium was tested for each SNP, and the genetic effects were evaluated by X2 test. Individual haplotype pair was predicted by the PHASE 2.0 software. Haplotype-specific and global p-value were obtained by the Hap-Clusting program. None of the single SNP was found to be related with thyroid cancer. Using the variable sliding windows for haplotype analysis, we found the most significant result of a global p value of 4.46 x 10-10 from the combination of SNPs rs966824, rs2301112 and rs2301113. The haplotype CAC yielded the most significant result among these five haplotypes (p-value = 2.21 x 10-5). This haplotype is located within the ODD (oxygen-dependent degradation) domain of HIF-1a gene. The haplotypes comprising from the SNPs rs966824, rs2301112 and rs2301113, which is involving the ODD domain formation, may play a role in the development of thyroid cancer.

Alteration of X-linked gene expression in a novel X-Linked Mental Retardation syndrome. *T.-J. Chen[1], TL. Lee[2], Y. Wang[1], Z. Chen[3], W.-Y. Chan[2], C. M. Tuck-Muller[1], J. E. Martinez[1]* 1) Dept Medical Genetics, Univ South Alabama, Mobile, AL; 2) Section on Developmental Genomics, Lab of Clinical Genomics, NICHD, NIH, Bethesda, MD; 3) Dept. of Human Genetics, UCLA, Los Angeles, CA.

In a previous report, we defined a novel XLMR syndrome in a family with six affected males with mental retardation, muscle atrophy, pigmentary abnormalities and ptosis, and two obligate carrier females in three generations. The defective gene was mapped to the region Xp11-Xp22 by linkage analysis using STR markers. To identify the defective genes for the family, oligo-Array CGH was performed. No deletion or duplication was detected in the probands of either family. To rule out a small deletion and/or duplication, X chromosome tiling array analysis was carried out. Although suspected deletions were detected, these deletions could not be confirmed by PCR analysis. The expression profile of X-linked genes in the probands lymphoblasts was surveyed by X-linked gene cDNA array. The cDNA array contained all known genes on the human X and Y chromosome with controls. The difference in expression level was determined by comparing the ratio of the experimental sample to the normal sample. The expression of at least 50 genes was reduced significantly (>3 fold). The other 21 genes had significantly increased expression (>3 fold). Among these differentially expressed genes, 6 known XLMR genes, 2 XLMR candidate genes and 2 transcriptional factor genes were up regulated, while 12 known XLMR genes, 5 XLMR candidate genes, and 8 transcriptional factor genes were down regulated. It is note worthy that expression of FMR1 and DMD genes decreased more than 10 fold. Thus, we hypothesized that the defective gene for this novel XLMR disorder encodes a transcriptional factor. Interestingly, reduced expression of the FMR1 and FMR2 genes and increased expression of UBE2A, SYP, and SYN1 genes could be associated with mental retardation and CNS anomalies in the XLMR family, while reduction in expression of DMD and increase in expression of the SMAP gene may be the cause of the muscle atrophy and ptosis. Alteration of expression of multiple transcriptional factor genes might result in other clinical abnormalities.

The Adaptor-related Protein complex 2, alpha 2 subunit (AP22) gene is a novel PPAR target gene. *N. Buroker[1], J.-Y. Huang[2], J. Barboza[1], X.-H. Ning[1], M. Portman[1]* 1) Dept Cardiology, Seattle Children's Hosp Res Inst, Seattle, WA; 2) Dept Pediatrics, School of Medicine, UW, Seattle, WA.

The peroxisome proliferator-activated receptors (PPARs) and the retinoid X receptors (RXRs) are members of the nuclear receptor superfamily, which consists of a large number of special transcription factors whose activities are regulated by their cognate ligands. These steroid hormone receptors are important regulators of gene expression and differentiation. These receptors form homo- (RXR) and hetero- (PPAR-RXR) dimers that bind DNA at various response elements (PPAR-RE and RXR-RE). We identify the PPAR/RXR REs in the promoter of the adaptor-related protein complex 2, alpha 2 subunit (AP22) gene. In this study a known PPARactivator (Wy14643) and DMSO (vehicle) was introduced into control and 337T thyroid hormone receptor (TR) transgenic mice. The 337T TR transgenic mouse has been created to reproduce the human genetic disease known as resistance to thyroid hormone (RTH). Heart tissue was extracted and AP22 expression was compared using Affymetrix 430_2 expression arrays and qRT PCR among four studies groups [control, control with Wy14643, 337T TR and 337T TR with Wy14643] consisting of seven mice per group. The gene expression of AP22 in the Wy14643 control and transgenic mouse groups was significantly up-regulated over the vehicle mouse groups for both the array ($p<0.01$) and qRT PCR ($P<0.01$) studies. Duplex oligo DNAs containing the PPAR/RXR motif (aggtca/tccagt) from the AP22 promoter were used in EMSA to verify binding of the PPAR and RXR receptors to their response elements. pGL4.0 [Luc] constructs of the AP22 promoter with and without the PPAR/RXR motifs were co-transfected with mouse PPAR , , or 1 into HepG2 cells and used in lucerifase assays to verify gene activation. In conclusion our study revealed that PPARregulates the mouse cardiac AP22 gene in both the control and transgenic mouse.

Discovery of rare variants via sequencing: Implications for association studies. *S. M. Leal, B. Li* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Common diseases can be due to functional variants with a wide spectrum of allele frequencies. To understand the architecture of allele frequencies and more importantly provide a biomedical resource for common diseases, the 1000 genome project is initially sequencing ~1,000 individuals from 10 different ethnic backgrounds. Currently genome-wide association studies use tagSNPs to uncover genes for common diseases caused by common variants. In the future there will be a shift to analyzing sequence data to understand the etiology of common diseases due to rare variants. We determined for a set sample size what proportion of rare variants can be identified. For a gene with 20 rare variants each with a frequency 0.1% if 1,000 individuals are sequenced the probability is 0.055, 0.956 and 0.999 that 100%, 75% and 50% of the variants will be uncovered. If only 200 individuals are sequenced these probabilities decrease to $2.3x10^{-10}$, $1.5x10^{-4}$ and $8.6x10^{-2}$, respectively. If each of the 20 variants are functional and have a genotypic relative risk of 5.0; sequencing 200 cases will identify 100% and 50% of the variants with probability $4.6x10^{-9}$ and 0.197, respectively. Sequencing genomes of 1,000 individuals from the same population will reveal ~87% of the variants with frequency of 0.1% with a power of 0.9; the number of identified variants falls to ~18% if only the genomes of 100 individuals are sequenced. The proportion of identified variants will be lower if variant frequencies are <0.1%. For the 1,000 genome project due to ethnic specific sample sizes many rare variants including those involved in disease etiology may not be observed. It is also not advisable to sequence a sample subset in order to discover rare variants and then genotype the remaining sample, since missing variants will dramatically reduce power of association studies.

Gene regulation in primates evolves under tissue-specific selection pressures. *R. Blekhman[1], A. Oshlack[2], A. E. Chabot[1], G. K. Smyth[2], Y. Gilad[1]* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Walter and Eliza Hall Institute of Medical Research, Parkville, Australia.

A long standing hypothesis is that changes in gene regulation play an important role in adaptive evolution, notably in primates. Consistent with this theory, the past decade of research has yielded an increasing number of cases where regulatory changes contribute to species-specific adaptations and to reproductive isolation. To identify adaptive regulatory changes in humans, we performed a genome-wide survey for genes whose regulation evolves under natural selection. To do so, we used a multi-species microarray to measure gene expression levels in livers, kidneys, and hearts from six humans, chimpanzees, and rhesus macaques. Using this comparative expression data, we identified a large number of genes, as well as specific pathways, whose regulation has likely evolved under stabilizing or directional selection. Among the latter set, we found an enrichment of genes involved in metabolic pathways, consistent with the hypothesis that shifts in diet underlie many regulatory adaptations in humans. Finally, we found clear evidence for tissue-specific selection pressures, as well as lower rates of protein evolution for genes whose regulation evolves under natural selection. These observations provide strong support to the notion that adaptive circumscribed changes in gene regulation have fewer deleterious pleiotropic effects compared with changes at the protein sequence level.

Comprehensive Polymorphism Analysis by Haplotype-Specific Extraction. *C. Hellbusch[1], H. Polin[2], M. Danzer[2], C. Gabriel[2], K. Lennartz[1]* 1) QIAGEN GmbH, Hilden, Germany; 2) Österreichisches Rotes Kreuz, Linz, Austria.

For molecular typing of Human Leukocyte Antigens (HLA) and many other genotyping applications the determination of allelic polymorphism combinations is important. Several methods including sequence-specific priming (SSP) or sequencing-based typing (SBT) can be employed but may result in ambiguous typing results, due to two or more different polymorphic allele combinations or new alleles. These can be resolved by haplotype-specific extraction (HSE). This unique method physically separates diploid genomic DNA into its haploid components. Data presented here show the comprehensive analysis of HLA loci by HSE performed with the QIAGEN EZ1 HaploPrep Kit*.

The extraction of the selected alleles is performed fully automated on a QIAGEN EZ1 workstation. After a probe-dependent hybridization and labeling process the targeted allele is subsequently coupled to magnetic beads for separation from nontargeted DNA. The HaploPrep probes show single-base specificity and provide high capture efficiency of the target DNA. Following HSE, analysis of the haplotypes of the targeted genes by SBT leads to clear sequences and thereby to an unambiguous allele identification.

Therefore, HSE represents a fast and effective method for improving genetic analysis in complex genetic contexts. It has been shown to work in combination with various techniques including conventional PCR and sequencing approaches, Pyrosequencing, real-time PCR, and restriction fragment length polymorphism (RFLP) analysis. With the rapidly increasing knowledge about polymorphism associated conditions and diseases, HSE may be used in the future for additional applications, e.g. pharmacogenetics or oncology testing.

* For Research Use Only. Not for use in diagnostics procedures. No claim or representation is intended to provide information for the diagnosis, prevention, or treatment of a disease.

Sex-specific genetic effect of phosphodietserase 4D (PDE4D) on carotid atherosclerosis. *Y. Liao[1, 2], H. Lin[3, 5, 7], M. Yu[6], C. Liu[3,7], S. Juo[1, 3, 4]* 1) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Taiwan; 2) Graduate Institute of Medicine, Kaohsiung Medical University, Taiwan; 3) Department of Neurology, Kaohsiung Medical University, Taiwan; 4) Center of Excellence for Environmental Medicine, Kaohsiung Medical University, Taiwan; 5) Department of Neurology, Hsiao-Kang Hospital, Kaohsiung, Taiwan; 6) Hepatobiliary Division and Department of Preventive Medicine, Kaohsiung Medical University Hospital, Taiwan; 7) Department of Neurology, Kaohsiung Medical University Hospital, Taiwan.

Background and Purpose The phosphodiesterase 4D(PDE4D) gene was reported as a susceptibility gene to stroke. The genetic effect might be attributed to its role in modulating the atherosclerotic changes in carotid artery. Using carotid intima-media thickness(IMT) and plaque index as phenotypes,this study sought to determine the influence of this gene on subclinical atherosclerosis. **Methods** Carotid ultrasonography was performed in 1013 stroke-free subjects age=52.612.2;47.6% men). Genotype distributions were compared among high-(plaque index4),low-risk(index =1-3),and reference(index =0) groups. We analyzed continuous IMT data and further dichotomized IMT using mean plus one standard deviation as the cutoff level. Rs702553 at the PDE4D gene was selected because it confers a risk for young stroke in our previous report. Previous young stroke data with additional 532 control subjects without ultrasonic data were shown as a cross-validation for genetic effect. **Results** The TT genotype was more common in men with a plaque index greater than four(20.0% in TT vs. 9.7% in AA+AT,p=0.008). Using dichotomized IMT data, men with the TT genotype had an odds ratio(OR) of 2.10 (p=0.032) for increased IMT at common carotid artery compared with AA+AT genotypes. In women, neither IMT nor plaque index was associated with rs702553. Sex-differential effect was also found in young stroke (OR=1.92,p=0.02 for men and 1.44,p=0.33 for women). **Conclusions** The present study demonstrates a sex-specific effect of PDE4D on IMT,plaque index and stroke, which highlights its influence on various aspects of atherogenesis.

The *APC* variant E1317Q predisposes to colorectal adenomas by relaxing the target for tumourigenic somatic APC mutations. *D. Azzopardi[1], A. R. Dallosso[1], S. Jones[1], V. Moskvina[2], N. Al-Tassan[1], G. T. Williams[3], S. Idziaszczyk[1], D. R. Davies[4], P. Milewski[5], S. Williams[5], J. Beynon[6], J. R. Sampson[1], J. P. Cheadle[1]* 1) Medical Genetics, Cardiff University, United Kingdom; 2) Biostatistics & Bioinformatics Unit, Cardiff University, United kingdom; 3) Department of Pathology, Cardiff University, United Kingdom; 4) Caerphilly District Miners Hospital, St Martins Road, Caerphilly, United Kingdom; 5) Pembrokeshire and Derwen NHS Trust, Withybush Hospital, Fishguard Rd, Haverfordwest, United Kingdom; 6) 6Department of Colorectal Surgery, Singleton Hospital, Sketty Lane, Swansea, United Kingdom.

Multiple rare non-synonymous variants in *APC* may play a role in inherited predisposition to colorectal adenomas. The mechanisms through which these variants might act remain unclear. It has been proposed that a specific level of -catenin signalling is required for colorectal tumour formation possibly mediated by selection for genotypes retaining one, or rarely two, 20 amino acid -catenin down regulating repeats (20AARs). We investigated the mechanism through which the non-synonymous variant E1317Q, that is located between the first and second 20AARs in *APC*, contributes to tumourigenesis. Comparison of the somatic mutation patterns in *APC* found in tumours from attenuated familial adenomatous polyposis patients that did (Family B) or did not (Patient S) co-inherit E1317Q highlighted significant differences between these tumours, with only 8.2% of tumours carrying E1317Q having somatic mutations predicted to result in mutant polypeptides retaining a single 20AAR, as compared to 61.5% of those which did not carry this variant ($P=9.16x10^{-9}$). *In vitro* assays and showed that E1317Q significantly impaired -catenin regulated transcription when expressed with weak truncating mutations within the -catenin down regulating domain ($P<0.05$). These data suggest that E1317Q relaxes the target for tumourigenic somatic *APC* mutations through its own effects on -catenin-associated signalling.

The genetic association of STAT4 with SLE occurs through independent effects. *A. M. Delgado-Vega[1], A. K. Abelson[1], S. Kozyrev[1], E. Sanchez[2], R. Velasquez[3], N. Eriksson[1], J. Wojcik[4], L. M. V. Prasad[1], G. Lima[5], S. D'Alfonso[6], S. Migliaresi[7], V. Baca[8], T. Witte[9], N. Ortego-Centeno[10], H. Abderrahim[4], B. Pons-Enstel[11], C. Gutierrez[12], A. Suarez[12], J. Martin[2], M. E. Alarcon-Riquelme[1]* 1) Uppsala U, Uppsala, Sweden; 2) Inst Parasitologia y Biomedicina Lopez-Neyra, Granada, Spain; 3) Inst Nal Medicina Genomica, Mexico city, Mexico; 4) Merck Serono, Geneva, Switzerland; 5) Inst Nal C.Medicas y Nutricion Salvador Zubiran, Mexico city, Mexico; 6) U of Eastern Piedmont, Novara, Italy; 7) Second U of Naples, Naples, Italy; 8) CMN Siglo XXI, Mexico city, Mexico; 9) Medical School Hannover, Hannover, Germany; 10) Hospital Clínico San Cecilio, Granada, Spain; 11) Sanatorio Parque, Rosario, Argentina; 12) U de Oviedo, Oviedo, Spain.

Aim. To confirm the genetic association of STAT4 with SLE in 5 independent sets of cases and controls. Methods: We typed 30 tag SNPs in 390 Spanish cases and 480 controls covering the STAT1-STAT4 region. SNPs surviving correction for multiple tests were typed and tested for association in 1581 cases and 1844 controls using real-time PCR. The predictive ability of STAT4 plus IRF5 SNPs was measured by the area under the ROC curve (C-Statistic). Expression and alternative splicing analysis was performed on PBMC. Results. After fine mapping, 4 SNPs remained significant and 3 had independent effects from rs7574865, having rs3821236 the strongest one. Association was replicated in separate sets of cases and controls, except for German and Mexican pediatric sets. High levels of STAT4 expression correlated with rs3821236, rs3024866 and rs7574865, all associated with SLE. The C-statistic increased when rs7574865 and rs2070197, the IRF5 risk haplotype tag, were included in the model compared to rs2070197 alone. No interaction was observed suggesting an additive effect. Conclusions. These data confirm STAT4 as a susceptibility gene for SLE with several independent gene effects, show a strong association signal located around intron 16 62kb from intron 3 and rs7574865, and suggest the presence of functional variants affecting levels of STAT4. Our results also suggest that STAT4 and IRF5 act additively to increase risk for SLE.

Analysis of human urea and nitric oxide cycle gene expression in a panel of normal human tissues. *M. Neill*[1], *M. Summar*[1, 2] 1) Dept Human Genetics, Vanderbilt Univ, Nashville, TN; 2) Dept Pediatrics, Vanderbilt Univ, Nashville, TN.

The urea cycle enzymes serve three important roles. First they are responsible for the processing of nitrogen to urea. The urea cycle is the only metabolic pathway capable of disposing of waste nitrogen. These enzymes also play a role in the amount of nitric oxide produced by the endogenous citrulline-NO cycle. Finally these enzymes are involved in arginine and citrulline production. Given the three distinct roles of these enzymes we postulated that these enzymes might be expressed in a tissue-specific manner. In this study, we have examined the expression of genes encoding the urea cycle and nitric oxide cycle enzymes in a panel of normal human tissues. mRNAs encoding carbamoyl phosphate synthetase (CPSI), n-acetyl glutamate synthase (NAGs), ornithine transcarbamoylase (OTC), argininosuccinate synthetase (AS), argininosuccinate lyase (AL), arginase I (ARG1), arginase II (ARGII), ornithine amino-transferase (OAT), citrin, ORNT1, endothelial nitric oxide (eNOS), inducible nitric oxide (iNOS) and neuronal nitric oxide (nNOS) were amplified by quantitative real-time reverse transcription-PCR assays (qRT-PCR)and normalized to a reference mRNA (GAPDH). We provide evidence that RNA from small intestine, ileum, liver, pancreas, kidney, brainstem, testis, skeletal muscle, spleen, and lung tissue can be amplified by qRT-PCR. We show that patterns of tissue expression for these genes are pedictive of the role of the tissue in either: urea production, citrulline/arginine export, nitric oxide production, or combinations of the above. These findings indicate that the genes involved in the urea and nitric oxide cycles are subject to tissue specific gene regulation. Given these findings it is reasonable to look for shared promoter cassettes amongs these genes which govern their tissue specific expression.

Two cases of mantle cell lymphoma with normal chromosomes 11 and 14 by G-banding but IgH/CCND1 gene fusion by FISH. *J. Xu[1], I. Chin-Yee[2], J. Mangel[2], K. Howson-Jan[2], C. Hamm[3]* 1) Cytogenetics, London Health Sciences Centre and University of Western Ontario, Canada; 2) Hematology, London Health Sciences Centre and University of Western Ontario, Canada; 3) Windsor Regional Cancer Centre, Canada.

Case 1. A 46-year-old male had monoclonal B cells representing ~60% of total leukocyte population in the bone marrow and being CD19/CD5, CD23, FMC7, and CD20 positive and expressing Kappa light chains. The findings suggested possibility of small cell lymphocytic lymphoma, chronic lymphocytic leukemia or mantle cell lymphoma (MCL). Routine G-banding showed a normal male karyotype, 46,XY[50]. However, FISH showed 72% of 200 interphase nuclei with one IgH/CCND1 fusion signal. No FISH signals of IgH/CCND1 fusion were detected in the metaphase chromosomes 11 and 14 examined. In light of the FISH result, this case was interpreted with a final diagnosis of MCL. Case 2: A 62-year-old male was found to have a small monoclonal population of cells (7%) in the bone marrow expressing CD19/CD5, CD20, FMC7 and Kappa light chains. This finding suggested a B-cell lymphoma, possibly MCL. G-banding analysis showed 45,X,-Y[3]/46,XY[23]. The loss of the Y is likely an age-related random event. FISH showed two IgH/CCND1 fusion signals in 14% of 200 interphase nuclei, which confirmed a clinical diagnosis of MCL. This was in keeping with the histology and immunophenotyping seen on his inguinal lymph node biopsy. Notably both of our cases showed that the cells bearing diagnostic IgH/CCND1 fusion were non-dividing in cultures and therefore were missed by routine G-banding and only detected by FISH. At least 22 cases of MCL were reported to have atypical cytogenetic presentations, including 1) absence of chromosomal t(11;14)(q13;q32) in metaphase cells but presence of IgH/CCND1 fusion in interphase cells; and 2) presence of the gene fusion as a result of micro-insertion of CCND1 into the 14q32/IgH locus in apparently normal chromosome 14. Our data adding to the literature emphasize that FISH or other molecular methods must be considered for accurate diagnosis of MCL cases with a normal karyotype by G-banding.

Centromeric DNA break in two reciprocal translocation carriers detected during pre-implantation genetic diagnosis (PGD). *J. Wang, J. Szymanska, R. Habibian, L. Dong, D. Fisher, S. Kou, Q. Huang, J. Chang, A. Hajianpour*
Genzyme Genetics, Monrovia, CA.

Balanced reciprocal translocation carriers are at risk for SAb or abnormal liveborn. Application of PGD by FISH can decrease the risk of these adverse outcomes by transferring only embryos having balanced chromosome (chr) constitution. We have adopted a pre-PGD FISH work-up protocol to select the appropriate probes for PGD that will detect all abnormal segregants. During these processes, we found two cases with unexpected breaks in the centromeric satellite DNA. Case 1 was originally reported as 46,XX,t(17;19)(p11.2;p12). Initial probes selected for pre-PGD work-up were tricolor 17pter, 19pter, and 17cen. The 17cen probe signal was found on both der(17) and der(19), indicating a break in the chr 17 satellite DNA, making this probe set unsuitable for PGD. Subsequently, the chr 19 centromere was also found on both der(19) and der(17). Apparently, both centromeres were split in this true whole arm translocation. The karyotype was revised to 46,XX,t(17;19)(p10;q10). Case 2 was originally reported as 46,XX,t(4;18)(q13;q11.2). Initial probes selected were 4qter, 18qter, and 18cen. The 18cen signal was found on both der(18) and der(4), indicating a break in chr 18 satellite DNA. The der(4) contains a portion of the chr 18 satellite DNA at 4q13, thus represents a dicentric chr. The karyotype was revised to 46,XX,t(4;18)(q13;q10). To date, only four cases of centromere breakage involving chrs 1, 16, and 18 have been reported in reciprocal translocations. Our serendipitous finding of such breaks in two cases, together with the proposition that breakage within the centromere (centromere misdivision, the McClintock mechanism) may be the most common mechanism for ring chr formation, suggests that centromere break may not be rare. These cases provide evidence that break or loss of centromeric satellite DNA does not impair centromere function. A systematic search for centromeric break in whole arm translocations and in reciprocal translocations in which one or both breakpoints are close to the centromere may provide further insight to centromere function and interaction.

Alternative Splicing of the Polycystic Ovary Syndrome (PCOS) susceptibility locus D19S884 in a mini-gene system. *C. Ackerman, A. Biyasheva, M. Urbanek* Department of Medicine. Feinberg School of Medicine, Northwestern University, Chicago, IL.

PCOS is a complex genetic disease that is one the most common causes of infertility and is defined by hyperandrogenemia and irregular menses. In addition to reproductive issues, PCOS is also associated with obesity, insulin resistance and increased risk of developing cardiovascular disease and type 2 diabetes. We have identified a PCOS susceptibility allele within a dinucleotide repeat $(CA)_n$, D19S884, in intron 55 of the fibrillin-3 (*FBN3*) gene on chromosome 19p13.2 that is associated with reproductive and metabolic phenotypes in affected women. Other dinucleotide repeat polymorphisms mapping to noncoding regions have been shown to act as intronic splicing enhancers or silencers, depending on their location and proximity to splicing recognition sequences. Therefore D19S884 may be important in alternative splicing or regulation of *FBN3* transcript levels. We generated mini-gene constructs of the *FBN3* genomic fragment containing D19S884 variants and flanking sequences. We PCR amplified the region containing D19S884 and inserted the products into a splicing reporter vector. A construct was generated for each of the 14 variants at D19S884 that has been observed in women with PCOS, including the PCOS susceptibility allele A8 $(CA)_{17}$. Constructs were transiently transfected into COS-7 cells, RNA isolated, and splicing efficiency assessed by RT-PCR. All variants except A8 demonstrated 100% splicing efficiency. While A8 showed some of the expected splice product, a large percentage of the transcript was not spliced. Surprisingly, A7 and A9, which differ from A8 by one CA repeat, showed normal splicing. The only difference between the A8 mini-gene construct and the other variants is the number of CA repeats. This indicates that D19S884 A8 transcripts have a defect in splicing that decreases the amount of normally spliced transcript and may reduce protein expression. This reduction in fibrillin-3 expression may confer susceptibility to PCOS. The mechanism of the splicing defect and whether this finding reflects the splicing pattern in the complete *FBN3* gene remains to be elucidated.

Prenatal testing of a novel EXT2 nonsense mutation in a Chinese family with hereditary multiple exostoses. *S.-J. Song[1], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) Department of Human Genetics, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Objective: Hereditary multiple exostoses (HME) is a genetically heterogeneous autosomal dominant disorder, characterized by multiple bony outgrowths. The objective of this study was to investigate the genetic basis of a Chinese family with HME in order to perform prenatal testing for HME in a fetus at 50% risk. Method: Haplotype analyses were performed with polymorphic microsatellite markers at three reported loci (EXT1, EXT2, and EXT3) associated with HME. Screening of the EXT1 and EXT2 genes was performed by direct sequencing of PCR fragments that covered the entire cDNA, following which prenatal testing of the fetus of the proband was performed. Results: It was determined that the EXT3 locus did not link to the family. DNA analysis of EXT1 and EXT2 revealed a novel nonsense mutation (c.1006C>T) in EXT2, which converts the Gln codon (CAA) to the termination codon (TAA) at codon 336 (Gln336X). Prenatal testing showed that the fetus was normal. Conclusion: A novel nonsense mutation in EXT2 was identified in a Chinese family with HME. This result extends the mutation spectrum of EXT2 and can be used for prenatal testing in HME families.

Proteomic Study of Hutchinson-Gilford Progeria Syndrome (HGPS). *L. Wang[1], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) Dept. Human Genetics, New York State Institute for Basic Research in Developmental Disabilities.

Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disorder that is characterized by segmental premature aging. It is caused by mutations in LMNA, the gene encoded an A-type nuclear lamin protein, lamin A/C. The most frequently occurred mutation is a single nucleotide change in exon 11 that results in a cryptic splice site and the subsequent loss of 50 amino acids within the carboxyl terminus of the lamin A/C proteins. The newly generated mutant lamin A, termed as progerin, may interfere with the nucleic structure and result in bleb formation of nuclei. Presently, the exact pathogenic mechanism of HGPS has not been elucidated. Earlier we have proposed the mutant progerin may have a dominant negative effect on the normal allele of lamin A/C. In this study, we have undertaken a further investigation to study if the expression of progerin may generate alteration of differential expression of proteins in HGPS. Proteomic approach with PF2D system was applied to identify differentially expressed proteins in HGPS cells. Twenty-six proteins down-regulated and four proteins up-regulated were identified. These proteins were classified into five groups: DNA transcription and translation, cell cytoskeleton, cell signal transduction, energy metabolism and cell cycle. Among these proteins, five proteins belonged to calcium-binding protein. Six proteins we interested were selected and validated in HGPS cells. Our study has opened a new avenue for studying the pathogenic mechanism underlying HGPS.

Mutation Spectrum of Kallmann Syndrome. *S. Sha[1], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Kallmann syndrome (KS) is a clinically and genetically heterogeneous disorder, which is characterized by the association of idiopathic hypogonadotropic hypogonadism (IHH) and anosmia or hyposmia. Mutations underlying KS have been identified in four genes KAL1, KAL2, KAL3 and KAL4 that account for nearly 30% of all KS cases. In this study, we have investigated the mutation spectrum among 35 Chinese KS patients with a molecular approach of combining PCR-sequencing and multiplex ligation-dependent probe amplification (MLPA). PCR-sequencing was employed for mutation screening among coding regions of KAL1, KAL2, KAL3 and KAL4 genes. Three point mutations, including two novel mutations K329N and A466V, and one known mutation E514K, were identified in KAL1 gene, which are localized in exon 7, 10 and 11, respectively. These mutations are located in FnIII-2 domain and in the linker region between FnIII-3 and FnIII-4 domains of KAL1 gene, and may be involved in influencing axon branching. MLPA was used to screen for microdeletion or microduplication of KAL1, KAL2, OA1, STS, NELF, GNRHR, GPR54 and GNRH1 genes. Microdeletions, including eight in KAL1 gene and three in KAL2 gene, were identified. In addition, duplications were also found in KAL1 and KAL2 genes. Our results suggest microdeletions and/or microduplications are the predominant genetic defects underlying KS. We recommend that a quantitative analysis such as MLPA should be applied to analyze KS in addition to directly sequencing KAL genes.

MUC20, a novel partner of anosmin-1, possibly involves in olfactory axon branching in Kallmann syndrome. *N. Zhong[1,2], S. Sha[2]* 1) Dept Human Genetics, New York State Inst Basic Res, Staten Island, NY; 2) Peking University Center of Medical Genetics, Beijing, China.

Genetic defect of anosmin-1 has been determined to associate with heterogeneous X-linked Kallmann syndrome (X-KS). However, the detailed pathogenic mechanism is yet unclear. In this study, we have employed the anosmin-1, which is encoded by the KAL1 gene, as the bait in a yeast two hybrid (Y2H) system to screen a human embryonic cDNA library to identify interactive partner(s) for anosmin-1. Our results showed that 16 candidates were identified. Among which, LASS2, L14, MUC20 and FGFR1 were verified by pulling-down experiments and interaction between MUC20 and anosmin-1 was further confirmed by co-immunoprecipitation and double-staining. Both MUC20 and anosmin-1 were detected in human embryonic brain tissues of 18-week, in addition to that anosmin-1 may be detected in 32-week human fetal brain and MUC20 in rat E18 brain by western blots. Truncation analysis showed that MUC20 associates with FnIII-3 and/or FnIII-4 domains but not FnIII-0, FnIII-1 or FnIII-2 of anosmin-1. Olfactory co-culture with cells that have been transfected with a plasmid expressing exogenous MUC20 showed that MUC20 may induce olfactory axon to branch. This suggested that MUC20 might play a role as a modulator for anosmin-1 in guiding axon branching and migration.

Identification of Genomic Microdeletions and Microduplications Among First-Trimester Miscarriages: Analysis by Cytogenetic Karyotyping, Microsatellite Genotyping and ArrayCGH. *Y.-X. Zhang[1], W. J.[2], B.-L. Wu[3], E. C. Jenkins[2], W. T. Brown[2], N. Zhong[1,2]* 1) Peking University Center of Medical Genetics, Beijing, China; 2) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 3) Children's Hospital, Harvard University, Boston, MA.

Miscarriage is the spontaneous loss of an embryo or fetus before the 20th week of pregnancy. Mostmiscarriage occurs before the end of first trimester (<13 weeks). Although many risk factors relate to this occurrence, genetic factors play the most important role. Usually chromosomal anomalies, including both numerical and structural abnormalities, underlie the majority of miscarriage etiologies. In this study, we employed a comprehensive approach combining cytogenetic karyotyping, PCR-based genotyping, and microarray-based comparative genomic hybridization (arrayCGH) to analyze chromosomal profiles of 115 first trimester miscarriages of Chinese patients. Seventy cases (61%) were found to have chromosomal anomalies, including 90% numerical and 10% structural. Cytogenetic karyotyping, PCR assay, and arrayCGH identified 78.6% (55/70), 2.9% (2 triploids), and 18.6% (13/70) of the anomalies, respectively. The advantage of using this combination approach is that microsatellite genotyping and arrayCGH can be accomplished in spite of culture failure and maternal cell contamination. In addition, arrayCGH can detect the submicroscopic chromosomal anomalies and gene dosage alterations. In this study, we demonstrated a microdeletion of 108 Kb and microduplications of 300-1,460 Kb.

Repetitive elements flank both breakpoints of a chromosome 3 inversion in a 3-generation family with short stature. *I. Hansmann, U. Dutta, D. Wand, D. Schlote* Inst Human Gen, Med Biol, Martin Luther Univ, Halle/Salle, Germany.

Chromosomal rearrangements are often associated with a specific phenotype and they are a significant cause of human disorders. Cytogenetic mapping is a powerful tool for identification of such disease genes. Here we report a case of short stature in a girl with a karyotype of 46, XX,inv(3)(p24.1q26.1). Cytogenetic analysis had revealed a familial pericentric inversion 3, being heterozygous in the proband, her mother and grand mother. In order to characterize the breakpoint physically; FISH (Fluorescence- in situ-hybridization) analysis with large YAC (Yeast Artificial Chromosome) and BAC (Bacterial Artificial Chromosome) clones were performed. Four p specific YACs and six BAC clones were used as probes for FISH. YAC clone CEPHy904H0787 (1090 kb) gave a split signal on the metaphase chromosomes of the proband. The split signal indicates that the target sequence carries the inversion breakpoint. Further, two BAC clones RP11666G20 and CTD2007B5 were identified spanning the breakpoint region, assigning the breakpoint to 3p24.1 and thus narrowed down the breakpoint region to 97.5 kb. Out of the 15 YACs and 10 BACs selected on the q arm, YAC CEPHy904G07889 (1610 kb) and BAC clone RP11-12N13 showed a split signal assigning the breakpoint to chromosomal band 3q26.1. Using sub cloned fragments of these BACs as well as Long range PCR products as probes the breakpoints were now located within a region of 3 kb and 5.3 kb on p and q respectively. Analysis of the genomic sequence surrounding the inversion breakpoints revealed 30% repetitive nature of the DNA containing LTR33A, MER67C, L2 and MER67D elements on p region and LTR16C, MER20, MLT2B1, LTR1B, simple repeats and low copy repeats on q region. We determine that the breakpoints occurred between these repetitive regions. The presence of these repetitive elements, especially MER and LTR elements at the junction of the breakpoints suggest that the inversion may be the result of these repetitive elements.

Defining phenotypes in quantitative traits: lessons from the study of myopia. *C. L. Simpson[1], P. Hysi[1], C. J. Hammond[2], P. M. Cumberland[1], J. S. Rahi[1]* 1) Ctr Pediatric Epid & Biostat, Inst Child Hlth, London, United Kingdom; 2) Twin Research and Genetic Epidemiology Unit, Kings College London, London.

Recent technological, computational and statistical advances have made study of complex quantitative traits more feasible. However, less attention has been paid to the importance of misclassification of phenotype which might lead to systematic bias and thus erroneous findings in genetic studies. Refractive error is the most common cause of reduced vision worldwide. It is an archetypal complex quantitative trait, although its highly skewed and leptokurtotic distribution poses additional analytical challenges. In epidemiological studies, this trait is frequently analysed as a categorical trait, most commonly by dichotomising into myopia versus normal refractive status, but without consensus on thresholds for classification. The purpose of this study was to investigate whether use of different clinically relevant myopia categories changed the results of linkage and association studies compared to quantitative trait analysis. We used both simulated datasets and real data from on-going genetic investigations of refractive error, including data from the UK Twin Study for linkage and from the 1958 UK Birth Cohort for association analysis. Varying the phenotype definition changed the numbers of affected and unaffected, as expected. In both the simulated and real datasets, the physical position with the highest LOD score or smallest p value varied significantly with the definition of the phenotype. LOD scores of 1 in the quantitative trait were frequently inflated to much more significant scores of 3 or more. Equally LOD scores of 3 or more in the quantitative trait were lower in the dichotomised traits. Using refractive error as an exemplar, we have shown that observed differences in the findings of linkage or association studies of quantitative traits may be attributable to misclassification of the phenotype which can occur when it is converted into a categorical trait using an arbitrary threshold. We suggest that, wherever possible, preference should be given to using the available quantitative trait measurements, especially if the underlying biology supports it.

Who owns those blood spot samples: Revisited. *A. A. A. Saadallah* NLNBS Genetics, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia.

Ethics pertains uniformly to the practice of public health, the execution of population programs, and the conduct of research. Newborn screening as public health service is recently spreading to nations outside the developed world as in the region of the Middle East and North Africa. The population of the MENA region has large family size, high level of inbreeding with consanguinity 25-70% and has a high occurrence of inherited metabolic diseases. Polymerase chain reaction technology renders biobanked tissue as blood samples a locale of interest for new modes of research generating a chain of bioethical and legal dilemmas in the West; as weighing the interests of the society and future patients against the interests of individuals in protecting their rights and integrity through proper consideration of adequate information. The matter of patient property of his or her sampled or excised tissue is held by certain bioethicists as inbuilt dilemma in biomedical research that might escalate legally to reach all the way to the Supreme Court. The issues that are under debate in the West will have to be examined as per the ethical standards, customary practices, and standpoints of the non-western countries. This author will attempt to compare and contrast special characteristics of societies in MENA region in relation to those in the West. Because of these predicted variations, the author claims that it is just a matter of time before healthcare providers and policy makers in MENA will confront matters involving societal ethics, education, legality, and legislation in relation to the newly introduced newborn screening programs, and the genetic testing, and subsequent research that will get tempted to use the millions of blood spots biobanked from the screening programs.

Genetic susceptibility to prostate cancer due to rare mutations in genes in the DNA repair pathway. *Z. Kote-Jarai[1], S. Jugurnauth[1], S. Mulholland[1], M. Guy[1], S. Edwards[1], D. Leongamornlert[1], N. Sodha[2], L. O'Brien[1], R. Wilkinson[1], A. Hall[1], D. Dearnaley[2], K. Muir[3], A. Artitaya Lophatananon[3], The. UKGPSC Collaborators[2], The. British Assoc Urol Surgeons[2], D. Easton[4], R. Eeles[2]* 1) Translational Cancer Genetics Team, The Institute of Cancer Research, Sutton, Surrey, UK; 2) The Royal Marsden NHS Foundation Trust, Sutton, Surrey, UK; 3) Univeristy of Nottingham Medical School, Queens Medical Centre, Nottingham ,UK; 4) CR-UK Genetic Epidemiology Unit, University of Cambridge, Cambridge, UK.

The causes of prostate cancer (PrCa) are still not well understood, but there is strong evidence that a proportion of cases occurs due to a genetic predisposition and the associated disease manifests at a young age of onset and/or in familial clusters. Linkage studies suggest multiple candidate loci, but so far none have identified high-risk PrCa predisposition genes. The first convincing high risk PrCa predisposition gene, BRCA2, was identified using a candidate gene analysis approach which showed that about 2% of men who are diagnosed with PrCa at <55 years have a germline mutation in their *BRCA2* gene. Since *BRCA2* has a direct role in DNA damage repair we are investigating the possibility that other genes in this pathway might be involved in PrCa predisposition. We have screened 6 such genes for germline mutations in blood DNA samples from men with PrCa. For the initial screen, the youngest affected individual was selected from 96 UK PrCa families with at least 3 affected individuals. The candidate genes were analysed by direct sequencing. When deleterious mutations were found, the contribution of the mutation to PrCa was established by screening additional DNA samples from familial and young onset patients. Rare mutations and genetic variants have been found in some genes in the DNA repair pathway and this pathway seems to be important in some instances of PrCa. The relative risks are moderate (about 2-3 fold) however these results might be be important in risk prediction, targeted screening and treatment of such individuals.

Towards Predicting Individual Risk for Age-related Macular Degeneration. *K. Spencer[1], L. M. Olson[1], P. Gallins[3], W. K. Scott[3], N. Schnetz-Boutaud[1], A. Agarwal[1], E. A. Postel[2], M. A. Pericak-Vance[3], J. L. Haines[1]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics, Duke University, Durham, NC; 3) Miami Institute for Human Genomics, University of Miami, Miami, FL.

Though genetic testing is available for many Mendelian disorders, few DNA tests reliably predict an individuals risk for complex genetic diseases. Age-related macular degeneration (AMD), the leading cause of blindness in the elderly, is rare among complex diseases in that evidence for multiple strong genetic and environmental factors has been established. Among these risk factors age, smoking, CFH, Y402H, and the ARMS2/HTRA locus explain a significant portion of disease, raising the possibility for development of a successful predictive algorithm. We used a subset of 352 AMD cases and 184 controls ascertained at Vanderbilt and Duke Universities to create both logistic regression (LR) and decision tree (DT) models of AMD. We then applied these models to an independent dataset of 89 cases and 48 controls also ascertained at Vanderbilt or Duke. The LR and DT agreed in predicted diagnosis ~87% of the time; the remaining 13% of the individuals were not classified. Of those classified, 79% were classified correctly (84.1% of cases and 67.7% of controls). Though these results are very encouraging, applicability of this model to the general population will be important. Efforts to test this algorithm in and independent, diverse cohort are ongoing.

Evidence for association between intron 1 of the follistatin gene *(FST)* and PCOS. *A. Biyasheva[1], R. S. Legro[2], A. Dunaif[1], M. Urbanek[1]* 1) Dept of Medicine, Northwestern University Feinberg School of Medicin, Chicago, IL; 2) Dept of Obstetrics and Gynecology, Pennsylvania State University, Hershey, PA.

Polycystic ovary syndrome (PCOS) is a genetically complex disorder and the most common form of annovulatory infertility among reproductive age women. PCOS is characterized by hyperandrogenemia and irregular menses and is associated with insulin resistance, obesity and increased risk of developing Type 2 diabetes mellitus. In our initial candidate gene screen, the gene encoding follistatin, *FST*, showed the strongest evidence for linkage with PCOS (Urbanek et al 1999 PNAS). However, mutation screening of FST followed by testing for association did not show evidence for association between sequence variation in *FST* and PCOS in our families (Urbanek et 2000 JCEM). Sequence analysis and association studies of *FST* coding variants by other investigators also failed to identify a PCOS-associated variant (Liao et al 2000 Hum Mol Reprod; Jones et al 2007 Hum Mol Reprod). However, we now carried out a broader analysis of the entire genomic region of FST including 20 kb upstream and downstream of the gene and all intronic sequences. An association study of 633 women with PCOS and 574 controls showed strong evidence for association of PCOS with variants in intron 1. The strongest evidence of association was with rs3756498 (?2=14.4, p=0.0001). This study is the largest and most complete analysis of genetic variation of FST in PCOS to date and underscores the importance of screening intronic regions in genetic studies of complex disorders. Follistatin binds and biologically inactivates activin, a member of the TGF superfamily, therefore playing a critical role in gonadal hormone secretion and development and function of the ovary. It is of great interest that FBN3, the gene that encodes fibrillin-3 and is the strongest PCOS candidate gene identified to date, may also act to sequester members of the TGF signaling pathway in a manner analgous to follistatin's sequestration of activin. The fact that the two strongest PCOS susceptibility loci identifed are believed to regulate TGF superfamily signaling, supports a critical role for this pathway in the etiology of PCOS.

Is locus heterogeneity or phenotype misclassification more costly for family-based association analysis? *D. Gordon[1], C. Chen[2], G. Yang[1], S. Buyske[1,2], T. Matise[1], S. Finch[3]* 1) Dept Genetics, Rutgers, State Univ of NJ, Piscataway, NJ; 2) Dept Statistics, Rutgers, State Univ of NJ, Piscataway, NJ; 3) Dept Applied Math Statistics, Stony Brook Univ, Stony Brook, NY.

Background: Both locus heterogeneity and phenotype misclassification can reduce the statistical power to detect association with disease genes in family-based studies. We ask the questions: (1) Is there a way to quantify the sample size increase for a fixed power and significance level due to each phenomenon? (2) Which phenomenon increases sample size more?

Methods: We derive the non-centrality parameter for the transmission disequilibrium test in the presence of locus heterogeneity and phenotype misclassification. This derivation provides an analytic solution to power in the presence of each. We test these calculations with simulation.

Results: The maximum difference between our simulation and analytic results is 0.015, suggesting that our analytic results may be used to design studies of TDT sample size requirements in the presence of locus heterogeneity or phenotype misclassification. Sample size increase is substantially greater for phenotype misclassification than for locus heterogeneity. The relative increase becomes more substantial as the disease prevalence becomes smaller.

Conclusions: While locus heterogeneity is an issue in family-based association analysis, correct classification of phenotype is a relatively more important issue for well-powered studies.

Duplication of ARX and IL1RAPL1 gene in a sex reversal patient with mental retardation. *Y. Wang, C. M. Tuck-Muller, J. E. Martinez, X. Qian, T.-J. Chen* Dept Med Gen, Univ South Alabama, Mobile, AL.

Most of reported cases of interstitial duplications of the short arm of the X chromosome in male have mental retardation and other clinical anomalies. Functional disomy for the dosage sensitive genes within duplication region is believed to play a major role in the phenotype. Most of the reported cases have duplication between Xp22.to pterm. In all of previously reported cases, duplication were determined by G-banding, FISH and linkage analysis. No duplication of individual gene has been directly associated with mental retardation. Here, we reported a sex reversal patient with severe mental retardation due to a duplication at Xp22.11p21.3. The patient is a phenotypic female. At birth, she had ambiguous genitalia and multiple congenital anomalies many, including macrocephaly, left amblyopia and left esotropia. She has developmental delay, seizure, and mental retardation. She has severe behavior problems with a very limit language ability. To precisely determine the duplication regions, high resolution oligo CGH array analysis was performed. The duplication was determined to be about 10 Mb in size from 22.92 Mb to 32.28 mb at hg18. 28 genes are located within this duplication, including about most part of DMD, GK, DAX1, and POLA gene. Two XLMR gene, ARX and IL1RAPL1, also included in the duplication. In a recent report, a smaller duplication, 637 kb, was discovered in two sex reversal sisters. The two sisters has gonadal dysgenesis but do not have mental retardation and other abnormalities. DAX1 and GK genes are included in the small duplication. It is obviously demonstrated that DAX1 cause the sex reversal in the patients of previous report and this report. Genes responsible for the mental retardation in our patient should locate outside the small duplication. Therefore, we hypothesized that ARX or IL1RAPL1 is a dosage sensitive gene. Duplication resulted in mental retardation might be due to the overexpress of either of the two genes. Gene express profile from the patient is under investigation.

Candidate gene association study of vulnerability to develop heroin addiction in African Americans: evidence for association at the glutamate receptor *GRIN2A*. *O. Levran[1], D. Londono[2], K. O'Hara[1], J. Rotrosen[3], P. Casadonte[3], S. Linzy[4], M. Randesi[1], J. Ott[2,5], M. Adelson[4,1], MJ. Kreek[1]* 1) The Laboratory of the Biology of Addictive Diseases , Rockefeller University, New York, NY; 2) The Laboratory of Statistical Genetics, The Rockefeller University, New York, NY; 3) VA New York Harbor Healthcare System and NYU School of Medicine New York, NY; 4) Dr. Miriam and Sheldon G. Adelson Clinic for Drug Abuse Treatment and Research, Las Vegas, NV; 5) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China.

Heroin addiction (HA) is a chronic complex disease with a substantial genetic contribution. This study was designed to identify gene variants predisposing to or protecting from HA in African Americans, with emphasis on candidate genes for addiction. We have performed a case-control association analysis by screening 1350 variants in 130 genes. The sample consisted of 202 former severe heroin addicts in methadone treatment and 167 healthy controls with no history of drug abuse. Single-SNP, haplotype and multi-SNP genotype patterns analyses were performed. Seventeen SNPs, showed the strongest evidence for association with HA (nominal $P < 0.008$ for allelic test). These SNPs are from genes encoding several receptors: adrenergic (*ADRA1A*), arginine vasopressin (*AVPR1A*), cholinergic (*CHRM2*), dopamine (*DRD1*), GABA-A (*GABRB3*), glutamate (*GRIN2A*), and serotonin (*HTR3A*), as well as alcohol dehydrogenase (*ADH7*), glutamic acid decarboxylase (*GAD1* and *GAD2*), the nucleoside transporter (*SLC29A1*), and diazepam binding inhibitor (*DBI*). The most significant result for haplotype association analysis was for *GRIN2A* (nominal $P = 0.000055$, corrected for multiple testing $P = 0.058$). This study corroborates few reported associations with alcohol and drug dependence as well as anxiety disorders, and extends the list of variants with protective and susceptibility effects on heroin addiction, which may be African-specific. Further studies will be necessary to confirm these associations and to elucidate the roles of these variants in drug abuse vulnerability.

Polymorphic *Alu* Insertions and the Genetic Structure of Population Groups from Punjab, Northwest India. *A. Bhanwer, A. Kumar, K. Matharoo, S. Sharma* Human Genetics, Guru Nanak Dev University, Punjab, India.

India presents with a pool of genetically and culturally diverse populations. The Punjab region of India has an extreme importance in understanding the peopling of India as it acted as a corridor to the foreign invaders from Eurasia and Central Asia. Keeping in mind the whole scenario, the present study was designed to explore the genetic diversities and affinities among the seven major ethnic groups: Brahmins, Jat Sikhs, Banias, Rajputs, Sainis, Gujjars and Harijans, from the region. A total of 276 individuals belonging to these population groups were analysed for five *Alu* Insertion/Deletion loci (ACE, PV 92, APO, D1, FXIIIB).

The average (over studied 5 loci) observed heterozygosity was 0.39 in Brahmins, 0.37 in Jat Sikhs, 0.38 in Banias, 0.32 in Rajputs, 0.42 in Sainis, 0.42 in Gujjars and 0.34 in Harijans. The average gene diversity values were 0.44, 0.41, 0.39, 0.41, 0.45, 0.38 and 0.41, respectively for Brahmins, Jat Sikhs, Banias, Rajputs, Sainis, Gujjars and Harijans.

It was observed that each *Alu* insertion was highly polymorphic in all the groups except for *Alu* APO. In Gujjars, the deletion allele for the *Alu* APO was found to be absent while the same revealed low level of polymorphism among the other studied endogamous groups. The overall study favours a deep in time inflow of genes to the region and then their expansion. This was followed by further split of population groups into largely isolated (endogamous) population groups. It is suggested that the structuring of the Indian population groups as various endogamous groups might have occurred within the Indian subcontinent without major influence from any external population source.

Examination of Candidate Genes in Age-Related Macular Degeneration. *L. M. Olson[1], K. Spencer[1], P. Gallins[3], W. K. Scott[3], N. Schnetz-Boutaud[1], A. Agarwal[1], E. A. Postel[2], M. A. Pericak-Vance[3], J. L. Haines[1]* 1) Dept Molec Phys and Biophysics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Duke Eye Ctr, Duke University, Durham, NC; 3) Institute for Human Genomics, University of Miami, Miami, FL.

Age-related macular degeneration (AMD) is a complex genetic disorder of the central retina characterized by large soft drusen, geographic atrophy, and/or choroidal neovascularization. Multiple pre-disposing genetic risk loci (CFH , ARMS2/HTRA1, C3) and protective loci (CFHR3/CFHR1 deletion, CFB/CC2) have been identified. However, the additional susceptibility loci with smaller marginal or interactive effects exist. We selected as candidate genes the complement C3 receptor subunit 3 (C3RA), pigment epithelium-derived factor (PEDF), and toll-like receptor 3 (TLR3) based on biological plausibility and/or to replicate previously proposed associations. We tested polymorphisms in these genes in two independent Caucasian datasets: a family-based dataset of 144 multiplex and 79 singleton families, and a dataset of 715 cases and 285 controls. We found no evidence of association for PEDF M72T in either dataset (p0.2 for both). A SNP in C3RA was weakly associated in the family-based dataset (p=0.03), but this effect was not replicated in the case-control dataset (allelic ^{2} p=0.25). Given the known association of C3 R102G with AMD, we tested for a C3-C3RA interaction using likelihood ratio testing, and observed weak evidence for interaction (p=0.07). A SNP in TLR3 was modestly associated in the family dataset (PDTgeno=0.01), and a neighboring SNP in linkage disequilibrium was nominally associated in the case-control dataset (p=0.01). However, after adjusting for known AMD susceptibility factors using logistic regression, neither the effects of C3RA nor TLR3 remained significant. None of the results survived severe or moderate correction for the number of SNPs tested within each gene. We did not detect strong evidence of association in any of the 3 candidates suggesting that it is unlikely that variation within these genes makes a large contribution to the etiology of AMD.

CAG repeat length variation on the background of the POLG gene SNPs. *B. Malyarchuk[1], M. Perkova[1], M. Derenko[1], T. Grzybowski[2]* 1) Institute of Biological Problems of the North, Magadan, Russian Federation; 2) The Nicolaus Copernicus University, Ludwik Rydygier Collegium Medicum, Institute of Forensic Medicine, Bydgoszcz, Poland.

The aim of our study was to investigate the pattern of distribution of the CAG repeats in the POLG gene genotypes and haplotypes. For this purposes, we have analyzed two linked POLG SNPs, in addition to the previously obtained data on CAG repeat length variation in populations of Russians (n=50) and Buryats (n=94) (see Table, where W is 10-CAG repeat, M is not10-CAG repeat, SNP1 is rs2238296, SNP2 is rs758130). Linkage disequilibrium analysis showed almost complete linkage of alleles for these loci in both populations.

POLG genotype and haplotype frequencies in Russians and Buryats

CAG	WW	WW	WW	WW	WW	WW	WM	WM	WM	MM	MM	W	W	W	M	M
SNP1	TT	TC	CC	TT	TC	TT	TT	TC	TT	TT	TC	T	T	C	T	C
SNP2	TT	TC	CC	TC	CC	CC	TT	TC	TC	TT	TC	T	C	C	T	C
RUS	0.22	0.34	0.14	0	0.06	0	0.16	0.02	0.02	0.02	0.02	0.47	0.04	0.35	0.13	0.01
BUR	0.29	0.43	0.11	0.02	0.04	0.02	0.05	0.04	0	0	0	0.54	0.05	0.36	0.05	0

Five haplotypes were either directly observed or inferred using the EM and ELB algorithms. Significant predominance of not-10 CAG alleles was found on TT haplotype. Analysis of nucleotide sequences of the POLG gene haplotypes in humans and chimpanzee has shown that two human haplotypes TT and CC could evolve separately for a long time, with a coalescence time of approximately 1.3 millions of years between them. It is important to note that CAG-repeat instability is associated almost exclusively with younger human haplotype TT. This work was supported by the grant from the FEB RAS (06-3-A-06-176).

Effect of vitamin A deficiency on the epigenomics of male germ cells. *C. N. Boucheron, V. Baxendale, O. M. Rennert, W. Y. Chan* NICHD/LCG/SDG, NIH, Bethesda, MD.

Vitamin A and its derivatives (the retinoids) participate in many physiological processes including vision, cellular differentiation and reproduction. The vitamin A actions in cells occur via the binding of its active metabolite, the retinoic acid, on its nuclear receptors (RARs and RXRs), which in turn regulate the expression of numerous genes. Vitamin A deficiency (VAD) is the leading cause of preventable blindness in children and a factor that increases the risk for severe infections. In addition, VAD affects the process of spermatogenesis, which is the subject of our present study. Spermatogenesis is a highly regulated process of differentiation and complex morphologic alterations that, in the postnatal testis, leads to the formation of sperm in the seminiferous epithelium. VAD induces early cessation of spermatogenesis, characterized by degeneration of all meiotic germ cells, leading to seminiferous tubules containing mostly type A spermatogonia (considered as the stem cells of spermatogenesis) and Sertoli cells. In this study, we want to define the molecular basis of the effect of VAD-induced arrest of spermatogenesis. Our experimental protocol (8-12 weeks of VAD) will allow us to perform transcriptome analysis (SAGE, microarray, RT-PCR), and methylation analysis (tiling array), to compare expression and epigenomic profiles between normal and VAD testis. We hope to identify genes responsible for the effect of VAD on spermatogenesis. *This research is supported by the Intramural Research Program of the NIH, NICHD.*.

-459C>T point mutation in 5' non-coding region of human JGB1 gene is linked to Charcot-Marie-Tooth neuropathy but not -713G>A. *M. Li[1], T. Cheng[2], P. Ho[2], Y. Song[1], S. Ho[2,3]* 1) Department of Biochemistry, University of Hong Kong; 2) Division of Neurology, University Department of Medicine, University of Hong Kong; 3) Research Center on Heart, Brain, Hormone and Healthy Aging, University of Hong Kong.

Charcot-Marie-Tooth (CMT) neuropathy is inherited with high genetic and clinical heterogeneity. The X-linked form (CMT-X) is linked to mutations in GJB1 gene. In order to explore more underling genes and mutations responsible for CMT disease, we conducted genome-wide linkage scan in two CMT pedigrees and mutation screening among subjects from both pedigrees as well as a control group. Subjects of the two pedigrees were genotyped by high-throughput technologies of Illumina and Affymetrix. Gene chip data were integrated and pre-processed by our tool, IGG, for genome-wide linkage analysis. Multipoint genome-wide linkage scan was performed by a 64-bit program, Merlin on a SUN Solaris Operating System. Both non-parametric and parametric models were tried in the linkage scan. A bioinformatics tool, Endeavour, was used to predict and prioritize the candidate genes within the region(s) from our linkage scan for follow-up mutation screening. Genomic DNA was extracted from peripheral blood from subjects by Qiagen Extraction kit according to protocol (Valencia, CA), and tested for mutations in the GJB1 gene by Applied Biosystems 3730xl DNA analyzer. The genome-wide linkage scan in two pedigrees revealed a candidate region, 2.5 cM or so at Chromosome Xq13.1. The total maximum LOD score is 5.68. The GJB1 gene, a known CMT-X gene was found in this region. A genomic variant, -459C>T identified in 5-untranslated region of exon 1 (numbering in relation to the translational [ATG] start codon) of GJB1 was co-segregated with CMT-patients in our pedigrees. But another variant -713G>A of this gene was found in both affected and unaffected in our study, which is inconsistent with a published report in a Taiwanese family. Our results support -459C>T but not -713G>A variant as a causative mutation in CMT-X, which can help clarify the causal mutations of CMT-X in the non-protein coding region of GJB1.

Haplotype analysis of *MHC2TA* and *KIAA0350* on chromosome 16p13 and risk for rheumatoid arthritis (RA). *P. G. Bronson[1], P. P. Ramsay[1], M. F. Seldin[2], P. K. Gregersen[3], L. A. Criswell[4], L. F. Barcellos[1]* 1) Univ of California, Berkeley, CA; 2) Univ of California, Davis, CA; 3) Feinstein Institute for Medical Research, NY; 4) Univ of California, San Francisco, CA.

An association between MHC genes, particularly those within the class II HLA region, and RA is well established, and accounts for ~30% of the genetic component for this disease. The identification of additional RA loci is critical to further our understanding of disease pathogenesis. Two candidate RA genes were chosen for this study based on strong hypotheses: (1) the MHC class II transactivator gene (*MHC2TA*), the most important transcription factor regulating genes required for class II MHC-restricted antigen presentation, and (2) the C-type lectin domain family 16, member A gene (*KIAA0350*), a putative immunoreceptor recently identified as a susceptibility locus for type 1 diabetes (T1D). Both loci are located together on 16p13, a chromosomal region previously implicated in RA linkage studies. Our study sample was comprised of 682 anti-CCP positive RA cases and 752 controls (90% N. European ancestry). We investigated 12 haplotype blocks encompassing 5 *MHC2TA* SNPs and 61 *KIAA0350* SNPs. We used the *haplo.stats* R package to compute MLE of haplotype probabilities with the EM algorithm and score statistics to test for association. Analyses were restricted to haplotypes with frequencies 5%. No association between RA and variation within *MHC2TA* was observed. However, the *KIAA0350* rs2903692-rs17673553 haplotype was associated with RA (global P=0.02); specifically, the *AG* haplotype was over-represented in cases (25.9%) vs. controls (21.5%) (OR=1.3, 95% CI=1.1-1.5, *P*=0.006). Our results suggest, for the first time, that genetic variation in *KIAA0350* contributes to risk for RA. Further studies are warranted to replicate this important result, and to investigate the possibility that *KIAA0350* may confer susceptibility to other autoimmune diseases.

Audioprofile-directed screening identifies novel mutations in human autosomal dominant deafness genes at the DFNA2 and DFNA9 loci. *M. S. Hildebrand[1], D. Tack[2], S. J. McMordie[1], A. DeLuca[2], I. Hur[2], C. Nishimura[1], P. Huygen[3], T. L. Casavant[2], R. J. H. Smith[1]* 1) Department of Otolaryngology, University of Iowa, Iowa City, IA; 2) Department of Electrical and Computer Engineering, University of Iowa, Iowa City, Iowa 52242, USA; 3) Department of Otorhinolaryngology, Radboud University Nijmegen Medical Centre, 6500 HB Nijmegen, The Netherlands.

Rationale: Gene identification in small families segregating autosomal dominant sensorineural hearing loss presents a significant challenge. To address this challenge, we have developed a machine learning based software tool, AudioGene v2.0, to prioritize candidate genes for mutation screening based on audioprofiling. Methods: We analyzed audiometric data from a cohort of 77 American families with high frequency autosomal dominant sensorineural hearing loss. Those families predicted to have a DFNA2 or DFNA9 audioprofile by AudioGene v2.0 were screened for mutations in the KCNQ4 or COCH genes respectively. Results: Two novel missense mutations and a stop mutation were detected in KCNQ4 in three American families predicted to have DFNA2-related deafness for a positive predictive value of 6.3%. The false negative rate was 0%. The missense mutations were located in the channel pore region and the stop mutation was in transmembrane domain S5. The latter is the first DFNA2-causing stop mutation reported in KCNQ4. In one DFNA9-predicted family a known pathogenic missense mutation was detected in the LCCL domain for a positive predictive value of 14.3%. In addition to hearing impairment, affected members of the DFNA9 family also exhibited vestibular dysfunction including a rare inner ear abnormality, superior semicircular canal dehiscence. Conclusions: Our data suggest: (1) mutations at the DFNA2 and DFNA9 loci are a common cause of high frequency, autosomal dominant hearing impairment in the American population; and, (2) that AudioGene audioprofile analysis can effectively prioritize genes for mutation detection in small families segregating autosomal dominant sensorineural hearing loss. AudioGene software will be made freely available to clinicians and researchers once it has been fullly validated.

Genome-wide association study identifies a susceptibility variant for narcolepsy. *T. Miyagawa[1], M. Kawashima[1,2], N. Nishida[1], J. Ohashi[1], R. Kimura[1,3], A. Fujimoto[1], M. Shimada[1], S. Morishita[4], T. Shigeta[4], L. Lin[2], SC. Hong[5], J. Faraco[2], YK. Shin[5], JH. Jeong[5], Y. Okazaki[6], S. Tsuji[7,8], M. Honda[9,10], Y. Honda[10], E. Mignot[2,11], K. Tokunaga[1]* 1) Dept of Human Genetics, Grad Sch of Med, Univ of Tokyo; 2) Center for Narcolepsy, Stanford Univ Sch of Med; 3) Dept of Forensic Med, Tokai Univ Sch of Med; 4) Dept of Computational Biology, Grad Sch of Frontier Sciences, Univ of Tokyo; 5) Dept of Neuropsychiatry, St. Vincents Hosp, The Catholic Univ of Korea; 6) Tokyo Metropolitan Matsuzawa Hosp; 7) Dept of Neurology, Grad Sch of Med, Univ of Tokyo; 8) Center for Integrated Brain Medical Science, Grad Sch of Med, Univ of Tokyo; 9) Dept of Sleep Disorders Research, Tokyo Inst of Psychiatry; 10) Japan Somnology Center, Neuropsychiatric Research Inst; 11) Howard Hughes Medical Inst, Stanford Univ Sch of Med.

Narcolepsy, a sleep disorder characterized by sleepiness, cataplexy and REM sleep abnormalities, is known to be strongly associated with human leukocyte antigen (HLA). However, multiple susceptibility genes in addition to HLA must also participated in the onset, since narcolepsy is obviously a complex disease. We conducted a genome-wide association study using 500K SNPs in 222 Japanese narcoleptics and 389 Japanese controls, with the replication study of top hits in 159 Japanese narcoleptics and 190 Japanese controls, then followed by the testing of 424 Koreans, 785 Caucasians and 184 African Americans. A SNP was significantly associated with narcolepsy in Japanese samples (odds ratio = 1.79, $P = 4.4 \times 10^{-7}$) and Korean samples (odds ratio = 1.40, $P = 0.03$). In Caucasian and African American samples, the same tendency was observed, although the frequency of the risk allele was much lower. The meta-analysis of the four populations gave $P = 5.9 \times 10^{-8}$, with an odds ratio of 1.63. The LD block including this SNP encompassed two genes. Furthermore, real-time quantitative RT-PCR assays showed that the transcription levels of these two genes were significantly lower in individuals possessing the risk allele. The present findings indicate that a polymorphism regulating expression levels of these two genes is a determinant of susceptibility to narcolepsy.

A novel sarcoidosis disease gene with potential relevance for related granulomatous inflammatory phenotypes identified by a genome-wide association study. *S. Hofmann[1], A. Franke[1], A. Fischer[1], G. Jacobs[1], K. Gaede[2], J. Mueller-Quernheim[3], M. Schuermann[4], M. Nothnagel[5], P. Rosenstiel[1], S. Schreiber[1]* 1) Institute of Clinical Molecular Biology, Christian Albrechts University, Kiel, Germany; 2) Leibniz Research Center Borstel, Germany; 3) Medical University Hospital Freiburg, Germany; 4) Institute of Human Genetic, University of Lübeck, Germany; 5) Institute of Medical Informatics and Statistics, Christian Albrechts University, Kiel, Germany.

Sarcoidosis is a complex chronic inflammatory disorder with predominant manifestation in the lung. In the first genome-wide association study (440,000 SNPs) of this disease, comprising 499 German sarcoidosis patients and 490 controls, we detected a series of genetic associations, the most prominent being with the *SARC2** gene. Validation in an independent sample (1,649 cases, 1,832 controls) confirmed the association (SNP rs00*: $P=3.0\times10^{-13}$, rs01*: $P=1.0\times10^{-5}$, allele-based test). Extensive fine mapping located the association signal to a region between exon 5 and exon 14 of *SARC2*. A common non-synonymous SNP (rs02*, TC, p.Arg00*Cys) was found to be strongly associated with sarcoidosis. The GWAS lead SNP and additional risk variants in the region (rs03*, rs04*, rs05*) were in strong linkage disequilibrium with rs02. Sequencing of all exons confirmed rs02 as a putative causative variant and revealed eight novel mutations. The SARC2 protein has complex and essential functions in several biological pathways, including apoptosis and proliferation. We also examined the association of *SARC2* with other granulomatous diseases (e.g. Crohn disease). Data suggest a potential relevance of *SARC2* as a risk gene for phenotypic related disorders and indicate it as a susceptibility locus of general importance. *anonymized, the gene name and SNP identification numbers will be present at the meeting ·

SACGHS policy recommendations for pharmacogenomics and the oversight of genetic testing. *A. Ferreira-Gonzalez, The Secretary's Advisory Committee on Genetics, Health, and Society* Virginia Commonwealth University, Richmond, VA.

The Secretarys Advisory Committee on Genetics, Health, and Society (SACGHS) has completed two reports that provide recommendations for pharmacogenomics (PGx) and the oversight of genetic testing. The pharmacogenomic report explores the opportunities and challenges associated with PGx research, development of PGx applications, and integration of these applications into clinical practice and public health. To realize the potential of PGx, SACGHS recommendations call for (1) adapting clinical trial designs and data collection tools to enhance assessment of PGx diagnostics and therapies, including sustained data collection to inform clinical practice, payment, and healthcare policy; (2) supporting regulation of PGx products that fosters innovation while ensuring patient safety and improved outcomes; (3) compiling evidence of the clinical utility of PGx testing to obtain coverage and adequate reimbursement of PGx technologies; (4) building a health information technology infrastructure that supports PGx research and PGx-based diagnostic testing, treatment decisions, and surveillance; (5) educating and training clinicians to ensure their competence with PGx technologies; and (6) ensuring equitable patient access to PGx technologies. For the oversight report, SACGHS used a broad interpretation of oversight to include not only federal and state governments and agencies, but also standard-setting organizations, knowledge-generating agencies, public and private sector payers, professional societies, health providers, patients, and consumers. Key SACGHS recommendations include (1) required proficiency testing (PT) for all nonwaived laboratory tests for which PT products are available, (2) Food and Drug Administration involvement to address gaps in the oversight of the clinical validity of genetic tests, (3) mandatory registration of all laboratory tests, (4) creation of a public-private partnership to evaluate the clinical utility and the health impact of genetic tests, and (5) identification of genetic education needs and development of clinical decision support systems. Both SACGHS reports are available at http://www4.od.nih.gov/oba/sacghs.htm.

A Sensitive Functional Assay Reveals Frequent Loss of Genomic Imprinting in Human Placenta. *J. G. Wetmur, L. Lambertini, A. I. Diplas, M.-J. Lee, R. Sperling, J. Chen* Mount Sinai Sch Medicine, New York, NY.

Loss of imprinting (LOI) is the gain of expression from the silent allele of an imprinted gene normally expressed from only one parental copy. LOI has been associated with neurodevelopmental disorders and reproductive abnormalities. The mechanisms of imprinting are varied, with DNA methylation representing only one. We have developed a functional transcriptional assay for LOI that is not limited to a single mechanism of imprinting. The method employs allele-specific PCR analysis of RT-PCR products containing common readout polymorphisms. With this method, we are able to measure LOI at the sensitivity of 1%. The method has been applied to measurement of LOI in human placentas. We found that RNA was stable in placentas stored for more than 1 hour at 4C following delivery. We analyzed a test panel of 26 genes known to be imprinted in the human genome. We found that 18 genes were expressed in placenta. Fourteen of the 18 expressed genes contained common readout polymorphisms in the transcripts with a minor allele frequency >20%. We found that 5 of the 14 genes were not imprinted in placenta. Using the remaining 9 genes, we examined 93 heterozygosities in 27 samples. The range of LOI was 0% - 96%. Among the 93 heterozygosities, we found 23 examples (25%) had LOI >3% and 8 examples (9%) had LOI 1 - 3%. Our results indicate that LOI is common in human placentas. Because LOI in placenta is common, it may be an important new biomarker for influences on prenatal epigenetics. This work was supported by grants NO1 AI50028, U19 AI06231, and P01 ES09584 from the National Institutes of Health and R827039 from the Environmental Protection Administration.

Spondylocheiro Dysplastic Form of the Ehlers-Danlos Syndrome - A Novel Recessive Entity Caused by Mutations in the Zinc Transporter Gene SLC39A13. *C. Giunta[1], NH. Elçioglu[2], B. Albrecht[3], G. Eich[4], C. Bürer-Chambaz[1], AR. Janecke[5], H. Yeowell[6], M. Weis[7], DR. Eyre[7], M. Kraenzlin[8], B. Steinmann[1]* 1) Division of Metabolism and Molecular Pediatrics, University Children's Hospital Zurich, Switzerland; 2) Department of Pediatric Genetics, Marmara University Hospital Istanbul, Turkey; 3) Institute of Human Genetics, University Duisburg-Essen, Germany; 4) Pediatric Radiology, Aarau; 5) Division of Clinical Genetics, Medical University, Innsbruck; 6) Division of Dermatology, Durham, NC; 7) Department of Orthopaedics, Seattle, WA; 8) Division of Endocrinology and Diabetes, Basel.

We present 6 patients from 2 consanguineous families who show EDS-like features and radiological findings of a mild skeletal dysplasia. The EDS-like findings comprise hyperelastic, thin, and bruisable skin; hypermobility of the small joints with a tendency to contractures; protuberant eyes with bluish sclerae; hands with finely wrinkled palms, atrophy of the thenar muscles and tapering fingers. The skeletal dysplasia comprises platyspondyly with moderate short stature, osteopenia, and widened metaphyses. Patients have an increased ratio of total urinary pyridinolines, lysyl pyridinoline / hydroxylysyl pyridinoline, of ~1 as opposed to ~ 6 in EDS VI or ~ 0.2 in controls. Lysyl and prolyl residues of collagens were underhydroxylated despite normal lysyl- and prolyl 4-hydroxylase activities in vitro, and underhydroxylation was a generalized process as shown by MS of the 1(I)- and 2(I)-chain derived peptides of collagen type I and involved at least collagen types I and II. Linkage and sequence analyses identified in all patients a homozygous c.483_491del9 mutation in SLC39A13 that encodes for the zinc transporter SLC39A13. We hypothesize that an increased Zn^{2+} content inside the ER competes with Fe^{2+}, a cofactor which is necessary for hydroxylation of lysyl and prolyl residues, and thus explains the biochemical findings. These data suggest a novel entity which we have designated spondylocheiro dysplastic form of EDS (SCD-EDS) to indicate a generalized skeletal dysplasia involving mainly the spine (spondylo) and striking clinical abnormalities of the hands (cheiro) in addition to the EDS-like features.

Pharmacogenetic analysis of CTLA4 gene polymorphisms and response to tremelimumab in patients with advanced melanoma. *L. Wood[1], J. Richmond[1], F. Gao[2], C. Bulanhagui[3], M. Penny[4]* 1) Pharmacogenomics, Pfizer, Groton, CT; 2) Global Statistics, Pfizer, New London, CT; 3) Oncology, Pfizer, New London, CT; 4) Molecular Medicine, Pfizer, New London, CT.

Background: Tremelimumab is a fully-human, immune-enhancing, monoclonal antibody targeted against CTLA4 that is in clinical development for the treatment of solid tumors. In recognition of the fact that variation in the drug target or other proteins related to tumor immunity may influence a patients response to tremelimumab, pharmacogenomic analysis has been incorporated into the clinical development plan. Methods: Three polymorphisms in the CTLA4 gene, a promoter (-318 C/T), an exon 1 (+49 A/G) and an intergenic (CT60) polymorphism, were genotyped in 268 patients from two tremelimumab trials. All patients had advanced melanoma that was refractory prior to treatment. Tremelimumab was administered at varying dosing regimes. Genotypes were correlated with clinical efficacy endpoints including progressive disease, objective tumor response, and survival at one year, as well as safety endpoints related to diarrhea and severity of diarrhea. Correlations were investigated via Fishers exact tests for contingency tables as well as through logistic regression assessing the interaction effect of sex and genotype. This analysis was powered to detect a relative risk in the >2 range. Results: The two studies were analyzed separately. Allele frequencies were not significantly different from published data, and no significant deviations from Hardy Weinberg Equilibrium were observed ($P < .05$). Data presented shows that no consistent trends were observed between any of the three CTLA4 genotypes and any clinical endpoint tested. Conclusions: No pharmacogenetic effect between the CTLA4 genotypes tested and response to tremelimumab was observed in these initial studies.

Dysregulation of nitric oxide synthesis from endogenous cellular arginine production underlies the complex phenotype in argininosuccinate lyase deficiency and supports metabolite channeling as basis of the Arginine Paradox. *A. Erez[1], Y. Chen[1], N. Bryan[2], J. Marini[3], O. Shchelockhov[1], N. Brunetti-Pierri[1], W. OBrien[1], W. Mitch[4], B. Lee[1,5]* 1) Dept Human Molecular Genetics, Baylor Col Medicine, Houston, TX; 2) Institute of Molecular Medicine The University of Texas - Houston Health Science Center; 3) Department of Pediatrics/ Nutrition USDA/ARS Children's Nutrition Research Center, BCM; 4) Gordon A. Cain Chair in Nephrology Baylor College of Medicine; 5) Howard Hughes Medical Institute.

Argininosuccinic aciduria (ASA) results from enzymatic deficiency of argininosuccinate lyase (ASL), which generates arginine, the precursor of nitric oxide (NO), from ASA. While patients may present with hyperammonemia, their complex natural history reflect other pathophysiologic processes. ASA is a unique genetic model that provides an opportunity to assess the different contributors to NO synthesis and may help explain the basis of the Arginine Paradox in NO biology. We first performed stable isotopic measurement of the flux of arginine to citrulline as a surrogate of whole body NO production. We found that ASA subjects showed significantly decreased NO production. To assess the consequences of ASL deficiency; we generated a hypomorphic mouse model of ASL by introducing a floxed/Neo+ allele. These mice have decreased Asl activity and unlike other models of urea cycle deficiency, they survive weaning exhibiting significant growth restriction, hypertension, liver dysfunction and die around 4 weeks of age. These clinical features could reflect deficiency of NO production. In fact, Asl deficient mice show significantly decreased protein nitrosylation indicating dramatic NO deficiency. These human and mouse genetic data support dysregulation of NO production as a critical pathophysiological process in urea cycle disorders and potentially secondary disorders of ureagenesis, proving that intracellular metabolite channeling of UC intermediates is a major mechanism for directly regulating NO production. From a therapeutic perspective, these data suggest that supplementation of UC intermediates may be more efficacious in a variety of disease processes attributed to NO dysregulation.

Development of genome-wide SNP panel (6.3k) for human identification using tagging approach. *S. Guha[1,2], G. Jianye[2], R. Chakraborty[2]* 1) Division of Molecular Genetics, Department of Pediatrics, Columbia University Medical Center, NY, USA; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, OH, USA.

Genome wide panels of Single Nucleotide Polymorphisms (SNPs), studied in four HapMap populations, yielded an wealth of information that are currently used primarily for detecting genes underlying complex disease phenotypes and quantitative phenotypes. Though in principle SNPs offer certain operational advantages over other types of genomic markers (e.g., STRs) for use in human identification, the developed panels of SNP markers for use in DNA forensics are of limited value because collectively they have limited power of discrimination, and do not have genome wide coverage. The main hindrance of developing genome wide panel of SNPs for human identification is the linkage disequilibria (LD) that exist between closely linked SNPs throughout the genome. High LD results in redundancy of genotypic information, and consequently loss in collective power of discrimination. However, the concept of tagged SNPs, employed in disease-gene association studies, can ameliorate this problem. In this computational study with the 500k genome wide dataset of four HapMap populations, we have used this concept that helped in eliminating SNPs that are of high LD with other informative ones. This yielded a panel of 6,354 highly informative SNPs. Being devoid of high LD between them (avg. r^2 0.05); they are collectively highly informative for human identification and relatedness between individuals. Further, this panel constitutes SNPs that are individually most informative i.e., small differences of frequencies of alternative alleles (avg. 0.20) and high heterozygosity (avg. H 0.47) as well as have low levels of allele frequency differences across the HapMap populations (avg. F_{ST} 0.03). The match probabilities of this panel for all four HapMap populations are 0.00. Studies of robustness of their genotypes in forensic samples and surveying their allele frequencies in world wide representative populations should provide a genome wide tagged set of SNPs for wider forensic applications.

Database Indexing for Production MegaBLAST Searches of the Human and Mouse Genomes. *A. A. Schaffer, A. Morgulis, G. Coulouris, Y. Raytselis, T. L. Madden, R. Agarwala* National Center for Biotechnology Information; National Institutes of Health; Department of Health and Human Services; Bethesda, MD 20894 USA.

The BLAST software package for sequence comparison speeds up homology search by preprocessing a query sequence into a lookup table. Numerous research studies have suggested that preprocessing the database instead would give better performance. However, production usage of sequence comparison methods that preprocess the database has been limited to programs such as BLAT and SSAHA that are designed to find matches when query and database subsequences are highly similar. We developed a new version of the MegaBLAST module of BLAST that does the initial phase of finding short seeds for matches by searching a database index. We also developed a program makembindex that preprocesses the database into a data structure for rapid seed searching. We show that the new ``indexed MegaBLAST'' is faster than the ``non-indexed'' version for most practical uses. We show that indexed MegaBLAST is faster than miBLAST, another implementation of BLAST nucleotide searching with a preprocessed database, for most of the 200 queries we tested. Indexed MegaBLAST is now used at NCBI for production nucleotide searches of the human and mouse genomes, handling over 13,000 user queries on typical weekdays. To deploy indexed MegaBLAST as part of NCBI's Web BLAST service, the storage of databases and the queueing mechanism were modified, so that some machines are now dedicated to serving queries for a specific database. The response time for such Web queries is now faster than it was when each computer handled queries for multiple databases. Linux command-line executables for blastn and makembindex, documentation, and some query sets used to carry out the tests we did are available in the directory: ftp://ftp.ncbi.nlm.nih.gov/agarwala/indexed_megablast.

INF- +874 Polymorphism in the first intron of the human INF- gene and kidney allograft outcome. *J. crispim[1,2, 3], I. Wastowski[1], C. Mendes-Júnior[1], C. Bassi[2], E. Castelli[2], R. Costa[4], L. Saber[5], F. Oliveira[3], P. Freire[3], E. Donadi[1,2]* 1) Department of Biochemistry and, University of São Paulo, Ribeirão Preto, SP, Brazil, SP; 2) Division of Clinical Immunology, University of São Paulo, Ribeirão Preto, SP, Brazil; 3) Department of Clinical Analysis; School of Pharmaceutical Sciences, University Federal Rio Grande of Norte (UFRN) Brazil; 4) Department of Pathology, FMRP-USP, University of São Paulo, Ribeirão Preto, Brazil, SPl; 5) Renal Transplant Unity, Clinical Nephrology, FMRP-USP, Brazil.

The aim of this study was to assess the effect of this genetics allelic variation on acute rejection or chronic allograft nephropathy after kidney transplantation. In order to determine a possible correlation between the INF- +874 polymorphism and kidney allograft outcome. After Human Research Ethics Committee Approval. we isolated genomic DNA from 74 patients who had received isolated kidney allografts, and we classified the 74 specimens into two groups: grafts presenting Banff features of rejection (RG) and a non-rejection (NRG) group and compared them with a control group of 163 healthy subjects. The INF- +874 polymorphism was genotyped in all groups. There was no significant difference in allelic and genotype frequencies of INF- + 874 polymorphisms between normal controls and kidney transplant patients. In the rejection group, the homozygous genotype T/T ($p = 0.0118$) was significantly increased in the group with acute rejection compared with the healthy control group. Similarly, considering only patients with chronic allograft nephropathy, the homozygous genotype T/T ($p = 0.0067$) significantly increased in the chronic allograft nephropathy group with compared with the healthy control group. Still, the analysis of the rejection group indicated a significant increased homozygous genotype T/T ($p=0.0061$) when compared with the control group. Homozygous genotype T/T that have been associated with increased level de INF- is associated with a high number of acute rejection and chronic allograft nephropathy episodes after transplantation.

FCG receptor IIB and IIIB polymorphisms and susceptibility to systemic lupus erythematosus and lupus nephritis : A meta-analysis. *Y. Lee, G. Song* Division of Rheumatology, Korea Univeristy, Seoul, Seoul, Korea.

Objective. The aim of this study was to explore whether polymorphisms of the FCG receptors (FCGRs) IIB T/I232 and FCGRIIIB NA1/NA2 confer susceptibility to systemic lupus erythematosus (SLE) and lupus nephritis (LN). Methods. The authors conducted a meta-analysis on associations between the FCGRIIB T/I232 and FCGRIIIB NA1/NA2 polymorphisms and SLE and LN susceptibility as determined using 1) allele contrast, 2) recessive, 3) dominant models, and 4) contrast of homozygotes, using fixed and random effects models. Results. A total of 16 separate comparisons were considered, involving 9 Asian, 6 European, and 1 African population samples, consisting of 2,887 SLE patients and 3,105 controls. Meta-analysis of the FCGRIIB T/I232 polymorphism revealed a significant association between the FCGRB T allele and the risk of developing SLE compared to the FCGRB I allele (OR = 1.207, 95% CI = 1.061 - 1.373, P = 0.004), with no evidence of between-study heterogeneity. In subjects of Asian descent, a significant association was observed between the FCGRIIB T allele and SLE (OR = 1.332, 95% CI 1.138 - 1.558, P < 0.001). However, in Europeans no such association was found. In contrast, no association was found between SLE or LN and the FCGRIIIB NA1/NA2 polymorphism in all subjects, or in European and Asian populations. Conclusions. This meta-analysis demonstrates that the FCGRIIB T/I232 polymorphism confers susceptibility to SLE, especially in Asian-derived populations. In contrast, no association was found between the FCGRIIIB NA1/NA2 polymorphism and susceptibility to SLE or LN in European or Asian populations.

Juvenile glaucoma associated with nail-patella syndrome. *K. Fukai[1], T. Oshimo[1], N. Higashi[2], T. Kitano[3], Y. Imai[4], H. Shintaku[5], M. Ishii[1]* 1) Dept Dermatology, Osaka City Univ, Osaka, Japan; 2) Higashi Dermatologic Clinic, Sakai, Japan; 3) Dept of Pediatric Orthopaedics Surgery, Osaka City General Hospital, Osaka, Japan; 4) Dept of Orthopaedics Surgery, Osaka City Univ, Osaka, Japan; 5) Dept of Pediatrics, Osaka City Univ. Osaka, Japan.

The nail-patella syndrome (NPS, OMIM#161200), also known as hereditary osteoonychodysplasia, is a rare autosomal dominant disorder that is characterized by nail and bone abnormalities and, frequently, renal disease, NPS is caused by a loss of function mutation in the transcription factor IMX1B at 9q34. A 5-year-old girl presented with hypoplastic fingernails from birth. Her thumbnails exhibited severe dysplasia, the index fingernails were ridged longitunianlly, and the thrid and fourth nails exhibited triangle lunules. The creases of the skin overlying the distal interphalangeal joints of the fingers were lost. X-ray examination of the knees and pelvis revealed absence of centers of calcification in the patella and the presence of typical iliac horns. No proteinuria or hematuria was detected. At the age of six, open angle glaucoma developed. This is unusual because most of the reported cases with the association of glaucoma are of the age 40 or older. Heterozygous deletion of two bases (c.368_369delTG) within the coding sequence of exon 3 of LMX1B was found. Unexpectedly, the same mutation was noted in the proband's father, who was thought to be 'normal' by physical examination. This underscores the importance of mutation analysis for the accurate genetic counseling.

The -514C/T polymorphism of hepatic lipase gene among Iranian patients with coronary heart disease. *K. Ghatreh Samani[1], M. Noori[2], M. Rohbani Nobar[3], M. Hashemzadeh Chaleshtory[4], E. Farrokhi[4]* 1) Department of Clinical Chemistry, Tabriz University of Medical Sciences, Tabriz, Iran; 2) Biotechnology Research Center, Tabriz University of Medical Sciences, Tabriz , Iran; 3) Drug Applied Research Center, Tabriz University of Medical Sciences, Tabriz , Iran; 4) Cellular and Molecular Research Center , Shahrekord University of Medical Sciences , Shahrekord, Iran.

The T allele of the hepatic lipase (HL) C-514T polymorphism was previously found to be associated with lower plasma HL activity. Here, we examined the association between this polymorphism and plasma HDL-cholesterol concentrations in patients with coronary arteries stenosis. We studied 342 subjects undergoing coronary angiography in two groups of non CAD (n=146) and CAD (n=196) . -514CT polymorphism was determined using polymerase chain reaction and restriction fragment length polymorphism (PCR-RFLP). After adjustment for age, smoking ,fasting blood glucose and body mass index, HDL-cholesterol concentrations were significantly higher in men with the C/T&T/T genotype than those with the C/C genotype(mean 38.6 and 34.7 respectively P=0.01). The frequency of T allele in non CAD was 0.136 and 0.226 in female and male respectively and 0.170 and 0.223 for female and male in CAD subjects.There was no difference in T allele frequency in CAD and none CAD groups in male and female (p=0.466 and 0.722 respectively). We concluded that -514CT of LIPC gene have a positive effect on HDL-C concentration especially in male gender .How ever, no difference were determined in frequency of T allele between CAD and normal arteries subjects. Key words: Hepatic lipase gene, HDL-C, Coronary artery stenosis, T allele.

Altered gene-expression in medication-free schizophrenia patients. *T. Rietkerk[1], M. P. M. Boks[1], W. Cahn[1], I. E. C. Sommer[1], R. L. van Ojen[1], S. de Jong[2], C. Schubart[1], R. S. Kahn[1], R. A. Ophoff[2]* 1) Department of Psychiatry and The Rudolf Magnus Institute of Neuroscience, University Medical Centre Utrecht, the Netherlands; 2) Complex Genetics Section, DBG-Dept Medical Genetics and The Rudolf Magnus Institute of Neuroscience, University Medical Centre Utrecht, the Netherlands.

Schizophrenia is a severe psychiatric disorder with a genetic contribution estimated at around 80%. Changes in gene-expression constitute a common mechanism by which genes affect the phenotype. We therefore performed a gene expression study in schizophrenia. RNA samples were taken from peripheral blood cells of schizophrenia and schizoaffective patients, who were free of antipsychotic drugs. Genome-wide microarray analysis was done to compare expression levels between 22 patients and 22 healthy controls, matched on age, sex and substance abuse. In addition we used another sample consisting of 33 healthy controls for further validation. In both case-ctrl analyses we observed significant expression changes in four genes after correcting p-values for the false discovery rate: SPTLC1, MYST3, USP49 and PPARBP. The SPTLC1 gene codes for serine palmitoyl-transferase which is a key enzyme in the biosynthesis of sphingolipids, the main components of myelin sheaths. The protein encoded by MYST3 is also involved in sphingolipid metabolism among other functions. The USP49 protein functions in the ubiquitin cycle and PPARBP is involved in androgen receptor functioning and transcription regulation. These four genes are expressed in brain-tissue as well. We identified genome-wide significant gene-expression changes in schizophrenia patients that are not attributable to medication effects. The finding of altered expression of SPTLC1 and MYST3, involved in sphingolipid metabolism, may reflect aberrant myelin formation in schizophrenia.

Association of I405V and -629C/A polymorphisms of cholesteryl ester transfer protein gene with high-density lipoprotein cholesterol levels in coronary artery disease. *M. Noori[1], K. Ghatreh Samani[2], M. Rohbani Nobar[3], M. Hashemzadeh Chaleshtory[4], E. Farrokhi[4], N. Aslanabadi[2]* 1) Biotechnology Research Cente, Tabriz University of Medical Sciences, Tabriz, Iran; 2) Biotechnology Research Center, Tabriz University of Medical Sciences, Tabriz , Iran; 3) Drug Applied Research Center, Tabriz University of Medical Sciences, Tabriz , Iran; 4) Cellular and Molecular Research Center , Shahrekord University of Medical Sciences , Shahrekord , Iran.

Background: Cholesteryl ester transfer protein (CETP) exchanges neutral lipids between lipoproteins. CETP gene is known to have many single nucleotide polymorphisms which have been associated with plasma high density lipoprotein cholesterol (HDL-C) concentrations. The role of CETP in the atherogenic process is still not fully clarified. We studied the association of -629C/A and I405V polymorphism in CETP gene with coronary artery disease (CAD). Methods: We undertook a cross- sectional analysis on two polymorphism of CETP gene among 323 consecutive patients who underwent coronary angiography. Association was analyzed among plasma lipid and lipoproteins, its gene polymorphisms and the finding in coronary angiography. Polymorphisms were determined using polymerase chain reaction and restriction fragment length polymorphism (PCR-RFLP). Results: The allele frequencies of -629C/A: A allele was 0.66; and that of I405V: V allele was 0.35. Study of association between I405Vpolymorphisms and plasma lipid and lipoprotein concentrations revealed no significant differences between three genotypes. A genotype based subgroup analysis revealed a significant increase in HDL-C in non-CAD patients with AA and CA genotype. There was significance difference with A allele frequency in CAD and non-CAD group. Conclusions: In the present study there was no change in HDL-C between the I405V genotypes and CAD prevalence was not significantly different among in these three genotypes. AA genotype of -629 CA polymorphism in promoter of CETP gene increased HDL but this genotype maybe associated with higher risk of CAD than CC genotype. Keywords: CETP gene, I405V, HDL cholesterol,-629C/A.

The international multidisciplinary Community Genetics Network. *L. P. ten Kate[1], L. Henneman[2]* 1) Dept Clinical Genetics, EMGO-Institute, VU University Medical Center, Amsterdam, The Netherlands; 2) Dept Public and Occupational Health, EMGO-Institute, VU University Medical Center, Amsterdam, The Netherlands.

The International Multidisciplinary Community Genetics Network is a non-commercial E-mail network aiming to facilitate communication among those working in the field of community genetics. This includes researchers, health professionals and others interested in genetic screening, genetic education, access and quality of genetic services or preconception care, genetics in primary care, genetic registries, genetics for low-income countries and other disadvantaged populations, public consultation and epidemiologic, economic, psychosocial, ethical and legal issues. The core activity is a monthly newsletter with a list of references to recent scientific papers of members and a continuously updated list of upcoming meetings. This allows a rapid spread of information towards other members, which is advantageous to the authors of papers or organizers of meetings, but also to readers who want to stay tuned on what others are doing. In addition members may present information on new activities in the newsletter, and publish calls for information (e.g. about validated research questionnaires or participants for a particular study). The Network was launched May 2007. One year later (June 1, 2008) the Network has 343 members in 51 countries worldwide, growing at a pace of 20-30 new members each month. One third of the membership comes from the United States (88 members) and Canada (26 members). Forty five percent of the members are from Europe and twelve percent from Asia. Updated numbers and further details will be presented at the ASHG annual meeting in Philadelphia. Those who want to have more information or want to become a member and obtain the newsletter, should send an E-mail to commgennet@gmail.com.

Samples in, data out? *B. Knoppers* Dept CRDP, Univ de Montreal, Montreal, PQ, Canada.

In the explosion of large, genomic or disease population studies seeking to pool or federate datasets, unforeseen issues arise. Prospective studies can map out future interoperability through broad consent and recontact mechanisms but the retrospective use of already collected samples and data may encounter severe limitations due to ELSI constraints. The 2008 passage of the Genetic Information Non-Discrimination Act (GINA) in the United States illustrates a legislative approach to the issue of potential discrimination in health insurance. Other countries have adopted this genetic-specific legislative model but in the context of biobanks. A second approach has been to subsume the issues of consent and confidentiality in genomic research under the personal data protection umbrella. Sufficient interpretative leeway may also be found via human rights protections as sufficiently flexible for the framing of sample and data access and use issues as they arise. Perhaps a medical-model would provide an avenue closer to the original intent of the sample-sources however. This would hold true across the spectrum going from population genomic studies, to molecular epidemiology, to hopefully, the translation into genomic medicine for common chronic diseases. An examination of examples from various international (GAIN; WTCC; ENGAGE) and national genomic studies (UK Biobank; CARTaGENE; Japan Biobank) will serve to test these models. If samples are voluntarily provided to be used in research, why are there barriers to access resulting data?

Genome-wide oligonucleotide Array CGH for etiological diagnosis of mental retardation and autism spectrum disorders: a multi-center experience on 1,551 clinical cases. *Y. Fan[1], B. Xiang[1], B. Wu[2], P. Li[3], M. Li[4], T. Chen[5], H. Zhu[1], Y. Shen[2], K. Lu[3], M. Mahoney[3], M. Seashore[3], A. Bale[3], J. McGrath[3], H. Andersson[4], T. Narumanchi[4], X. Hu[4], Y. Wang[5], J. Martinez[5], U of Miami Clin Genet Group* 1) University of Miami Miller School of Medcine, Miami, FL; 2) Harvard Medical School, Boston, MA; 3) Yale University School of Medicine, New Haven, CT; 4) Tulane University School of Medicine, New Orleans, LA; 5) College of Medicine, University of South Alabama, Mobile, AL.

Mental retardation (MR) occurs in ~3% of the general population whereas about 1/150 children have an autism spectrum disorder (ASD). ~70% of autism patients also have MR. Recent aCGH studies have revealed pathogenic gene copy number variations (CNVs) in >10% of patients with MR and ASDs in addition to chromosomal abnormalities detectable by conventional karyotyping. We have collected aCGH results on 1,551 cases from 5 cytogenetics laboratories where Agilent 44K platform has been used as a clinical test. Among these cases, 1,441 had unexplained MR and 110 had a diagnosis of autism or ASD. Pathogenic CNVs were detected in 6.8% ~14% of cases with MR by 5 different labs with an overall detection rate of 11.6%. In ASD patients, the overall detection rate for pathogeinc CNVs was 10.9% but varied from 3.2% to 16.7% in 3 labs. It is apparent that pathogenic CNVs occur with a similar frequency in patients with MR and ASD. Our results have demonstrated that a genome-wide array CGH such as the 44K is a powerful diagnostic tool for patients with unexplained MR or autism. With the collective data, we are able to address the important issues involved in clinical use of aCGH, such as the criteria of interpretation of CNVs, cutoff range, confirmation, and cost-effectiveness of test. Further comparison and characterization of the recurrent novel pathogenic CNVs identified in our study will lead to discovery of new clinical syndromes and disease genes.(U of Miami Clin Genet Group: P Jayakar, D Barbouth, S Sacharow, K Wierenga, V Carver, A Morales, LJ Elsas).

Multiple mechanisms of RET kinase domain mutations in Hirschsprung disease: A structure-function study. *B. D. Hyndman, T. S. Gujral, J. R. Krieger, L. M. Mulligan* Division of Cancer Biology and Genetics , Cancer Research Institute, Queen's University, Kingston, Ontario, Canada.

The proto-oncogene RET encodes a receptor-tyrosine kinase important for kidney morphogenesis and maturation of several neural crest-derived cell lineages of the peripheral nervous system. Mutations of the RET gene have been reported in Hirschsprung disease (HSCR), a congenital abnormality associated with the absence of enteric ganglia in the intestinal tract, and are thought to result in loss of RET function. With the recent publication of the three-dimensional structures of inactive and activated RET we set out to characterize the molecular mechanisms of HSCR mutations and how they can lead to receptor dysfunction. We used our RET kinase three-dimensional models to predict structural changes and downstream functional consequences of 23 HSCR-associated missense mutations located within the RET tyrosine kinase domain. A representative subset of these mutants were evaluated in cell based assays to examine the functional effects of these mutations on RET. Briefly, assays were performed to determine the effects of the mutations on RET protein localization to the cell surface, RET autophosphorylation following ligand binding as well as on its ability to interact with adaptor proteins and activate downstream signaling pathways. We also evaluated the ability of the various RET mutants to induce changes in cell growth and apoptosis. We show that HSCR mutations in the tyrosine kinase domain vary in the degree of RET impairment, and that not all mutations have the same effects on RET-mediated processes. Our data indicate that HSCR mutations of RET can result in dysfunction of the RET protein by several mechanisms, depending on both the position, and type of mutation. Importantly, these effects are not limited to kinase inactivation.

Caucasian prostate cancer patients and VEGF gene haplotypes. *K. Yanamandra[1], M. Ankem[4], D. Napper[1], P. B. Boggs[2], H. Chen[1], S. A. Ursin[1], G. Mills[3], J. A. Bocchini Jr.[1], R. Dhanireddy[5]* 1) Dept Pediatrics, LSU Medical Ctr, Shreveport, LA; 2) Allergy Clinic, Shreveport, LA; 3) Feist-Weiller cancer center, Shreveport, LA; 4) Dept Urology, Robert Wood Johnson Medical School, New Brunswick, NJ; 5) Dept Pediatrics, UT Health Sciences Center, Memphis, TN.

Prostate cancer is the second leading cause of death among male cancer patients second only to lung cancer. A host of genetic factors influence the tumorigenesis and cancer etiology, especially the combination of low-penetrance gene polymorphisms (1,2) Because angiogenesis is a major feature and is an essential process in the development, growth and metastasis of malignant tumors (3-5), in the present investigation we began to study the role of Vascular Endothelial Growth Factor (VEGF) gene polymorphisms in the etiology of prostate cancer. Our study population was Caucasian patients and controls. We have studied the influence of VEGF gene SNPs both in the promoter and in the coding regions, in thirteen prostate cancer patients and ninety five controls. The genetic polymorphism studies were carried out by microplate PCR RFLP and allele specific PCR genotyping methods. Among the genetic markers studied, mutant genotypes in the promoter and coding region of VEGF gene showed a significant difference in their frequencies (odds ratio(OR) 9.5, p value 0 for -460T, OR 2.7, p value 0.02 for -1154G). Also, the haplotype data analysis revealed that the VEGF-460T/VEGF-1154G haplotype frequency was significantly higher among the prostate cancer patients compared to the controls (OR 2.4, p value 0). Based on our experimental data we conclude that the VEGF-460T/VEGF-1154G haplotype was a significant risk factor in the etiology of prostate tumorigenesis among Caucasians. References: 1. Pseudogene-derived IKBKG Gene Mutation in Incontinentia Pigmenti. *NC. Lee[1], CH. Huang[2], WL. Hwu[1], YH. Chien[1], TM. Ko[2]* 1) Dept Medical Genetics & Pediatrics, National Taiwan Univ Hosp, Taipei, Taiwan; 2) Ko's Obstetrics and Gynecology Clinic, Taipei, Taiwan.

Background Incontinentia pigmenti (IP; MIM #308300) is a rare X-linked-dominant disease involving abnormalities in the skin, hair, teeth, nail, eyes, and the central nervous system. IKBKG (NEMO; GeneID:8517) is causal gene, and a recurrent deletion of exon 4-10 accounts for 60-90% of the detected mutations. Recently, a pseudogene IKBKGP (NEMO; GeneID: 246210) containing exon 3-10 of IKBKG in an opposite direction was located close to IKBKG. Materials and Methods Thirty-two blood samples and 9 prenatal samples from 20 families were analyzed for IKBKG gene mutation. Long-range PCR was performed to detect the 4-10 deletion. For samples negative for the exon 4-10 deletion, direct sequencing of each exon was performed. Pseudogene-specific primers were used to amplify the IKBKGP pseudogene followed by direct sequencing. Results Mutations of the IKBKG gene were identified in 11 families (13 patients and 2 fetuses). Therefore, the detection rate was 55% (11 in 20 families). Among the 11 families, 7 had the exon 4-10 deletion (63.6% of the detected mutations). Besides, 1 family had a novel mutation c.1110insTTdelC (p.Ala371CysfsX24). While another 3 families had a novel mutation c.520-523dupCAGG (p.Ala174GlnfsX15) in exon 5. In Family 1, the c.520-523dupCAGG mutation of the IKBKG gene was only found in the patient (heterozygous), but heterozygous c.520-523dupCAGG mutation in IKBKGP was found in the patient, the mother, the youngest aunt, and the grandmother, indicating this mutation was already resident in the pseudogene in the unaffected mother and relatives. Discussion We demonstrated that the c.520-523dupCAGG mutation in the IKBKGP gene was carried in several individuals in one family including the mother of the patient. In the patients, the mutation was resided at both the true gene and the pseudogene. Therefore it is likely that a recombination occurred and the true gene was converted by the pseudogene. This is the first evidence for the involvement of the pseudogene for small mutations in IP.

Spectrum of Development in Aicardi Syndrome. *B. L. Kroner[1], W. D. Gaillard[2]* 1) Statistics and Epidemiology, RTI International, Rockville, MD; 2) Neurosciences, Children's National Medical Center, Washington, DC.

Purpose: Aicardi syndrome (AIC) is a rare neurological disorder clinically defined by agenesis of the corpus callosum (ACC), chorioretinal lacunae and infantile spasms. Other features include brain, eye and skeletal abnormalities and global developmental disabilities. AIC is presumed to be X-linked but no gene has been identified. Few reports identify children who have unassisted ambulation, speech and self-help skills. We sought to describe the spectrum of developmental in AIC and to identify early predictors of high functioning cases. Methods: 95 cases of AIC, at least 2 yrs of age, were identified from a parent survey which included questions on signs/symptoms related to the diagnosis of AIC, seizure history and treatment, developmental progress and autistic-related behaviors. Results: Median age of child at the time of survey was 10 yrs (range 2-30 yrs). Daily seizures occurred in 53 (58%). 46 (48%) had at least one autistic-related behavior. 19% had a chronic or permanent loss of skills due mostly to seizures (61%), medications (35%), and surgery or illness (25%). 51 cases (59%) had a developmental age (DA) <12 months. Of these, mean age at seizure onset was 2 months, 28% have partial ACC, 63% have vertebral anomolies, 27% have microphthalmia, 61% eats by mouth, and 10% recognize a familiar adult. 30 cases (34%) had a DA >24 months. Of these, mean age at seizure onset was 3.2 months, 41% have partial ACC, 23% have vertebral anomolies, 7% have microphthalmia, 100% eats by mouth, and 93% recognize a familiar adult. Example of skills accomplished in the 30 with DA >24 months include: walk alone (83%), toilet trained (57%), dresses self (27%), use utensil to eat (88%), count 5 objects (50%), read words (23%), understand conversation (77%) and speak >20 words (67%). Conclusions: Developmental disabilities are common in AIC but a higher proportion than previously reported have unassisted ambulation, independent life skills, verbal communication and demonstrated academic learning. Possible early predictors of higher functioning status include age at seizure onset >3 months; partial ACC; absence of secondary AIC features, and early cognitive awareness.

Which first? Array Comparative Genomic Hybridization or G-banded karyotype. *F. Li[1], E. Lisi[1], J. Hoover-Fong[1], V. Kottoor[1], J. Chinsky[1], D. Batista[2,3]* 1) McKusick-Nathans Institute od Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Pathology, Johns Hopkins University, Baltimore, MD; 3) Cytogenetics Laboratory, Kennedy Krieger Institute, Baltimore, MD.

We present two patients to discuss the implications of a-CGH and the two-step approach currently used in cytogenetics. Patient 1 was an 11 year-old girl mildly dysmorphic with gross developmental delay. G-banding showed an abnormality in chromosome 11 initially interpreted as a deletion within band p13: del(11)(p13p13). A-CGH showed no copy number changes in chromosome 11 or others. The karyotype was reevaluated as a possible inversion: inv(11)(p11.3p13). Patient 2 was a newborn girl dysmorphic with severe cardiac defect. 20 G-banded cultured peripheral blood cells showed normal karyotype. A-CGH was suggestive of mosaic trisomy 14. FISH showed trisomy 14 in 6% of cultured vs. 21% of uncultured peripheral blood cells. This discrepancy is likely due to different cell populations studied; all types of nucleated cells are analyzed in the uncultured specimen, whilst selective growth advantage of karyotypically normal lymphocytes might exist in the cultured specimen. FISH of uncultured cells should more accurately represent the level of mosaicism in the patients blood and be comparable to the a-CGH result. Our current two-step diagnostic approach is to first perform karyotype analysis. If normal, a-CGH is used to evaluate smaller genomic changes. These two patients were examples of a-CGH providing information beyond conventional cytogenetics. In patient 1, the chromosome 11 abnormality was misinterpreted by initial G-banding. However, if only array had been performed, the probable inverted 11 would be missed while the inversion could be related to the patients phenotype. In patient 2, a-CGH detected mosaic trisomy 14 that was also missed by the initial G-banding. Should we reverse the sequence of the tests or perhaps routinely perform them together? A-CGH and chromosome G-banding are two independent techniques providing complementary information. Simultaneous execution of these complementary tests would reduce tests turn around time and provide the most complete information possible to the patient.

Concurrence of Muir-Torre and Turcot Variants of Hereditary Nonpolyposis Colorectal Cancer (HNPCC). *C. A. Griffin, J. E. Axilbund, C. D. Gocke, A. Piurek, F. M. Giardiello, K. M. Murphy* Depts of Pathology, Oncology, and Medicine, Johns Hopkins Univ, Baltimore, MD.

HNPCC is a cancer-predisposition syndrome causing primarily colorectal (CRC) and/or endometrial cancer at an early age. Recognized variants are Muir-Torre syndrome (MTS), in which sebaceous skin tumors are identified, and Turcot syndrome type I, in which astrocytomas and glioblastomas occur. To our knowledge, the presence of manifestations of both variants in a family with a documented mutation in a mismatch repair gene has been reported only twice. We have recently seen 3 families with mismatch repair gene mutations and both sebaceous tumors and brain tumors. The first is a family that met Amsterdam-I criteria in which the proband presented with CRC at age 41, sebaceous adenoma (SA) and sebaceous carcinoma (SC) at age 44, and mixed anaplastic astrocytoma (MAA) at age 45. Microsatellite instability (MSI) was observed in both the SA and MAA. He had a brother and father with colon cancer. Deletion of exons 8-15 in MSH2 was identified in the father. The second family did not meet Amsterdam-I or II criteria, but included an individual with mucinous CRC of the cecum at age 46, SC at age 55, MAA at age 57, and deletion of exons 1-6 in MSH2. His mother had uterine cancer at age 45 and stomach or CRC at age 55, and his brother, also mutation positive, had a son with glioblastoma at age 23. The third family includes an individual with early CRC, a reference to sebaceous adenoma, and a documented IVS9+1G>A MLH1 mutation; there is a paternal history of glioblastoma, multiple individuals with early onset CRC and several cases of small intestine and uterine cancers. Medical record confirmation of the skin lesion and brain tumor is pending. If verified, this will be the first example of concurrent MTS and Turcot syndrome associated with a MLH1 mutation. These families confirm the coexistence of both MTS and Turcot variants in kindreds with HNPCC and suggest that the manifestations of both sebaceous skin lesions and astrocytic brain tumors in HNPCC may not be as rare as previously thought.

***TCOF1* presents differential allelic expression in lymphocytes: a potential mechanism to explain clinical variability in Treacher Collins syndrome?** *C. Masotti[1], D. O. Vidal[2], A. Splendore[1], J. E. de Souza[3], R. Moura[2], F. Cavalher[2], T. Felix[4], N. Alonso[5], A. A. Camargo[2], M. R. S. Passos-Bueno[1]* 1) Instituto de Biociencias, Universidade de Sao Paulo, SP, Brazil; 2) Ludwig Institute for Cancer Research, Sao Paulo Branch, Hospital Alemao Oswaldo Cruz, Brazil; 3) Pos-Graduaçao em Bioinformatica, USP, Brazil; 4) Departamento de Genetica Medica, Hospital de Clinicas de Porto Alegre, UFRGS, Brazil; 5) Departamento de Cirurgia Plastica, Hospital das Clinicas da Faculdade de Medicina, USP, Brazil.

Treacher Collins syndrome (TCS) is an autosomal dominant craniofacial disorder caused by null mutations in *TCOF1* gene, which are predicted to lead to mRNA degradation by nonsense mediated mRNA decay (NMD). Haploinsufficiency of the gene product (treacle) during embryonic development is the supposed molecular mechanism underlying TCS. Among TCS patients with pathogenic mutations, no genotype-phenotype correlation has been observed so far and we have hypothesized that clinical variability may be associated to variation in gene expression levels of the wild-type allele. In the present report we investigated if *TCOF1* transcript levels in lymphocytes were associated to phenotypic variation in TCS. We detected a wide variation of *TCOF1* expression among normal and affected individuals and found a significant difference in *TCOF1* mRNA levels between these two groups. Although we herein demonstrate for the first time that patients' mature cells do not have the same amount of *TCOF1* transcripts as normal individuals, we did not observe any association between transcript levels and severity of the phenotype. We also investigated the methylation status of *TCOF1* promoter's CpG island from normal and TCS affected individuals. The absence of methylated cytosines suggested that this regulatory mechanism is not responsible for individual *TCOF1* expression variation. However, we detected differential expression of *TCOF1* alleles in lymphocytes from patients and controls: some individuals can have one allele with extreme skewed expression, while others can have both alleles equally expressed. We discuss the possibility of association of this mechanism to the remarkable TCS phenotype variation.

Mutation scanning novel transcripts for the CMTX3 gene mutation. *M. Brewer[1,2], G. Nicholson[1,2,3], P. Polly[4,5], M. Kennerson[1,2,3]* 1) Northcott Neuroscience Lab, ANZAC Research Institute, Sydney, NSW, Australia; 2) Faculty of Medicine, University of Sydney, Sydney, NSW, Australia; 3) Molecular Medicine Laboratory, Concord Hospital, Sydney, NSW, Australia; 4) Cancer Pharmacology Unit, Concord Hospital, Sydney, NSW, Australia; 5) Department of Pathology, University of New South Wales, Sydney, NSW, Australia.

X-linked Charcot-Marie-Tooth (CMTX) disease is a common inherited degenerative disorder of the peripheral nerve. CMTX3 is one of five CMTX loci. Our overall aim is to identify the gene mutation causing CMTX3 disease. CMTX3 was first mapped to Xq26-q28 in 1991 [1]. Our laboratory mapped and refined the locus to a 2.5 Mb region on chromosome Xq26.3-q27.1 [2, 3]. The CMTX3 region contains 12 annotated genes (UCSC Genome Browser, Build 36.1). Exclusion of the coding region, splice elements and untranslated region (UTR) of these genes for pathogenic mutations along with expression of partial uncharacterised transcripts in the interval suggests that the disease could be caused by a novel gene. Bioinformatic analyses identified 11 UniGene expressed sequence tag (EST) clusters and 23 single ESTs in the region. Expression of ESTs in neural specific tissue libraries, fetal brain, spinal cord and skeletal muscle, prioritised ESTs to be characterised and screened. Full-length transcripts of ESTs were constructed using 5- and 3-Rapid Amplification of cDNA Ends (RACE). Characterised transcript exons have been routinely screened for the pathogenic mutation using High Resolution Melt analysis. 1. Ionasescu et al. Am J Hum Genet (1991) 48, 1075-1083. 2. Huttner et al. Penetrance of *CARD15* genetic variants in the general population: inflammatory bowel disease, biochemical markers and meta-analyses. *S. Yazdanyar[1], P. R. Kamstrup[1], M. Weischer[1], A. Tybjærg-Hansen[2], B. G. Nordestgaard[1]* 1) Department of Clinical Biochem, Herlev Hospital, Copenhagen University Hospital , Herlev, Denmark; 2) Department of Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark.

Background: In case-control studies of Europeans, Arg702Trp, Gly908Arg, and Leu1007fsincC in the *CARD15* gene associate with the inflammatory bowel disease Crohns disease, but not with ulcerative colitis; however, the penetrance in the general population is unknown. We hypothesized that *CARD15* genetic variants influence risk of inflammatory bowel disease and levels of inflammatory biochemical markers in the general population. In addition, we performed meta-analyses of previous case-control studies. **Methods:** From the general population, we examined 10,597 participants from The Copenhagen City Heart Study, and 32,999 participants from The Copenhagen General Population Study. A total of 162 participants were diagnosed with Crohns disease and 376 with ulcerative colitis from 1976 through July 2007. Meta-analyses included 25 studies for Crohns disease and 14 studies for ulcerative colitis. **Results:** In the combined general population studies, 89% were non-carriers, 11% heterozygotes, and 0.4% compound heterozygtes or homozygotes. For Crohns disease, odds ratios for *CARD15* heterozygotes were 1.2(95% confidence interval 0.8-1.9) and 3.3(0.8-13.6) for compound heterozygotes and homozygotes combined versus non-carriers; corresponding values for ulcerative colitis were 1.1(0.8-1.5) and 0.7(0.1-5.1). Genotype did not influence levels of inflammatory biochemical markers. In the meta-analysis of case-control studies of Crohns disease, odds ratios for heterozygotes were 3.2(2.8-3.8) and for compound heterozygotes and homozygotes combined 10.2(6.4-16.4) versus non-carriers; corresponding values for ulcerative colitis were 1.2(0.9-1.5) and 1.5(0.6-4.0). **Conclusions:** In meta-analyses, *CARD15* genetic variants associate with increased risk of Crohns disease in case-control studies of Europeans; however, the penetrance of these variants is most likely low in the European general population.

Localisation of a fifth gene involved in Autosomal Dominant Hypercholesterolemia. *M. MARDUEL[1], A. MARQUES[1], M. ABIFADEL[1,2], J. BONNEAU[1], M. DEVILLERS[1], D. ERLICH[1], A. MUNNICH[1], J.-P. RABES[1,3], C. BOILEAU[1,3], M. VARRET[1]* 1) Hopital Necker, INSERM U781, Université PARIS Descartes, France; 2) Faculté de Pharmacie, Université Saint-Joseph, Beirut, Lebanon; 3) Laboratoire de Biochimie et de Génétique Moléculaire, CHU Ambroise Paré (AP-HP & Université Versailles-Saint-Quentin-en-Yvelines), Boulogne, France.

Autosomal Dominant Hypercholesterolemia (ADH) is a major risk factor for atherosclerosis, witch cardiovascular complications are the most important cause of morbidity and mortality in industrial country. Genetic factors involved in cholesterol homeostasy are multiple, but identification of genes linked to ADH have contributed to a best understanding of cholesterol metabolism. ADH was initially associated to mutations in 2 genes : LDLR and APOB. Our team has shown that defects in at least 2 other genes (HCHOLA3 and HCHOLA4) are implicated in the disease. We identified HCHOLA3 as PCSK9 (proprotein convertase subtilisin/kexin type 9) and located HCHOLA4 at 16q22.1 in a 5.31 cM interval. Through the ADH French Research Network, we collected genetic material from a large french pedigree (35 samples : 15 affected, 16 normocholesterolemics and 4 spouses). Linkage and sequencing analyses in this family excluded the involvement of the LDLR, APOB and PCSK9 genes. Furthermore, the study of 6 microsatellite markers spanning the HCHOLA4 interval clearly excluded linkage to this locus. These results demonstrate the existence of a HCHOLA5 gene. To evaluate the power of the family for linkage, simulations were carried out. Average and maximum lod score were 2.1 and 4.0 indicating that the statistically-significant threshold of 3 could be reached in this single family. The genomewide scan for 21 individuals was realized with 10k affimetrix arrays. Linkage analyses, using parameters compatible with ADH, allowed us to identify a single locus of 0.9 cM and 939.3 kb (maximum LS = 3.5) including 35 genes. Some of them encode proteins of the cholesterol metabolism and are currently analysed. Identification of HCHOLA5 could reveal a new aspect of cholesterol metabolism, and may lead to the development of new preventive method and/or better aimed drugs.

Constitutional MLH1 promoter methylation as a cause of MLH1 inactivation in patients with early-onset colorectal cancer. *Q. Wang[1, 2], J. Auclair[2], C. Lasset[3], V. Bonadona[3], F. Desseigne[4], S. Giraud[1], J.-C. Saurin[5], M.-O. Joly[6], A. Puisieux[1,2]* 1) Plate-forme Mixte de Génétique Constitutionnelle des Cancers Fréquents, Centre Léon BérardHospices Civils de Lyon, Lyon, France;; 2) Laboratoire de recherche translationnelle, Centre Léon Bérard, Lyon, France; 3) Dept d'Epidermiologie et Génétique, Centre Léon Bérard, Lyon, France; 4) Dept Médecine, Centre Léon Bérard, Lyon, France; 5) Service d'Hépatogastroenterologie, Centre Hospitalier Lyon Sud, Lyon, France; 6) Laboratoire Central dAnatomie et de Cytologie Pathologiques, Hôpital Edouard Herriot,Lyon, France.

Inactivation of the DNA mismatch repair system (MMR) is responsible for a common cancer syndrome, HNPCC, as well as a proportion of sporadic colon cancers. Recently, germline methylation of MLH1 and MSH2 promoters has been demonstrated in putative HNPCC patients, as a mechanism leading to gene inactivation. However, the inheritance of such epigenetic event remains questionable. This leads us to hypothesize that epimutation is one of the causes involved more specifically in young sporadic colon cancer patients because 1) it results in germline monoallelic MMR gene silencing, and consequently, an increased susceptibility and 2) it does not appear to be stably transmitted to offspring. Thus a limited or non-existent family history may be expected. We analyzed 95 sporadic colon cancer patients diagnosed before the age of 50 years using methylation-specific PCR (MCP) combined with sequencing of bisulfite-treated DNA fragments. A total of 4 cases with germline MLH1 promoter epimutation were identified. Interestingly, one case displayed a MSS phenotype with normal MLH1 immunostaining. We also observed discordant results between the sequencing approach and MSP methods. Our results suggest that germline epimutation of MLH1 promoter is responsible for a small proportion of sporadic early-onset colon cancers (4%) and, currently used pre-selection and detection conditions need to be improved to increase the sensitivity and specificity.

Genome wide association study and follow-up analysis of visceral and subcutaneous abdominal fat in Hispanics: the IRAS Family Study. *J. Norris[1], C. Langefeld[2], M. Talbert[2], M. Wing[2], T. Haritunians[3], T. Fingerlin[1], A. Hanley[4], K. Taylor[3], S. Haffner[5], J. Rotter[3], D. Bowden[2], L. Wagenknecht[2]* 1) Colorado School of Public Health, Denver, CO; 2) Wake Forest University, Winston-Salem, NC; 3) Burns and Allen Cedars-Sinai Research Institute, Los Angeles, CA; 4) University of Toronto, Toronto, ON, Canada; 5) University of Texas Health Sciences Center at San Antonio, San Antonio, TX.

Purpose: To identify candidate genes and loci associated with computed tomography (CT)-derived measures of adiposity in Hispanic participants from the IRAS Family Study. Methods: In 1190 Hispanic individuals from 92 families from the San Luis Valley, CO and San Antonio, Texas, we measured CT-derived visceral adipose tissue (VAT), subcutaneous adipose tissue (SAT), visceral: subcutaneous ratio (VSR), and waist/hip ratio (WHR). A pilot genome-wide association study (GWAS) was carried out with 318K single nucleotide polymorphisms (SNPs) in 229 individuals from the San Antonio site. SNPs were analyzed for association with VAT, SAT, VSR and WHR, and those with evidence of association to these phenotypes were genotyped in the entire set of Hispanic samples (n = 1190), adjusting for admixture using a principal components analysis of 80 ancestry informative markers (AIMs). Results: Several SNPs were strongly associated in the pilot GWAS ($p<1x10^{-5}$) and were confirmed to be significantly associated in the follow-up (FUP) analysis of the entire Hispanic sample, including: rs7543757 ($p_{GWAS}=4.6x10^{-6}$; $p_{FUP}= 0.009$) for VAT; rs1377445, ($p_{GWAS}=7.2x10^{-6}$; $p_{FUP}= 0.0038$), rs4754373 ($p_{GWAS}=9.5x10^{-7}$; $p_{FUP}=2.7x10^{-5}$), and rs11212913 ($p_{GWAS}=6.5x10^{-6}$; $p_{FUP}=0.00035$) for SAT, and rs4541696 ($p_{GWAS}=6.1x10^{-6}$; $p_{FUP}=0.0036$), rs371004 ($p_{GWAS}=3.5x10^{-6}$; $p_{FUP}=0.0007$), rs4134351 ($p_{GWAS}=1.6x10^{-6}$; $p_{FUP}=0.0002$) for VSR. While none of the aforementioned SNPs are in genes, several SNPs in genic regions were associated at slightly larger GWAS p-values. Conclusions: Several candidate loci have been identified that are strongly associated with VAT, SAT and VSR in Hispanic Americans in a two-stage genetic association study.

Association of complement factor H, LOC387715, HTRA1 and apoE polymorphisms with age-related macular degeneration in Hungary. *I. Balogh[1], G. Losonczy[2], A. Fekete[1], Z. Voko[3], L. Takacs[2], I. Kaldi[4], E. Ajzner[5], E. Dzsudzsak[1], V. Nagy[2], M. Kasza[2], A. Vajas[2], A. Berta[2]* 1) Clinical Biochemistry, University of Debrecen, Debrecen, Hungary; 2) Department of Ophthalmology, University of Debrecen, Debrecen, Hungary; 3) Department of Preventive Medicine, University of Debrecen, Debrecen, Hungary; 4) Department of Ophthalmology, Kenézy Gyula County Hospital, Debrecen, Hungary; 5) Central Laboratory, Josa Andras County Hospital, Nyiregyhaza, Hungary.

Age-related macular degeneration (AMD) is a leading cause of irreversible central vision loss in the elderly worldwide. The multifactorial disease has a strong genetic component. The goal of this study was to establish the frequency of Tyr402His polymorphism of the CFH gene, Ser69Ala polymorphism at LOC387715, rs11200638 polymorphism of the HTRA1 gene and different ApoE alleles in Hungarian patients with AMD and to determine disease risk conferred by these factors. Materials and methods: In a case-control study, we performed clinical and molecular genetic examination of 105 AMD patients and 95 unrelated healthy controls. According to disease severity, 48 patients (46%) were assigned to the early and 57 patients (54%) to the late AMD subgroup. Results: Carriers of at least one CFH, LOC387715 or HTRA1 risk allele were at 1.8-fold (95%CI:1.0-3.3), 2.0-fold (95%CI:1.1-3.6) or 2.2-fold (95%CI:1.2-4.0) increased disease risk, respectively. In the early AMD subgroup, homozygous CFH, LOC387715 or HTRA1 polymorphisms conferred 4.9-fold (95%CI: 1.7-14.2), 7.4-fold (95%CI: 2.1-26.2) or 10.1-fold (95%CI: 2.5-40.8) greater likelihood of disease, respectively. In the late AMD subgroup, carriers of two CFH, LOC387715 or HTRA1 risk alleles were at 10.7-fold (95%CI: 3.7-31.0), 11.3-fold (95%CI: 3.2-40.4) or 13.5-fold (95%CI: 3.3-55.4) greater disease risk, respectively. We found no association between ApoE alleles and AMD in our groups. Conclusions: The CFH, LOC387715 and HTRA1 polymorphisms strongly associate to the development of AMD in Hungary. The association is particularly strong when homozygous risk alleles are present and in late stages of the disease.

FISH analysis of acute graft-versus-host disease in living-related liver transplant with one-way donor-recipient HLA-matching. *K. Kanehira[1], D. L. Riegert-Johnson[2], D. Chen[1], S. D. Grinnell[1], G. V. N. Velagaleti[1]* 1) Department of Lab Medicine & Pathology, Mayo Clinic, Rochester, MN; 2) Department of Internal Medicne, Mayo Clinic, Rochester, MN.

Acute graft-versus-host disease (GVHD) is an uncommon complication following liver transplant but the outcome is often fatal. Clinical diagnosis of GVHD is difficult because the clinical presentations, fever, skin rash, diarrhea and bone marrow failure, are non-specific. We describe a severe GVHD case in a female patient who underwent living-related liver transplant from her son for primary biliary cirrhosis and secondary cholangiocarcinoma. The HLA typing of the donor was homozygous at all loci. The recipients HLA was haploidentical to the donor, forming a donor-dominant one-way HLA match. Four weeks after transplantation, the patient developed pancytopenia which required treatment with granulocyte-colony stimulating factor. Bone marrow aspirate revealed severely hypoplastic marrow. FISH analysis of bone marrow using X- and Y-chromosome specific probes demonstrated that 80% of marrow cells were donor origin. FISH analysis of peripheral blood also showed that 90% of cells were donor-derived. Comparison of Giemsa-stained cell morphology and FISH using the same bone marrow smear slide revealed that genotype of erythroid precursor cells was predominantly male pattern, suggesting hematopoiesis of donor-derived stem cells in recipient bone marrow. Six weeks after transplant the patient developed diarrhea and an erythematous maculopapular skin rash on her back. A diagnosis of acute GVHD was made and treatment with methylprednisolone was instituted. Despite the treatment the patient developed respiratory failure and sepsis and died 46 days after transplantation. Our result showed that FISH analysis using sex chromosome probes is useful to confirm the diagnosis of GVHD following organ transplantation from a donor of the opposite sex. We also found that hematopoietic stem cells in liver graft can migrate to the recipients bone marrow. Further study is required to clarify contribution of donor-derived hematopoiesis to development of GVHD and/or engraftment.

Identification and characterization of a *NUP98-PHF23* fusion gene in acute myeloid leukemia. *J. Reader[1], J. S. Meekins[2], I. Gojo[3,4], Y. Ning[1,2]* 1) Program in Human Genetics; 2) Dept of Pathology; 3) Dept of Hematology-Oncology, University of Maryland School of Medicine, Baltimore, MD; 4) Marlene and Stewart Greenebaum Cancer Center, Baltimore, MD.

NUP98 is a promiscuous fusion partner gene linked to hematological malignancies. We identified a cryptic 11;17 translocation in an acute myeloid leukemia (AML) patient creating a novel in-frame fusion between *NUP98* exon 13 with *PHF23* exon 4. *NUP98* encodes a nucleoporin and has been involved in more than 20 different fusions. *PHF23* is an uncharacterized gene encoding a protein containing a plant homeodomain (PHD) found in chromatin remodeling proteins. The fusion partners of *NUP98* form two distinct groups: homeobox (*HOX*) genes and non-homeobox (non-*HOX*) genes. The non-*HOX* fusion partner genes, which include *NUP98-PHF23*, are diverse in function and are only related by possessing and retaining coiled-coil domain(s). The majority of research has focused on the mechanism of *NUP98-HOX* genes in leukemogenesis; therefore, our interests lie in further characterizing this novel non-*HOX* fusion gene. We hypothesize that *NUP98* fusion genes act as aberrant transcription factors that bind to DNA leading to transcriptional dysregulation. In order to test if *NUP98-PHF23* is able to confer an oncogenic phenotype, we cloned the full length fusion gene into an expression vector and expressed it in fibroblast cell line NIH-3T3 and myeloid cell line K562 for localization, differentiation and chromatin immunoprecipitation (ChIP) analyses. We have shown that *NUP98-PHF23* fusion protein has nuclear localization in NIH-3T3 cells. In K562 cells, the *NUP98-PHF23* fusion protein can partially block TPA-induced differentiation and preliminary ChIP and real time quantitative PCR (Q-PCR) analysis shows increased binding of the fusion protein to the promoter of *HOXA9*. These results indicate that *NUP98*-non-*HOX* fusions may function through *HOX* dependent pathways. Future directions include gene expression studies, identifying potential interacting co-factors and determining whether *NUP98-HOX* and *NUP98*-non-*HOX* have a shared mechanism in leukemogenesis which, in turn, could lead to new potential therapeutic targets.

Meta-analysis of SRD5a2 V89L and A49T polymorphisms and prostate cancer. *J. Li[1,2], R. Coates[2], M. Gwinn[2], M. Khoury[2]* 1) Cancer Division CDC, Atlanta, GA; 2) NOPHG CDC, Atlanta, GA.

The SRD5a2 gene codes for prostatic steroid 5A-reductase type 2, a critical enzyme in the metabolism of androgen. Two SRD5a2 missense substitutions, V89L and A49T, have been studied for association with prostate cancer. A 2003 meta-analysis by Ntais et al found no association with V89L and only a modest association with A49T, which they suggested might be explained by bias. Since 2003, many additional genetic association studies of these variants have been published with conflicting results. We conducted a meta-analysis to reexamine this association. We identified 25 eligible case-control studies published before October 2007, including the 11 analyzed by Ntais et al. We performed a meta-analysis of 22 association studies of V89L (10,088 cases; 10,120 controls) and 16 studies of A49T (5,386 cases and 5,912 controls). To account for variations among studies, we used a random effects model to summarize results. For the V89L polymorphism, we found no increase in risk associated with the L allele compared with the V allele (OR=0.99; 95% CI=0.94-1.05). Results were similar for different racial/ethnic groups. Models contrasting LL with VV found no association with prostate cancer; results were similar for both recessive and dominant models. For the T allele of A49T, we found a small effect that was not statistically significant (OR=1.23; 95% CI=0.94-1.61). The comparison of TT versus AA showed risks ranging from protection to harm (OR=1.21; 95% CI=0.46-3.15) and results were similar for both recessive and dominant models. Our study suggests that the V89L polymorphism is not associated with risk of prostate cancer. Risk related to A49T is uncertain, despite results of 16 studies. Disease selection bias, small sample size, convenience sampling, and genotype misclassification may influence the validity of meta-analysis of these studies. So far, no genome-wide association study of prostate cancer has examined the V89L and A49T polymorphisms directly because neither of them is interrogated by commercial chips in common use. Well designed population-based studies with appropriate genotyping could further elucidate the role of SRD5a2 polymorphisms in prostate cancer.

Genetic Variation in IL6 and LRP5 is Associated with Osteoporosis in the Marshfield Clinic Personalized Medicine Project: Evidence for Interaction with Smoking. *P. Giampietro[1], C. McCarty[1], B. Mukesh[1], F. McKiernan[1], D. Wilson[1], A. Shuldiner[2], J. Liu[2], J. LeVasseur[1], L. Ivacic[1], T. Kitchner[1], N. Ghebranious[1]* 1) Dept Med Genetics, Marshfield Clinic, Marshfield, WI; 2) University of Maryland School of Medicine, Baltimore, MD.

A nested case-control study within the Marshfield Clinic Personalized Medicine Cohort was performed to assess the relative impact of cigarette smoking,statin use,genetic polymorphisms, and one-way interaction of these factors on the development of osteoporosis in post-menopausal women. The study group consisted of 309 postmenopausal Caucasian females with osteoporosis(DXA T-scores -2.5 (spine, femur or radius))and 293 matched controls with normal BMD values. The ethnic composition of the sub population studied was 99.7% Caucasian with predominant German ancestry. Cases differed from controls with respect to BMI (cases: 32.9 +/-6.7 vs. controls: 26.9+/- 5.0 kg/m^2; $p<0.001$), mean age(70.4 + 9.4 vs. 61.6+ 8 years,$p<0.001$)and smoking (70.2% cases never smokedvs.60.1% controls;$p=0.02$), but not statin use. Fourteen SNP alleles corresponding to VDR, ESR1,COL1A1,IL-6,TGF-,ApoE and LRP5 genes,chosen based upon known functional consequences or prior evidence for association in other studies were genotyped using MALDI-TOF. The IL6-C634GC(rs1800796) allele of the promoter region was found to be associated with osteoporosis (odds ratio(OR) for CC+CG = 2.51 (95% CI=1.33, 4.75; $p=0.0047$),independent of statin use or smoking status. This finding replicates the association of rs1800796 with osteoporosis reported by Ota et al.(J Hum Genet 2001;46: 267)in a Japanese population. However,we found the opposite allele associated with osteoporosis suggesting the causative variant may be on a different haplotype in the two populations. On stratification for smoking,an association with LRP5 C135242T (rs545382)and osteoporosis emerged (OR 2.8 in smokers with the CT genotype (95% CI= 1.1, 7.0 $p=0.03$),suggesting a role for an environmental interaction in this association. In conclusion, we provide evidence for a role of genetic variation in IL6 and LRP5 in osteoporosis risk in Caucasian women,the latter manifest only in smokers.

Alterations in gene expression in the MPS VII mouse brain. *R. Rozen[1], D. Smirnov[1], E. Rappaport[1], Z. Zhang[1], E. Cabacungan[1], V. Cheung[1-3], J. H. Wolfe[1,2]* 1) Stokes Research Institute, Childrens Hospital of Philadelphia; 2) University of Pennsylvania, Philadelphia PA; 3) Howard Hughes Medical Institute.

Mucopolysaccharidosis (MPS) VII, Sly disease, is a rare multi-system disease causing mental retardation and death in childhood or early adulthood. MPS VII is one of more than 60 lysosomal storage diseases (LSD). MPS VII is caused by a deficiency in -glucuronidase (GUSB) leading to accumulation of glycosaminoglycans (GAGS) in cells. The murine model of MPS VII shares most of the clinical signs of the human disease. However, little is understood about the cellular and molecular mechanisms involved in mental retardation. Neurological abnormalities in the MPS VII mouse include: 1) behavioral deficits suggesting hippocampus (HC) involvement; and 2) pathological neurodegenerative lesions and astrogliosis in specific regions of the brain including the HC and the cortex (CTX). To determine if specific changes in gene expression and/or pathways contribute to these pathologies, we performed microarray analysis (Affymetrix Mouse 430A 2.0) on HC and CTX samples from 5 and 10 month old normal and MPS VII littermates. We found a limited set of genes (357) showing a 2 fold change ($p<0.01$) in both brain regions which were altered in the MPS VII mice. Changes were seen in lysosomal enzymes and astrocyte activation markers that are consistent with previous pathological findings. Increases in inflammatory markers have been observed in some mouse models of LSD. Changes in neural cell development markers were also seen. A decrease in oligodendrocyte markers suggest alterations in myelination, which are seen in some LSD but have not been reported for MPS. Nine genes were chosen for further analysis: two lysosomal enzymes (GUSB, HEXB), two astrocyte markers (GFAP, LYZS) and five oligodendrocyte markers (ASPA, MBP, MOBP, OLIG2 and PLP1). The changes in direction and magnitude were validated using quantitative RT-PCR (TaqMan). Riboprobes for the nine genes are being constructed to localize changes within the HC and CTX. The data suggest several avenues to peruse in understanding the cellular and molecular basis of mental retardation in a neurogenetic disease.

GenTAC: The National Registry of Genetically Triggered Thoracic Aortic Aneurysms and Cardiovascular Conditions. *C. L. Maslen, and the GenTAC Registry Consortium* Oregon Health & Science U, Johns Hopkins U, U Pennsylvania, U Texas-Houston, Baylor Coll Med, Cornell U, U Michigan, NHLBI, NIAMS, RTI International.

Funded by the National Institutes of Health, GenTAC is a multicenter, longitudinal, observational cohort study of patients at risk for thoracic aortic aneurysms and aortic dissections (TAAD) due to underlying genetic conditions. GenTAC is establishing a registry of clinical data (physical findings, family history, images, and surgical reports) and banked specimens (DNA, plasma, and aortic tissue) from 2800 patients. Clinical data will be updated 2 years after enrollment. The study will compare cross-sectional and longitudinal data regarding phenotypes and risk factors. It will focus on gene-specific phenotypic features, treatment, and outcomes and on identification of imaging methods and plasma biomarkers that can improve the diagnosis and treatment of TAAD. GenTAC began enrollment in November 2007 and should be completed in September 2010. As of May 2008, it comprised 245 patients with a mean age of 34 years (range, 1 to 87 years). Primary diagnoses include Marfan syndrome (MFS), 113 (46%); bicuspid valve (BAV) with aneurysm or a family history of aneurysm, 65 (27%); familial thoracic aortic aneurysm, 34 (14%); idiopathic TAAD in patients less than 40 years, 25 (10%); Loeys-Dietz syndrome, 6 (2%); Turner syndrome, 7 (3%); and Ehlers-Danlos syndrome, 7 (3%). Some patients fit into more than one diagnostic category. The current registry comprises 224 Caucasian (91%), 8 Hispanic (3%), 6 Asian (2%), 6 black (2%) patients, and one of Pacific descent. The mean age at diagnosis was 21 years (range, 0 to 72 years). A total of 69 dissections occurred in 29 patients (9 with MFS, 10 with familial TAAD, 6 with BAV, and 4 with idiopathic TAAD), and 129 have a history of surgical intervention. Researchers have collected blood samples from 202 patients and saliva specimens from 59 patients. GenTAC will be a rich source of clinical and genetic data that will increase our understanding of the genetic basis and clinical management of TAADs. Investigators interested in using GenTAC for ancillary studies should contact the registry at gentac-registry@rti.org or http://gentac.rti.org.

A Heterozygote-Homozygote Test of Hardy-Weinberg Equilibrium. *J. S. Sinsheimer[1,2], J. J. Zhou[1], J. C. Papp[2], K. Lange[1,2]* 1) Dept Biomathematics, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Linkage and association methods typically rely on the principle of Hardy-Weinberg equilibrium (HWE). Although a number of HWE tests exist, most cannot be applied when subjects are related or when the markers are non-codominant. We develop the Heterozygote-Homozygote (HH) test, which can be used with both pedigrees and individuals. In the HH test, the homozygote-heterozygote ratio is estimated by maximizing the likelihood using an efficient quasi-Newton algorithm. The analysis of over 1250 highly polymorphic, multi-allelic markers using extended CEPH pedigrees takes on the order of an hour on a PC with ~130 genotyped individuals where some founder genotypes are missing. Non-codominant markers present no computational difficulties; therefore tightly linked snps can be used in combination without first estimating individuals haplotypes. Using both simulations and actual data examples, we find that the HH test has the appropriate type I error rate and excellent power.

Imatinib Response in CML Patients with Deletions on the Derivative Chromosome 9. *A. L. Berger-Zaslav[1], S. Spitzer[2], T. Mercado[1,2], S. Richard[3], T. Pardee[3], E. Knorr[1], D. Tully[1], K. Zamkoff[3]* 1) Cytogenetics, UHMC, Stony Brook, NY; 2) Molecular Genetics, UHMC, Stony Brook, NY; 3) Blood and Marrow Stem Cell Transplantation Program, UHMC, Stony Brook, NY.

Ph results from a reciprocal (R) translocation (T) of chromosomes 9 and 22. The BCR/ABL gene is formed on the der(22) and the ABL/BCR gene on the der(9). FISH identified unexpected deletions (D) of the T product in 10-15% of patients (Pts) with CML. Studies have shown atypical (AT) abnormal (AB) findings were associated with a more rapid progression (P) to blast crisis (BC) and a shorter overall survival. We previously reported two cases of CML with a D of the ABL/BCR on the der(9). We present follow-up data on these Pts and a third. Initially all Pts were placed on hydroxyurea (H) and allopurinol followed by imatinib therapy (IT). Pts were monitored every 3 m for a y. Pts were evaluated using standard cytogenetic techniques (20 metaphases (Ms) when possible); FISH (200 nuclei (N) each; BCR/ABL DCDF Abbott Mol.), and by quantitative PCR (Roche Biochem.). Initial results were Pt 1: 25 y male in chronic phase (CP) with the T in all Ms, the AT in 194/200 N, and a BCR/ABL/G6PDH ratio of 1.8. Pt 2: 44 y male in CP with the T in all Ms, and a del(6)(q13) in 6/20 Ms, the AT in 159/200 N and a BCR/ABL/G6PDH ratio of 0.2. Pt 3: 57 y female in BC, chromosome analysis was not possible, the AT was present in 157/200 N and a BCR/ABL/G6PDH ratio of 1.8. After induction Pt 1 had a partial cytogenetic response (CR) but no decrease in the BCR/ABL/G6PDH ratio. Pts 2 and 3 showed a significant CR, and had a molecular response (MR) by a 3 log decrease. After 9 m Pt 1 had a partial CR and no MR. Pt 2 achieved remission (RE). Pt 3 never achieved RE. Ds on the der(9) may be a poor prognostic indicator (PI). Early studies were based on H or interferon. Recent studies have demonstrated that this is also true for D Pts on IT. All Pts reported here have AT DS on the der(9). Two of 3 Pts (1 and 3) had a poor response to IT. Even though our Pt sample is small the data corroborates that Ds on the del(9) maybe a poor PI. More studies of Pts with Ds will be useful in determining the significance of these findings.

Frequency of XRCC1 Arg194Trp polymorphism in lung cancer Mexican patients. *MP. Gallegos[1], JM. García[1], G. Morgan[2], AM. Puebla[1], G. Zuñiga[1]* 1) Dept Med Molec, Guadalajara, CIBO, IMSS, Jalisco, Mexico; 2) Centro de Radio Neurocirugía, Hospital de Especialidades, CMNO, IMSS.

Lung cancer is a cause of multiple investigations worldwide due to the high incidence in developed countries and developing. In Mexico it presents as a major health problem, just in the state of Jalisco in 2005 ranked fifth death by cancer, with a frequency of 12.66%. Based on the foregoing different studies in literature have focused on the role they have systems of DNA repair (BER) in cancer and have described the association between Arg194Trp polymorphism in the gene XRCC1 with lung cancer in different populations world. However, there are contradictions in this regard. In Mexico there are no studies of the association between Arg194Trp polymorphism in the gene XRCC1 with lung cancer, which is why in through a descriptive study analyzed 100 samples of DNA Genomic patients with lung from the Hospital de Especialidades, CMNO, IMSS. Guadalajara Jalisco. Mexico. As well as 100 controls samples from Jalisco general population. By PCR a fragment of 491 bp was amplified and identified by Msp I restriction enzyme on electrophoresis gels polyacrylamide to 6% (29:1) after staining with silver nitrate. The frequency of genotypes: Trp / Trp was 4% (5 / 100) and 1% (1 / 100); the Arg / Trp 25% (25/100) and 21% (21/100) and Arg/Arg 70% (70/100) and 78% (78/100) in patients and controls respectively without showing association between the Arg194Trp polymorphisms in the gene XRCC1 with lung cancer [OR 5.21 (CI95% 0.56-248.98)] in the tested sample, so it is concluded that this polymorphism is not associated directly with lung cancer of the tested sample of the Mexican population.ñ.

Arg194Trp polymorphism XRCC1 of gene is not associated with breast cancer from Western of Mexico. *MJ. Renteria[1], M. Morgan[3], AM. Puebla[1], D. Ontiveros[2]* 1) Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Hospital de Gineco-Obstetricia, CMNO,IMSS, Jalisco; 3) Centro de Radio-Diagnostico, Hospital de Especialidades, CMNO, Jalisco.

Breast cancer as health problem worldwide for this reason multiple investigations to achieve understand its pathogenesis with the aim of halting their advance. In Mexico is a major cause of death in women between 35 to 50 years, only in the state of Jalisco in 2006 year the 67% (86/128) of deaths reports were for breast cancer. Based on the foregoing different studies in literature have focused on the role they have systems of DNA repair (BER) in cancer and have described the association between polymorphism Arg194Trp in XRCC1 gene with breast cancer in different populations in the world. However, there are contradictions in this regard. In Mexico there are not studies of the association between Arg194Trp polymorphism in the gene XRCC1 with breast cancer, which is why in through a descriptive study analyzed 156 samples of DNA genomic of women with breast cancer from the Hospital de Especialidades del CMNO, IMSS Guadalajara, Jalisco; Mexico, and samples of 100 women controls the general population of Jalisco. By PCR amplification a fragment of 491 bp and the identification of polymorphism were performed by restriction enzyme MspI means electrophoresis gels polyacrylamide to 6% (29:1) after staining with silver nitrate. The frequency of genotypes: Trp / Trp was 4% (6 / 156) and 1% (1 / 100); the Arg / Trp 17% (26/156) and 21% (21/100) and Arg / Arg 79% (124/156) and 78% (78/100) in patients and controls respectively without showing association between polymorphisms of Arg194Trp of XRCC1 gene in breast cancer patients [OR 3.96 (CI95% 0.47-183.93)]. In the sample analyzed, so it is concluded that this polymorphism is not associated directly with the breast cancer of the tested sample of the Mexican population.

Postnatal diagnosis of 46,XY/45,X mosaicism in dichorionic/diamniotic monozygous twins with discordant gender and somatic phenotypes. *A. M. Svensson[1,2], S. T. South[2,3], A. Rope[3]* 1) Dept. of Pathology, Univ. of Utah & ARUP Laboratories, Salt Lake City, UT; 2) ARUP Laboratories, Salt Lake City, UT; 3) Division of Medical Genetics, Department of Pediatrics, University of Utah Health Sciences Center, Salt Lake City, UT.

We describe a pair of dichorionic, diamniotic, monozygous twins with different ratios of 46,XY/45,X mosaicism. At birth, the female twin displayed mildly ambiguous genitalia and coarctation of the aorta. She died in the newborn period from necrotizing enterocolitis. Her karyotype, performed on stimulated peripheral blood, demonstrated 45,X/46,XY mosaicism, with 45,X in 10 cells and 46,XY in 10 cells. Her male twin's karyotype was evaluated simultaneously and also showed 45,X/46,XY mosaicism with 45,X in 3 cells and 46,XY in 47 cells. Zygosity analysis on DNA from peripheral blood, utilizing a panel of 15 short tandem repeat markers and amelogenin, demonstrated monozygosity. No other cell types were available for analysis in either twin. At the age of 3½ months the male twin showed normal development, with phenotypically normal external male genitalia. Apart from a small umbilical hernia, no other phenotypical abnormalities were seen. The occurrence of dichorionic, diamniotic, heterokaryotypic, monozygotic twinning with discordant sexual and somatic phenotypes due to different ratios of mosaicism is extremely rare. Dichorionic, diamniotic, monozygotic twins are assumed to have separated very early in embryogenesis. Possible mechanisms behind the generation of mosaicism in monozygotic twins include mitotic nondisjunction leading to loss of the Y chromosome. Skewed spatial allocation of the abnormal cells may then cause the two cell populations to recognize each other as different and split into two distinct cell masses. Any twin of a sibling demonstrating 45,X/46,XY mosaicism should be evaluated for this rare, yet possible, phenomenon to ensure appropriate screening and medical management, as well as to provide accurate recurrence risk counseling.

IL-1ra VNTR polymorphism frequency in breast cancer patients and controls from western of Mexico. *AM. Puebla[1], H. González[1], G. Morgan[2], D. Ontiveros[3], MP. Gallegos[1]* 1) Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Centro de Radio-Neurodiagnostico, Hospital de Especialidades, CMNO, IMSS, Jalisco; 3) Hospital de Gineco-Obstetricia, CMNO, IMSS, Jalisco.

Breast cancer is a health problem globally, is the most frequent cause of death among women 35 to 50 years in Mexico, regarded as the leading cause of death among females. These forced our society to carry out studies to understand the pathophysiology of the disease to stop their advance and find the cure more effective. Actually have been studies on the participation of interleukin as proinflammatory molecule in the pathogenesis of cancer. In the present study we investigate the frequency VNTR polymorphism in the gene IL-1ra in120 patients with breast cancer from Hospital de Gineco-Obstetricia, CMNO, Guadalajara, Jalisco, Mexico, and 118 healthy subjects from general population of Guadalajara. Through the PCR were amplified the VNTR alleles 1 (442bp, 4 repetitions), 2 (270bp, 2 repetitions) and 4 (365bp, 3 repetitions) of gene IL-1ra. Posteriori were identified through in polyacrylamide (6%) gels electrophoresis after staining with silver nitrate. The frequency for the 1 allele was 0.38 and 0.56 and allele 2 of 0.52 and 0.44 respectively in patients and controls. The alleles 3 and 4 were observed only in breast cancer showing a frequency of 0.05 for both alleles. Showing significant differences $p < 0.05$. The frequency of 1 allele of the gene VNTR IL-1ra in the control group was higher in comparison to breast cancer patients showing as a protective allele in the tested sample of Mexican population [OR of 0.45 (CI95% 0.25 to 0.82)].

Integration and systems analysis of the genetics of common human multigenic disease. *S. De[1], Y. Zhang[1], J. R. Garner[1], S. A. Wang[2], K. G. Becker[1]* 1) Gene Expression and Genomics Unit, RRB, National Institute on Aging, National Institutes of HealthBaltimore, MD 21224; 2) Division of Computational Bioscience, Center for Information Technology, National Institutes of Health, Bethesda, MD 20892.

Complex multigenic diseases such as cardiovascular disease, autoimmune disorders, neurological disorders and metabolic diseases make up a majority of mortality and morbidity in developed countries. In this study, positive disease associations from the Genetic Association Database (GAD) (Becker et al. 2004) as well as mouse genetic and phenotypic data from the mouse MGI database were used. Disease associated genes and mouse gene-phenotypes were were compared using a unique method similar to phyologenetic classification. First the distance between the diseases were calculated by pairwise comparison of the genes associated with specific diseases. The disease/phenotype relationships were calculated from the distance matrix using Fitch based on the Fitch and Margoliash method of constructing phylogenetic trees. The Neighbor-Joining method of Saitou and Nei (1987) was also used to visualize larger sets. Although Fitch performed more consistently in randomized inputs, Neighbor gave very similar results. A more traditional method of Hierarchical Clustering was also used to determine distance relationships between human disease associated gene sets as well as mouse phenotype gene sets. This approach, based on gene sharing, identified major groupings of disease, placing related disorders in appropriate general disease/phenotype categories, as well as positioning highly related disorders closer in space. This was true for 480 common human diseases, as well as for genes related to 1,056 mouse phenotypes. In addition, we have used these human and mouse disease/phenotype gene sets to rapidly and systematically interrogate public disease based microarray datasets showing disease specificity. This analysis suggests higher order structure and disease relevance in genetic associations mined from published literature. This approach may be developed to make predictions regarding aggregate multigenic risk of developing related common complex disorders. Supported by the IRP of the NIA,and CIT, NIH.

Efficacy of clinical diagnosis of chromosome disorders in cases with dysmorphic features and the cytogenetic findings: A study of 438 cases with dysmorphic features. *F. M. Badr[1,2], K. AlSaidi[2], K. AlMuteri[2], M. M. AlSamman[2], S. S. Binhassan[2]* 1) Faculty of Medicine, King Fahad Medical City, Riyadh, KSA; 2) Cytogenetics and Molecular Cytogenetics Laboratory, King Fahad Medical City, Riyadh, KSA.

Objectives : To report the incidence and distribution of chromosome disorders confirmed by different cytogenetic techniques among cases with dysmorphic features clinically diagnosed as genetic disorders. Subjects and Methods : A total of 438 newborn babies and infants up to 4 years old were referred by clinicians for cytogenetic analysis. Indications for referral were multiple congenital anomalies, and a wide spectrum of dysmorphic features. All cases were karyotyped by conventional G-banding technique and fluorescence insitu hybridization (FISH) was done on interphase cells or on metaphase chromosomes. Results : 137 cases were diagnosed clinically as specific chromosome disorders. All cases referred as Edward, Patu's syndromes (trisomy 13 & 18) and Klinefelter were positively confirmed by cytogenetic testing. Only 57 cases out of 100 clinically diagnosed as Down's syndrome (trisomy 21) were confirmed cytogenetically. Concordance between clinical diagnosis of cases as Turner syndrome with karyotype analysis was very low (5%). Non specified dysmorphic feature cases revealed an incidence of 10.7%; with structural chromosomal aberrations. Of the latter, deletions were the most frequent (37%), translocation (7%), isodicentric ((7%), duplication (21%), marker chromosome (7%), and complex rearrangements (21%). Conclusion: The highest concordance ratio between clinically diagnosed cases and positive cytogenetic findings included chromosome disorders with well recognizable symptoms as the case with trisomies 13, 18 & 21. The low concordance ratio between referral cases and chromosomal abnormalities could be due to the inclusion of cases which mimic phenotypic description of clinically recognizable chromosome syndromes. Other factors which lead to suspicion of chromosome aberration are increased maternal age, consanguinity and familial history.

An adult Acute Leukemia Diagnosed as either AML M_4 or M_5 by Morphologies; and as Non-M_3 AML by Flow Cytometry; the Result was Revised as AML M_{3v} Based on Final Cytogenetic Findings. *H. O. Shah[1, 2], J. Z. Tao[1], D. Mockler[1], S. Naik[1], J. H. Lin[1, 2, 3]* 1) Dept Pathology, Cytogenetics, Nassau Univ Med Ctr, East Meadow, NY; 2) Health Sciences Center, Stony Brook, SUNY; 3) New York College of Osteopathic Medicine, NY.

A 43-year old woman with a history of HIV was admitted to our hospital with a 2-day fever and dehydration. The peripheral smear showed a marked leukopenia (0.6 K/mm^3) and majority of leukocytes were immature showing monocytoid nuclear features characterized by paler, lacy chromatin, occasional reniform and bilobed nuclei and nucleoli. The cytoplasm showed sparse fine granules with no apparent Auer rods. The flow cytometry of immature cells from peripheral blood were positive for CD34, CD33, CD117, CD13 markers, and negative for CD4, CD38, HLA-DR, and B and T lymphoid markers. The marrow flow cytometry showed similar results. A preliminary diagnosis non-AML M_3, of acute myelogenous leukemia of monocytoid features (either M_4 or M_5) was made. Three days following the admission, cytogenetic result of classic 46, XX,t(15;17) (q22;q21) was obtained. The patient was then treated with the protocol for AML M_3. AML M_3 comprises about 5 - 10 % of all AML with a median age of 35 - 40 years old. Morphologically, M3 variant of AML (AML M_{3v}) show fine, sparse cytoplasmic granules, even though specific esterase can elucidate abundant reaction in cytoplasm. Initial leukopenia is most commonly seen in classic M_3, however there is higher frequency of clinical disseminated intravascular coagulation with bleeding in AML M_{3v} . On the contrary to this case, the patient showed initial severe leukopenia with non-classic blasts and no bleeding episodes.

Fetal phenotype of four cases of campomelic dysplasia harbouring novel mutations of SOX9 gene. *F. Lalatta[1], B. Gentilin[1], F. Forzano[2], F. Faravelli[2], M. Baffico[2], M. Lituania[3], P. Ficarazzi[4], T. Rizzuti[5], P. Bianchi[6], E. Grosso[7], M. F. Bedeschi[1]* 1) Medical Genetics Unit, Fondazione IRCCS Ospedale Maggiore Policlinico Mangiagalli e Regina Elena,Milano, Italy; 2) Medical Genetics Unit; E.O. Ospedali Galliera, via Volta 6 Genova Italy; 3) Fetal Medicine Unit; E.O. Ospedali Galliera, via Volta 6 Genova Italy; 4) Obstetrics and Gynecology Unit; Fondazione IRCCS Ospedale Maggiore Policlinico Mangiagalli e Regina Elena,Milano, Italy; 5) Patology Unit;Fondazione IRCCS Ospedale Maggiore Policlinico Mangiagalli e Regina Elena,Milano, Italy; 6) Pediatric Unit; Ospedali Riuniti di Bergamo, Largo Barozzi 1, Bergamo Italy; 7) SCDU Medical Genetics Ospedale S. Giovanni Battista (Molinette) Torino Italy.

Campomelic dysplasia (CD) is a rare congenital skeletal disorder characterized by bowing of the long bones and a variable association of other skeletal and extraskeletal defects, with or without XY sex reversal. CD is caused by mutations in the SRY-box 9 gene (SOX9), a dosage-sensitive gene expressed in chondrocytes and other tissues and located at 17q24. The genotype and phenotype correlation of campomelic dysplasia is still unclear. In the prenatal period the most characteristic sign of campomelic dysplasia is the shortening and marked anterior bowing of long bones, particularly of femur and tibia. Narrow chest, scoliosis, talipes equinovarus, and flat facial profile are other sonographic features commonly present. Increased nuchal translucency, polyhydramnios, and anomalies of the central nervous, cardiac, and renal systems have also been described. We report four cases of campomelic dysplasia detected before the 22nd week of gestation and suspected in the first or second trimester of pregnancy by prenatal ultrasound. The pregnancies were all terminated and the diagnosis of campomelic dysplasia has been confirmed on clinical and radiographic examination of the fetuses. In all cases molecular analysis detected three novel mutations in the SOX9 gene which occurred de novo. Subsequent investigation demonstrated the pathogenetic nature of these mutations.

Inference of haplotypic phase and missing genotypes in polyploid populations and copy number variation regions. *S. Y. Su, D. J. Balding, C. J. M. Coin* Department of Epdimiology and Publuc Health, Imperial College Loncon, London, United Kingdom.

Haplotype-based approaches are powerful tools for association studies, linkage disequilibrium(LD) studies, analysis of copy number variation (CNV) and ancestral inference. However, carrying out a haplotype-based analysis on the basis of genotype data is difficult in polyploid organisms due to lack of an appropriate phasing program. Polyploidy is common in plants (e.g. potato, wheat) as well as in some animals (e.g. goldfish, salmon). Polyploidy also occurs in humans, one such as example is trisomy 21--a common genetic disorder causing Down syndrome. Moreover, heart and liver cells are known to have variable ploidy, as do cancer cells. Copy number variation also results in `local changes in ploidy along the genome. Here, we present a method and software for inference of haplotype phase and missing genotypes from genotype data in a polyploid population. Each sample in the population can have a different ploidy. Our method employs a hidden Markov model (HMM) and a sampling algorithm to infer haplotype structure jointly in multiple samples. Our method also accurately calculates the uncertainty in this estimate. To evaluate the performance of our method, we pair real haploid genotype data to create artificial diploid, triploid, and tetraploid genotype data of known haplotypic phase. The results of the simulation study demonstrate that our method for phasing polyploid genotypes performs well in terms of switch error rate and imputation error rate. Comparing with existing methods, our method is more accurate than fastPHASE for diploids, while there is no existing program available for haplotype phase inference in triploids and tetraploids.

Prenatal manifestation and management of mother and child affected by Spondyloperipheral dysplasia with a C-propeptide mutation in COL2A1. *M. F. Bedeschi[1], V. Bianchi[1], L. Colombo[2], F. Natacci[1], S. Giglio[3], E. Andreucci[3], L. Trespidi[4], B. Acaia[4], A. Superti-Furga[5], F. Lalatta[1]* 1) Clinical Genetics Unit, Fondazione IRCCS Ospedale Maggiore Policlinico Mangiagalli e Regina Elena, Milan, Italy; 2) Neonatal Intensive Care Unit, Fondazione IRCCS Ospedale Maggiore Policlinico Mangiagalli e Regina Elena, Milan, Italy; 3) Department of Clinical Pathophysiology and Medical Genetics Unit, AOU Meyer, Univ. of Florence, Florence,Italy; 4) Obstetrics and Gynecology Clinic I, Fondazione IRCCS Ospedale Maggiore Policlinico Mangiagalli e Regina Elena, Milan, Italy; 5) Dept. of Pediatrics, Univ. of Freiburg, Germany.

It is not unusual for patients with rare conditions to remain undiagnosed until adulthood. In such cases, a pregnancy may result in unexpected problems and special needs. A 28-year-old primigravida was referred at 17 weeks gestation for counselling for possible Dyggve-Melchior-Clausen syndrome, a recessive disorder. She had a skeletal dysplasia with a flat face, short trunk, scoliosis and lumbar hyperlordosis, platyspondyly, and short toes II to V, suggesting the diagnosis of a collagen 2 disorder and specifically of spondyloperipheral dysplasia (MIM 156550). The proband was counselled about the probability of dominant rather than recessive inheritance and offered prenatal diagnosis by sonography. Serial US examinations at 17 to 20 weeks showed fetal macrocephaly, narrow thorax, and shortening and bowing of long bones. The parents opted for continuation of the pregnancy. The baby was delivered at week 33 for maternal reasons, had severe respiratory distress for four weeks but eventually recovered. Mutation analysis revealed a heterozygous nonsense mutation in the C-propeptide coding region of COL2A1 (c.4339 A>T, K1447X) confirming the diagnosis of SPD as well as the geno-pheno correlations between C-terminal COL2A1 mutations and the SPD-Torrance spectrum (Zankl et al, AJMG 133A:61-67, 2005). This case illustrates the importance of a correct diagnosis in adulthood, when individuals with rare conditions have a need to know about recurrence risk, pregnancy-associated risks, as well as potential complications in the newborn.

DETERMINATION OF DNA INDUCED DAMAGE WITH PARACETAMOL IN HUMAN AMNIOCYTES WITH NORMAL AND ABNORMAL KARYOTYPE BY UNICELLULAR ELECTROPHORESIS. *R. Báez-Reyes[1,3], JC. Báez-Reyes[2], G. Razo-Aguilera[1,3]* 1) Deparment of Genetics, National Institute of Perinatology; 2) Deparment of Histophatology, UNAM; 3) Deparment of Morphology, Biologhical Sience School, IPN. Mexico,City.

INTRODUCTION: The unicellular electrophoresis (UE) or comet assay is a very sensitive method to detect the direct damage to the DNA.. The migration of the DNA or tail of the comet represent the damage taken place by the toxic agent. OBJECTIVE: To determine the damage to the basal and induced DNA with paracetamol by means of the UE in amniocytes with normal and abnormal karyotype. MATERIAL AND METHODS: We took a sample of amniotic liquid from 30 women for cytogenetic study. We realized G bands for cytogenetic analysis. Later on, subcultures were made to be treated with 13g/ml of paracetamol during 0, 15, 30 and 45 min. Before and after each time of exhibition the cells were tripsinizing and absorbed in agarose gels to be processed by mean of UE. It was calculated the average of migration of the DNA and the standard error, the results were compared with the Student t test. RESULTS: 15 fetuses had normal karyotype (8 male and 7 female) and 15 had abnormal karyotype. With regard to the basal damage we obteined a migration of the DNA in non cultivated amniocytes of: 2.19 + 0.98 m for the normal fetuses and of 1.44 + 1.77 m for the abnormal ones. In the cultivated amniocytes of: 2.55 + 3.24 for the fetuses with normal karyotype and of 3.44 + 1.61 m for fetuses with abnormal karyotype. In relation to the damage induced by the paracetamol a migration of DNA it was observed: 3.25 + 0.23 m (control), 14.49 + 5.19 m (15 min), 19.62 + 11.4 m (30 min) and 4.11 + 1.01 m (45 min) for the cases with normal karyotype and of: 2.17 + 0.97 m (control), 24.71 + 13.56 m (15 min), 20.48 + m (30 min) and 6.31 + 10.6 m (45 min) for the cases with abnormal karyotype. CONCLUSIONS: The unicellular electrophoresis is an useful methodology to value the damage to the basal DNA and induced by paracetamol in amniocytes of fetuses with normal and abnormal karyotype.

Two Adult Siblings with Arginine:Glycine Amidinotransferase Deficiency: further characterization of clinical and biochemical phenotype. *K. Wierenga[1], M. Dowling[1], A. Verma[1], S. Stabler[2], S. H. Zeisel[3], D. Dimmock[4], L.-J. Wong[4], C. Wagner[5], S. H. Mudd[6]* 1) University of Miami, Miami, FL; 2) University of Colorado, Denver, CO; 3) UNC, Chapel Hill, NC; 4) Baylor College of Medicine, Houston, TX; 5) Vanderbilt Univ., Nashville, TN; 6) Lab Mol Biol, NIMH, Bethesda, MD.

Arginine:glycine amidinotransferase (AGAT) catalyzes the first enzymatic step in the biosynthesis of creatine by converting arginine and glycine to ornithine and guanidinoacetate (GAA). AGAT deficiency results in cellular creatine deficiency, as initially described in 4 members of an Italian family. We now report a second family. A female and male sib pair (now aged 26 and 23 years), children of first-cousin parents, had developmental delay with severe speech delay in childhood. At age 16, the sisters adaptive behavior score was 69; at age 13, the brothers IQ was 40. At age 25, the sister developed progressive proximal muscle weakness. Serum creatine kinase and muscle biopsy were unremarkable. Empiric creatine supplementation (10 g/d) resulted in normalization of muscle strength; communication skills and cognition however showed little improvement. GAA was below the levels for detection in urine and plasma, consistent with a diagnosis of AGAT deficiency. Evidence that these sibs are homozygous for a deleterious AGAT gene mutation will be reported elsewhere at this meeting. After 7 months on creatine therapy, NMR spectroscopy showed brain creatine peaks of 40% of normal in both patients. Concurrent IQs were 53 and 50, respectively. Although AdoMet utilization for methylation of GAA must be impaired in these patients, fasting plasma AdoMet was not elevated, nor was methionine. AdoHcy, cystathionine, total cysteine, serine, arginine, ornithine, and sarcosine were normal. Total homocysteine was low-normal. Free choline was high; betaine was low. Phosphatidylcholine and sphingomyelin were low-normal. In conclusion, AGAT deficiency should be considered in patients with mental retardation, especially those who also develop proximal myopathy. Creatine supplementation can reverse the myopathic deficit in AGAT deficiency. Whether significant cognitive improvement occurs following long-term creatine therapy remains unknown.

A patient with Iris Coloboma with Ptosis, Hypertelorism, and Mental Retardation Syndrome showing unusual Brain Malformation. *S. Sakazume[1], Y. Narumi[1], S. Sato[3], K. Maruyama[3], T. Takagi[3], M. Watanabe[2], A. Nishi[4], T. Shiihara[2]* 1) Dept Genetics, Gunma Childrens Med Ctr, Shibukawa, Gunma, Japan; 2) Dept neurology, Gunma Childrens Med Ctr, Shibukawa, Gunma, Japan; 3) Center of peinatal medicine, Gunma Childrens Med Ctr, Shibukawa, Gunma, Japan; 4) Dept surgery, Gunma Childrens Med Ctr, Shibukawa, Gunma, Japan.

We present a patient with Iris Coloboma with Ptosis, Hypertelorism, and Mental Retardation Syndrome (ICPHMR) having band heterotopia in cranial MR. The case reports of this syndrome is limited and causative genetic defect has not been known yet. Pathological and imaging study of brain may leard to confirm syndrome criteria in a future. Baraitser and Winter (1988) described one familial, brother and sister, and sporadic cases diagnosed as Iris Coloboma with Ptosis, Hypertelorism, and Mental Retardation Syndrome (ICPHMR). In three literatures, chromosome anomalies were reported associated with ICPHMR. Pallotta (1991) reported a boy with same phenotype having pericentric inversion of chromosome 2: inv(2)(p12q14), Ramer et al. (1995) assembled two of the individuals having identical pericentric inversions involving 2p12-q14. Now we know that patient reported by Ayme et al. (1979) having pericentric inversion in chromosome 2. One of the candidate genes of ICPHMR is PAX8 which may work as a key gene for forebrain construction. Surely some patients with ICPHMR reported to have brain anomaly, especially lissencephaly. Data accumulations related to brain anomalies are important to ICPHMR gene cloning. This patient is a boy borne with uneventful delivery following 41 weeks of gestation. Multiple anomalies were noted with characteristic face including iris coloboma, hydronephrosis, and lissencephaly. Using University of Ryu-Kyu Data Base for Malformation Syndrome (URDBMS), ICPHMR is the most likely diagnosis considering his facial appearance. Cranial MR at 5-day-old revealed diffuse pachygyria with sub cortical band heterotopia, and periventricular heterotopia was also noted. The molecular studies including genome array should be planned for further diagnosis.

Alternative methods to detect gene-gene interactions. *L. De Lobel[1], H. De Meyer[1], G. Baele[1], M. Kogevinas[3], k. Van Steen[2]* 1) Department of Applied Mathematics and Computer Science, Ugent, Belgium; 2) Department of electroengineering, Université de Liège,Belgium; 3) Respiratory and Environmental Health Research Unit, Municipal Institute of Medical Research (IMIM), Barcelona, Spain.

The search for susceptibility loci in gene-gene interactions imposes a methodo- logical and computational challenge on statisticians due to the large dimensionality of the modeling of epistasis. In a time where genome-wide scans are common, new powerful methods are required to handle the huge amount of feasible gene-gene in- teractions. A solution is to reduce data by preliminary screening of the markers to select the best candidates for further analysis. When the screening technique and statistical analysis are independent, the same data can be used to conduct both analyses. A method to detect gene-gene interactions developed for rather small data is the Multifactor Dimensionality Reduction method (MDR). MDR is a nonpara- metric, model-free data reduction technique that has become a standard in epistatic research. In this study, we examined the power of MDR in larger data and compared it to other approaches. To improve the performance of MDR in this setting, we used Random Forests (RF) as screening method before executing MDR. We found that the power of MDR increased when noise is rst removed by creating a collection of candidate markers with RF. Apart from a simulation study, the approach is also applied to asthma data from the ECRHS study.

Qualitative analysis reveals differential expression of splice variants of TGIF1 gene in oral squamous cell carcinoma. *T. Liborio[1], F. C. A. Xavier[2], L. F. Matizonkas-Antonio[2], M. G. Silva-Valenzuela[3], D. M. Carraro[4], L. P. Kowalski[4], F. A. Soares[4], J. Câmara[1], F. D. Nunes[2]* 1) Pathology Department, Federal University of Amazonas, Manaus, Brazil; 2) Molecular Pathology Laboratory, School of Dentistry, University of São Paulo, Brazil; 3) Biochemist Department, School of Chemistry, University of São Paulo, Brazil; 4) Hospital Ac Camargo, São Paulo, Brazil.

TGIF1 homeobox gene is subject to the alternative splicing process, which represents an important molecular mechanism responsible for proteome complexity. Different splice variants (SV) may be associated with distinctive behaviors in cancer. TGIF1 transcripts were previously detected in oral squamous cell carcinoma (OSCC), although possible divergences of SVs expression are currently unknown. Expression of different SVs of TGIF1 in OSCC was compared to the adjacent non-tumoral margin (NT) and was associated with clinical and histological parameters. Expression of TGIF1 generic protein was also analyzed. Forty eight samples of OSCC and 12 of NT were used. Total RNA was extracted using TRizol solution. Transcripts of TGIF1 were previously amplified by RT-PCR using a generic primer and then submitted to specific primers for SVs 1, 2, 5, 7 and 8. The protein expression was analyzed by immunohistochemistry in 46 paraffin-embedded tissues. All SVs have the same expression frequency in both OSCC and NT samples. However, SVs are differently expressed in the OSCC patients due to association between SVs 1/4 (p-value: 0,001), 1/8 (p-value: 0,02), 2/4 (p-value: 0,017), 4/5 (p-value: 0,032), and 4/8 (p-value: 0,023). It was not observed association between SVs expression with clinical and histological parameters. Kaplan Meier univariate analysis revealed correlation of SVs 1 (log-rank: 0,0769) and 8 (log-rank: 0,0958) with patients survival, both correlated with a lower risk of death. The simultaneous expression of TGIF1 protein not only in the nucleus but also in the cytoplasm of the cell was correlated with poorly differentiated OSCC (p-value: 0,05). SVs of TGIF1 are differentially expressed in OSCC, possibly suggesting different roles for them in oral carcinogenesis.

Inverted duplication with terminal deletions: toward the identification of a preponderant mechanism. *S. Leclercq[1], MC. De Blois[2], E. Pipiras[3], G. Quenum[2], C. Dupont[3], F. Baverel[1], A. Lebbar[1], JM. Dupont[1]* 1) AP HP, Unité de Cytogénétique, Hôpital Cochin-Saint Vincent de Paul, Paris; 2) AP HP, Service de Cytogénétique, Hôpital Necker, Paris; 3) AP HP, Service de Cytogénétique, Hôpital Jean-Verdier, Bondy.

Inverted dupliation with terminal deletion (inv dup del) are complex chromosomal rearrangements. Two mechanisms are proposed to explain their origin. The best known case involves the short arm of chromosome 8. Inv dup del 8p arise through non allelic homologous recombination (NAHR) between two misaligned olfactory receptor (OR) gene cluster. From the distal to the proximal 8p region, the inv dup del 8p comprises three segments: one deleted, one present as a single copy and one inverted duplicated. The second proposed mechanism involves a U type exchange, leading to end-to-end fusion. The initial event would be a DNA double strand break in a subtelomeric region leading to chromosome instability. In this case, no single copy region would be observed between the deleted and duplicated regions. Inv dup del are now reported for an increasing number of chromosome ends. Usually they are isolated cases with a restricted molecular cytogenetic study so the 8p mechanism could not be extended to other chromosome ends. We report the results of a retrospective study of 5 inv dup del cases involving 4q, 11p, 18p, 20p and Xq ends aiming to establish a main mechanism of formation. We used oligo-array (NimbleGen HG18-WG Tiling 385K) tiling the full genome at a median probe spacing of 6.000 bp in order to detect any single copy region. In three out of five cases, no single region is detected, the NAHR mechanism could be excluded. It seems to be more appropriate to suggest a U type exchange mechanism. The oligo-array data enable us to localize the initial theoretical break. In none of our studied cases, this locus is associated with a hotspot breakpoint or a fragile site. Thus, an accidental break probably generated these rearrangements. To date, it seems difficult to propose a unique mechanism. Further exploration among a more important cohort will be necessary to precise frequency of each mechanism.

Identification of a Patient with Partial Hexasomy for the Prader-Willi Angelman Syndrome Critical Region Due to a Tricentric Supernumerary Marker Chromosome 15. *N. L. Hoppman-Chaney[1], D. B. Dawson[1], L. P. Nguyen[1], S. Sengupta[1], E. McPherson[2], K. Reynolds[2], G. Velagaleti[1]* 1) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 2) Marshfield Clinic, Marshfield, WI.

Deletions and imprinting abnormalities of the Prader-Willi Angelman Syndrome Critical Region (PWASCR), located at chromosome 15q11.2-q13, typically result in either Prader-Willi or Angelman Syndrome. Recently it has been recognized that extra copies of the PWASCR, derived from intrachromosomal duplication or generation of a supernumerary marker chromosome (SMC), have detrimental phenotypic effects as well. Hexasomy for the PWASCR is extremely rare as only 6 cases have been described to date; 2 of which are due to a tricentric SMC 15 with 4 copies of the PWASCR. These patients typically have a broad range of phenotypic findings, including hypotonia, seizures, developmental delay and mental retardation. We identified a 13 year old female patient referred for developmental delay and seizure disorder with a tricentric SMC 15 through routine G-banding chromosome studies. C-banding and fluorescent in situ hybridization (FISH) using probes D15S10, SNRPN, and D15Z1 confirmed the presence of three chromosome 15 centromeres as well as 4 copies of the PWASCR on the SMC in approximately 60% of interphase cells, in addition to 2 copies on the normal chromosome 15s. Methylation-sensitive multiplex ligation-dependent PCR amplification using a commercially available kit revealed that the extra copies of the PWASCR contained on the marker chromosome bear a methylation pattern similar to a normal maternal chromosome, implying maternal inheritance. In conclusion, these results confirm the presence of 4 copies of the critical region on the SMC, resulting in hexasomy for the PWASCR. The extra copies of the critical region are likely maternally imprinted, consistent with the patients phenotype as paternal inheritance of such a marker chromosome is believed to be benign. The patient has some phenotypic overlap with Prader-Willi Syndrome including hypotonia, mild short stature, and obesity. Microsatellite marker testing is currently underway to confirm maternal inheritance of the SMC.

46,XY,i(18)(q10)/46,XY,del(18)(p11.1) mosaicism in an infant with mild congenital anomalies. *S. Kantarci[1,2], J. Picker[2,3], A. B. S. Giersch[2,4], S. Lincoln[3], M. L. Gorman[1]* 1) Beth Israel Deaconess Medical Center, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Children's Hospital, Boston, MA; 4) Brigham and Women's Hospital, Boston, MA.

A newborn male infant was referred to the Genetics Clinic because of hypotonia, respiratory distress, heart murmur, and minor dysmorphic features. The pregnancy and spontaneous vaginal delivery were uneventful. Review at 4 months of age was normal for hearing, vision and systemic review. Developmentally there were no concerns; he was interactive, alert, aware and vocalizing. He fed well, and was generally happy. Physical examination at 4 months of age revealed atrial and ventricular septal defects and borderline aortic arch hypoplasia. Mild nonspecific enlargement of the liver and spleen were detected by abdominal ultrasound. Head circumference was 25th centile, height 10th centile and weight 25th -50th centile. Forehead was mildly sloped, nose flattened and ears had everted prominent lobes with posterior creases and notched and flattened upper helices.The upper limbs had rhizomelic shortening, but the lower limbs were normal. There were no other dysmorphic features and neurological exam was entirely normal. Cytogenetics of peripheral blood showed a mosaic karyotype: 46,XY,i(18)(q10)[14]/46,XY,del(18)(p11.1)[6]. To our knowledge, only five cases with mosaic i(18q)/del(18p) have been reported. Clinical findings of this mosaic constitutional abnormality are not yet fully delineated due to the limited number of cases and therapeutic abortion of the affected fetuses. Clinical findings of del(18p) include growth deficiency, variable degrees of mental retardation, muscular hypotonia, speech delay, craniofacial dysmorphism (holoprosencephaly, broad face, ptosis, strabismus, hypertelorism, low nasal bridge, micrognathia, large protruding ears), hypopituitarism, and limb, genital and cardiac abnormalities. Findings of i(18q) are characteristic of both trisomy 18 and del(18p), or characteristic of trisomy 18 alone. Our case, similar to the previously reported five mosaic cases, show primarily the findings of del(18p) rather than i(18q).

Ultrasound findings in 92 cases of trisomy 18. *B. E. Kamen[1], P. A. Romitti[2], S. R. Patil[3], V. Kancerla[2], K. Borowski[3,4], J. Yankowitz[4]* 1) College of Medicine, University of Iowa, Iowa City, IA; 2) Department of Epidemiology, College of Public Health; 3) Department of Pediatrics, College of Medicine; 4) Department of OB/GYN.

OBJECTIVE: Recognizing trisomy 18 (T18) is important to provide options and counseling to patients. We determined the percent of T18 fetuses that had abnormal prenatal ultrasound findings, the types of abnormalities and proportion of fetuses with each. STUDY DESIGN: In this retrospective chart review, all women with a pregnancy complicated by fetal T18 who had a prenatal ultrasound examination at our institution between July 1989 and March 2006 were included. Sonograms were reviewed, identifying anatomical, and cord, growth and amniotic fluid abnormalities. Average number of organ systems affected, number of abnormalities and number of patients with each abnormality were calculated. Cases that had no or mild anomalies were closely reviewed to ascertain risk factors for failure to detect serious sonographic pathology. RESULTS: 92 cases were identified. Patients were most commonly referred due to isolated defects (29.3%). The average gestation age at first ultrasound was 20.2 weeks and average maternal age was 32.2 years. Eighty four percent of all fetuses had one or more defects which increased to 85% if ultrasounds prior to 14 weeks were excluded. The central nervous system (65%) and cardiac system (61%) were the most commonly affected organs. The most common individual defects were VSDs (50%), postured hands (37% each) and choroid plexus cysts (36%). Of the 13 patients with no abnormalities after 14 weeks, four ultrasounds failured to visualize all anatomy, 3 were twin pregnancies with discordant growth, 3 had isolated CPCs and 3 had a normal ultrasound. Ten of these 13 women were 35 years of age or older. CONCLUSION: This largest study to date (based on a Medline search) shows that about 85% of fetuses with T18 have severe anomalies on prenatal ultrasound. Caution should be exercised in patient counseling following ultrasound when factors like advanced maternal age or abnormal serum screening are coupled with either failure to adequately visualize all anatomy or mild abnormalities are seen.

Exonic hepatic lipase variant associated with insulin resistance in the NHLBI Family Heart Study (FHS). *M. F. Feitosa[1], P. An[1], R. H. Myers[2], J. S. Pankow[3], M. A. Province[1], I. B. Borecki[1]* 1) Washington Univ, St. Louis, MO; 2) Boston Univ, Boston, MA; 3) Univ Minnesota, Minneapolis, MN.

The hepatic lipase gene (LIPC) plays a major role in lipoprotein metabolism and belongs to a network of genes implicated in dyslipidemia and diabetes pathogenesis. The homeostatic model assessment (HOMA-IR), which is calculated as a function of fasting glucose and insulin, has been used to quantify insulin resistance. We investigated whether HOMA was associated with LIPC variants in Caucasians from pedigree-based FHS data and also follow-up in a FHS genome wide association study (FHS GWAS) of 1000 largely unrelated subjects. First, we genotyped 19 tag-SNPs spanning ~137 kb including LIPC in 591 families (2238 subjects). A family-based association test (FBAT) showed significant association (p=0.0019, FDR-p=0.0360) in women between HOMA-IR and rs17190678, which is in linkage disequilibrium (LD) with variants within exon-5 of the gene (r2=0.60). Further, we genotyped 897 unrelated FHS GWAS subjects with 110 tag SNPs across 264 kb of LIPC. There was evidence of association between HOMA-IR with rs6083, a SNP within exon 5 of LIPC (p=0.00072, FDR-p=0.020, by using PLINK). The association was stronger after excluding diabetics or subjects taking medication for diabetes (rs6083: p=0.00037). Association was also found between HOMA-IR with SNPs in introns 4, 6, and 8 (rs17190650, rs7178362, and rs17269397, respectively; 0.000083p0.00053, 0.0092FDR-p 0.019). These four LIPC markers are in LD with each other (0.77LD0.97) based on the CEU HapMap data. The non-synonymous LIPC variant (rs8063; Ser215Asn) minor allele (frequency=0.37) is associated with higher HOMA-IR level, suggesting greater insulin resistance. To construct a proper replication sample, we excluded from the case-control sample all subjects in the pedigree discovery sample, leaving N=351 subjects. The association of HOMA-IR with the four LIPC markers remained (0.004p0.025), despite a 60% reduction in the sample size. This is the first report of association of LIPC Ser215Asn influencing insulin resistance. The current findings suggest that LIPC may be part of the suite of genes that link diabetes and dyslipidemia.

Gene and Pathway-Based Analysis Second Wave of Genome-wide Association Studies. *L. Luo[1], G. Peng[2], H. Siu[2], Y. Zhu[2], P. Hu[2], S. Hong[2], J. Zhao[3], X. Zhou[4], J. Reveille[4], C. Amos[5], L. Jin[2], M. Xiong[1]* 1) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030; 2) School of Life Science, Fudan University, Shanghai 200433 , China; 3) Department of Medicine, Emory University of School of Medicine, Atlanta, GA 30306; 4) Division of Rheumatology, Medical School, University of Texas of Texas Health Science Center at Houston, Houston, TX 77030; 5) Department of Epidemiology, University of Texas, M. D. Anderson Cancer Center, Houston, TX 77030.

Despite great success of GWA studies in identification of common genetic variants associated with complex diseases, the current GWA studies have focused on single SNP analysis. However, Single SNP analysis often identifies a number of most significant SNPs that account for only a small proportion of the genetic variants and offers limited understanding of complex diseases as an integrated whole. To overcome these limitations, we propose gene and pathway-based genome-wide association analysis as a new paradigm for GWA studies. As a proof of concept, we performed a comprehensive gene and pathway-based genome-wide association studies for eleven diseases in seven studies. We found that 42 significant genes and 45 pathways associated with rheumatoid arthritis in WTCCC studies which were replicated in NARAC&EIRA studies, 7 significant genes and 10 pathways associated with type 2 diabetes in WTCCC which were replicated in DGI and 82 significant genes and 30 pathways associated with Parkinson's Disease in NINDS Parkinsonism study which were replicated in NINDS Parkinson disease study. Our results showed that the proposed new paradigm for GWA studies not only identified the genes that include significant SNPs found by single SNP analysis, but also detected new genes in which each single SNP conferred small disease risk, but their joint actions were implicated in the development of diseases. The results also demonstrated that the new paradigm for GWA studies were able to identify biologically meaningful pathways associated with the diseases which were confirmed by gene-set rich analysis using gene expression data.

Comprehensive Analysis of miRNA, mRNA, Methylation and Genotype Data. *H. Dong[1,2], X. Fang[3,2], H. Siu[1], L. Luo[2], G. Peng[1], Y. Zhu[1], R. Chen[4], D. Wheeler[4], M. Xiong[2,1]* 1) Dept Genetics, School of Life Science, Fudan University, Shanghai 200433, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77225, USA; 3) School of mathematical sciences, Peking University, Beijing 100871, China; 4) Human Genome Sequencing Center, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas 77030, USA.

With great progress in experimental technologies, during the past decade, in addition to transcription factors, novel gene regulatory mechanisms have been discovered. Both genomic and epigenetic alterations such as DNA variations, transcription factors, MicroRNAs (miRNAs) and Methylation play crucial roles in a variety of regulations. In order to decipher regulatory mechanisms we investigated 900,660 SNPs, expression profiles of 470 miRNA, 2, 994 Methylation and 11,860 genes in 145 shared brain cancer samples from TCGA project. We found that total 100,481 SNPs and 263 cis-SNPs which significantly regulated expressions of miRNA. On average, each miRNA was regulated by 1,441SNPs and 0.875 cis SNP (P-value < 5.6*10-8). We also found that miRNA significantly influenced total 409 pathways and that on average, each miRNA regulated 20 pathways. We discovered that miRNA significantly regulated expressions of 4265 genes among which there were 44 transcription factors. Some results were confirmed by other sources. We use network models as a framework and structural equations as an analytic tool to integrate analysis of various regulatory components and construct a unified network that connect all components of miRNA, mRNA, Methylation and SNPs. These results reveal novel and deep mechanisms of regulation and provide valuable information for future research in gene regulatory systems.

The G67E mutation in hMLH1 is associated with an unusual presentation of HNPCC. *V. Yu[1,2], E. Hoffman[3], S. Shanley[2], S. Payne[4], S. Fisher[4], R. Barnetson[6], I. Frayling[5], A. Barrett[7], A. Arden-Jones[2], M. Clyne[3], J. Offman[3], J. Virgo[3], R. Eeles[2,8]* 1) Faculty of Medicine, MRC Clinical Sciences Centre, London, London, United Kingdom; 2) Cancer Genetics Unit, Royal Marsden Hospital, Fulham Road, London, SW3 6JJ, UK; 3) MRC Genome Damage and Stability Centre University of Sussex Science Park Falmer BN1 9RQ; 4) North West Thames Regional Genetics Service, Northwick Park & St Marks Hospital, Watford Road, Harrow, London, HA1 3UJ, UK; 5) Institute of Medical Genetics, Cardiff University, School of Medicine, Heath Park, Cardiff, UK; 6) Colon Cancer Genetics Group, University of Edinburgh Cancer Research Centre and MRC Human Genetics Unit, Western General Hospital, Edinburgh, EH4 2XU, United Kingdom; 7) University of East Anglia Norwich NR4 7TJ United Kingdom; 8) Institute of Cancer Research, Brookes Lawley Building, 15 Cotswold Rd, Belmont, Sutton, Surrey, SM2 5NG, UK.

Mutations in the mismatch repair genes are associated with hereditary nonpolyposis colorectal cancer (HNPCC). Here we identify and characterize a new variant of hMLH1 that confers a loss-of-function mismatch repair (MMR) phenotype. The mutation changes the highly conserved G67 residue to a glutamate (G67E) and is reminiscent of the hMLH1-G67R allele, which is present in several HNPCC cohorts. hMLH1-G67R has previously been assessed to confer loss-of-function, and two functional assays suggest that the hMLH1-G67E protein fails to sustain normal MMR functions. In the first assay, hMLH1-G67E abolishes the proteins ability to interfere with MMR in yeast. In the second assay, mutation of the analogous residue in yMLH1 (yMLH1-G64E) causes a loss-of-function mutator phenotype similar to yMLH1-G64R. Despite these molecular similarities, family analysis shows that the cancer spectrum associated with hMLH1-G67E are atypical of HNPCC and different from those found in families carrying the hMLH1-G67R allele. This suggests hMLH1 may have different functions in certain tissues and/or that additional factors may modify the influence of hMLH1 in causing HNPCC.

Genome-wide association scans for secondary traits using case-control samples. *G. M. Monsees[1], P. Kraft[1,2]* 1) Dept of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Dept of Biostatistics, Harvard School of Public Health, Boston, MA.

Genome-wide association studies (GWAS) require considerable investment, so researchers often study multiple traits collected on the same set of subjects to maximize return. This has lead many many GWAS to adopt a case-control design; however, improperly accounting for case-control ascertainment can lead to biased estimates of association between markers and secondary traits. We show that under the null hypothesis of no marker-secondary trait association, naïve analyses that ignore ascertainment or stratify on case-control status have proper Type I error rates except when both the marker and secondary trait are independently associated with disease risk. Under the alternative hypothesis, these methods are unbiased only when the secondary trait is not associated with disease risk. We also show that inverse-probability-of-sampling-weighted (IPW) regression provides unbiased estimates of marker-secondary trait association. We use simulation to quantify the Type I error, power and bias of naïve and IPW methods. IPW regression has appropriate Type I error in all situations we consider, but has lower power than naïve analyses. The bias for naïve analyses is small provided the marker is independent of disease risk. Considering the majority of tested markers in a GWAS are not associated with disease risk, naïve analyses provide valid tests of and nearly unbiased estimates of marker-secondary trait association. Care must taken when there is evidence that both the secondary trait and tested marker are associated with the primary disease, a situation we illustrate using an analysis of the relationship between a marker in FGFR2 and mammographic density in a breast cancer case-control sample.

A Disease Severity Scoring System for Type 1 Gaucher Disease. *S. vom Dahl[1], M. D. Cappellini[2], T. Cox[3], E. H. Giannini[4], G. A. Grabowski[4], W. L. Hwu[5], H. Mankin[6], A. M. Martins[7], C. Sawyer[8], N. Weinreb[9], M. Yeh[8], A. Zimran[10]*
1) St. Franziskus Hosp, Cologne, Germany; 2) Univ degli Studi di Milano, Milano, Italy; 3) Univ of Cambridge, Cambridge, UK; 4) Cincinnati Childrens Hosp Medical Center, Cincinnati, USA; 5) National Taiwan Univ Hosp, Taipei, Taiwan; 6) Mass General Hosp, Boston, USA; 7) Univ Federal de Sao Paulo, Sao Paulo, Brazil; 8) Genzyme Corp, Cambridge, USA; 9) Univ Res Foundation for Lysosomal Storage Disorders, Coral Springs, USA; 10) Shaare Zedek Medical Center, Jerusalem, Israel.

Introduction: A validated disease severity scoring system (DS3) for type 1 Gaucher disease (GD1) is needed to monitor progression and treatment response in individuals and to compare patient cohorts in clinical studies. Objective: To develop and test the reliability and validity of a DS3 to assess and monitor GD1 in adults. Methods: DS3 domains were established by an expert physician group using nominal group technique (NGT) consensus formation methodology. Items within domains were selected by Delphi survey of 32 physician experts in GD1. The expert group determined appropriate measurement techniques for each variable, and measurements were weighted considering how much morbidity and mortality each contributes to GD1. Twelve physicians with expertise in GD1 and no prior exposure to the DS3 rated content validity and feasibility and scored patient profiles using the DS3 and the Clinical Global Impression Severity Scale (CGI-S). Results: The DS3 includes bone, hematological, and visceral domains, which were populated with weighted measurements of GD1 signs and symptoms. Relevance, feasibility, and inter-rater reliability were assessed by content validity index (83%), feasibility index (92%), and intraclass correlation (0.89), respectively. Patient profile DS3 scores were highly correlated with CGI-S scores (R^2=0.90). Conclusions: The DS3 working model is feasible, relevant, and reliable for assessing disease severity in adults with GD1. DS3 scores highly correlate to those obtained by a validated severity scale (CGI-S), but are more specific to GD1 and responsive to change. Testing in larger patient cohorts and of additional aspects of reliability and validity will continue.

Rare mutation detection utilizing different Next Generation DNA sequencing platforms. *D. Smith[1], A. Huehls[2], B. Eckloff[3], S. Middha[4], Y. Asman[4], J. P. Kocher[4], M. Barker[5], P. Milos[6]* 1) Lab Med & Path/Exper Path, Mayo Clinic, Rochester, MN; 2) Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN; 3) Advanced Genomics Technology Center, Mayo Clinic, Rochester, MN; 4) Health Sciences Research, Mayo Clinic, Rochester, MN; 5) Applied Biosystems, Foster City, CA; 6) Helicos Biosciences Corporation, Cambridge, MA 02139.

There are now multiple platforms available that have the capabilities of utilizing multiple parallel DNA sequencing to sequence millions of DNA templates. There are numerous applications of this novel technology including the ability to detect rare mutations from biological fluids. We decided to test three of the currently available platforms which produce short sequence reads to compare their ability to detect rare mutations: the Illumina Genome Analyzer, the ABI SOLID system and the Helioscope from Helicos. We chemically synthesized a wild type 58 base pair region from exon 5 of the p53 gene and cloned this into the bacterial vector pUC57. We also cloned four different mutations within this same region of the p53 gene. The fragments were then cloned into E. coli to take advantage of the fidelity of bacterial replication. Single clones with the correct insertions were then grown up to produce large quantities of intact plasmid for dilution experiments. We then made seven different mixtures of plasmids for deep sequencing. The first corresponded to 100% wild type sequence. The remaining six had different concentrations of all four different mutations ranging in concentration from 2% all the way down to 0.02%. While we started this experiment by cutting out a 200 base pair piece containing the synthetic p53 insertion we quickly realized that each of these sequencing platforms could easily completely deep sequence the entire 2710 bp pUC57 plasmid with the insertions. The resulting overlapping short sequence reads generated were then aligned to determine the ability of each of these three platforms to detect rare mutations and to determine what frequency of rare mutations could be detected with each platform. These technologies clearly have the ability to detect rare mutations and thus have tremendous clinical potential.

Genome-wide Pathway Analysis. *M. Xiong[1], L. Luo[1], G. Peng[2], Y. Zhu[2], C. Amos[3]* 1) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030; 2) School of Life Science, Fudan University, Shanghai 200433 , China; 3) Department of Epidemiology, University of Texas, M. D. Anderson Cancer Center, Houston, TX 77030.

To meet conceptual and technical challenge raised by GWA and take full advantage of the huge opportunities provided by GWA, we propose to develop gene and pathway-based genome-wide association studies as a new paradigm for genome-wide association studies of complex disease. One framework to test for association of genes with disease is to directly develop statistics for global testing association of genes with disease. Another framework is to combine p-values of individual SNP tests. In this report, we will focus on combining individual association tests of SNPs because this approach has close relationships with the traditional single SNP-based association analysis. The popular method for combining individual evidence is meta-analysis. Widely used meta-analysis is to combine independent P-values of individual tests. However, in general, correlations among p-values of SNPs within the gene exist due to LD among SNPs. Correlations among SNPs will invalidate the methods for combining independent p-values. Therefore, to perform gene and pathway-based GWA studies, we need to develop methods for combining dependent p-values which take correlations among SNPs into account. We propose three statistics for combining dependent P-values: Linear Combination Test, quadratic test and Decorrelation test. We calculate type 1 error of the developed statistics and study influence of the correlations among SNPs or genes on the test statistics. We assembly about 1,000 pathways from KEGG and BIOCART pathway database. The proposed statistics have been applied to genome-wide association studies of five diseases. The preliminary results show that the proposed methods dramatically increase the power to identify the genes and pathway associated with the diseases and improve the ability to replicate the association finding. The results also demonstrate that the pathway-based association analysis makes interpretation of the results and unravel the mechanism of the diseases much easier.

Three Ways of Genome-wide Pathway Analysis. *X. Zhou[1], H. Xiong[2], L. Luo[3], F. Arnett[1], M. Xiong[3]* 1) Division of Rheumatology, Medical School, University of Texas of Texas Health Science Center at Houston, Houston, TX 77030; 2) Department of Computer Science,Texas A&M University,College Station, TX 77843; 3) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030.

We assume that three types of data: genome-wide time course gene expression data, genome-wide genotype data and clinical endpoint of phenotypes are available. Traditional genome-wide association (GWA) studies is to use a SNP as a basic unit of association and to test association of a single SNP at a time. Similar to gene set enrichment analysis of gene expression data, we propose a pathway-based GWA studies that use a pathway as a basic unit of association and test association of a pathway with the disease. We also propose how to use continuous state-space model to connect cis and trans eQTLs to significantly differentially expressed pathway. We propose a general procedure for jointly performing three ways of genome-wide association analysis of complex diseases, which uses pathway analysis as a unified strategy for conducting genome-wide association studies and network model as a general framework for integration of genotype, gene expression and phenotype data. The procedure consists of two steps. First step is to perform genome-wide pathway analysis of gene expression, pathway-based GWA studies of disease and pathway-based genetic analysis of time course gene expression using state-space model. Second step is to use network model and meta-analysis to jointly conduct three ways of genome-wide pathway analysis, which will lead to deciphering path from genomic information through gene expression to clinical endpoints of disease. The proposed methods have been successfully applied to real systems sclerosis data.

Identification of novel CDH1 germline mutations in diffuse gastric cancer and lobular breast cancer. *W. Zeng[1], K. Gonzalez[1], M. Parra[1], H. Dominguez[1], C. Fong[1], S. Sommer[2], J. S. Saldivar[1]* 1) Molecular Diagnostic Laboratory, City of Hope National Me, Duarte, CA; 2) Department of Molecular Genetics, City of Hope National Medical Center, Duarte, CA.

Germline mutations in the CDH1 gene which encodes E-cadherin, a cell-cell adhesion protein, have been identified in hereditary diffuse gastric cancer. Associations between CDH1 germline mutations and both lobular breast cancer and signet ring carcinoma of the colon have been reported in HDGC families. Since offering CDH1 full gene sequencing for clinical testing, 93 diffuse gastric cancer families have been analyzed in our laboratory. All of the 16 coding exons and associated intron junctions of the CDH1 gene were directly sequenced using ABI 3730 sequencer. A total of 24 germline mutations were found in 93 families, giving a detection rate of about 26%. Of the 24 mutations identified, eighteen were in families that had at least two or more cases of gastric cancer in a family, with at least one diffuse gastric cancer diagnosed before age 50 years (18/24; 75%); the other six mutations were distributed equally in six families with two mutations each found in patients meeting the 2nd, 3rd, and 4th revised IGCLC criteria1. Twelve of these mutations identified were novel: 4 splicing mutations, 7 truncating mutations (4 nonsense, 1 deletion, and 2 insertions), 1 missense/splicing mutation. Among those probands who tested positive for a mutation, one had bladder cancer at 52 years of age followed by diffuse gastric cancer diagnosed at 54 yrs; another proband had Hodgkin's disease at 14yrs followed by a diagnosis of diffuse gastric cancer at 26 years. The current data identified additional 13 novel mutations in the CDH1 gene. The occurrence of extra-gastric tumors associated with CDH1 mutations warrants further investigation. 1. Brooks-Wilson et al. J Med Genet. 2004; 41: 508-17.

Continuous State-Space Model for Genetic Analysis of Time-Course Gene Expression Data. *H. Xiong[1], L. Luo[2], F. Arnett[3], X. Zhou[3], M. Xiong[2]* 1) Department of Computer Science,Texas A&M University,College Station, TX 77843; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030; 3) Division of Rheumatology, Medical School, University of Texas of Texas Health Science Center at Houston, Houston, TX 77030.

Enormous difficulties arise from analyzing large temporal observations in gene regulation and signal transduction networks. Traditional quantitative genetics has primarily studied traits that are measured at a specified location or time. DNA is assigned a static role. The traits are investigated as isolated and static variables. Therefore, they have limited power to untangle the complicated biological networks and to decipher the mystery of the paths that connect genotypes and phenotypes. In this report, we propose to use a continuous state-space model for genetic studies of gene regulation and signal transduction networks, Specifically, we model time-course gene expression data of genetic networks as a dynamic biological system which will finally lead to stochastic differential-algebraic equations. The concept of a dynamic system that originally arose from the Newtonian mechanics is now widely used as a basic framework for scientific research. Dynamic models not only focus on functional values themselves, but also focus on the rates of changes of functions. Dynamic models allow us to simultaneously model both the function itself and its derivatives. We propose to use EM algorithms to estimate the parameters of stochastic differential-algebraic equations which are based on continuous Kalman filter. We then develop statistics to test association of SNPs with gene regulation and signal transduction networks. We use both simulation and real time course gene expression and genome-wide genotype data of systems sclerosis to validate the models. Preliminary results show that continuous state-space models are powerful tool for investigation of genetics of time course gene expression data and other longitudinal genetic studies of complex diseases.

Mapping a novel locus for microcephaly, learning disability, and congenital cardiovascular and renal anomalies.

C. L. Beaulieu[1], K. M. Boycott[2], D. R. McLeod[1], A. M. Innes[1], J. S. Parboosingh[1] 1) Dept of Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 2) Dept of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

The Hutterites are a genetically isolated Anabaptist group living on the North American prairies; their population numbers over 40,000, the majority of whom are descendants of 89 founders. An autosomal recessive neurodevelopmental disorder was identified in four patients from two consanguineous Hutterite families. To our knowledge the clinical presentation is unique and to date undescribed. The patients have distinctive facial features, congenital malformations of the heart and genitourinary system, borderline microcephaly, and nonverbal learning disability. The facial features include very tall forehead with high anterior hairline, deep-set eyes with short palpebral fissures, long nose with overhanging columnella, and full lips. The spectrum of congenital malformations includes ventricular septal defect, patent ductus arteriosis, and horseshoe kidney. Karyotype and baseline metabolic studies were normal.

An identity-by-descent mapping approach was used to identify the locus for this disorder. The patients were genotyped using a 50K-SNP microarray which identified a single, strong homozygous region on 16p13.3 which was shared between all of the patients. To confirm and refine the boundaries of this region, microsatellite markers were genotyped for the patients, the parents, and the available unaffected siblings. The disease locus was refined to a region of 5.1Mb containing 160 known or predicted genes. No other recessive disorders with similar clinical features are currently mapped to this region. Prioritization of genes within the region through data searching and microarray expression analysis is underway, and no mutations have been identified by sequence analysis of 40 genes.

Identification of Men with a genetic predisposition to ProstAte Cancer: Targeted screening of *BRCA1/2* mutation carriers and controls. The IMPACT study. Pilot results show a high frequency of positive biopsy. *A. Mitra[1], E. Bancroft[2], R. Eeles[1]* 1) Institute of Cancer Research, London, UK; 2) Royal Marsden Hospital NHS Foundation Trust, London, UK.

IMPACT, an international collaborative study is a targeted prostate cancer (PrCa) screening study of men with a known germline mutation which is thought to predispose to the disease. Male *BRCA1/2* mutation carriers and a control group who have tested negative for a mutation known to be present in their family, are screened annually with a serum PSA test. The threshold for prostate biopsy is PSA > 3ng/ml. The study is designed to recruit men over a period of 5 years and has been running for 31 months. The pilot data for 237 men aged 40-69 years (median age 54 years) from the first screening round has been collected. In total, 6 men have had a PrCa diagnosed and 2 men are awaiting biopsy. The European Randomised Study for Prostate Cancer (ERSPC) PSA threshold is PSA >= 3ng/ml. The number of men with a PSA>= 3ng/ml in IMPACT is 17/237 (7.1%) compared with 2048/10191 (20.0%) in the ERSPC. Of note, the PSA assay in the ERSPC produces values that are ~20% higher than the assay used in IMPACT, but this would still not account for this difference. The median age of men in IMPACT is 54 years compared with 66 years in the ERSPC. This may account for the lower biopsy rate. However, in IMPACT, of those biopsied at this threshold, 6/13 (46%) are positive for PrCa whereas in ERSPC this value was 541/1850 (29%). The PrCas that develop in mutation carriers have a higher proportion of Gleason pattern 4 or more advanced disease compared with non-carriers. Targeted screening based on *BRCA1/2* germline mutation is feasible and the biopsy rate is acceptable. The proportion of positive biopsies is much higher than in the population based screening studies and the disease is aggressive. These pilot data indicate that the main IMPACT study should proceed and that targeted screening based on genotype has a high yield of positive biopsy.

Improved clinical outcome in a Pompe disease patient increased from 20 to 40 mg/kg Myozyme every 2 weeks. *K. Kim[1,2], S. Widera[1], B. Burton[1,2]* 1) Division of Genetics, Children's Memorial Hospital, Chicago, IL; 2) Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, IL.

We report on a 4 year old boy, RC, with Pompe disease, who exhibited significant clinical and biochemical improvement following an increase in biweekly Myozyme (alglucosidase alfa) dose from 20 mg/kg to 40 mg/kg. RC was diagnosed with Pompe disease when increased glycogen content was noted on muscle biopsy at age 9 mos and deficiency of acid -glucosidase activity was demonstrated in multiple tissues. He was felt to have late-onset infantile type based on clinical symptoms and *GAA* mutation results. Enzyme replacement therapy (ERT) with biweekly infusions of Myozyme at 20 mg/kg was initiated at age 20 mos. At the start of ERT, RC had generalized hypotonia, myopathic facies, calf pseudohypertrophy, and motor delay. He was crawling, cruising and pulling to stand with assistance. Echo and ECG were normal. Apnea was noted on polysomnogram. Myozyme infusions were well tolerated with no infusion associated reactions (IARs) observed. After 10 mos of therapy, RC could take a few independent steps but continued to exhibit an exaggerated broad-based and lordotic gait with side to side steps. No additional gains in motor milestones were subsequently observed. After 18 mos on ERT, Myozyme dose was increased to 30 mg/kg for 3 mos and then further increased to 40 mg/kg after infusions were well tolerated and parents reported increased activity level and endurance. On exam after 6 mos of biweekly infusions of Myozyme at 40 mg/kg, RC was more active and vigorous with improved muscle strength and tone and a dramatically improved gait. His facial appearance was more animated. No IARs and no change in antibody titers were observed at the increased dose. A decrease in urine hexose tetrasaccharide levels was observed. Based on our experience, we conclude that improvement of skeletal muscle symptoms can be observed in some patients with an increase in Myozyme dose. Higher doses can be well tolerated in some young patients without observed IARs. Therefore, Myozyme dosing should be patient specific and higher doses should be considered and further investigated to achieve an improved outcome.

The male-determining gene SRY is a hybrid of DGCR8 and SOX3, and is regulated by the transcription factor CP2. *Y. Sato, T. Shinka, K. Sakamoto, Y. Nakahori* Tokushima Univ, Tokushima, Japan.

In mammals, sex is determined by the presence or absence of the Y chromosome that bears a male-dominant sex-determining gene SRY, which switches the differentiation of gonads into male testes. The molecular signaling mechanism turning on the switch, however, has remained unclear for 18 years since the identification of the gene. Here, we describe how this gene emerged and started to work. From amino acid homology, we realized that SRY is a hybrid gene between a portion of the first exon of DiGeorge syndrome critical region gene 8 (DGCR8) and the high-mobility group (HMG) box of SRY box-3 (SOX3) gene. We pinpointed the regulatory sequence in the SRY promotor region by searching for a common motif shared with DGCR8 mRNA. From the motif search between DGCR8 mRNA and the SRY upstream sequence, we found that the TFCP2 binding motif is present in both. TFCP2 overexpression led to up-regulation of SRY mRNA expression, and TFCP2 suppression by RNA interference (RNAi) significantly reduced SRY mRNA expression. Furthermore, electrophoretic mobility shift assay (EMSA) demonstrated that TFCP2 acts as a regulator by directly binding to the SRY promoter. We conclude that SRY is a hybrid gene composed of two genes, DGCR8 and SOX3; and TFCP2 is an essential transcription factor for SRY expression regulation.

Correlation between *EGFR* mutations and the effectiveness of gefitinib in patients with lung adenocarcinoma. *M. Takasu[1], H. Nishioka[1], T. Mawatari[1], E. Iwamoto[1], S. Kondo[1], H. Yamaguchi[2], K. Nakatomi[2], Y. Nakamura[2], S. Kohno[2], K. Tsukamoto[1]* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci; 2) Second Dept Inter Med, Nagasaki Univ Sch Med.

Objective: Somatic mutations of the epidermal growth factor receptor (*EGFR*) show dramatic clinical and radiographic response to the EGFR tyrosine kinase inhibitors, gefitinib, against patients with non-small cell lung cancer. There are hot-spot mutations of *EGFR*, such as 9- to 18-bp deletion in exon 19 and L858R point mutation in exon 21. The aim of this study was to evaluate correlation between *EGFR* mutations and the effectiveness of gefitinib in Japanese patients with lung adenocarcinoma. Methods: All of 46 samples (11 samples of fresh frozen surgical specimens, 14 paraffin-embedded surgical specimens, 10 transbronchial lung biopsy (TBLB) specimens, and 11 pleural fluid) from Japanese patients with lung adenocarcinoma, who received gefitinib treatment in the Nagasaki University Hospital or other hospitals in Nagasaki were examined the deletion of exon 19 and L858R of exon 21 of *EGFR* using mutant-enriched PCR assay. Subsequently, the outcomes of patients with or without *EGFR* mutations were compared with the effectiveness of gefitinib. Results: *EGFR* mutations (16 deletions and 14 L858R mutations) were detected in 23 patients (50%) out of all 46 patients. Response rate to gefitinib was 95.8% in patients with *EGFR* mutations, whereas 36.4% in those without mutations. The sensitivity and specificity of this analysis were estimated at 74.2% and 93.3%, respectively. The frequency of false-negative samples were higher in TBLB or pleural fluid than that in fresh frozen and paraffin-embedded surgical specimens. Conclusion: This study showed a significant clinical benefit of gefitinib in patients with *EGFR* mutations and indicated the availability of *EGFR* mutation analysis by mutant-enriched PCR assay. However, further studies are needed to establish the DNA-based diagnosis combining other gene mutation analysis and microdissection technique, in order to screen patients of high chemosensitivity to gefitinib and to decrease in the false-negative rate.

Identification of the disease gene susceptible to the progression of primary biliary cirrhosis in Japanese patients.

N. Iio[1], T. Inamine[1], S. Higa[1], F. Noguchi[1], S. Kondo[1], M. Nakamura[2], H. Ishibashi[2], K. Omagari[3], K. Tsukamoto[1] 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci; 2) Clin Res Center, Natl Hosp Organi Nagasaki Med Center; 3) Dept Nutr, Siebold Univ Nagasaki.

Objective: Primary biliary cirrhosis (PBC) is a chronic and slowly-progressing autoimmune liver disease and is a multifactorial disease. In order to identify the unknown genetic determinants of onset, the disease severity, and progression of PBC, we examined an association of single nucleotide polymorphisms (SNPs) in the retinoid X receptor beta (*RXR*) gene as a candidate gene, because RXR is a nuclear receptor, which regulates expression of hepatobiliary transports and enzymes involved in bile acid metabolism and detoxification in the liver. Methods: The study subjects comprised 148 Japanese patients with PBC and 150 age- and gender-matched healthy control subjects. Patients were classified into three different clinical stages (I, II, and III) based on the findings of liver biopsy and clinical manifestations. Clinical stages I + II were defined as non-jaundice stage, whereas stage III was defined as jaundice stage. The two SNPs in *RXR*, rs2076310 and rs2072915, were detected by PCR-restriction fragment length polymorphism. Subsequently haplotypes were constructed from these SNPs. The frequencies of alleles, haplotypes, and diplotypes were compared between PBC patients and control subjects, as well as between subgroups of PBC patients by logistic regression analysis using SPSS 15. Results: Logistic regression analyses revealed that a haplotype, Hap 3, and a diplotype, Hap 1/Hap 3, in *RXR* were significantly increased in jaundice-stage PBC patients compared with nonjaundice-stage PBC patients [$P = 0.0004$, odds ratio (OR) = 6.96 and $P = 0.0002$, OR = 13.29, respectively]. Conclusion: The present study is the first report demonstrating the association between the haplotype and diplotype of *RXR* and the susceptibility to severe progression of PBC. Therefore, *RXR* is a genetic determinant of the progression of PBC, and could potentially be applied to DNA-based diagnosis in Japanese patients with PBC as a strong genetic biomarker for predicting the progression and prognosis of PBC.

Sequential change of gene expression profiles in the liver of Long-Evans cinnamon rats at different stages of developing hepatitis. *J. Kim[1], J. H. Kim[1], J. Y. ParK[1], G. Kim[1, 2], H. Yoo[1, 2]* 1) Genome Reserch Center , Asan Medical Center, Seoul, Korea; 2) Medical Genetic Clinic, Department of Pediatrics, Asan Medical Center, University of Ulsan, Seoul, Korea.

Wilson disease (WD), an autosomal recessive disorder of copper transport, is one of the most common inherited metabolic disorders in Korea. The Long-Evans cinnamon (LEC) rat, a natural animal model for Wilson disease caused by the mutation in the Atp7b gene homologous to the human ATP7B gene, shows similar clinical features as human Wilson disease including extensive copper accumulation in the liver with hepatitis and decreased serum ceruloplasmin level. This study was undertaken to investigate the sequential change of gene expression profiles in the liver of Long-Evans cinnamon rats at different stages of developing hepatitis. Total RNA was isolated from liver tissues of 9 LEC (each 3 animals per 6, 12, 24 weeks of age) and 9 wild type Long-Evans agouti (LEA) rats (each 3 animals per 6, 12, 24 weeks of age). Subsequently, total RNA was reverse-transcribed to cDNA using a T7 oligo(dT) primer. Second-strand cDNA was synthesized, in vitro transcribed, and labeled with biotin-NTP. Labeled cRNA samples were hybridized to each Rat-12 expression bead (Illumina, Inc., San Diego, USA). Detection of array signal was carried out using Amersham fluorolink streptavidin-Cy3 (GE Healthcare Bio-Sciences, Little Chalfont, UK) following the bead array manual. Arrays were scanned with an Illumina bead array Reader confocal scanner. Array data export processing and analysis was performed using Illumina BeadStudio. The results show that 278 genes turned out to be significantly differentially expressed among 22,517 target genes. At the age of 6 weeks, 23 were up-regulated and 29 down-regulated. At the age of 12 weeks, 68 were up-regulated and 33 down-regulated. At the age of 24 weeks, 87 were up-regulated and 38 down-regulated. During the progression of liver disease of LEC rats, the genes of molecular function related to oxidative stress, inflammation and apoptosis were up-regulated while the genes related to ribosomal protein, cytochrome oxidase and solute carrier family proteins tended to be down-regulated.

Polymorphisms of *iNOS* are associated with anti-tuberculosis drug-induced hepatotoxicity in Japanese patients with tuberculosis. *T. Mawatari[1], S. Fujie[1], M. Yosida[1], N. Higuchi[2], K. Tsukamoto[1]* 1) Dept Phrmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci; 2) Dept Pharmacy, Nagasaki Univ Hosp Med Dent.

Objective: Tuberculosis (TB) is a re-emerging infectious disease. TB care involves serious problems including the occurrence of adverse effects of anti-TB drugs. Our focus of interest in this study was hepatotoxicity, because it is the major and severe adverse effect. Recent studies suggest that hepatotoxicity is induced through reactive oxygen and nitrogen species by acetaminophen in mice. Thus, the aim of this study is to investigate whether polymorphisms of the inducible nitric oxide synthase (*iNOS*) gene, which is induced by reactive oxygen species and generates reactive nitrogen species, is associated with anti-TB drug-induced hepatotoxicity in Japanese patients with pulmonary TB.**Methods**: The study subjects comprised 100 Japanese patients with new onset of pulmonary TB treated at least with isoniazid and rifampicin-containing regimen for six or nine months. Nine single nucleotide polymorphisms (SNPs) in *iNOS* were determined by PCR-restriction fragment length polymorphism and PCR-direct DNA sequencing methods. Subsequently, haplotypes were constructed from the two SNPs, rs11080344 and rs3794756, because of the significant association of these SNPs with hepatotoxicity. The frequencies of alleles, genotypes, haplotypes, and diplotypes were compared between TB patients with and without hepatotoxicity.**Results**: Logistic regression analyses revealed that the frequency of a C/C genotype at the rs11080344 site in *iNOS* were significantly higher in TB patients with hepatotoxicity than those without it [$P = 0.044$, odds ratio (OR) = 2.87]. Moreover, a haplotype, Hap 1, and its homozygous diplotype, Hap 1/Hap 1, were significantly increased in TB patients with hepatotoxicity compared with those without it ($P = 0.0463$, OR = 2.098 and $P = 0.0086$, OR = 5.357, respectively).**Conclusion**: The present study is the first report demonstrating the association between *iNOS* polymorphisms and the susceptibility to anti-TB drug-induced hepatotoxicity. Therefore, the Hap 1/Hap1 diplotype in *iNOS* could be useful as a new biomarker for predicting anti-TB drug-induced hepatotoxicity.

Identification of novel mutations and the common mutation in the human *NOTCH3* gene of Korean patients with cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). *G. Kim[1], J. Lee[1], I. Lee[1], J. Park[2], S. Choi[1], H. Yoo[1,2,3]* 1) Med Genetics Clinic & Lab, Asan Medical Center, Seoul, Korea; 2) Genome Research Center for Birth Defects & Genetic Disorders, Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a small vessel disease of the brain, which is characterized by recurrent subcortical ischemic attacks, stepwise or progressive cognitive decline, and white-matter abnormalities on brain magnetic resonance images (MRI). The disease is caused by mutations of the NOTCH3 gene, which encodes a transmembrane receptor expressed in vascular smooth muscle cells. It has been reported that the mutations of NOTCH3 were mostly found in EGF-like domain 2-8 of NOTCH3 protein, which corresponded to exon 2 through 6 of the gene. To characterize molecular defects of the NOTCH3 gene in Korea patients with clinical diagnosis of CADASIL, we screened 840 unrelated patients with stroke, cerebral infarction, and/or vascular leukoencephalopathy by PCR-directed sequence analysis of hot spots on NOTCH3 gene using genomic DNA from peripheral blood leukocytes. We identified 27 distinct nucleotide variations in 130 out of 840 unrelated patients tested, including 22 cystein involved variations, four non-cystein involved variations (R75P, R75Q, P167S, L989R) and a indel mutation (p.Asp353_Cys355delins(8)). Ten novel mutations were identified (p.Asp353_Cys355delins(8), C65Y, R75Q, P167S, C285F, C291S, S414C, C606R, C971S, L989R). The R544C mutation was the most common mutation, which was identified in 71 out of 130 patients. In conclusion, we have identified 27 distinct mutations including 10 novel mutations of the NOTCH3 gene. The R544C accounts for 54.6% of disease alleles in Korean patients with CADASIL. Genetic testing should be considered as a confirmatory diagnostic test in clinically ambiguous cases.

Two cases with methionine adenosyl transferase deficiency presented with isolated hypermethioninemia on neonatal screening test. *H. Yoo, J. Ko, I. Lee, C. Cheon, G. Kim* Medical Genetics Clinic & Laboratory, Dept Pediatrics, Asan Medical Ctr, University of Ulsan College of Medicine, Seoul, Korea.

Neonatal screening for homocystinuria by measuring blood spot methionine concentrations is a common medical practice in worldwide. However, hypermethioninemia without homocystinuria (isolated hypermethioninemia) is also detected, and there is a possibility to be mistaken for homocystinuria. The conversion of methionine to S-adenosylmethionine by methionine adenosyl transferase (MAT) is the major pathway of methionine metabolism. Isolated hypermethioninemia is a clinically benign metabolic disorder associated with MAT I/III deficiency in liver due to the MAT1A gene mutation. Clinical manifestations are variable and poorly understood, and treatment for isolated hypermethioninemia remains controversial. We diagnosed two cases of isolated hypermethioninemia using the amino acid analysis and MAT1A gene analysis in newborns with increased methionine level detected by neonatal screening test for homocystinuria. They had no clinical symptom except increased level of blood spot methionine (8.0 and 4.0 mg/dL) on repeated screening tests. Serum amino acid quantitative analysis by HPLC was performed at 25 and 17 days old. Serum methionine (821 and 748 mol/L) and homocysteine (22.4 and 20.3 mol/L) levels were elevated. However, homocystine was not detected and cystine levels were normal. Low methionine diet was started, and analysis of the CBS gene (for homocystinuria) and the MAT1A gene (for MAT deficiency) was performed. We could not find any mutation in the CBS gene. However, MAT1A gene analysis revealed that they were compound heterozygote (p.Y92H/p.R299C, p.K97N/p.R199C). Three mutations are novel except p.R199C. They are 9 and 6 months old now, and develop normally without any treatment. Although serum methionine levels were persistently elevated during the follow-up period, serum homocysteine level has been normalized. Further studies for the natural history of isolated hypermethioninemia are necessary for reducing unwarranted anxiety of the parents and the health care professionals.

Combined Individual- and Family-level Genetic Association Analyses that Adjust for Population Stratification Bias. *L. Mirea[1,2], L. Sun[1,3], J. E. Stafford[1,3], S. B. Bull[1,2]* 1) Public Health Sciences, Univ of Toronto, Canada; 2) Samuel Lunenfeld Research Inst, Toronto, Canada; 3) Statistics, Univ of Toronto, Canada.

Population stratification bias (PSB) remains a serious concern in genetic association studies employing independent individuals. In the absence of empirical data regarding population structure, family-based designs can provide robust estimates, but association tests are less powerful due to uninformative allele transmissions. When both individual- (IA) and family-level (FA) analyses can be performed, the comparison between IA vs. FA has been used as a test for PSB and a basis for reporting either IA or FA results (Abecasis et al. 2000 *Am J Hum Genet* 66: 279-292), or pooling IA from case-control and FA from trio data (Chen and Lin, 2008 *Genet Epidemiol* early view). As an alternative, we derive and evaluate a novel test statistic Z_w that combines IA and FA using weights based on the observed evidence for PSB. To illustrate, for a quantitative trait measured in single individuals and trio offspring, the most efficient association analysis (IA_{tot}) employs all independent probands ignoring parental genotypes. Evidence for PSB is provided by the p-value (p_{EQ}) testing equality between orthogonal IA_o and FA_o components derived from analyses restricted to trios. We compute B_w as a weighted linear combination of IA_{tot} and FA_o estimates using weights p_{EQ} and (1- p_{EQ}), respectively. The test statistic Z_w is obtained by standardizing B_w under the null hypothesis of no association employing a robust covariance matrix, with significance evaluated assuming an asymptotic N(0,1) distribution. Using simulations, we show that for a variety of scenarios with and without PSB, the type I error of Z_w is always closer to nominal than that of previous approaches reporting either IA_{tot} or FA_o. In the absence of PSB, Z_w achieves greater power than FA_o, thus establishing Z_w as the best compromise between type I error control and power. A similar Z_w statistic can be computed for case-control and trio data. The adjustment for PSB is SNP-specific and depends on the power to detect PSB, and can be used in conjunction with other methods for correcting PSB in candidate gene or genome-wide studies.

Niemann-Pick type C disease (NP-C) is a considerable diagnosis in juvenile and adult-onset psychiatric disorders.

P. Bauer[1,2], T. Boettcher[2,3], W. Meyer[4], P. Martus[5], S. Weiss[2], R. Oheim[2], K. Heinze[2], M. Wittstock[2], A. Rolfs[2] 1) Dept Medical Genetics, Univ Tubingen, Tubingen, Germany; 2) Neurobiology Laboratory, Dept of Neurology, Univ Rostock, Rostock, Germany; 3) Dept of Neurology, Klinikum Neubrandenburg, Neubrandenburg, Germany; 4) Queen Mary Univ London, St. Bartholomew's and the Royal London School of Medicine, London, UK; 5) Institute of Biometry and Medical Epidemiology, Charité Berlin, Berlin, Germany.

Background: Niemann-Pick type C (NP-C) disease is an autosomal recessive neurovisceral storage disorder characterised by an intracellular trafficking deficit for cholesterol and other complex lipids. A wide spectrum of clinical symptoms includes hepatic and pulmonary disease and neurodegeneration with epilepsy, ataxia and neuropsychiatric disorders. The disorder is caused either by mutations in the NPC1 or the NPC2 gene. Usually, the first clinical symptoms of NP-C disease appear between ages of 4 and 10 years. However, there is raising evidence that the percentage of adult manifestations in NP-C disease is more frequent than up to now presumed. Objective: In order to assess NP-C frequency, genotypes and phenotypes, we completely sequenced the NPC1- and NPC2-gene in 189 adult Caucasian patients (aged between 15 and 51 years) hospitalized in psychiatric or neurological institutions diagnosed as having psychiatric diseases in combination with neurological symptoms, like epilepsy, ataxia, dystonia or dementia. ,. Results: In 19 (10%) of these patients, two pathogenic NPC1-mutations were identified, while in 7 patients only one mutation was detectable. Two pathogenic NPC2 mutations were observed in 3 patients which correspond to about 15% of all NPC disease cases. Conclusion: The high frequent of NPC disease in adult patients with neuropsychiatric symptoms makes it necessary to improve on one side the knowledge of this disease among neurologists and psychiatrists but should also implement NPC1 testing in all cases with unclear neuropsychiatric manifestations especially where a combination of hallucinations, epilepsy of any kind, facial dystonia and gait disorder is present.

A theoretical basis for using allele sharing distance to detect population stratification. *X. Gao* Miami Inst Human Genomics, Univ Miami Miller Sch Medicine, Miami, FL.

There is a long history of using allele sharing distance (ASD) and closely related metrics for population stratification analysis. However, the theory for this practical usage has not been reported. In this work, we describe the theoretical background for using ASD on single nucleotide polymorphism (SNP) genetic data for human population stratification analysis. In showing the proof, We lay the ground work for a general distance-based method for classifying subpopulations using SNPs and ASD.

High-resolution array-CGH Analyses of Common Hematological Malignancies Using Custom Designed Cancer-specific Oligonucleotide Arrays. *M. Li*[1, 2, 3, 4], *X. Hu*[1, 4], *D. Mercer*[1], *H. Safah*[3, 4] 1) Hayward Genetics Center; 2) Dept. of Pediatrics; 3) Tulane Cancer Center, Tulane Univ. Sch. Med; 4) Louisiana Cancer Research Consortium, New Orleans, LA.

Conventional cytogenetics and FISH have played crucial roles in the clinical diagnosis and treatment of hematological malignancies. However, the poor growth and/or poor morphology of malignant cells, along with limited FISH probe availability and resolution and sometimes conflicting results between cytogenetics and FISH, can make accurate clinical diagnosis difficult. We have designed a combined targeted-/whole-genome array system using the Agilent 4 x 44K format specific for cancer. 21,664 oligonucleotide probes were selected from the Agilent eArray system that target more than three hundred oncogenes, tumor-suppressor genes, and known cancer-associated chromosome regions. The average probe density was 71 probes per gene/region. Intervals between above genes or regions were filled relatively evenly with approximately 21,500 probes to cover the whole genome. To validate the array, we applied it to 20 cases of hematological malignancies, including AML, ALL, and multiple myeloma. Using the array, we not only confirmed most of the genetic aberrations identified by cytogenetics or FISH, but also clarified many controversial results between cytogenetics and FISH, and corrected misinterpreted FISH results. For example, a marker chromosome that was negative for the BCR/ABL1 fusion by FISH was proved to be a Philadelphia chromosome with a partial deletion; and a duplication of the p53 gene diagnosed by FISH was revised to be a rearrangement that had split the p53 gene probe. In addition, many small copy number alterations (CNAs), including intra-gene deletions and duplications were detected in patients with normal or abnormal karyotype. These CNAs appear to be significant in predicting patient response to therapeutic regimens and will cast new light on defining new genomic regions involved in disease pathogenesis. Our experience also highlights the importance of using combined targeted and whole-genome arrays in cancer diagnoses.

Association of GRIK1 gene in Schizophrenia: case-control and family-based studies. *Y. Hirata, N. King, JL. Kennedy* Neurogenetics section, the Centre for Addiction and Mental Health, Toronto , Ontario, Canada.

Purpose: One mechanism now emerging from genetic studies of schizophrenia worldwide is the glutamate system. Glutamate receptors mediate a vital part of neurotransmission in the mammalian central nervous system and play an important role in synaptic plasticity and the regulation of neurodevelopment. GRIK1 (GluR5 receptor) is expressed in the hippocampus and the Purkinje cells of the cerebellum. Thus our purpose was to examine genes that are implicated in the glutamate system. We have previously studied two of the glutamate system genes - GRIN1 and GRIN2B. In the current investigation, our focus was to analyze another important member of the glutamate system, GRIK1, in both case-control and family based samples for schizophrenia. Methods: We examined 11 SNPs across the GRIK1 gene in a sample of 182 case-control pairs and 104 small nuclear families. Genotyping was done using standard PCR methods. Statistical analyses were performed by using the Statistical package for the Social Sciences, version 10.0 (SPSS 2000) for the case-controls. For the family-based samples, the Family Based Association Tests (FBAT) were used. Results: In this study, we defined one block by Haploview 3.0 LD plot: 14Kb that included two SNPs. We did not observe any association with a specific allele, genotype or haplotype in our case-control samples. However, significant associations with alleles and genotypes were observed in our family-based samples, as follows for SNPs rs2832484 (p=0.020), rs2832489 (p=0.020), rs455892 (p=0.007), rs457474 (p=0.006), and rs460917 (p=0.006). For genotypes, we found some significant results in the family sample: rs2832484 (p=0.040), rs2832489 (p=0.040), rs455892 (p=0.039), rs457474 (p=0.030), rs460917 (p=0.030). Conclusion: Conclusions: We found an association between GRIK1 and schizophrenia in our family-based sample. On the other hand, our case-control study did not show any significant results. The family sample has a younger age of onset and stronger family history, and this may account for the difference in results between the two samples. Further work, at least in familial cases, is warranted.

1M SNP genome wide association for addiction: replicated results and comparisons of two analytic approaches.

G. Uhl[1], T. Drgon[1], C. Johnson[1], D. Walther[1], P.-W. Zhang[1], C.-Y. Li[1,2], J. Hess[1], Q.-R. Liu[1] 1) Dept Molec Neurobiology, NIH IRP (NIDA)Baltimore, MD; 2) Center for Bioinformatics, Coll Life Sci, Peking Univ, China 100871.

Addictions are substantially-heritable complex disorders whose molecular genetic bases have been only partially elucidated. We now report 1M SNP genome wide association (GWA) results for addiction vulnerability in each of two samples of ethnically-matched, well characterized substance dependent vs control subjects (n = 1620). We describe and compare converge then cluster and cluster then converge analytic approaches to assessing the convergence between the results obtained from the two samples, in conjunction with Monte Carlo and permutation statistics. The genes that we identify are expressed in brain regions that include hippocampus and amygdala much more than expected by chance. More are related to cell adhesion processes than expected by chance. Many of these genes help to establish and maintain neuronal connections. Others help to identify a number of readily-approachable candidate targets for antiaddiction pharmacotherapeutics. The methods that we describe to assess convergence between independent samples provide additional tools for assessment of convergent GWA results.

PTEN variant c.210-7~-3del5: low penetrance or modifying role in cancer predisposition? *J. Mester, P. Kessler, B. Leach, S. Gustafson, T. Sadler, F. Mularo, K. Waite, M. Orloff, C. Eng* Genomic Medicine Institute, Cleveland Clinic Foundation, Cleveland, OH.

PTEN encodes a phosphatase implicated in multiple cancer pathways. Germline deleterious mutations are present in 85% of individuals with Cowden syndrome (CS) and 65% with Bannayan-Riley-Ruvalcaba syndrome (BRRS). With 10 years of PTEN testing, some variations of uncertain significance (VUS) have been discovered. c.210-7~-3del5 appears pathogenic as it involves nucleotides close to the consensus intron 3 splice acceptor. After a total enrollment of 2,238 accruing by CS and CS/BRRS-like features over 2.5 years, 2 unrelated probands were found to have this VUS. A third proband presented to cancer genetics clinic with a referring diagnosis of VHL. The VUS was absent in 300 controls and 1,000 individuals with breast cancer only. The first proband, a 60-year-old female, had clinical features meeting CS diagnostic criteria including breast ductal carcinoma-in-situ (at age 59), thyroid cyst, 8 lipomas and macrocephaly. The second was a 4-year-old male with macrocephaly and developmental delay. The third proband was a 30-year-old female presenting with bilateral renal tumors and a pancreatic mass. She had normal intelligence and 2 Shagreen patches. Brain MRI revealed subtle tubers. We gave the clinical diagnosis of tuberous sclerosis (TSC) and found the TSC1 Q343X mutation. Her brother and father shared the VUS but neither had features of TSC or CS. PTEN RNA and protein studies in all 5 were normal: splice aberrations and upregulation of the AKT and MAPK pathways were not found. Literature review found the VUS in 3 TP53 mutation negative Li-Fraumeni syndrome (LFS)/LF-like patients. One had endometrial cancer and a family history of sarcoma, breast, lung, and colon cancer; 13 others studied were negative. In another series 2/26 had the VUS, one whose uncle had renal cell carcinoma. Both had normal PTEN mRNA studies. Taken together, these suggest that PTEN c.210-7~-3del5 may play a low penetrance or modifying role in broad cancer predisposition, notably of CS-related neoplasias. If this postulate is correct, then the VUS must carry out its role independent of known pathways.

Fanconi Anemia: Craniofacial Analysis Using 3-D Stereophotogrammetry. *R. T. McIntosh[1], D. L. Domingo[1], N. Tomona[1], R. Popat[1], S. Mitchell[1], N. Giri[2], B. P. Alter[2], T. C. Hart[1]* 1) NIDCR/NIH, Bethesda, MD; 2) CGB/DCEG/NCI/NIH, Bethesda, MD.

BACKGROUND: Fanconi anemia (FA) is a rare genetic chromosome instability disorder characterized by bone marrow failure, predisposition to malignancies & physical abnormalities (e.g., growth retardation). It consists of at least 13 complementation groups (FANCA,B,C,D1,D2,etc.) manifesting diverse clinical phenotypes. Craniofacial features (e.g., microcephaly, microphthalmia) remain poorly characterized. OBJECTIVE:To characterize facial features in FANCA patients using computerized surface models. METHODS: 16 Cauc FANCA patients (9males,7females,4-42yrs,median:18.7yrs) & 16 gender-, race- & age-matched healthy controls were imaged with stereophotogrammetry (3dMD System). The following age subsets were analyzed: <12yrs(n=4); 12-19yrs(n=5); & >20yrs(n=8). Using 14 facial landmarks, mean 3-D facial models were configured & analyzed with MorphostudioTM algorithms (finite-element analysis [FEA], function manager analysis [FMA]). RESULTS: All mean FA facial models appeared grossly smaller than the mean control models. Decreased facial volumes were most highly pronounced among FANCA patients age 12-19 compared to their controls. FEA measured the most significant reductions ($p<0.01$) in the following regions: glabella(15-32%), periorbital region(10-31%) & philtrum/perioral tissues(15-22%). FMA measured significantly shorter lower facial 3rd segments in the 12-19yr-old patients (mean:50.07mm vs. 58.24mm in controls)($p<0.05$). Among FA subjects >20 yrs, significant volume reductions ($p<0.01$) were observed in the philtrum/perioral(10-22%) & midface regions(9-12%). This oldest age group also had significantly narrower alar tissues (mean:30.44mm vs. 33.46mm in controls, $p<0.05$), although no significant vertical length reductions were detected. CONCLUSIONS: Non-radiation morphometrics quantified the abnormal facial gestalt of FANCA patients. Decreased surface volumes & linear segments reflect the growth retardation associated with this disorder. Quantification of facial compartments further defines previously reported FA facial features & may shed additional insight on this complex disease.

Power of model selection methods for high dimensional genome-wide association data. *Z. Wu, H. Zhao* Yale School of Medicine, Yale University, New Haven, CT.

Genome-wide association studies (GWAS) are characterized by the collection of hundreds of thousands of genetic markers and potential complex interactions among them to affect disease susceptibility. Although most commonly used, single marker based analysis is likely not optimal in the presence of multiple disease susceptibility genes and their interactions. Exhaustive search among models involving multiple markers is computationally intensive or even prohibitive, and it also suffers from an increased chance of finding false positive results due to the number of models (exponential in the number of SNPs jointly considered) explored. On the other hand, standard model selection methods, e.g. forward selection, may miss truly associated markers if disease susceptible genotypes/alleles only have small marginal effects yet large interaction effects. It is apparent that a delicate balance needs to be achieved between computational efficiency, statistical power, and low false positive rates, in the analysis and interpretation of GWAS data. Although highly important, this problem has only been partly explored to date by limited simulation studies. In this article, we derive analytical results for the statistical power of different marker selection methods, and address various factors that have impact on the choice of appropriate analysis methods.

ELAVL4: a depression-associated gene in Alzheimer and Parkinson disease. *M. Slifer[1], G. Beecham[1], G. Wang[1], E. Martin[1], J. Gilbert[1], J. Haines[2], J. Vance[1], M. Pericak-Vance[1]* 1) MIHG, Univ Miami, Miami, FL; 2) Vanderbilt, Center for Human Genetics Research, Nashville, TN.

To date, most genetic studies have focused on individual diseases. However, many complex diseases share features in common. Alzheimer (AD) and Parkinson (PD) disease are the two major neurodegenerative disorders of adults. The natural history of both diseases includes progressive cognitive and motor dysfunction. Molecularly, alpha-synuclein aggregates in the characteristic plaques of AD affected brains and Lewy bodies of PD affected brains. In addition, about half of those suffering from AD or PD develop depression. For this study, we explored the genetic basis of AD and PD with depression. As part of a larger case-control AD GWAS (n=988), using the Illumina 550K SNP marker set, we performed association testing on 207 AD cases with depression. All controls (n=496) are free of depression (i.e. euthymic) and cognitively intact by history and cognitive testing. AD with depression risk is associated with SNPs in ELAVL4 ($p<2.8x10-7$; odds ratio 1.8 (CI=1.5-2.3)) that exceed an FDR-BUM threshold for multiple testing. ELAVL4 is not associated with AD risk in a euthymic subset of AD (n=285; p=0.89). Interestingly, we had the initial report of an association for ELAVL4 with age-at-onset in PD. Subsequently, two other groups have found similar results (association with PD risk) in their independent PD datasets. Based on the AD results, we proceeded to test whether ELAVL4 is also acting through the depressed PD subset. When the PD dataset (n=754) was stratified by depression, the age-at-onset effect is only observed in the depressed subset of PD participants (n=198; p=0.003). The concurrence of results from two different common neurodegenerative diseases is remarkable, providing further evidence that common pathophysiological mechanisms may underlie both AD and PD and that ELAV4 is an important gene in both disease etiologies.

Potential mechanisms underlying tumorigenesis in *PALB2* mutation carriers with breast cancer. *N. Hamel[1], M. Couillard[1], A. D. Darnel[2], M. D. Tischkowitz[2], W. D. Foulkes[1,2]* 1) Dept Med Genetics, McGill Univ Health Ctr, Montreal, Canada; 2) Dept Med Genetics, Sir MB Davis Jewish General Hospital, Montreal, Canada.

PALB2 is a modest contributor to breast cancer susceptibility and germline mutations have been observed to segregate with breast cancer in several families. PALB2 is known to interact directly with BRCA2 and appears responsible for BRCA2 localization to the nucleus. While *PALB2*s contribution to breast cancer risk is clear, the mechanism by which heterozygous germline mutations lead to the development of breast tumors remains uncertain. Physical loss of the wild-type allele is a common mechanism by which heterozygous germline mutations in tumor suppressor genes become dominant in genomically unstable tumor cells. This phenomenon is frequently observed in *BRCA2*-related tumors. However, we did not observe similar loss of heterozygosity in breast tumors from 6 patients carrying one of 3 distinct *PALB2* truncating mutations, where mutant and wild-type *PALB2* alleles are all clearly retained. Since *PALB2* promoter methylation could be another means to suppress expression of the wild-type allele, we sequenced a 549bp CpG island including the transcription initiation site in tumors and matching blood samples from all patients, but failed to observe evidence of hypermethylation in tumors. These results suggest that wild-type PALB2 may still be expressed in *PALB2* tumors. Given the physical interaction between BRCA2 and PALB2, we speculated that simultaneous reduction in the levels of both proteins may conceivably result in an increased risk of tumor development; thus, we decided to also examine LOH and methylation status of *BRCA2* in our *PALB2* tumors. We found evidence of LOH at selected microsatellite markers flanking *BRCA2* in some tumors, but no consistent allelic loss across all tumors. Because *BRCA2* LOH in sporadic breast tumors is a frequent event, the significance of these observations is unclear. On the other hand, *BRCA2* promoter methylation has never before been observed in either sporadic or *BRCA*-related breast cancer, so any findings of hypermethylation here would be intriguing. *BRCA2* promoter methylation analysis is on-going.

Validation of an oligonucleotide microarray-based comparative genomic hybridization platform for clinical cytogenetic diagnosis. *S. Yu[1], D. Bittel[1], N. Kibiryeva[1], C. Saunders[1], M. Butler[2], D. Zwick[1], L. Cooley[1]* 1) Children's Mercy Hospital, Kansas City, MO; 2) 6410 Hillside St. Shawnee, KS 66218.

Comprehensive validation of any microarray platform is necessary to implement comparative genomic hybridization (aCGH) for clinical tests. Thirty two different specimens with previously identified chromosomal imbalances and thirteen blinded specimens were included in this study by using aCGH method with Agilents 244K oligo CGH microarray chips. All tests for this validation study were successful. The aCGH analysis was in agreement with all forty three samples with known chromosomal aberrations and the two remaining samples with reported normal results were confirmed as having no clinically relevant chromosomal aberrations. The chromosomal analysis results in three cases were improved by our aCGH-244K tests. In one case with 46,XX,der(4)ins(4;1)(35.2;q42.3q32.3), the inserted material was identified to be a 24.2 Mb DNA segment from chromosome 1p32.3p31.11 instead of 1q42.3q32.3. In one case with 46,XY,der(10)t(8;1)(q23;q26.3), our aCGH-244K results indicated a one-way translocation without involvement of chromosome 10q26.3. In one case with 46,XX,del(9)(q13q21.12), deletions at proximal ends of both arms of chromosome 9 were identified. Six cases with 22q11.2 deletion syndrome were found to have deleted regions ranging from 2.49 Mb to 2.56 Mb on one copy of chromosome 22q11.2. Four cases have common proximal breakpoints and five have common distal breakpoints. A candidate gene for autism (A2BP1) on chromosome 16p13.2 was deleted in a case which was confirmed as having a 199 Kb deletion involving the 5 end of this gene. A small number of copy number variations (CNVs) (~7/per sample) with sizes ranging from 400 bp to 1.6 Mb were revealed. With assistances from public and our own databases, as well as verification methods using quantitative real-time PCR, we see no difficulties in interpreting results from our aCGH-244K platform. These results demonstrate the utility of the array-CGH format as a powerful diagnostic tool for detection of genomic imbalances associated with genetic disorders.

Using Drosophila heart to uncover the genes contributing to Down syndrome congenital heart disease. *T. R. Grossman[1], A. Gamliel[2], R. J. Wessells[3], O. Taghli-Lamallem[4], K. Jepsen[2], J. R. Korenberg[5], M. G. Rosenfeld[2], R. Bodmer[4], E. Bier[1]* 1) Sec Cell & Dev Biol, Univ California, San Diego, La Jolla, CA; 2) HHMI, Dept Med, UCSD, La Jolla, CA; 3) Univ Michigan, Ann Arbor, MI; 4) Burnham Institute Med Res, La Jolla, CA; 5) Cedars-Sinai Medical Center, Los Angeles, CA.

Down syndrome (DS) is a major cause of congenital heart disease (CHD) and the most frequent known cause of atrioventricular septal defects. It has been suggested that DS-CHD is a multigenic disease that results from elevated expression of several genes from the DS-CHD candidate region, which include SH3BGR, DSCAM, WRB, Collagen VI A1 and A2, Collagen XVIII and HES1 genes. In attempt to identify which genes are responsible for DS-CHD we used the Drosophila heart as an in vivo assay system where we mis-expressed human and fly DS-CHD candidate genes using the UAS/GAL4 system and tested the effect on the heart physiology. In order to identify possible gene interactions we also mis-expressed all pairwise combinations. The effect on heart physiology was analyzed using sensitive heart function assays such as electrical pacing and high-speed video recordings from adult fly hearts. Our results show that mis-expression of certain DS-CHD candidate genes results in significant heart defects, including increased rate of pacing stress-induced heart failure. We found that out of all double gene combinations tested only two showed a synergistic aggravation of the heart phenotypes when simultaneously mis-expressed in the fly heart. In order to confirm our results in a mammalian system, we generated double transgenic mice with the two genes that we found to have the strongest interaction in the fly heart. Our preliminary data show that cardiac specific over-expression of two DS-CHD genes results in heart malformations. Taken together, our data suggest that two specific genes from the DS-CHD region on chromosome 21 may be responsible for the congenital heart defects in Down syndrome.

Scan of 640 SNPs of 43 candidate cleft lip or palate genes in the nonsyndromic cleft lip or palate patients of Lithuania. *V. Kucinskas, L. Ambrozaityte, A. Matuleviciene, E. Preiksaitiene* Human & Medical Gen, Vilnius Univ, Vilnius, Lithuania.

Orofacial clefts represent complex phenotype and reflect a breakage in the normal mechanisms during embryological development of the face. The incidence of cleft lip and/or cleft palate (CL/P) in the population of Lithuania is 1 in 544 newborns. As complex diseases may be caused by different causal mechanisms, many genes are considered as candidate loci for nonsyndromic CL/P responsible for this malformation. 104 triads of Lithuania of a child affected with nonsyndromic cleft lip and/or palate or cleft palate only and both his/her parents were included in this study. DNA microarray of 640 SNPs of 43 candidate cleft lip or palate genes was designed and produced by AsperBiotech, Estonia. The SNPs in the DNA microarray are distributed within and outside the genes. This experiment was carried out using arrayed primer extension - based genotyping technology (APEX-2). 20 SNPs were excluded from further analysis in the population of Lithuania having low call rate. Association statistics was performed by TDT/S-TDT, introduced by Spielman et al. 1993. This study showed statistically significant association of 18 SNPs (i.e. 2.9% of the investigated SNPs) to nonsyndromic cleft lip or palate. Six SNPs are at oddment distribution of the genes on the microarray - CDH1 gene (rs7188750 p=0.033), FOXE1 gene (rs973473 p=0.0338), LHX8 gene (rs17096272 p=0.003), MMP3 gene (rs629946 p=0.019), MMP9 gene (rs6032619 p=0.035), MSX2 gene (rs17063892 p=0.014). Three associated SNPs are of BMP2 gene - (rs17731603 p=0.014; rs6077060 p=0.039; rs235730 p=0.034). Most significant results involve/include FGF1, FGF2 and FGFR1 genes where nine SNPs in total show statistically significant results - (rs10064637 p=0.041; rs33995 p=0.004; rs10070885 p=0.004; rs249923 p=0.028; rs2034461 p=0.012; rs308434 p=0.012; rs308395 p=0.041; rs3804158 p=0.045; rs6987534 p=0.048). First results of our study suggest significant association of 18 allelic variants in ten out of 43 investigated genes that are possibly contributing to the aetiology and pathogenesis of nonsyndromic cleft lip or palate.

Cutis aplasia, facial dysmorphic features, congenital heart abnormalities and mental retardation in a child with a cryptic deletion in 19p13.3. *H. Al-Kateb[1], A. Hahn[2], J. M. Gastier-Foster[3,4], D. L. Thrush[3], L. Jeng[1], S. E. McCandless[2], C. A. Curtis[1]* 1) Univ Hosp Case Human Gen Lab, Case Western Reserve Univ, Cleveland, OH; 2) Univ Hosp Case Human Gen, Case Western Reserve Univ, Cleveland, OH; 3) Nationwide Children's Hospital, Columbus, OH; 4) The Ohio State University Columbus, OH.

Advances in technology have made it feasible to discover chromosomal microdeletions that are difficult to recognize by conventional chromosomal analysis. Here we report the use of chromosomal microarray, fluorescence in-situ hybridization (FISH), and molecular genetics techniques to delineate and characterize a de novo constitutional deletion within 19p13.3 in a girl with multiple congenital anomalies. Her phenotype includes cutis aplasia of scalp, structural heart abnormalities, macrocephaly, hypotonia, mild mental retardation, dysmorphic facies and conductive hearing loss. Review of the literature revealed a few case reports of larger deletions, most of which include the subtelomeric region, which appears to be intact in our patient. Initial microarray analysis (Signature Select 1.0) revealed a 6-BAC-clone deletion within 19p13.3 with an estimated deletion size of 1.612 Mb. FISH studies delineated the proximal deletion breakpoint to within BAC clone RP11-125C3 and the distal deletion breakpoint to a region within or near the proximal portion of BAC RP11-648B14. Using SNPs we determined that the deletion is of paternal origin and we refined the proximal deletion breakpoint by 50kb and confirmed the absence of BAC RP11-268O21, which is immediately proximal to RP11-648B14. Based on these findings, the deletion is estimated to be approximately 1.93 Mb, encompassing at least 72 genes. Two genes in the deleted region appear to be good candidates for the patients observed craniofacial and cardiac anomalies: guanine nucleotide binding protein (G protein), alpha 11 (Gq class)(GNA11) and Transducin-like Enhancer of Split 2 (E(sp1) homolog, Drosophila)(TLE2). Work to better define the breakpoints is ongoing, both to gain insight into the mechanism that led to this deletion and to correlate the genotype and phenotype of this patient.

Two independent alleles at 16p13 are associated with Addisons disease. *B. Skinningsrud[1,2], E. S. Husebye[3,4], S. H. Pearce[5], D. O. McDonald[5], K. Brandal[1], A. B. Wolff[3], K. Løvås[3,4], T. Egeland[1], D. E. Undlien[1,2]* 1) Department of medical genetics, Ullevål University Hospital, N-0407 Oslo, Oslo, Norway; 2) Institute of Medical Genetics, University of Oslo, N-0315 Oslo, Norway; 3) Section of Endocrinology, Institute of Medicine, University of Bergen, N-5021 Bergen; 4) Department of Medicine, Haukeland University Hospital, N-5021 Bergen, Norway; 5) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, NE1 3BZ, United Kingdom.

It is known that different autoimmune diseases often share the same susceptibility genes. In this study we aimed to investigate if loci found associated with common autoimmune diseases in recent genome wide association studies, also could be susceptibility loci for autoimmune Addisons disease. A total of 139 tagging SNPs in eleven candidate genes (IL2, IL21, IL2RA, CLEC2D, CD69, ERBB3, PTPN11, SH2B3, CLEC16A, CIITA and PTPN2) were genotyped in a case/control study design consisting of Norwegian Addisons disease patients (n = 332) and Norwegian healthy control individuals (n = 1029). Five SNPs were subsequently selected for analysis in a United Kingdom sample set consisting of Addison's disease patients (n =214) and controls (n = 190). Polymorphisms in CLEC16A and CIITA remained significantly associated with Addison's disease in the Norwegian sample set at the 0.05 level, even after correction for multiple testing. CLEC16A and CIITA are both located at 16p13, but linkage disequilibrium patterns and logistic regression analyses suggest that SNPs in these two genes are independently associated with Addison's disease. We were not able to confirm these associations in the UK material, however, this may well be due to limited sample size and lack of statistical power. In conclusion, two alleles at 16p13 are independently associated with risk of Addison's disease in the Norwegian population, suggesting this chromosomal region to harbour common autoimmunity gene(s), CLEC16A and CIITA being possible independent candidates.

Mapping of two new gene loci for Dandy-Walker Malformation. *M. Dasouki[1], D. Persons[2], G. Lushington[3]* 1) Dept of Pediatrics, Univ of Kansas Med Ctr, Kansas City, KS; 2) Dept of Pathology, Univ of Kansas Med Ctr, Kansas City, KS; 3) Molecular Graphics and Modeling Laboratory, Univ of Kansas, Lawrence, KS.

Dandy-Walker malformation (DWM) is a heterogeneous disorder which consists of cerebellar hypoplasia and and cystic dilation of the fourth ventricle often causing developmental delay, hypotonia, and ataxia. About 50% of affected patients have mental retardation and some have hydrocephalus. Both syndromic & non-syndromic, familial & isolated forms of DWM had been reported in the literature. Heterozygous deletion of the linked genes ZIC1 and ZIC4 was demonstrated to be involved in Dandy-Walker malformation in mice and humans. Here, we report on two unrelated children with DWM and chromosomal abnormalities that were identified prenatally. On prenatal ultrasound examination, patient 1 was found to have DWM. Pregnancy was terminated. No autopsy was done. An unbalanced karyotype [46,XX,del6p24.2,inv dup 8p11.2p21.3] was found in the product of conception. The mother had a normal phenotype with abnormal chromosomal complement [46,XX,t(3;6)(p26.2; p24.2),invdup 8p11.23p21.3]. At 3 years of age, patient 2 has coarse facies, speech delay, asymptomatic VSD, ASD & DWM. Blood chromosomal analysis showed an abnormal mosaic pattern: 46,XY,der(2)t(2;17)(q37.3;q25)(6)/46,XY(14). Array CGH & subtelomeric FISH probe analysis confirmed the partial trisomy for distal 17q25 and smaller partial monosomy for 2q37.3. In silico analysis of possible candidate genes in both regions revealed that NEDD9 is predicted to a fairly high probability to participate in short-hop protein-protein interaction networks with ZIC1 (via NEDD9-SMAD1-GLI3-ZIC1, NEDD9-SMAD2-GLI3-ZIC1, and NEDD9-SMAD3-GLI3-ZIC1), and is also predicted to share a common interaction partner (namely SMAD1) with the human ortholog ZNF423 whose mutation causes Dandy-Walker malformation in mice. These predictions, confirmed by experimental observations reported in KEGG, support the presence of a "DWM" locus that maps to distal 6p. The duplicated region of chromosome 17q contains several genes that encode multiple ciliary proteins that could be involved in DWM. Work is still ongoing to detect protein-protein interactions in this region.

***IGRP* is associated with type 2 diabetes and fasting plasma glucose levels in the Chinese population.** *C. Hu, C. Wang, R. Zhang, X. Ma, J. Xu, W. Jia, K. Xiang* Shanghai Diabetes Institute, Department of Endocrinology and Metabolism, Shanghai Jiao Tong University Affiliated Sixth Peoples Hospital, Shanghai, China.

Islet-specific glucose-6-phosphate catalytic subunit related protein (IGRP, also known as G6PC2) is a candidate for the low glucose-6-phosphate enzyme activity in islet and thus modulate glucose-stimulated insulin secretion. A recent genome-wide association study found the SNP rs560887 on *IGRP* was associated with fasting plasma glucose levels and beta-cell function in the general population. However, HapMap data showed that rs560887 was a rare variant in the Chinese population. Therefore, we used selected two SNPs (rs492594 and rs13387347) capturing all the common variants of this gene at r^2=0.8 based on HapMap CHB data and genotyped them in 3338 Shanghai Chinese using a SEQUENOM platform. The SNP rs13387347 was associated with type 2 diabetes in our population (OR 1.15 95% CI [1.05 - 1.27], *P* = 0.003, empirical *P* = 0.011 by 10,000 permutations). The rare allele C was significantly higher is the controls. By analyzing the quantitative traits in the controls, we found rs13387347 was associated with fasting plasma glucose concentration (*P*=0.0031). Our finding confirm the previous finding that *IGRP* was associated with glucose metabolism and reveal a novel associated SNP for type 2 diabetes susceptibility in the Chinese population.

Mutation negative mixed polyposis syndrome: polyp burden and cancer risks. *H. Leach, C. Eng* Genomic Medicine Inst, Cleveland Clinic, Cleveland, OH.

Literature review reveals only 2 large kindred with hereditary mixed polyposis syndrome (MPS). These authors characterize MPS by the presence of atypical juvenile polyps, adenomas, and colorectal cancer. 1 family was linked to BMPR1A, suggesting this to be a variant juvenile polyposis syndrome (JPS). Families with true MPS pose a challenge, as limited information is available about polyp burden and malignancy risk. We report on 64 unrelated patients with at least 5 gastrointestinal (GI) polyps of whic at least 1 is hyperplastic or hamartomatous. Patients were excluded from analysis if they met the diagnostic criteria for JPS, Peutz-Jeghers syndrome, PTEN-hamartoma tumor syndrome, or hyperplastic polyposis syndrome and were mutation negative for STK11, BMPR1A, SMAD4, PTEN, ENG, and MYH. Information was collected about polyp pathology, number, location, and age of onset and history of cancer. Mean number of colorectal polyps was 22/patient. Of the 64 patients, 26 underwent at least one upper endoscopy (EGD) and 7 (11%) had a mean of 8 polyps in the upper GI tract. Mean age of first polyp was 47 years, and ½ of the patients had 3 different types of polyps. 27 patients were diagnosed with cancer, of which 14 (22%) had colorectal cancer compared to 5% in the general population ($p < 0.0001$). The median age of colorectal cancer diagnosis was 56 years (mean 53 years, 99% CI 40-66), which is significantly younger than the general population median (71 yrs). 31 patients (48%) reported 1 first-degree relative (FDR) with polyps and 7 (11%) 1 second-degree relative (SDR) with polyps. 21 patients (33%) reported 1 FDR with colorectal cancer and 27 (42%) reported 1 affected SDR. The genetic etiology of polyposis in these patients is yet to be determined. However, given the breadth of polyp type and higher incidence of upper GI tract polyps and colon cancer, increased surveillance is indicated for patients and their family members. We recommend more frequent colonoscopies and at least a baseline EGD at the time of diagnosis. Patients should be counseled that the risk of colorectal cancer is increased, and family members should be advised that they are at increased risk for the same syndrome, potentially as high as 50%.

The Genetic and Rare Diseases Information Center (GARD) introduces a new online collection of information resources. *S. Von Schuch[1], M. Waite[1], J. Lewis[1], M. Della Rocca[1], D. Lea[2], H. Hyatt-Knorr[3]* 1) Lockheed Martin, Rockville, MD; 2) National Human Genome Research Insitute, Bethesda, MD; 3) Office of Rare Diseases, Bethesda, MD.

In 2001, the Office of Rare Diseases (ORD) and the National Human Genome Research Institute (NHGRI) at the National Institutes of Health (NIH) established the Genetic and Rare Diseases Information Center (GARD) to enhance the publics knowledge of genetic and rare disorders. Over the last 7 years, GARD has developed customized, comprehensive responses in English and Spanish to requests for information from patients, family members, health professionals and the general public. During this time, GARD has received close to 22,000 inquiries concerning more than 5,500 specific conditions. In 2008, GARD introduced a new online collection of information resources (http://rarediseases.info.nih.gov/GARD/) on the ORD Web site to provide the public with unlimited access to its extensive English-language information resources. Now when a person submits a question to GARD about a particular condition, the question is edited to ensure confidentiality and posted to the conditions Web page. Both the original inquirer and the general public will have access to the responses provided by experienced Information Specialists. A list of resources is also added to each conditions page to help users search for more information and find the answers to their questions. Resources are separated into different categories, including more information, support groups, research and clinical trials, services, and conferences. GARD Information Specialists remain available to assist users and answer any new questions. In 2009, GARD plans to expand its online collection to include Spanish-language information resources. The new GARD Web pages have averaged about 15,000 unique visitors since launching in February. The total number of visits has steadily increased over the past three months, with more than 45,000 visits during the month of April. As GARD receives more questions from the public on genetic and/or rare diseases, the collection of information and resources will continue to grow.

Investigation of GRIA3 Receptor Gene and Migraine Susceptibility. *T. Esposito[1], F. Fernandez[2], R. Lea[2,3], A. Aloia[1], R. Chimienti[1], A. Ciccodicola[1], G. Di Iorio[4], F. Gianfrancesco[1], L. R. Griffiths[2]* 1) Inst Genetics & Biophysics, CNR, Naples, Italy; 2) G.R. C., School of Med Sci, Griffith University, Gold Coast, Australia; 3) Inst of Environmental Sci and Research, Wellington, New Zealand; 4) Headache Service - Dep of Neurological Sci, II University of Naples, Italy.

Migraine is a debilitating neurological disorder characterised by recurrent attacks of severe headache, affecting 12% of Caucasian populations. Previously we reported the localisation of a migraine locus on chromosome Xq24-28. To define the associate region and to investigate for candidate genes we selected 19 candidate genes that, on the basis of their potential functional significance or physical position, may be involved in the pathophysiology of familial migraine. SNPs were selected in all described candidate genes and were genotyped in five Australian extended migraine pedigrees. Haplotype analysis and key recombination events showed two associated regions at Xq24 and the distal end of Xq28. This specific region contains a glutamate (GRIA3) receptor gene, which is a potential candidate gene for migraine susceptibility. We looked for functional SNPs, sequencing the exonic and regulatory region of GRIA3 gene in a cohort of Australian subject and we found an associated regulative variant -1722T/C. This variant was analysed in a large Australian population (275 unrelated Caucasian migraineurs versus 275 controls). Chi-square analysis showed significant differences in allele and genotype frequencies (P = 0.03). In order to replicate and validate these findings in a different population, we recruited an Italian cohort of migraine and control subject (150 migraineurs versus 150 healthy individuals). We genotyped the -1722T/C variant in the Italian panel and we found a significant association between this variant and migraine phenotype (p=0.003). Bioinformatics predictions showed that the C variant could affect putative binding sites for heat shock factor (HSF) altering the consensus sequence nGAAn, this change could alter the response of GRIA3 gene to stress condition. Further functional studies are currently underway.

PGD ON 2,438 EMBRYOS FROM 261 CYCLES DUE TO PARENTAL RECIPROCAL TRANSLOCATIONS, ROBERTSONIAN TRANSLOCATIONS OR PERICENTRIC INVERSIONS. *A. Benner, R. Pen, A. Kittai, W. G. Kearns* Shady Grove Center for Preimplantation Genetics, Rockville, MD.

Objective: Carrier couples with a structural chromosome rearrangement have an approximate 50% chance of producing genetically unbalanced gametes. Therefore, these couples are at high risk of producing genetically unbalanced embryos that can result in implantation failure, a miscarriage or a live birth with a genetic disorder. This study of 261 PGD cycles from referring clinics was performed to determine embryo structural chromosome balances due to parental rearrangements.

Materials and Methods: 171 patients underwent 261 *in vitro* fertilization (IVF) cycles for genetic imbalances due to parental structural chromosome rearrangements. Laser-assisted embryo biopsy was performed on 2,438 day-3 embryos. Multi-color fluorescence *in situ* hybridization using telomere and/or genomic loci DNA probes was used to determine embryonic genetic balances due to parental structural chromosome rearrangements. These included reciprocal translocations, Robertsonian translocations and pericentric inversions. Clinical pregnancy (CP) was defined by ultrasound identification of an intrauterine gestational sac and fetal heart beat.

Results: Thirty percent (79/261) of all cycles had no transfer because all tested embryos were either 1) genetically unbalanced or 2) genetically balanced but found to be morphologically abnormal in development and quality on the day of transfer. Seven percent (179/2,438) of embryos had no diagnosis because of poor embryo quality. The total CP rate for all structural chromosome aberrations was 23% (40/171). Breaking them down by the type of aberration shows a 23% (16/69) CP rate for reciprocal translocations, a 22% (18/83) CP rate for Robertsonian translocations and 32% (6/19) CP rate for pericentric inversions. The average biochemical pregnancy rate was 8.8% (15/171) per patient.

Conclusions: This data shows that PGD for structural chromosome abnormalities may increase the likelihood of a carrier couple of a structural chromosome rearrangement having a healthy baby.

Cystic Fibrosis prenatal screening of 103,600 individuals in an HMO: Molecular/clinical outcomes and a dramatic reduction in CF incidence. *D. Witt, C. Wold, P. Goonewardena, E. Louie, S. Rosenfeld* Genetics Dept, Kaiser Permanente, San Jose, CA.

We report on 8 years (11/99-12/07) of data from a cystic fibrosis (CF) prenatal screening program in an HMO. The program is unique because of its large size and integrated laboratory and clinical services that enable the analysis of comprehensive data and outcomes.

CF screening is offered in early pregnancy to couples in whom at least one partner is Caucasian. The pregnant woman is offered screening first, followed by her male partner if she is found to be a carrier. At-risk couples (both partners are carriers) are offered genetic counseling and prenatal diagnosis. Pregnancy termination is offered to couples with affected fetuses. The testing panel consists of 35 CFTR gene mutations.

Data are reported on 103,600 individuals with 3,514 carriers and 103 at-risk couples in 132 pregnancies. Specific CFTR gene mutations/frequencies will be reported. 87 pregnancies (66%) had prenatal diagnosis and 23 (26%) were affected. 17 of the 23 affected were predicted to result in severe CF of which 16 (94%) were terminated, and 6 of the 23 were predicted mild/asymptomatic of which 4 (67%) were terminated. 45 pregnancies (34%) did not undergo prenatal diagnosis but only 31 (23%) actively declined while the others were ineligible due to miscarriage or late presentation. The 45 untested pregnancies resulted in 11 affected babies of whom 6 were predicted to be severe and 5 predicted to be mild/asymptomatic. During the same period, 13 other babies with CF were born who were not identified prenatally either because of parental choice, test insensitivity and/or they did not fit ethnicity screening criteria. Overall, 52% (16/31) of pregnancies that would have led to the birth of a child predicted to have severe CF were terminated, thereby reducing the incidence of CF by approximately one-half.

The utility and benefits of CF screening as measured by personal choice and overall impact on disease incidence will be discussed.

Classification of genetic diseases for the clinician and the researcher: new tools developed by Orphanet. *S. Ayme, A. Rath, M. Georget, V. Lanneau, M. Hanauer* Orphanet, INSERM SC11, Paris, France.

Nomenclature of genetic diseases has evolved a lot during the past years, but no one knows how to establish the catalogue of human genetic diseases as a definition of what is a disease is lacking. OMIM is often cited as a catalogue of human genetic diseases when it is a catalogue of human genes. To overcome this difficulty, Orphanet (www.orpha.net) has established a database of phenotypes. The definition of what is a disease is the phenotype which has to be distinct for a clinician. Every phenotype is classified in the multiple possible classification systems to allow an understanding of its aetiology, of its physiopathology of or its range of expression. Every phenotype has a unique identifier which will remain stable and is linked to its parent disease and to its children diseases in the different classification systems. This includes all the published classifications and expert classifications established at Orphanet to meet the needs of the clinicians. They are based on the classical medical specialties and sub-specialties. Currently over 2,500 major phenotypes are classified and indexed. The users of the website can query by disease name at any level of precision, and by gene or by sign. They can visualise where the disease fits in the different classifications. This new service is expected to provide a bridge between clinicians and biologists for a mutual benefit. It is also expected to help make genetic diseases more visible in the health care information systems by providing a stable nomenclature of all existing phenotypes and to permit the interfacing of different databases. The data are available on request to all research and clinical groups which may need them.

Investigating the pathogenesis and therapy of Friedreich ataxia using mouse model cell lines. *C. Sandi, R. Mouro Pinto, S. Al-Mahdawi, M. A. Pook* CCCB/BICGP, Division of Biosciences, School of Health Sciences and Social Care, Brunel University, Middlesex, UB8 3PH, UK.

Friedreich ataxia (FRDA) is an autosomal recessive trinucleotide repeat disease caused by expanded GAA repeats in the first intron of the FXN gene. Normal individuals have 5 to 30 GAA repeat sequences, whereas affected individuals have 70 to 1600 repeats. The effect of the GAA expansion mutation is to reduce the expression of frataxin, a mitochondrial protein involved in iron-sulphur cluster biosynthesis. Evidence suggests that the GAA repeat expansion may adopt an abnormal triplex structure that interferes with FXN gene transcription. It has also been suggested that GAA repeats may produce a heterochromatin-mediated gene silencing effect. There is no effective therapy for FRDA. In order to gain further understanding of FRDA pathogenesis, the physiological function of frataxin and to develop an effective system for testing potential therapies, mouse models of FRDA are considered essential. We have recently generated a GAA repeat expansion mutation-based FRDA mouse model that exhibits GAA repeat instability, epigenetic changes and progressive mild pathology representative of FRDA. We now describe the establishment of fibroblast and neuronal stem cell lines from this FRDA mouse model. We find that mouse FRDA fibroblasts are significantly more sensitive to hydrogen peroxide-induced oxidative stress than control cells. We further show how these cultured cells are now being used to investigate epigenetic-based drug therapies for FRDA.

PREIMPLANATATION GENETIC SCREENING (PGS) FOR ANEUPLOIDY IN 93 COUPLES UNDERGOING DONOR EGG IN VITRO FERTILIZATION (IVF) CYCLES. *R. Pen[1], A. Benner[1], P. Kearns[1], A. Kittai[1], P. Browne[2], W. G. Kearns[1]* 1) Shady Grove Center for Preimplantation Genetics, Rockville, MD; 2) Shady Grove Fertility Reproductive Science Center, Rockville, MD.

Objective: To determine the prevalence of aneuploidy in couples undergoing donor egg IVF cycles, since PGS for aneuploidy is not a common recommendation for the donor egg patient group.

Materials and Methods: Ninety-three couples underwent donor egg IVF-PGS due to poor outcomes from prior fertility therapy. Laser-assisted embryo biopsy was performed on day-3 and PGS was done on 1,215 cleaving embryos from 93 initiated cycles. The mean donor age is 26.5 years (21- 31). Multi-color fluorescence *in situ* hybridization was used to determine aneuploidy for chromosomes 13, 14, 15, 16, 17, 18, 21, 22, X and Y. Hybridization, stringency washes and fluorescent microscopy were performed. Clinical outcomes (aneuploidy, embryo transfer, clinical pregnancies and delivery rates) of these cycles were determined. Clinical pregnancy was defined by ultrasound identification of an intrauterine gestational sac and fetal heart beat.

Results: All 93 women had an embryo transfer. Four percent (49/1,215) of the embryos were not diagnosed due to poor blastomere quality. Forty-eight percent (560/1,166) of the embryos were abnormal for at least one of the 10 chromosomes tested. Seventy-three percent (442/606) of the cytogenetically normal embryos developed into a blastocyst. The clinical pregnancy rate was 77% (72/93) per patient and 77% (72/93) per embryo transfer. There were no miscarriages, misdiagnoses, nor identified mosaic embryos.

Conclusions: This aneuploidy screening data from donor egg cycles provides insight into the presence of aneuploidy in a low risk population. Pregnancy rates were similar in these patients to those undergoing donor egg IVF without PGS. The miscarriage rate is 0% which may be due to the aneuploidy screening of the preimplantation embryos.

A Multicenter, Randomized, Dose Frequency Study of the Safety and Efficacy of Cerezyme Infusions Every 4 Weeks Versus Every 2 Weeks in the Maintenance Therapy of Patients with Type 1 Gaucher Disease. *P. Kishnani on behalf of the CZ-011-01 Study Investigators* Department of Pediatrics, Division of Medical Genetics, Duke University Medical Center, Durham, NC.

Introduction: Cerezyme (imiglucerase, Genzyme Corporation) is the current standard treatment for type 1 Gaucher disease (GD1). Most patients are infused every 2 weeks. A less frequent infusion schedule at the same total 4-week dose might be equally effective and more convenient. Objective: To compare the safety and efficacy of two dosing frequencies of Cerezyme for patients with GD1. Methods: A phase IV, multicenter, randomized 24-month trial enrolled 95 clinically stable adult GD1 patients (mean age 47 years; range 18-82 years) who had received Cerezyme 2 years. Patients were randomized to continue their total 4 week dose as 1 infusion every 2 weeks (Q2) or 1 infusion every 4 weeks (Q4). The primary analysis used a composite endpoint of relative change in hemoglobin level, platelet count, liver and spleen volumes, or progression of bone disease and bone crisis. A post-hoc analysis was performed based upon maintenance of therapeutic goals (Pastores et al. Sem Hematol 2004; 41(4 Suppl 5:4-14). Results: Mean 4-week doses (U/kg) of Cerezyme were 70.424.9 for Q2 (n=33) and 69.721.3 for Q4 (n=62). The primary analysis endpoint was maintained in 80.8% of Q2 and 63.2% of Q4 patients at 24 months. Per the post-hoc analysis, 100% of Q2 and 88.5% of Q4 patients maintained therapeutic goals at 24 months. No Cerezyme-related serious adverse events were reported. Conclusions: Infusing a total 4-week dose of imiglucerase every 4 weeks appears to be safe and well-tolerated in the majority of patients in this cohort and may be considered for some stable adult GD1 patients who have achieved therapeutic goals on Cerezyme therapy. The dosing frequency of Cerezyme, as with dose itself, must be individualized based upon physician judgment and patient needs as determined by regular and comprehensive monitoring. Long term follow-up of patients on a Q4 dosing regimen is necessary to determine other clinical outcomes, such as bone mineralization and marrow infiltration.

Identifying a risk factor for the development of gonadal tumors in patients with abnormal sexual development.

M. Beaulieu Bergeron[1,2,4], P. Brochu[1,2], M. Blumenkrantz[5], E. Lemyre[3,4], N. Lemieux[1,2,4] 1) Pathology Cell Biology, University of Montreal, Montreal, Canada; 2) Pathology, CHU Sainte-Justine, Montreal, Canada; 3) Pediatrics, CHU Sainte-Justine, Montreal, Canada; 4) Research Center, CHU Sainte-Justine, Montreal, Canada; 5) Pathology, McGill University Health Center, Montreal, Canada.

Patients with a disorder of sex development (DSD) and a Y chromosome are at risk of developing gonadal tumors, mainly gonadoblastomas (GBs) and dysgerminomas (DGs). These tumors would arise from germ cells that proliferate under the influence of TSPY (Yp11.2) in undifferentiated gonadal tissue (UGT) of dysgenetic gonads. On the contrary, gonadal streaks are thought to pose no threats of progressing into GBs as they do not contain germ cells. In order to verify this hypothesis, we retrospectively studied the gonads of 25 patients with a DSD and a Y chromosome who underwent prophylactic gonadectomy. The cohort included 10 females and 1 male with an isodicentric Y chromosome [idic(Y)], 1 female with a ring Y chromosome [r(Y)], 1 female with a Y chromosome derived from a translocation with an X chromosome [der(Y)t(X;Y)], 7 females and 1 male with a 46,XY constitution, and 2 males and 2 females with a 45,X/46,XY constitution. The region containing TSPY was still present in all patients. Histological review of gonads revealed the presence of UGT in 10 patients, streak gonads in 13 patients, and dysgenetic testes in 2 patients. 7 out of the 10 patients with UGT developed gonadal tumors: 4 females with an idic(Y) presented a GB, 2 XY females had bilateral DGs and/or GBs, and 1 45,X/46,XY female had a GB. As for the 3 patients with UGT and no tumors (a female with a der(Y)t(X;Y), a male with an idic(Y), and a 45,X/46,XY male), prophylactic gonadectomy at the very young age of 17, 13 and 19 months respectively might have prevented tumorigenesis. On the other hand, 1 female with an idic(Y) and no UGT developed a burned-out GB, although artefacts complicated the histological study. In conclusion, our retrospective study suggests that UGT is indeed at risk for developing GBs and/or DGs in individuals with a Y chromosome, including TSPY, and a DSD.

CHOP T/C and C/T Haplotypes Contribute to Early-Onset Type 2 Diabetes in Italians. *C. Gragnoli* Dept Endocrinology, Hershey Medical Ctr, Hershey, PA.

Type 2 diabetes (T2D) is characterized by impaired insulin secretion, insulin insensitivity and decreased beta-cell mass. Multiple genes contribute to T2D. The chromosome 12q13.1 region is in linkage to T2D in different populations, including our Italian dataset. CHOP is a candidate gene for the linkage, as it is located in the chromosome 12q13.1 region, and may contribute to T2D by increasing beta-cell apoptosis susceptibility and by impairing insulin sensitivity. Objective. Our goal was to identify any potential CHOP gene variants contributing to T2D in our Italian early-onset T2D families, which show linkage to the CHOP region. Material and Methods. We directly sequenced the CHOP gene in 28 Italian probands of the linked T2D families and in 115 control subjects. We performed genotype and haplotype association tests with T2D of the identified SNPs. We performed model-free and parametric association haplotype tests with T2D. Results. We identified three SNPs (5'UTR-c.279T>C, 5'UTR-c.120A>G and +nt30C>T (F10F) in CHOP. These SNPs are in complete linkage disequilibrium. The genotype association test showed an association trend with T2D of the TT (F10F) and AG (-c.120A>G). The haplotype association test provided significant results for the haplotypes T/C (frequency=0.33) and C/T (frequency=0.01) (at 5'UTR-c.279T>C and +nt30C>T, respectively) under non-parametric analysis (p-value=0.0000), recessive model (p-value=0.0000) and additive model (p-value=0.0014). Conclusions. Our data show that CHOP described haplotypes T/C and C/T, as an additive and as a homozygous variant, contribute significantly to T2D in our Italian early-onset group. We conclude that the CHOP T/C and C/T haplotype contributes to our T2D linkage signal on chromosome 12q13.1.

Clinical and Molecular Insights into Branchio-Oculo-Facial Syndrome (BOFS). *J. M. Milunsky[1,2], T. Maher[1], G. Zhao[1], D. Chitayat[3], M. Cunningham[4], W. Meschino[5], A. Megarbane[6], H. Stalker[7], R. Zori[7], A. Lin[8]* 1) Ctr. Human Genetics, BUSM, Boston, MA; 2) Dept. Pediatrics/Genetics and Genomics, BUSM, Boston, MA; 3) Dept. Pediatrics, Hosp. for Sick Children, Toronto, Canada; 4) Dept. Pediatrics, University of Washington, Seattle, Washington; 5) Dept. Pediatrics, University of Toronto, Toronto, Canada; 6) Unit of Medical Genetics, University Saint-Joseph, Lebanon; 7) Div. of Genetics, University of Florida, Gainesville, FL; 8) Genetics Unit, MGH, Boston, MA.

Branchio-Oculo-Facial Syndrome (BOFS) is a rare autosomal dominant cleft palate-craniofacial disorder with variable expression. Major features include cutaneous and ocular anomalies, typical facies, and less commonly, renal and ectodermal anomalies. We recently determined that mutations involving *TFAP2A* result in BOFS (Milunsky et al, 2008). We have now studied a total of 10 families (14 affected individuals) that meet the cardinal diagnostic criteria. The 3.2Mb deletion including the *TFAP2A* gene detected in family 1(affected son/mother)has also been found in the maternal grandmother who has a branchial cleft cyst and hearing loss. Members of this family were the only BOFS patients without typical CL/P. 9/10 families had missense mutations detected in the *TFAP2A* gene in the highly conserved exons 4 and 5 (basic region of the DNA binding domain). The missense mutations appear to cluster in an apparent hotspot region between amino acids 254 and 256 (6/9 patients). Mutations of amino acid 254 occurred in 4 unrelated families (R254G/R254W). In one of these families, the father (white forelock, pre-auricular sinus and supernumerary nipple) appears to be a mosaic (R254G) in blood. Thus far, genetic heterogeneity has not been observed. The clustering of mutations supports a tiered molecular approach to the analysis starting with sequencing of exons 4 and 5 and, if negative, full sequencing of the gene followed by deletion analysis if unrevealing. There was some clinical variability with the deletion family, with little variability between patients having missense mutations. More patients need to be studied to better appreciate if there are mutation-specific genotype phenotype correlations.

Increased copy number of genes encoding the sister chromatid cohesion complex conveys a syndrome distinct from Cornelia de Lange. *J. R. Lupski[1,9,10,11], F. Zhang[1], E. Brundage[1], A. Scheuerle[2], B. Lanpher[3], R. P. Erickson[4], Z. Powis[4], H. B. Robinson[5], P. L. Trapane[6], D. Stachiw-Hietpas[7], K. M. Keppler-Noreuil[8], S. R. Lalani[1,11], T. Sahoo[1,11], A. C. Chinault[1], A. Patel[1,11], S. W. Cheung[1,11], J. Yan[1]* 1) Mol & Human Gen, Baylor Col of Med; 2) Tesserae Gen, TX; 3) Dept of Pedi, Vanderbilt U, TN; 4) Dept of Pedi, U of Arizona, AZ; 5) Dept of Path, Akron Children's Hospital, OH; 6) Med Col of Wisconsin; 7) Children's Hospital of Wisconsin, WI; 8) Dept Pedi/Med Gen, U of Iowa, IA; 9) Dept. of Pedi, Baylor Col of Med; 10) Texas Children's Hospital; 11) Med Genet Lab, TX.

Cornelia de Lange Syndrome (CdLS) is a multisystem congenital anomaly disorder. Heterozygous mutations in three genes (*NIPBL*, *SMC3* and *SMC1A*), encoding components of the sister chromatid cohesion apparatus, are responsible for ~50-60% of CdLS cases. Recent studies have revealed a high degree of genomic rearrangements (e.g. deletions and duplications) in the human genome, which result in gene copy number variations (CNV). CNVs have been associated with a wide range of both Mendelian and complex traits including disease phenotypes such as Charcot-Marie-Tooth type 1A, Pelizaeus-Merzbacher, Parkinson, Alzheimer, autism and schizophrenia. Increased versus decreased copy number of the same gene can potentially cause either similar or different clinical features. We identified duplications on chromosomes 5 or X using genome wide array Comparative Genomic Hybridization (aCGH). The duplicated regions contain either the *NIPBL* or the *SMC1A* genes. The patients share some common features including mental retardation, developmental delay, sleep abnormalities, and crainofacial and limb defects. The systems affected are the same as in CdLS, but clinical manifestations are distinct from CdLS. Our results confirm the notion that CNV of genes can be a common mechanism for human genetic diseases. Defining the clinical consequences for a specific gene dosage alteration represents a new reverse genomics trend in medical genetics that is reciprocal to the traditional approach of delineation of the common clinical phenotype preceding the discovery of the genetic etiology.

Optimizing approximate Bayesian computation methods for sequence-based studies of population history. *R. L. Raaum[1,2], C. J. Mulligan[3]* 1) Anthropology, Lehman College & the Graduate Center, City University of New York, New York, NY; 2) New York Consortium in Evolutionary Primatology; 3) Anthropology, University of Florida, Gainesville, FL.

Many Bayesian methods used in population genetic studies are computationally intensive and may not be practically applied to all questions of interest. One of the most promising new methods being developed is approximate Bayesian computation (ABC). In this method summary statistics from the observed data are compared to those calculated from simulated data to estimate parameters of interest. However, ABC is a relatively new approach and few of the analytic choices for this method have been thoroughly evaluated. Here we present the results of our analysis of some of these choices. First, we determined when the computationally efficient infinite sites model may be used in the simulations instead of a more complex model (e.g. HKY). We modeled four types of commonly studied human sequence data: mitochondrial hypervariable, mitochondrial coding, autosomal non-coding, and Y non-coding. We found that parameter estimates based on HKY simulations were significantly better than the infinite sites based estimates for both mitochondrial sequence types, but that the estimates did not differ significantly for the two nuclear sequence types. Second, we determined if using more summary statistics improves the estimate by adding more information or worsens the estimate by introducing noise. For this, we calculated parameter estimates using 2, 4, or 6 statistics, and found no statistically significant difference among any of these estimates. Third, many studies have used nucleotide diversity (pi) and number of segregating sites (ss), but these statistics have not been demonstrated to be more accurate or precise than other potential statistics. To determine the best set of statistics, we compared the accuracy and precision of parameter estimates based upon all possible pairs of a selection of 11 statistics. We found that pi and ss is not a universally optimal selection for the population models we evaluated, and that no single pair of statistics is universally optimal for commonly estimated parameters.

Mutations in the Type I Collagen C-propeptide Cleavage Site Cause a Distinct Phenotype Based on Slower Procollagen Processing. *A. M. Barnes[1], K. Lindahl[2], M. Whyte[3], T. Hefferan[4], C.-J. Rubin[2], A. Kindmark[2], O. Ljunggren[2], J. C. Marini[1]* 1) BEMB, NICHD/NIH, Bethesda, MD; 2) Dept of Endocrinology, Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Shriner's Hospital for Children, St. Louis, MO; 4) Dept of Orthopedics, Mayo Clinic, Rochester, MN.

Osteogenesis imperfecta (OI), or brittle bone disease, is often caused by mutations in the type I collagen genes; over 800 have been described. Mutations in type I procollagen C-propeptide cleavage site are of particular interest because they disrupt a unique processing step. We identified two children with mild OI who had cleavage site mutations in *COL1A1* (P1: 1(I)Asp1041Asn) or *COL1A2* (P2: 2(I)Ala1029Thr). P1 had a normal *LRP5* sequence. P1 DEXA Z-score and pQCT vBMD were +3, contrasting with radiographs demonstrating osteopenia and os-in-os vertebrae, and histomorphometry revealing increased bone remodeling, without a mineralization defect or signs of osteosclerosis. P2 had a DEXA z-score of 0, gracile long bones with radiographic osteopenia, and decreased BV/TV and increased BFR without a mineralization defect on histomorphometry. Both P1 and P2 are at the 75th percentile for height. The dermal fibrils of P1 had a normal diameter with a smooth surface, while P2 had small fibrils including some with blebs. Steady-state collagen electrophoresis showed slight backstreaking of 1(I) and 2(I) in cell layers of both probands. The baseline of P1 chains was delayed, while those of P2 migrated normally. Chain incorporation was normal in P1 and slightly delayed in P2. Pericellular processing of P1 was delayed, with increases in both pC1 and pro2, while P2 had increased pC2 and pro2 and normal processing kinetics. These mutations seem to define a novel phenotype within type I collagen defects. In combination with a recently reported adult with pro1(I)Ala1040Thr substitution (Int Conn Tis 82S1: CC01), our cases suggest that defects in pro1(I) processing can lead to high BMD in childhood, with radiographic signs of osteopetrosis occurring subsequently. Pro-1(I) cleavage appears crucial to C-propeptide processing, while defective pro-2(I) specific or non-specific cleavage occurs after 1(I) processing.

New candidate genes for osteoporosis identified by linkage and linkage disequilibrium analysis of QTL on chromosome 1p36. *H. Zhang[1], K. Sol-Church[2], H. Rydbeck[1], D. Stabley[2], L. D. Spotila[3], M. Devoto[1,4,5]* 1) The Childrens Hospital of Philadelphia, Philadelphia, PA; 2) Nemours Childrens Clinic, Wilmington, DE; 3) ScienceScribe, Haddonfield, NJ; 4) Dept. of Pediatrics and Dept. of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Department of Experimental Medicine, University La Sapienza, Rome, Italy.

Low BMD is one of the major risk factors for osteoporosis. Following a whole genome scan in a sample of Caucasian families recruited through probands with low BMD, a region on 1p36 near marker D1S214 received support as a candidate quantitative trait locus (QTL) for BMD from both linkage (maximum lod-score = 2.87) and linkage disequilibrium analysis ($P < 0.01$). In an attempt to better characterize the genetic risk factors for low BMD located in this genomic region, we have now genotyped the same group of families for 1095 single nucleotide polymorphisms (SNPs) located across 11 Mb on chromosome 1p36 at an average spacing of 10 Kb. Linkage and linkage disequilibrium analyses have been performed by means of the variance component approach. Multivariate variance component linkage analysis indicated two QTLs for femoral neck BMD, lumbar spine BMD and trochanter BMD simultaneously on chromosome 1p36, with maximum lod-scores of 4.37 at 12 cM (~3.7 Mb) and 3.59 at 22 cM (~8.2 Mb). Linkage disequilibrium analysis identified several SNPs potentially associated with BMD, including the RERE gene intragenic SNP rs11121179 ($p = 0.000005$ for lumbar spine BMD) and the intergenic SNP rs579992 ($p = 0.00004$ for femoral neck BMD). Other candidate genes in this region include G1P2, SSU72 and CCDC27 ($p < 0.001$ for association with at least one of the BMD traits). This study supports the presence in 1p36 of QTLs that affect BMD at multiple skeletal sites and suggests several new candidate genes for further analyses. Replication of our results in other independent cohorts is warranted.

Haploinsufficiency of *Rai1* causes features reminiscent of metabolic syndrome. *J. Yan[1], W. Bi[1], P. K. Saha[2], L. Chan[2], J. R. Lupski[1,3,4]* 1) Dept Molecular & Human Gen, Baylor Col Medicine; 2) Department of Molecular and Cellular Biology; 3) Department of Pediatrics, Baylor College of Medicine; 4) Texas Children's Hospital, Houston, TX.

Heterozygous mutations in the *RAI1* gene are responsible for the majority of clinical features in the Smith-Magenis syndrome (SMS), a multiple congenital anomaly disorder. Both *Df(11)17*/+ mice, with a heterozygous 2 Mb deletion in the mouse chromosome 11 region syntenic to the SMS critical region, and *Rai1*+/- mice manifest abnormalities recapitulating some SMS clinical phenotypes, including craniofacial defects and obesity. The craniofacial abnormalities and obesity are normalized in *Dp(11)17*/*Rai1*+/- animals, trisomic for ~20 genes but disomic (N=2) for *Rai1*, demonstrating these traits or endophenotypes are caused by *Rai1* gene dosage. Further characterization of the obesity phenotype demonstrated that *Rai1*+/- mice had increased food intake and stored more fat in individual adipose cells. The blood cholesterol levels were increased, which has also been observed in individuals with SMS. Glucose tolerance test indicated insulin insensitivity. The leptin levels were elevated in the *Rai1*+/- mice. These features are reminiscent of metabolic syndrome. Our mouse model thus provides an opportunity to study not only the molecular mechanisms for multiple features in SMS but also common traits such as obesity.

Assessment of Carboxypeptidase M (CPM) Amplification: A surrogate marker for MDM2 amplification in the discrimination of well-differentiated liposarcomas from lipomas. *M. R. Johnson, A. R. Seys, C. W. Roth, A. A. King, R. L. Hulshizer, X. Wang, R. V. Lloyd, A. M. Oliveira* Mayo Clinic, Rochester, MN.

Background. Discrimination of well-differentiated liposarcoma/atypical lipomatous tumor (WDL/ALT) from lipoma can be diagnostically challenging. However, cytogenetic identification of ring and giant rod chromosomes strongly support the diagnosis of WDL/ALT. These abnormal chromosomes are mainly composed of sequences derived from bands 12q13-15, which contain several amplified genes including MDM2, CPM, CDK4, TSPAN31, and others. MDM2 is amplified in 99% of WDLs, and up to 30% of other sarcomas. CPM encodes for carboxypeptidase M, a membrane-bound peptidase that is located 11 kb upstream from MDM2. A comparative assessment of MDM2 and CPM was conducted on a series of lipomatous tumors to discriminate WDL/ATL from lipomas. Design. Seventeen WDL/ALT, 22 ordinary lipomas, and 16 other mesenchymal tumors were evaluated by MDM2 and CPM amplification using FISH on 4 m paraffin-embedded tissue sections. All experiments were performed by co-hybridizing MDM2 or CPM (custom designed probes) with a commercially available centromere 12 specific probe (CEP12, Vysis). Two hundred cells/tumor were evaluated by 2 technologists without prior knowledge of the diagnosis. Results. All WDL/ATL showed amplification of both MDM2 and CPM (usually 20 copies/cell). All lipomas and the 16 other mesenchymal tumors were negative for MDM2 or CPM amplification. Conclusions. CPM was co-amplified with MDM2 amplification in 100% of WDL/ALT but in none of the other tumors evaluated; including the 22 ordinary lipomas. Therefore, FISH for CPM amplification can be used as an alternative diagnostic tool for the diagnosis of lipomatous neoplasms.

Initial experiences with the Affymetrix 6.0 SNP Array. *M. de Andrade[1], E. Atkinson[1], W. Bamlet[1], M. Matsumoto[1], S. Maharjan[1], S. Kardia[2]* 1) Div Biostatistics, Mayo Clinic, Rochester, MN; 2) Epidemiology, University of Michigan, Ann Arbor, MI.

In an era of genome-wide association analyses, researchers are facing the challenge not only of analyzing a large volume of data but also of processing the genotype data and creating appropriate workflows. We present our experiences in working with the Affymetrix 6.0 Genome-Wide Human SNP Array including the workflows that we have created. In particular, we focus on the issues prior to genotype extraction, assessment of genotype accuracy, and automation of the workflows recognizing that the Affy 6.0 data will eventually be used for analysis using a wide range of study designs. We will share our experience working with Birdseed1 and 2 using individual plate and all plates to generate genotype call, examining replicate samples and the challenges with quality control measures in sibships. We will present our workflow and initial results using 900 samples of hypertensive sibships from Rochester, MN.

Deletion of 6q25-qter: Candidate region for brain and urinary system development genes? *N. Qin[1,2], E. Mahmoud[3], A. Hajianpour[4], M. Kanzawa[1], B. Huang[1,2]* 1) Dept Cytogenetics, Genzyme Genetics, Orange, CA; 2) Division of Human Genetics UCI; 3) Division of Neonatal-Perinatal Medicine UCI Medical Center; 4) Dept Cytogenetics, Genzyme Genetics, Monrovia, CA.

We report here a male infant with a terminal deletion of 6q25.3-qter and having apparent brain and urinary tract system malformations more severe than those described in most published cases. The proband was born at 39 weeks gestational age by C-section to a 19 year-old, gravida 2, para 2, Hispanic mother and a 28 year-old father. The APGAR Scores were 7 and 7 at one and five minutes of life. Pregnancy was complicated by the finding of hydrocephalus, cleft lip and palate at 24 weeks of gestational age. Chromosome analysis on amniotic fluid revealed a normal male karyotype at 450 band level (done at another laboratory). Parents continued pregnancy. At birth, the infant was observed to have hydrocephalus with open fontanels, hypotelorism, midline cleft lip and palate, moderate abdominal distension, bilateral clenched fists and rocker bottom feet. Cranial ultrasound reported severe hydrocephalus, minimal brain substance (consistent with holoprosencephaly). The Abdominal X-ray demonstrated a large fluid-filled intra-abdominal mass. The Abdominal ultrasound showed a small liver, normal right kidney, however, failed to visualize the left kidney and the bladder. Postnatal cytogenetic analysis on peripheral blood showed a subtle terminal deletion of the long arm of one chromosome 6 at 550 band level, which was confirmed by FISH studies. Patient died at about 17 hours of life. The presence of a subtle terminal deletion of the long arm of chromosome 6 with multiple congenital abnormalities may suggest high gene density in chromosome band 6q25-ter region. These genes may be sensitive to haploinsufficency, as evident from the infants severe abnormal phenotype, especially those major abnormalities detected in his brain and urinary tract system. In conclusion, a 6q25-qter segment may serve as a candidate region for genes involving in brain and urinary tract system development.

Two cases of Maple Syrup Urine Disease patients detected by Neonatal Screening Test with four novel mutations of BCKDHA in Korea. *I. Choi[1], J. Ko[2], G. Kim[1], J. Lee[1], C. Cheon[2], H. Yoo[1,2]* 1) Medical Genetics, Asan Medical Center, Seoul, Korea; 2) Dept. of Pediatrics, Asan Medical Center, Ulsan College of Medicine, Seoul, Korea.

Maple syrup urine disease (MSUD) is an autosomal recessive disorder involving the metabolism of the branched chain amino acids (BCAA) such as leucine, isoleucine and valine. This disorder results from a defect in branched chain -ketoacid dehydrogenase (BCKDH) complex. Impaired activity of BCKDH complex causes accumulation of branched-chain L-amino and 2-oxo acid, leading to neurotoxic damage to developing brain. Disease-causing mutations have been identified in the BCKDHA, BCKDHB or DBT genes encoding for the E1, E1; and E2 subunits of the BCKDH complex. MSUD presents with varying clinical features. Their genotype is also heterogeneous. Severity of the disease, ranging from classical to mild variant type, is commonly classified on the basis of various characteristics such as onset of symptom, responsiveness to thiamine therapy, and residual enzyme activity. We report two unrelated Korean MSUD patients, 10 and 17 day-old girls, who were detected by tandem mass spectrometry and confirmed by BCKDHA and BCKDHB gene analysis. They did not show any sign of neurological deterioration except increasing level of serum leucine (13.6 and 34.6 mg/dL) on repeated tandem mass screening test. BCAA-restricted diet and thiamine supplementation were prescribed. Leucine (808 and 4109 mol/L) and alloisoleucine levels were elevated on serum aminoacid analysis by HPLC, and -ketoacid (2-ketoisocaproic acid, 2-ketoglutaric acid) was detected in their urine. We performed BCKDHA and BCKDHB gene analysis using patients leukocyte, and they were confirmed as compound heterozygotes with four novel sequence changes (p.Arg279His, p.Pro324_Lys325dup, p.Ser46GlnfsX17, p.Thr211Met) in BCKDHA gene. They are 8 and 11 months old now, and develop normally without neurological complication. MSUD is a fetal disease, however better outcomes are expected if early diagnosis and prompt management are provided.

Copy number variations in patients with overgrowth syndromes detected by array-CGH. *V. Malan[1,2], S. Chevallier[1], C. Coubes[3], D. Lacombe[4], L. Pasquier[5], J. Soulier[6], N. Morichon-Delvallez[1,2], M. Vekemans[1,2], A. Munnich[1,2], V. Cormier-Daire[1,2], L. Colleaux[1,2]* 1) Département de Génétique et INSERM U781, Hôpital Necker Enfants Malades, Paris, France; 2) Université Paris Descartes, Paris, France; 3) Service de Génétique Médicale, CHU Saint- Eloi, Montpellier, France; 4) Service de Génétique Médicale, CHU Pellegrin, Bordeaux, France; 5) Service de Génétique Médicale, Hôpital Sud, Rennes, France; 6) Laboratoire d'Hématologie, Hôpital Saint- Louis, France.

Overgrowth syndromes are a heterogeneous group of conditions including endocrine hormone disorders, several genetic syndromes and many situations with thus far unexplained mechanisms.Interestingly, chromosomal anomalies have been identified in patients with overgrowth such as dup(4)(p16.3),dup(15)(q26qter)and del(9)(q22.3q22.33).Thus,we hypothesized that the sensitivity of array-CGH could improve the genetic diagnosis of overgrowth conditions. Eighty six patients with unexplained overgrowth syndrome were analyzed using a 1 Mb resolution array-CGH. Patients were classified into two groups: group I (40 cases) includes patients with a clinically known syndrome (i.e Sotos syndrome) whereas group II (46 cases) includes patients with unclassified overgrowth syndrome.We detected 10 possibly pathogenic imbalances in 9 patients (11.6%): two belong to group I while 7 belong to group II. Four imbalances correspond to deletions and 6 to duplications.No recurrent abnormality was identified.FISH analyses confirmed the chromosomal abnormalities in 7 cases while the remaining cases are still under investigation.Firstly, these results demonstrate that array-CGH is able to provide a high diagnostic yield in patients with overgrowth syndrome. Secondly, while chromosomal deletions are most often associated with growth retardation, we found that the majority of the imbalances detected in our patients are duplications.Thirdly, careful re-examination of patients may allow the delineation of novel clinically recognizable overgrowth syndromes. Finally, besides their importance for diagnosis and genetic counseling, these data may pave the way to the search of genes involved in the pathogenesis of overgrowth.

Pathogenic Copy Number Variations (CNVs) in patients with borderline intellectual functioning. *C. Romano, S. Reitano, D. Greco, E. Avola, P. Failla, G. Belfiore, S. Buono, M. Elia, O. Galesi, L. Castiglia, M. Fichera* IRCCS Associazione Oasi Maria Santissima, Troina, Italy.

Array CGH in patients with mental retardation and normal karyotype, shows causative CNVs in a percentage of 5-25% depending on techniques used and selection of patients. We applied this new technique in 22 patients classified as Borderline Intellectual Functioning (BIF) with a global intelligence quotient (IQ) in the range 71-84, according to DSM-IV-TR criteria, and we found 5 patients carrying a clinically relevant CNV (22.7%). The clinical checklist published by De Vries et al. (2001) was administered for each patient and showed that 3/5 (60%) carriers of chromosomal rearrangements and 11/17 (64.7%) patients negative to array-CGH analysis had a score of 3 or above. Candidates to array-CGH analysis are frequently patients with mental retardation and a Chromosomal phenotype, but our results suggest that this selection may not be the best clue for the diagnosis of chromosomal aberrations.

Novel polymorphisms in PPARG and ADIPOQ genes increase type 2 diabetes risk in Asian Indian Sikhs: Evidence of gene-gene interaction. *D. K. Sanghera[1], Y. F. Demirci[2], L. Ortega[1], L. Been[1], S. K. Ralhan[3], G. S. Wander[3], N. K. Mehra[4], J. R. Singh[5], J. J. Mulvihill[1], M. I. Kamboh[2]* 1) Dept Pediatrics, Univ Oklahoma HSC, Oklahoma, OK; 2) Department of Human Genetics, Univ of Pittsburgh, PA; 3) Hero DMC Heart Institute, Ludhiana, India; 4) All India Institute of Medical Sciences and Research, New Delhi, India; 5) Guru Nanak Dev Univ, Amritsar, India.

Asian Indians, 25% of world populations comprise highest number of diabetics of the world, reasons underlying the high prevalence are not understood. Studies point to strong genetic predisposition in response to certain environmental factors. In this study, we have examined the roles of peroxisome proliferator activated-receptor gamma (*PPARG*) and adiponectin (*ADIPOQ*) genes for affecting type 2 diabetes (T2D) risk in Asian Indian Sikhs. We genotyped 15 tagSNPs in *PPARG* and 5 tagSNPs in *ADIPOQ* in 562 T2D cases and 540 controls and examined their association with T2D. Three SNPs in the *PPARG* gene were significantly associated with T2D under recessive (rs1175073, p=0.021; rs1801282/Pro12Ala, p=0.007) and dominant (rs3892175, p=0.008) models after adjusting for the effects of age and sex. Also, two SNPs from *ADIPOQ* gene (rs182052, p=0.036 and rs7649121, p=0.034) were significantly associated with T2D under dominant model. In two-point haplotype analysis, GC haplotype of rs3892175 and rs1801282 in *PPARG* revealed significant association with T2D (^{2}=10.3; p=0.001; permutations p=0.002). Similarly, GA haplotype of rs182052 and rs7649121 in *ADIPOQ* showed significant association with T2D (^{2}=6.60; p=0.010; permutations p=0.03). In gene-gene interaction, rs3892175 and rs1801282 from *PPARG* revealed a strong interaction with rs7649121 from *ADIPOQ* in response to increasing the risk to T2D (p=1.08X10^{-3}). To further confirm this, we tested the association of T2D among risk allele carriers. The risk alleles of three interacting SNPs; rs3892175, rs1801282, and rs7649121 showed the strongest association with T2D (p=3.72X10^{-4}) compared to all other SNPs and alleles tested. Our new findings strongly suggest that the genetic variation in *PPARG* and *ADIPOQ* loci could be a major risk factor for the development of T2D in Indian Sikhs.

The recurrent mutation p.R674Q in the perinatal myosin heavy chain gene (MYH8) is associated with trismus-pseudocampodactily (TPS) in two brothers coming from Calabria, a region of Southern Italy. *G. Bonapace[1], F. Ceravolo[1], M. G. Pascale[1], S. Sestito[1], R. Apa[1], M. T. Moricca[1], P. Strisciuglio[2], D. Concolino[1]* 1) Dept of Pediatrics, Univ Magna Graecia, Catanzaro, Italy; 2) Dept of Pediatrics, Univ "Magna Graecia", Catanzaro, Italy; Present address: Dept of Pediatrics Univ Federico II, Naples, Italy.

Introduction:TPS is a rare autosomal dominant distal arthrogryposis characterized by an inability to open the mouth fully (trismus) and an unusual camptodactyly of the fingers that is apparent only upon dorsiflexion of the wrist . TPS is also known as Dutch-Kentucky syndrome because a Dutch founder mutation is presumed to be the origin of TPS cases in the Southeast US, including Kentucky. To date only a single mutation, p.R674Q, in MYH8 has been reported to cause TPS. We report on two brothers with TPS syndrome who were found to have the same MYH8 mutation pR674Q previously described in other families . Patients description and Methods:These patients were two brothers of unrelated healthy parents. Physical examination at age 29 and 19 respectively revealed: a limited mouth opening reduced flexion of the trunk and hips, pseudocaptodactily and feet deformities. Genomic DNA was extracted, using standard protocols, from peripheral lymphocytes.The entire coding region of MYH8 was PCR amplified using previously reported primers [Veugelers et al., 2004] and HotstarTaq DNA polymerase (Qiagen, Inc., Valencia, CA) following the manufacturers recommendations. PCR products were purified by PCR purification Kit I (Eppendorf) Purified PCR products were sequenced using the ABI BigDye Terminator v.1.1 chemistry (Applied Biosystems, Inc., Foster City, CA) and an ABI 310 automated sequencer (Applied Biosystems, Inc.). Results:The presence of the p.R674Q (c.2021G>A) mutation was confirmed in both patients by restriction digestion with BsiW I (New England Biolabs,) Discussion: These results demonstrating that all cases of TPS studied to date are caused by an identical c.2021G>A mutation in MYH8 that causes the p.R674Q substitution, support the use of MYH8 testing in patient with a clinical diagnosis of TPS syndrome coming from different geographical areas.

Large family with an unusual SNRPN microdeletion : Interest of prenatal diagnosis. *J.-F. Vanbellinghen, L. Mutesa, A.-C. Hellin, S. Bertoli, G. Pierquin, V. Bours* Department of Human Genetics, University Hospital Liège, Belgium.

The Prader-Willi syndrome (PWS) is a complex genetic disorder due to the loss of function of genes in 15q11-q13 which are subject to genomic imprinting and expressed from the paternal allele only. The PWS is characterized by diminished fetal activity during pregnancy, severe hypotonia and feeding difficulties in early infancy, hypogonadism, small hands and feet, craniofacial dysmorphism, and hyperphagia leading to profound obesity in later enfancy or early childhood. Whereas the majority of PW patients have a de novo large deletion commonly encompassing the imprinting centre (IC), the SNRPN and UBE3 genes or due to maternal uniparental disomy (mUPD), the microdeletion of SNRPN are rare and appear to have a high recurrence risk. We report a large Caucasian family with a partial SNRPN gene microdeletion. To identify this deletion, we used methylation-specific multiplex ligation-dependent probe amplification (MS-MLPA) kit (MRC-Holland, Netherland) consisting of 43 probes detecting the copy number variation inside the Prader-Willi-Angelman critical region (15q11-q13). This deletion was identified in an affected child and in a fetus during a prenatal testing. The extensive familial study showed that several individuals were carriers of the microdeletion with high potential risk of PWS in inheritance. This report points out the interest of MS-MLPA technique versus Southern Blotting and importance of genetics counselling in family with SNRPN microdeletion.

Fasting status and dietary intake influence genetic associations for the APOA1/C3/A4/A5 gene cluster and triglyceride levels. *K. Brown[1], J. D. Smith[2], C. Shephard[2], M. Wong[2], M. J. Rieder[2], D. A. Nickerson[2], D. C. Crawford[1]* 1) Vanderbilt University, Nashville, TN; 2) University of Washington, Seattle, WA.

Increased triglyceride (TG) levels are associated with cardiovascular disease and are influenced by genes and environment. APOA1/C3/A4/A5 gene cluster variation has been associated with TG levels, and recent evidence suggests these variations interact with dietary intake of fatty acids. To expand these findings, we tested for an association the APOA1/C3/A4/A5 gene cluster with TG levels in 7157 participants in the population-based Third National Health and Nutrition Examination Survey (NHANES III). Seven tagSNPs were genotyped in 1236/1056 European-Americans (EA), 947/744 African-Americans (AA), and 1001/713 Mexican-Americans (MA) >17 years of age with fasting/non-fasting TG levels. All analyses were adjusted for total cholesterol, HDL, age, body mass index, and gender and stratified by race/ethnicity and fasting status. Among fasting participants, rs675 (p=0.04) and rs5104 (p=0.04) were associated with decreased and increased TG levels, respectively, in MAs while rs4520 (p=0.001) was associated with increased TG levels in both MAs and EAs (p=0.04). Among non-fasting participants, rs651821 (p=0.005), rs5104 (p=0.0002), rs5100 (p=0.02) and rs5092 (p=0.004) were associated with increased TG levels in MAs, rs5091 (p=0.010) was associated with decreased levels in MAs, and rs651821 (p=0.005) was associated with increased TG levels in AAs. Interaction terms for each SNP and dietary intake of fatty acids, protein, carbohydrates, and alcohol, expressed as the percentage of total energy intake, were tested for an association with ln(TG) levels using linear regression adjusting for covariates and marginal terms. Among fasting participants, 26 interaction terms were significant at $p<0.05$ and one term was significant at $p<0.0001$. Among non-fasting participants, 37 interaction terms were significant at $p<0.05$ and 8 were significant at $p<0.0001$. Both associated SNPs and interaction terms explained 2-12% of the variability in ln(TG) levels in our models. These results suggest fasting status and dietary intake influence the genetic associations we observed for TG levels in NHANES III.

Molecular diagnosis of Menkes disease: Genotype-phenotype correlation. *L. B. Møller, M. Mogensen, N. Horn*
Kennedy Center, Gl.Landevej 7, 2600 Glostrup, Denmark.

Menkes disease (MD) is an X-linked, multisystemic lethal disorder of impaired copper metabolism caused by mutations in the gene, ATP7A. ATP7A contains 23 exons and encodes a P-type ATPase of 1,500 aa. The ATP7A protein is a member of the CPx-type transmembrane ATPase family that performs ATP-driven translocation of metal cations across cellular membranes. The ATP7A protein is localised to the transGolgi membrane but translocated to the plasma membrane in response to increased copper concentration. In addition to the severe classic form of MD leading to death in early childhood, milder forms are observed in 5-10% of the patients. Occipital horn syndrome is the mildest allelic form of MD. To date more than 200 different mutations affecting ATP7A has been identified. These mutations include missense mutations, splice site mutations, small deletions/insertions and larger deletions/duplications of one or several exons. In order to correlate the genetic defect with the clinical expression we have investigated the effect of selected mutations on the resulting ATP7A transcript and on the resulting protein product. We will discuss the results of these investigations, and how these observations contribute to our knowledge about the function of the copper-transporting ATPase, ATP7A.

Stage-specific upregulation of epigenetic genes and IC-*SNRPN* transcripts during human spermatogenesis. *B. Horsthemke[1], M. Wawrzik[1], A. N. Spiess[2], K. Buiting[1]* 1) Institut für Humangenetik, Universitätsklinikum Essen, Germany; 2) Abteilung für Andrologie, Universitätskrankenhaus Hamburg-Eppendorf, Germany.

The imprinted domain in human 15q11-q13 is controlled by an imprinting center (IC), which overlaps the 5' part of the paternally expressed *SNRPN* gene. The gene has at least four alternative start sites, including *PWRN1*, which was previously reported to be a separate gene. The region also contains *C15orf2*, which is predominantly expressed in testis, but also in brain, where expression is imprinted, as well as the testis-specific gene *PWRN2*, which is transcribed from the opposite strand. It is unclear, when the IC-*SNRPN* locus is activated during spermatogenesis and which epigenetic factors are involved in this process. We have addressed this question by mining microarray-based gene expression data of testicular biopsies from men with different types of spermatogenic failure (complete tubular atrophy, Sertoli-cell only syndrome, arrest before meiosis, arrest at meiosis, arrest at round spermatides, and uniform hypospermatogenesis; n=27) and with normal spermatogenesis (n=8). The expression patterns of several spermatogenesis genes (*SYCP3*, *TNP1*, *PRM1* and *PRM2*) revealed that the data can be used to determine the stage-specific up- and downregulation of genes. The following epigenetic genes are upregulated before or at early meiosis: *CTCFL*, *SUV39H2*, *EZH2*, *BRDT*, *DNMT1* and a truncated form of *MBD2*. *MBD3L1* is upregulated at the round spermatid stage. Little or no germ cell-specific upregulation was seen for *MBD1*, the long form of *MBD2*, *MBD3*, *MBD3L2*, *MBD4*, *MBD5*, *MBD6*, *MECP2*, *DNMT2*, *DNMT3A*, *DNMT3B*, *DNMT3L*, *SUV39H1*, *HDACs*, and *CTCF*. This analysis shows that several epigenetic factors play an important role at specific stages of spermatogenesis. A complex pattern was seen for the IC-*SNRPN* locus: a hitherto unreported transcript was upregulated before or at early meiosis, whereas the *PWRN1-SNRPN* and *PWRN2* transcripts were upregulated at the round spermatid stage and expressed from the haploid genome. The *SNRPN* upstream transcripts may play a role in activating the paternal copy of 15q11-q13.

Identification of Notch1 as a potential biomarker in multiple myeloma patients by DNA Microarray. *S. Gupta, A. Dwivedi, S. Adhvaryu* Dept Pathology, Univ Texas Hlth SCSA, San Antonio, TX.

Multiple Myeloma (MM) is an incurable B-cell malignancy characterized by monotypic plasma cells in the bone marrow. MM is known to develop resistance to conventional therapies with average survival of 3-5 years. Understanding the molecular pathogenesis of MM will potentially improve the scope for designing newer strategies to treat MM. Currently, the underlying genetic changes contributing to initiation and progression of MM are not well known. Identifying these key molecular anomalies would help in its diagnosis and treatment. Our study attempted to identify biomarkers associated with development of MM. DNA was extracted from the cell pellets from the bone marrow specimens from MM patients received for cytogenetic analysis and an unpaired copy number variation (CNV) analysis was performed by using the Affymetrix SNP 6.0 chips. Several unique biomarkers were identified as amplified or deleted, including Notch1, which was found to be amplified in more than 75% of the MM samples analyzed. Notch signaling plays a key role in the development and differentiation of various hematopoietic lineages. Notch signaling receptors are expressed in hematopoietic stem cells and its ligands are found to be expressed in bone marrow stroma. This provides a microenvironment for maintenance of hematopoietic stem cells and their development/ differentiation into other blood cell lineages. Role of Notch signaling in the pathogenesis of T-cell leukemia is well established. However, role of Notch signaling in development of B-cell neoplasm such as MM is not clear. Notch1 signaling, via its ligand Jagged1, has been shown to promote tumor cell growth and survival. Recent publications emphasized direct role of Notch signaling in the pathogenesis of MM. Other findings showing inhibition of Notch signaling induces apoptosis of MM cells and enhanced sensitivity to chemotherapy further substantiates our hypothesis. Our findings clearly underscore the role of Notch signaling pathway in MM. Further investigation in this area could help in establishing Notch1 as an important biomarker of MM and in designing specific treatment of MM.

Identification of a case of Limb-Girdle Muscular Dystrophy Caused by Uniparental Disomy of Chromosome 4. *R. E. Pyatt, M. Hart-Kothari, J. Frick, D. Lamb Thrush, M. Pastore, C. Shilling, X. Q. Rosales, J. Mendell, J. M. Gastier-Foster* Nationwide Childrens Hospital, Columbus, OH.

Limb-Girdle Muscular Dystrophy (LGMD) is a group of disorders which present with weakness and wasting of the voluntary muscles mainly around the pelvic and shoulder regions. LGMDs are caused by defects in multiple genes and can be autosomal dominant (type 1) or autosomal recessive (type 2). Further subdivisions are based on presentation, onset of weakness, and the involvement of specific muscle groups. LGMD2E is characterized by autosomal recessive inheritance, mutations in the beta-sarcoglycan gene (SGCB), and severe, childhood-onset of muscle weakness. The proband was first evaluated at age 9 with hip stiffness, difficulty climbing stairs, abnormal gait when running, and enlarged calf muscles. During routine mutation analysis of the SGCB gene on chromosome 4, the proband presented as apparently homozygous for a single base substitution in exon 4 (452C>G [T151R]) with no other alterations in the coding regions or exon-intron boundaries observed. Subsequent analysis of the SGCB gene in the probands parents revealed the mother to be a heterozygous carrier of the same mutation while no pathologic alterations were found in the father's gene. These results suggested the presence of a large deletion including exon 4 on the paternal allele, a de novo mutation, uniparental disomy, or nonpaternity. Uniparental disomy is the inheritance of both copies of a chromosome pair from a single parent. Microsatellite analysis was conducted using the PowerPlex 16 identity panel to exclude nonpaternity. To test for uniparental disomy of chromosome 4, the alleles for 10 additional microsatellite markers were compared between the proband and parents. Loci on chromosome 4 demonstrated exclusive inheritance of maternal alleles with no paternal contribution. These results represent the first reported case of LGMD caused by UPD.

Evaluation of genes responsible for homocysteine metabolism in a pseudoexfoliation glaucoma case control sample. *J. L. Wiggs[1], B. Fan[1], T. Li[1], C. Grosskreutz[1], L. Pasquale[1], T. Chen[1], D. Rhee[1], E. DelBono[1], J. L. Haines[2]* 1) Dept Ophthalmology, Harvard Medical Sch, MEEI, Boston, MA; 2) Center for Human Genetics Research, Vanderbilt School of Medicine, Nashville, TN.

Glaucoma is a genetically and phenotypically heterogeneous disorder that causes irreversible degeneration of the optic nerve and is a leading cause of blindness worldwide. Pseudoexfoliation glaucoma (PXF) and primary open-angle glaucoma (POAG) are the two most common forms of the disease. Recently, SNPs in LOXL1, coding for a protein that participates in elastogenesis, were significantly associated with PXF, however the risk haplotype is also prevalent in control samples, indicating that additional genetic factors and/or environmental exposures could contribute to this complex disease. Previous studies have indicated that plasma levels of homocysteine are elevated in patients with PXF suggesting that the genes determining homocysteine levels may be good candidates for secondary genetic factors. In the present study, we evaluated five genes that participate in homocysteine metabolism (CBS, MTHFD1, MTHFR, MTR, MTRR) in 215 PXF patients and 181 controls. Genotypes for 9 SNPs (including nonsynonomous SNPs with possible biologic effect) were obtained using either the TaqMan assay or direct genomic sequencing. Single-SNP association analysis was performed using SAS statistical software and pairwise-SNP interaction analysis was performed using PLINK. None of these SNPs were independently associated with PXF and only a weak interactive effect was found for one SNP in MTRR (rs161870, L206L) with LOXL1 ($p = 0.074$). These results suggest that this group of genes responsible for homocysteine metabolism does not contribute significantly to PXF. Future studies include investigation of additional SNPs and associated haplotypes in this group of genes as well as SNPs and haplotypes associated with genes coding for proteins that contribute to the maintenance of elastic fibers and composition of the extracellular matrix that are also excellent candidates for additional genetic factors that could contribute to this common blinding disease.

FOLLOW UP OF FIVE LINKAGE PEAKS FOR AUTISM IN EXTENDED UTAH KINDREDS. *K. Allen-Brady[1], N. Matsunami[2], J. Stevens[2], L. Baird[2], R. Robison[3], D. Cannon[3], J. Miller[3], T. Leppert[2], C. Pingree[3], M. F. Leppert[2], W. McMahon[3], H. Coon[3]* 1) Gen Epidemiology, Univ Utah, Salt Lake City, UT; 2) Human Genetics, Univ Utah, Salt Lake City, UT; 3) Psychiatry, Univ Utah, Salt Lake City, UT.

Autism is a complex, early-onset behavioral disorder characterized by impairments in social interactions and communication, and by repetitive and stereotyped behaviors and interests. Recent studies have revealed a highly complex genetic landscape for autism spectrum disorders, with many potential genes of varying and as yet unknown importance. Extended pedigree studies may play an important role in clarifying genetic findings. Our previous genome scan in a single six-generation extended Utah pedigree identified three linkage regions meeting criteria for genome-wide significance at 3q13.2-q13.31, 3q26.31-q27.3, and 20q11.21-q13.12. Two additional regions (7p14.1-p11.22 and 9p24.3) met criteria for suggestive significance. We have followed up these regions in our sample of 33 families with 125 affected subjects (total n=386). Evidence for linkage appears to be supported in this expanded set of families for the regions on chromosomes 20q11.2-q13.1 (maximum non-parametric score = 3.51, p=0.00023 at 64.8 cM) and 3q26-q27 (maximum non-parametric score = 3.77, p=0.000084, at 184.6 cM). Other regions showed less support in other kindreds, and may indicate susceptibility genes unique to the original pedigree.

A genome-wide quantitative association analysis of plasma homocysteine levels in schizophrenic patients. *S. de Jong[1], JW. Muntjewerff[2], M. Hoogendoorn[3], R. S. Kahn[3], R. A. Ophoff[1,4]* 1) Complex Genetics Section, DBG-Department of Medical Genetics, University Medical Centre, Utrecht, The Netherlands; 2) GGz Nijmegen, Mental Health Institute, Nijmegen, The Netherlands; 3) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Centre Utrecht, Utrecht, The Netherlands; 4) Rudolf Magnus Institute of Neuroscience, University Medical Centre Utrecht, The Netherlands.

In addition to being an independent risk marker for cardiovascular disease, increased plasma total homocysteine increased levels have also been related to Alzheimers disease and schizophrenia. It has been discovered that homocysteine elicits a DNA damage response in neurons. This suggests a mechanism by which homocysteine may contribute to the pathogenesis of neurodegenerative disorders. Many environmental factors such as low folate or cobalamine intake and genetic factors influence the homocysteine concentration in plasma. A common variant in the MTHFR gene has been clearly associated with elevated homocysteine levels and increased schizophrenia risk. Other genetic variants that modulate homocysteine levels are genes of interest to study in relation to the risk of schizophrenia. For this study, plasma homocysteine levels were determined in 70 schizophrenic patients. meeting DSM-IV criteria for schizophrenia. All subjects were unrelated and of Dutch Caucasian descent. Sample collection was carefully done in uniform conditions between subjects. Genome-wide SNP data was available for these subjects. A genome wide quantitative association analysis was performed using PLINK including haplotype analysis. Age and gender were taken as covariates and significance of results was determined using permutations and false discovery rate. Results reveal no significant genome wide association. However, considering a priori knowledge, the common variant in the MTHFR gene was also found to be significantly associated with homocysteine levels. Lager sample size and inclusion of a control group would increase statistical power to detect associated SNPs. Results of this study can help in unraveling the genetic regulation of homocysteine and the relationship with schizophrenia.

AML with multiple copies of unrearranged MLL gene: a distinct cytogenetic entity. *G. Sun[1], L. Montella[1], C. Barnabe[1], W. Henderson[1], J. Tripodi[1], H. Tamim[2], B. Saidman[3], R. Moser[4]* 1) Genzyme Genetics, New York, NY; 2) Atlanta Cancer Care, Decatur, GA; 3) Wyoming Valley Health Care Systems, Wilkes Barre, PA; 4) St. Francis Medical Center, Trenton, NJ.

The MLL gene at 11q23 is often involved in acute leukemias, mostly present as reciprocal translocations, as partial tandem duplication (PTD) in trisomy 11 or a normal karyotype, and also as double minutes (dmin) or homogenously staining region (hsr). There have been occasional case reports on unrearranged MLL gene in AML. We recently studied four such cases. We believe that this category of gene copy number alteration is not uncommon in AML, particularly in treatment-related AML and that it should bring our attention when analyzing the karyotypes that show normal chromosomes 11 and derivative chromosomes with unknown material attached. FISH is essential for confirmation. As MLL gene copy alteration plays a pivotal role in leukemogenesis and portends a poor clinical outcome, it is important to recognize this distinct cytogenetic entity in AML. Patient JR is a 63 year old female with ovarian cancer post chemotherapy before the diagnosis of AML M4. Cytogenetics showed der(15)t(11;15),der(22)t(11;22),der(13)t(11;13),der(22)t(11;22). Patient GJ is a 68 year old female diagnosed as AML M7 arising from an MPD/MDS, showing 2 unrelated clones: one with del(5)(q15q31)and another complex with der(14)t(11;14)x2,der(21)t(11;21). Patient JB is an 86 year old male diagnosed as AML M5b with a history of thrombocytopenia and suspected T-cell proliferative disorder. Cytogenetics revealed 2 unrelated abnormal clones: one with der(7)t(7;11)(q32;q21)x2 and another +8. Patient EC is a 97 year old female with a diagnosis of AML on peripheral blood (subtype unknown). Cytogenetics showed der(13)t(11;13). All MLL genes were intact without translocation or amplification using a break-apart probe (Vysis). Interestingly, three of the four patients showed segmental translocations to each of the acrocentric chromosomes with the same breakpoints q21 on chromosomes 11 and p13 on acrocentric chromosomes. The homologous DNA sequences in the breakpoints may play a role in mediating the translocations.

Genealogical relationships and genetic distance between two tone language-speaking native communities in the Mexican states of Oaxaca & Hidalgo. *A. Sanchez-Boiso[1], R. Peñaloza-Espinosa[2], R. Sánchez-Urbina[1], E. Castro-Sierra[3], RI. Ortiz-de Luna[1], L. Buentello-Malo[4], F. Salamanca-Gómez[2], R. Cerda-Flores[5], V. Morán-Barroso[1]* 1) Dept Genetics, Hosp Infantil Mexico Fed Gomez, Mexico City, Mexico; 2) UIMGH, Hospital de Pediatría CMNSXXI; 3) LPAFA, HIMFG; 4) IIA, UNAM; 5) Genética de Poblaciones y Bioinformática, CIBIN-IMSS.

Mexico has a diversity of native groups. There are relatively few mtDNA studies of native Mexican populations in regard to their mitochondrial haplogroup profiles associated to their linguistic characteristics. Relating to populations in the American continent, haplogroups A, B, C & D are the most frequently reported. In the present study, genetic distance between two tone language-speaking communities, Zapotec-speaking, Juchitán, Oaxaca, and Otomi-speaking, San Antonio el Grande, Hidalgo, is analyzed based on their genealogical relationship. Thirty-eight samples were studied in San Antonio el Grande, and 38 in Juchitán. DNA was isolated and PCR of Amerindian haplogroups carried out using either enzymatic restriction (haplogroups A, C & D) or polyacrylamide gel (haplogroup B) techniques. Finally, a main component statistical analysis was undertaken to determine similarities or differences between populations based on haplogroup frequency. Analysis of frequencies of the 4 haplogroups provided evidence of both San Antonio & Juchitán showing a greater frequency of haplogroups A and B and a lesser one of haplogroups C and D. In each population, there was a minority of individuals who did not possess the 4 Amerindian haplogroups studied. These frequencies were analyzed using Miller RxC method, employing 50,000 tests and confirming results with main component analysis (SPSS v15.0). Results obtained indicate that the population from San Antonio and the population from Juchitán apparently belonging to the same linguistic family, and notwithstanding the considerable geographic distance (ca. 500 mi.) separating either, with non-tone language-speaking groups inserted between them, share similar frequencies of the 4 haplogroups investigated.

Association Studies of 22 Candidate SNPs with Late-Onset Alzheimers Disease. *J. A. Figgins[1], R. L. Minster[1], F. Y. Demirci[1], S. T. DeKosky[2], M. I. Kamboh[1]* 1) Dept Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Neurology, Univ Pittsburgh, Pittsburgh, PA.

Alzheimers disease (AD) is a complex and multifactorial disease with the possible involvement of several genes. With the exception of the APOE gene as a susceptibility marker, no other genes have been shown consistently to be associated with late-onset AD (LOAD). A recent genome-wide association study of 17,343 gene-based putative functional single-nucleotide polymorphisms (SNPs) found 19 significant variants, including 3 linked to APOE, showing association with LOAD (Hum. Mol. Genet. 2007; 16:865-73). We set out to replicate the 16 new significant associations in a large case-control cohort of American Caucasians. Additionally, we examined six variants present in positional and/or biological candidate genes for AD. We genotyped the 22 SNPs in up to 1,009 Caucasian Americans with LOAD and 1,010 age-matched healthy Caucasian Americans, using 5' nuclease assays. We did not observe a statistically significant association between the SNPs and the risk of AD, either individually or stratified by APOE. However, one SNP on chromosome 17q13 revealed significant association with age-at-onset of AD ($p = 0.00196$) and two linked SNPs on chromosome 1q21 were associated with disease duration ($p = 0.006$; $p = 0.0014$). The association of studied variants with LOAD risk was not statistically significant in our sample, but may be relevant to some quantitative traits related to AD.

Gene expression response to hydrogen peroxide identifies possible new components of the response to reactive oxygen species. *K. A. Chapman[1], K. G. Ewens[2], R. S. Spielman[2]* 1) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Reactive oxygen species (ROS) are known to influence key cellular processes including cellular stress, apoptosis, and immunologic response, and are implicated in human diseases including Alzheimers disease, ischemia-reperfusion injury, and atherosclerosis. Our goal was to survey expressed genes for transcriptional response to ROS produced by hydrogen peroxide (H_2O_2). Lymphoblastoid cell lines (LCLs) from four HapMap individuals were treated with 9, 90, or 900 M H_2O_2, for 4, 12, 24, or 48 h. Controls were grown for the same periods without exposure to H_2O_2. The mRNA from the cells was pooled within each of the 4 doses x 4 durations, and expression profiles were obtained with the Affymetrix Human Gene 1.0 ST array. The gene expression fold change was then calculated for each treatment. The largest number of transcripts (88) with expression responses greater than 3-fold was found in the LCLs treated with 900 M for 4 hours, so we restricted further analysis to this group.

We found strong expression changes in several genes previously known to respond to ROS. For example, three genes responsive to p53 were activated: GDF15 (fold change compared to untreated: 4.7), CDKN1A (3.1), and PPM1D (3.5). Other examples are the ROS-responsive gene, HMOX1 (2.9) and apoptosis related G-protein coupled receptor GPR109B (PUMA-G, 6.0). In addition, we identified several gene families that have not been previously characterized as components of the ROS response. These include the small RNAs SCARNA9 (6.3 fold change) and SNORD 116-6 (5.02), the miRNA regulator DND1 (4.34), and the zinc finger binding protein ZNRD1 (4.10). Thus our approach allows further studies on previously known genes, and also identifies new ROS-responsive genes, which will expand the understanding of the biological effects of ROS exposure.

Array comparative genomic hybridization detects genomic imbalances in samples from stillborn infants. *G. Raca[1,2], A. Artzer[4], L. Thorson[4], J. Shu[1], S. Huber[1], J. S. Laffin[1], P. Modaff[3], R. M. Pauli[3]* 1) UW Cytogenetic Services, State Laboratory of Hygiene, Madison, WI; 2) Department of Pathology, UW-Madison; 3) Wisconsin Stillbirth Service Program (WiSSP), Clinical Genetics Center, UW-Madison; 4) Department of Medical Genetics, UW-Madison.

Current testing methodologies fail to explain late pregnancy loss (stillbirth) in up to 60% of cases, resulting in inaccurate recurrence risk assessment and limited clinical management in subsequent pregnancies. Array comparative genomic hybridization (aCGH) has been successfully applied to samples from early pregnancy loss, but has rarely been used in evaluation of stillbirth. We hypothesized that aCGH could establish etiologic diagnosis in a much higher proportion of stillborn infants than could classic cytogenetics, by detecting both gross and submicroscopic deletions and duplications, and by not requiring viable tissue for growth in vitro. We analyzed 15 frozen tissue samples from stillborns with multiple congenital anomalies, obtained through the Wisconsin Stillbirth Service Program (WiSSP). For all 15 samples results of classic cytogenetic analysis were either normal or unobtainable. Samples were tested in a blinded fashion using commercially available 1Mb BAC Arrays (PerkinElmer). aCGH detected two abnormalities, trisomy 21 and an unbalanced translocation between chromosomes 3 and 10. With the detection rate of more than 13%, our preliminary results support the clinical value of aCGH testing in stillbirth. The information about each of the two detected abnormalities would have been helpful in counseling of the parents, had it been available at the time of pregnancy loss. aCGH analysis should be considered instead of or in addition to karyotyping for routine diagnostic evaluation of late intrauterine death. aCGH could also be a valuable research tool to 1) examine the etiologic role of submicroscopic deletions and duplications in intrauterine death, 2) identify critical regions and candidate genes for specific developmental anomalies present in tested stillborns, and 3) identify candidate chromosomal regions that are critically involved in survival through late gestation.

Expectations for Research Result Disclosure: A Qualitative Analysis of Public Opinion Regarding a Proposed National Biobank. *J. Murphy[1], J. Scott[1], D. Kaufman[1], G. Geller[2], L. LeRoy[3], K. Hudson[1]* 1) Genetics & Public Policy Ctr, Johns Hospkins Univ, Washington, DC; 2) Johns Hopkins University, Baltimore, MD; 3) Abt Associates, Cambridge, MA.

Introduction: The National Institutes of Health and other federal health agencies are considering establishing a national biobank to study of the roles of genes and environment in human health. A pilot public engagement study was conducted to assess public attitudes and concerns about the proposed biobank, including the expectations for return of individual research results. Methods: A total of 141 adults of different ages, incomes, genders, ethnicities, and races participated in 16 focus groups in six locations across the country. Focus group members were queried about their views and preferences relating to return of five different types of research results: (1) identification of a gene variant that increases the risk for asthma (treatable condition), (2) identification of an environmental factor that increases risk for asthma (environmental factor), (3) identification of a gene variant that increases risk for Alzheimer disease (untreatable condition), (4) identification of a gene variant with a higher prevalence in a racial or ethnic group, and (5) identification of a gene variant of unknown significance. Results: Focus groups participants voiced a strong desire to be able to access individual research results, regardless whether or not an intervention was available. Recognizing the wide range of possible research results from a large cohort study, they repeatedly and spontaneously suggested that cohort study participants be given on-going choices, often using Internet analogies such as setting preferences or filters. Conclusion: Our focus group analysis indicates that access to individual research results was viewed as a valuable incentive for participating in the proposed biobank. The project described was supported by Grant Number U01HG004206 from the National Human Genome Research Institute.

Prenatal diagnosis of anophthalmia/microphthalmia by ultrasound: Recommendations for further testing and counseling. *A. Schneider, T. Bardakjian* Dept Genetics, Albert Einstein Medical Ctr, Philadelphia, PA.

Anophthalmia and Microphthalmia (referred to as A/M) may involve one or both eyes, and may occur as an isolated birth defect or with other anomalies (part of a syndrome). A/M is heterogeneous and rare with an incidence of about 1 in 10,000. Ultrasound diagnosis of anophthalmia/microphthalmia is possible in the second trimester, usually 20 weeks gestation or after. Transvaginal ultrasound can detect A/M as early as 14 weeks. There is a paucity of information in the medical literature regarding further work-up and management of a fetus diagnosed with A/M. The A/M registry at Albert Einstein Medical Center has been collecting clinical data in a registry for the past 13 years and facilitates eye development gene research for those affected with A/M. Based on the experience and data analysis of over 300 cases of A/M, recommendations for the work-up of prenatally diagnosed A/M will be discussed. Newer eye development genes like SOX2 are now known to be the etiology of A/M in 15-20% of cases of bilateral A/M and a smaller percentage of unilateral A/M. From the registry data, about 11% of cases of A/M are due to chromosome abnormalities. A systematic review of tiers of testing including cytogenetic, molecular and additional ultrasound examinations will be discussed. Outcomes based on registry data can be used as an additional tool to help counsel families about this rare disorder.

***Creld1* mutations increase susceptibility to congenital heart defects in Down syndrome.** *S. M. Cherry[1], G. T. Fouad[2], C. L. Maslen[2], R. H. Reeves[1]* 1) Physiology, Johns Hopkins University, Baltimore, MD; 2) Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR.

Down syndrome (DS) affects approximately 1 in 700 newborns and comprises a broad range of phenotypes, including congenital heart defects (CHD). Approximately 20% of DS individuals have an atrioventricular septal defect (AVSD), an incidence that is 2000-fold higher than in the general population. Dosage imbalance for chromosome 21 clearly contributes to heart defects in DS, but other genetic or environmental factors must contribute as well.

A recent study identified polymorphisms in the *CRELD1* locus that are associated with AVSD in individuals with DS (Maslen *et al*., 2006). To establish a biological basis for this interaction, we have initiated studies of CHD in animal models of Down syndrome. First, mouse gene-targeting was used to create a null allele of *Creld1* (*Creld1*$^{-}$); homozygous *Creld1*$^{-/-}$ die by embryonic day 12.5 and exhibit abnormal heart development. *Creld1*$^{+/-}$ mice, however, appear phenotypically normal, indicating that loss of a single allele does not cause heart defects. We then introduced the *Creld1* null allele into Ts65Dn mice, which have segmental trisomy for chromosome 16, representing nearly half of the human chromosome 21 orthologs. About 15% of newborn Ts65Dn have defects of the outflow tract, with occasional errors in development of the secondary atrial septum; overall CHD is less severe than in humans. Initial data indicate that more than 50% of mice that are both trisomic and heterozygous for the *Creld1* mutation (Ts65Dn, *Creld1*$^{+/-}$) display septal defects at birth, including both ASD and VSD. These data support the hypothesis that *Creld1* acts as a modifier of CHD in individuals with DS. We are currently crossing this mutation into mice with smaller segmental trisomies to localize the orthologous region of chromosome 21 responsible for this interaction.

On the replication of genetic associations: Timing can be everything! *J. Lasky-Su[1], H. Lyons[2], V. Emilsson[3], I. Heid[4,8], C. Molony[3], B. Raby[1], E. Silverman[1], D. Levy[5], M. McQueen[6], N. Laird[7], C. Papoutsakis[11], G. Dedoussis[11], C. O'Donnell[5], H. Wichmann[4,8], J. Celedon[1], E. Schadt[3], J. Hirschhorn[2,9], S. Weiss[1], K. Stefansson[10], C. Lange[1,7]* 1) Channing Laboratories, Dept Med, Brigham & Womens Hosp, Boston, MA; 2) Divisions of Genetics and Endocrinology, Program in Genomics, Childrens Hospital, Boston, MA; 3) Rosetta Inpharmatics, LLC, a wholly owned subsidiary of Merck & Co., Inc., Seattle, WA; 4) GSF-National Research Centre for Environment and Health, Institute of Epidemiology, Neuherberg, Germany; 5) National Heart, Lung, and Blood Institute and its Framingham Heart Study, Framingham, MA; 6) University of Colorado at Boulder, Boulder, CO; 7) Harvard School of Public Health, Boston, MA; 8) Institute of Medical Informatics, Biometry, and Epidemiology, Ludwig-Maximilians-University, Munich, Germany; 9) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 10) deCode Genetics, Inc., IS-101 Reykjavik, Iceland; 11) Department of Nutrition and Dietetics, Harokopio University, Athens 17671, Greece.

The failure to replicate genetic association findings is most commonly believed to be attributable to insufficient statistical power, population stratification, heterogeneity or environmental influences. Another potential cause for non-replications is a genetic effect that varies by age. If not taken into account during the design and the analysis of the study, age-varying genetic associations can be the reason for non-replication. Using the 100K SNP scan of the Framingham Heart Study (FHS), we identify an age-varying association between a SNP in ROBO1 and obesity. Based on these data, we hypothesized that there is an age-gene interaction. This finding was followed-up in 8 independent samples comprised of 13,584 individuals. The association replicates in 5 of the 8 studies, showing an age-dependent relationship ($p = 3.92 \times 10^{-9}$). This study illustrates that if the specifics of age-varying genetic effects are not considered in the selection of both the follow-up samples and in the statistical analysis, important genetic associations may be missed.

Novel REEP1 isoforms and their impact on subcellular localization and genetic testing. *S. Zuchner[1], J. Huang[1], T. Deconinck[2,3], J. Price[1], M. Pericak-Vance[1], G. Wang[1], P. de Jonghe[2,3], G. Montenegro[1]* 1) Human Genomics, Miami Institute for Human Genomics, University of , Miami, FL; 2) Molecular Genetics Department, Flanders Interuniversity Institute of Biotechnology, University of Antwerp, Antwerp, Belgium; 3) Division of Neurology, University Hospital Antwerpen, Antwerpen, Belgium.

Background: Recently we have shown that mutations in REEP1 cause hereditary spastic paraplegia (HSP) type 31. REEP1 is now considered the third most common HSP gene and genetic testing is frequently carried out according to the reported gene annotation. REEP1 is a protein of unknown function, but we have shown in-vitro its mitochondrial localization. Methods: We performed extensive cDNA studies, including exon walking, RACE-PCR, and studying intragenic conserved non-coding elements. Sequencing analysis was carried-out at a large sample of HSP index patients. In-vitro experiments were performed at transiently transfected cell lines. Results: We further studied the genetic structure of REEP1 and identified additional exons and alternative isoforms. In screening a large collection of HSP patients we identified a novel mutation in one of the new REEP1 exons. Interestingly, at least one new isoform is missing the mitochondrial targeting signal at the N-terminal end of REEP1. In cell culture experiment we are evaluating the subcellular localization of the main REEP1 isoforms. Discussion: The identification of additional coding exons inREEP1 has important consequences for genetic testing in SPG31. Future genetic tests should include these novel coding exons. The subcellular localization of REEP1 could be significantly different in the expressed isoforms. How this relates to the pathology of SPG31 will be an important part of future functional studies.

Nuclear APC in DNA repair. *M. Zeineldin, J. Cunningham, KL. Neufeld* Molec Bioscience, Univ Kansas, Lawrence, KS.

Mutation of the Adenomatous polyposis coli gene (Apc) is an early step in progression of about 80% of colorectal cancers. The product of the Apc gene, APC, is a large protein implicated in many cellular functions including cellular proliferation, migration, adhesion, and chromosome segregation. APC shuttles between the cytoplasm and nucleus using several nuclear localization signals (NLS) and nuclear export sequences (NES). Our lab has a long standing interest in nuclear functions of APC. To facilitate our studies, we have developed mice that are defective in nuclear import of APC because of mutations in two nuclear localization signals in APC [APC(mNLS)]. Others have suggested that APC participates in long-patch base excision repair (LP-BER). In the nucleus, oxidation, reduction or alkylation of DNA leads to modified bases which are repaired using BER. Using our mouse model as well as cultured colon cell lines, we have further explored the potential role of nuclear APC in DNA repair and examined the regulatory mechanisms that control APC stability. We will provide evidence that APC(mNLS) mouse embryonic fibroblasts (MEFs) have a reduced ability to repair DNA damaged by alkylating agents compared to MEFs with wild-type APC. In addition, we have evidence to suggest that hsp70 participates in stabilization of APC by preventing it from being degraded through the ubiquitin-proteasome pathway.

Genetic ancestry and risk of breast cancer among US Latinas. *L. Fejerman[1], E. M. John[2], S. Huntsman[1], K. Beckman[3], S. Choudhry[1], E. Perez-Stable[1], E. Gonzalez Burchard[1], E. Ziv[1]* 1) Dept Med, Univ California, San Francisco, CA; 2) Northern California Cancer Center, Fremont, CA; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Background: US Latinas have a lower incidence of breast cancer compared to non-Latina White women. This difference is partially explained by differences in the prevalence of known risk factors. Genetic factors may also contribute to this difference in incidence. Latinas are an admixed population with most of their genetic ancestry from Europeans and Indigenous Americans. We used genetic markers to estimate the ancestry of Latina breast cancer cases and controls and assessed the association with genetic ancestry, adjusting for reproductive and other risk factors. Methods: We typed a set of 106 ancestry informative markers (AIMs) in 440 Latina women with breast cancer and 597 Latina controls from the San Francisco (SF) Bay area and estimated genetic ancestry using a maximum likelihood method. Odds ratios (OR) and 95% confidence intervals (CI) were estimated using logistic regression with known risk factors included as covariates. Results: Higher European ancestry was associated with increased breast cancer risk (OR=4.17; 95% CI: 2.13-8.17, p0.001). When known risk factors and place of birth were adjusted for, the association with European ancestry was attenuated but remained statistically significant (OR=2.58; 95% CI: 1.22-5.45, p=0.013). Conclusions: Among Latinas in the SF Bay Area, women with higher European ancestry are at higher risk for breast cancer, even after adjustment for known risk factors. Further work is needed to determine if the association is due to genetic differences between populations or possibly due to environmental factors not measured.

Effect of an educational consent video on family study research participants' preferences for future use of DNA.

S. Lewis[1], K. Spates[1], G. D. Hughley[2], C. Burant[3], P. M. Marshall[2], G. L. Wiesner[1,4] 1) Dept Genetics, Case Western Reserve University, Cleveland, OH; 2) Dept Bioethics, Case Western Reserve University, Cleveland, OH; 3) Frances Payne Bolton School of Nursing, Case Western Reserve University, Cleveland, OH; 4) Center for Human Genetics, University Hospitals Case Medical Center, Cleveland, OH.

Genetic researchers and public health officials working to establish large human DNA repositories for long-range health research struggle with privacy issues related to sharing of DNA when possible future research directions are unknown. Access to DNA samples from repositories can improve genetic research efficiency by reducing the need for re-collection of samples. However, to protect autonomy and privacy of research participants, guidelines for informed consent may ask that participants indicate their preference for future use of DNA. We previously reported on future use preferences of 2226 genetic study participants in which 49% chose UNRESTRICTED future use if identifiers were removed; 46% chose RECONTACT before allowing use; and 4% chose NO FUTURE USE. To assess the effect of the consent process on choices we examined preferences among a sub-group of 240 African American participants recruited as part of a multi-center study of informed consent. Participants were randomized to view either a 10-minute "educational" or "placebo" video during the informed consent process. In the educational arm, 117 participants viewed a potential participant and recruiter engaged in an informed consent conversation. In the placebo arm, 123 participants viewed nature footage. Surprisingly, significant differences in preferences for future use between the two groups were found (p=.007), with those who viewed the educational video (17%) less likely to choose unrestricted future use than those who viewed the placebo video (35%). Differences persisted when controlling for demographic factors. Understanding the impact of viewing an educational video on preferences for future use of DNA may help researchers design tools to inform and educate participants about open ended uses of DNA collections and data sets in genetic studies.

PREIMPLANTATION HLA TYPING FOR STEM CELL THERAPY OF GENETIC DISORDERS. *A. Kuliev, S. Rechitsky, T. Sharapova, I. Barsky, O. Verlinsky, I. Tur-Kaspa, Y. Verlinsky* Reproductive Genetics Institute, Chicago, IL.

Preimplantation HLA typing is part of our preimplantation genetic diagnosis (PGD) program for single gene disorders, which has presently been performed for 178 different genetic conditions in 1462 cases, yielding the birth of 500 unaffected children. Preimplantation HLA typing allows the stem cell treatment of affected siblings for whom no other treatment is available. This was applied not only together with PGD, but also for sole purpose of the pre-selection of the HLA matched embryos, which become of special value with progress in stem cell transplantation treatment of an increasing number of severe congenital and acquired bone marrow disorders. Overall we performed preimplantation HLA typing in 242 cases, representing the worlds largest series, yielding birth of 37 healthy HLA matched babies. A total of 153 cases were performed in combination with PGD for different genetic disorders (thalassemia, sickle cell disease, Fanconi anemia (FA), Wiscott-Aldrich syndrome (WAS), X-linked adrenoleukodystrophy (X-ALD), X-linked hyper hyperimmunobulin M syndrome (HYGM), X-linked hypohidrotic ectodermal displasia with immune deficiency (HED-ID), Krabbe disease and inherited form of Diamond-Blackfan anemia (DBA), involving the pre-selection of unaffected children who were also HLA identical to the affected sibling. Successful stem cell transplantation treatment with the use of stem cells obtained from PGD children has been achieved in more than a dozen patients with genetic and acquired diseases, including thalassemia, FA, DBA, X-linked HYGM and HED-ID.

Cytogenetic studies of meiotic recombination in human females. *T. Hassold[1], T. Naluai-Cecchini[2], S. Cherry[1], T. Hansen[1], K. W. Broman[3], E. Cheng[2]* 1) Sch Molecular Biosci, Washington State Univ, Pullman, WA; 2) Dept Ob/Gyn, University of Washington, Seattle, WA; 3) Department of Biostatistics and Medical Informatics, University of Wisconsin-Madison, Madison, WI.

Until recently, almost all studies of meiotic recombination in humans have been based on genetic linkage analyses. However, the application of immunofluorescence methodology now allows us to directly visualize meiotic exchanges; i.e., by analyzing cross-over associated proteins (e.g., MLH1) in pachytene stage spermatocytes and oocytes, we can determine the number and distribution of exchanges in individual gametes. Utilizing this approach, several groups have now initiated studies of human female meiosis, but in most of these the focus has been on meiotic process, and not specifically on recombination. Thus, we recently initiated studies of a series of human fetal ovarian samples, aimed at evaluating the utility of MLH1 as a marker of crossing-over in females and asking whether chromosomes without cross-overs and sub-optimal cross-over patterns - situations thought to predispose to human nondisjunction -- are, indeed, a feature of human female meiosis. In this report we summarize results on an initial series of 411 prophase oocytes from 12 fetal ovarian samples. Our results indicate that MLH1 foci are a useful marker of cross-overs in females as well as males and that, as in males, there is significant among-individual variation in the levels of recombination. However, we also identified important temporal differences between human males and females in the way in which MLH1 loads onto the synaptonemal complex, demonstrating sex-specific variation in the control of the recombination pathway. In analyses of non-disjunction prone chromosomes, we identified a high proportion of exchangeless chromosomes 21 and 22, as well as an increased proportion of distal exchanges on chromosome 16. These observations are consistent with linkage analyses of human trisomies, confirming assumptions of the role of recombination in predisposing to human nondisjunction.

Gender differences in UGT2B17 expression and activity. *C. J. Gallagher, R. M. Balliet, J. E. Muscat, P. Lazarus*
Departments of Pharmacology and Public Health Sciences, Penn State College of Medicine, Hershey, PA.

UGT2B17 is a phase II metabolizing enzyme involved in the glucuronidation of androgens as well as exogenous compounds including the tobacco carcinogen 4 (methylnitrosamino) 1 (3 pyridyl) 1 butanol (NNAL) and cancer treatment drugs including suberoylanilide-hydroxamic-acid (SAHA). UGT2B17 is expressed in many tissues including liver, lung, and prostate and is down-regulated by androgens in prostate tissue. Due to the fact that this gene metabolizes and is regulated by androgens, we hypothesized that there may be gender differences in the expression and activity of this gene. We performed reverse-transcription PCR on 77 human liver RNA samples and assayed the expression of UGT2B17 cDNA using real-time PCR. We then assayed microsomes from these same human liver samples (HLMs) for activity against NNAL and SAHA using ultra-performance liquid chromatography (UPLC). We demonstrated that liver specimens from men exhibited an 8-fold higher expression of UGT2B17 mRNA than women (P-value < 0.001). In addition, HLMs from men exhibit a 2-fold higher glucuronidation activity against NNAL (P-value < 0.02) and a 2-fold higher glucuronidation activity against SAHA (P-value = 0.001). When stratifying this data by the genotype of the UGT2B17 gene deletion polymorphism, similar patterns were observed for glucuronidation of both substrates, with individuals with less than two copies of the UGT2B17 gene exhibiting less glucuronidation activity than individuals who have 2 copies of the UGT2B17 gene for both men and women. These data are consistent with a hormonal regulatory mechanism for UGT2B17 in humans and suggest that glucuronidation activities, at least for UGT2B17, may differ with gender. Women who smoke a comparable level of cigarettes have been shown to be at greater risk for lung cancer than men, this could be in part due to lower UGT2B17 expression and lower NNAL detoxification in women. This data may also have pharmacological implications in the dose of cancer therapy drugs (such as SAHA) given to men and women.

Human Embryonic Stem Cell Lines with Genetic and Chromosomal Disorders. *Y. Verlinsky, N. Strelchenko, V. Kukharenko, A. Sckumatov, S. Rechitsky, O. Verlinsky, A. Kuliev* Reproductive Genetic Inst, Chicago, IL.

Human embryonic stem cell (hESC) lines with abnormal genotypes provide an unlimited source for analysing the primary mechanisms of congenital disorders, and the development of the methods for cellular therapy. Based on our ongoing preimplantation genetic diagnosis (PGD) program, which currently includes more than 7000 PGD cases, we have developed the genetic disease specific hESC line repository, consisting of a total of 58 genetically abnormal lines. It contains eleven hESC lines with chromosomal abnormalities, including four translocations, two trisomies, two triploidies and three sex chromosomal aneuploidies, and 47 with different single gene disorders, thirteen obtained from the embryos with autosomal recessive, twelve X-linked and twenty two autosomal dominant disorders, the latter including hESC lines with dynamic mutations and those with genetic predisposition to cancer. The resulting collection represents the worlds first hESC line bank with genetic disorders, currently available for stem cell research of genetic disorders (www.stemride.com).

Combined Genome-wide Linkage and Association Analysis of extended Utah prostate cancer pedigrees identifies significance at 8q12. *GB. Christensen, J. Farnham, NJ. Camp, LA. Cannon-Albright* Dept Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT.

We performed genome-wide linkage and case/control association studies in 27 prostate cancer cases from 2 extended, informative, high-risk Utah pedigrees. All relationships between cases within pedigrees were more distant than first degree. Genotyping was performed with the Illumina 550k SNP set, after exclusion of 58,000 markers failing quality control. For controls, we selected caucasians from the Illumina Icontrol data set (n=1,579), also genotyped for the 550k SNPs. Our initial screen for association included naive Fishers Exact Test, ignoring the familial relationships between cases, under three models: dominant, recessive, and an allele test. 54 distinct markers were selected for secondary screening with a significance cut off of p $1e^{-5}$. Secondary screening was performed using Genie software, which included known relationships between cases. In the secondary screen 1 marker reached the genome-wide significance threshold of p $3.4e^{-7}$. This marker was on chromosome arm 8q12 (p=$1e^{-7}$). In addition to providing the best overall GW association evidence, 5 of the top 8 associations from the secondary screening were also at 8q12; 9 SNPs in a 217kb region at chromosome 8q12 passed stage 1 screening. Other regions with markers reaching p $3e^{-6}$ included: 4 other markers at 8q12, 4p13, 2p25, 7p21, 17q22, and 21q21. We also performed linkage analysis in the 2 pedigrees. We selected a set of 27,157 SNPs from the Illumina 550k set, with no evidence of LD, and used the Smith (1996) inheritance model. Two regions showed suggestive evidence of linkage; chromosome arm 2p (hetLOD=2.44) and chromosome arm 8q12-q21 (max hetLod = 2.28). The SNPs showing significant evidence for association were in chr 8q12. This small study shows the power and synergistic utility of using both linkage and association analysis in high risk pedigrees. The 8q12 region identified as significant for prostate cancer predisposition has not been previously reported for linkage or association, but is recognized for LOH.

Dosage changes in both nuclear and mitochondrial genomes in autism spectrum disorders. *M. Smith, P. L. Flodman, C. Devine, M. A. Spence* Dept Pediatrics, Univ California, Irvine, Irvine, CA.

Lymphoblastoid DNA samples from 10 autism families, (8 triads and 2 with twins), were studied using the Affymetrix 6.0 SNP chip. Data were analyzed to identify in probands, de novo copy number changes in unique sequence DNA that did not overlap with known polymorphic copy number changes. The average number of such changes per proband was 11.5, range 1-58; roughly half were within genes. The number of variants was inversely correlated with proband IQ score. Genomic instability may be present in subject AU44-201 with 58 changes. He has a 559kb deletion on 18p11.2 that encompasses gene SMCDH1 (structural maintenance of chromosomes 1). Subject AU28-202 has 17 de novo unique sequence copy number changes. She is hemizygous for the NEIL1 gene, a glycosylase that repairs oxidation induced DNA damage. The variants found in our sample were not present in 30 triads in the HapMap data. The MZ twins in family AU 80 were identical for 99.8 percent of SNPs. However, they showed marked differences in the number of de novo unique sequence copy number changes; 14 in AU80-202 and 3 in AU80-203. Phenotypes differ markedly in the two, twin AU80-202 is much more severely affected. Three autism affected subjects from 3 different families showed duplication of a unique sequence segment on chromosome 19 that included genes GLTSCR2, EHD2, HBII 115 and SEPW. In subject AU44-201 the duplication extended further and included the GLTSCR1 gene. GLTSCR1 and 2 are brain expressed genes. We also identified unique sequence de novo copy changes within genes associated with autism in other studies. These genes included Glutamate receptor 6, (GRIK2) 6q16.3, CNTNAP2 on chromosome 7q35 and NLGN1 on 3q26.31. Variants in PCDH11X occurred in males in three families. It is possible that these variants may represent polymorphisms in PCDH11Y. Hybridization intensity was assessed for SNPs between 410 and 16,141 bases of the mitochondrial DNA sequence. In 8 of 11 autistic probands (3-18 years) there was reduced hybridization intensity within the 9.6-13.7 kb region, indicative of deletions of variable length. Decreased hybridization intensity in this region was also noted in 7 of 90 HapMap samples.

MLL PARTIAL TANDEM DUPLICATIONS ARE PRESENT IN CORD BLOOD SAMPLES. *D. Mercer[1], X. Hu[1], M. M. Li[1,2]* 1) Human Genetics Program, Tulane Univ Medical Sch, New Orleans, LA; 2) Department of Pediatrics; Tulane Univ Medical Sch, New Orleans, LA.

Leukemia-associated genetic alterations play important roles in leukemogenesis. They also serve as biological markers in the diagnosis, prognosis, treatment, and follow-up of hematopoietic malignancies. Specifically, partial tandem duplications (PTDs) of the MLL (mixed lineage leukemia) gene are strongly associated with AML (acute myeloid leukemia) and confer a poor prognosis to patients harboring them. We previously reported on the presence of MLL PTDs in the peripheral blood of healthy individuals and in prenatal samples when evaluated with nested RT-PCR. Upon confirming that these aberrations arise early in human development through cultured amniocytes and chorionic villi, we further sought to search for their presence in cord blood samples. We obtained 53 umbilical cord blood samples from newborns and performed nested RT-PCR to detect MLL PTDs. Forty of the 53 samples showed at least one MLL PTD (75%). Sequencing showed the most common exon fusions were 9/3 (20 samples), 10/3 (11 samples), and 11/3 (7 samples). In addition, we performed antibody staining and flow cytometry on a subset of cord blood samples and 2 known positive peripheral blood samples. Each of these blood samples were stained with CD2, CD7, and CD14 antibodies, then subjected to flow cytometry. Nested RT-PCR for MLL PTDs was repeated on each subfraction, which demonstrated presence of MLL PTDs in lymphoid subfractions and absence of MLL PTDs in myeloid subfractions. However, this may be due to poor myeloid cell recovery. The incidence of MLL PTDs in cord bloods was intermediate of that found in prenatal samples (100%) and peripheral bloods (49%), suggesting that the genetic abnormality occurs during cell division. Since MLL PTDs have been shown to be present throughout life in healthy individuals, other factors must be necessary to lead to malignant transformation. We suspect that one of these factors may be the cell lineage in which the alteration originates. A greater number of samples for flow cytometry are needed before this can be confirmed.

Motivators for participation in a whole genome sequencing study: The ClinSeq experience. *F. M. Facio, B. B. Biesecker, S. Brooks, J. Loewenstein, L. G. Biesecker* Natl Human Genome Res Inst, NIH, Bethesda, MD.

Introduction: ClinSeq is a pilot study to investigate and develop large-scale medical sequencing (LSMS) and whole genome sequencing (WGS) for clinical research. A distinctive aspect of ClinSeq is that subjects can choose to receive individual genotype results. Existing literature shows that altruism, benefits to self, and benefits to family are major motivators for research participation. ClinSeq provides a novel setting to examine motivators for participation in the context of LSMS/WGS. The purpose of this qualitative study was to explore the reasons individuals participate in a LSMS/WGS study. Methods: 337 individuals (age 45 to 65), who enrolled in ClinSeq between January 2007 and May 2008, were asked an open-ended question about their reasons for participating in the study and their demographics. Responses were imported into NVIVO 7 for coding and analysis. The sample size provided data saturation. The primary coder coded all 313 responses. The secondary coder coded 25% of the responses. Inter-coder reliability was 95.4%. Results: Of 337 enrollees, 313 (93%) provided responses. The majority were White (89%), highly educated (85%), and of high socio-economic status (66%). Two main themes were identified: altruism and seeking health information for oneself, with each theme arising from distinct groups. Conclusion: Our results show that ClinSeq subjects share motivations with both general research participants, as well as with those who come forth for genetic studies. Although personal health benefits is a more salient theme among disease cohorts than among healthy volunteers, many of our volunteers cited this as a motivator. Investigation of our subjects health related attributes will reveal how their background parallels this finding. To our knowledge this is the first cohort to undergo LSMS/WGS with the option of receiving individual genotype results, which provides a unique opportunity to study the theme of benefits to self in the context of personalized genomics research. We will discuss the implications of our results for future translational genomics research and describe follow-up studies to explore preferences towards LSMS/WGS.

Genome-wide Case Control Association Study for Familial Melanoma identifies 2 significant associations. *J. Farnham[1], SA. Leachman[2], NJ. Camp[1], LA. Cannon-Albright[1]* 1) Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT; 2) Dermatology Department, University of Utah School of Medicine, Salt Lake City, UT.

We performed a genome-wide case control association study in 87 melanoma cases from 21 informative, high-risk Utah pedigrees. All relationships within pedigrees were more distant than first degree. Genotyping was performed with the Illumina 550k SNP set, after exclusion of 58,000 markers failing quality control and 14,000 markers on the X chromosome (not analyzed). For controls, we selected caucasians from the Illumina Icontrol data set (n=1,579); all were genotyped for the 550k SNPs. Our initial screen for association included naive Fishers Exact Test, ignoring the familial relationships between cases, under three models: dominant, recessive, and an allele test. 49 distinct markers were selected for secondary screening that surpassed a significance threshold of p $1e^{-5}$. Secondary screening was performed using Genie software, which accounts for the known relationships between cases. In the secondary screen 3 markers in 2 regions reached the genomewide significance threshold of p $3.4e^{-7}$. The most significant marker was on chromosome arm 6q22 ($p=5e^{-8}$). The 2 other markers were both on chromosome arm 16p13, located in A2BP1/FOX1 ($p = 2e^{-7}$ for each). A2BP1, ataxin-2 binding protein-1 (A2BP1) gene, also called FOX1. Other regions with markers reaching p $5e^{-6}$ included: chromosome arms 2q12, 2q24, 2q32, 8p23, 12p13, 17p11, 18q22, and 20q13 (20Mb from the recently reported association at 20q11). This study represents the first complete genome wide association study reported for familial melanoma. This study shows the power and utility of association analysis in related cases from high-risk pedigrees. Two significant regions of association were identified, neither of which has been previously reported.

Genetic Admixture, Preterm Delivery and Related Traits among African American Mothers. *H. J. Tsai[1, 2], Y. Yu[1, 2], S. Zhang[1, 2], C. Pearson[3], K. Ortiz[3], X. Xu[4], H. Bauchner[3], B. Zuckerman[3], X. Wang[1, 2]* 1) Mary Ann and J. Milburn Smith Child Health Research Program, Childrens Memorial Hospital and Children's Memorial Research Center, Chicago, IL; 2) Dept Pediatrics, Northwestern Univ Sch Med, Chicago, IL; 3) Department of Pediatrics, Boston University School of Medicine and Boston Medical Center, Boston, MA; 4) Center for Population Genetics, University of Illinois at Chicago School of Public Health, Chicago, IL.

In the U.S., the rate of preterm delivery (PTD) is significantly higher in African Americans (17.8%) than non-Hispanic whites (11.5%). Such disparity cannot be fully explained by differences in socio-environmental factors. In this study, we used 57 ancestry informative markers (AIMs) to estimate genetic ancestry in 812 mothers enrolled in a case-control PTD study at Boston Medical Center who self-reported their ethnicity as black. We first estimated ancestral proportion among African American mothers using AIMs. Second, we investigated the association of genetic ancestry with PTD and related traits. Finally, we examined the potential population stratification confounding in this case-control PTD study. The estimated average African ancestral proportion was 0.900.13 in this sample. We found significant associations of ancestral proportion with PTD as a whole and PTD subgrouped by the presence of maternal hypertensive disorders. In addition, marginal associations were found with spontaneous PTD, medically induced PTD and very PTD. We did not observe significant confounding due to population stratification in this case-control PTD study. In summary, African ancestral background was significantly associated with an increased risk of PTD as a whole and within certain preterm subgroups. Our data underscore the need for more intensive investigation of genetic admixture in African Americans such as genome-wide admixture mapping to identify novel susceptibility genes of PTD.

Kernel Based Adaptive Cluster (KBAC): A Powerful Method to Detect Associations for Complex Traits due to Rare Variants in the Presence of Gene x Gene and Gene x Environment Interactions. *D. J. Liu[1,2], S. M. Leal[2]* 1) Department of Statistics, Rice University, Houston, TX 77005; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77025.

Common diseases can be due to multiple functional variants with allele frequencies ranging from rare to common. Both gene x gene and genes x environment interactions can play a role in disease susceptibility. Although whole genome association studies using tagSNPs are a powerful approach for detecting common variants, they are underpowered to detect associations with rare variants due to indirect mapping. The development of cost-effective sequencing technologies enables the detection of rare variants for use in association studies. Although methods used for the analysis of common variants are applicable to sequence data, their performance is poor for analyzing rare variants and their power may be further reduced in the presence of interactions. We developed a novel method, *Kernel Based Adaptive Cluster* (KBAC) to carry out direct association studies of rare variant data. This method can be used for gene mapping with or without the presence of gene x gene and gene x environmental interactions. Significance for the KBAC method can either be determined empirically through permutation or using the derived asymptotic distribution when the sample size is sufficiently large. It is demonstrated through extensive simulations motivated by real data (e.g. Hirschsprungs Disease, Breast Cancer) that the KBAC method has superior performance than univariate and multivariate tests for detecting associations with or without interactions. The KBAC method is powerful and robust even in the presence of misclassification error where either non-causal variants are included in or casual variants are excluded from the analysis. The KBAC method can be applied to the analysis of sequence data from either whole genomes or candidate genes.

Harnessing Nature's Powerful DNA Sequencing Engine: Single Molecule Real Time Sequencing-by-Synthesis. *S. W. Turner* Pacific Biosciences, 1505 Adams Drive, Menlo Park, CA.

SMRT (single molecule real time) DNA sequencing is a novel, high throughput method for sequencing DNA. Historically, the majority of DNA sequence data collected has been acquired through the use of DNA polymerase enzymes. However, the methods used squander the inherent power of the enzyme as a sequencing engine. Viewed as such, DNA polymerases can read up to 1000 bases per second per molecule, do so over DNA lengths of 100,000 bases or more, replicate with high fidelity and consume only one molecule per base sequenced. To harness this power, Pacific Biosciences has developed a method of eavesdropping on template-directed synthesis by DNA polymerase in real-time. Two critical technology components enable this process: The first is phospholinked nucleotides where, in contrast to other sequencing approaches, the fluorescent label is attached to the terminal phosphate rather than the base. The enzyme cleaves away the fluorophore as part of the incorporation process, leaving behind completely natural double-stranded DNA. The second critical component is zero-mode waveguide (ZMW) confinement technology that allows single-molecule detection at concentrations of labeled analogs relevant to the enzyme. Through the combination of these innovations, our technology allows the speed, processivity, efficiency and fidelity of the enzyme to be exploited. We show proof-of-concept data that indicate this will be a high-throughput sequencing technology. We will present a novel sample prep concept that facilitates whole genome shotgun sequencing directly from genomic DNA, compatible with molecular consensus sequencing that enables detection of rare mutants. We will also show how the wealth of biophysical data that emerges from real-time sequencing enables biological and medical studies previously inaccessible to sequencing technology.

A network-based analysis of GWAS in multiple sclerosis identifies immunological and neural pathways associated with disease susceptibility. *S. E. Baranzini[1], M. R. Barnes[2], J. Wang[1], R. Lindberg[4], P. Khankhanian[1], P. M. Matthews[2], L. Kappos[4], C. Polman[3], S. L. Hauser[1], R. A. Gibson[2], J. R. Oksenberg[1], N. W. Galwey[2]* 1) Department of Neurology, UCSF, San Francisco, CA; 2) GlaxoSmithKline Research and Development, Harlow, England; 3) Department of Neurology, Vrije Universiteit Medical Center, Amsterdam, Netherlands; 4) Neurology and Department of Biomedicine, University Hospital Basel, Basel, Switzerland.

Multiple sclerosis (MS) is a common and severe neurological disease of young adults. Genome-wide association studies (GWAS) testing several hundred thousand SNPs have been performed in MS and other complex diseases. Typically, the number of markers in which the evidence for association exceeds the genome-wide significance threshold is very small, and markers that do not exceed this threshold are generally neglected. Classical statistical analysis of these datasets in MS revealed genes with known immunological functions. However, many of the markers showing modest association may represent false negatives. We hypothesize that certain combinations of genes harboring these types of markers can be identified if they belong to a common biological pathway. Here we conduct a pathway-oriented analysis of two GWAS in MS that takes into account all SNPs with nominal evidence of association ($p<0.05$). Gene-wise p-values were superimposed on a human protein interaction network and searches were conducted to identify sub-networks containing a higher proportion of genes associated with MS than expected by chance. These sub-networks, and others generated at random as a control, were categorized for membership of biological pathways. GWAS from 8 other diseases were analyzed to assess the specificity of the pathways identified. In the MS datasets we identified sub-networks of genes from several immunological pathways including cell adhesion, communication, and signaling pathways. Remarkably, neural pathways, namely axon-guidance and synaptic potentiation, were also over-represented in the MS datasets. In conclusion, in addition to the immunological pathways previously identified, we report here for the first time the potential involvement of neural pathways in MS susceptibility.

Lower *IL2RA* Expression by Cis-acting Regulation Increases T1D Genetic Susceptibility. *H. Q. Qu[1], D. J. Verlaan[2], B. Ge[2], Y. Lu[1], C. L. K. Lam[2], L. Marchand[1], E. Harmsen[2], T. J. Hudson[3], T. Pastinen[2], C. Polychronakos[1]*
1) Endocrine Genetics, McGill University Health Centre, Montreal, Québec, Canada; 2) McGill University and Genome Québec Innovation Centre, Montréal, Québec, Canada; 3) Ontario Institute for Cancer Research, Toronto, Ontario, Canada.

Background The expression of *IL2RA* is an important marker of $CD4^+CD25^+$ regulatory T cells (T_{reg}). Targeting at *IL2RA*, IL2 treatment to promote the expansion of T_{reg} is in clinical trials for autoimmune diseases (ClinicalTrials.gov NCT00525889). Association of T1D with the *IL2RA* locus was first identified using a multilocus test(Vella,et al.2005). This association was replicated independently in our dataset of 949 European family trios, and mapped to the 5' of the *IL2RA* region(Qu,et al.2007). A recent study reported that the most significant T1D association was with -10,388 C/A (ss52580101, Lowe,et al.2007). **Objectives** (1)To see whether ss52580101 entirely accounts for the T1D association; (2)To detect and map cis-regulatory variation of *IL2RA* levels with a potential to explain the T1D association. **Methods** We measured differential allelic expression in unspliced heteronuclear RNA by normalized sequencing (Ge, et al. 2005, Pastinen, et al. 2005) in 55 parental LCLs of CEU (the European HapMap set) and 18 parents of diabetic children at four intronic SNPs. Differences in allele ratios between DNA and the corresponding RNA were taken as evidence of a transcriptional effect and correlated to genotype at T1D-associated makers. **Results** (1)The T1D association could not be entirely explained by ss52580101 as the effect of a SNP in intron 1 remained significant ($P=7.15x10^{-4}$) after regression for ss52580101. (2)We identified a haplotype, marked by the T1D predisposing allele of rs3118470, which is highly associated ($P=5.58x10^{-6}$) with a transcriptional effect resulting in lower *IL2RA* mRNA level. **Conclusion** This transcriptional allelic effect provides a plausible explanation of the T1D susceptibility: lower *IL2RA* expression may decrease IL2 signaling in the suppression of autoimmunity by T_{reg}, consistent with a similar effect of lower IL2 production determined by the *Idd3* locus in the NOD mouse(Yamanouchi, et al. 2007).

A multistage genome-wide SNP association study identifies a novel gene associated with susceptibility to type 2 diabetes mellitus. *K. Miyake[1], K. Yasuda[2], Y. Horikawa[3], M. Kasuga[1,2], Study Group of the Millennium Genome Project for Diabetes Mellitus* 1) Kobe University Graduate School of Medicine, Kobe, Japan; 2) Research Institute, International Medical Center of Japan, Tokyo, Japan; 3) Gifu University School of Medicine, Gifu, Japan.

As part of a national project designated the Millennium Genome Project in Japan, we performed a multistage genome-wide association study (GWAS) of type 2 diabetes mellitus (T2D) in Japanese with 100,000 SNPs. In the first stage, we compared the 187 diabetic subjects with two different control groups, reference data for 752 subjects in JSNP database and the 752 subjects for the other disease groups of this project. Two additional rounds of screening (second stage: cases vs. controls = 752 vs. 752, third stage: 672 vs. 672) identified 10 SNPs associated with T2D in the Japanese population. The most significant association was obtained with Gene-A, which had not been reported by GWASs in Caucasians, and dense mapping within the gene revealed that a common SNP showed the lowest *P* value of 6.7×10^{-13} (odds ratio (OR) = 1.49). In two independent Japanese panels (1521 vs. 1544 and 1433 vs. 1444), this SNP was reproducibly associated with the risk of T2D ($P = 9.6 \times 10^{-10}$ and 6.9 × 10-^{10}). The meta-analysis with 8790 Japanese subjects yielded a *P* value of 3.0×10^{-29} (OR = 1.43). Replication studies for the association of this gene with T2D in other Asian population as well as Caucasian are under way. Among control subjects, the risk allele of this SNP was associated with impairment of insulin secretion. Since none of the T2D susceptibility genes, which were previously revealed by GWASs in Caucasians, were detected in this multi-stage GWAS, we performed replication studies using the Japanese panels for eleven loci. We found that *TCF7L2*, *SLC30A8*, *HHEX*, *CDKN2B*, *IGF2BP2* and *CDKAL1* were reproducibly associated with T2D in Japanese. In summary, we identified a novel T2D susceptibility gene by a multistage genome-wide association study and also found the reproducibility of six T2D susceptibility genes in Japanese.

Orthotopic Liver Transplant for Arginase Deficiency. *B. Shaffer[1], S. Shankar[1], E. Nicholas[1], K. Weisiger[1], C. Zlatunich[1], W. O'Brien[2], S. M. Kang[3], L. Ferrell[4], P. Rosenthal[5], S. Packman[1]* 1) Medical Genetics Dept, UCSF, San Francisco, CA; 2) Molecular and Human Genetics Dept, BCM, Houston, TX; 3) Surgery Dept, UCSF, San Francisco, CA; 4) Pathology Dept, UCSF, San Francisco, CA; 5) Pediatric Gastroenterology, UCSF, San Francisco, CA.

Individuals with arginase deficiency (Arg Def) often suffer from poor growth, plateaued cognitive development, neurodevelopmental decline, spastic diplegia, loss of ambulation, and loss of bladder and bowel function. These manifestations occur despite few episodes of significant hyperammonemia, and, in the face of adherence to medical and dietary management. Orthotopic liver transplantation (LT) has not been employed in treatment of Arg Def. We describe the clinical course of one such case. Our patient is a 30 mo boy identified through newborn screening. Arg Def was confirmed by red blood cell enzyme assay that showed *zero* activity. Treatment with with Buphenyl and reduced arginine intake was begun. He had several mild hyperammonemic episodes with rapid resolution on treatment. Liver transaminases were intermittently elevated (AST/ALT up to 10X nl) without evidence of liver failure; abdominal ultrasound was normal. However, linear growth fell from the 75th centile at 10 mo to <5th at 29 mo; weight fell from the 90th to the 50th centile. Arginine levels (checked biweekly) were typically 2X nl (~50% of values), but were as high as <5X nl (~5% of values). Gastrostomy tube was placed at 27 mo to facilitate nutritional management. Spastic diplegia was noted at 26 mo, with progressively worsening contractures and decline in verbal skills by 28 mo. To prevent further deterioration, he underwent an uncomplicated LT at 29 months. Histologic examination of the explant revealed areas of pale swollen cells in peri-portal to mid zonal location. Post-transplant arginine levels normalized rapidly on a normal diet. His neurologic examination revealed reductions in spasticity and reflexes. With due recognition of the risks of LT, we submit that in Arg def with early neurologic or cognitive decompensation, LT is warranted, to potentially alter the disease impact and natural history of this disorder.

Sequence analysis of small RNAs present in preimplantation mouse embryos. *Y. Ohnishi[1,2], A. Toyoda[3], Y. Totoki[3], T. Watanabe[4], H. Sasaki[4], K. Tokunaga[2], Y. Sakaki[3], H. Hohjoh[1]* 1) National Institute of Neuroscience, NCNP, Tokyo, Japan; 2) Department of Human Genetics, Graduate School of Medicine, Univ Tokyo, Tokyo, Japan; 3) RIKEN Yokohama Institute, Yokohama, Japan; 4) Division of Human Genetics, Department of Integrated Genetics, NIG, Mishima, Japan.

Small RNAs (18-32 nucleotides in length) including small interfering RNAs (siRNAs) and microRNAs (miRNAs) are thought to play an essential role in biological functions. In this study, we focused on the small RNAs present in the course of early development of mouse embryo and constructed cDNA libraries for such small RNAs at the stages of oocyte, compacted 8- to 16-cell embryo (2.5 d.p.c.) and blastocyst (3.5 d.p.c.). After sequencing and annotation of clones, we found that the small RNAs derived from retrotransposon and miRNAs were abundantly present in oocyte and blastocyst, respectively. From the sequence analysis, most of the miRNAs (e.g., miR-290 cluster) appeared to be expressed in the 8-cell stage embryo and blastocyst. In contrast, maternally derived miRNAs (e.g., miR-let-7 family) seemed to be decreased during early development. The difference in the miRNA expression levels were also confirmed by RT-real time PCR. We further examined the small RNAs derived from retrotransposons and pseudogenes in oocytes and embryos, since recent studies showed that endogenous siRNAs generated from retrotransposons and pseudogenes were able to regulate their own expression by RNAi in growing oocytes. [Watanabe et al. Nature, 453(7194): 539-43, Tam et al. Nature, 453(7194): 534-8]. Of such candidates, we focused on small RNAs derived from LINE-1 (L1) retrotransposon, which were abundantly present in preimplantation embryos. When the GFP transcripts carrying the L1 sequence in its 3-UTR was introduced into fertilized egg, it was observed that the transcript was significantly decreased in 2-cell stage embryo. In addition, the level of L1 appeared to be increased in *Dicer* knock down embryos. Taken together, the results suggest that small RNAs derived from the L1 retrotransposon may be also involved in regulation of its expression in preimplantation mouse embryos.

Physician's attitude for New Genetic Testing services in Japan. *T. Ohata, A. Tsuchiya, M. Watanabe, T. Sumida, F. Takada* Dept Med Gen,Grad Sch Med Sci, Kitasato Univ, Sagamihara, Japan.

The purpose of genetic testing, users of genetic testing, and places to be provided genetic testing have been diversifying in Japan. Some New genetic testing for predicting disease susceptibility of multifactorial diseases have been appeared, and are provided by some clinics not specialized in medical genetics or sold to consumers via web sites directly. We conducted the survey of physicians (7528 general practitioners: GPs and 503 clinical geneticists: CGs) about new genetic testing services in 2007. The clinical validity and utility of new genetic testings that are actually provided were evaluated by those physicians.

Percentage of physicians who answered "useful "

	GPs	CGs
Obesity	55.8	31.4
Hypertension	62.2	37.0
Diabetes Mellitus	65.4	33.1
Alzheimer disease	58.4	35.7

General practitioners considered these testing more useful compared to clinical geneticists. These findings suggested that these new genetic testing services may be provided by physicians not specialized in medical genetics. Considering the possibility of expanding the use of genetic testing, it is necessary to establish integrative criteria to assess the analytical and clinical validities and clinical utility of genetic testing, share information necessary to provide testing, such as counseling information.

The effect of blood glucose variability on the development and progression of microvascular complications: results from the DCCT/EDIC study on type I diabetes mellitus (DM). *A. S. Rigby[1], S. L. Atkin[2], E. S. Kilpatrick[3]* 1) Academic Cardiology, University of Hull, UK; 2) Department of Diabetes, HYMS, UK; 3) Department of Clinical Biochemistry, Hull Royal Infirmary, UK.

The risk of developing microvascular complications in DM is related to the glycemic control of an individual. What remains controversial is whether glycemic instability may confer a risk to complications in addition to that predicted by the mean blood glucose (BG) value alone. We wanted to determine whether glucose variability during the original period of the DCCT influenced long-term risk of developing microvascular complications during EDIC. In the DCCT a capillary BG profile and HbA1c was taken quarterly. BG was assessed at 7-points daily: pre/post breakfast, pre/post lunch, pre/post supper & bedtime. Mean BG was calculated as an area under the curve. Instability of BG (within-day) during the DCCT was calculated using 2 methods: the standard deviation (SD) of daily blood glucose around the mean from each quarterly visit; also as the mean amplitude of glycemic excursion (MAGE). HbA1c measurement (unlike that of glucose profiling) continued after the DCCT into EDIC. Retinopathy development/progression was defined as a change of >=3 units in the 25-point Early Diabetic Retinopathy Treatment Study score since the end of the DCCT. Analyses were stratified by DCCT treatment group (intensive/conventional). GEE logistic regression was used to assess the effect of glycemic variables on retinopathy over repeated time-points adjusting for age, sex and disease duration. The number (%) of patients with retinopathy at years 1, 2, 3 and 4 of EDIC was 15/369 (4%), 37/443 (8%), 47/419 (11%) and 146/1208 (12%) respectively. In the intensive group there was no significant relationship between BG variability and retinopathy (SD: OR=0.92, 95% CI= 0.72,1.15, P=0.45; MAGE: OR=0.99, 95% CI=0.88,1.10, p=0.81). Both mean BG during the DCCT (OR=1.29, 95% CI=1.16,1.43, p<0.0001) and mean HbA1c in EDIC (OR=1.35, 95% CI =1.14,1.60, p=0.001) were significantly associated with retinopathy. It is reassuring that patients with large glycemic variability are at no greater risk to retinopathy than their mean BG level suggests.

Infantile-onset ascending spastic paralysis (IAHSP) caused by maternal uniparental heterodisomy with partial isodisomy of a chromosome 2 harboring a novel splice acceptor site mutation (IVS9-2AT) in the gene *ALS2*. *U. Muller[1], N. Wolf[2], P. Winter[1], H. Hackstein[3], D. Vater[2], T. Herzfeld[1]* 1) Inst. of Human Genetics, Justus-Liebig Univ, Giessen, Germany; 2) Dept. of Child Neurology, Ruprecht-Karls-Universität, Heidelberg, Germany; 3) Inst. of Clinical Immunology and Transfusion Medicine, Giessen, Germany.

Infantile-onset ascending spastic paralysis (IAHSP, OMIM #607225) is a rare autosomal recessive early onset motor-neuron disease. Mutations in the gene *ALS2* are the underlying cause of IAHSP and of the two clinicallly related motor neuron diseases juvenile primary lateral sclerosis (JPLS, OMIM #606353) and juvenile amyotrophic lateral sclerosis (ALS2, OMIM #205100). To date 14 mutations have been described in *ALS2*. Thirteen are homozygous and one is compound heterozygous. Most mutations (9) were detected in patients with IAHSP. We analyzed *ALS2* in a German IAHSP patient with non-consanguineous parents. Sequencing of all 34 exons and intron/exon boundaries of *ALS2* identified a homozygous splice acceptor site mutation in intron 9 of *ALS2* (IVS9-2AT). RT-PCR experiments showed that the mutation results in skipping of exon 10. This causes a frame-shift in exon 11 and a premature stop codon. We then investigated the parents and found the IVS9-2AT mutation in the heterozygous state in the mother but not in the father. Once non-paternity was excluded, we analyzed various polymorphic loci on chromosome 2 in the parents and in the patient. The absence of paternal alleles indicated maternal uniparental disomy. While homozygosity was observed at several loci including *ALS2*, other loci were heterozygous, i.e. both maternal alleles were present. The findings demonstrate maternal uniparental heterodisomy with partial isodisomy of chromosome 2 in the patient. A likely mechanism is non-disjunction during meiosis I and subsequent trisomy 2 rescue or gamete complementation. This case emphasizes that non-consanguineous parents of children homozygous for a rare autosomal recessive disease should to be tested before giving risk estimates for subsequent children.

Pontine dysplasia in a child with CHARGE syndrome. *J. van den Ende[1], K. Plaskie[2], P. Govaert[3]* 1) Dept Medical Genetics, University Hospital Antwerp, Wilrijk, Belgium; 2) Neonatal Intensive Care Unit, University Hospital Antwerp, Wilrijk, Belgium; 3) Neonatal Intensive Care Unit, Sophia Childrens`s Hospital- Erasmus MC, Rotterdam, the Netherlands.

CHARGE syndrome is an autosomal dominant condition caused by mutations in the CHD7 gene. The clinical picture is quite variable, between as well as within families. There does not seem to be a clear genotype-phenotype correlation. Before the gene was identified clinical criteria were used to make the diagnosis. The most important criteria were: coloboma, heart defects, choanal atresia, retarded growth/ development, genital hypoplasia, and ear anomalies/deafness, making up the acronym CHARGE. Now that the clinical picture is becoming more defined other features seem to be more important, like for example orofacial clefts and CNS malformations. Hypoplasia of the semi-circular canals and defects in the olfactory bulb development appear to be present in virtually all patients with CHD7 mutations. This finding, together with the fact that even subtle CNS malformations in CHARGE syndrome are associated with increased mortality, stresses the importance of neuro imaging, preferably by MRI, in all cases with even mild suspicion of CHARGE syndrome. We describe a case of a newborn with cleft lip and palate, deafness, and severe breathing problems, lacking most of the primary criteria for CHARGE syndrome. Subtle alterations in the pontine/cerebellar region on the ultrasound and MRI scan of the brain raised the suspicion of CHARGE syndrome. Subsequently a CT scan of the middle ear revealed absence of normal semi-circular canals, and finally DNA analysis of the CHD7 gene confirmed the diagnosis of CHARGE syndrome.

Genetic causes for inner ear malformation (Mondini Dysplasia, Enlarged Vestibular Aqueduct- and Pendred Syndrome). *R. Birkenhager, R. Laszig, A. Aschendorff* Department of Otorhinolaryngology, Head and Neck Surgery, University Hospital, Killianstrasse 5, D-79106 Freiburg, Germany.

Background: Pendred-Syndrome, an autosomal-recessive disorder is characterized by sensorineural deafness and goiter. This syndrome is one of the most common forms of syndromic deafness. Hearing loss is prelingual in the majority of the cases, only a subset of patients have a progressive hearing loss later in life. The deafness is associated with temporal bone abnormalities ranging from isolated enlargement of the vestibular aqueduct to Mondini dysplasia, a more complex malformation that also includes cochlear hypoplasia. PDS is caused by mutations in the SLC26A4 gene. The SLC26A4 gene is expressed in the non-sensory epithelia of the inner ear. Recently an additional gene FOXI1 was described which mayalso be responsible for Pendred- Syndrome and Mondini dysplasia. The FOXI1 gene is involved in the transcriptional control of the SLC26A4 gene. In this study we analysed 64 patients with EVA and hearing loss to distinguish between Pendred-, EVA-syndrome and Mondini dysplasia. **Methods:** Individual exon and intron transitions of the SLC26A4 and FOXI1 gene of patients were PCR sequenced. A genome-wide linkage analysis was accomplished using the 500 K genotyping. **Results:** In the analysed patients with Pendred-Syndrome and/or enlargement of the vestibular aqueduct, a total of twenty-one different SCL26A4 mutations were detected, by contrast mutations could not be detected in the FOXI1 gene. In the SLC26A4 gene a mutation could not be detected in 42 % of the cases. With a genomewide SNP analysis, of these families it was possible to identify potential new gene loci responsible for the Enlarged Vestibular Aqueduct Syndrome and Mondini dysplasia. **Conclusions:** These results suggested in contrast to the literature that the FOXI1 gene is not the main factor involved in Pendred- and Enlarged Vestibular Aqueduct Syndrome. Our results indicate evidences of an accessory gene for the Enlarged Vestibular Aqueduct Syndrome and specially for Mondini dysplasia.

DNA integrity and seminal antioxidant analysis in idiopathic infertile Indian men. *M. B. Shamsi[1], S. Venkatesh[1], P. Talwar[2], R. K. Sharma[2], S. Mukherjee[3], R. Kumar[3], S. Arora[4], D. S. Arya[4], R. Dada[1]* 1) Dept. of Anatomy, AIIMS, New Delhi, India; 2) ART Centre.Army Research and Referral Hospital New Delhi, India; 3) Dept of Urology, AIIMS, New Delhi, India; 4) Department of Pharmacology. AIIMS, New Delhi India.

Infertility affects about 15 -20 % people in the reproductive age. About 30 - 40 % of infertile men have raised Reactive Oxygen Species levels and low antioxidant levels, leading to oxidation of nucleotides and malondialdehyde production from membranes by lipid peroxidation. Seminal plasma from 39 idiopathic infertile males and 27 healthy controls was evaluated for Superoxide Dismutase (SOD), Glutathione (GSH), Malondialdehyde (MDA) and Catalase (Cat) by biochemical method. The DNA integrity of sperms was assessed by Single Cell Gel Electrophoresis (SCGE). The Comets in SCGE were classified into four categories (category A- no DNA migration to D-highest DNA migration) as observed by a micrometer attached to the eyepiece.Significant difference (p=0.492) in the assayed AO and MDA levels were observed in infertile patients and healthy controls. Motility was positively correlated with AO and negatively with MDA levels in both the patient and control group. MDA had positive correlation (p=0.471) with sperm morphological deformities. No correlation between sperm concentration and AO was observed in study group but an increased MDA level was associated with sperm count in patients but not in controls. Greater group D comet images were observed in infertile patients having low seminal antioxidant or higher MDA profile. The viability was positively associated with the number of comets in category A in patients and controls. Greater the sperm number higher will be the MDA production in OS, therefore in patient group a direct correlation of MDA and sperm number was observed whereas in controls due to insignificant OS no such correlation was observed. OS induces DNA aberrations, leading to apoptosis in the sperm leading to longer tails in the SCGE and decreased viability of sperms. This study provides an insight to the important role played by AO and DNA integrity in the maintenance of reproductive potential of sperms.

Rare de novo CNVs: Matching mouse gene knockout models to human mental retardation. *C. Webber[1], J. Y. Hehir-Kwa[2], DQ. Nguyen[1], B. B. A. de Vries[2], J. A. Veltman[2], C. P. Ponting[1]* 1) MRC Functional Genomics Unit, Oxford University, Oxford, United Kingdom; 2) Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Rare structural genomic variations such as copy number variants (CNVs) frequently underlie common neurological disorders including mental retardation (learning disability), autism and schizophrenia. A major impediment to the clinical interpretation of these variants is that CNVs are also widespread in the general population. We have analysed a set of 148 rare genomic structural variants associated with mental retardation that were gathered from 17 publications and the DECIPHER database. In addition to Gene Ontology, tissue-expression and functional pathway annotations, we exploited the new wealth of genomic data from over 4000 mouse gene knockout experiments to forge links between these structural variants and their associated phenotypes. Mental retardation-associated structural variants were significantly enriched in (i) genes whose mouse orthologues, when disrupted, result in specific neuronal phenotypes, (ii) genes with known roles in human neurodegenerative pathways, in particular Parkinsons disease (iii) genes with enhanced expression in the brain relative to other tissues, and (iv) genes involved in transcriptional regulation. We find a significant association between the phenotypes from mouse gene knockout experiments and additional phenotypes of individual patients, such as cleft palate. Furthermore, we find that most of these enrichments were increased after removing those genes also overlapped by apparently benign CNVs. By exploiting these enrichments we have identified 125 genes enriched in variants that contribute to mental retardation and associated phenotypes.

Kluver-Bucy syndrome In a Child with Neurofibromatosis - type 1 (NF-1). *M. Miller[1], L. Kleiner[2]* 1) Dept Medical Gen, Children's Med Ctr, Dayton, OH; 2) Dept Neurosurgery, Children's Med Ctr, Dayton, OH.

Kluver-Bucy syndrome is a very rare, human behavior disorder that was originally described in monkeys who had both temporal lobes removed. These monkeys had visual agnosia, altered sexual behavior, and oral stimulation behaviors. Humans who incur bilateral temporal lobe dysfunction can also develop a similar clinical picture as in the temporal lobe lobectomized monkeys, but they do not typically show all of the clinical features. Kluver-Bucy syndrome has been described in humans in the following clinical settings: herpes simplex encephalitis (most common etiology), head trauma, severe dementia, Pick's disease, surgical lesions, and cerebrovascular disease. It is very rare in children, and has not been described in NF-1. AH is a 10 year old male with known NF-1 based on multiple cafe-au-lait spots and a prior optic glioma. His elementary school principal sent a letter to his treating physicians pleading for help in trying to understand his bizarre and threatening behaviors including: hypersexualism (he is constantly touching boys and girls in their genitals and grabbing girls breasts), inappropriate emotional responses (he would giggle and smile when being disciplined), and outbursts of anger. Review of his head MRI showed that on T2 sequence there were bilateral and symmetrical 1.3 cm lesions of high signal intensity (UBOs= unidentified bright objects) in the amygdala of both temporal lobes, findings thought to be consistent with Kluver-Bucy syndrome. This is the first example of Kluver-Bucy syndrome in association NF-1 in which there are the typical UBOs of NF-1 located in the anatomic region associated with Kluver-Bucy syndrome, the medial temporal lobes.

Model-independent linkage analysis and tests of association for familial idiopathic scoliosis and a candidate region on chromosome 6. *C. Justice[1], N. H. Miller[2], B. Marosy[3], D. Behneman[1], A. F. Wilson[1]* 1) Genometrics Section, IDRB, National Human Genome Research Institute, NIH, Baltimore, MD; 2) University of Colorado, The Childrens Hospital, Denver; 3) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Familial idiopathic scoliosis (FIS) is a lateral curvature of the spine present in the late juvenile or adolescent period in otherwise normal individuals. It affects 2-3% of the pediatric population, and 0.2-0.5% of the population require active treatment. Idiopathic scoliosis is believed to be a complex genetic disorder in which expression of the disease state may depend on several genetic and possibly environmental factors. Previous studies have suggested autosomal dominant, X-linked and multifactorial modes of inheritance. As part of a large collaborative study of FIS, 202 families with at least two individuals with a lateral curvature greater than or equal to 10 degrees were ascertained and clinically characterized. A genomic-wide screen identified candidate regions on chromosomes 6, 9, 16 and 17 [Miller et al. 2005]. The candidate region on chromosome 6 was genotyped with SNPs using the Ilumina platform. SNP marker density was ~ 58 Kb, with 537 SNPs genotyped on 6q13-q21. FIS was analyzed both as a quantitative and a qualitative trait, in which the curvature determining the threshold for affectation status was set at values of 10 and 30 degrees. Model independent sib-pair linkage analysis was performed with SIBPAL [S.A.G.E., v5.0, Case Western Reserve University, Cleveland, OH]. Tests of association were performed with FBAT [Rabinowitz and Laird 2000; Laird, Horvath, and Xu 2000; Horvath et al. 2004] for FIS as a qualitative trait and with ASSOC [S.A.G.E., v5.0] for FIS as a quantitative trait. Haplotypes of two, three and four SNPs were also tested for association with FBAT. The most significant results for the linkage analysis were obtained when the affectation status was set at 10 degrees or greater, with p-values 0.05 in a region spanning from 74 to 80 Mb. Association analyses for the whole sample resulted in several significant p-values.

NR4A2: Modeling Cellular Lithium Response. *R. C. McEachin[1,2], H. Chen[1], B. J. Keller[3,2], A. R. Prossin[1], Y. Bai[2], N. E. Carlson[4], P. Zandi[5], M. G. McInnis[1,2]* 1) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 2) National Center for Integrative Biomedical Informatics, Univ Michigan, Ann Arbor, MI; 3) Dept Computer Science, Eastern Michigan University, Ypsilanti, MI; 4) Dept Biostatistics, University of Colorado, Denver, CO; 5) Dept Mental Health, The Johns Hopkins University, Baltimore, MD.

Lithium is effective in the treatment of mania for approximately 70% of patients with Bipolar Disorder (BD). However, the mechanism of lithium's action is poorly understood. Using a new algorithm called Prioritizing Disease Genes by Analysis of Common Elements (PDG-ACE), we developed a novel, statistically significant, biologically plausible hypothesis on the genetic etiology of lithium's action in treating bipolar mania. Since lithium exerts an environmental influence on cells, we first identified candidate genes differentially expressed with lithium treatment in a cellular model, starting with Illumina's Human Ref8_V2 BeadChip and confirming these results by RT-PCR. Based on these analyses, we prioritized NR4A2 and FOS for further analysis and applied the PDG-ACE algorithm. PDG-ACE results led us to hypothesize that NR4A2 and FOS modulate cellular responses to lithium via dopamine signaling. Using GeneGo's MetaCore database, we developed a genetic model incorporating the hypothesized influences of lithium on dopamine signaling via NR4A2 and its network of interactors. Genes in this network are significantly enriched (p-value < 0.01) for "lithium", "dopamine", and "Bipolar Disorder" in MeSH annotation of publications tagged for these genes. In addition, 13 of the 50 genes in this network are under NPL interactions peaks for BD (p-value < 0.01). The hypothesis developed and tested in this analysis is consistent with a role for the NR4A2 network in cellular responses to lithium treatment, models response and non-response of individuals to lithium treatment, and is consistent with comorbid substance abuse often seen in BD. We also propose novel candidate genes for understanding lithium's action in BD, including genes that are known therapeutic targets of other drugs that may be useful in treatment of BD.

Identification of novel *HMGA1* and *HMGA2* fusion genes in lipoma. *X. Wang, R. L. Hulshizer, R. Q. Zamolyi, V. Pannain, M. R. Johnson, R. B. Jenkins, R. V. Lloyd, A. M. Oliveira* Dept of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Lipomas are among the most common benign soft tissue tumors. Cytogenetic and molecular genetic analyses have shown that 60-80% of them contain rearrangements of the chromatic remodeling genes *HMGA2* (60-80%) and *HMGA1* (5-10%). In lipomas, *HMGA2* but not *HMGA1* fusion genes have been identified. Herein, we describe two novel *HMGA2* fusion genes and the novel *HMGA1-LPP* fusion gene.

Three ordinary lipomas were characterized at the cytogenetic level and showed the following karyotypes: 46,XX,inv(12)(q13q15), 46,XY,add(12)(q24.1), and 46,XX, t(3;6)(q27;p21.1). Frozen tissue material was available from the first two cases but only paraffin tissue was available from the third for further analysis. Fluorescence in situ hybridization(FISH) using custom-designed probes for *HMGA1*, *HMGA2*, and *LPP* were performed to verify the involvement of these loci. RACE RT-PCR, semi-quantitative RT-PCR, and direct sequence analysis were used to confirm the structure and transcriptional upregulation of the fusion transcripts.

Molecular cytogenetic and genetic analyses showed that the lipoma with inv(12) contained a fusion of the *HMGA2* 3-UTR region to a genomic sequence 143kb upstream to the *DCN* locus on 12q21. The lipoma with add(12) had a fusion of the *HMGA2* 3-UTR region to a genomic area 230kb upstream to the *DYRK2* locus on 12q15. RT-PCR and sequence analysis confirmed these chimeric sequences. The lipoma with t(3;6) showed juxta-position of the *HMGA1* to the *LPP* locus, as evident by FISH analysis on paraffin embedded tissue. Semi-quantitative RT-PCR analysis indicated transcriptional upregulation of these genes.

We have identified three novel lipoma fusion genes in ordinary lipoma, including two *HMGA2* fusions and the novel *HMGA1-LPP*. Our findings are consistent with the current hypothesis that suggests deletion or substitution of suppressor sequences in the 3-UTR of *HMGA2* results in its transcriptional upregulation.

Common and cancer type-specific loss-of-heterozygosity (LOH) in the tumor stroma and epithelium of 3 carcinoma types associated with clinical outcome. *M. Orloff, L. Zhang, Y. Xu, C. Eng* Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH.

The role of the tumor microenvironment (stroma) in carcinogenesis and progression has grown in the last decade. We sought to analyze the pattern of in-common and cancer type-specific somatic genomic alterations in epithelium and stroma of breast (BC), prostate (CaP) and head and neck squamous cell (HNSCC) carcinomas. Genomic DNA from tumor epithelium (Ep) and stroma (St) from 413 patients with BC (175), CaP (116) and HNSCC (122) were subjected to 400-microsatellite marker genome-wide LOH analysis. After adjustment for multiple testing (FPRP < 0.5), compartment-specific LOH at a marker was scored as significantly higher (hotpsot) or lower (coldspot) than the average across its relevant chromosome. Notably, there were 16 markers found to be hot/cold-spots of LOH in Ep and/or St which were in-common among all 3 cancer types. These comprised 11 that were St-specific, 2 Ep-specific and 2, D17S2180 and D12S297, which showed significant LOH in both compartments. While we found compartment-specific hot/cold-spot markers of LOH common to all 3 cancer types, there were no hot/cold-spots of LOH specific for any single cancer type only. Overall increased frequencies of LOH across markers in Ep, but not St, correlated with increasing tumor grade (G) for all 3 cancer types. For BC and HNSCC, but not CaP, overall increased St genomic alterations correlated with regional nodal metastases (pN). There were only 2 markers associated with clinicopathologic features that were single cancer type-specific: LOH at D17S2180 in both Ep and St, with G in HNSCC; and LOH at D22S1045 in both compartments with pN. Interestingly, our study reveals that stroma- and epithelial-specific genetic alterations that are in-common among the 3 solid tumors are overwhelmingly more frequent than single cancer type-specific LOH. This suggests common biomarkers for prognosis among several solid tumors. Importantly, our observations help to limit the number of molecular targets for treatment or prevention across several common carcinomas, hence facilitating more precise and compartment-specific therapeutic options.

Cri du Chat mosaicism: a new case with partial deletion and partial deletion/duplication of the short arm of chromosome 5, leading to an unusual phenotype. *A. Nucaro[1], D. Murru[2], MS. Ristaldi[1], L. Boccone[2]* 1) CNR, Istituto di Neurogenetica e Neurofarmacologia, Monserrato, Cagliari, Monserrato, Cagliari, Italy; 2) Dipartimento di Scienze Biomediche e Biotecnologie, Università di Cagliari, Italy.

The Cri du Chat Syndrome(CdCS) is one of the most common deletion syndromes, involving the short arm of chromosome 5, with an incidence of 1 in 50.000 live births. The following are the characteristic features of this syndrome: microcephaly, hypertelorism, round face, micrognatia, epicanthic folds, prominent nasal bridge, hypotonia and severe psychomotor retardation. Patients also show a high pitched cri similar to the mewing of a cat. Deletions and duplications of chromosome 5p have been described in the literature. Mosaicism represents only 3% of this cytogenetic aberration. Up to date, only cases of de novo mosaic 5p anomalies involving two or three rearranged cell lines, with deletions and duplications, have been described. Herein, we report the first case of a patient affected by multiple congenital anomalies and a mosaicism, with two rearranged cell lines: one with a 5p deletion; the other with a 5p deletion/duplication. Our patient did not show the characteristic features described in patients with 5p duplications, but a phenotype compatible with CdCS. Our case represents the first description of a mosaicism with deletion and deletion/duplication of a portion of the short arm of chromosome 5.

Bayesian joint analysis of multiple datasets intended to enhance panic disorder linkage peak on chromosome 7 instead yields evidence of linkage to chromosomes 2q and 17. *M. Logue[1], S. R. Bauver[1], S. P. Hamilton[2], J. A. Knowles[3], A. J. Fyer[4,5], M. M. Weissman[5,6], R. R. Crowe[7]* 1) Genetics Program, Boston Univ Sch of Medicine, Boston, MA; 2) Dept of Psychiatry and Institute for Human Genetics, Univ of California, San Francisco; 3) Keck Sch of Medicine, Univ of Southern California; 4) New York State Psychiatric Institute; 5) Dept of Psychiatry College of Physicians and Surgeons, Columbia Univ; 6) Division of Epidemiology, New York State Psychiatric Institute; 7) Dept of Psychiatry, Univ of Iowa.

Panic disorder is one of the most common anxiety disorders and has substantial comorbidity with other psychiatric disorders and physical ailments. In this paper, we follow-up on our previous findings of a panic disorder region of interest on chromosome 7 obtained using the posterior probability of linkage, or PPL. In Logue et al. 2003, using the 23 pedigrees of the Iowa (IA) linkage data (Crowe et al 2001), we obtained a 2-point PPL of 80% - indicating an 80% chance of a risk locus linked to marker D7S521. Here, we perform a multipoint PPL analysis of the IA data, which increased the peak PPL on chromosome 7 to 88%. These results were combined with a PPL-based analysis of the 120 pedigrees of the Columbia University (CU) genome screen (Fyer et al 2006). Even though earlier analysis with of a subset of the CU data (23 pedigrees, Knowles et al 1998) had provided evidence for linkage to chromosome 7, PPL analysis of the full 120 pedigree CU dataset did not provide further evidence of linkage to this region, and the PPL resulting from joint analysis was 84%. However, joint analysis yielded substantial evidence of linkage to chromosome 2p (PPL = 94% at 74 cM), and chromosome 17 (PPL = 42% at 124 cM), based on strong peaks obtained in the CU pedigrees. There were few regions where joint analysis produced a larger PPL than the individual datasets, most notably, at 39 cM on chromosome 16 (PPL = 25%). This region had been noted previously in the IA data, and has been identified as possibly containing a gene for mitral valve prolapse. The PPL is consistently low elsewhere, with PPLs < 5% for 97% of the genome.

Comparative phenotypic and biochemical analyses of the *Crtap-/-* mice and patients with recessive osteogenesis imperfecta. *R. Morello[1], D. Baldridge[1], J. Lennington[1], T. Bertin[1], E. Munivez[1], M. Jiang[1,5], Y. Chen[1,5], D. Keene[2], D. Rimoin[3], D. Krakow[3], D. Cohn[3], P. Byers[4], B. Lee[1,5]* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Shriners Hospital for Children, Portland, OR; 3) Cedars-Sinai Medical Center and David Geffen School of Medicine, UCLA; 4) University of Washington, Seattle, WA; 5) Howard Hughes Medical Institute, Houston, TX.

We and others have demonstrated that null mutations in either *CRTAP* (Cartilage-associated protein) or *LEPRE1* (coding for Prolyl 3-hydroxylase 1 (P3h1), leprecan) cause lack of type I collagen prolyl 3-hydroxylation and recessive forms of osteogenesis imperfecta (OI). Crtap, P3h1, and cyclophilin B (Prolyl cis-trans isomerase) form a molecular complex in the endoplasmic reticulum (rER) that is responsible for proper collagen post-translational modification. We have now analyzed the stability of this complex in primary human skin fibroblasts derived from patients with null mutations in *CRTAP* or *LEPRE1*. We demonstrate both by immuno-fluorescence and western blot that *LEPRE1-/-* fibroblasts completely lose expression of the CRTAP protein and similarly, *CRTAP-/-* fibroblasts do not express P3H1. These data suggest that both proteins are required in order to form a stable complex in the rER and that lack of either CRTAP or P3H1 cause degradation of the interacting partner. Parallel to these observations, a comprehensive analysis of the phenotype of the *Crtap-/-* mice, a mouse model of recessive OI, shows multiple tissue abnormalities, including in the lungs, kidneys, skin and cartilage. Interestingly, in both the lung and kidney we observe an early onset (P10) increase in cellular proliferation by BrdU staining, suggesting an altered tissue growth rate perhaps due to abnormal matrix to cell signaling. These data suggest CRTAP may exert more widespread effects on collagen homeostasis including types V in skin and type IV in kidney. These studies point to the requirement for prolyl 3-hydroxylation in the widespread regulation of collagen structural and signaling function and suggest a broader clinical assessment of patients with these conditions.

A systematic analysis of the proteins of the human neutrophil phagocytic vacuole. *A. P. Walker[1], M. Radulovic[1,2], A. Sanchez Sierra[1], A. W. Segal[1]* 1) Dept. Medicine, UCL, London, United Kingdom; 2) Dept. Medicine, Imperial College, London, United Kingdom.

Neutrophils comprise the front-line defence of the innate immune system, due to their ability to engulf and degrade invading micro-organisms by phagocytosis. The importance of neutrophil phagocytosis for human health is demonstrated by chronic granulomatous disease, where mutation of subunits comprising the NADPH oxidase complex impairs the respiratory burst that kills microbes, leading to recurrent infections. This study was undertaken to systematically characterise the proteins of the human neutrophil phagocytic vacuole in order to better understand this vital process. Human neutrophils were incubated with latex beads and phagosomes were purified by sedimentation on sucrose density gradients. Proteins from phagosomes or phagosomal membranes were resolved on 1D gels for tryptic digestion and mass spectrometry. 359 proteins were identified by at least two peptides. Notably, 19 RABs were identified including RAB18, RAB35 and RAB8A, which have not previously been recognised in human or mouse neutrophil phagosomes. RABs are small GTPases which act as molecular switches by cycling between GTP- and GDP-bound states. They are important regulators of the different steps of vesicle trafficking. Comparative analysis showed RABs to be the most highly conserved type of protein identified, with nine members conserved to Drosophila melanogaster. ELMO1 (engulfment and motility 1) was identified for the first time in human neutrophil phagosomes; ELMO1 activates rac leading to rearrangement of the actin cytoskeleton for engulfment. The data were scanned for representation of canonical pathway members using GENMAPP software, highlighting the regulation of the actin cytosketon that is essential for the formation and trafficking of the phagocytic vacuole. Ingenuity Pathways Analysis was used to map molecular interactions within the datasets, showing extended networks of cytoskeletal proteins important for vesicle trafficking in phagocytosis.

A general framework for formal tests of interaction after exhaustive search methods with applications to MDR-PDT. *T. Edwards[1], E. Torstenson[2], S. Dudek[2], E. Martin[1], M. Ritchie[2]* 1) Center for Genetic Epidemiology and Statistical Genetics, Dept. of Human Genomics, University of Miami, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

As genetic epidemiology looks beyond mapping single disease susceptibility loci, interest in detecting epistatic interactions between genes has grown. The dimensionality and comparisons required to search the epistatic space, the danger of over-fitting, and the inference for a significant result pose challenges for testing epistatic disease models. The Multifactor Dimensionality Reduction Pedigree Disequilibrium Test (MDR-PDT) was developed to test multilocus models in pedigree data. In the present study we rigorously tested MDR-PDT with new cross-validation (CV) and omnibus model selection algorithms by simulating a range of heritabilities, odds ratios, minor allele frequencies, and numbers of interacting loci. Additionally, given that the permutation-based hypothesis test of the MDR-PDT does not evaluate effect modification across genotypes and that this property might inflate the Type I error rate for the null hypothesis of no interaction, we implemented a regression-based permutation test. We found that MDR-PDT performs similarly with 5 and 10 fold CV. We additionally implemented a the matched odds ratio fitness metric and demonstrate that it improves power. We also demonstrate that fitting a regression model on the same data as analyzed by MDR-PDT is a biased procedure and is not a valid test of interaction. The regression-based permutation test implemented here conducts a valid test of interaction after a search for multilocus models, and can be used with any method that conducts a search to find a multilocus model representing an interaction.

Isolation and characterization of Arms2 interacting proteins. *K. Huang, G. Sarawgi, L. Tian, D. Stambolian*
Department of Ophthalmology, FM Kirby Center for Molecular Ophthalmology, University of Pennsylvania, Philadelphia, PA.

Age related Macular Degeneration (AMD) is a common, multi-factorial disease of the macula. Genetic variants at chromosome 1q31-32 and 10q26 are strongly associated with this disorder and may account for as much as 50% of the disease risk. In the 10q26 locus, a strong association has been identified between AMD and SNP rs10490924, which is located within the human ARMS2 gene. ARMS2 encodes a small 12 kD protein that is highly conserved between humans and old world monkeys, both of which have maculas. However, ARMS2 homologs are not present in the genomic sequences of nonprimates that lack maculas, indicating that ARMS2 may play an important role in macular formation. Although ARMS2 is expressed in the retina, retinal pigment epithelium (RPE) and placenta, its function is unknown. To explore the function of ARMS2 in the human retina and RPE, we performed yeast two hybrid screens using full length ARMS2 cDNA as bait and either human retina or RPE/choroid cDNA as prey. We identified three retinal genes that specifically interact with ARMS2: HCHC1 (host cell factor C1, a transcription factor), AFF1 (AF2/FMR2 family member 1) and PTPRD (protein tyrosine phosphatase receptor type D). Characterization of the relationships between ARMS2 and its interacting proteins should provide important information about the function of ARMS2 in macular development and disease.

Neocentromere formation in a stable rearranged chromosome 7 with Class II pericentric interstitial deletion and the formation of ring chromosome 7. *S. A. Ebrahim[1,2], H. Jiang[3], R. Te[2], A. N. Mohamed[1,2]* 1) Detroit Medical Center Univ. Lab. Cytogenetics; 2) Childern Hospital of Michigan; 3) Dept Pathology, Wayne State Univ, Detroit, MI.

Neocentromeres (NEO) are newly derived functional centromeres formed in marker or rearranged chromosome outside the normal centromere location. Since the discovery of the 1st human NEO in 1993, over 90 patients with NEO formation have been reported for all chromosomes with the exception of chromosome 7. We describe a 7 years old boy with developmental delay who has NEO in a previously undescribed chromosome. Routine blood chromosome analysis and FISH revealed a 47,XY,r(7)(p12q21.2),+neo(7)(pterp14neop14p12::q21.2qter)[20].ish r(7)(D7Z1+,WCP7+,ELN+,pter-,qter-),+neo(7)(D7Z1-,WCP7+,ELN- ,pter+,qter+)karyotype. Each metaphase examined had one normal chromosome 7, one chromosome 7 with interstitial deletion of the short and long arms segments[del(7)], and a small ring chromosome derived from the deleted chromosome 7 segments. The ring chromosome stained positive on C-staining, while the del(7) stained negative, indicating the absence of the centromeric region from the del(7). FISH with chromosome 7 centromere specific probe showed that the ring chromosome contained the chromosome 7 centromere and that no alpha-satellite DNA material was present on the del(7), consistent with neocentromere formation. FISH with subtelomeric probes showed the presence of normal short and long arm subtelomere signals on the normal and the del (7), but not the ring 7. FISH with ELN probe for the 7q11.23 region showed positive hybridization, to the normal and ring 7, but no hybridization is observed on the del(7). FISH with whole chromosome 7 paint confirmed the origin of the ring 7 and the del(7) and ruled out an exchange with other chromosome. Ring chromosomes derived from chromosome 7 are rare and a deletion of chromosome 7 with NEO formation has not been reported. This is the first published case of a class II analphoid chromosome derived from chromosome 7, suggesting that this region may possibly be a new site for neocentromere formation.

Autism and germline mosaicism for a *NLGN4* alteration: Genetic counseling implications. *S. Newton[1], G. Zhao[1], H. Tager-Flusberg[2], J. M. Milunsky[1,3]* 1) Center for Human Genetics, BUSM, Boston, MA; 2) Human Development Program, BUSM, Boston, MA; 3) Department of Pediatrics/Genetics and Genomics, BUSM, Boston, MA.

NLGN4 (Neuroligin4) is an X-linked gene located at Xp22.33. The neuroligin (NLGN) family of proteins play a role in synaptogenesis. NLGN mutations have been hypothesized to lead to deficits in cognitive and developmental processes. Mutations in *NLGN4* have been reported in individuals with autism spectrum disorder (ASD), mental retardation, pervasive developmental disorder(PDD), and a variety of neuropsychiatric conditions. We present the first known case of germline mosaicism for a *NLGN4* alteration. The two probands are brothers, ages 5 and 3 yrs, who have been extensively evaluated and found to have classic ASD. They have atypical social interaction, minimal eye contact, difficulty in communication, and repetitive interests and stereotypies. Antenatal courses were unremarkable. Their mother reports no exposures to chemicals, radiation, or severe illness during the pregnancies. Both brothers have developmental delay (especially language), but do not have a history of regression, seizures, neurological trauma, hearing loss, or major medical concerns. Both brothers were found to be hemizygous for the R87W alteration in exon 1 of the *NLGN4* gene. This alteration is not present in the SNP database, was not found in more than 300 normal individuals tested, and is predicted to be possibly damaging by PolyPhen and not tolerated by SIFT. All additional genetic testing on both brothers was negative, including high resolution chromosomes, 500K SNP microarray, Fragile X syndrome, and *NLGN3* sequence analysis. Their mother was found to be negative for the R87W alteration in blood and buccal swabs, and their father was negative for the alteration in blood, ruling out an alteration on the *NLGN4* Y-chromosome homologue. Maternity and paternity was confirmed molecularly. Their mother was found to have mildly skewed X-inactivation (75%:25%) of unknown significance. This report of gonadal mosaicism for a *NLGN4* alteration in 2 brothers with autism has significant implications for genetic counseling and provides further evidence for the causative role of *NLGN4* alterations in the development of ASD.

A Confidendence-Limit Based Approach to the Assessment of Hardy-Weinberg Equilibrium. *S. Wellek[1], K. A. B. Goddard[2,3], A. Ziegler[4]* 1) Dept. of Biostatistics, CIMH Mannheim/University of Heidelberg, Mannheim, Germany; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH, 44106, USA; 3) Center for Health Research, Kaiser Permanente Northwest, Portland, OR, 97227, USA; 4) Institute of Medical Biometry and Statistics, University of Lübeck, Germany.

The classical chi-squared procedure for the assessment of genetic equilibrium is flawed by the fact that it is tailored for detecting violations of HWE although the majority of applications in genetic epidemiology require to establish approximate compatibility of the model assumption with the distribution underlying the data. In Wellek (2004) [Biometrics 60, 694-703], the methodology of statistical equivalence testing was exploited for the construction of tests for problems in which the assumption of approximate compatibility of a given genotype distribution with HWE plays the role of the alternative hypothesis one aims to establish.In the present contribution, we derive a procedure which serves the same purpose but uses confidence limits rather than critical bounds of a significance test of the null hypothesis of absence of marked deviations from HWE. Interval estimation relates to the same parametric function which was previously chosen as the target parameter for constructing an exact conditional UMPU test of equivalence with a HWE-conforming genotype distribution. This population parameter is shown to admit a direct genetical interpretation as a measure of relative excess heterozygosity. For the construction of confidence limits, both asymptotic and exact methods are used.

***APOA2* genetic variation and its relationship with plasma HDL-cholesterol levels.** *M. I. Kamboh[1], S. M. Hollister[1], A. S. Dressen[1], C. H. Bunker[2], R. F. Hamman[3], C. M. Kammerer[1], F. Y. Demirci[1]* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA; 3) Preventive Medicine and Biometrics, Univ Colorado Denver, Aurora, CO.

Coronary heart disease is a major public health concern affecting millions of people worldwide. Low levels of high density lipoprotein cholesterol (HDL-C) have been shown to increase the risk for cardiovascular disease. The major genetic loci associated with HDL-C were recently identified through genome-wide association studies, which investigated influences of common variants on common traits. Relatively few studies have investigated the impact of rare variants on common diseases. The aim of our study was to evaluate the role of *APOA2* genetic variation (a biological candidate gene involved in HDL metabolism) in relation to HDL-C levels in epidemiological samples of African Blacks and U.S. non-Hispanic Whites (NHWs). We resequenced the entire *APOA2* gene in selected individuals with HDL-C levels in the upper 5^{th} percentile (47 NHWs and 48 Blacks) and the lower 5^{th} percentile (48 NHWs and 47 Blacks), allowing us to identify both rare and common variants. We detected a total of 26 variants (25 single nucleotide substitutions and 1 microsatellite); 12 of which were previously unreported. Of the 12 new variants, 6 were present in NHWs and 6 in Blacks. We observed an increased number of minor alleles of *APOA2* variants (either increased heterozygosity for rare variants or increased homozygosity for common variants) in subjects with low HDL-C levels that was more pronounced in NHWs. Of the 9 variants that were screened in the larger NHW (n=623; 8 variants) and Black (n=788; 5 variants) samples with TaqMan SNP genotyping assays to date, significant association was found for variants 2233C>T/rs6413453 (p=0.028) and 3251A>G (p=0.023) in NHW females. Complete genotyping of the remaining variants will allow us to determine the extent to which the *APOA2* variants influence the HDL-C levels.

Population-based analysis of copy number variation detects common variants of all sizes. *S. Yoon[1], D. Malhotra[1], M. Kusenda[2], S. Kudaravalli[3], V. Makarov[1], J. Kendall[1], A. Leotta[1], A. Bhandari[1], A. Dewan[7], X. Zhao[1], T. Walsh[4], J. Lloyd[1], B. Yamrom[1], J. Ho[7], A. Singleton[8], J. McClellan[5], M.-C. King[4,6], M. Wigler[1], K. Ye[9], J. Sebat[1]* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) Graduate Program in Genetics, State University of New York at Stony Brook, NY; 3) Department of Genetics, University of Chicago, Chicago, IL; 4) Department of Medicine, University of Washington, Seattle, WA; 5) Department of Psychiatry, University of Washington, Seattle, WA; 6) Department of Genome Sciences, University of Washington, Seattle, WA; 7) Yale School of Public Health, Yale University, New Haven, CT; 8) Neurogenetics Laboratory, National Institute on Aging, NIH, Bethesda, MD; 9) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY.

Copy number variants (CNVs) that are individually common in the population are likely to play a role in human traits and disease risk. However, the majority of common variants have not yet been discovered, and little is known about their distribution in different populations. Here we used a population-based CNV discovery method to detect common variation from microarray data. Intensity data from low-resolution and high-resolution microarray CGH platforms were examined from 2 populations, consisting of 2355 and 87 individuals respectively. A pair of oligonucleotide probes was sufficient to detect CNVs with minor allele frequencies of approximately 0.1 and greater. A total of 519 common CNVs were detected with a median size of 2369 bp. 190 CNVs identified were novel polymorphic sites not previously reported in humans and most variants differed strikingly in size and frequency than CNVs previously reported at the same sites. Population data were used to further elucidate patterns of structural variation at individual loci; for instance, in defining the fine-scale structures of individual CNV alleles in a complex region of the genome, and in determining allele frequencies and patterns of linkage disequilibrium (LD) for a subset of CNVs. This method represents an alternative strategy for CNV analysis of population data with greater power to ascertain common variation.

***APOM* sequence analysis in relation to plasma HDL-C levels.** *F. Waqar[1], F. Y. Demirci[1], A. S. Dressen[1], C. H. Bunker[2], R. F. Hamman[3], C. M. Kammerer[1], M. I. Kamboh[1]* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA; 3) Preventive Medicine and Biometrics, Univ Colorado Denver, Aurora, CO.

Atherosclerosis is the major cause of morbidity and mortality worldwide. High plasma concentrations of high density lipoprotein cholesterol (HDL-C) are known to protect against atherosclerosis. *APOM* is an apolipoprotein found predominantly in HDL and was reported to have anti-atherogenic functions. The purpose of this study was to examine the impact of *APOM* genetic variation on HDL-C levels in epidemiological samples of African Blacks and American non-Hispanic Whites (NHWs). The entire *APOM* (~2.3 kb) and flanking regions (~1 kb of 5 and ~0.5 kb of 3) were resequenced in selected individuals with HDL-C levels in the upper 5th percentile (47 NHWs and 48 Blacks) and the lower 5th percentile (48 NHWs and 47 Blacks) to identify both common and rare variants. A total of 25 single nucleotide substitutions were identified of which 9 were observed in both ethnic groups and 16 were previously unreported to the best of our knowledge. Of 15 variants identified in NHWs, 4 had minor allele frequency (MAF) of 5% and 11 MAF of <5%. In NHWs, 6 rare variants (MAF <5%) were unique to the low HDL group vs. 2 rare variants unique to the high HDL group. Of 19 variants identified in Blacks, 7 had MAF of 5% and 12 MAF of <5%. In Blacks, equal number of unique rare variants were observed in both the low and high HDL groups (4 in each group). None of the high or low HDL group-unique rare variants identified in Blacks were observed in NHWs. One of the 2 high HDL group-unique rare variants identified in NHWs was more commonly observed in Blacks and had higher MAF in high HDL group as compared to low HDL group. Three of the 6 low HDL group-unique rare variants identified in NHWs were also more commonly observed in Blacks and 2 had higher MAF in low HDL group as compared to high HDL group. Genotyping of these identified variants in the entire set of NHW (*n*=623) and Black (*n*=788) samples, that will help to determine the influence of *APOM* genetic variation on plasma HDL-C levels, is underway.

Genetic analysis of candidate genes for HDL-C in the Iranian INTERHEART study sample reveals associations consistent with European populations. *Z. Dastani[1,2], R. Do[1], M. R. M. Hasani[3], A. Montpetit[4], T. J. Hudson[4], S. Yusuf[5,6], J. Genest[1,2], J. C. Engert[1,2], S. S. Anand[5,6] on behalf of the INTERHEART Investigators* 1) Department of Human Genetics, McGill University, Montréal, QC, Canada; 2) Cardiovascular Genetics Laboratory, McGill University Health Centre, Montréal, QC, Canada; 3) Tehran University, Tehran, Iran; 4) McGill University and Genome Quebec Innovation Centre, McGill University, Montreal, QC, Canada; 5) Population Health Research Institute, McMaster University, Hamilton, ON, Canada; 6) Department of Medicine, McMaster University, Hamilton, ON, Canada.

Coronary artery disease (CAD) is the leading cause of death worldwide and a complex genetic disease. Both environmental and genetic factors lead to atherosclerosis and the subsequent manifestation of clinical disease. HDL-C has been demonstrated to be a strong risk factor for CAD. We examined the possible association between 103 candidate genes and HDL-C in an Iranian study sample. The samples are part of the INTERHEART genetics study that includes individuals enrolled from 154 centers in 52 countries for a global case/control study of acute MI. Previous work by our group established that the genetic background of Iranians was sufficiently different from either Europeans or Arabs that they should be analyzed separately. Several significant associations were found in Iranians. Consistent with previous reports, SNPs in the genes CETP, LPL, ABCA1, SCARB1, LIPC and APOA5 were associated with HDL cholesterol levels (all p values less than 0.007). One significant SNP (rs3764261) in CETP and another (rs18800588) in LIPC had been recently identified in genome wide association studies of HDL-C. In addition, several SNPs in CETP, and LPL were also associated with plasma levels of ApoA1 (p values less than 0.003). This study reveals consistent genetic association results between the INTERHEART Iranian sample and European populations for genes of major effect on HDL-C metabolism.

Complexities in Linkage Analysis for Modifier Genes. *W. Li[1], L. Sun[4,5,1], M. Corey[2,4], R. Dorfman[1], J. Zielenski[1], P. Durie[3], LJ. Strug[2,4]* 1) Genetics and Genomic Bio; 2) Child Health Evaluative Sci; 3) Phys and Exper Medicine; 4) Pub Health Sci; 5) and Statistics, U of Toronto, Toronto, Canada.

Introduction Classic Mendelian diseases e.g. Cystic Fibrosis (CF), are now the subject of modifier studies to understand variation such as disease severity. Blackman et al. (2006) studied Meconium Ileus (MI) in CF families, using non-parametric linkage (NPL) analysis, and found that CFTR, the CF gene, was a determinant of MI. Motivated by their findings, we used NPL and parametric linkage analysis (MMLS, Hodge et al, 1997) in a genome scan of our CF families. MMLS uses trait values robust to misspecification (excluding disease model (MOI)) and uses concordant (C) and discordant (D) MI families. NPL does not require MOI or trait values to be specified, but generally uses affecteds only. We show how NPL can provide confusing results in modifier gene studies. **Methods** We used GENEHUNTER for MMLS and NPL multipoint analyses of MI. 74 families with two CF children were analyzed; 17 of the CF-sibs were C for MI, while 57 were D. **Results** MMLS identified a novel MI locus, D12S1656 (HLOD=2.94), but at D7S522 in CFTR HLOD=0.88. Only 17 families were positive at D7S522, all of whose CF-sibs were C for MI. In contrast, NPL resulted in linkage at both D7S522 (Z=5.26) and D12S1656 (Z=2.11). Using a modified NPL approach that assesses *undersharing* among D sibships as evidence for MI-linkage, we observed *oversharing* (z=9.21) at D7S522 and *undersharing* (z=-2.19) at D12S1656. **Discussion** In modifier studies, siblings C for the modifier trait are C for the disease. Thus, NPL cannot attribute the linkage signal to one phenotype, unless NPL is modified to analyze the Ds for *undersharing* (e.g. D12S1656). Yet this modification cannot detect pleiotropy in modifier studies, because the same locus cannot show both *oversharing* and *undersharing* among the same sibships that are C for the disease but D for the modifier trait (e.g. D7S522). In contrast, parametric analysis can differentiate MI- from CF-linkage and we concluded that D7S522 is linked to CF not MI, and D12S1656 is a novel MI locus. **Conclusion** Care must be taken when interpreting results from standard NPL analysis in modifier gene studies.

Identification and Characterization of genes targeted by ETV6, a transcriptional repressor involved in childhood leukemia. *C. Malouf[1,2], S. Langlois[1], J. Larose[1], D. Sinnett[1,3]* 1) Research Center CHU Sainte-Justine, Montreal, Canada H3T 1C5; 2) Department of Biochemistry, University of Montreal, Montreal, Canada H3T 1J4; 3) Department of Pediatrics, University of Montreal, Montreal, Canada H3T 1C5.

Acute lymphoblastic leukemia (ALL) is a sporadic cancer accounting for about 25% of all pediatric cancer cases. Hemizygous deletions at chromosome 12p12-13 are observed in 26-47% of childhood pre-B ALL cases suggesting the presence of a tumour suppressor gene (TSG) at this locus. Accumulating evidence points to ETV6 as being the most probable TSG targeted by the deletions. ETV6 is a ubiquitously expressed ETS transcription factor with very few known targets. To understand ETV6s function, we previously conducted a microarray analysis that identified 87 genes co-modulated according to ETV6 expression. Among them, the expression of IL18, LUM, SPHK1, TP53 and PTGER4 was significantly correlated with that of ETV6 in leukemia patients. We propose that these genes are direct targets of ETV6. To address this hypothesis, we investigated the promoter activity of all 5 genes in function of ETV6 expression. First, we subcloned the proximal promoters into a gene reporter system (F. luciferase). The promoter constructs were used to perform transient co-transfections in Jurkat and HeLa cell lines with an ETV6 cDNA construct. This suggested that the promoter regions of all 5 genes are direct transcriptional targets of ETV6. These observations are supported by chromatin immunoprecipitation studies indicating an enrichment of ETV6 in the promoters of the 5 genes. Using mutant ETV6 constructs, we discovered that both functional domains, PD and ETS (protein and DNA interactions), are implicated in the transcriptional repression of the genes. This study shows that transcription of IL18, LUM, SPHK1, TP53 and PTGER4 is directly regulated by ETV6 through various molecular mechanisms. We are currently modulating the expression of these genes in leukemia cells to better understand the ETV6 regulation network. This work is another step towards the understanding of the functions of ETV6 and the impact of its inactivation in childhood leukemia.

MFG Maximized: Testing for Disease-Related Maternal-Fetal Genotype Incompatibilities Using the Software Package Mendel. *E. J. Childs[1], T. Ylisaukko-oja[2,3], J. A. Turunen[2], K. Rehnström[2], L. Peltonen[2,3], K. Lange[1], C. G. S. Palmer[1], J. S. Sinsheimer[1]* 1) University of California Los Angeles, Los Angeles, CA; 2) Biomedicum, Helsinki, Finland; 3) University of Helsinki, Finland.

Maternal-fetal genotype (MFG) incompatibility is a gene-gene interaction that adversely affects the developing fetus by inducing a maternal immunological attack, and thereby increase susceptibility to disease. Statistical methods for examining MFG incompatibility as a risk factor for disease using a nuclear family based candidate gene approach have been developed (Sinsheimer et al. 2003, Kraft et al., 2004; Hsieh et al, 2006). Because some of the families collected as part of a study can be large and complex, containing multiple generations and marriage loops, we extend the MFG test to allow for arbitrary family structures. We modify the MFG test by replacing the nuclear-family based mating type approach with Otts representation of a pedigree likelihood, and change the usual Mendelian transmission probability to include a maternal-fetal incompatibility parameter. This computationally tractable approach is implemented using Mendel 8.0 software (Lange et al. 2001), which has an option that allows the user to fit his or her own likelihood. This extension requires a slightly more stringent assumption of random mating that was not necessary in the earlier MFG tests. However the modified test allows for easy inclusion of offspring specific covariates such as offspring genetic risks, sex, age and environmental exposure effects through the penetrance function, to model multiallelic loci as well as biallelic loci, and to use quantitative phenotypes. As a side benefit, this implementation is less data specific and more user friendly than our earlier versions. To illustrate the implementation, we test for the effects of RHD incompatibility on autism spectrum disorders in a data set that includes extended families.

Common Genetic Variants on Chromosome 9p21 Predict Myocardial Injury after CABG Surgery. *K.-Y. Liu[1], J. D. Muehlschlegel[1], T. E. Perry[1], A. A. Fox[1], C. D. Collard[2], S. C. Body[1], S. K. Shernan[1]* 1) Dept Anesthesiology, Perioperative and Pain Medicine, Brigham & Women's Hosp, Boston, MA; 2) Baylor College of Medicine, Div. Cardiovascular Anesthesia, Texas Heart Institute, Houston, TX.

Coronary artery disease is the leading cause of death worldwide. Nearly one million people annually suffer perioperative myocardial injury (PMI) during or after surgery. A recent genome wide association study identified an association between Myocardial Infarction in non-surgical populations and common genetic variants on chromosome 9p21, adjacent to genes for the cyclin-dependent kinases *CDKN2A/B*. We hypothesized that these variants are also responsible for PMI after isolated primary Coronary Artery Bypass Graft (CABG) surgery.

In a prospective observational study of 877 Caucasian CABG patients at 2 US centers, we genotyped 61 haplotype-tagging SNPs, covering 436 kbp of the *CDKN2A* and *CDKN2B* genic region. A multivariable logistic model was used to adjust for previously identified clinical covariates of PMI including severity of coronary disease. Multiple testing of SNPs was corrected for with family-wise (FW) errors.

After CABG, 10% of patients developed PMI, defined as a peak postoperative cTnI greater 8.25 mcg/L. Among the 61 SNPs examined, rs10116277 (G) and rs6475606 (C) are in perfect linkage disequilibrium and describe a single haplotype that is significantly associated with PMI, after accounting for clinical covariates (multiplicative model OR=1.7, 95% CI 1.3-2.4, asymptotic $P=5.7x10^{-4}$, FW empirical P=0.039). The two SNPs are 87 and 72 kbp 5 of *CDKN2A* and *CDKN2B*, respectively. The GC haplotype frequencies for the overall cohort, cases and controls are 41%, 53% and 40%, respectively. Levels of postoperative cTnI clearly showed incrementally increase for each additional copy of the GC haplotype.

In conclusion, we have identified common genetic variants in 9p21 associated with PMI. The functional mechanisms remain to be elucidated.

.

Functional Characterization of Human BBS3 Mutations. *D. Y. Nishimura[1], C. C. Searby[2], V. C. Sheffield[1, 2]* 1) Dept Pediatrics, Univ Iowa, Iowa City, IA; 2) HHMI, Univ Iowa, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a genetically heterogenous autosomal recessive disorder with the primary clinical features of obesity, pigmented retinopathy, plydactyly, hypogenitalism, renal anomalies and learning disabilities. Associated features of BBS include diabetes mellitus, hypertension and congenital heart defects. There are currently 14 BBS genes known that map to 12 different chromosomes. Seven of the BBS genes have been demonstrated to form a complex that has been termed the BBSome. It has been postulated that the BBS proteins are involved in trafficking within cells and cilia. The BBS3 protein ARL6 is part of a gene family that plays a role in the trafficking process. We have utilized the ARPE19 cell line to examine the protein function of both wild type and mutant ARL6 proteins. Native expression of ARL6 has been documented at the centrosome, basal body and within primary cilia in ARPE19 cells. Expression constructs were utilized to express wild type and mutant ARL tagged proteins. All of the ARL6 mutants examined exhibit decreased protein stability and have a strikingly different subcellular localization pattern when compared to wild type ARL6. Therefore, we conclude that the known human mutations in BBS3 are likely to impact both the expression level of the protein as well as potentially interfere with normal cellular localization.

Studies of genome-wide association data support a genetic overlap between type 2 diabetes and prostate cancer.

K. S. Elliott[1], E. Zeggini[1], N. J. Timpson[2], N. W. Rayner[1], C. J. Groves[3], M. I. McCarthy[2] 1) WTCHG, Oxford, UK; 2) Univ of Bristol, UK; 3) OCDEM, Oxford, UK.

Recent genome-wide association (GWA) studies have identified and confirmed many type 2 diabetes (T2D) susceptibility genes. Several of these T2D loci (*PPARG, TCF7L2, CDKN2A, HHEX* and *IGF2BP2*) have known roles in cancer pathogenesis. Association of T2D and prostate cancer (PrCa) at alternate alleles of the same SNP in *HNF1B* support a shared genetic aetiology between the two diseases. Furthermore recent papers report association with T2D and PrCa at separate unassociated variants in the *JAZF1* gene. To formally assess this genetic relationship we compared T2D meta-analysed GWA data from the DIAGRAM Consortium with publicly available GWA PrCa data from the CGEMS project. We searched for more additional cases of reciprocal associations between T2D and PrCa and found subtle association ($p=0.003$, n=16,896 genes) with the opposite allele of the much reported PrCa allele of rs1447295 on 8q24 near the *MYC* gene. Secondly we looked for further instances of genes containing association with both T2D and PrCa and found a signficant over-representation of PrCa signals ($p<0.001$) in genes containing confirmed T2D variants compared to all autosomal genes $p=3x10^{-8}$: in all, six of these regions (*CDKAL1, NOTCH2, CAMK1D, JAZF1, HNF1B* and *KCNJ11*) contained such a PrCa signal. In the reciprocal analysis, there were just the two known T2D signals (*HNF1B* and *JAZF1*) (defined by $p<0.001$) in the 10 confirmed PrCa gene regions ($p=0.102$). For SNPs where there were data available for both diseases (n=393,763), when we looked SNP-by-SNP, genome-wide, for evidence of association signals ($p<0.01$) shared between T2D and PrCa, we found 73 instances representing 42 independent signals compared to an expectation of 8.3 under the null ($p<10^{-6}$). Of these 42 signals, 22 showed discordant and 20 showed concordant directions of association. The non-random co-localisation of T2D and PrCa signals at the genome-wide level indicates undefined overlaps in aetiological mechanisms. The over-representation of PrCa signals in T2D gene regions strengthens the evidence of an overlapping genetic basis for T2D and PrCa.

Genome-wide meta-analysis identify the genes in the regulation of HDL and triglyceride in inbred strains of mice. *Z. Su, M. Leduc, K. Darvishi, R. Korstanje, B. Paigen* The Jackson Laboratory, Bar Harbor, ME 04609.

Many quantitative trait loci (QTL) regulating plasma HDL and triglyceride (TG) concentrations have been identified from independent crosses between inbred strains of mice. We performed a meta-analysis using QTL controlling plasma levels of HDL and TG by assembling a collection of 150 QTL for HDL and 57 QTL for TG from 43 genome-wide scans. The non-redundant QTL were analyzed using the truncated product method. We divided the mouse genome into 100 bins of approximately equal size (~25-30 Mb), and QTL were assigned to the corresponding bins according to their peak locations. Our analysis revealed significant evidence (LOD4.3) of linkage for HDL to 35 regions and TG to 25 regions. For HDL, 9 genomic regions had LOD scores above 20 and 8 had LOD scores between 10-20. For TG, two regions on chromosomes 1 and 2 had LOD scores above 10. Some bins for HDL contained candidate genes for which considerable evidence existed from both studies in the mice and humans, leading us to conclude that these were the HDL QTL genes. Some of the bins with the highest LOD scores contained multiple QTL genes. QTL genes include *Apoa2* on Chr 1, *Apoa1* on Chr 9, *Lipg* on Chr 18, *Lcat* and *Galnt2* on Chr 8, and *Scarb1*, *Mvk*, and *Acads* on Chr 5. Evidence for these and other genes will be reviewed. Our results demonstrated the presence of numerous relatively significant regions that control plasma lipid levels in the mouse. The combinations of human-mouse comparative genomics, haplotyping of mouse strains, gene sequencing and expression studies will help to prioritize and identify the candidate genes.

Genetic Control of Gene Expression at the H1/H2 Locus on Chr17q21 in Patients with Coronary Artery Disease.

K. R. Fitch[1], M. Elashoff[1], S. E. Daniels[1], W. E. Kraus[2], E. R. Hauser[2], S. Rosenberg[1], J. A. Wingrove[1] 1) CardioDx, Inc., Palo Alto, CA; 2) Duke University, Durhan, NC.

Recent studies have shown that gene expression levels in circulating blood cells can be correlated with coronary artery disease (CAD) in patients. The extent to which genetics might influence this correlation however is not clear. We previously measured gene expression in 248 samples from the Duke University CATHGEN registry (a biorepository of clinical and angiographic data in the Duke Databank for Cardiovascular Disease) using 41K Human Whole Genome Agilent microarrays. To identify genes whose expression levels might vary due to underlying genetic differences, a statistical approach was used to discover loci with distinct bimodal expression patterns across the patient population. Eight array features were identified that showed discrete bimodal expression patterns, in addition to being correlated with the extent of CAD. Interestingly, all of these features mapped to 17q21. The ethnic distribution suggested that a genetic component might contribute to the bimodal pattern: 89% of African Americans fell within the lower expressed peak compared to 59% for Caucasians. Targeted genotyping of a subset of the CATHGEN patients (n=144) identified a SNP (rs9468) that was highly correlated with gene expression at these 8 loci (p value range 1.5E-09 to 2.81E-57). Further analysis revealed that rs9468 is linked to a previously described 900kb inversion, referred to as the H1/H2 locus, which is flanked by several copy number variable sites (CNVs). To investigate the relationship between the H1/H2 haplotype and gene expression, RT-PCR was used to assess both gene expression and copy number for 8 genes in the interval. The expression patterns of 4 genes in the central single copy portion (no CNVs) were independent of haplotype, whereas the expression of 4 genes that overlapped CNVs were highly associated with H1/H2 allele status. This is one of the first descriptions of gene expression changes associated with the H1/H2 locus at 17q21. Further studies will be needed to elucidate the molecular basis of the genetic influence on gene expression at this locus.

Using transmission rates in family-based genome-wide association studies to estimate platform-specific genotyping errors that cannot be detected by standard quality control filtering. *D. Fardo[1], R. Tanzi[2], L. Bertram[2], S. Weiss[3], D. Pinto[4], S. Scherer[4], C. Lange[1, 3]* 1) Dept Biostatistics, Harvard Sch Public Health, Boston, MA; 2) Dept of Neurology, Massachusetts General Hospital, Harvard Medical School, Charlestown, MA; 3) Channing Laboratory, Harvard Medical School, Boston, MA; 4) Centre for Applied Genomics, University of Toronto, Toronto.

An intuitive way to assess the genotyping error rate of genome-wide SNP chips that will persist in the data, even after strict data quality control (QC) filters have been applied, is to utilize family samples that have been genotyped on the same platform. Since the null hypothesis of no association will be true for the vast majority of SNPs on a chip, the number of SNPs for which the minor allele is over-transmitted should be about the same as the number of SNPs for which the major allele is over-transmitted. If the two transmission numbers are very different, this can be indicative of genotyping errors at a platform-wide level after QC filtering or of differential missing genotypes. In this communication, we provide guidelines on how to assess the magnitude of the underlying platform-wide genotyping error based on the transmission ratio for a given number of genotyped SNPs and given the study sample size. The dependence of the transmission ratio on the genotyping error and the percentage of missing genotypes is examined. We illustrate the importance of the transmission ratio as a QC assessment tool in genome-wide association studies by estimating the systematic genotyping error of some of the most commonly used genotyping platforms (Affymetrix 20K, Affymetrix 100K, Affymetrix 500K, Perlegen 650K and Illumina 550K).

Multivariate genome-wide linkage scan of age at menarche and contemporaneous skeletal age and body mass in healthy girls from the Fels Longitudinal Study. *B. Towne[1], J. Blangero[2], S. A. Czerwinski[1], E. W. Demerath[3], D. L. Duren[1], K. D. Williams[1], T. D. Dyer[2], S. A. Cole[2], R. J. Sherwood[1], W. C. Chumlea[1], R. M. Siervogel[1]* 1) Wright State University Boonshoft School of Medicine, Dayton, OH; 2) Southwest Foundation for Biomedical Research, San Antonio, TX; 3) University of Minnesota, Minneapolis, MN.

A complex series of orchestrated processes comprise normal growth and development, and different measures of growth and development are often correlated. We used variance-components methods implemented in SOLAR (Almasy and Blangero, 1998) to conduct univariate and multivariate genome-wide linkage scans for QTL influencing age at menarche (AAM) and contemporaneous skeletal age (SA) and body mass index (BMI) in 321 healthy girls from 61 families in the Fels Longitudinal Study. AAM data were obtained from questionnaires administered at exams conducted regularly throughout childhood, estimates of SA were made from hand-wrist radiographs using the FELS method (Roche et al., 1988), and BMI was calculated as kg/m^2. SA and BMI at AAM were derived by linear interpolation using data from the two exams most closely bracketing AAM. The heritablities of AAM, SA@AAM, and BMI@AAM were all significant: 0.52 0.16, 0.80 0.14, and 0.66 0.18, respectively. The highest multipoint LOD scores for each trait considered individually were: AAM LOD = 1.47 on chromosome 11 at 72 cM, SA@AAM LOD = 1.25 on chromosome 18 at 103 cM, and BMI@AAM LOD = 2.21 on chromosome 3 at 42 cM. A multivariate linkage analysis of all three traits considered simultaneously, however, revealed a significant LOD score of 3.51 on chromosome 7p at 39 cM, and a suggestive LOD score of 2.39 on chromosome 10q at 101 cM, two chromosomal regions not strongly implicated in univariate linkage analyses. This study illustrates the power of multivariate genome scans of correlated measures to uncover QTL harboring genes that influence sets of related traits, in this instance genes that impact a suite of related traits pertaining to the timing and tempo of growth and maturational events during female pubertal development. Supported by NIH grants R01HD12252, R01HD36342, and R37MH59490.

A Tangled Web: Exclusive Patent Rights and Genetic Testing for Long QT Syndrome. *M. Angrist, S. Chandrasekharan, C. Heaney, R. Cook-Deegan* Institute for Genome Sciences & Policy, Duke University, Durham, NC.

What effects do gene patents have on access to and quality of genetic testing? We consider Long QT syndrome, which causes the hearts electrical system to malfunction and whose symptoms may include fainting, seizures, arrhythmia and cardiac death. Some 70% of LQTS is due to mutations in 5 genes; knowing the mutant gene can have a major impact on therapy. Patent rights to the 5 genes are exclusively licensed to PGx Health (PGx). In 2007 a reference lab CEO and a medical geneticist testified before Congress that LQTS patent exclusivity is anti-competitive and quality has suffered. The geneticist said that PGx's testing has on occasion been incomplete and/or inaccurate. Both contended that the $5400 test is overpriced and is not routinely covered by 3rd-party payers. They charged that there was a 2-year period when commercial genetic testing was not available and patients may have died as a result. The reference lab said it tried to sublicense the LQTS patents and was rebuffed by PGx and prior licensees. PGxs parent firm, Clinical Data (CLDA), maintained that only through exclusive licensing has it been able to invest in and develop accurate and safe genetic testing for LQTS. CLDA said it works closely with academics to ensure that its test is state-of-the-art. It said it requires at least 2 clear analyses for every test and that all positives are confirmed. Its LQTS test is covered by Medicare and many private insurers and state Medicaid programs. CLDA also suggested the complaining lab was being disingenuous since said lab had approached CLDA about buying its lab unit and recently obtained an exclusive license to another LQTS gene. After interviewing the major stakeholders, we conclude that commercial LQTS testing is tightly linked to gene patents and licenses. The sole provider model, as embodied by PGx, results in other labs being excluded. Exclusive licensing of different genes to different labs can lead to cross-licensing or litigation. Disparate payer policies can obstruct access to genetic testing when contracts do not cover needy patients. This can happen even without patenting, but patents can exacerbate the problem by granting exclusive rights.

Clinical and molecular analysis of PTEN promoter variant -1084C/T in 22 families with PTEN Hamartoma Tumor Syndrome (PHTS): mutation-specific genetic counseling. *E. Edelman, C. Eng* Genomic Med Inst, Cleveland Clinic Fndn, Cleveland, OH.

PHTS comprises several different syndromes such as Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BRRS) characterized by PTEN mutations and a risk of breast and thyroid cancers. In ~10% of CS, a mutation is identified in the PTEN promoter. PTEN promoter variant of unknown significance (VUS) -1084C/T was previously reported in 3/751 (0.4%) white population controls. We report on a series of 22 families with -1084C/T and otherwise normal PTEN sequence. 12/18 informative probands met clinical diagnostic criteria for CS/BRRS. The remaining families had some PHTS features but did not meet full criteria. All 15 females had breast involvement of which 14 were carcinoma. Patients with -1084C/T were more likely to have breast cancer (p=0.0008) and less likely to have macrocephaly (p=0.0001), benign thyroid disease (p=0.0001), and GI (p=0.034) and cutaneous hamartomas (p=0.0001) compared to other CS/BRRS without this VUS. Interestingly, 3 patients were reported to have papillary thyroid carcinoma rather than the typical follicular type in PHTS. Compared to the general population, patients with -1084C/T were more likely to have macrocephaly (p=0.0001), breast cancer (p=0.0001), and lipomas (p=0.0018). PTEN downstream dysfunction was characterized by decreased PTEN protein and/or increased P-Akt and P-MAPK. Family analysis was possible in 2 cases: in 1, the VUS was de novo in the context of clinically unaffected parents, and in another, inherited from an unaffected father. -1084 is highly conserved among species and results in reduced binding of p53 to the PTEN promoter. Therefore, our integrative clinical, genetic and functional molecular analyses suggest that -1084C/T is a pathogenic promoter mutation associated with a particularly high risk of breast cancer compared to all intragenic PTEN mutations. Additionally, if -1084C/T patients develop thyroid cancer, it tends to be papillary instead of the more typical PHTS-associated follicular histology. Further work along these lines will garner accurate risk data to allow for mutation-specific genetic counseling.

Gene Expression Responses to Endoplasmic Reticulum (ER) Stress in Humans. *R. S. Spielman[1], B. A. Dombroski[1], W. M. Ankener[1], K. A. Chapman[2], K. G. Ewens[1]* 1) Dept of Genetics, Univ Pennsylvania Sch Medicine, Philadelphia, PA; 2) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

The cellular response to endoplasmic reticulum (ER) stress is a key process in cell survival. The responses, including changes in gene expression, are crucial to cell function; if ER homeostasis cannot be restored, the cell undergoes apoptotic cell death. Identifying determinants of genetic variation in ER stress response will contribute greatly to understanding the process and its role in health and disease. Here we address two questions: 1. Which genes show the greatest expression responses to ER stress, and 2. Which expression responses show heritable variation? The experiments were carried out with lymphoblastoid cell lines from 14 Caucasian and 12 African American monozygotic (MZ) twin pairs. We induced ER stress with thapsigargin or tunicamycin and analyzed gene expression with Affymetrix U133 Plus 2.0 arrays. Among the 986 transcripts with response greater than 1.5-fold, some were previously known to be involved in ER stress; examples are DDIT3/CHOP (fold-change 3.2), CEBP/B (5.3) and TRIB3 (4.6). In addition, there were strong expression responses by some genes not known to be ER stress responsive, e.g., INHBE (14.4 fold) and VLDLR (10.9). The changes in more than 700 of the 986 transcripts were statistically significant even after Bonferroni correction. Some, but not all, of the new findings can be accommodated within current understanding of ER stress pathways. For assessment of heritable variation, the gene expression changes in six of the Caucasian MZ twin pairs treated with tunicamycin were analyzed by analysis of variance (ANOVA). From the ANOVA we also calculated the intraclass correlation coefficient (ICC). We used the ICC to rank the genes for heritable variation in expression response to ER stress. Among those with high ICC were several known to be involved in ER stress: IRE1/ERN1 (ICC= 0.82), HERPUD1 (0.97), ATF4 (0.89), and ATF3 (0.86). There are also genes with high ICC that have not previously been implicated in ER stress. This analysis provides evidence for genetic variation in gene expression response to ER stress.

Capture-recapture methods for counting copy-number variants in the human genome. *I. Ionita-Laza, C. Lange, N. Laird* Dept Biostatistics, Harvard Univ, Boston, MA.

Copy-number variation represents a substantial source of genetic variation and has recently emerged as a potential contributor to disease risk. The number of common copy-number variants and their frequencies are of great interest for human genetic applications; they are currently unknown, and subject to speculation. In this paper we provide a method to estimate the number of common copy-number variants, assuming high-quality data is available on a small set of at least two individuals. Our method is related to capture-recapture techniques commonly used in ecology to estimate the size of a particular species. An application of the methodology to paired-end sequence data on two individuals illustrates that while the number of rare copy-number variants can be very large, the number of common copy-number variants is small and, surprisingly, can be estimated from data on a few individuals. The method is particularly relevant in the context of the ``1000 Genomes Project'' which will produce deep sequence data for two trios by the end of the year. When data on many more individuals is available, we present methodology that provides estimates of the number of new variants to be discovered in a new dataset of a specified size.

Frequency of Copy Number Variants (CNVs) in Ashkenazi Jewish Parkinsons disease Patients and Controls. *M. Verbitsky[1], S. Kisselev[2], M. Wei[2], H. Mejia-Santana[4], H. Andrews[4,5,6], S. Fahn[7], J. Lee[4], K. Marder[1,4,5,7], L. N. Clark[1,2,3]* 1) Taub Institute, Columbia University, New York, NY; 2) Department of Pathology, Columbia University, New York, NY; 3) Center for Human Genetics, Columbia University, New York, NY; 4) G. H. Sergievsky Center, Columbia University, New York, NY; 5) Department of Psychiatry, Columbia University, New York, NY; 6) Department of Statistics, Columbia University, New York, NY; 7) Department of Neurology, Columbia University, New York, NY.

Studies of CNVs affecting the SNCA (PARK1) and Parkin (PARK2) loci in familial Parkinsons disease (PD) have shown that CNVs at genes associated with PD can cause or modify the disease phenotype. A recent study (Simon-Sanchez et al, 2008), identified CNVs by analyzing a dataset from a genome wide SNP scan in a cohort of unique and unrelated individuals comprised of PD patients and controls from a Caucasian population. CNVs in both PD patients and control subjects were detected in PARK2. However, no structural alterations were observed at known PD loci including PARK1, DJ_1 (PARK7), PINK1 (PARK6) or LRRK2 (PARK8). In the current study we set out to find CNVs that may contribute to PD susceptibility by performing a genome-wide scan of CNVs in early onset PD (EOPD) patients and controls from a genetically isolated population, Ashkenazi Jews (AJ). Such population is more likely to be enriched for founder mutations, increasing the power of a case-control study in revealing susceptibility alleles. We used Illumina Human610-Quadv1.0 DNA BeadChips, which include 550,000 evenly spaced tag SNPs derived from HapMap data in addition to approximately 60,000 additional markers that specifically target regions known or likely to contain CNVs. A total of 200 subjects that includes 100 AJ EOPD patients and 100 AJ controls were genotyped. PD patients and controls were a subset of participants in the NY PD AJ study (NS050487). All patients and controls have been previously evaluated for mutations in identified PD susceptibility genes including Parkin, DJ_1, PINK1, GBA and LRRK2. Biostatistical analysis of the data is currently in progress and its results will be presented in the study.

Cytogenetic characterization of a dermatofibrosarcoma protuberans with a complex karyotype including an unbalanced der(22)t(17;22)(q22;q13). *N. Christacos[1], T. Tchen[1], J. Jahn[1], J. Scheerle[1], J. Meck[1], J. Mize[2], F. Wodajo[3], P. Mowrey[1], A. Meloni-Ehrig[1]* 1) Quest Diagnostics, Nichols Institute, Chantilly, VA; 2) Inova Fairfax Hospital Lab, Falls Church, VA; 3) Inova Fairfax Hospital and Hospital for Children, Fairfax, VA.

We report a unique case with an unbalanced t(17;22)(q22;q13) in a 51 year old female with the clinical indication of sarcoma of the upper left back. The pathology report suggested findings most consistent with a high grade sarcoma although a dermatofibrosarcoma protuberans (DFSP) with sarcomatous transformation had been considered. Conventional G-band chromosome analysis was performed and revealed a complex abnormal karyotype including two copies of a derivative chromosome 22 arising from a translocation between chromosomes 17 and 22 [der(22)t(17;22)(q22;q13)]. Additional FISH studies were performed on metaphase cells using the LSI 22 (BCR) probe and probes to the subtelomeric region of the long arm (q) of chromosome 17 and confirmed the presence of two copies of the derivative chromosome 22. Interestingly, the FISH studies also identified a cryptic rearrangement of chromosome 9 as probes for the subtelomeric regions of the short and long arms of chromosome 9 are included with the subtelomeric probe for 17q. The t(17;22) has been reported in cases of DFSP; however, the majority of DFSP cases reported have shown excess of sequences of chromosomes 17 and 22 usually in the form of supernumerary ring chromosomes or marker chromosomes. Fusion of the COL1A1 gene at 17q21~q22 and the PDGFB gene at 22q13 has been shown to occur in both the ring and translocated chromosomes. Thus, these cytogenetic findings were crucial to providing the specific diagnosis of DFSP with sarcomatous transformation in this patient. This case demonstrates the importance of conventional cytogenetic analysis as well as molecular cytogenetic FISH studies in providing critical information to help arrive at an accurate diagnosis and therefore determining treatment and clinical prognosis.

Accuracy of Genome-Wide Imputation of Untyped Markers and Impacts on Statistical Power for Association Studies. *K. Hao, E. Schadt* Genetics, Rosetta Inpharmatics, Seattle, WA.

Genotyping arrays employed by WGAS only assay a small proportion of SNPs in the human genome. In addition, various SNP arrays assay different sets of SNPs, causing challenges in comparing results and meta-analysis. Genome-wide imputation of untyped markers addresses these issues in a direct fashion. 384 Caucasian American liver donors were genotyped using Ilmn650Y arrays. In parallel, 200 Caucasian American and 200 African American subjects were genotyped using the Affymetrix SNP 6.0 array. We compared two genotype imputation methods: MACH and BEAGLE, and found them to perform similarly with respect to imputation accuracy. The Affx6.0 and Ilmn650Y results were comparable, and they give better imputation results than Affx500K or Ilmn317K sets. In Caucasians, 90% of the 2.5 million HapMap release22 SNPs were imputed at 98.5% accuracy. As expected, imputation of poorly tagged SNPs (untyped SNPs in weak LD with typed markers) was not as successful. It was more challenging to impute genotypes in the African American, which is likely due to (1) shorter LD blocks and (2) populations admixture. To address issue (2), we pooled HapMap CEU and YRI data as an imputation reference set, which greatly improved overall performance. 80% of the HapMap SNPs were imputed at 97.5% accuracy in the African American. We measure ~40,000 liver mRNA expression traits for the liver donors and conducted eQTL mapping using imputed SNPs. The ~40,000 phenotypes scored provide a path to empirically determine how the power to detect associations is affected by using imputed SNPs vs. assayed SNPs only. That is, at a fixed false discovery rate, the number of cis-eQTL discoveries detected by various methods can be interpreted as their relative statistical power in GWAS. We find that imputation improves power by 5% for studies using the Ilmn317K array, but decreases power by 8% for Ilmn650Y studies. This shift in power is likely due to the dense SNP arrays already covering most of the genetic variation in a population, so that adding more markers via imputation results in little gain in genetic coverage, but a significant gain in the multiple testing penalty.

Screening and replication using the same data set: Testing strategies for family-based studies in which all probands are affected. *A. Murphy*[1,2,3], *S. T. Weiss*[1,2,3], *C. Lange*[1,3,4] 1) Department of Medicine, Harvard Medical School, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 3) Center for Genomic Medicine, Brigham and Women's Hospital, Boston, MA; 4) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

For genome-wide association studies in family-based designs, we propose a powerful two-stage testing strategy that can be applied in situations in which parent-offspring trio data are available and all offspring are affected with the trait or disease under study . In the first step of the testing strategy, we construct estimators of genetic effect size in the completely ascertained sample of affected offspring and their parents that are statistically independent of the family-based association/transmission disequilibrium tests (FBATs/TDTs) calculated in the second step of the testing strategy. For each marker, the genetic effect is estimated(without requiring an estimate of the SNP allele frequency) and the conditional power of the corresponding FBAT/TDT is computed. Based on the power estimates, a weighted Bonferroni procedure assigns an individually adjusted significance level to each SNP. In the second stage, the SNPs are tested with the FBAT/TDT statistic at the individually adjusted significance levels. Using simulation studies for scenarios with up to 1,000,000 SNPs, varying allele frequencies and genetic effect sizes, the power of the strategy is compared to standard methodology (e.g., FBATs/TDTs with Bonferroni correction). In all considered situations, the proposed testing strategy demonstrates substantial power increases over the standard approach, even when the true genetic model is unknown and must be selected based on the conditional power estimates. The practical relevance of our methodology is illustrated by an application to a genome-wide association study for childhood asthma, in which we detect two markers meeting genome-wide significance that would not have been detected using standard methodology. Funding: U01 HL065899-06, U01 HL065899 and P01 HL083069.

Effects of stage of reproduction, nutrient status, and genes on serum homocysteine in reproductive age women. *S. K. Shapira[1], A. Yesupriya[2], J. Robitaille[1], R. Fisk Green[1], H. C. Hamner[1], J. E. Kimmons[3], K. S. Crider[1]* 1) NCBDDD, CDC, Atlanta, GA; 2) NOPHG, CDC, Atlanta, GA; 3) NCCDPHP, CDC, Atlanta, GA.

Elevated serum homocysteine (Hcy) has been associated with adverse pregnancy outcomes, such as preterm birth, stillbirth, and low birth weight, as well as with cardiovascular disease and stroke. To evaluate genetic and environmental factors affecting Hcy, our study utilized survey data of 2,012 reproductive age women (17-44 years) from the NHANES III DNA Bank (1991-94). Associations between genetic variants (MTHFR 1298A-C, 677C-T, and 116C-T, MTRR 66A-G, and CBS 844ins68) and Hcy were tested using linear regression models that adjusted for demographic, reproductive, dietary, and environmental factors. To examine possible effect modification, models were stratified by race/ethnicity, reproductive stage in relation to pregnancy (never, currently, 2 years, >2 years), and total folate intake (low vs. adequate, accounting for both folic acid from vitamins and food folate). Significant associations with mean Hcy were detected only for MTHFR 677C-T. Mean Hcy among TT women was higher compared with CC women (9.5 vs.7.1 mol/L, $p<0.001$). When stratified by total folate intake, TT women with low intake had higher mean Hcy, compared with CC women (16.7 vs. 7.6 mol/L, $p<0.001$), while TT and CC women with adequate intake had similar mean Hcy (7.1 vs. 6.8 mol/L, $p=0.44$). Mean Hcy differed by genotype (TT vs. CC) for whites (17.9 vs. 7.7 mol/L, $p=0.003$) and Mexican Americans (8.8 vs. 6.5 mol/L, $p=0.006$) with low total folate intake, although the difference was smaller for the latter. Models could not be stratified for blacks because of the low TT prevalence. A similar genotype effect was seen for women with low total folate intake in all reproductive stages except currently pregnant, where TT women had lower mean Hcy compared with CC women (4.9 vs. 7.0 mol/L, $p=0.003$). These results suggest that the effect of total folate intake on the association between MTHFR 677C-T and Hcy is modulated by stage of reproduction and race/ethnicity. Therefore, adequate total folate intake appears to be important for reproductive age women, particularly those with the MTHFR 677TT genotype.

Single nucleotide polymorphisms (SNPs) in DNA repair pathway genes may play a role in breast cancer. *M. E. Sehl, L. R. Langer, J. C. Papp, L. Kwan, J. L. Seldon, G. Arellano, J. Reiss, E. F. Reed, S. Dandekar, Y. Korin, J. S. Sinsheimer, Z. F. Zhang, P. A. Ganz* University of California, Los Angeles.

DNA damage recognition and repair is well known to play a major role in cancer risk. We investigated 104 SNPs in 17 genes whose protein products are involved in double strand break repair (DSBR). We used a case-control study design involving 399 participants of the UCLA Familial Cancer Registry. The cases were diagnosed with either breast cancer alone or with both breast and ovarian cancer; and the controls had similar familial risk of breast cancer and were well-matched for demographic and environmental risk factors for breast cancer. Log additive and dominant models were used to investigate associations between SNPs and breast cancer, with models adjusted for age, education and Ashkenazi Jewish ancestry. Haplotype analyses were carried out on genes in which more than one SNP was found to be significantly associated with breast cancer. We found that 12 of the polymorphisms from 8 genes (XRCC4, XRCC2, NBS1, RAD21, TP53, BRIP1, and ZNF350) are associated with breast or breast and ovarian cancer. Most notable were three SNPs located in introns of RAD21: rs16888927 (aOR 0.51, p=0.004), rs16888997 (aOR 0.56, p = 0.002) and rs16889040 (aOR 0.013, p = 0.013), using dominant genetic models. When only those participants with known BRCA1 and BRCA2 status (N=306) were included, these three SNPs remained significant in both log additive and dominant models adjusted for BRCA1 and BRCA2 status. Using a false discovery rate of 15%, we find that 3 SNPs from RAD21 and 1 from BRIP remained significant after adjusting for multiple testing. There was an association found between the C-A-A haplotype for RAD21 (aOR 1.6, p = 0.0068), although this did not surpass the level of significance of the effects of single SNPs in this region alone. We conclude that SNPs within or near a number of DSBR DNA repair pathway genes are associated with breast cancer in individuals from a high-risk population, suggesting that other genes in the DSBR pathway in addition to BRCA1 and BRCA2 may affect breast cancer risk.

Complexity at breakpoint junctions of 1p36 interstitial deletions indicates mechanisms of formation. *M. Gajecka*[1], *A. J. Gentles*[2], *K. L. Mackay*[1], *C. Glotzbach*[1], *L. G. Shaffer*[1] 1) School of Molecular Biosciences, Washington State University, Spokane, WA; 2) School of Medicine, Stanford University, Stanford, CA.

Deletions of 1p36 occur in approximately 1 in 5,000 newborns. To date, we have ascertained 145 cases with monosomy 1p36, representing four possible classes of rearrangements: pure terminal deletions, interstitial deletions, unbalanced translocations, and complex rearrangements. For each individual, the type of rearrangement, deletion size, and parental origin of the deletion was determined using array CGH, FISH and genotyping. To further understand the mechanisms for chromosome rearrangements, we investigated the breakpoint junctions at the sequence level in more than 20% of our cases. Here we present the breakpoint junction evaluations in 18 interstitial deletions. Among these cases, in addition to the major deletion, further events were identified, including small deletions, duplications, and triplications, insertions of both unidentified and known sequences, and inversions at the breakpoint junctions. Our results show high complexity at the breakpoint junctions and indicate involvement of multiple mechanisms in the DNA breakage and repair process during rearrangement formation. Although the causes of the chromosomal breaks that initiate the interstitial deletion formation are unknown, the joining mechanisms are consistent with features of the nonhomologous end-joining (NHEJ) pathway.

Association Mapping of Brain Gene Expression Regulators. *C. Liu[1], L. Cheng[1], JA. Badner[1], DW. Craig[3], M. Josephson[3], SL. Christian[2], ES. Gershon[1,2]* 1) Department of Psychiatry, The Univ Chicago, Chicago, IL. 60637; 2) Department of Human Genetics, The University of Chicago, Chicago, IL 60637; 3) The Translational Genomic Research Institute, Phoenix, AZ 85004.

Gene expression variation may be involved in complex disease risk. Linkage and association methods have been used to map expression regulatory elements in the genome. We performed a genome-wide SNP based association mapping of gene expression regulators, using DNA from 135 specimens in the Stanley Medical Research Institute (SMRI) brain collection of Caucasian brain samples. Affymetrix 5.0 was used to obtain genotypes. Gene expression data of prefrontal cortex was produced using Affymetrix Human Genome U133A arrays, and published by Altar et al. Expression of 3431 transcript probes with variable expression was correlated with high quality genotypes of 238389 SNPs with minor allele frequency no less than 0.1. Association tests were performed separately in cis- and trans- candidate regions. We used the SOLAR program to estimate a sporadic model for the expression data of each probe incorporating covariates provided by SMRI, including age, gender, brain pH, and others. The residuals were the phenotypes for association analysis. We then used PLINK to perform linear regression analysis to test for quantitative trait locus association between expression residuals and SNP genotypes. The Wald p-value and permutation were used to evaluate the significance of association. All region-wide/genome-wide significant cis and trans findings were also analyzed for additive and epistatic interactions. 757 cis- associations had $p < 0.05$ with permutation corrected for region-wide tests. 114 of these are significant after Bonferroni correction for the phenotypes that have been tested. Cis- regulations of genes HBS1L, RPS26, ITGB3BP, and C9orf95 replicate previous findings. 158 trans- associations showed association after permutation correction for the SNPs tested. But none survived correction for the number of expression phenotypes. Potential master regulators, epistatic and additive interactions were also observed. The identified expression regulators were further explored in disease association data.

A test for genetic association that incorporates information from other sources. *J. Wang, S. Shete* Epidemiology, UT MD Anderson Cancer Center, Houston, TX.

To assess genetic association between single-nucleotide polymorphisms (SNPs) and disease status, the logistic regression model or generalized linear model is typically employed. However, information from other resources could also be used to construct a more powerful test, such as information from markers from the same genetic region. To develop a more powerful statistical test for genetic association studies, we quantified the significance of the information from these other sources, and integrated it to the standard regression approaches that use cases and controls. Results from simulation studies and real disease studies demonstrate that the new approach is more powerful than the traditional logistic regression model. And the type I error probabilities of our approach were also well controlled. For our approach, we derived exact formulas to compute p-values. Although the exact p-values are simple and straightforward to compute and interpret, the derivations of underlying assumptions might make the exact p-values based on the explicit formulas either too conservative or too liberal. Therefore, we also developed an approach to estimate empirical p-values using a re-sampling procedure.

A variant in the telomerase RNA component is associated with short telomere length. *O. T. Njajou[1], L. Pawlikowska[1], D. S. Evans[1], N. Bendjalali[1], P.-Y. Kwok[1], E. H. Blackburn[1], A. B. Newman[2], G. Tranah[1], M. Nalls[3], S. Kritchevsky[4], T. B. Harris[3], R. M. Cawthon[5], W.-C. Hsueh[1] For the Health ABC Study* 1) University of California, San Francisco, CA; 2) University of Pittsburgh, Pittsburgh, PA; 3) NIA, Bethesda, MD; 4) Wake Forest University, Winston-Salem, NC; 5) University of Utah, Utah, UT.

Telomeres are DNA capping structures protecting the ends of mammalian chromosomes, which shorten as the cell divides. This shortening is compensated for by the enzyme telomerase. We evaluated the association of polymorphisms in the telomerase RNA component (TERC) with telomere length (TL) in 3075 participants in the Health ABC study (age range: 68-80 years, 51% female, 1794 white and 1281 black). Five variants were identified in TERC by sequence analysis covering the entire gene of 451 bp. From these, only one (rs2293607, G/A) had a minor allele frequency (MAF) > 5%, (A allele, MAF = 0.24 in white and 0.07 in black). Telomere length was measured by quantitative PCR (qPCR) method. Genotyping and TL measurements in leukocytes were successful in 2620 individuals (1542 white and 1078 black). Modeling of the association of SNP genotype with TL by analysis of variance and linear regression adjusting for age, sex, recruitment sites and race revealed that a dominant model for the minor allele was a best fit to the data. Around 42% (655) of white and 14% (148) of black participants were carriers of the A allele. The mean TL in kilo base-pairs (kbp) was significantly shorter in carriers of the A allele compared to non-carriers among whites; 4.86 0.04 kbp vs. 4.69 0.05 kbp (P = 0.009); but not among blacks; 4.88 0.04 kbp vs. 4.84 0.1 kbp (P = 0.7). There was a significant association between TL and the AA/AG genotypes in whites (adjusted beta = -0.17 + 0.06 Kbp, P = 0.005), but not in blacks (adjusted beta = -0.04 + 0.10 Kbp, P = 0.7). Our results in blacks may be underpowered due to the low frequency (0.07) of the A allele in this population. We found that a common variant in the TERC gene is associated with telomere length, which suggests that TERC may play a role in telomere homeostasis in normal blood cells.

SNPs in Ly9 gene observed no association with rheumatoid arthritis in Japanese population. *A. Suzuki[1], Y. Kochi[1], E. Kanno[1], K. Kobayashi[1], R. Yamada[1, 2], K. Yamamoto[1, 3]* 1) Ctr for Genomic Med, Kanagawa, RIKEN, Yokohama City, Japan Akari Suzuki; 2) Laboratory of Functional Genomics and Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 3) Dept of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

Multiple studies have been reported that disease-associated human single nucleotide polymorphisms (SNPs) were detected. These studies indicated an important factor regarding genetic factors of RA and autoimmune diseases; some of the RA-susceptible polymorphisms also increase the risks of other autoimmune diseases as reported for e.g., STAT4 (ref1) and FCRL3 (ref2) with RA and SLE. Recently, it was also reported that three SNPs, rs509749, rs3817407 and rs1333065 in Ly9 which is one of the SLAM gene family, were associated with systemic lupus erythematosus (SLE). We investigated allele frequencies of 3SNPs in Ly9 using 830 RA patients and 658controls. 3SNPs in Ly9 had no association in a Japanese population (rs509749; P=0.3266, rs3817407; P=0.0746, rs1333065; P=0.8329). Furthermore, we selected 9 tagging-SNPs in Ly9 from the HapMap project uging the method of Gabriel et.al. to cover densely. The most significant SNP was rs4017732 (P=0.0005, OR=0.66) and the others were not significantly different (P>0.01). We performed replication study using independent case and control set, however we could not validate the association of the rs4017732 (P>0.01). 1) Remmers, E.F. et al. N Engl J Med 357, 977-86 (2007). 2) Kochi, Y. et al. Nat Genet 37, 478-85 (2005). 3) de Bakker, P.I. et al. Nat Genet 37, 1217-23 (2005).

A Text-Based Strategy to Identify Common Pathways In Regions Implicated by Association Studies. *S. Raychaudhuri[1,2,3], R. M. Plenge[1,2], M. J. Daly[1,3]* 1) Broad Institute, Cambridge, MA; 2) Division of Rheumatology, Brigham and Women's Hospital, Boston, MA; 3) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA.

Genome-wide association (GWA) studies for diseases and clinical phenotypes have begun to identify associated variants in multiple regions of the genome. To deliver on the promise that these studies will provide insight into the biological mechanisms of disease however, we need to identify the specific genes and functional pathways implicated by disease-associated variants. One approach is to identify the key relationships between genes from associated regions. Here we describe a statistical method, *Gene Relationships Among Implicated Loci* (GRAIL), which assesses the degree of relatedness between genes in regions implicated by GWA studies using published text within PubMed Abstracts. We apply GRAIL to the results of recent successful GWA meta-analyses: 19 SNPs associated to serum lipid levels and 42 SNPs associated with height. In each case, GRAIL identifies highly significant subsets of related genes within the regions implicated by these SNPs and additionally identifies keywords that describe the relevant functions that significantly link genes from distinct associated regions. We then further test the ability of this text-based method to prioritize regions for replication studies, proposing that those regions that include genes that are functionally related to genes in other regions would be enriched for true positive associations. In examining top 74 results from a recent Crohns disease meta-analysis, GRAIL identifies a subset of regions containing genes with significantly more relationships to genes in other associated regions than expected by chance. These regions were in fact enriched (p = 0.001) for true positive associations in a subsequent replication effort, where the 10 out of 11 highest scoring regions replicate. This demonstrates the clear ability of GRAIL to identify relevant functional connections between novel associated regions in an objective, automated fashion. We will further demonstrate the ability of GRAIL to interpret copy number variant regions in autism.

TNFA -308G>A promoter polymorphism disease severity, but not response to anti-TNF therapy in patients with rheumatoid arthritis. *M. Coenen[1], E. Toonen[1], J. Fransen[2], W. Kievit[2], A. de Brouwer[1], T. Radstake[2], C. de Gendt[3], T. Jansen[4], H. Scheffer[1], P. van Riel[2], P. Barrera[2], B. Franke[1], the DREAM consortium* 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, the Netherlands; 2) Department of Rheumatology, Radboud University Nijmegen Medical Centre, Nijmegen, the Netherlands; 3) Department of Rheumatology, Rijnstate Hospital, Arnhem, the Netherlands; 4) Department of Rheumatology, Medical Centre Leeuwarden, Leeuwarden, the Netherlands.

Rheumatoid arthritis (RA) is a severe chronic inflammatory disease and genetic factors are known to play an important role in its pathogenesis. Genetic factors are also involved in determining the prognosis of RA and the response of patients to therapy. For the treatment of patients it would be worthwhile if their disease outcome and response to treatment could be predicted at the beginning of the disease. In this way each individual patient could be treated in the most adequate way. We investigated whether the -308G>A promoter polymorphism in the *TNFA* gene is associated with response to anti-TNF treatment and/or disease severity in patients with RA. Two patient samples were genotyped for the *TNFA* -308G>A promoter polymorphism (rs1800629) using TaqMan SNP genotyping. One sample (n=426) consisted of patients from the Dutch Rheumatoid Arthritis Monitoring (DREAM) register, for whom detailed information on their response to anti-TNF therapy was available, the other consisted of patients from a long-term observational early RA inception study (n=208). The -308G>A polymorphism was not associated with anti-TNF response at 3 and 6 months. The GG genotype, and more specifically the G allele, was associated with increased radiographic joint damage over a period up to 9 years after diagnosis, independently of age, gender, rheumatoid factor status and disease activity. Our data show that the suitability of the *TNFA* -308G>A promoter polymorphism as a marker for response to monoclonal anti-TNF antibodies in clinical practice is still questionable, and confirm that the polymorphism is associated with RA disease severity.

Dynamic Modification Strategy of the Israeli Prenatal Carrier Screening Protocol: Inclusion of the Oriental Jewish Group to the Cystic Fibrosis Panel. *O. Reish[1, 2], Z. Borochowitz[3], V. Adir[3], M. Shohat[4], E. Pras[5], A. Storch[6], A. Orr-Urtreger[7], Y. Yaron[7], S. Shalev[8], F. Fares[9], R. Gershoni[10], T. Falik-Zaccai[11], D. Chapman-Shimshoni[1]* 1) Genetics Inst, Assaf Harofeh Medical Ctr, Zerifin, Israel; 2) Sackler School of Medicine, Tel Aviv University, Tel Aviv; 3) Bnai-Zion Medical Center,Haifa; 4) Rabin Medical Center, Petah Tikva; 5) Sheba Medical Center, Tel-Hashomer; 6) Meir Medical Center, Kfar Saba; 7) Tel Aviv Medical Center, Tel Aviv; 8) Ha'emek Hospital, Afula; 9) Carmel Medical Center, Haifa; 10) Rambam Medical Center, Haifa; 11) Western Galilee Hospital, Nahariya.

Purpose: To determine the carrier frequencies of the recently identified mutations in CF patients in Jews of Oriental origin, in Israel. **Methods:** Ten medical centers participated in the study. Three mutations were screened in Iraqi Jews : two splice site mutations - 3121-1G>A and 2751+1insT and one nonsense mutation - the Y1092X. The I1234V a missense mutation within the nuclear binding domain of CFTR gene was screened in Jews of Yemenite origin. **Results:** In 3474 chromosomes derived from Iraqi Jews, the 3121-1G>A ,Y1092X and 2751+1insT mutations had a carrier frequency of 1:68.5 and 1:435 respectively while the third mutation was not detected. In 2072 screened Yemenite chromosomes, the I1234V mutation disclosed a 1:130 carrier frequency. **Conclusion:** The 3 Iraqi mutations add up to an allele frequency of 0.84% which stands within the Israeli Society of Medical Geneticists' inclusion criteria of 1:60 carrier frequency and therefore, prompted the inclusion of Iraqi Jews to the prenatal screen. The 2751+1insT that was detected in patients only, was included in the screening panel to optimize detection rate. The I1234V has not met the criteria for inclusion, but is offered on diagnostic basis and can be added to the screening panel of protocol-recommended-origins when mixed with Yemenite. This study demonstrates the dynamic modifications of the Israeli prenatal CF screening protocol based on newly detected founder mutations confirmed in a large scale population, while taking into account mutation impact and inter-communal admixture.

Association of *GIRK3* gene polymorphisms with methamphetamine and alcohol dependence. *D. Nishizawa[1], J. Hasegawa[1], S. Kasai[1], H. Ujike[2,13], N. Ozaki[3,13], Y. Sekine[4,13], T. Inada[5,13], M. Harano[6,13], T. Komiyama[7,13], M. Yamada[8,13], M. Iyo[9,13], N. Iwata[10,13], I. Sora[1,11,13], S. Higuchi[12], K. Ikeda[1], Japanese Genetics Initiative for Drug Abuse (JGIDA)* 1) Dept Molecular Psychiatry, Tokyo Inst Psychiatry, Tokyo, Japan; 2) Department of Neuropsychiatry, Graduate School of Medicine and Dentistry, Okayama University, Okayama, Japan; 3) Department of Psychiatry, Nagoya University Graduate School of Medicine, Nagoya, Japan; 4) Department of Psychiatry and Neurology, Hamamatsu University School of Medicine, Hamamatsu, Japan; 5) Department of Psychiatry, Seiwa Hospital, Institute of Neuropsychiatry, Tokyo, Japan; 6) Department of Neuropsychiatry, Kurume University School of Medicine, Kurume, Japan; 7) Division of Psychiatry, Iida Hospital, Ritsuzan-Kai med Corp, Iida, Japan; 8) Department of Psychogeriatrics, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan; 9) Department of Psychiatry, Graduate School of Medicine, Chiba University, Chiba, Japan; 10) Department of Psychiatry, Fujita Health University School of Medicine, Toyoake, Japan; 11) Department of Psychobiology, Tohoku University Graduate School of Medicine, Sendai, Japan; 12) Institute of Clinical Research, National Alcoholism Center Kurihama Hospital, Yokosuka, Japan; 13) Japanese Genetics Initiative for Drug Abuse (JGIDA).

This study investigated whether polymorphisms in the *GIRK3* gene, a candidate gene for rewarding effects, could be indices of risk factors for methamphetamine (METH) and alcohol dependence in Japan. In the association study for five single nucleotide polymorphisms (SNPs), significant difference was found in allele frequency (p=0.0279) for the C1339T single nucleotide polymorphism (SNP) between the METH-dependent and control subjects. Also, significantly higher frequencies were observed in the alcohol-dependent patients for the GTCCG (p=0.0005) and CCTCA (p=0.0346) haplotypes compared to the control subjects. Although the underlying molecular mechanism remains to be elucidated, our data indicate that the *GIRK3* C1339T SNP and haplotypes could serve as markers for predicting the vulnerability to METH or alcohol dependence.

COL5A1 Gene Duplication and Trisomy 9q34 in a Patient with a Complex Ehlers Danlos Syndrome Phenotype.

S. Kallish, J. Keenan, R. E. Schnur Department of Pediatrics, The Children's Regional Hospital at Cooper University Hospital, Camden, NJ.

A 41-year-old woman was referred for evaluation of vascular Ehlers Danlos syndrome (EDS), a diagnosis given to her at age 13. She had a history of developmental delay and congenital heart disease. Connective tissue variations included shoulder dislocations, scoliosis, easy bruising, and poor wound healing.

The patient appeared prematurely aged with numerous atrophic scars. She had translucent skin and easily visible vasculature. She had a positive Gorlin sign, thoracic kyphoscoliosis, arachnodacytyly, and hyperextensibility of the thumbs. Dysmorphic features included maxillary hypoplasia with a tall chin and forehead. Her eyes were closely spaced and deep-set. She had a narrow nasal bridge, a palpably bifid nasal tip, and a high palate with a midline bulge.

The patient was found to have a duplication of the 9q subtelomeric region translocated onto distal 10q. The 10q subtelomere was not deleted. Thus, the patient has a pure trisomy of the 9q subtelomeric region. CGH confirmed partial trisomy 9q34.11q34.3.

Significantly, the *COL5A1* gene maps to this region. *COL5A1* mutations cause classical EDS. Fibroblasts from our patient were assayed for types I and III collagen with normal results. After finding the 9q duplication, the skin biopsy was studied for *COL5A1* RNA expression. All three *COL5A1* alleles were expressed.

COL5A1 duplication of in this patient suggests that this may directly contribute to her features of EDS. Her phenotype is consistent with other reported cases of duplications of 9q and Marfanoid features. One hypothesis is that the overproduction of *COL5A1* protein leads to excess production of 1(V) homotrimers rather than the heterotrimers that comprise normal type V collagen. Diagnostic testing of collagen genes in patients with connective tissue abnormalities should potentially include screens for gene duplications in addition to sequencing and deletion analysis.

mtDNA mutation screening in blood and sperm of infertile oligoasthenozoospermic (OA) men. *S. Venkatesh[1], R. Kumar[1], R. Kumar[2], NP. Gupta[2], RK. Sharma[3], RN. Bamezai[4], R. Dada[1]* 1) Anatomy, Laboratory for Molecular Reproduction and Genetics, New Delhi, India; 2) Department of Urology, AIIMS, New Delhi, India; 3) ART center , Army Research and Referral Hospital, N Delhi; 4) School of life sciences, JNU, New Delhi, India.

Sperm mitochondria are source of energy (ATP) for spermatogenesis and sperm motility by oxidative phosphorylation (OXPHOS) pathway. mtDNA is highly susceptible to free radical mediated damage and also accumulate mutation due to a very basic repair mechanism and lack of protamines. Since the number of mtDNA in male germ cell are very few as compared to somatic cell, we studied the frequency of mutation in blood (somatic) and sperm cells and to also determine which is ideal to study in understanding pathogenesis of OA. The study included 45 infertile patients with 20% progressive motile and 20 million sperm/ml in the semen and 30 age and ethnically matched fertile controls (who have initiated a successful pregnancy in the last 12 months). Semen analysis was performed according to WHO (1999) guidelines. Both blood and sperm DNA were isolated and sequenced for the mitochondrial genes (ND, Cyt b, CO I, and ATPase) by standard PCR-DNA sequencing protocol. More number of nucleotide changes was detected in the sperm mtDNA than the blood mtDNA of the OA patients. An average of 11.1 nucleotide changes were observed in the mtDNA of sperm compared to the mtDNA of the blood (6.6) for 10 nucleotides [7028 (CO I), 8279, 8280, 8701, 8860 (ATPase), 12612, 12705 (ND5), 15043, 15226, 15257(Cyt.b). Based on our results we conclude that frequency of nucleotide changes are more in the germ cells compared to the somatic cells. Thus molecular screening of germ cell mtDNA is a better diagnostic marker than somatic cells to understand the etiology of OA and counsel these men before they opt for ICSI.

A potential common genetic pathway linking depression to cardiovascular disease. *J. Zhao, R. Patel, A. Zafari, V. Vaccarino, A. Quyyumi* Dept Medicine, Emory Univ, Atlanta, GA.

Background: Coronary artery disease (CAD) and depression are prevalent comorbidity of major clinical significance. Genetic factors and inflammation are implicated in both disorders. We hypothesized that genetic variants in inflammatory pathways related to leukotriene metabolism explain the comorbidity of depression with CAD. Methods: Caucasian subjects undergoing coronary angiography at Emory University had genotyping for 12 SNPs in the leukotriene A4 hydrolase gene (LTA4H). CAD was defined as 50% stenosis in 1 epicardial coronary artery or a history of MI. Controls were subjects with completely smooth coronary arteries and no history of MI. Depression was defined as a score 10 in the Patient Health Questionnaire 9. Single marker analysis was assessed by the 2 test. Haplotype associations were tested using likelihood ratio tests. Empirical significance levels were determined by permutation tests. The relationship between genetic variants and CAD or depression was further determined using logistic regression, adjusting for traditional coronary risk factors. Results: The sample for analyses included 1319 angiographic CAD patients and 425 controls (30.4% female). Of these, 198 were depressed. None of the SNPs was individually associated with either CAD or depression. However, a six-SNP haplotype in LTA4H, named HapE, showed a significant protective effect on both CAD (OR = 0.55, 95% CI [0.37-0.83], p = 0.005) and depression, independent of traditional risk factors including age, sex, smoking, history of diabetes and hypertension. The protective effect of HapE on depression was only observed in women (OR = 0.28, 95% CI [0.11-0.72], p = 0.008), but not in men (OR = 0.98, 95% CI [0.56-1.72], p = 0.94). The prevalence of HapE in the study population was ~ 14%. Conclusion: HapE protects against both CAD and depression. It explains 6% of the comorbidity of depression with CAD. Our finding provides the first evidence that genetic variants in leukotrienes may underlie the link between depression and CVD, and may be implicated in the gender difference in depression. Replication and functional studies are needed to test this hypothesis.

In vitro modulation of TCF7L2 gene expression in human pancreatic cells. *K. Khalooghi[1], S. Hashemi[2], N. Mehraban[1], P. Amiri[1], J. Tavakkoly Bazzaz[1], B. Larijani[1], MM. Amoli[1]* 1) Endocrinology and metabolism research centre, Tehran university, medical sciences; 2) Department of genetics, Faculty of Medicine, Tehran university, medical sciences.

Background: Several studies have recently reported strong association between type 2 diabetes and variation in the transcription factor 7-like 2 (TCF7L2) gene, which has been confirmed by several other genome-wide studies. However the physiological implications of this transcription factor on the pathogenesis of type 2 diabetes is not yet known. Aim: The aim of this study was to investigate the alteration in TCF7L2 gene expression in human pancreatic cell line in response to various factors in vitro. Methods: MIA Paca-2 cell line (Human Pancreas cell line) was cultured in the presence of curcumin, lipopolysaccaride and Glucose (low and high concentration). TCF7L2 gene expression was determined using quantitative real-time RT-PCR. Results: Treatment with curcumin significantly increased TCF7L2 gene expression to 3.24 fold (1.7-log fold) (p 0.003) compared to the controls while treatment with LPS decreased TCF7L2 gene expression to 0.88 -fold (-0.18-log). On the other hand, glucose increased TCF7L2 gene expression in pancreatic cell line. Conclusion: Our data suggest a role for TCF7L2 in glucose homeostasis. The contrary effect of curcumin and LPS on expression of TCF7L2 in pancreatic cells supports a role for TCF7L2 in their survival and function in inflammatory conditions.

Familial interstitial Xq27.3q28 duplication encompassing the FMR1 gene: a "contre-type" of Fragile X syndrome? *M. Rio[1], V. Malan[1,2], A. Toutain[3], JM. Lapierre[1], S. Gobin[1,2], G. Royer[1], JP. Bonnefont[1,2], A. Munnich[1,2], M. Vekemans[1,2], L. Colleaux[1,2]* 1) Département de génétique, Unité INSERM 781, Hôpital Necker-Enfants Malades, Paris, France; 2) Université Paris Descartes, Paris France; 3) Service de génétique, hôpital Bretonneau, Tours, France.

X-linked mental retardation is a very common disorder which accounts for 5-10% of cases of retardation in males. Fragile X syndrome is one of the most common inherited form resulting from loss of expression of the FMR1 gene. Partial duplication of the long arm of the X chromosome is uncommon. It leads to functional disomy of the corresponding genes and has been reported in males with mental retardation. Using1 Mb array comparative genomic hybridization (array CGH), we identified a small interstitial Xq27.3q28 duplication encompassing the FMR1 gene in a large X linked syndromic mental retardation family. The two males, initially referred for genetics work up because of mental retardation, share a similar clinical phenotype including bilateral testicular ectopia, small stature and minor facial dysmorphism. They also have phenotypic features caused by testosterone deficiency: gynecomastia, sparse body hair, high pitched voice and small testicles. The duplication was confirmed by fluorescence in situ hybridization and segregates with the disease in the families. The three carrier females were all asymptomatic and have a skewed X inactivation pattern. We suggest that Xq27.3q28 duplication results in a novel clinically recognizable syndrome. Interestingly, clinical features observed in our patients are opposite of those observed in fragile X syndrome patients such as macroorchidism and tall stature. Although additional patients will be necessary to further delineate this condition, our data already suggest that increased FMR1 gene copy number may be responsible for the phenotype in our patients. Fine molecular characterization of this duplication is presently underway to determine other genes that might contribute to the clinical features observed in these patients.

Mapping Short Reads to the Human Genome. *S. Katzman[1], D. Haussler[1,2,3]* 1) Department of Biomolecular Engineering, Univ California, Santa Cruz, Santa Cruz, CA; 2) Center for Biomolecular Science and Engineering, Santa Cruz, CA; 3) Howard Hughes Medical Institute, Santa Cruz, CA.

Ultra high throughput DNA sequencing (UHTS) technologies are characterized by low cost per base sequenced, but have read lengths much shorter than the 500-1000bp reads from Sanger sequencing technology. Although UHTS promises inexpensive whole genome human resequencing, mapping its 25, 35, or 50bp reads to the human reference presents a difficult challenge. In the presence of errors and polymorphism, policies for mapping a read must ensure a high level of accuracy. Here we characterize the mappability of the human genome by checking for matches of nmers from the reference sequence to anywhere else in the reference. Single reads, even of high quality, that are shorter than 30bp will leave a significant portion of the human genome unmapped. Above that length there is a gradual improvement. But paired-end reads of sufficient length, even of 30mers, may provide a way to escape shorter islands of unmappability in the human genome. Still, we demonstrate that false mapping from regions not represented in the reference may be a serious problem. It may lead to an unacceptably high rate of false SNPs, getting worse rather than better with increasing depth of coverage.

Implementation of the JaundiceChip as a Clinical Diagnostic Tool. *C. Liu[1], B. Richardson[1], A. Schalk[1], R. Mourya[2], J. A. Bezerra[2], K. Zhang[1]* 1) Human Genetics, Cincinnati Children's, Cincinnati, OH; 2) Gastroenterology, Cincinnati Children's, Cincinnati, OH.

Background: Inheritable neonatal intrahepatic cholestasis is one of the leading liver diseases in children. Mutations in ATP8B1, ABCB11, ABCB4, JAG1 and SERPINA1 have been detected in patients with different types of the disease. Identification of the mutations in these patients confirms specific diagnosis and guides personalized treatment. However, due to the lack of hot spots, sequencing has been used to identify the disease causing mutations, which is very time consuming and costly. Method: To address this issue, a resequencing microarray, JaundiceChip, was developed as a research tool to sequence the coding regions of these five genes. To translate the technology into a clinical diagnostic setting, new protocol and analysis algorithm were developed and validated to improve the sensitivity and specificity of the assay. Results: Thirty samples were tested using an updated fragmentation and hybridization protocol based on Affymetrixs recommendation. As a result, the average call rate reached 98.7%, a big increase from 93.5% as previously shown. To further increase the sensitivity of the chip, no call positions from 30 chips were plotted and two major groups with distinct patterns were identified. The first group contains 108 positions that are fixed in every sample tested, corresponding to 46% of no call positions. Three of them overlap with reported missense mutations in JAG1 gene. The second large group contains 10% of no call positions, which are unique to only one of the samples tested and called out in the other 29 samples. New analysis algorithm was developed to read out these positions and identified three missense mutations and one small deletion. All mutations reported by GSEQ software were subjected to direct confirmational sequencing and 100% accuracy was achieved. Conclusion: The re-sequencing based JaundiceChip provide a new tool for molecular diagnosis of inherited cholestatic liver diseases with high sensitivity and specificity.

Frequency of the Copy Number Variants Affecting the *OTC* Locus in Patients with OTC Deficiency. *O. A. Shchelochkov[1], L. Y. Tang[1], A. Pursley[1], F. Li[1], M. Geraghty[2], U. Lichter-Konecki[3], P. M. Fernhoff[4], S. Copeand[5], T. Reimschisel[6], S. Cederbaum[7], B. Lee[1], A. C. Chinault[1], L. J. Wong[1]* 1) Dept Mol & Hum Genetics, Baylor Col Medicine, Houston, TX; 2) Dept of Genetics, Childrens Hospital Eastern Ontario, Canada; 3) Childrens National Medical Center, Washington, D.C; 4) Dept of Hum Genetics, Emory University, Decatur, GA; 5) Dept of Pediatrics, University of Iowa, Iowa City, IA; 6) Div of Med Genetics, Washington University School of Medicine, St. Louis, MO; 7) UCLA Medical Center, Los Angeles, CA.

Ornithine transcarbamylase (OTC) deficiency is an X-linked inborn error of metabolism with the estimated prevalence of 1:14,000. Previously reported data suggest that only approximately 80% of OTC deficiency (OTCD) patients have an identifiable mutation by sequencing the *OTC* gene.

To elucidate the molecular etiology in patients with clinical signs of OTCD and negative *OTC* sequencing, we performed array comparative genomic hybridization (aCGH) using a custom-designed targeted 44k oligonucleotide array.

DNA samples from a total of 56 OTCD patients were analyzed. Thirty nine patients (39/56 or 69.6%) were found to have disease-causing point mutations in the *OTC* gene. The remaining 17 patients (17/56 or 30.4%) showed normal sequencing results or failure to amplify all or part of the OTC gene. Among those patients, eight (8/56 or 14.3%) were found to have deletions ranging from 24 kb to 10.6 Mb, all involving the *OTC* gene. Nine OTCD patients (9/56 or 16.1%) had normal sequencing and oligoarray results. Analysis of the deletions did not reveal shared breakpoints, suggesting that non-homologous end joining or replication-based mechanism might be responsible for the formation of the observed rearrangements.

In summary, we demonstrated that approximately half of the patients with negative *OTC* sequencing may have *OTC* gene deletions readily identifiable by the targeted oligonucleotide-based aCGH. Thus, aCGH should be considered in *OTC* sequencing-negative patients with classic symptoms of the disease. Further studies are necessary to elucidate the molecular mechanisms of observed rearrangements.

.

Preimplantation Genetic Diagnosis for Nonsyndromic Deafness by polar body and blastomere biopsy. *G. Altarescu, T. Eldar-Geva, B. Brooks, E. Haran-Zylber, E. J. Margalioth, E. Levy-Lahad, P. Renbaum* Zohar PGD Lab & IVF Unit, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Objective: 1- To develop an efficient and reliable universal protocol for PGD of nonsyndromic deafness; 2- assess heterozygosity rates of polar body 1 (PB1), marker informativity and Allele Drop Out rates (ADO) for polar body and blastomere PGD. Design and Methods: Polar bodies 1 and 2 (PB1 and PB2) and blastomere biopsy was performed by mechanical drilling. Three mutations GJB2 35delG, 167delT and GJB6 delD13S1830 and the markers: D13S141, D13S175, D13S633, D13S1275, D13S250, D13S232, GJB2-AT1, GJB2-AT2, GJB2-TG1, GJB2-TG2, GJB2-AC1, were used to set up a universal multiplex PCR protocol to be used for PGD in non syndromic deafness. Results were only assigned for samples with at least three informative flanking markers (including the familial mutation). Results: Eight couples underwent 19 PGD cycles resulting in a pregnancy rate of 21% and delivery of 3 unaffected children. Six cycles (32%) were performed by polar body biopsy, 6 by blastomere biopsy, 6 by frozen blastomere biopsy and in one cycle by both PB and blastomere biopsies. In 17 cycles (90%) at least 2 embryos were transferred and in one cycle one embryo was transferred. The rate of successful diagnosis for blastomere PGD was 91% and for PB PGD, 87%. Only 11 of 68 PB1s (17%) were heterozygote. Similar ADO rates (19%) were observed for both heterozygote PB1s and blastomeres. While all families had at least two informative markers on each side of the gene for PB PGD, none had 4 fully informative markers for blastomere PGD. Conclusions: We have developed a universal single cell multiplex protocol for nonsyndromic deafness with a high efficiency of diagnosis for PGD. Although PB PGD allows more informative marker assessment, most PB1 are homozygous, and ADO rates were seen to be similar, therefore, blastomere biopsy appears to be the method of choice for this autosomal recessive disease.

Molecular Characterization of Ataxia Oculomotor Apraxia in Saudi Arabia. *D. M. Bakheet[1], N. A. Al Tassan[1], L. J. Al Sharif[1], D. S. Khalil[1], T. S. Al Khairallah[2], S. A. Bohlega[2]* 1) Department of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh 11211, Saudi Arabia; 2) Department of Neurosciences, King Faisal Specialist Hospital & Research Centre, Riyadh 11211, Saudi Arabia.

Background: Ataxia with Oculomotor Apraxia (AOA) is a rare autosomal recessive disorder with two subtypes. AOA1 presents with cerebellar ataxia and oculomotor apraxia between 2 and 18 years of age and is accompanied later in life by sensory-motor neuropathy which may be associated with choreathetosis or mental retardation, hypoalbuminemia, hypercholesterolemia, normal immuno-globins and alpha-fetoprotein levels. Patients with AOA2 present with gait ataxia, cerebellar atrophy, sensory- motor neuropathy, ocular-motor aparaxia, elevated immuno-globins and alpha-fetoprotein levels with a later age of onset (10-22 years). Although the two forms are not quite distinctive phenotypically,two different genes (*APTX* and *SETX*) on chromosome 9 have been linked to AOA. **Objective:** This study aims to screen for mutations in patients with AOA. **Methods**: Five Saudi families with a clear diagnosis of either AOA1 or AOA2(2 or more affected individuals) have been identified and enrolled in this study. Comprehensive screening for the whole open reading frame (ORF) of genes of interest were performed. **Results:** A novel truncating mutation (c.6859 C>T, R2287X) in the *SETX* gene was identified in one family with AOA2, while the other families with either AOA1 or AOA2 have been negative for mutations in both genes. Analysis of *MRE11* gene, which is known to be implicated in ataxia like (AT-like) disorder, identified a common reported mutation W210C in exon 7 in two families with AOA1 phenotype. The remaining families were negative for mutations in the ORF of all 3 genes highlighting allelic or genetic heterogeneity of these disorders. Investigation of this heterogeneity is underway through screening of non-coding regions of these 3 genes, and also genome-wide linkage analysis. **Conclusion:** These results demonstrate the genetic diversity of this disorder and indicate the possible involvement of more genes in the development of this disease.

DNA copy number variations in major psychosis. *J. Tang[1,3], L. Cheng[1], D. Craig[2], M. Josephson[2], S. Christian[1], E. Gershon[1], X. Chen[3], C. Liu[1]* 1) Departments of Psychiatry and Human Genetics, University of Chicago, Chicago, IL; 2) The Translational Genomic Research Institute, Phoenix, AZ; 3) Institute of Mental Health, The Second Xiangya Hospital, Central South University, Changsha, Hunan, P.R. China.

In order to identify copy number variations (CNVs) in schizophrenia, bipolar disorder and major depression, and to test correlations between CNVs and these diseases, we analyzed CNVs in postmortem brain DNA from individuals with DSM-IV diagnosed SZ (50), BD (49), MD(15) and matched controls (49),provided by the Stanley Medical Research Institute Brain - Array and Consortium Collections. The Affymetrix 5.0 SNP array was used for genotyping. Partek software was used to obtain estimates of CNVs. Copy number baseline was created from pools of all control samples,and the intensity of each samples data was normalized to the copy number baseline. CNVs were detected using a Hidden Markov Model, with a region defined as consistent variation in at least 3 adjacent probes. Secondary analyses of the genomic DNA hybridization data were performed, on allele signal ratio and loss of heterozygosity (LOH), which can give support information on CNVs. 2502 CNVs (from 1226 loci) were detected from autosomes. 22 CNVs (from 20 loci) were detected from X chromosome. The average number of CNVs detected per individual was 15.5. Of 2524 CNVs, 1148 CNVs were heterozygous deletions, 562 CNVs were homozygous deletions, and 814 CNVs were duplications. The median size of CNVs was 31kb. Three large CNVs on chromosome 9 were detected in schizophrenia and bipolar diseases. We compared the CNVs identified in our analysis to those present in the Database of Genomic Variants. 156 CNVs (96 loci) in our data were novel CNVs. Of 2524 CNVs, 906 CNVs are singleton CNVs, and 1618 CNVs were non-singleton CNVs. In tests for association for 43 common CNVs, CNV-304 has marginal significant P value (p=0.086) after Bonferroni correction. We further investigated genes that were deleted or duplicated exclusively in patients. 35 genes in CNVs were recorded exclusively in patients with major psychosis:6 in bipolar disorder,8 in major depression and 21 in schizophrenia.

Functional Impact of Polymorphisms in the Promoter Region of the Apoptosis Gene MDM2. *M.-E. Lalonde[1], D. Sinnett[1,2]* 1) CHU Ste-Justine, University of Montreal, Montreal, Quebec, Canada; 2) Department of Pediatrics, University of Montreal, Montreal, Quebec, Canada.

Introduction: MDM2 is involved in the intrinsic apoptosis pathway. Thus deregulations in the expression levels of the MDM2 gene could lead to an accumulation of cells (due to a lack of apoptosis), creating a favourable environment for genetic instability, oncogene activation and tumorigenesis. Furthermore, the MDM2 promoter region contains regulatory polymorphisms (rSNPs) that could influence its expression and modify its transcription levels. Materials and Methods: The initial search for rSNPs in the MDM2 proximal promoter was done using the dbSNP database. Seven rSNPs were selected for genotyping in 40 individuals of European descent. We then tested the impact of the three most frequent promoter haplotypes on expression levels using a luciferase gene reporter assay in 4 different cell lines (HeLa, HepG2, JEG3 and Jurkat). Gel shift experiments were also carried out to test the impact of the promoter rSNPs on nuclear protein binding to putative transcription factors binding sites. Results and Discussion: Following genotyping we identified 3 common promoter haplotypes characterised by a combination of 4 rSNPs. Gene reporter assays revealed allelic differences in MDM2 promoter activity: haplotype -1494G-1208_-1169del -182G was shown to increase the expression level 5-fold when compared to the promoter haplotype -1494G-1208_-1169nondel -182C. Furthermore, the gel shift experiments showed differential DNA-protein binding at these different positions. Conclusion: These promoter rSNPs/haplotypes are associated with variable MDM2 expression levels at least in vitro. Because of the highly allele regulated nature of apoptosis, such allelic imbalance may contribute to tumorigenesis. Acknowledgements: This project was supported by Genome Canada/ Québec and the Quebec Optimist Clubs.

The ESR2 gene polymorphism is associated with increased risk of high tension glaucoma in women. *F. Mabuchi[1], Y. Sakurada[1], K. Kashiwagi[1], Z. Yamagata[2], H. IIjima[1], S. Tsukahara[1]* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Japan.

Purpose: To assess whether genetic polymorphisms of estrogen receptor beta (ESR2) are associated with primary open angle glaucoma. Methods: Japanese patients with normal tension glaucoma (NTG, n = 213), and high tension glaucoma (HTG, n = 212), and 191 control subjects were analyzed for the ESR2 gene polymorphisms (rs1256031 and rs4986938) using allele specific primer PCR technique, and genotypic and allelic frequency differences between NTG, HTG patients and control subjects were estimated. The mean age at the time of blood sampling was 63.7 13.6 years (SD) in patients with NTG, 62.9 14.8 years in patients with HTG, and 65.7 11.4 years in the control subjects. Results: Although no statistically significant differences of the genotype and allele frequencies were found out between the NTG patients and the control subjects, there were significant differences in the genotype frequencies of rs1256031 and rs4986938 between the HTG patients and control subjects in women (P = 0.033 and P = 0.043 respectively, Chi-square test). The frequencies of the C allele of rs1256031 and G allele of rs4986938 were significantly higher in patients with HTG compared to the control subjects in women (rs1256031: 53.6% vs. 43.4%, P = 0.044; rs4986938: 89.2% vs. 80.6%, P = 0.027, Fishers exact test). Conclusion: The ESR2 gene polymorphisms are associated with HTG, and may be used as a marker for this disease association in women.

Prenatal diagnosis of Holt-Oram syndrome through ultrasonography and molecular analysis. *S. M. Weiss, C. L. Yates* Northwestern University, Chicago, IL.

Holt-Oram syndrome (HOS) is an autosomal dominant disorder characterized by upper-extremity malformations, a personal or family history of congenital heart defects, and an increased risk for cardiac conduction disease. Upper-extremity malformations involve the radial, thenar or carpal bone(s). Most common cardiac defects include atrial and ventricular septal defects. Approximately 70% of individuals who present with clinical criteria have an identifiable mutation in the TBX5 gene [12q24.1]. TBX5 encodes for a transcription factor that plays a role in cardiac septation and limb development. Approximately 85% of TBX5 gene mutations are de novo. Prenatal diagnosis of low risk pregnancies is difficult due to the variable expressivity of the gene mutations and the overlap of clinical features with numerous other conditions. We report on an affected fetus ascertained through routine ultrasound in a G2P1001 woman with an unremarkable family history. Unilateral absence of the radius and a possible heart defect were identified on level II ultrasound at 19w2d. Subsequent fetal echocardiogram suggested atrial septal defect (ASD). Amniocentesis revealed a normal 46, XX karyotype. Testing on amniocytes for a mutation in the TBX5 gene revealed a heterozygous G>T nucleotide substitution in exon 4 (D111Y), resulting in the replacement of an aspartic acid with a tyrosine at amino acid position 111 of the TBX5 protein product. Prompt diagnosis through TBX5 gene mutation analysis allowed for accurate genetic counseling and expectant management.

Genetic Structure Analysis of an East African Population. *M. Luo[1], J. Sainsbury[1], G. Vandomselaar[3], T. Ball[1], J. Kimani[2], F. Plummer[1,3]* 1) Dept Medical Microbiology, Univ Manitoba, Winnipeg, MB, Canada; 2) University of Nairobi, Nairobi, Kenya; 3) National Microbiology Laboratory, Winnipeg, MB, Canada.

As the cradle of humanity, East Africa contains the most genetically diverse population owing to early settlements and migrations. The population has also been under extensive selective pressure by various infectious diseases. Genetic epidemiology and disease association studies require a clear understanding of existing population genetic substructure to avoid spurious associations. We conducted population substructure analysis of a population of women enrolled in the Pumwani Sexworker cohort in Nairobi, Kenya using three different approaches. HLA class I (A, B, C) were genotyped and haplotypes of more than 800 women were analyzed using arlequin 3.11; 444 polymorphic SNPs randomly selected from 23 chromosomes from 432 individuals enrolled in the Pumwani Sexworker cohort were analyzed and compared with SNPs data from three HapMap populations, CEU (European), YRI (African) and CHB+JPN (Asian) using Structure 2.2; and Principle component analysis (PCA) of 423,688 SNPs with HelixTree(v6.3.6, Golden Helix). These analyses showed that there is no significant population substructure in this East African population. As expected this East African population co-clusters with the African YRI population, but is genetically more diverse than the YRI population sample included in the HapMap study.

Let-7d: A regulator of epithelial-mesenchymal transition (EMT) and idiopathic pulmonary fibrosis (IPF). *K. Pandit[1], D. Corcoran[1], H. Yousef[1], D. Handley[1], A. Ben-Yehudah[1], A. Pardo[2], M. Selman[2], O. Eickelberg[3], M. Yarlagadda[1], P. Ray[1], P. Benos[1], N. Kaminski[1]* 1) University of Pittsburgh, USA; 2) Instituto Nacional de Enfermedades Respiratorias, Mexico; 3) University of Giessen Lung Center, Germany.

Introduction: IPF is a chronic, lethal lung disease resulting in death within 3-5 years of diagnosis. TGF- plays a central role in the pathogenesis of IPF, with SMAD3 being its effector molecule. In this study, we investigated the effect of TGF- on the microRNA, let-7d and the role of this microRNA in the pathogenesis of IPF. **Methods and Results:** Discriminative motif analysis of upstream regions of intergenic microRNAs recognized a SMAD3 binding site in the promoter of let-7d. Electrophoretic mobility shift assay and SMAD3 chromatin immunoprecipitation were performed to confirm the let-7d/SMAD3 binding. Stimulation of A549 cells with recombinant TGF-, led to a decrease in let-7d ($p<0.05$) 6h later and a corresponding increase in HMGA2 ($p<0.05$) as quantified by qRT-PCR. HMGA2 is a key regulator of the TGF--induced EMT known to be expressed only during embrogenesis and carcinogenesis. Transfection of A549 cells with a let-7d inhibitor resulted in an increase in HMGA2 and markers of EMT including N-cadherin, vimentin and -smooth muscle actin, by qRT-PCR and immunofluorescence. Let-7d is downregulated in IPF lungs ($p<0.05$) compared to control lungs by qRT-PCR. In control lungs, let-7d was localized in the bronchial and alveolar epithelial cells by in situ hybridization. HMGA2, a target of let-7d, is increased 12-fold in IPF lungs by qRT-PCR and localizes to alveolar epithelial cells by immunohistochemistry. Ongoing experiments include inhibition of let-7d in the lungs of mice by intratracheal administration of a chemically-modified oligonucleotide to study fibrotic changes in the lung tissue. **Conclusion:** Our results suggest that let-7d is under direct transcriptional regulation of TGF- and is a key mediator of EMT. Thus, let-7d occupies a strategic place in the TGF- signaling pathway; its downregulation in IPF suggests that it plays a major role in the pathogenesis of this devastating disease.

Maternal uniparental disomy 14 spectrum and differential diagnosis of Prader-Willi syndrome. *S. Saitoh[1], K. Hosoki[1], M. Kagami[2], T. Ogata[2]* 1) Dept Pediatrics, Hokkaido Univ Sch Medicine, Sapporo, Japan; 2) Dept Endocrinology and Metabolism, National Research Institute for Child Health and Development, Tokyo, Japan.

Maternal uniparental disomy 14 [upd(14)mat] is characterized by intrauterine growth retardation, neonatal hypotonia, small hands and feet, a characteristic facies including prominent forehead and precocious puberty. These phenotypes of upd(14)mat resemble those of Prader-Willi syndrome (PWS), in particular during the infancy. In our series of molecular investigation of patients who were initially suspected to have PWS, we have identified five patients with upd(14)mat and one patient with an epimutation of chromosome 14q32.2. All patients were initially identified by a DNA methylation test for the *MEG3* gene, and subsequent microsatellite polymorphism studies confirmed the parental origin of each chromosome 14 allele. In the patients with upd(14)mat, 3 patients had full upd(14)mat with a normal karyotype, 1 patient had mosaic upd(14)mat with a normal karyotype, and 1 patient had full upd(14)mat with a mosaic supernumerary marker of chromosome 14 origin. The patient with epimutation of 14q32.2 was thoroughly investigated for microdeletion, segmental upd, and DNA methylation status in 14q32.2, and microdeletion and segmental upd were ruled out. The IG-DMR, which is the proposed primary imprinting site, and the *MEG3* promoter were hypomethylated, indicating a maternal epigenotype on the paternally derived chromosome 14. The clinical features of these 6 patients were basically consistent with those of reported phenotypes for upd(14)mat, including pre- and postnatal growth retardation, although the patient with an epimutation had a normal birth weight. Patients with the upd(14)mat phenotype who have a small deletion of paternal origin in 14q32.2 have been reported (Kagami et al, Nat Genet 40:237-42, 2008). Therefore, it is now clear that the upd(14)mat phenotype is caused not only by upd(14)mat but by epimutation or small deletions.

The rise and fall of mtDNA mutations in cultured single cells. *Y.-G. Yao[1, 3, 4], S. Kajigaya[1], X. Feng[1], L. Samsel[2], J. P. McCoy[2], N. S. Young[1]* 1) Hematol Branch, NHLBI, NIH, USA; 2) Flow Cytometry Core Facil, NHLBI, NIH, USA; 3) Key Lab Anim Models & Human Dis Mech, Kunming Inst Zool, Kunming, Yunnan, China; 4) State Key Lab Genet Res & Evolut, Kunming Inst Zool, Chinese Acad Sci, Kunming, Yunnan, China.

We have described a marked level of mtDNA sequence variation in single hematopoietic cells from healthy human donors and leukemia patients. To test whether single cells can quickly acquire mtDNA mutations and lead to this mutation pattern, we compared mtDNA sequence variation among single CD34+ cells, single colonies grown from CD34+ cells, and single cells from a colony grown from a CD34+ cell after one-week culture. Single cells from a Jurkat T cell line culture, a subclone of Jurkat cell established from one cell after one-month culture, and single cells from a colony of the subclone culture were analyzed to discern potential effects of long- and short-term culture. Single CD34+ cells harbored more mutations than did single colonies grown from CD34+ cells from the same donor. Colonies from adults had higher levels of point mutations than did those from cord blood. The proportion of cells harboring mutations varied within different colonies and did not present a uniformly homogeneous pattern. Proliferation of a single cell harboring certain acquired mutation(s) could cause a change of the main haplotype in the expanded cell population. These results provide new insights into the rise and fall of mtDNA mutations in cultured hematopoietic cells and caution their causal role in the aging of hematopoietic stem cells.

Genome-wide association scan of tag SNPs for congenital heart defect. *J. J. Kim[1], K. J. Kim[2], I. S. Park[2, 3], J. K. Lee[1, 2]* 1) Asan Institute for Life Sciences, University of Ulsan College of Medicine, Seoul, Korea; 2) Genome Research Center for Birth Defects and Genetic Disorders, Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Korea.

Congenital heart defects (CHDs) are the most common developmental anomaly, affecting approximately 1% of all live births and the leading cause of death in newborns. Despite the many advances in our understanding of cardiac development, the etiology of CHDs is only partly illuminated. Numerous epidemiologic studies have established the heritable nature of CHDs. However, very few genes causing CHDs have been identified so far. Our aim was to identify genetic variants involved in the risk of CHDs. A genome-wide association scan with the Illumina HumanHap300-Duo array was performed in 13 familial cases of CHDs and 90 normal controls. The overall genotype call rate was 99.9%. Allelic comparison was made between cases and controls for 276,644 single nucleotide polymorphisms (SNPs). Thirty six SNPs were statistically significant after Bonferroni correction. The most strongly associated SNP ($P = 4.78^{10-11}$) was rs3856852 at 5 flanking region of the CRBN gene on chromosome 3p26.3. We found several possible significant regions harboring biologically meaningful genes associated with heart development. For example, the significant rs801521 SNP was located in the intron region of the HDAC9 gene encoding histone deacetylase 9, which has been reported to play a role in heart development. Another significant SNP, rs2157727 was located in 5 flanking region of the CLDN5 gene that is commonly deleted in patient with velocardiofacial syndrome. Further replication studies are needed to confirm these association results and identify real causative SNPs for CHDs.

***CDKL5* disruption by t(X;18) in a girl with West syndrome.** *A. Nishimura[1,2], T. Takano[3], T. Mizuguchi[1], H. Saitsu[1], Y. Takeuchi[3], N. Matsumoto[1,2]* 1) Department of Human Genetics, Yokohama City University of Medicine, Yokohama, Japan; 2) The Yokohama City University 21st Century Center of Excellence (COE) Program of MEXT; 3) Department of Pediatrics, Shiga University of Medical Science, Otsu, Shiga, Japan.

Breakpoint sequences of the balanced translocation t(X;18)(p22;p11.2) found in a girl with West syndrome were determined. Der(X) breakpoint lost three nucleotide with two nucleotide with unknown origin added, and der(8) never lose or add any nucleotides. *CDKL5* at Xp22 was found to be disrupted in the intron 17. This is the third case of West syndrome due to CDKL5 disruption by the chromosomal translocation.

An Epistatic Model for Characterizing the Genetic Control to Complex Diseases. *T. Liu[1], A. Thalamuthu[1], JJ. Liu[1], RL. Wu[3], C. Chen[2]* 1) Genome Institute of Singapore, Singapore; 2) Dept. of Pharmacology, National University of Singapore & Dept. of Medicine, National University Hospital, Singapore; 3) Department of Statistics, Genetics Institute, University of Florida, Gainesville, FL.

Interactions within and between different genes, coined the epistasis, have been increasingly recognized to be of paramount importance in the pathogenesis of most common human diseases, such as cancer or cardiovascular disease, and patients' responsiveness to a medicine. The most common approaches for detecting genome-wide epistasis are based on genetic mapping that associates phenotypic variation of a trait with a linkage map constructed by polymorphic markers. Integrating the principle of quantitative genetics, we here propose a computational model for dissecting a complex disease into its genetic action and interaction components composed of causal single nucleotide polymorphisms (SNPs) in a simple case-control association study. The model is also extended to infer disease-associated haplotypes and used to probe concrete nucleotoxic sites that contribute to variation in a complex disease with a simple case-control design, and thus provide a way to push epistasis identification at the DNA sequence level.We formulated a mixture-model framework to compute the frequencies of haplotypes through the EM algorithm, and test the differences of the occurrence of haplotype combination that leads to epistasis of various kinds between the case and control groups. For each kind of epistasis, the 2 statistics was derived from a two by two contingency table based on combined haplotype frequencies between the case and control groups. Computer simulations show that the method is more powerful and informative than existing approaches. Testing the new model on a stroke candidate-gene case-control data set, we identify several within-gene and between-gene interactions from different candidate genes that trigger significant interaction effects on stroke.

X-linked female-limited epilepsy and cognitive impairment caused by protocadherin 19 mutations. *L. M. Dibbens[1], P. S. Tarpey[2], K. Hynes[1], M. A. Bayly[1], I. E. Scheffer[3], D. H. Geschwind[4], S. McKee[5], S. F. Berkovic[3], M. R. Stratton[2], J. C. Mulley[1], J. Gecz[1]* 1) Dept Genetic Medicine, Women's & Children's Hosp, North Adelaide, Australia; 2) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 3) Epilepsy Research Centre and Department of Medicine , University of Melbourne, Victoria, Australia; 4) Neurology Department and Semel Institute for Neuroscience and Behaviour , University of California at Los Angeles, Los Angeles, California, USA; 5) Northern Ireland Regional Genetics Service, Belfast City Hospital, Belfast, Northern Ireland, UK.

Epilepsy and Mental Retardation limited to Females (EFMR) is an X-linked disorder with an unusual pattern of sex-limited expression. Human disorders arising from mutations on the X chromosome are typically characterized by affected males and unaffected carrier females. In contrast, EFMR spares transmitting males and affects only carrier females. EFMR is characterized by early onset seizures in previously normal infants, followed by developmental regression of varying severity. Five new EFMR families were ascertained on the basis of their inheritance pattern. Haplotype analysis of the five families was consistent with gene localization on Xq22. Aided by systematic re-sequencing of 737 X chromosome genes we identified mutations in the Protocadherin 19 (PCDH19) gene in seven EFMR families. Five mutations result in the introduction of a premature termination codon. Study of two of these demonstrated nonsense mediated decay of mRNA. The two missense mutations are predicted to affect adhesiveness of PCDH19 through impaired calcium binding. Murine and human brain expression analyses of PCDH19 support an important role in brain function. These results identify protocadherins as a new gene family directly associated with epilepsy and brain cognition. We are now investigating the role of PCDH19 in other related neurological conditions.

CD14 -550C/T polymorphism modifies the effect of daycare attendance on total and specific IgE levels in children. *S. Hattori[1], Y. Mashimo[1], M. Funamizu[1], N. Shimojo[2], Y. Okamoto[3], Y. Kohno[2], A. Hata[1], Y. Suzuki[1]* 1) Department of Public Health; 2) Department of Pediatrics; 3) Department of Otolaryngology, Chiba University Graduate School of Medicine, Chiba, Japan.

Although results of studies examining a relation between daycare attendance and development of asthma have been conflicting, a consistent inverse relation between daycare attendance and atopy or serum IgE levels has been reported. CD14 is a pattern recognition molecule for bacterial endotoxin and involved in the Toll-like receptor pathways. Polymorphisms in the CD14 gene have been shown to modify effect of environmental factors such as endotoxin on the development of atopy and allergic diseases. Daycare attendance is thought to increase chance of infection. If frequent exposure to endotoxin is one of the mechanisms of protective effect of daycare attendance against atopy, a CD14 polymorphism may modify this daycare effect. Four hundreds and seventy-three school children with 6 to 12 years of age were asked whether they had attended daycare in the first 2 years of life. We determined total and 8 specific IgE levels and genotyped CD14 -550C/T in 410 children. Effects of the gene, daycare, and their interactions on the serum IgE levels were evaluated with generalized linear models. Atopy (one or more positive specific IgE) was evaluated with logistic regression models. Daycare attendance was associated with lower total IgE levels in the entire study population (P=0.022). In children with CC genotype, daycare showed little effects on the total IgE value (log(total IgE): daycare(-): 1.980.76; daycare(+): 1.880.77, P=0.54). In children with CT or TT genotype, daycare significantly lowered the total IgE level (daycare(-): 2.090.63, daycare(+): 1.580.51, P=0.000097). The interaction between daycare attendance and the polymorphism was significant for both total IgE (P=0.0034) and mite-specific IgE (P=0.00023). This interaction was also significant for atopy (P=0.0075). The effect of daycare attendance on the IgE levels and atopy was modified by CD14 -550C/T genotype. The mechanism that daycare attendance affects atopic status probably involves innate immune responses to microorganisms.

Unique 2, 17 autosomal translocation in an infertile man. *M. Kumar[1], S. Venkatesh[1], D. Pathak[1], RK. Sharma[2], R. Dada[1]* 1) Lab. for Molecular Reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India; 2) ART center, Army Research and Referral Hospital, New Delhi.

Chromosomal aberrations are one of the most common genetic causes associated with male infertility. In spite Y chromosomal defect attribute to impaired spermatogenesis, autosomes also play an important role in regulating spermatogenesis. Here we report a novel translocation involving chromosome 2 and chromosome17 in a 34 years old infertile man with severe oligozoospermia. Pedigree showed no family history of infertility. 72 hours blood culture was set up, GTG banding was done, and chromosomes were classified according to ISCN guidelines. Repeated semen analysis showed highly viscous and incomplete liquefaction even after 30 minutes with sperm count 1 million/ml. Peripheral karyotype analysis revealed 46, XY t(2;17) (qter;q12) chromosome complement. To the best of our knowledge such autosomal translocation in q arm of chromosomes 2 and 17, has not been previously reported. Though several studies have been shown role of sex chromosomes in the germ cell production, autosomes also play an important role in regulation of spermatogenesis. Such autosomal translocation result in severely impaired spermatogenesis and manifest as oligozoospermia. Thus a large number of cases with autosomal structure abnormalities need to be studied to establish genotype and phenotype correlation and to understand the role of autosomal genes in germ cell development and differentiation. Additional study of cases parent genotype, fluorescent in situ hybridization and molecular screening is necessary to characterize the gene involved in translocation, position effect and its impact on regulation of germ cell development.

A Comprehensive Evaluation of SNP Genotype Imputation. *D. Ellinghaus[1], M. Nothnagel[2], S. Schreiber[1,3], M. Krawczak[2,3], A. Franke[1]* 1) Institute for Clinical Molecular Biology, Kiel, Germany; 2) Institute of Medical Informatics and Statistics, Christian-Albrechts-University, Kiel, Germany; 3) PopGen Biobank, Christian-Albrechts-University, Kiel, Germany.

Genome-wide association studies have contributed significantly to the genetic dissection of complex diseases. In order to increase the power of existing marker sets further, methods have been proposed to predict individual genotypes at untyped loci from other marker sets by imputation, usually employing HapMap as a reference population. Although various imputation algorithms have been used in practise already, a comprehensive evaluation of these approaches, using genome-wide SNP data from one and the same population, is still lacking. We therefore investigated three genotype imputation programs (IMPUTE, MACH, and PLINK) using data from 449 German individuals genotyped in our laboratory for three different, commercially available genome-wide SNP arrays (Affymetrix 5.0 [500k], Affymetrix 6.0 [1000k], and Illumina 550k). Since the same 449 DNA samples were genotyped on all arrays, and since the arrays contained only partially overlapping marker sets, extensive genome-wide benchmarking using varied confidence thresholds became possible through a comparison of the imputed and observed genotypes derived with the different arrays. We observed that HapMap-based imputation in a European population is powerful, accurate and reliable, even in highly variable genomic regions such as the extended MHC on chromosome 6p21. However, while genotype predictions were found to be highly accurate for all three programs, the number of SNPs for which imputation was actually carried out varied substantially.

Significance of cytokines and ICAM as susceptibility genes for end stage renal disease. *G. Tripathi[1], P. Ranganath[2], S. N. Sankhwar[1], R. K. Sharma[3], S. Agrawal[2]* 1) Urology, CSM Medical University, Lucknow, Uttar Pradesh, India-226003; 2) Department of Medical Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow -226014; 3) Department of Nephrology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow -226014.

Objectives Cytokines and intercellular adhesive molecules (ICAM) play crucial role in different immunopathological conditions and hence may be responsible for pathogenesis of primary kidney disease and progression to end stage renal disease (ESRD). We have made an attempt to explore the role of different polymorphisms of these cytokines and ICAM genes as a susceptibility factors for ESRD. **Methods** The distribution of cytokine and adhesion molecule gene polymorphisms was analyzed in 258 ESRD patients and ethnically matched 569 controls. Individuals were genotyped for IL-4 (C590T), IL-6 (G174C), TNF- (G308A and G238A) and ICAM -1 (A469G) gene polymorphisms using standard PCR-RFLP based method. **Results** There was a significant difference between ESRD patients and control groups both at the biochemical parameters and at genotypic level. Significant difference was observed in genotype frequencies of the TNF- -308AA (p=0.001, OR=7.61, 95%CI=2.1-27.9), TNF- -238AA (p=0.001, OR=5.8, 95%CI=2.2-15.1). Further C allele of IL-6 -G174C and G allele of ICAM-1 A469G were significantly different in ESRD when compared to controls (p=0.0001; OR=5.5, 95%CI=3.9-7.7 and p0.0001; OR=3.8, 95%CI=3.1-4.7) respectively. For the IL-4 C590T polymorphism, though the homozygous mutant genotype (TT) was not found to be significantly associated with ESRD, a statistically significant association with T allele (p=0.0001) was found with the ESRD. Further, combined analysis revealed a higher risk in ESRD patients with low IL-4 and high IL-6 producing genotypes and high producing genotype of TNF- (308 and 238) with the increase risk of ~6.0 fold and 3.3 fold respectively. The haplotype analysis of TNF- (308 and 238) reveled high risk genotype with the risk ~8.5 fold (p=0.034). **Conclusions** Our results suggest that IL-6, IL-4, TNF- and ICAM gene polymorphism may be a risk factor for ESRD.

Differential Downregulation of Gastrin by IL1B Promoter Polymorphism through Signalling Intermediates NFKB and SMAD7. *D. Datta De[1], M. Maitra[2], S. Bhattacharjya[1], A. Choudhury[3], G. K. Dhali[3], S. Roychoudhury[1]* 1) Molecular and Human Genetics Department, Indian Institute Of Chemical Biology, Kolkata, West Bengal, India; 2) Department of Pediatrics and Molecular Biology, UT Southwestern Medical Center, Dallas, Texas; 3) Departments of Medicine and Gastroenterology, Institute of Postgraduate Medicine and Experimental Research, Kolkata-700 020, India.

More than half of the worlds population is chronically infected by Helicobacter pylori. IL1B promoter polymorphisms -511 C>T and -31C>T have been associated with Helicobacter pylori mediated gastro-duodenal diseases. Gastrin,a gastric acid-modulating hormone,is involved in the pathogenesis of gastro-duodenal ulcerations.The present study investigated the effect of IL1B promoter polymorphism on the transcriptional activity of the human gastrin promoter in a gastric epithelial cell line, AGS,and analyzed the underlying molecular mechanisms.Treatment of AGS with IL1B resulted in a 20-fold reduction in gastrin expression.Detailed investigation revealed that IL1B represses gastrin through TAK1, TAB1 that ultimately up regulates NFkB. A 40% release of IL1B mediated gastrin repression,as a result of inhibition of NFkB translocation,further suggested the presence of NFkB independent pathway.It was observed that IL1B up regulates Smad7, which inhibits gastrin expression by 6 folds.These results were also validated in vivo, where, at least a 3 fold lower expression of Smad7 and NFkB in H. pylori infected individual with ulcer compared to infected asymptomatic individuals was observed. NCOR and HDAC1 were also involved in repression of gastrin by IL1B.A 3-fold increase in IL1B expression was observed when AGS cells were transfected with -31TIL1B expression construct in comparison to -31CIL1B.This differential effect of IL1B promoter variants on its transcription subsequently translated in a 2 fold greater repression of gastrin by -31TIL1B. The signaling intermediate NFkB and Smad7 also revealed higher expression in the -31TIL1B transfected AGS cells. Experiments with HDAC inhibitor also suggested that at a particular dose, the repression on the gastrin promoter in -31CIL1B-transfected cells was greater than in cells transfected with -31TIL1B.

First evidence for an association of a functional variant in the miRNA-510 target site of the serotonin receptor type 3E gene with diarrhea predominant irritable bowel syndrome. *J. Kapeller[1], L. A. Houghton[2], H. Mönnikes[3], J. Walstab[4], D. Möller[1], H. Bönisch[4], B. Burwinkel[5], F. Autschbach[6], B. Funke[6], F. Lasitschka[6], N. Gassler[7], C. Fischer[8], P. J. Whorwell[2], W. Atkinson[2], C. Fell[2], K. J. Büchner[9], M. Schmidtmann[3], A.-S. Wisser[3], G. Rappold[1], B. Niesler[1]* 1) Dept. of Human Molecular Genetics, University of Heidelberg, Germany; 2) Neurogastroenterology Unit, University of Manchester, Wythenshawe Hospital, UK; 3) Dept. of Medicine, Inst. of Neurogastroenterology, Martin-Luther Hospital Berlin, Germany; 4) Inst. of Pharmacology and Toxicology, University of Bonn, Germany; 5) Molecular Epidemiology, DKFZ Heidelberg, Germany; 6) Inst. of Pathology, University of Heidelberg, Germany; 7) Inst. of Pathology, RWTH Aachen, Germany; 8) Inst. of Human Genetics, University of Heidelberg, Germany; 9) Div. of Hepatology, Gastroenterology and Endocrinology; Charité Berlin; Germany.

Diarrhea predominant irritable bowel syndrome (IBS-D) is a complex disorder related to dysfunctions in the serotonergic system. As cis-regulatory variants can play a role in the etiology of complex conditions, we investigated the untranslated regions (UTRs) of the serotonin receptor type 3 subunit genes *HTR3A* and *HTR3E*. Mutation analysis was carried out in a pilot sample of 200 IBS patients and 100 healthy controls from the United Kingdom. The novel *HTR3E* 3'UTR variant c.*76G>A (rs62625044) was associated with female IBS-D (P = 0.033, OR = 8.53). This association was confirmed in a replication study including 119 IBS-D patients and 195 controls from Germany (P = 0.0046, OR = 4.92). Pooled analysis resulted in a highly significant association of c.*76G>A with female IBS-D (P = 0.0002, OR = 5.39). In a reporter assay, c.*76G>A affected binding of miR-510 to the *HTR3E* 3'UTR and caused elevated luciferase expression. *HTR3E* and miR-510 co-localize in enterocytes of the gut epithelium as shown by *in situ* hybridization and RT-PCR. This is the first example indicating microRNA related expression regulation of a serotonin receptor gene with a cis-regulatory variant affecting this regulation and appearing to be associated with female IBS-D.

Short Tandem Repeat Typing Technologies used in Diagnosis Testing. *M.Ali. Saremi*[1,2] 1) Kawsar Genomic Research Center, Tehran, Tehran, Iran; 2) Baqiyatallah Medical Sciences University - Human Genetics Research Center, Tehran, Iran.

Micro satellite DNA loci or short tandem repeats (STRs) are abundant in eukaryotic genomes and are often used for diagnosis testing of closely related populations or species. These diagnosis testing are usually constructed by using some genetic distance measure based on allele frequency data, and there are many distance measures that have been proposed for this purpose. In the past the efficiencies of these distance measures in diagnosis testing have been studied mathematically or by computer. Because short tandem repeat (STR) loci are highly polymorphic, they are very useful for studying the evolutionary relationships of closely related populations or species. However, a number of statistical problems should be solved before this approach can be used effectively. Five ml of blood samples were obtained from the cases and their parents, in 7 ml falcon tubes. They were subsequently divided into two tubes, one for the stock and next uses and the other containing ethylene (EDTA) anticoagulant for use in PCR analysis. For DNA analysis, standard RGDE DNA extraction procedure was used to extract DNA from collected blood samples. PCR amplification was performed using primer sequences for five STR markers. Primer sequences were obtained from the Genome Database (http://www.gdb.org/). These markers are polymorphic and have recently been used for molecular diagnosis and parental origin determination in other population. The results of the fluorescent PCR analysis are shown effective application of STR markers for diagnosis of genetic diseases. The estimate of the recombination frequency in a population and precise mapping of the recombination events are critical for genetic counseling and prenatal diagnosis. This analysis can be easily performed thanks to an automated, fast, and accurate method based on the separation by capillary gel electrophoresis of the fluorescent-labeled amplified alleles of STRs that span the entire etiologic genetic factors. I am grateful to Saremi Mahnaz and Maghsoudi Sahar from Kawsar Genome Research Center for revising and editing the text.

Immunogenetics of systemic sclerosis: new clues for pathophysiology and related pulmonary fibrosis. *Y. Allanore[1], P. Dieudé[2], M. Guedj[2], J. Wipff[1], A. Munnich[1], C. Boileau[1]* 1) INSERM U 781, Necker Hosp, Paris, France; 2) CHU Bichat, Rheumatology, Paris, France.

Systemic sclerosis (SSc) is a severe orphan connective tissue disease with no proven effective drug. Our aim is to unravel the genetic factors underlying SSc which belongs to complex diseases. Some data suggest that the autoimmune component of SSc may be shared with that seen in other complex immune diseases, with micro-array studies suggesting a type I interferon signature. Therefore we tested the hypothesis that the PTPN22 and IRF5 (a regulator of interferon alpha production) genes, both involved in various autoimmune diseases, are associated with SSc. We tested DNA from individuals of European French Caucasian origin. SSc patients with the co-occurrence of auto-immune diseases associated with PTPN22 or IRF5 were excluded prior to the respective analyses. 659 SSc patients and 504 controls were genotyped for 7 PTPN22 SNPs including rs2476601 (1858C>T). The IRF5 rs2004640 (G>T) functional SNP was genotyped in a discovery set (427 SSc patients and 380 controls) and in an independent replication set (454 SSc patients and other 380 controls). No association was detected between the 7 PTPN22 SNPs tested and SSc. Haplotype analysis revealed a strong association between a risk haplotype carrying the 1858T allele (P = 1.52x10-7) and SSc. The meta-analysis of the available data (1772 SSc patients and 1262 controls) provided further evidence that PTPN22 rs2476601 confers susceptibility to SSc, particularly in the anti-topoisomerase I positive patients. Association between the IRF5 rs2004640 TT genotype and SSc was found in both discovery and replication sets. In combined populations, the TT genotype frequency was significantly increased in SSc patients compared to controls (P=0.002, OR 1.58, 95%CI 1.18-2.11). An association was observed in the sub-group of patients with positive antinuclear antibodies (Pcorr=0.04, OR 1.59 [1.16-2.17]) and fibrosing alveolitis (Pcorr=0.001, OR 2.07 [1.38-3.11]). No interaction between PTPN22 and IRF5 SNPs was detected. These data provide new insight into the pathogenesis of SSc, including clues to the mechanisms leading to specific disease subtypes.

Genetic contribution to all cancers: the first demonstration using the model of breast cancers from Poland stratified by age at diagnosis and tumor pathology. *J. Lubinski[1], M. Korzeń[2], B. Górski[1], C. Cybulski[1], T. Dębniak[1], A. Jakubowska[1], K. Jaworska[1], D. Wokolorczyk[1], K. Mędrek[1], J. Matyjasik[1], T. Huzarski[1], T. Byrski[1], J. Gronwald[1], B. Masojć[1], M. Lener[1], A. Szymańska[1], J. Szymańska-Pasternak[1], P. Serrano Fernandez[1], S. Narod[3], R. Scott[4]* 1) Intl Hereditary Cancer Ctr, Pomeranian Med Univ, Szczecin, Poland; 2) Technical Univ of Szczecin, Szczecin, Poland; 3) Centre for Research on Womens Health, Univ of Toronto, Toronto, Ontario, Canada; 4) Discipline of Medical Genetic, Univ of Newcastle, and the Hunter Medical Research Inst, Newcastle, Australia.

The aim of the study is to verify the hypothesis that genetic polymorphisms are associated with the predisposition to all malignancies. Using as a model breast cancers from the homogenous Polish population (West Pomeranian region) after stratification of 977 patients by age at diagnosis (under 51 years and above 50 years) and by tumour pathology (ductal cancers - low and high grade, lobular cancers, ER-positive/negative) we tested this hypothesis. Altogether 20 different groups of breast cancer cases have been analyzed. The results were compared to a group of unaffected controls matched by age, sex, ethnicity and geographical location and originated from families without cancers of any site among relatives. Molecular alterations selected for analyses included those which have been previously recognized as being associated with breast cancer predisposition. Statistically significant differences between the breast cancer cases and controls were observed in 19 of the 20 analyzed groups. Genetic changes were present in more than 90% of the breast cancer patients in 18 of 20 groups. The highest proportion of cases with constitutional changes - 99.3% (139/140) was observed for lobular cancers. The number and type of genetic marker and/or the level of their association with the specific cancer predisposition was different between groups. Markers associated with majority of groups included: BRCA1, CHEK2, p53, TNRnTT, FGFRnAA, XPD CC/AA and XPD GG. Some markers appeared to be group specific and included polymorphisms in CDKN2A, CYP1B1, M3K nAA, and RS67.

Genomewide Association Study in Ankylosing Spondylitis Identifies Major non-MHC Genetic Determinants of Disease Susceptibility. *D. Evans[1], P. Leo[2], A. Sims[2], W. Maksymowych[3], M. Ward[4], M. Stone[5], P. Rahman[6], M. Weisman[7], R. Inman[8], D. Gladman[8], J. Davis[9], T. Learch[7], L. Savage[10], L. Diekman[11], P. Danoy[2], J. Pointon[12], X. Zhou[11], P. Wordsworth[12], J. Reveille[11], M. Brown[2,12]* 1) Univ of Bristol, Bristol, UK; 2) Univ of Queensland, Brisbane, Australia; 3) Univ of Alberta, Edmonton, Canada; 4) Intramural Research Program, NIAMS, Bethesda, MD; 5) RNHRD, Bath, UK; 6) Memorial Univ, St John's,Canada; 7) Cedars-Sinai Med Ctr, Los Angeles, CA; 8) Toronto Western Hospital, Toronto, Canada; 9) UCSF, San Francisco, CA; 10) Spondylitis Assn of America, Sherman Oaks, CA; 11) Univ of Texas-Houston HSC, Houston, TX; 12) Univ of Oxford, Oxford, UK.

Ankylosing spondylitis (AS) is an inflammatory arthritis, which can lead to fusion of the spine and other affected joints. In order to identify genetic variants predisposing to AS, we enrolled Australian (n=69), British (n=1016) and North American (n=983) cases of European descent fulfilling modified New York Criteria. Control genotypes were obtained from the 1958 British Birth Cohort(n=1500) and from the Illumina iControlDB database (n=3434). Cases were genotyped for 317K SNPs using the Illumina HumHap300 SNP chip. Analysis was performed using Eigensoft to correct for population substructure. The well-known MHC association with AS was confirmed, as were associations with ARTS-1, IL23R and around IL-1R2/R1. Two regions not previously reported achieved genome-wide significance,on chromosome 2p15(p=1.1x10-14) and chromosome 21q22(p=2.6x10-10). 21 unique regions achieved suggestive significance, including SNPs in the gene TNFR1(p=4.8x10-6),over expression of which causes sacroiliitis in mice,and near TRADDD, which interacts with TNFR1(p=3.2x10-5). A confirmation study of these findings is near completion. Finally, we computed likelihood ratios to determine the diagnostic potential of screening individuals for these genetic variants. For many genotypic combinations, the positive and negative predictive value of genetic tests surpassed other diagnostic instruments including MRI scanning. The high prognostic value of genetic tests for AS suggests that they may be of use in screening in both clinical and population settings.

Analysis of matrix metalloproteinase-2 gene polymorphisms in high myopia. *E. Hsi, H. Juo* Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan.

Purpose: The sclera contains approximately 90 percent collagen. The matrix metalloproteinase-2 (MMP2) is responsible for degradation of scleral extracellular matrix, which may contribute to myopia. This study was aimed to systemically investigate the polymorphisms at MMP2 and their relationship to high myopia.
Methods: A total of 470 cases and 618 controls were included in the study. A case was defined as a refraction -6 D and control -1.5 D. Seventeen tagging single nucleotide polymorphisms (tSNPs) were genotyped. Statistical analyses included Hardy-Weinberg equilibrium (HWE) test, chi-squared test to evaluate the genotypic effect, linkage disequilibrium (LD) estimation, LD block construction and haplotype analysis. Subset analysis was also conducted for cases with highly myopic parents. The Bonferroni correction was used to correct for multiple testing.
Results: One SNP was not in HWE and thus was removed for further analysis. Single marker analyses did not find any SNP with a significant p value after correcting for multiple testing. There were five haplotype blocks and the fourth block yielded an overall p value of 3×10^{-5} in our first batch of sample (n=1006), and 2×10^{-3} the replication sample (n=710).
Conclusions: This is the first large human study to comprehensively study the tSNPs at the MMP2 gene for high myopia. Our study indicated that a rare causal allele is in strong LD with the fourth block, which showed a significant protective effect against high myopia.

Altered brain gene expression profiles associated with the pathogenesis of phenylketonuria in a mouse model. *J. W. Park, E. S. Park, E. N. Choi, H. Y. Park, S. C. Jung* Dept Biochemistry, School of Medicine, Ewha Womans Univ, Seoul, Korea.

Phenylketonuria (PKU) is an autosomal recessive disorder caused by a deficiency of phenylalanine hydroxylase (PAH), which catalyzes the conversion of phenylalanine to tyrosine. The resultant hyperphenylalaninemia causes mental retardation, seizure, and abnormalities in behavior and movement. Gene expression profiling of brain tissue from a mouse model of PKU revealed overexpression of transthyretin (Ttr), sclerostin domain containing 1 (Sostdc1), alpha-Klotho (Kl), prolactin receptor (Prlr), and early growth response 2 (Egr2). The upregulated state of these genes in brain tissue was confirmed using real-time PCR and Western blotting. In contrast to its overexpression in the brain, TTR expression was low in the sera of PKU mice offered unrestricted access to a diet containing phenylalanine. Expression of TTR decreased in a time-dependent manner in 0.9 mM phenylalanine-treated HepG2 cells and in 1.2 mM phenylpyruvate-treated HepG2 cells. In contrast, expression of TTR increased in 0.5 mM phenyllactate-treated HepG2 cells. The modification of TTR gene expression by phenylalanine, phenylpyruvate and phenyllacate could be mediated through Ttr promoter region. These findings indicate that Ttr and other genes play important roles in the pathogenesis of PKU and that phenylalanine and its metabolites, phenylpyruvate and phenyllactate might have a direct effect on the level of TTR in serum.

Alteration of gene expression related to carbohydrate metabolism in placenta of fetus with intrauterine growth restriction. *M. H. Lee[1], Y. J. Jeon[1], Y. J. Kim[2], S. C. Jung[1]* 1) Dept Biochem, School of Medicine, Ewha Womans Universtiy, Seoul, Korea; 2) Dept Obstet and Gynecol, School of Medicine, Ewha Womans Universtiy, Seoul, Korea.

Intrauterine growth restriction (IUGR) is caused by malnutrition of placenta that carries nutrient and oxygen to the fetus. IUGR is suggested to have important consequences for adult health by increasing the risks of metabolic disorder such as hypertension, diabetes, and obesity. The aim of this study was to investigate whether IUGR is associated metabolic disease. Here, we used cDNA microarray analysis to identify differentially expressed metabolic genes in placentas of fetus with IUGR compared with placentas of the normal control group. The expression of genes related to carbohydrate metabolism was up-regulated in placentas of fetus with IUGR including dihydrolipoamide S-acetyltransferase (E2 component of pyruvate dehydrogenase complex, DLAT), 6-phosphofructo-2-kinase/fructose-2, 6-biphosphatase 2, lactate dehydrogenase C, IGFII, and Insulin. In contrast to the result, IGFI was down-regulated in placentas of fetus with IUGR. In the IUGR group, the glucose concentration was significantly decreased in maternal serum and in cord blood. However insulin concentration was increased in maternal serum and in cord blood. Moreover IGFII concentration was higher in maternal serum and lower in cord blood. These results suggest that alteration of carbohydrate metabolism in fetus with IUGR might be important for metabolic disorder cause after birth.

Searching for the natural RNA substrates of DAZAP1, a testis-abundant hnRNP protein. *P. Yen, C. Y. Chung, C. L. Hsu, F. P. Hsiao* Inst Biomedical Sci, Academia Sinica, Taipei, Taiwan.

Deleted in Azoospermia Associated Protein 1 (DAZAP1) was originally identified through its interaction with DAZ, a spermatogenic factor encoded by the human Y chromosome. It is an hnRNP protein that is expressed most abundantly in the testis. It shows a dynamic expression pattern during mouse spermatogenesis, and has the ability to shuttle between the nucleus and the cytoplasm in somatic cells. In addition, it is excluded from the transcriptionally inactive XY bodies in pachytene spermatocytes. These properties suggest a role of DAZAP1 in RNA transcription and transport. The phenotypes of *Dazap1* mutant mice that manifested both infertility and growth retardation indicates that DAZAP1 is required for spermatogenesis as well as normal mouse development. The natural RNA substrates of DAZAP1 remain elusive, though Hori et al. previously showed that DAZAP1 selectively binds in vitro to RNAs containing two consensus sequences AAAUAG and GU1-3AG in separate loop structures. In an attempt to identify DAZAP1s RNA substrates, we used the SNAAP (isolation of specific nucleic acids associated with proteins) technique to immunoprecipitate DAZAP1 associated RNAs from mouse testis extracts using an anti-DAZAP1 antibody. Subsequent differential display using 8 random primers identified several transcripts that were selectively pulled down by the anti-DAZAP1 antibody. Real-time PCR quantification showed that the levels of these transcripts were much lower in the testes of Dazap1 mutant mice than those of the wild-type mice. Additional experiments will be performed to verify the binding of DAZAP1 to these transcripts and to elucidate how DAZAP1 regulates their expression.

Exploration of genes related to X-linked mental retardation (XLMR) by in-house X-tiling array. *S. Honda[1], S. Hayashi[1], I. Imoto[1], I. Inoue[2], T. Yabe[3], K. Tokunaga[4], E. Nakagawa[5], Y. Goto[6], J. Inazawa[1]* 1) Dept Mol Cytogenet, Med Res Inst, Tokyo med & dent Univ, Tokyo, Japan; 2) Div Mol Life Sci, Sch Med, Tokai Univ, Isehara, Japan; 3) Tokyo Metropolitan Red Cross Blood Cent, Tokyo, Japan; 4) Dept Hum Genet, Grad Sch Med, Univ Tokyo, Tokyo, Japan; 5) Div Child Neurol Musashi Hosp, Natl Center Neurol & Psychiat, Tokyo, Japan; 6) Dept MentalRetardation and Birth Defect Res, Natl Inst Neurosci, Natl Cent Neurol & Psychiat, Tokyo, Japan.

An estimated 10-12% of mental retardation (MR) is caused by mutation on the chromosome X. Although 82 X-linked mental retardation (XLMR) genes have been identified to date, many XLMR genes remain to be identified. Known XLMR genes have been identified by conventional positional-cloning strategies, but cryptic chromosome copy number aberrations (CNAs) cannot be detected by routine karyotyping due to its limited resolution, thus we constructed a high-density chromosome X array (MCG X-tiling array), which contains a total of 1001 bacterial artificial chromosome (BACs) throughout chromosome X except pseudoautosomal regions, to identify novel XLMR-associated genes. We have screened 115 families with XLMR or probable XLMR by array-CGH using MCG X-tiling array, and detected CNAs related to MR in 7 families (6%). Among these 7 families, 3 had CNAs in regions involved in known XLMR-associated genes, whereas, other 4 families had CNAs involved in genomic materials which have never been reported. Among them, 2 families had identical CNAs at Xp: arr cgh Xp22.2×2, Xp21.3×2, although those two families are not consanguineous. The CNAs showed complicated recombination and involvement of a part of genes, suggesting that the recombination may be relevant to MR. To investigate the genomic recombination, we carried out inverse-PCR and identified that the recombination breakpoint with CNAs. We next performed genomic PCR which can detect the recombination breakpoint to screen the recombination in the general population from different ethnic group, suggesting that it is possible that this recombination was occurred in Mongol and introduced into Japan.

XY/XX chimerism presenting as hemihypertrophy with pigmentary abnormalities in a male with normal sexual differentiation. *L. Van Maldergem[1 and 2], M.-F. Portnoi[3], M. Gerard-Blanluet[1], M. Cadot[4], S. Lemerle[4]* 1) Clinical Genetics Unit, Centre hospitalier intercommunal, Creteil, Ile-de-France, France; 2) Centre de génétique humaine, Université de Liège, Liège, Belgium; 3) Service de génétique et embryologie médicales, CHU Armand-Trousseau, Paris, France; 4) Service de pédiatrie, centre hospitalier intercommunal, Creteil, France.

A boy born to non-consanguineous parents presented with marked left body hypertrophy, including asymmetric skull and enlarged left limbs. He developed scoliosis. Facial appearence was striking for irides heterochromia, bushy eyebrows and ocular proptosis. Areas of brownish skin hyperpigmentation on left inferior abdominal quadrant, left arm and left leg were present from infancy. His clinical course indicated a stunted growth (-4SD) for which he received growth hormone therapy. His puberty at 13y resulted in fully developed male external genitalia. At 15y, his height was 151 cm(3rd centile). His intelligence is normal. Although karyotype was 46, XY on leukocytes, due to pigmentary abnormalities, we decided to test the hypothesis of a chromosomal mosaicism and evaluated karyotype on cultured fibroblasts grown after skin biopsies taken from hyper- and normo-pigmented areas. A 46,XY/ 46,XX chimerism was evidenced:94/6 cells in hyperpigmented area and 96/4 cells in normal skin region after FISH study. Chimerism results from fusion of different zygotes in the same embryo. Thus, presence of two cell lines resulting from assembly of two fertilized eggs are present in the same individual. It is an exceptional phenomenon with 31 cases being reported until now. Within this group, XY/XX chimerism represents only a few cases and is usually diagnosed on the basis of aberrant blood group typing or abnormal sexual differentiation. Chimerism escapes diagnosis whenever different cell lines harbour the same gender and when aberrant blood group typing is missed. To the best of our knowledge, only one XY/XX patient with normal sex differentiation has been reported until now(Lipsker et al.2008). Here we provide evidence that hemihypertrophy, short stature and irides heterochromia also belong to the clinical spectrum of this exceptional tetragametic phenotype.

Candidate genes controlling longevity in Koreans. *J. W. Park[1,2], D. H. Kim[1,2], Y. Jee[2], H. Y. Cho[2], S. C. Park[3], J. B. Park[1,2]* 1) Dept. Molecular and Cellular Biology, Sungkyunkwan Univ., School of Medicine, Suwon, Korea; 2) Ctr. Genome Research, Samsung Biomedical Research Inst., Seoul, Korea; 3) Dept. Biochemistry, School of Medicine, Seoul National Univ., Seoul, Korea.

Long-lived people may have a unique genetic makeup which is more resistant to the prevalent age-related diseases such as diabetes mellitus, cardiovascular disease, and cancer than the general population. We performed a high-throughput candidate gene study on a genome-wide scale to identify susceptibility variants controlling longevity using 137 nonagenarians/centenarians and 213 young healthy controls ascertained from the Korean Centenarian Study. Among 1,536 SNPs genotyped, we evaluated 486 informative markers located in 179 genes in a series of different association analyses under five genetic models. A total of 60 genes among 179 candidate genes yielded nominal significance in either of allelic or genotypic ^{2} - test. Particularly, six genes (i.e. ADCY3, EGFR, PAX4, PPP1R1A, ALDH2, and CDK10) attracted much attention as potent candidate genes affecting longevity. Among eleven genes consistently yielded significant evidence for allelic, genotypic and haplotypic analyses (i.e. HK2, ERBB4, PCSK1, ITK, EGFR, PAX4, LPL, LYN ADCY9, CDK10, and PPP1R16B), PCSK1 ($p = 0.008$), EGFR ($p = 0.003$), PAX4 ($p = 0.008$), and LYN ($p = 0.002$) remained significant even after the Bonferroni correction for multiple testing. In two way interaction analyses, six, one, three, and two pairs of loci for each of four age-gender groups yielded statistical significance. The results from different statistical analyses consistently supported that the presence of the gene variants might confer susceptibility to longevity in Koreans. While the generalizability of the finding is uncertain, genes identified here may lay the foundations for further studies.

The Study of Mitochondrial A3243G Mutation in Different Tissues. *Y. MA[1], Y. QI[1], F. FANG[2], Y. YANG[3], Y. ZHANG[1], S. WANG[1], P. PEI[1], Y. XU[1]* 1) Central laboratory, Peking University First Hospital, Beijing, China; 2) Department of Pediatrics,Bejing Childrens Hospital, Beijing, 100045, China; 3) Department of Pediatrics, Peking University First Hospital, Beijing, 100034, China.

The most frequent syndromic manifestation of A3243G mutation is the mitochondrial encephalomyopathy, lactic acidosis and stokelike episodes syndrome (MELAS). The A3243G mutation level was higher and more stable in DNA isolated from muscle than that from blood, however, patients often reject the invasive muscle biopsy, and only take mutation analysis in blood, which can reduce the positive mutation level detection, particularly in the oligosymptomatic patients and the asymptomatic relatives. Thus A3243G mutation analysis in blood was not a good choice. Therefore, we compared the A3243G mutation level in five easy accessible tissues of MELAS syndrome patients carrying the A3243G mutation and their maternal relatives, to find the most sensitive tissue, and establish the best and non-invasive inspection method.We studied 33 MELAS patients known to harbor A3243G mutation and their 50 maternal relatives. 18 maternal relatives show oligosymptomatic, and 32 relatives manifest asymptomatic. Total DNA was extracted from the peripheral blood, urine, hair folic, saliva and muscle tissue of the patients and relatives. A3243G mutation was detected by PCR-RFLP method. A3243G mutations were detected in all tissues of the 33 MELAS patients. A3243G mutation ratio in urine was significantly higher than that of blood (t=-11.13, P0.0001), and was similar to that of muscle tissue. A3243G mutations were detected in one tissue or all tissues of the 44 maternal relatives. There were 9 relatives in whom the mutation was not detected in blood while it was clearly present in urine. A3243G mutation ratio in their urine were significantly higher than that of blood (t=-6.87, P0.0001). We observed a close correlation between the level of A3243G mutation in blood and saliva for many patients and relatives (Pearsons correlation coefficient, r=0.651, p=0.001). These data strongly support urine is a good tissue of choice for the diagnosis of A3243G mutation, and the level of A3243G mutation in saliva can represent that in blood.

C2ORF34, A new methyltransferase gene deleted in patients with the 2P21 deletion syndrome. *R. Parvari[1,2], S. Buriakovsky[1,2]* 1) Dept Genetics & Virology, Ben Gurion Univ, Beer Sheva, Israel; 2) National Institute of Biotechnology Negev, Ben Gurion Univ, Beer Sheva, Israel.

The 2p21 deletion syndrome is a unique recessively inherited syndrome presented by an extended Bedouin family. The clinical manifestations of the syndrome were cystinuria, mental and growth retardation, hypotonia, facial dysmorphism and reduced activity of mitochondrial encoded respiratory chain enzymatic complexes. Our previous study revealed the molecular basis of this syndrome as a homozygous deletion of 179,311 bp on chromosome 2p21, and thus was subsequently named the 2p21 deletion syndrome. Further studies to define the transcription content of this interval showed that it includes 4 protein coding genes: type I cystinuria SLC3A1, phosphatase 2C and two uncharacterized genes KIAA0436 and C2orf34. The C2orf34 gene has its first exon in the deletion and thus is not expressed in patients. C2orf34 is highly conserved during evolution and ubiquitously expressed including the tissues affected by the syndrome. We present evidence for its function as a methyltransferase. We hypothesize that the absence of this gene in the patients may have a major contribution to the clinical presentation of the patients.

Successful treatment of spinocerebellar ataxia 6 by systems therapy with medicinal herbs. *T. Okabe* Dept Integrated Traditional Medicine, University of Tokoy Graduate School of Medicine, Hongo, Tokyo, Japan.

The spinocerebellar ataxias (SCAs) are clinically and genetically a heterogeneous group of neurodegenerative disorders. At present,we have no effective therapeutic tools. We report here two cases of spinocerebellar ataxia 6(SCA6)with typical symptoms, which were improved after administration of a mixture of traditional medicinal herbs. A 60-year-old Japanese female suffered from gait disturbance, ataxia and dizziness. Head MRI revealed a typical atrophic image in cerebellum. Genetic tests revealed an expanded allele of 22 CAG repeats at the spinocerebellar ataxia type 6 locus. She was diagnosed as SCA6. A mixture of 18 medicinal herbs (modified Chinkan-sokufu-to) was given according to the differential diagnosis based on the guideline of traditional herbal medicine. Most of the symptoms were remarkably improved after 60 days of the herbal treatment. One year after discontinuation of the treatment, she complained of gait ataxia. She was treated with the modified Chinkan-sokufu-to for 60 days. Gait ataxia was markedly improved by the second treatment. 15 months after discontinuation of the second treatment, she complained of gait ataxia again. The same remedy was given for 60 days. Gait ataxia was remarkably reduced again. Her total ataxia score was improved from 20 to 3 on a 100-point semiquantitative International Cooperative Ataxia Rating Scales(ICARS). Another case was a 75-year-old Japanese male suffered from unsteadiness of gait, ataxia of gait and stance and positional vertigo. Head MRI revealed a typical atrophic image in cerebellum. Genetic tests revealed an expanded allele of 22 CAG repeats at the spinocerebellar ataxia type 6 locus. He was diagnosed as SCA 6. A mixture of 18 medicinal herbs (modified Chinkan-sokufu-to) was given. Two weeks after the administration of the medicinal herbs, positional ataxia disappeared. Most of the symptoms were remarkably improved after 60 days of the herbal treatment. Together with the first case, the results imply therapeutic potential of the medicinal herbs for spinocerebellar ataxia 6.

INCREASED DNA DAMAGE SENSITIVITY IN SMC1A-MUTATED CORNELIA DE LANGE SYNDROME CELLS. *A. Musio[1, 4], M. L. Focarelli[2, 3], M. Paulis[2, 3], P. Vezzoni[2, 3]* 1) Istituto di Tecnologie Biomediche, CNR, Pisa, Italy; 2) Istituto di Tecnologie Biomediche, CNR, Segrate (Mi), Italy; 3) Istituto Clinico Humanitas, Rozzano (Mi), Italy; 4) Istituto Toscano Tumori, Florence, Italy.

Sister chromatids cohesion is a fundamental aspect of chromosome behavior that ensures the accurate inheritance of the genetic information during mitosis and meiosis. The central player of this process is cohesin, a protein complex composed of a heterodimer of SMC1A and SMC3, associated with SCC1 and SCC3/SA3. Several other proteins (NIPBL, ESCO2, PDS5A, PDS5B) are involved in the loading, unloading, maintenance and function of this complex. The finding that cohesin participates in a growing assortment of chromosome-related processes provides the possibility that new roles for cohesin factors will be discovered. Therefore it would not be surprising if cohesin complex members are involved in human diseases. Recently, we found that mutations in SMC1A are responsible for a subset of Cornelia de Lange syndrome (CdLS), accounting for 5% of cases. CdLS is a multisystem developmental disorder with classic features of characteristic facial dysmorphia, upper extremity malformations, hirsutism, cardiac defects, growth and cognitive retardation, and gastrointestinal abnormalities that display a wide spectrum of clinical severity. Furthermore, some CdLS patients developed metaplasia esophagus, Barrett esophagus and esophageal adenocarcinoma, suggesting a genetic predisposition to esophageal alterations in CdLS. Results from our laboratory showed that SMC1A-mutated patients have spontaneous genome instability and cells are sensitive to genotoxic agents further supporting the notion that SMC1A play a role in genome maintenance.

Polymorphisms of genes in dopamine pathway determine susceptibility to Parkinsons disease and may influence mortality and aging. *Y. Fang[1], Z. Bochdanovits[1], P. Rizzu[1], D. Sondervan[1], D. Deeg[2], N. van Schoor[2], B. Post[3], J. van Hilten[4], P. Heutink[1]* 1) Dept Clinical Genetics, Free University Medical Center (VUMC), Amsterdam, Netherlands; 2) EMGO institute, VUMC, Amsterdam, Netherlands; 3) Dept of Neurology, Academic Medical Center, Amsterdam, Netherlands; 4) Dept of Neurology, LUMC, Leiden, Netherlands.

Parkinsons disease (PD) is a complex genetic disorder with an unclear etiology. Parkinsonism appears when dopamine in the neural cells decreases. Dopamine and its metabolic pathway play a crucial role in the PD pathological progress. We systematically investigated the genetic effect and interaction of sequence variation in genes of the dopaminergic pathway for the risk of PD. With our selection criteria we selected 145 out of 1918 single nucleotide polymorphisms (SNPs) across six major genes in the pathway. 127 SNPs with calling rate95%; and in Hardy-Weinberg equilibrium were successful genotyped in two independent Dutch PD cohorts and a control cohort. We identified 3 SNPs: rs10743152 in the promoter region of the TH gene; non-synonymous SNP, rs4531, in the DBH gene and rs11575575 from 3-end of the DDC gene, to be significantly associated with increased risk of PD in combined late-onset PD cohort (n=313) versus age and gender-matched control cohort (n=706).The T-allele carriers of those SNPs increased 1.52, 1.34 and 1.65 times risk of PD respectively (all p0.001). The same PD-risk genotype of the rs10743152 was associated with 2.6 years decreased age (p0.001) and increased 30% risk of morality (p=0.005) compared to non T-allele carriers in the control cohort (n=1319). We observed an interaction between rs10743152 of TH gene and rs4531 of the DBH gene for the risk of PD (p=0.04). No interaction (p=0.52) but an additive effect between the T-carrier of rs10743152 and the non 266-carrier of the SNCA-REP1 repeat of the SNCA gene for the risk of PD was found: two risk genotype carriers increase 2.8 times risk of PD compared to non risk genotype carriers (p0.001). Our results indicate that TH might affect the normal aging process, and the risk of develop PD is a consequence of the age related neurological deterioration associated with TH.

Study of audiometric measurements using principal components analysis. *E. Fransen[1], J. R. Huyghe[1], O. Thas[2], L. Van Laer[1], G. Van Camp[1]* 1) Center for Medical Genetics, University of Antwerp (CDE), Antwerp, Belgium; 2) Departement of Applied Mathematics, Biometrics and Process Control, University of Gent (UGent), Ghent, Belgium.

The most important technique to test an individuals hearing capability is a pure-tone audiometry (PTA). A test subject has to respond to sound stimuli of a certain sound level (in decibel, db) and a well-defined frequency (conventional including 0.25, 0.5, 1, 2, 4 and 8 kiloHerz (kHz). At each frequency, one records the lowest sound level that the patient responds to, which is referred to as the hearing threshold. Our research interest is the elucidation of genetic and environmental risk factors for age-related hearing impairment. Typically, a statistical association is tested between the hearing phenotype and the putative risk factor. On the phenotypic side, we have to deal with two complicating factors: First, age and sex are two covariates we have to account for. Second, we want to reduce the dimension of our thresholds recording (at six frequencies) to a lower-dimensional observation. To correct for age and sex, linear regression models were fitted at each of the different frequencies, regressing log-transformed hearing threshold on age + age². Then, principal components (PC) analysis was used to reduce the dimension of this six-variate observation. The first PC was a size component accounting for 55% of the variance. The second PC showed a contrast between subjects with a uniform hearing loss across all frequencies (flat audiogram) and subjects with hearing loss in high frequencies only (sloping audiogram). The third PC identified a subgroup of subjects with hearing loss restricted to 2 and 4 kHz, an audiometric pattern that is the hallmark of noise-induced hearing loss. These different types of hearing loss are possibly correlated to different pathological changes in the inner ear. Using the PCs, we have reanalyzed the role of environmental risk factors and candidate genes on age-related hearing loss.

Large BRCA1 and BRCA2 genomic rearrangements in Belgian breast-ovarian cancer families. *K. Storm, S. Willocx, W. Wuyts, N. Van der Aa, J. van den Ende, B. Blaumeiser* Dept Medical Genetics, University and University Hospital of Antwerp, Antwerp, Belgium.

Background: BRCA1 and BRCA2 germ-line mutations predispose to breast and ovarian cancer. Most of the alterations are point mutations or small insertions/deletions in BRCA1 or BRCA2. Large genomic rearrangements of BRCA1 account for 0-36 % of all disease causing mutations in various populations, while large genomic rearrangements in BRCA2 are more rare. In our screening approach for the BRCA genes, screening of the complete coding sequence of both genes is completed by MLPA screening for larger genomic rearrangements. While little data can be found on BRCA1 genomic rearrangements in the Belgian population, knowledge of BRCA2 genomic rearrangements in our population is still unknown. Methods: Multiplex ligation-dependent probe amplification (MLPA) was used to analyze 305 Belgian breast and/or ovarian cancer patients (including high-risk families, single early-onset cases, and familial cases with a more modest risk for BRCA mutations) in whom a deleterious mutation in BRCA1 and BRCA2 was not detected by DGGE and/or sequencing analysis. Results: Two different genomic rearrangements were detected in 8 patients: A recurrent exon 13 deletion in BRCA1 was identified in 6 high risk families (~2 %), accounting for 17,1 % (6/35 index cases) of all BRCA1 mutations in our Belgian population. In BRCA2, a novel in-frame exon 19 deletion (within a DNA-binding domain of BRCA2) was characterized in 2 high risk families (~0.7 %), accounting for 7,7 % (2/26 index cases) of our BRCA2 families. Conclusion: In Belgium, women eligible for BRCA1 and BRCA2 mutation screening, when found negative, could benefit from screening for large genomic rearrangements in both genes BRCA1 and BRCA2. Genomic rearrangements should be screened in high risk families, especially when breast cancer occurs together with ovarian cancer.

Assessment of morphological features in BRCA1 and BRCA2 carriers. *S. Shanley[1], K. Bishop[1,2], V. Murday[3], M. Wilmot[3], DGR. Evans[4], D. Eccles[5], S. Hodgson[6], S. Ashley[1], L. Ashcroft[7], A. Tutt[8], E. Bancroft[1], G. Gui and the Breast Unit[1], A. Baildam[7], A. Howell[7], G. Royle[9], D. Easton[10], R. Eeles[1, 11]* 1) Cancer Genetics Unit, Royal Marsden NHS Foundation Trust, Sutton UK; 2) Department of Genetic Medicine, VanderBilt University, Nashville, Tennessee, USA; 3) West Scotland Regional Genetics Service Ferguson Smith Centre for Clinical Genetics Yorkhill NHS Trust Glasgow UK; 4) Academic Unit of Medical Genetics and Regional Genetics Services St Marys Hospital, Manchester UK; 5) Wessex Clinical Genetics Service Princess Anne Hospital Southampton UK; 6) South West Thames Regional Genetics Service St Georges Hospital Cranmer Tce, London UK; 7) Christie Hospital, Withington, Manchester UK; 8) Oncology Unit Guys and St Thomas' NHS Foundation Trust London UK; 9) Department of Surgery, Royal South Hants Hospital, Southampton UK; 10) Strangeways Research Laboratory, Worts Causeway, Cambridge UK; 11) Institute of Cancer Research Downs Rd Sutton UK.

Some cancer predisposition syndromes are associated with specific morphological features which can assist in making a clinical diagnosis eg macrocephaly and mucocutaneous lesions in Cowden Syndrome. No specific features have been noted in association with the BRCA1 and BRCA2 phenotypes but few data have been collected. In a study comparing side effects of breast radiation and chemotherapy in female BRCA carriers versus women with sporadic breast cancer, participants were also invited to have clinical photographs and basic clinical measurements. Clinical photographs were examined independently by two clinical geneticists who were unaware of the mutation status of individuals. Data are presented on 41 pairs of BRCA carriers with control participants who were matched for age and treatment regimens.

Identification of Novel Loci for Insulin Sensitivity and Disposition Index in GWAs of Hispanic Americans: The IRAS Family Study. *N. Palmer[1], C. Langefeld[2], J. Ziegler[2], F. Hsu[2], S. Haffner[3], T. Fingerlin[4], J. Norris[4], Y. Chen[5], S. Rich[6], T. Haritunians[5], K. Taylor[5], R. Bergman[7], J. Rotter[5], D. Bowden[1]* 1) Biochemistry, Wake Forest Univ, Winston-Salem, NC; 2) Public Health Sciences; Wake Forest Univ, Winston-Salem, NC; 3) Medicine; Univ of Texas, San Antonio, TX; 4) Preventive Medicine & Biometrics; Univ of Colorado, Denver, CO; 5) Medical Genetics Institute; Cedar-Sinai Research Institute, Los Angeles, CA; 6) Public Health Genomics; Univ of Virginia, Charlottesville, VA; 7) Physiology & Biophysics; Univ of Sourthern California, Los Angeles, CA.

To date, Genome Wide Association studies (GWAs) of T2D have identified genes for -cell function. We measured insulin sensitivity (S_I), insulin secretion (acute insulin response; AIR) and Disposition Index (DI; quantitative measure of the compensatory relationship between SI and AIR) DI=S_IxAIR) using the frequently sampled intravenous glucose tolerance test with minimal model analysis in non-diabetic Hispanic Americans from the Insulin Resistance Atherosclerosis Family Study. A GWAs (*n*=229, 34 families) was performed with 318K SNPs. Association analysis adjusted for age, gender, center & BMI used a variance component measured genotype approach in SOLAR. SNPs associated with glucose homeostasis measures (*n*=672 SNPs) were genotyped in the entire cohort (*n*=1190, 92 families). Among the top hits for S_I in the combined analysis, VIPR1 (involved in smooth muscle relaxation; P=2.1x10^{-4}), MAGI1 (involved in cell-cell contact; P=3.8 x10^{-4}), 2 SNPs (P<2.2x10^{-4}) upstream of AK097474 (hypothetical gene in muscle & liver) and 3 SNPs in a nongenic region (15q24.1; P<1.8x10^{-3}) were associated. Among the top hits for DI in the combined analysis, SLC1A4 (sodium-dependent solute carrier; P=3.3x10^{-4}) and PGM1 (involved in glucose synthesis & breakdown; P=3.4x10^{-4}) were associated. Noteworthy, MAGI1 and MYH13 (myosin skeletal muscle polypeptide) were in the top 10 genic hits for S_I and DI. In summary, candidate loci for S_I and/or DI in Hispanic Americans have been identified using GWAs. These loci have not been revealed in T2D GWAs in European-derived populations.

Mutation spectrum of the dystrophin gene in 433 Japanese dystrophinopathy cases. *Y. Takeshima, M. Yagi, Y. Okizuka, H. Awano, Z. Zhang, K. Saiki, M. Matsuo* Dept Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan.

[Background] Duchenne and Becker muscular dystrophies are caused by mutations in the dystrophin gene. Mutation analysis of the dystrophin gene is indispensable not only to provide proper clinical information but to apply the molecular therapies, which depend on the type of mutation in each case. However, the large size of dystrophin gene (3000kb and 79 exons) hampers the detection of small mutations including nonsense, splice site, and small deletion/insertion mutations. To clarify the responsible mutations of all cases, comprehensive mutation analysis of the dystrophin gene employing not only genomic DNA but mRNA was performed in dystrophinopathy cases. [Patients and Methods] A total of 433 Japanese dystrophinopathy cases were recruited. Gross gene arrangements were detected by Southern blotting, MLPA analysis, or semi-quantitative PCR analysis by capillary electrophoresis, and small mutations were analyzed by RT-PCR or direct sequence method using genomic DNA or cDNA as template. [Results] 265 (61%) and 39 (9%) cases had large deletions and duplications encompassing at least one exon, respectively. Small deletion/insertion mutations less than several hundred nucleotides were disclosed in 32 (7%) cases. Nonsense and splice site mutations were identified in 65 (15%) and 28 (6%) cases, respectively. X-chromosome abnormalities were disclosed in 3 cases. In remaining one case, however, no mutation was detected. There were several noteworthy cases as follow. First, 2 cases with duplication mutations had two noncontiguous duplicated regions. Next, 2 cases with insertion sequences composing of ~608bp and ~325bp, respectively had insertions of retrotransposons. In 3 cases deep intronic mutations activating the cryptic splice sites were disclosed. [Conclusions] Comprehensive mutation analysis revealed the responsible gene mutations in 99.8% of the dystrophinopathy cases, and the present result disclosed the highest mutation detection rate.

Gene expression levels in African Americans vary with both cis and trans genetic ancestry. *A. L. Price[1], N. Patterson[2], D. C. Hancks[3], S. Myers[4], D. Reich[5], V. G. Cheung[3,6,7], R. S. Spielman[3]* 1) Harvard School of Public Health, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) University of Pennsylvania, Philadelphia, PA; 4) Oxford University, Oxford, UK; 5) Harvard Medical School, Boston, MA; 6) Children's Hospital of Philadelphia, Philadelphia, PA; 7) Howard Hughes Medical Institute, Philadelphia, PA.

Variation in gene expression is a fundamental aspect of human phenotypic variation. Several recent studies have analyzed gene expression levels in cell lines from populations of different continental ancestry and reported population differences at a large number of genes. However, it is currently unknown to what extent these population differences are due to genetic, environmental, or other effects. To address this, we have analyzed gene expression levels in African-American cell lines, which differ from previously analyzed cell lines in that individuals from this population have variable proportions of continental ancestry. By relating gene expression levels in 89 African Americans to their genome-wide proportion of European ancestry, we validated observed differences between 60 Europeans and 60 Africans, providing strong evidence of genetic effects. Furthermore, we accurately inferred local ancestry (0, 1 or 2 European chromosomes) at each location in the genome using dense genotype data, in order to distinguish the effects of local ancestry at the cis locus of each gene from the effects of trans ancestry at other loci. Both cis and trans ancestry effects were strongly statistically significant. By comparing the magnitude of these effects, we estimate that 12 3% of all genetically heritable variation in human gene expression is due to cis variants.

5,10 Methylenetetrahydrofolate Reductase C677T Gene Mutation Associated Unsuccessful Assisted Reproduction. *B. OZTURK[1], B. YAZAR[2], O. ILBAY[2], H. COMERT[2], N. ERCELEN[2]* 1) Department of Clinical Genetics, East Carolina University Brody School of Medicine, Greenville, NC, USA; 2) Genetics and Genomic Sciences Center, VKV American Hospital, Istanbul, TURKEY.

Thrombophilia has been associated with adverse pregnancy outcomes and recurrent pregnancy loss. However, it may also contribute to assisted reproductive failure (ARF). To determine the association of specific inherited thrombophilias and ARF, the prevalence of factor V Leiden (FVL), prothrombin G20210A and 5,10 Methylenetetrahydro-folate Reductase (MTHFR) C677T gene mutations were investigated. A consecutive series of 14 women with ARF was enrolled in the study group. Control group was 40 women with at least one successful pregnancy and no history of pregnancy loss. Mean age of the study group was 33.3 years (range, 28-41) versus 33.8 (range, 24-45) in control group. Mean number of ARF was 1.9 (range,1-5) in the study group. At least one thrombophilic defect was found in 85.7 % of total study group women compared with 57.5 % in controls (p<000.1, OR: 4.448, 95 % CI: 2.2-8.8). Presence of MTHFR mutations was associated with an extremely significant increased risk for ARF (71 versus 43%, p= 0.0001, OR: 3.245, 95 % CI: 1.8-5.8). The presence of FVL mutation showed no significant increased risk for ARF (14 versus 13%, p= 1.0000, OR: 1.167, 95 % CI: 0.1-6.8). In addition none of the patients in the study group had prothrombin mutation (p= 1.0000, OR: 0.9080, 95 % CI: 0.03-23.6). C677T MTHFR mutation might be a risk factor for ARF especially in younger age women. Definitive conclusions require analysis of larger series to confirm the result.

Genetic Similarity Matching for Genome-wide Association Studies with Related Individuals. *W. Guan, L. Liang, M. Boehnke, G. R. Abecasis* Dept Biostatistics, Univ Michigan, Ann Arbor, MI.

Recently, genome-wide association (GWA) studies have drawn great interest as a promising tool to dissect the genetic basis of complex diseases such as hypertension, diabetes, and bipolar disorder. Population stratification is a major concern that can lead to spurious disease-marker association or mask a true association. We have proposed a similarity score matching method that matches cases and controls based on their identity-by-state similarity scores using the large amount of genotype data from GWA studies. We now extend our method to the analysis of related case and control samples. We apply a new test statistic, based on the work of Thornton et al. 2007, to correct the correlation between the related samples and matched case-control pairs. Through computer simulations, we demonstrate that our method correctly controls type I errors, and has improved power compared to genomic control in the presence of stratification. We illustrate our method with data from the Pritzker Consortium Bipolar GWA study.

Homozygous R316Q mutation in the obesity-associated FTO gene causes a severe polymalformative syndrome. *S. Boissel[1,3], O. Reish[2,3], F. Molinari[1], N. Kadhom[1], C. Golzio[1], H. Etchevers[1], A. Munnich[1], L. Colleaux[1]* 1) INSERM U781, Université Paris Descartes, Paris, France; 2) Department of Medical Genetics, Assaf Harofeh, Israel; 3) Equally contributors.

We report on a large inbred family including 9 affected children presenting a novel syndrome characterized by severe intra-uterine growth and psychomotor retardation, delayed myelinization, cleft palate, cardiac and genital anomalies, hypertonicity and premature death. Extensive metabolic and genetic workup were normal. As the pedigree suggested an autosomal recessive mode of inheritance, autozygosity mapping was performed identifying a unique 6.5 Mb long region of shared homozygosity on 16q12 between D16S411 and D16S3140 markers. We identified a homozygous missense variation within the FTO gene (c.947G>A, p.R316Q), which co-segregated with the disease, was not found in 400 control alleles and altered a highly conserved residue. While recent studies have revealed a strong association between intronic variants in FTO and obesity, the pathophysiological mechanism underlying the phenotype observed in our family remains questionable. FTO encodes a 2-oxoglutarate-dependent nucleic acid demethylase involved in DNA and/or RNA lesions repair. The R316 residue is involved in iron- and 2OG-coordination and a recent study showed that a R316A substitution abolishes Fto activity in-vitro. To further understand the consequences of the p.R316Q variant, western blotting and immunofluorescence experiments were performed on patient and control fibroblasts. We found that the amount of FTO protein is significantly reduced in patient cells even though the nuclear localization is not affected. Moreover, patient fibroblasts display signs of senescence including growth defects, limited replicative lifespan and altered cell morphology. Mass spectrometry assays and cellular sensitivity to methylating agents measurements are underway to further characterize this cellular defect. To conclude, our data suggest that homozygous FTO null mutations are responsible for a newly described polymalformative syndrome. They also provide the first example of a disorder related to a recently identified nucleic acid repair pathway.

Validation of the association between the *COL1A1* polymorphism and high myopia in the Japanese population.

H. Nakanishi[1,2], R. Yamada[2,3], N. Gotoh[1,2], H. Hayashi[1,2], A. Otani[1], A. Tsujikawa[1], K. Yamashiro[1], N. Shimada[4], K. Ohno-Matsui[4], M. Mochizuki[4], M. Saito[5], K. Saito[5], T. Iida[5], F. Matsuda[2], N. Yoshimura[1] 1) Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan; 3) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 4) Ophthalmology and Visual Science, Tokyo Medical and Dental University Graduate School, Tokyo, Japan; 5) Ophthalmology, Fukushima Medical University, Fukushima, Japan.

The collagen type alpha 1 (*COL1A1*) gene encodes the pro-alpha1 chains of type collagen and is located on chromosome 17q21.33, where a myopia susceptibility loci (MYP5, 17q21-22) has been previously reported. Type collagen is a major component of sclera, remodeling of which is a characteristic finding of a highly-myopic eyeball wall. The *COL1A1* was recently reported to be associated with high myopia in the Japanese population. To validate this positive association, we conducted a systematic case-control association study using the tagging single nucleotide polymorphism (tSNP) approach. Eight tSNPs, including rs2075555 and rs2269336 (previously reported to be high myopia-susceptible SNPs in Japanese), were selected to tag the linkage disequilibrium blocks harboring the *COL1A1*. These tSNPs were genotyped using the Taqman SNP assay. A total of 427 unrelated Japanese cases with high myopia (axial length 26.50 mm in both eyes) and 420 Japanese controls were recruited. There was no association noted between high myopia and rs2075555 (P=0.47, Pc0.99) and rs2269336 (P=0.40, Pc0.99). No significant associations were seen with further tSNPs tests. This study did not replicate the previously reported positive association between the *COL1A1* and high myopia in the Japanese population. To elucidate whether the *COL1A1* gene in the MYP5 locus is associated with high myopia in the Japanese population, additional genetic and molecular biological studies are needed.

IVF is a risk factor for small intestinal stenosis/atresia; A population-based study of Kanagawa Birth Defects Monitoring Program in Japan, 2001-2005. *K. Kurosawa[1], Y. Kuroki[1], T. Yasojima[2]* 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Kanagawa Association of Obstetricians and Gynecologists, Kanagawa, Japan.

Intestinal stenosis/atresia is one of the most common birth defects, characterized by the complete or partial occlusion of the lumen of a segment of intestine with a variety of clinical signs including abdominal distention, bilious vomiting, and polyhydroamnios. Underlying causes for the atresia/stenosis, especially in the region of small gut, include malrotation, meconium ileus, cardiovascular anomalies, and Down syndrome. The etiological mechanism represents vascular disruptions. Data from the Kanagawa Birth Defects Monitoring Program (KAMP) were used to identify infants with small intestinal stenosis/atresia. Case records with a code for intestinal stenosis/atresia were reviewed to substantiate the diagnosis of small intestinal stenosis/atresia and analyze the associated malformations in the cases. As the information on pregnancy by the assisted reproductive techniques of the cases were recorded only in the cases with multiple births, analysis and comparison were made in the case groups according to the singleton, multiple births with IVF, and multiple births with non-IVF. We identified 30 infants born with small intestinal stenosis/atresia in Kanagawa Prefecture during 2001-2005. The birth prevalence was 2.12 per 10,000 births, results consistent with findings from other population-based studies using case definitions. Of 30 cases, we identified 4 cases born after IVF. In the group of multiple births including 1710 cases, all the 2 cases with the disorder were born after IVF. Even though the prevalence of malformed infants born in multiple births significantly higher than those born from singleton, we could not identify the cases with the disorder from 1119 cases born after spontaneous non-IVF. These results suggest that the IVF is a risk factor for small gut stenosis/atresia. Even though the risk for small gut stenosis/atresa after IVF has only a small practical consequence, further analysis is important for considering the etiological mechanisms in the disorder.

Genetic Regulation of Cervical Cytokine Concentrations by Toll-like Receptors. *K. K. Ryckman[1,2], S. M. Williams[1,2], M. A. Krohn[3], H. N. Simhan[3]* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 3) Magee-Womens Research Institute, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Objective: Toll-like receptors (TLRs) are critical components of the innate immune system and function not only in recognizing bacterial micro-organisms but also in inducing local expression of pro- and anti- inflammatory cytokines. Therefore, the purpose of this study was to assess the impact of genetic variation in TLR genes on cervical concentrations of pro- and anti- inflammatory cytokines and to determine if this relationship is influenced by bacterial vaginosis (BV). Study Design: Four single nucleotide polymorphisms (SNPs) in TLR2 and thirteen in TLR4 were examined for associations with eleven cervical pro- and anti- inflammatory cytokine levels in 52 black and 64 white women. Results: White, but not black, BV negative women with the CC/CT genotype at rs1554973 have lower cervical levels of interleukin-1 beta (IL-1) compared to women with the TT genotype. Additionally, in white women rs1927911 and rs2149356 are associated with cervical IL-1, interleukin 6 (IL-6) and tumor necrosis factor alpha (TNF-) concentrations. Importantly, these associations are affected by BV status. For example, women with the CC genotype at rs1927911 or rs2149356 have higher cervical levels of IL-1 and IL-6 than women with the CT/TT or AA/AC genotypes, respectively; however, this association is only present in BV negative women. In contrast individuals with the CC genotype at rs1927911 or rs2149356 have higher cervical concentrations of TNF- than women with the CT/TT or AA/AC genotypes, respectively; an association that is only present in BV positive women. Conclusion: Our study demonstrates that polymorphisms in the TLR4 gene are associated with pro-inflammatory cervical immune responses, particularly in the context of bacterial vaginosis. Additionally, these patterns of association are different in black and white women.

Association of the HLA-A, -B, -C alleles with severity of malaria in Thailand. *K. Hirayasu[1,2,3], J. Ohashi[1], K. Kashiwase[3], T. Ichihara[3], M. Minemoto[3], H. Hananantachai[4], A. Ogawa[3], M. Takanashi[3], K. Tokunaga[1], J. Patarapotikul[4], T. Yabe[3]* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) JSPS Research Fellow; 3) Tokyo Metropolitan Red Cross Blood Center, Tokyo, Japan; 4) Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand.

[Purpose] Malaria is one of the most important infectious diseases, affecting 300 million people and causing more than 1 million deaths annually worldwide. Although HLA-B53 was reported to be associated with resistance to severe malaria in West Africans, comprehensive analysis of HLA class I polymorphism in the pathogenesis of malaria severity has not been fully described yet. In this study, we examined a possible association of HLA-A, B, and C alleles with severity of Plasmodium falciparum malaria.

[Methods] 203 mild malaria, 165 non-cerebral severe malaria, and 109 cerebral malaria patients living in northwest Thailand near the border with Myanmar were enrolled in this study. High-resolution HLA typing was performed by Luminex Multi-Analyte Profiling system with a WAKFlow HLA typing kit. Samples showing ambiguous patterns were subjected to sequencing-based typing. The carrier frequencies of the HLA alleles were compared between pairs of malaria patient groups using the Fishers exact test based on a 2 x 2 contingency table.

[Results] In our study population, a total of 34, 62, and 23 alleles were detected at HLA-A, B, and C loci, respectively. Furthermore, a novel HLA-B allele has been identified. In addition, a weak association was observed between HLA-B*4601 and cerebral malaria (P=0.01), consistent with previous studies of the Myanmar population (Tokai J Exp Clin Med 23(2):81-83, 1998), and our low-resolution HLA data in Thailand (Jpn J Infect Dis 58:25-28, 2005). Further analyses are currently under investigation.

Genomewide linkage and fine mapping identifies ELP4 as a major susceptibility gene for Rolandic epilepsy in two independent samples. *D. K. Pal[1], L. J. Strug[2], T. Clarke[1], B. Bali[1], T. Chiang[4], M. Chien[2], J. J. Russo[3]* 1) Dept Psychiatry, Columbia University, New York, NY; 2) Child Health Evaluative Sciences, The Hospital for Sick Children, Toronto, Canada; 3) Columbia Genome Center and Dept of Chemical Engineering, Columbia University, New York, NY; 4) Centre for Computational Biology, The Hospital for Sick Children, Toronto, Canada.

Introduction. Rolandic epilepsy (RE) is the commonest human epilepsy accounting for 15-20% of all new cases. It is defined by the EEG trait of centrotemporal sharp waves (CTS). A genomewide linkage screen for CTS in 38 families, ascertained through an RE proband, identified a major CTS locus at 11p13 (multipoint lod 4.30) at marker D11S914. We fine mapped this linkage region. **Methods**. We collected DNA from 50 RE cases and 190 controls free of neuropsychiatric disorders, matched for sex and ethnicity. 32 genic tag SNPs were typed around the linkage peak and a further 12 SNPs typed in and around the region of maximal association. A subset of 29 SNPs was typed in an independently collected Canadian sample of 40 RE cases and 137 controls. Genotyping was performed blind to center and caseness by deCODE Genetics (Iceland). **Results**. The US dataset revealed strong evidence of association with four SNPs in the Elongator complex protein 4 (*ELP4*) gene. rs964112 in intron 3-4 provided the smallest p-value (0.00084), significant after Bonferroni correction (OR=2.13, 95% CI 1.35-3.45). In the replication sample, the same gene was implicated, the smallest p value occuring 105 kB away at rs2104246 in *ELP4* intron 9-10 (OR=2.92 95%CI 1.55-5.52, p=0.00062). Resequencing 40 RE cases, we found no coding region mutations. **Discussion**. We present evidence from two independent datasets that variants in *ELP4* are associated with the CTS trait, strongly predisposing to Rolandic epilepsy. *ELP4* is a component of Elongator, which associates with RNA polymerase II. *ELP4* is highly expressed during fetal development in forebrain areas implicated in the developmental pathology of RE including frontal cortex, basal ganglia and hippocampus. The lack of a coding sequence mutation suggests a possible fault in regulatory control.

Prenatal diagnosis of trisomy 18 mosaicism: 24 new cases and review of the literature. *L. Ballarati[1], L. Camurri[2], G. Nocera[3], L. De Grada[1], C. Corti[1], L. Larizza[1,4], D. Giardino[1]* 1) Lab. Citogenetica Medica e Genetica Molecolare IRCCS Istituto Auxologico Italiano Milano, Italy; 2) Arcella Analisi Mediche GENIMED Padova, Italy; 3) SS di Citogenetica Clinica Ostetrico Ginecologica Università di Milano AO Fatebenefratelli e Oftalmico Milano, Italy; 4) Genetica Medica Dip. Di Medicina Chirurgia e Odontoiatria Universita di Milano, Italy.

Dysomy-trysomy mosaicism could derive from a mitotic postzigotic nondisjunction event in an originally euploid zygote or from a postzigotic loss of a supernumerary chromosome in an aneuploid zygote. Disomy-trisomy chromosomal mosaicism prenatally detected on Chorionic Villus Sampling (CVS) could be represented by: I) the simultaneous presence of a disomic and a trisomic cell line in either cytotrophoblast, mesenchyme or both, or II) the presence of a non mosaic trisomy in the cytotrophoblast concomitant with a homogeneous disomic cell line in the mesenchyme or viceversa. The finding of mosaicisms on CVS raises problems for diagnosis and counselling, because they may not reflect the fetal chromosomal constitution. We report on a total of 24 cases recruited from 3 Italian laboratories found to bear trisomy 18 mosaicism on CVS. 21 cases belong to group I, while only 2 to group II. In the remaining case only direct preparation could be performed. As regards group I, the direct preparations showed a trisomic mosaic in 18 out of 21, with a long-term culture karyotype homogeneously euploid in 13, homogeneously aneuploid in 2 and mosaic trisomic in 3 cases. In the remaining 3 cases, the direct preparation karyotype was homogeneously euploid, whereas the culture showed a trisomy 18 mosaic karyotype. In the 2 cases belonging to group II the cytotrophoblast was euploid and the mesenchyme showed a homogeneous 18 trisomy complement. After genetic counselling, all cases were addressed to further investigation on amniotic fluid samples. Our findings indicate a confined placental mosaicism (CPM) in 16 cases and a true fetal mosaicism (TFM) in 5. No information on the pregnancies outcome was available in the remaining 3 cases. Our data will be discussed and compared to the previously reported cases in an attempt to better define the TFM-related risk.

Complex chromosome 18p rearrangements in two patients with immunological disorders. *M. P. Recalcati[1], E. Valtorta[1], L. Romitti[2], M. Manfredini[3], R. Vaccari[4], L. Larizza[1,5], P. Finelli[1,6]* 1) Laboratorio di Citogenetica Medica e Genetica Molecolare, Istituto Auxologico Italiano, Milano; 2) S.C. Anatomia, Istologia patologica Citogenetica, Ospedale Niguarda Ca Granda, Milano; 3) S.C. Ostetricia e ginecologia, Ospedale Niguarda Ca Granda, Milano; 4) S.C. Neuropsichiatria Infantile, Ospedale Niguarda Ca Granda, Milano; 5) Laboratorio di Genetica Medica, Ospedale San Paolo, Università of Milan, Milano; 6) Dipartimento di Biologia e Genetica per le Scienze Mediche, Università di Milano, Milano.

We report on the cases of two female patients bearing complex rearrangements involving chromosome 18p. Molecular cytogenetic analyses, performed by array-CGH and BAC FISH enabled the precise identification of the affected18p region with the novel order of the genomic sequences . The first patient has a 2 Mb terminal deletion associated with an 8,7 Mb inverted duplication of the adjacent region, while the latter has a more extended 10 Mb terminal deletion associated with a 4,5 Mb quadruplication of the adjacent region and a 1,7 Mb duplication of the pericentromeric region. The patients share dysmorphic features typical of the 18p- syndrome, such as growth retardation, epicanthal folds, long philtrum and toes defects, but suffer from opposite immunological disorders. The first patient has a form of immunological deficiency that manifests with recurrent pulmonary infections and low level of IgA, while the other suffers from an autoimmune form of juvenile rheumatoid arthritis (JRA). Deletion of chromosome 18pter has been linked to immunological disorders and a number of , patients have been described showing the tendency to develop autoimmune disorders including juvenile diabetes, rheumatoid arthritis, thyroiditis, Graves disease; however lack of reduction of serum IgA has been also frequently reported. The relationships between 18p terminal deletion and immunity have been so far not fully explored (dissected/deepened). The refined molecular cytogenetics characterization of different 18p chromosomal rearrangements versus patients specific clinical evaluations could foster our understanding on the role of the 18p region in the immune response.

A new autosomal recessive syndrome with death in early childhood: Wide anterior fontanel, sparse hair, prominent forehead, thickened eyelids, hypoplastic maxilla and late-erupting teeth. *E. Utine, Y. Alanay, D. AktaÅŸ, K. BoduroÄŸlu, M. AlikaÅŸifoÄŸlu, E. Tunçbilek* Clinical Genetics, Pediatrics, Hacettepe Univ, Ankara, Turkey.

Four patients are presented from three distinct families, with strikingly similar facial features, very sparse and fine hair, delayed closure of anterior fontanel and delayed eruption of teeth. Facial features included long face with frontal prominence, thickened eyelids, hypertelorism and epicanthic folds, hypoplastic maxillae, long and deeply grooved philtrum with a thin upper lip, and prominent and low-set ears. All four had a low-normal birth weight and failure to thrive, with delay in fontanel closure and dentition despite chronologically appropriate bone age. Three of them had mild delay in developmental milestones. Three of the patients died after severe clinical courses, presenting with systemic hypertension and renal dysfunction in two and with pulmonary hypertension in one. Parental consanguinity was present in all three families. To the best of our knowledge, this association had not been previously reported, and striking similarity in facial features and clinical findings of these four patients, born to three distinct families with parental consanguinity, suggests a possibility of a newly recognized syndrome with autosomal recessive inheritance.

ADAMTSL2 mutations in geleophysic dysplasia are responsible for a dysregulation of TGF pathway. *C. Le Goff[1], F. Morice-Picard[1], N. Dagoneau[1], L. W. Wang[2], C. Perrot[1], Y. J. Crow[3], F. Bauer[4], E. Flori[5], C. Prost-Squarcioni[6], D. Krakow[7], G. Ge[8], D. S. Greenspan[8], D. Bonnet[9], M. Le Merrer[1], A. Munnich[1], S. S. Apte[2], V. Cormier-Daire[1]* 1) Dept of Genetics, INSERM U781, Hôpital Necker, Paris, France; 2) Department of Biochemical Engineering, Lerner Research Institute, Cleveland, USA; 3) Leeds Institute of Molecular Medicine, Leeds, UK; 4) Clinique Paofai, Fare Tony, Papeete, Tahiti; 5) Dept of Genetics, Hôpital de Hautepierre, Strasbourg, France; 6) CNRS UPRES 3410, Hôpital Avicennes, France; 7) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, USA; 8) Department of Pathology and Laboratory Medicine, University of Wisconsin, Madison, USA; 9) Service de Cardiologie Pédiatrique, Hôpital Necker, Paris, France.

Geleophysic dysplasia (GD, OMIM 231050) is an autosomal recessive disorder characterized by short stature, brachydactyly, thick skin, hepatomegaly and cardiac valvular anomalies often responsible for an early death. Studying six GD families, we first mapped the disease gene to chromosome 9q34.2 (Zmax = 4.52 at = 0 at the gt-AL590710 locus) and identified five distinct nonsense/missense mutations in the A Disintegrin And Metalloproteinase with Thrombospondin repeats- like 2 gene (ADAMTSL2), which encodes a secreted glycoprotein of unknown function. In situ hybridization of human foetal tissues showed that ADAMTSL2 is widely expressed, particularly in tissues involved in GD (skin, heart and growth plate). Functional studies in HEK293 cells showed that ADAMTSL2 mutations lead to a decreased secretion of the mutated proteins, possibly due to the misfolding of ADAMTSL2. A yeast two-hybrid screen revealed that ADAMTSL2 interacts with Latent TGF Binding Protein 1 (LTBP1), which plays a major role in the storage of latent TGF- in the extracellular matrix and regulates its availability. To determine the functional significance of this interaction, we quantitated TGF- and found a significant increase of total and active TGF in the culture medium and the nuclear localization of phosphorylated Smad2 in GD fibroblasts. These data suggest that ADAMTSL2 mutations may lead to a dysregulation of TGF signalling as the underlying mechanism of GD.

The del(8)(p23) syndrome and aniridia. *J. G. Pappas[1], K. E. Daley[1], I. K. Gadi[2]* 1) Dept Pediatrics,Human Genetics, New York Univ, Sch Medicine, New York, NY; 2) Laboratory Corp America, Dept. Cytogenetics, Research Triangle Park, NC.

We present a 17-month-old boy with terminal microdeletion 8p23.2. He was born 38.5 weeks of gestation anthropometrically appropriate for gestational age. At 2.5 months, his weight was slightly over the 97th centile, his length and occipitofrontal circumference (OFC) was between the 25th and 50th centile, he had increased tone of all extremities, palpable metopic ridge, up-slanted palpebral fissures, aniridia, nystagmus, low set posteriorly rotated ears with over-folded upper helices, small upturned nose, down-turned corners of the mouth, hypoplasia of the nails on the fifth digits in hands and feet, small umbilical hernia and diastasis recti. There was no family history of aniridia or other ocular abnormalities. Chromosome analysis revealed an apparently normal 46,XY karyotype at 500 GTG band resolution. Comparative genomic hybridization array (aCGH) analysis with 607 locus specific BAC clones revealed decreased fluorescence of five BAC clones specific to segment 8p23.2 to 8pter. Fluorescence in situ hybridization (FISH) with an 8p subtelomeric probe confirmed the deletion in one 8p homologue. Karyotype and FISH with the 8p subtelomeric probe in the parents were normal. At 17 months our patient had microcephaly, mild developmental delays and dysmorphic features. This clinical presentation is common in the del(8)(p23) syndrome (Hutchinson R et al, 1992; Paez MT et al 2008; Bert BA et, 2001). del(8)(p23) that encompasses the GATA4 gene is associated with congenital cardiac malformations (Devriendt K et al, 1999). In our case, the GATA4 gene was not included in the deleted segment according to aCGH and there were no cardiac defects by echocardiography. Aniridia has not been reported in the medical literature as a feature of the del(8)(p23) syndrome. The 11p deletion associated with WAGR was not seen in our case and clinically there were no features of any known syndrome associated with aniridia. Our case further supports the hypothesis that the haploinsufficiency of GATA4 is the cause of cardiac defects in the del(8)(p23) syndrome and suggests that aniridia may be a feature of this syndrome.

Type II chaperonin BBS genes, BBS6 and BBS12, are required for BBSome formation. *Q. Zhang, S. Seo, V. Sheffield* Dept Pediatrics, HHMI, Univ Iowa, Iowa City, IA.

Bardet Biedl Syndrome (BBS) is a pleiotropic disorder with primary feature of obesity, retinal degeneration, polydactyly, kidney abnormalities, and cognitive impairment. Other features include hypertension and diabetes. To date, twelve BBS causing genes have been identified through genetic linkage, homozygosity mapping, and comparative genomic analysis. BBS1, BBS2, BBS7 and BBS9 contain beta propeller domains, BBS4 and BBS8 contain multiple TPR domains, BBS5 has two Boo domains, BBS3 has an arf-like domain, BBS11 is an E3 ubiquitin ligase, and BBS6, BBS10, and BBS12 have type II chaperonin like domains. Knockout mice studies together with studies in other model organisms have demonstrated that BBS genes have cilia related functions. Recently seven of the twelve BBS proteins (BBS1, 2, 4, 5, 7, 8, and 9) have been shown to form a complex called the BBSome. The function of the BBSome involves ciliary membrane biogenesis. However little is known about the function(s) of the three chaperone-like BBS genes. Using tissues from BBS knockout mice generated in our laboratory, we show that Bbs1, Bbs2, and Bbs7 protein levels are greatly decreased in Bbs6 knockout mice. There is little change in mRNA levels in these knockout mice. These data suggest that Bbs6 plays a role in stabilizing Bbs1, Bbs2, and Bbs7 proteins. The presence of a beta propellar domain in Bbs1, Bbs2 and Bbs7 suggests that Bbs6 plays a role in the proper folding of the beta propeller structures shared by these three BBS proteins. Biochemical analysis in cultured cells demonstrate that Bbs6, Bbs12 and Bbs7 are co-immunoprecipitated. Bbs7 is required for Bbs6 and Bbs12 interaction, and Bbs6 is required for Bbs7 and Bbs12 interaction. These data indicate that mutation of the chaperonin-like BBS genes, Bbs6 and Bbs12, disrupt BBSome formation by affecting three BBSome subunits Bbs1, Bbs2, and Bbs7 protein stability.

Bilateral oblique facial clefts and extremity anomaly following first trimester efavirenz and other antiretroviral exposures. *A. Shanske[1], K. Beckerman[2], R. Wright[2], Shanske* 1) Depts. of Peds, and; 2) Ob-Gyn, Albert Einstein Coll. of Med, Bronx, NY.

Oblique facial clefts are very rare congenital deformities.Craniofacial clefts and amniotic bands may be part of the amnion rupture syndrome. The amniotic cavity expands during the 12th week of gestation pressing against the chorion and obliterating the extraembryonic coelom. Rupture results in compression or band defects. Our patient has both a compression defect of the forearm and band defects of the craniofacial region. The infant girl was the 2945 gm product of a 37 week gestation complicated by advanced maternal HIV and gestational diabetes. A bilateral cleft lip and palate and swollen left forearm were noted by ultrasound. She was delivered by NSVD to a 35 year old mother who has been HIV positive for 18 years. Her viral load was undetectable during the pregnancy. She received zidovudine/lamivudine and efavirenz before pregnancy through 9 weeks gestation when she was changed to zidovudine/lamivudine and lopinavir/ritonavir and insulin was added for her diabetes. The newborn examination revealed bilateral oblique facial clefts (a Tessier cleft number 3 on the left and number 4 on the right) and right microphthalmia with an ectopic right lacrimal duct protruding from the right inner canthus. The HC was 33.5 cm. A circumferential constriction band encircled the left forearm. Efavirenz (EFV)is a highly potent non-nucleoside reverse transcriptase inhibitor in wide use. Because of a high number of craniofacial defects in cynomolgus monkeys, it is the only antiretroviral that is rated by the FDA Pregnancy Category D. A recent study of data collected in the Antiretroviral Pregnancy Registry, www.APRegistry.com, found no increase in birth defects in 4,000 prospectively monitored 1st trimester exposures compared with 2nd and 3rd. Prospective monitoring of 364 EFV-exposed pregnancies did not show an increase in the prevalence of birth defects after 1st trimester exposure. This child represents the first association of amniotic rupture sequence after EFV exposure and highlights the importance of prospective evaluation of 1st trimester exposures to this potential teratogen.

Cell populations of Human Anterior Capsular Plaque. *J. Kaid, AR. Vasavada* Iladevi Cataract & IOL Research Centre, Ahmedabad-380052, Gujarat, India.

Anterior capsular plaque (ACP) is a type of cataract located just below the anterior surface of the crystalline lens and develops due to abnormal differentiation of lens epithelial cells (LECs). Little is known about the form of abnormal differentiation of cells and hence the origin of the ACP. In present study the cell populations of congenital human ACP were studied based on the location and differentiation of cells. Differentiation study was performed using antibodies against pax6 for undifferentiated LECs, -smooth muscle actin (SMA) for epithelial mesenchymal transition, -crystallin for fiber cell differentiation along with collagen type I, collagen type IV and -crystallin. The human ACP revealed non-plaque and plaque region. The non-plaque region was largely consisted of pax6 positive cells. Within the plaque region, surface cells were positive to pax6 while the cells suspended in the extracellular matrix were either positive to SMA or -crystallin. Most of the cells of plaque were positive for -crystallin and surrounded by a network of collagen type IV. Human ACP consisted of heterogeneous population of undifferentiated and differentiated population of cells. Among the differentiated population an attempt was seen for both epithelial mesenchymal transition and fiber cell differentiation.

Noninvasive Fetal Gender Determination Assay on 3091 Cases. *Y. Wang, K. Thompson* Clinical Mol Diagnostic Lab, Ctr Med Gen, Houston, TX.

Thirty years of practice have shown that prenatal Diagnosis is a powerful weapon against incidents of some lethal diseases passed through inheritance. However, the possibilities of fetal-maternal hemorrhage, infection, and miscarriage caused by the invasive procedures hamper its usefulness in some high-risk pregnant women. The discovery of cell free fetal DNA in maternal circulation has opened up a new avenue for noninvasive prenatal diagnosis. The diagnoses of fetal gender, rhesus D status, and single-gene disorders have been successfully done by analysis of cell free fetal DNA in maternal plasma. The main challenge that remains an obstacle to these molecular noninvasive prenatal diagnoses being accepted as a large scale routine practice is the fact that cell-free fetal DNA presents only 3-6% of the total DNA in maternal plasma. We report here that we have done fetal gender determination assay on 3091 cases in our laboratory using cell free fetal DNA extraction from maternal plasma with Real-Time PCR. Confirmed through ultrasound so far, the accuracy of the test was 98.51% at the beginning, and after technique improving, the accuracy increased to 99%. It is well known that about 1400 genes have been mapped to the X chromosome, 40% of which are known to be associated with disease phenotypes. Fetal Gender determination certainly merits medical significance. Furthermore, the experience which we have obtained from the noninvasive fetal gender determination screening has built a foundation to develop other noninvasive prenatal diagnosis assays and put them on large scale routine clinical tests.

An Unbiased Estimator of Gene Diversity in Samples Containing Related Individuals. *M. DeGiorgio*[1], *N. Rosenberg*[1,2] 1) Center for Computational Medicine and Biology, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics and the Life Sciences Institute, University of Michigan, Ann Arbor, MI.

Gene diversity is sometimes estimated from samples that contain inbred or related individuals. If inbred or related individuals are included in a sample, then the standard estimator for gene diversity produces a downward bias, caused by an inflation of the variance of estimated allele frequencies. We develop an unbiased estimator for gene diversity that relies on kinship coefficients for pairs of individuals with known relationship, and that reduces to the standard estimator when all individuals are non-inbred and unrelated. Applying our estimator to data simulated based on allele frequencies observed for microsatellite loci in human populations, we find that the new estimator performs favorably compared to the standard estimator, in terms of both bias and mean squared error. For human population-genetic data, we find that a close linear relationship observed between gene diversity and distance from East Africa is preserved when adjusting for the inclusion of close relatives.

GENOME-WIDE SCAN. A NEW GENE OF SUSCEPTIBILITY IN CHILDHOOD ONSET SYSTEMIC LUPUS ERYTHEMATOSUS IN MESTIZO-MEXICAN PATIENTS. *R. Velázquez-Cruz[1], H. García-Ortiz[1], L. Uribe-Figueroa[1], F. Espinosa-Rosales[2], V. Baca[3], L. Orozco[1]* 1) Investigación, Instituto Nacional de Medicina Genomica, SS; 2) Servicio de Inmunología, Instituto Nacional de Pediatría, SS; 3) Hospital de Pediatría Centro Médico Nacional Siglo XXI, IMSS. Mexico City, MEXICO.

Systemic lupus erythematosus (SLE) is a complex illness, prototype of autoimmune diseases that is characterized by production of autoantibodies and multi-organ manifestations. Only 15-17% of all SLE patients has an onset before the 16 years old. In this work, 100 female SLE patients less than 16 years old, which fulfilled the American College of Rheumatology (ACR) criteria for the diagnosis of nephritis and 100 female healthy controls, were recruited from three tertiary medical centers from Mexico City. We performed a genome-wide association scan using the platform Affymetrix 100K SNP mapping array. After applying the filters of quality, 104,890 SNPs were used to the association study. Aside from the expected association between SLE and the HLA region on chromosome 6p21, we found evidence of association in three regions: 1p13.3 (PTPN22), 1q25.1 (TNFSF4, rs10798269) and 2q32 (STAT1, rs1467199). STAT1 was the strongest associated gene to be involved in the susceptibility of the illness. To validate this finding we used TaqMan assay to carry out an association study in an independent group of 230 cases and 300 controls. The SNP rs1467199 was associated with the susceptibility of SLE, also when we used this last methodology (P=0.010; OR =1.46, 95%CI: 1.09-1.97). Furthermore, when the sample was stratified by gender, distribution of the STAT1 SNP revealed a stronger association with female patients (P=0.0011; OR=1.72, 95%CI: 1.23-2.39). Our preliminary results suggest that there are important differences between these new regions associated with SLE in Mestizo-Mexican and those reported in other populations. Further studies are necessary with samples of different populations to validate our results.

Analysis of East Asia Genetic Substructure: Population Differentiation and PCA Clusters Correlate with Geographic Distribution. *C. Tian[1], R. Kosoy[1], A. Lee[2], P. Gregersen[2], J. Belmont[2], M. Seldin[1]* 1) Rowe Program Human Genetics, Univ California Sch Medicine, Davis, CA; 2) North Shore-LIJ Res Inst, Manhasset, NY, Baylor Col Med., Houston TX.

Accounting for genetic substructure within European populations has been important in reducing type 1 errors in genetic studies of complex disease. As efforts to understand complex genetic disease are expanded to other continental populations an understanding of genetic substructure within these continents will be useful in design and execution of association tests. In this study, population differentiation(Fst) and Principal Components Analyses(PCA) are examined using >200K genotypes from multiple populations of East Asian ancestry(total 298 subjects). The population groups included those from the Human Genome Diversity Panel[Cambodian(CAMB), Yi, Daur, Mongolian(MGL), Lahu, Dai, Hezhen, Miaozu, Naxi, Oroqen, She, Tu, Tujia, Naxi, and Xibo], HapMap(CHB and JPT), and East Asian or East Asian American subjects of Vietnamese(VIET), Korean(KOR), Filipino(FIL) and Chinese ancestry. Paired Fst(Wei and Cockerham) showed close relationships between CHB and several large East Asian population groups(CHB/KOR, 0.0019; CHB/JPT, 00651; CHB/VIET, 0.0065) with larger separation with FIL(CHB/FIL, 0.014). Low levels of differentiation were also observed between DAI and VIET(0.0045) and between VIET and CAMB(0.0062). Similarly, small Fsts were observed among different presumed Han Chinese populations originating in different regions of mainland of China and Taiwan(Fst < 0.0025 with CHB). For PCA, the first two PCs showed a pattern of relationships that closely followed the geographic distribution of the different East Asian populations. For example, the four corner groups were JPT, FIL, CAMB and MGL with the CHB forming the center group, and KOR was between CHB and JPT. Other small ethnic groups were also in rough geographic correlation with their putative origins. These studies have also enabled the selection of a subset of East Asian substructure ancestry informative markers(EASTASAIMS) that may be useful for future genetic association studies in reducing type 1 errors and in identifying homogeneous groups.

Relation of Paraoxonase (*PON2*) Polymorphisms with PON Activity and Systemic Lupus Erythematosus (SLE).

S. Dasgupta[1], F. Y. Demirci[1], A. Dressen[1], A. Kao[2], C. Kammerer[1], S. Manzi[2], M. I. Kamboh[1] 1) Dept. Human Genetics, Univ. Pittsburgh, GSPH, Pittsburgh, PA; 2) Lupus Center of Excellence, University of Pittsburgh, Pittsburgh, PA.

SLE, a severe autoimmune disease that predominantly affects women at their child bearing age, is characterized by chronic inflammation which can virtually affect almost every organ in the body. It is now well accepted that inflammation plays a major role in the atherosclerotic process and SLE women at their 35-44 years of age have 50 fold higher risk of premature coronary heart disease (CHD) than in general population. Many studies have reported that low PON activity is associated with increased risk of CHD and our studies have shown that low PON activity is independently associated with SLE. *PON1*, *PON2* and *PON3* are members of the paraoxonase multigene family, clustered on chromosome 7q21.3-22.1. Two nonsynonymous SNPs in the PON1 gene (L55M and Q192R) have been shown to be major regulators of PON activity. The purpose of this study was to determine the impact of *PON2* polymorphims on PON activity and SLE risk. We screened a total of 19 *PON2* tag SNPs as documented in HapMap and SeattleSNP databases in 345 Caucasian SLE women and 454 Caucasian healthy control women, using pyrosequencing, RFLP or TaqMan allelic discrimination methods. One of the SNPs significantly deviated from Hardy-Weinberg equlibrium and hence was excluded from further analysis. Pairwise linkage disequlibruim (LD) and tagger analyses identified 14 tag SNP bins that would capture the entire set of 18 *PON2* SNPs in our sample. None of the 18 SNPs were found to be associated with SLE risk in single site analysis. Seven SNPs were found to be associated (P0.01) with serum PON activity when adjusted for age, BMI and smoking in single site analysis. In a multiple regression model that included also the two *PON1* coding SNPs (L55M and Q192R), only two *PON2* SNPs remained significant (P0.05) that accounted for about 1.5 % of the PON activity variation. These results indicate that in addition to *PON1* SNPs, *PON2* genetic variation also contributes towards serum PON activity although to a much lesser degree.

Acceptance and compassion: prejudicial attitudes to patients bearing genetic disorders. *J. Forbes[1,2], C. Riolfi[1,2], A. Bogochvol[1,2], T. Genesini[1,2], E. Macedo[1,2], M. Zatz[1]* 1) Human Genome Research Center, University of São Paulo (USP), São Paulo, São Paulo, Brazil; 2) Institute of Lacanian Pshychoanalysis (IPLA), São Paulo, São Paulo, Brazil.

The diagnosis of a degenerative condition, such as a neuromuscular disease, tends, at first, to provoke in the patient a reaction of rage or denying of the fact. These subjective behaviors are usually followed by the acceptance of the patient and the compassion of his family. The knowledge of being affected by a progressive untreatable disorder makes them think they have found a destiny to follow. We do not agree with this approach and consider that this is an inappropriate way to deal with this situation. Our hypothesis is that besides the impact on normal relatives, this approach precipitates the patients disability and increases the speed of the diseases progression. In opposition to this established trend, we have treated twenty four patients with different neuromuscular conditions, with a novel psychoanalytical technique, which is based in dis-authorizing the socially standard expected behavior. The patients (7 myotonic dystrophy, 5 limb-girdle muscular dystrophy, 4 cerebelar ataxias, 3 facio-scapulohumeral, 2 Duchenne, 1 Becker, 1 Friedreich's ataxia, 1 congenital muscular dystrophy) were seen in a weekly basis by a trained team of supervised psychoanalysts. Preliminary results were discussed by the group and documented in video. After three months, we observed a significant modification in patients behavior. We were able to witness the replacement of acceptance by invention; and of compassion for shared responsibility. The results are surprising, and in addition to the patients they are causing a great impact in their families and in the involved clinical team.

Exploratory Analyses for Positive Natural Selection in Amerindian Populations. *R. Kosoy[1], C. Tian[1], M. Ransom[1], W. C. Knowler[2], R. L. Hanson[2], G. Silva[3], J. W. Belmont[4], M. F. Seldin[1]* 1) UC Davis, Davis, CA; 2) NIDDK, NIH, Phoenix, AZ; 3) Obras Sociales del Hermano Pedro, Antigua, Guatemala; 4) Baylor Col Med., Houston, TX.

Studies in European, East Asian (EAS) and African populations have provided evidence for the role of natural selection in the evolution of their genomes. Other evidence suggests that some positively selected alleles are paradoxically associated with adverse effects in modern populations. In order to identify genetic variants that might predispose to major medical problems (type 2 diabetes (T2D) and rheumatoid arthritis (RA)) in Amerindians (AMI) we are exploring for evidence of positive selection unique to AMI group(s). Information from genome scans (Illumina 300K SNP) in 23 Pima and 24 Maya AMI and public HapMap data from EAS were analyzed using three approaches: 1) population differentiation as measured by AMI/EAS Fst value distribution; 2) allele frequency spectrum analyses using composite likelihood ratio test (CLR); and 3) integrated haplotype analyses (iHS) for detection of recent selective sweeps. The distribution of the significant signals detected by each of the methods is nonrandom, suggesting multiple loci subject to positive selection. First, 127 SNPs with Fst > 0.6 in twenty-seven 300 kb segments (7.8 x106 bp) contrasts 652 SNPs with Fst >0.6 present in the rest of the genome (~2.7 x 109 bp). For allele frequency spectrum analyses a total of 168 autosomal locations showed CLR p values of <0.002 (p values determined by neutral model coalescent simulations). Of these 69 were specific for AMI and 53 for EAS suggesting strong differences in selection in these populations. Similarly several loci were suggested by iHS methods. Notably, some of the loci were identified by both Fst and CLR tests. Also, of particular note were three genes located within 100 kb of the putative selection peaks: taste receptor, type 1, member 1 (TAS1R1), melanin-concentrating hormone receptor 1 (MCHR1) and CD86. The first two may play a role in predisposition to T2D, and CD86, a ligand for the CD28 T cell co-receptor, may be a potential candidate for increased prevalence of RA in AMI populations.

Genome-wide linkage and association scans for quantitative trait loci of serum lactate dehydrogenase -- the Framingham Heart Study. *J. Lin[1], A. Cupples[2], G. Zheng[1], J. Joo[1], C. O'Donnell[3]* 1) Office of Biostatistics Research/DPPS/NHLBI/NIH Bethesda, MD; 2) Department of Biostatistics, Boston Univeristy, Boston, MA; 3) Framingham Heart Study/NHLBI/NIH, Boston, MA.

Serum lactate dehydrogenase (LDH) is used in diagnosing heart, liver, and muscle diseases, especially to help monitor a heart attack. Family studies have reported that serum LDH variation is significantly determined by genetic factors with heritability estimates approximately 50%. Three genes coding for LDH isoenzymes were mapped to chromosome 11q15 and 12p12. To date, no linkage or association analysis on serum LDH levels has been reported. We carried out a 10 cM microsatellite genome-wide linkage scan and a 100K SNP genome-wide association scan for quantitative trait loci of LDH in a community-based Caucasian cohort, the Framingham Heart Study. Our study population consisted of 330 families with 1702 individuals being microsatellite genotyped and 1343 individuals SNP genotyped. Using variance-component linkage methods, the heritability was estimated at 41%. The genome-wide linkage analysis yielded several chromosomal regions with LOD scores between 1 and 2.5 on chromosomes 3, 4, 7, 8, 9, 19 and 20, respectively. The 100K SNP genome-wide association study did not identify any SNP with genome-wide significance ($p<10-7$). None of the 32 SNPs with a p-value<10-4 was close to the chromosomal regions where the LDH genes reside or within the linkage peaks. Our study demonstrated a strong genetic effect on the variation of LDH levels. Instead of a single gene with a large effect, there may be several genes with small effects in controlling the variation of serum LDH. Those genes appear to be located on chromosomal regions that differ from where the genes encoding LDH isoenzymes reside.

Genotype and tissue effects on alternative splicing of the TCF7L2 gene in tissues important to Type2 Diabetes(T2DM)pathogenesis. *A. Mondal[1, 2], S. Das[1, 2], W. Chu[1, 2], N. Sharma[1, 2], S. Elbein[1, 2]* 1) University of Arkansas for Medical Sciences; 2) CAVHS, Little Rock, AR.

SNPs of the TCF7L2 gene are the strongest genetic risk factors for T2DM,but the variants are intronic and of unknown function.TCF7L2 has multiple alternative splice forms,but no data are available on this in tissues playing key role in T2DM pathogenesis. We hypothesized that TCF7L2 SNPs altered T2DM risk by changing expression of alternative splice forms in human tissues involved in T2DM pathophysiology.We isolated total RNA from human subcutaneous (sc)adipose and muscle biopsy samples,HepG2 cells and a commercial total pancreas RNA sample to identify all TCF7L2 splice forms using 5and3RACE technique and PCR based cloning. We quantified total and transcript isoform specific TCF7L2 levels in sc.adipose of 78 healthy non diabetic human subjects who were genotyped for SNPs rs7903146 and rs12255372 and who represented a wide range of BMI and S_I.In adipose we found two alternate 3ends of TCF7L2 mRNA, one isoform being 262bp shorter then the other.The shorter isoform was not observed in muscle.We confirmed expression in all tissues of a previously reported 69bp alternatively spliced exon within intron3(exon 3a),and identified a novel 141bp exon within intron4(exon 4a) expressed only in muscle tissue and HepG2 cells. In muscle,we also observed a novel 235bp exon formed by alternative splicing of parts of exons3 and4.A 73bp alternatively spliced exon from within intron13(13a) was present in all tissues and was present the most abundant isoform in the pancreas. We observed 16 different TCF7L2 alternatively spliced transcripts.Based on screening >80 clones each in adipose,muscle, pancreas and HepG2 cells, we identified 8,14,8 and 10 isoforms,respectively.Whereas total TCF7L2 levels in sc.adipose were not correlated with BMI or S_I,transcripts retaining exon 13a in adipose were significantly correlated with BMI (p=0.01)and %fat(p=0.002).Furthermore,exon13a containing transcripts were significantly associated with genotype at SNP rs7903146(p=0.03). These studies suggest that TCF7L2 intronic SNPs may alter alternative splicing or transcript-specific stability of TCF7L2 in human adipose.

Y chromosomal short tandem repeats (Y-STRs) and its association with azoospermia factors (AZF) microdeletions of infertile males. *L. Pliss[1], I. Pelnena[1], A. Puzuka[2], A. Sabule[3], S. Rozane[3], A. Ivanovs[2,3], V. Baumanis[1], A. Krumina[2]* 1) Latvian Biomedical Research and Study Centre, Riga, Latvia; 2) Riga Stradins University, Riga, Latvia; 3) Latvia State Centre for Forensic Medical Examination, Riga, Latvia.

Introduction.A series of polymorphic Y-chromosomal short tandem repeats (Y-STRs) show high levels of heterogeneity and thus provide a useful tool for population studies as well as for searching association with so called the infertility haplotype. The most common genetic cause of human Y-linked male infertility is partial or complete deletions of the AZF region on the Y chromosome. The aim of the present study was to characterize 12 Y-STRs haplotype variation in infertile males that possess AZF region microdeletions. Materials. Objects for studies of Y-STRs variation and its association with male infertility were five individuals with different spermatogenic arrest. Methods. 12 Y-STRs were determined by PowerPlex Y System (Promega, USA). Microdeletions in AZF region were determined by two multiplex PCR amplifications using ten primer pairs. Internal PCR control (ZFX/ZFY) was used as well as DNA sample from a fertile male and female. Results. Out of five analyzed samples, we have found 2 cases with microdeletions that were observed in three AZF regions at SY86 and SY84 (AZFa), SY127 and SY134 (AZFb), and SY254 and SY255 loci in DAZ gene family (AZFc). 3 individuals showed Y chromosomal microdeletions only in AZFc region. Two individuals with AZFc region microdeletions belonged to the most frequent haplogroup among Baltic Sea region populations, N3a1, and Y-STRs haplotypes of these samples were almost identical. For two samples with complete AZF region microdeletions, most of Y-STRs that are localized in the long arm of Y chromosome were deleted except DYS438 and DYS392. Y-STRs from the short arm of Y chromosome have been amplified, and the following alleles were observed: 15 (DYS19) and 13/14 (DYS393). Conclusion. Use of Y-STRs provides the precise location of AZF region microdeletions in comparison with non-polymorphic STS loci and points on the presence or lack of Y-chromosome arms (isochromosome).

Pre-symptomatic risk assessment for complex genetic diseases. *B. Padhukasahasram, E. Halperin, J. Wessel, D. Thomas, E. Silver, H. Trumbower, N. J. Schork, M. Cargill, D. A. Stephan* Navigenics Inc., Redwood Shores, CA, U.S.A. 94065.

The prevalence of common chronic non-communicable diseases (CCND) far overshadows the prevalence of both monogenic and infectious diseases combined. Common SNP variants account for a substantial portion of the genetic risk for such diseases and when used in context will allow for more personalized and focused exposure mitigation, early detection, and early intervention paradigms. We present a novel measure called the genetic composite index (GCI), which considers only summary statistics of the effects of common genetic variants and show its predictive power as a clinical classifier. Predictive power of the GCI varies by condition and when combined with environmental data should provide an additional tool for clinical decision-making. It will also facilitate prospective studies testing whether actions based on the knowledge of genetic load lead to significant medical benefits and whether this knowledge motivates individuals to adopt healthier lifestyles.

A new case of Cranio-Lenticulo-Sutural dysplasia. *S. Boyadjiev Boyd[1], C. Nauta[1], A. Hata[1], C. Naydenov[2], E. Zackai[3], J. Kim[1]* 1) Dept Pediatrics, Section of Genetics, UCD Med Ctr, Sacramento, CA; 2) Department of Chemistry and Biochemistry, Medical University Sofia, 1431 Sofia, Bulgaria; 3) Division of Human Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania.

We delineated Cranio-lenticulo-sutural dysplasia (CLSD; OMIM 607812, Boyadjiev-Jabs syndrome) as a new autosomal recessive syndrome in a consanguineous family where five males and one female have distinctive craniofacial features (large and late-closing fontanels, hypertelorism), early onset cataracts, and mild generalized skeletal dysplasia. Linkage analysis mapped the locus to chr. 14q13-q21 and a F382L mutation was identified in SEC23A. Detailed molecular and biochemical analysis of wild type and mutant SEC23A, an integral member of the COPII-mediated ER-to-Golgi trafficking pathway, led to better characterization of intracellular trafficking in health and disease. A zebrafish morpholino model recapitulated the human phenotype. Recently, an unrelated individual with clinical features consistent with CLSD was identified. Molecular analysis of SEC23A identified a novel heterozygous M702V SEC23A mutation involving a highly conserved residue. This missense mutation was inherited from the unaffected father and was not present in 400 control chromosomes. No mutations were found in the maternal alleles and SEC23A real-time PCR analysis showed normal expression of both alleles. Biochemical characterization by in vitro COPII vesicle budding assay documented that the M702V mutation results in impaired COPII vesicle formation. Our data suggest that CLSD may be more common than previously thought and should be considered in the evaluation of patients with late-closing fontanels. Alternative inheritance patterns may exist for this syndrome.

EDA signaling is required for sweat gland development and hair subtype formation. *C. Cui, M. Kunisada, D. Esibizione, E. Douglass, D. Schlessinger* Laboratory Genetics, NIA/NIH, Baltimore, MD.

EDA signaling is pivotal in the initiation of skin appendages. Its possible involvement in appendage subtype determination and post-induction stage appendage development, however, has not been studied systematically. To address these issues we manipulated conditional expression of an Eda-A1 transgene in Tabby mice, where the transgene is the only source of active ectodysplasin (Eda). We find that Eda-A1 restores sweat glands and all hair subtypes in Tabby, but each require its action at an idiosyncratic time of development: by E17 for guard, by E19 for awl, and starting at E18 for zigzag/auchen hair. Guard and awl hairs were indistinguishable from their wild-type counterparts; but restored zigzag and auchen hairs, while recognizable, were somewhat smaller and lacked characteristic bends. Notably, secondary hair follicle formation of awl, auchen, and zigzag hairs required higher Eda-A1 expression level than did guard hair or sweat glands. Furthermore, Eda-A1 expression is required until the early dermal papilla stage for guard hair germs to make follicles, but is dispensable for their maturation. Similarly, sweat gland pegs require Eda-A1 at an early stage to form mature glands. Thus we infer that Eda signaling is needed for the determination and development of various skin appendages at spatiotemporally restricted intervals.

A novel ERG rearrangement in acute myeloid leukemia with t(16;21)(p11;q22) and t(15;17)(q22;q21) translocations. *S. Hazourli, J. Hébert* Quebec Leukemia Cell Bank, Maisonneuve-Rosemont Hospital Research center, Montreal, PQ, Canada.

Cytogenetic and molecular studies have established a correlation between acute promyelocytic leukemia (APL) and the presence of the specific t(15;17)(q22;q21) translocation leading to the PML-RARA fusion gene. In APL patients, the t(15;17) predicts a favourable differentiation response to all-trans retinoic acid (ATRA) and a very good survival. We here report a unique case of immature acute myeloid leukemia (AML) with basophilia, presenting a t(16;21)(p11;q22) translocation and an additional t(15;17)(q22;q21) translocation identical to the APL translocation by G-banding. The presence of the t(15;17) translocation as a secondary event and in non-promyelocytic leukemia, is unusual. In our case, FISH analysis with a PML-RARA dual color probe revealed one fusion signal on the derivative chromosome 15, suggesting a PML-RARA positive fusion. However, the second fusion signal was absent and no other RARA rearrangement was detected using a breakapart RARA probe. RT-PCR analysis confirmed the absence of PML-RARA fusion transcripts. These results suggest that the chromosomal breakpoints are located in the vicinity of the PML and RARA genes. The t(16;21) translocation is a rare event in AML, in myelodysplastic syndrome and in the blastic phase of chronic myelogenous leukemia, conferring a poor prognosis. This translocation fused the FUS gene on chromosome 16 to a member of the ETS transcription factor (ERG) on chromosome 21, generating an oncogenic FUS-ERG fusion, also found in Ewing's tumours. In our case, molecular cytogenetics investigation of the t(16;21)(p11;q22) chromosomal breakpoints with BAC probes, confirmed the involvement of the ERG oncogene on the chromosomal band 21q22. However, the translocation breakpoint on 16p11.2 was centromeric to the FUS gene. To our knowledge, this is the first case of AML showing a t(16;21) translocation associated with a t(15;17). The t(15;17) in this case was molecularly different from the APL translocation. Furthermore, a potential novel ERG fusion gene was identified in this leukemia.

Reversal of glycogen storage disease type III related cardiomyopathy with high protein diet. *A. Dagli[1], R. Zori[1], H. McCune[1], T. Ivsic[3], M. Maisenbacher[1], D. Weinstein[2]* 1) Dept Peds, Div Gen & Met, Univ Florida, Gainesville, FL; 2) Dept Peds, Div of Endocrinology, Univ Florida, Gainesville, FL; 3) Dept Peds, Div of Cardiology, Univ Florida, Gainesville, FL.

Glycogen storage disease type III is caused by a deficiency of glycogen debranching enzyme leading to impaired release of glucose from glycogen. Accumulation of glycogen with short outer chains occurs. Most patients (85%) have muscle and liver involvement (GSD IIIa). These individuals have hypoglycemia, hyperlipidemia and hepatomegaly with elevated transaminases in childhood. In adolescence and adulthood, progressive muscle weakness and hypertrophic cardiomyopathy can be predominant features. The management consists of cornstarch supplementation and high protein diet. Conventionally, it is believed that this management is effective in preventing hypoglycemia but does not prevent or improve progressive myopathy or cardiomyopathy. Slonim et al (1981) reported marked improvement in muscle strength and mass after initiation of a high protein diet in a child with GSD III. There has been little discussion regarding the effect of high protein intake on myopathy and cardiomyopathy since this case report.

We report a 22 year old male with GSD IIIa diagnosed with severe cardiomyopathy at 14 years of age. A high protein intake of 2g/kg was recommended with no improvement in the cardiomyopathy. For the past one and a half years, however, we increased the protein intake to 3g/kg/day combined with restriction of simple carbohydrates. There was significant reversal of cardiomyopathy as seen on echocardiography, with left ventricular mass improving from 284g to 143g and left ventricular mass index improving from 160g/m2 to 78g/m2 in a span of one year. With this case we would like to emphasize the role of high protein intake in patients with GSD III and cardiomyopathy.

Studying genetic contributions by mother and child to susceptibility: efficient design and analysis for diseases of early life. *M. Shi[1], D. M. Umbach[1], S. H. Vermeulen[2], C. R. Weinberg[1]* 1) Biostatistics Br, NIEHS, Res Triangle Park, NC; 2) Department of Endocrinology, Department of Epidemiology, Biostatistics and HTA (133) & Department of Human Genetics, Radboud University Nijmegen Medical Centre, PO Box 9101, 6500 HB Nijmegen, The Netherlands.

The prenatal environment can play an important role in the etiology of disease, particularly for conditions with onset early in life, such as childhood cancers and birth defects. To capture the potential effects on risk from both maternal and fetal genotypes, investigators can use designs that require genotyping of affected offspring and their mothers , e.g. the population-based case-mother/control-mother design or the hybrid case-parent triad/controlparents design. For the case-mother/control-mother design, the usual logistic regression analysis fails to fully exploit the fact that the pairs are mothers and their offspring. We show that by enforcing three natural and plausible nested levels of assumptions (i.e. Mendelian inheritance, mating symmetry, and parental allelic exchangeability) we can improve the efficiency of this design. Calculations reveal that these improvements over the usual logistic analysis can be substantial, even if only the Mendelian assumption is honored. We also consider an alternative hybrid design where offspring-mother dyads, instead of parents, serve as population-based controls, a design that is especially valuable when control fathers are hard to recruit. We show that this design retains the ability to test for mating symmetry and absence of population stratification bias and can be used to estimate offspring and maternal genotypic effects even when these assumptions do not hold, but with reduced power. We compare the power of the alternative hybrid design and the case-mother/control-mother design with the previously described case-parent triad and hybrid with control parents designs, and show that the two proposed designs perform well in certain scenarios.

RUNX1-USP42 is a recurrent fusion gene in acute myeloid leukemia. *A. Giguère[1], P. Chagnon[2], J. Hébert[1,2]* 1) Quebec Leukemia Cell Bank, Maisonneuve-Rosemont Hospital Research center; 2) Institute for Research in Immunology and Cancer, University of Montreal.

The RUNX1 gene encodes a transcription factor essential for the development of definitive hematopoiesis. In acute leukemia, RUNX1 is frequently rearranged with several partner genes in chromosomal translocations. Recently, a new cryptic t(7;21) translocation involving RUNX1 and a deubiquitinating enzyme, USP42 was described in a childhood acute myeloid leukemia (AML). USP42 belongs to the ubiquitin-specific peptidase (USP) family which shares highly conserved regions of amino acid sequence that form the catalytic domain of these enzymes. We describe the identification of USP42 as a recurrent partner gene of RUNX1 in leukemic cells of an adult patient with AML. The karyotype was 46,XY,del(5)(q22q33),?del(21)(q22). Spectral karyotyping and FISH with BAC probes revealed a cryptic t(7;21)(p22;q22) translocation involving RUNX1 and USP42. An in-frame fusion between exon 7 of RUNX1 and exon 3 of USP42 and an alternative transcript with a deletion of RUNX1 exon 6 were confirmed by RT-PCR and sequencing. A 10-fold upregulation of USP42 mRNA was detected in the t(7;21) leukemic cells by quantitative RT-PCR. No other t(7;21) positive case was detected in a RT-PCR study of 109 samples of myeloid leukemia. Sequencing of genomic DNA and bioinformatics analysis revealed a 7bp microhomology near the translocation breakpoint and an in vitro topoisomerase II consensus cleavage site in intron 2 of USP42. A non-homologous end-joining repair mechanism may be involved in the generation of this fusion. By immunofluorescence, we demonstrated a nuclear expression of the chimeric protein suggesting that RUNX1-USP42 might inhibit RUNX1-mediated transactivation, a mechanism of leukemogenesis previously described in other RUNX1 fusion proteins. We are currently evaluating the expression of different known RUNX1 target genes in the leukemic cells positive for RUNX1-USP42, in order to better understand the oncogenic potential of this fusion. USP42 is part of a novel class of genes involved in the pathogenesis of leukemia and its role in hematologic cancers remains to be studied.

Four novel mutations of the *Italic Text*IRF6*Italic Text* gene in Thai families with Van der Woude syndrome. *K. Suphapeetiporn, P. Yeetong, V. Shotelersuk* Division of Medical Genetics and Metabolism, Department of Pediatrics, Chulalongkorn University, Bangkok, Thailand.

Van der Woude syndrome (VWS) is a dominantly inherited disorder characterized by cleft lip with or without cleft palate and lip pits. It remains the most common syndromic form of oral clefts. Mutations in the *Italic Text*interferon regulatory factor 6 gene*Italic Text* (*Italic Text*IRF6*Italic Text*) have been identified in patients with Van der Woude syndrome. Its mutations also result in non-syndromic cleft lip with or without cleft palate in some populations. We identified four unrelated Thai families with VWS and performed mutation analysis by PCR-sequencing the entire coding region of the *Italic Text*IRF6*Italic Text* gene. Four potentially pathogenic mutations, c.145CT (p.Q49X), c.171TG (p.F57L), 1306CG (p.L436V), and IVS3-3CG were successfully detected in four unrelated patients. All these mutations were not detected in at least 100 unaffected ethnic-matched control chromosomes and have never been previously reported. The p.Q49X and p.F57L mutations were located in the highly conserved DNA binding domain while the p.L436V was located at the most carboxy-terminal region ever reported. This study demonstrated that several distinct mutations of *Italic Text*IRF6*Italic Text* occurred in the Thai families with VWS and thus expanded the spectrum of the *Italic Text*IRF6*Italic Text* gene mutations.

State Space Reduction in Hidden Markov Model for Haplotyping, Imputation and Analysis of Shotgun Sequence Data. *W. Chen, Y. Li, G. R. Abecasis* Center for statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

The size of datasets utilized for gene-mapping studies to access the human genetic variation is rapidly increasing. It is now common to analyze genome-wide association studies (GWAS) with information on 100,000s of SNPs for 1000s of individuals and whole genome shotgun sequencing is rapidly becoming feasible. It is now clear that imputation of missing genotypes can improve power for GWAS and attempts are now underway to combine 'low-depth' shotgun sequence data across many individuals. However, accurate estimation of haplotypes and missing genotypes in these large datasets remains an important but challenging computational problem. Here, we describe a series of computational enhancements for hidden Markov models (HMM) that describe the haplotypes in each individual as an imperfect mosaic of other sampled haplotypes and which are a key component of several algorithms for genotype imputation and analysis of shotgun sequence data. Our enhancements take advantage of similarity among haplotype segments between individuals to reduce the number of distinct states that must be modeled in the HMM and results in no loss of accuracy. Simulation and analysis of real datasets show that our method can reduce computing time by a factor of 2-5x and reduce memory usage by a factor of 6-16x compared to current implementations of these HMMs. We hope this algorithm will be a useful addition to the toolbox of human geneticists.

Sapropterin (Kuvan) is safe and effective in patients under 4 years of age with phenylketonuria (PKU). *D. Hartung[1,2], H. Bausell[1], R. Katz[1], B. K. Burton[1,2]* 1) Dept Genetics, Children's Memorial Hosp, Chicago, IL; 2) Feinberg School of Medicine, Northwestern University, Chicago, IL.

In December, 2007, Kuvan was approved by the FDA for use in patients with hyperphenylalaninemia due to tetrahydrobiopterin(BH4)-responsive PKU. Clinical trials of Kuvan did not include children under 4 years of age. Since FDA approval, 11 children under 4 years of age (range 7 mo- 4 yrs) with PKU have been treated with Kuvan in the PKU Clinic at Children's Memorial Hospital in Chicago. All were well-controlled with mean blood phenylalanine (phe) levels below 360 umol/L at the time of initiation of drug therapy. Blood phe levels and diet records were obtained at baseline, 24 hrs, 1 wk and 2 wks; the dose used was 20 mg/kg/day given in apple juice. Response was defined as a decline in the blood phe level of 30% below baseline. 7 pts were responders; 2 non-responders and 2 not yet determined. The mean decline in blood phe among responders was 58% (range 32-74). One pt. experienced diarrhea when drug was initiated; this resolved within one wk. on continued treatment. No other adverse events were reported. Total length of time on therapy for all patients ranged from 1-5 months. A 2 yo responsive pt on a medical food (formula) was able to discontinue this and is now on an unrestricted diet. Two infants with mild PKU under one year of age were started on Kuvan without dietary restrictions when their blood phe levels reached a threshold requiring intervention. They remain on unrestricted diets with blood phe levels in the near normal range. The other 4 responsive patients have had their diets liberalized to varying degrees while maintaining excellent blood phe control. We conclude that Kuvan can be safely and effectively used in children under 4 years of age. Significant diet liberalization can be achieved in many patients without sacrificing blood phe control. In some patients, Kuvan alone can provide excellent blood phe control without the need to institute dietary restrictions.

Association of Variants in the -endomannosidase (*MANEA*) Gene with Cocaine-related Behaviors. *L. A. Farrer[1], H. R. Kranzler[2], Y. Yu[1], R. D. Weiss[3], K. T. Brady[4], J. F. Cubells[5], J. Gelernter[6]* 1) Genetics Program, Boston Univ Sch Medicine, Boston, MA; 2) Department of Psychiatry, Univ Connecticut Sch Medicine, Farmington, CT; 3) Alcohol and Drug Abuse Treatment Program, McLean Hospital, Belmont, MA; 4) Department of Psychiatry and Behavioral Sciences, Medical Univ South Carolina, Charleston, SC; 5) Department of Human Genetics, mory Univ Sch Medicine, Atlanta, GA; 6) Department of Psychiatry, Yale Univ Sch Medicine, New Haven, CT.

Cocaine dependence (CD) and related behaviors are highly heritable, but no genetic associations have been consistently demonstrated. Our recent genome-wide study identified association of cocaine-induced paranoia (CIP) with a SNP in the -endomannosidase (*MANEA*) gene in European American (EA) and African American (AA) family-based samples enrolled in a genetic study of drug dependence. To pursue this finding, we conducted a comprehensive genetic association study of *MANEA* with CD and CIP. A total of 3,992 individuals from two family-based samples (EA and AA) and two case-control samples (EA and AA) were classified as CD, CIP or control using the Semi-structured Assessment for Drug Dependence and Alcoholism and genotyped for 11 SNPs spanning *MANEA* and its surrounding region. Association of CD and CIP with individual SNPs and haplotypes was evaluated using family-based and population-based methods. CIP was associated with six SNPs in the EA families and nine SNPs in the AA families. The strongest evidence in the total sample of families was observed with 3 markers located in the promoter and 3 UTR regions ($0.000004 < p < 0.00005$). The association of *MANEA* SNPs with CD in both family samples was much weaker. In the AA case-control sample, multiple markers were significantly associated with CIP and CD. CIP and CD were also significantly associated with a two-SNP haplotype in the EA case-control sample. The *A* allele of the 3 UTR SNP rs9387522 was associated with increased risk of CIP in all four datasets. Our findings suggest that CD and associated behaviors may involve biological pathways not typically thought to be associated with brain metabolism.

Genetic Polymorphisms of Glutathione-S-Transferase P1, T1 and M1 in Pediatric Patients with Acute Lymphocytic Leukemia in a Philippine Tertiary Hospital. *C. L. T. Silao[1,2], M. M. L. B. Alcausin[1], P. D. Fajardo[3], A. Goleta-Dy[3], E. Melendres[3], E. M. dela Paz[1,2], C. D. Padilla[1,2]* 1) Section of Genetics, Department of Pediatrics, University of the Philippines-Philippine General Hospital; 2) Institute of Human Genetics, National Institutes of Health Philippines; 3) Section of Hematology and Oncology, Department of Pediatrics, University of the Philippines-Philippine General Hospital.

Researches on cancer are geared towards identifying genes and other host factors that may increase or decrease susceptibility risk. Glutathione-S-transferases (GSTs) are major detoxifying polymorphic enzymes that modify susceptibility in various cancers including acute lymphocytic leukemia (ALL). ALL is the most common form of malignancy in childhood with its incidence varying from race to race. This paper determines the frequency of Glutathione-S-transferase polymorphisms (P1, T1, and M1) in Filipino pediatric patients with ALL and in a pediatric control population. It also compares the frequencies between the two groups. All pediatric patients with ALL undergoing treatment at the UP-PGH Medical Center from January to June 2007 were enrolled. Subjects without ALL from the UP-PGH Outpatient Department, age and sex matched, were included as controls. Genomic DNA was extracted from peripheral blood of each subject. Determination of GSTM1 and T1 polymorphisms were done using polymerase chain reaction while restriction fragment length polymorphism analysis was employed for the GSTP1 polymorphism. Comparison between the genomic frequencies of control and ALL patients was done using Matched Odds Ratio. Statistical analysis showed a trend towards protection from having ALL with the presence of GSTT1 and GSTM1 polymorphisms, with OR 0.59 (95% CI: 0.24-1.36) and OR 0.86 (95%CI: 0.36-2.00), respectively. Having the GSTP1 polymorphism, however, was shown to be a risk factor to having ALL with OR 1.7 (95% CI: 0.74-4.15). Differences in the frequencies of GST polymorphisms were noted between the control group and patients with ALL. GSTT1 and GSTM1 polymorphisms appear to be protective from having ALL while having the GSTP1 polymorphism confers increased risk for ALL.

Association of FMR1 repeat size and verbal intelligence quotient (VIQ) independent of FXTAS-associated motor symptoms. *E. G. Allen[1], A. Abramowitz[2], K. Charen[1], D. Hamilton[1], M. Leslie[1], R. Letz[3], G. Novak[1], M. Rusin[4], L. Shubeck[1], J. L. Juncos[5], S. L. Sherman[1]* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept Psychology, Emory Univ, Atlanta, GA; 3) School of Public Health, Emory Univ, Atlanta, GA; 4) Independent Practice, Atlanta, GA; 5) Emory Univ School of Med, Dept Neurology, Atlanta, GA.

A CGG repeat sequence located in the 5 untranslated region of the FMR1 gene when expanded leads to fragile X spectrum disorders. When greater than 200 repeats, the gene is silenced due to hypermethylation, and the lack of protein leads to fragile X syndrome (FXS). Alleles with 55-200 unmethylated repeats, termed premutation alleles, have been associated with ovarian insufficiency (FXPOI) and a late-onset tremor/ataxia syndrome (FXTAS). Several groups have reported neuropsychological deficits among carriers of the premutation, particularly among males with FXTAS. We have previously shown a subtle but significant effect of FMR1 repeat size on verbal intelligence quotient (VIQ) as measured by the Wechsler Adult Intelligence Scale - III (WAIS-III) among 216 females ages 18-50 years. Now, we have confirmed these findings in a study sample of 202 males (n with premutation=84) and 527 females (n with premutation=323) ages 18-85. All subjects completed a neuropsychological test battery including WAIS-III. Repeat size, as a continuous variable, explained 2% of the variation in VIQ based on all study subjects when the model was adjusted for age, race, education, and gender (p-value for repeat size =0.0002). Among 65 males over the age of 50 years (n with premutation =51), the results were more striking: repeat size explained 26% of the variation in VIQ adjusting for the sample covariates (p-value for repeat size <0.0001). Surprisingly, the presence of motor symptoms (tremor or ataxia) was not significant in this model. This suggests that the observed decrease in VIQ is independent of motor symptoms of FXTAS. These findings, including individual WAIS-III subtests, will be presented.

The perception of the university student: genetics, bio-technology and future biomedical applications at a university in Bogota, Colombia. *F. Suarez, A. Ordonez* Instituto de Genética Humana, Universidad Javeriana, Bogota, Colombia.

OBJECTIVE: This project aims to describe the perception, knowledge and attitudes about genetics and its biomedical applications, in a group of university students, as well as determining the degree of information about genetic studies in humans and their uses in research and health services. METHODS: We conducted a qualitative study with university students using 5 focus groups with 5 members each (25 students) and 10 individual semi-structured interviews. The sessions were digitally recorded and a moderator was guiding the group through a discussion around five specific subjects: eugenics, homosexuality, intelligence, bio-technology and transgenic food and their possible relations with biomedical applications, research, and diagnostic techniques. The subjects were students of different areas of knowledge including, engineering, nutrition, psychology, philosophy and theology, all of the students were in their second or third year at the University. The interviews were conducted at one of the main Universities in the capital City Bogotá - Colombia. The analysis of the recordings was conducted using the Atlasti software 5.0 to extract and systematically analyze complex phenomena (students viewpoints) embedded in the narratives from the focal group sessions and interviews. RESULTS: The Participants expressed ideas that confuse the meaning of inheritance and the meaning of birth defect, they agreed that homosexuality was a genetic trait and that definitely there must be a greater access to prenatal diagnostic services in order to genetically improve future generations, including features and traits like the intelligence and sexual orientation. However, most of those interviewed found inconvenient discrimination against people based on their genetic traits. In contrast to the agreement with the human genetic improvement, most participants were in disagreement with the idea of mass distribution of genetically modified food as a solution to the actual alimentary crisis. The reasons and consequences of these attitudes are analyzed in the context of an underdeveloped country.

Premenopausal Breast Cancer Care at a Major Referral Center: Opportunities for Improvement. *K. M. Hennan, K. M. Moore, A. F. Wagner* OB/GYN, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

BACKGROUND: Treatment of breast cancer during reproductive years can be difficult given issues of fertility and potential for premature ovarian failure. Also, these women often have family histories of breast and/or ovarian cancer and may require genetic counseling and testing. OBJECTIVE: This study sought to describe the characteristics of premenopausal breast cancer patients and review their perceptions of care, barriers to treatment, and their recollections of genetic and menopausal symptom counseling. METHODS: Surveys were sent to all living, premenopausal women diagnosed with breast cancer at the OU Breast Institute from 2003-06. Demographics were obtained via chart review. Statistics were performed via SAS v9.1. RESULTS: 176 surveys were mailed; 29 were sent to patients >50 and were excluded. Of the remaining 147, 11 had incorrect addresses and 2 were deceased resulting in 134 eligible. 72(55%) were returned. For the entire cohort, 48% had Medicaid, and 49% private insurance. 43% lived in rural, 8% urban and 49% in metro communities. 68% were Caucasian, 11% Hispanic and 10% Black. Genetic Risk: 36 women(50%) reported a family history of breast or ovarian cancer. 53% had affected 1relatives, and 56% had family diagnosed <50yo. Discussions related to genetic and ovarian cancer risks were reported in 49% and 32%. 13% of patients received genetic counseling, and 18% genetic testing. The majority reported that it was not suggested(72%). Insurance type and size of referral community had no significant effect on whether genetic counseling occurred. The size of referral community had no significant effect on receiving genetic testing. CONCLUSIONS: 1)The majority was pleased with and did not perceive barriers to care, but there was 18% who did experience difficulty. 2)Only 49% of patients recalled genetic discussions, and this was unevenly offered by a variety of medical providers. 3)50% reported high risk family histories, which should prompt a genetic counseling referral. A statewide process which streamlines access and referral for genetic counseling and screening would be valuable initiatives for the future Oklahoma Cancer Institute.

Alternate mechanisms for BRCA1 silencing in young women with breast cancer. *E. M. Wong[1], A. Dobrovic[2], L. Smith[1], J. Hopper[3], M. Jenkins[3], A. Tesoriero[1], M. Brown[4], M. Southey[1], Breast Cancer Family Registry* 1) Department of Pathology,The University of Melbourne; 2) Peter MacCallum Cancer Centre; 3) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology,The University of Melbourne; 4) School of Molecular and Microbial Sciences, The University of Queensland.

Breast cancer is the most common carcinoma in women.Identifiable *BRCA1* and *BRCA2* mutations do not explain the majority of early-onset breast cancers with a strong family history.Currently known *BRCA1* mutations explain 10% of early-onset breast cancers and 20% of early-onset breast cancers with a strong family history.A proportion of women without identifiable BRCA1 mutations come from multiple-case families that show linkage to the loci and/or have breast tumour morphology consistent with carrying a *BRCA1* mutation.We therefore hypothesize that there may be additional inactivating mechanisms in *BRCA1* that are yet to be described.Using Multiplex Ligation-dependent Probe Amplification(MLPA),we screened for large genomic alterations in 132 case probands(diagnosed under 40 years) from the Australian Breast Cancer Family Study(ABCFS) with either a strong family history and/or BRCA1-like tumour morphology.We found 5 probands with large deletions in *BRCA1*:two had large deletions of *BRCA1* Exons1A-23 and 3 others had deletions of Exons1A-2,Exon5 and Exon20,respectively.To assess the potential for rare and common genetic variants in the regulatory regions of BRCA1 to be associated with breast cancer risk,we used High-Resolution Melt(HRM) analysis and a case-control study of early-onset breast cancer(ABCFS) to study 7 SNPs within the 3UTR and a highly conserved 116bp region.Twelve SNPs in the 5UTR and promoter region of BRCA1 and two evolutionally conserved regions within Intron2(CNS-1;CNS-2) and *BRCA1* Exon2 were also screened.The SNPs selected for analysis are predicted in silico to affect either the binding of *BRCA1* regulatory elements or to create a secondary structure change in the RNA.We will present the outcomes of our screen for large genomic alterations and regulatory region genetic variants and their association with breast cancer risk.

MicroRNA regulation and the variability of human cortical gene expression. *R. Zhang*[1,2,3], *B. Su*[1,2] 1) State Key Laboratory of Genetic Resources and Evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, Yunnan, China; 2) Kunming Primate Research Center, Chinese Academy of Sciences, Kunming , Yunnan, China; 3) Graduate School of Chinese Academy of Sciences, Beijing , China.

Understanding the driving forces of gene expression variation within human populations will provide important insights into the molecular basis of human phenotypic variation. In the genome, the gene expression variability is different among genes, and at present, most research has focused on identifying the genetic variants responsible for the within population gene expression variation. However, little is known about whether microRNAs (miRNAs), which are small noncoding RNAs modulating expression of their target genes in the human genome, could have impact on the variability of gene expression. Here we demonstrate that miRNAs likely lead to the difference of expression variability among genes. With the use of the genome-wide expression data in 193 human brain samples, we show that the increased variability of gene expression is concomitant with the increased number of the miRNA seeds interacting with the target genes, suggesting a direct influence of miRNA on gene expression variability. Compared with the non-miRNA-target genes, genes targeted by more than two miRNA seeds have increased expression variability, independent of their functional categories or targeted miRNA types. In addition, SNPs located in the miRNA binding sites could further increase the gene expression variability of the target genes. We propose that miRNAs are one of the driving forces causing expression variability in the human genome, which might eventually contribute to phenotypic variation in humans.

RENAL DYSPLASIA - COARCTATION OF AORTA. A NEW ASSOCIATION/SYNDROME: A REPORT OF 6 CASES. *B. Chung, D. Chitayat* Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

Renal dysplasia is a congenital disorder of the kidneys, characterized by undifferentiated mesenchyme, immature collecting tubules and abnormal organization and is nearly always cystic. Aortic coarctation is defined as a narrowing of the aorta in the area where the ductus inserts. It may be seen as an isolated defect or associated with congenital abnormalities of the aortic valve and the left heart. The concurrent findings of aortic coarctation and renal dysplasia have not been described previously. We report a series of 6 cases with aortic coarctation and renal dysplasia with different degree of severity and outcomes. Case series (table): The 6 cases were of mixed ethnic background. Family history of renal problems was noted in 3 of the 6 patients and one case was the product of a consanguineous marriage (first cousins). All but 1 had bilateral multicystic renal dysplasia detected antenatally and only in 2 was the coarctation detected prenatally. One patient had facial features consistent with Potter sequence. Three others had common facial features with a high flat forehead, large fontanelles, deep-set eyes, hypertelorism, short noses, slightly low-set ears, single palmer creases and deep-set nails. There was no evidence of severe intrauterine growth retardation or other major birth defects. All had normal karyotypes (patient 3 had a familial inversion of chromosome 18 inherited from his mother) and no deletion at 22q11.2. One pregnancy was terminated, one child died at 3 days of life, one survived and has end-stage renal failure and mild-to-moderate developmental delay and the other 3 survived without major issues following repair of the coarctation. The combination of renal dysplasia and congenital heart defects is rare and has been reported in a variety of chromosome abnormalities, single gene disorders (Meckel syndrome) and VACTERL association. However, the combination of renal dysplasia and coarctation of aorta is a rare event and can represent a hitherto new condition with yet unknown mode of inheritance. Parental consanguinity in one of our cases suggests autosomal recessive mode of inheritance.

ART3 is a novel risk gene for Alzheimer disease. *H. D. Yamagata[1], Z. Zhang[2], W. Zhong[2], R. Hata[3], H. Akatsu[4], K. Kamino[5], M. Takeda[5], K. Kosaka[4], T. Miki[2]* 1) Dept Preventive Medicine, Ehime University Graduate School of Medicine, Toon, Ehime, Japan; 2) Dept Geriatric Medicine, Ehime Univ Grad Sch Med, Toon, Ehime, Japan; 3) Dept Functional Histology, Ehime Univ Grad Sch Med, Toon, Ehime, Japan; 4) Choju Medical Institute, Fukushimura Hospital, Toyohashi, Japan; 5) Division of Psychiatry and Behavioral Proteomics, Osaka Univ Grad Sch Med, Suita, Japan.

Alzheimer disease (AD) is a complex multifactorial disease in which many genetic and environmental factors are involved. We have performed an association study using functional candidate gene approach. The Ethics Committee of Ehime University School of Medicine approved the study protocol. Patients were selected using NINCDS-ADRDA criteria for definite or probable AD. ADP-ribosyltransferase 3 (ART3) gene is significantly upregulated only in the AD hippocampus compared with control. We studied genotypes of the ART3 polymorphisms in 374 patients with sporadic AD and 379 healthy controls. Genotyping was performed using the TaqMan-PCR method. Among the three SNPs in the ART3 gene, one SNP showed different distribution between AD and control. The frequency of both alleles and genotypes was significantly increased in patients with AD than in control subjects (P 0.0001). In the APOE-4 non-carrier subgroup, the risk allele showed significant association (OR = 2.86; 95% CI = 1.84-4.43). These results indicate that the ART3 is a novel risk gene for AD regardless of the APOE genotype. ART3 has been reported to be associated with non-obstructive azoospermia (infertlity). However, there are no reports regarding the association of ART3 gene polymorphism with AD. Our data should be further examined by functional analysis of ART3 polymorphisms in AD.

A kinship-based modification of the Armitage trend test to address hidden population structure and small differential genotyping errors. *C. Rakovski, D. Stram* Preventive Med, Univ Southern California, Los Angeles, CA.

Aims: We propose a modification of the well-known Armitage trend test to address the problems associated with unaccounted population structure in genome-wide case-control studies. We also provide insights into the analysis of family data from the perspective of populations with multiple highly correlated strata. Methods: The new test adopts beneficial traits from three existing testing strategies: the Eigenstrat, mixed model, and genomic control while avoiding some of their disadvantageous characteristics, such as the tendency of the principal components method to over-correct in certain situations or the failure of the genomic control approach to reorder the adjusted tests based on their significance levels. The new procedure is based on Gauss-Markov estimators derived from a straightforward linear model with an imposed variance structure proportional to an empirical relatedness matrix. Conceptual and analytical similarities to and distinctions from other approaches are emphasized throughout. Results: Our simulations show that the power performance of the proposed test is extremely promising compared to all competing strategies. The power gains are especially large when small differential DNA differences between cases and controls are present. Lastly, the new test offers adequate power even when applied to family data with discordant sib pairs and missing parental genotypes. Conclusion: The proposed modified approach attains higher power than that of the existing commonly implemented tests. Its performance improvement is dramatic when systematic differences between cases and controls exist.

BRACHYTELEPHALANGIC CHONDRODYSPLASIA PUNCTATA. A RARE X-LINKED SKELETAL DYSPLASIA PRESENTING AS PIRIFORM APERTURE STENOSIS AND CAUSED BY MUTATION IN THE ARYLSULFATASE E (ARSE) GENE. *S. Miller[1], B. Chung[2], D. Chitayat[2]* 1) Diagnostic Imaging, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

Brachytelephalangic chondrodysplasia punctata (B-CDP) is a relatively benign form of CDP. It was first described in 1976 & later discovered to be X-linked & caused by a defect in the arylsulfatase E (ARSE) gene. We report a patient with B-CDP presenting with respiratory distress & narrowed nasal passage. Case report: Our patient was born at 34 weeks. His mother had GDM requiring insulin. Otherwise the pregnancy was uncomplicated & antenatal ultrasounds were normal. There was no maternal history of autoimmune diseases or teratogen exposure. Delivery was spontaneous & vaginal. His growth parameters were all normal. He had depressed nasal bridge & other unique facial features, short fingers with broad finger tips & hypotonia. He had no cataract & ichthyosis. Recurrent respiratory distress required repeated oral intubations as there were difficulties in passing the tube nasally. CT scan showed right anterior piriform aperture stenosis. Additionally, the nasal cartilage was deficient & there were stippling at the paranasal sinuses, nasal septum, C1 and odontoid. Skeletal survey confirmed the puncta at C1 & revealed additional puncta at various areas. The distal phalanges of digits appeared shortened and broadened. The karyotype was 46,XY & maternal screening for lupus was negative. Analysis of the ARSE gene showed a hemizygous A>G substitution in exon 7, causing p.Thr306Ala. This has not been previously reported. The threonine codon is evolutionarily conserved & is probably disease-causing. Functional analysis is in progress. From a recent review, so far 57 male patients with features of B-CDP have undergone ARSE testing, mutations have been detected in 31 but there were no obvious genotype-phenotype correlation. Respiratory problem is present in 30% of cases. With the prominent nasal hypoplasia, obstructed nasal passage causing respiratory distress is expected to be common. High index of suspicion is important for making the diagnosis.

A Novel Generalized Hypertrichosis - Scoliosis - Spina Bifida Syndrome: Phenotypic Features and Genetic Mapping. *X. Zhang[1], D. D. Shang[1], H. W. Zhu[2], Q. Liu[1], M. Sun[1], Y. Ao[1], W. Yang[1], T. Jing[2]* 1) Department of Medical Genetics, Peking Union Medical College, Beijing, China; 2) Center for Genetic Medicine, Lanzhou University, Lanzhou, China.

X-linked congenital generalized hypertrichosis (CGH) was mapped to chromosome Xq26-q27 in 1994. However, the disease gene has not yet been identified. We found a large Han Chinese family with CGH. Affected males in the families have severe hypertrichosis, scoliosis and spina bifida while the affected females only show mild hypertrichosis, suggesting an X-linked inheritance. To the best of our knowledge, this is the first report of an X-linked genetic syndrome that has a combination of the three manifestations. We performed genotyping and two-point linkage analysis using microsatellite markers on Xq to define the disease locus. The critical region was reduced to a 5.6cM interval at Xq26.3-q27.2. Mutation screening was preformed in all of the annotated genes (25 known genes with 222 exons), the pseudogenes (25 genes with 41 exons), some of the highly conserved non-coding sequences (54), all of the annotated non-coding RNA sequences (3), and some predictive transcription factors binding sites (6). The results didn not reveal any disease-causing mutation. We also extracted mRNA from skin fibroblast cells and skin tissues both from patients and normal controls, and performed RT-PCR to examine several candidate genes. Comparison between the amplified fragments in both subjects revealed no significant differences. Using the Affymetrix Genome-Wide Human SNP Array 6.0, we did not detect copy number changes in the critical region. In summary, we report a new X-linked genetic syndrome of generalized hypertrichosis accompanied with congenital scoliosis and spina bifida. We mapped the genetic locus to an interval of 5.6cM at chromosome Xq26.3-q27.2. Extensive mutation screening has not found potential pathogenic alterations.

Artemis cleaves cruciform-forming palindromic DNA leading to recurrent translocation in humans. *H. Inagaki[1], T. Ohye[1], H. Kogo[1], T. Kato[1], M. Tong[1], M. Tsutsumi[1], B. S. Emanuel[2], H. Kurahashi[1]* 1) Div Molecular Genetics, ICMS, Fujita Health Univ, Toyoake, Aichi, Japan; 2) Div Human Genetics, the Childrens Hospital of Philadelphia, Philadelphia, PA.

The t(11;22)(q23;q11) is a recurrent constitutional translocation in humans. The breakpoints on both chromosomes have been located within characteristic sequences, palindromic AT-rich repeats (PATRRs). We propose that the PATRRs form cruciform structures, and induce double-strand-breaks that are illegitimately repaired through non-homologous end joining. Since the breakpoints are mainly located near the center of the PATRRs, it is possible that the tip of cruciform DNAs are cut by Artemis, a hairpin opening enzyme in V(D)J recombination. We established a plasmid-based model system for the PATRR-mediated translocation using cultured cell lines. When Artemis was knocked down by siRNA, translocation-induced GFP signals decreased. Further, overexpression of Artemis increased the GFP signals in a dose-dependent manner. Combined with the data that the cruciform-forming PATRR was first cleaved diagonally in this model system, the translocation is generated from two successive cleavage reactions: diagonal cleavage of the PATRR by an unknown structure-specific nuclease, and hairpin-opening at the newly formed DNA ends by Artemis. Since the actual breakpoint sequences of human t(11;22)s were quite similar to those of this model system, our results strongly suggest cleavage of cruciform DNA structures as a mechanism that leads to palindrome-mediated translocation in humans.

Evaluating the performance of Affymetrix SNP 6.0 platform in the Japanese population. *N. Nishida[1], A. Koike[2], Y. Ogasawara[1], Y. Ishibashi[1], Y. Uehara[1], K. Tokunaga[1]* 1) Dept Human Genetics, Univ Tokyo, Tokyo, Japan; 2) Central Research Laboratory, Hitachi, Ltd, Tokyo, Japan.

Together with technology developments on large-scale single nucleotide polymorphism (SNP) genotyping, genome-wide association studies (GWAS) with hundreds of thousands of SNPs allow the identification of candidate genetic loci for multifactorial diseases in different populations. However, genotyping errors caused by genotyping platforms or genotype calling algorithms may lead to inflation of false associations between markers and phenotypes. In addition, the number of SNPs available for GWAS in the Japanese population has been investigated using only 45 samples in the HapMap project, which could lead to an inaccurate estimation of the number of SNPs with low minor allele frequencies. We genotyped 200 Japanese samples in order to estimate the number of SNPs available for GWAS in the Japanese population and to examine the performance of the current SNP Array 6.0 platform and the genotype calling algorithm Birdseed. About 20% of the 909,622 SNP markers on the array were revealed to be monomorphic in the Japanese population. Consequently, 661,599 SNPs were available for GWAS in the Japanese population, after excluding the poorly behaving SNPs. The Birdseed algorithm accurately determined the genotype calls of each sample with a high overall call rate of over 99.5% and a high concordance rate of over 99.8% using more than 48 samples after removing low-quality samples by adjusting QC criteria. We perform genome-wide SNP typing with the current SNP Array 6.0 platform, and perform high-resolution mapping with the DigiTag2 assay after genome-wide search for disease susceptibility regions. We are currently carrying out GWAS for various multifactorial diseases as joint research projects in order to identify candidate susceptibility or resistance loci in the Japanese population.

A study of single nucleotide polymorphism at PCSK9 gene in Chinese elders with hypercholesterolemia. *M. M. GU[1,3], X. L. WU[1,3], X. F. Pang[2,3], H. M. Yang[1], H. D. Song[2], Z. G. Wang[1,2]* 1) Department of Medical Genetics, Shanghai Jiao Tong University School of Medicine, Shanghai, China; 2) Ruijin Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China; 3) These authors contributed equally to this work.

Familial hypercholesterolemia (FH) is characterized by raised serum LDL cholesterol levels leading to accelerated atherosclerosis and increased risk of premature coronary heart disease. FH is commonly caused by some mutations in the LDLR, APOB or PCSK9. To investigate single nucleotide polymorphism (SNP) of PCSK9 (Proprotein convertase subtilisin/kexin type 9) gene in hypercholesterolemia group of Chinese elders, We investigate 73 patients (average age 70.269.54) from Ruijin hospital. Sequences spanning the exons, intron-exon boundaries, 5 and 3UTR of PCSK9 gene were detected by PCR-sequencing. A total of 22 SNPs were identified for the PCSK9 gene. All of them were transition. Five novel SNPs were found in our results, including R93V and A168V with amino acid change. Two variants, I474V and E670G which are related with LDL-C according to the report before, also were detected in this group. The hypercholesterolemia group of Chinese elders has not only the reported SNP changes at I474V and E670G, but also changes at the new SNP site of R93C and A168V, which are discovered for the first time in PCSK9 gene. Results obtained in this study provide some suggestive information for association studies on the plasma level of LDL-C with the PCSK9 variants in the hypercholesterolemia group of Chinese elders.

Sperm mitochondrial ATPase gene mutation and low seminal antioxidant levels in idiopathic asthenozoospermic men. *R. Dada[1], R. Kumar[1], S. Venkatesh[1], M. Tanwar[1], MB. Shamsi[1], R. Kumar[2], NP. Gupta[2], A. Bhat[3], RN. Bamezai[3], RK. Sharma[4]* 1) Laboratory for Molecular Reproduction and Genetics, Department of Anatomy, All India Institute of Medical Sciences, New Delhi, India; 2) Department of Urology, AIIMS, New Delhi, India; 3) School of life sciences, JNU, New Delhi, India; 4) ART center, Army Research and Referral Hospital, New Delhi.

Approximately 15% of the married couples failed to achieve parenthood after one year of regular unprotected intercourse, where approximately 40% of the male factor infertility is diagnosed as idiopathic. Seminal antioxidant enzymes, which maintain the physiological levels of ROS are lowered in known and unknown pathological conditions. Since mitochondrial DNA (mtDNA)is the key genome for the production of energy in the form of ATP, they are also both source and target of ROS. The present study includes 40 infertile asthenozoospermic men and 30 proven fertile controls. Semen analysis (WHO,1999)and seminal Catalase, glutathione peroxidase, and malondialdehye (MDA) levels were estimated. mtDNA was amplified and sequenced by standard PCR-DNA sequencing protocol. Infertile men had significantly lowered sperm count (43.3 4.1 Vs 62.1 16.2) and percent progressive motility (11.8 7.0, Vs 66.3 10.4) than fertile controls. Semen MDA levels of infertile group was found to be significantly higher, where catalase, and glutathione peroxidase (GPx) levels were significantly lower in infertile men compared to control men. mtDNA sequencing showed high frequency of nucleotide changes in the ATPase 6 (8279, 8280, 9098 & 8394) and ATPase 8 (8701, 8860 & 8879) genes of infertile men as compared to controls. Hence increased lipid peroxidation and low antioxidant levels induced oxidative stress coupled with ATPase mutation in OXPHOS pathway may be involved in impaired motility in such cases. Thus chronic exposure of the sperm to the high levels of ROS and lipid peroxidation may lead to irreversible changes in the mitochondrial and nuclear DNA. Early diagnosis of low antioxidant levels and oxidative stress and prompt management with antioxidants may prevent irreversible DNA damage in such cases.

Association testing with principal-components-based correction for population stratification. *M. Abney[1], M. S. McPeek[2]* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept of Statistics, University of Chicago, Chicago, IL.

We consider the use of principal components (PC) to correct for population structure in case-control association testing. We propose a new method, PC-POPCORN, which could be considered an improvement to the EIGENSTRAT method of Price et al. 2006. In a simple class of models that include population substructure and admixture, we demonstrate that PC-POPCORN gives a test statistic that is correctly calibrated under the null hypothesis of no association, in the sense that the test statistic can be shown to be asymptotically chi-square-distributed in the presence of population structure, while EIGENSTRAT does not. We demonstrate circumstances under which PC-POPCORN performs well, but EIGENSTRAT gives inflated type 1 error or reduced power, while in other cases, both methods perform equally well. More generally, we provide an explicit justification for the use of PC to correct for population structure in case-control association testing.

The influence of choline or riboflavin intake and mild methylenetetrahydrofolate reductase deficiency on reproductive outcomes and congenital heart defects in mice. *J. Chan, L. Deng, R. Rozen* Human Genetics, McGill University, Montreal, Quebec, Canada.

Dietary and genetic disruptions in folate metabolism may affect embryonic development due to the essential role of folate in methylation reactions and nucleotide synthesis. A common polymorphism in methylenetetrahydrofolate reductase (MTHFR), 677CT, is found in 10 - 15% of North American and European populations, and results in mild MTHFR deficiency in homozygous TT individuals. Previous studies by our group have shown that low dietary folate and mild MTHFR deficiency increase reproductive loss, intrauterine growth delay and congenital heart defects in mice. However, the relationship between MTHFR and other nutrients involved in folate metabolism, especially choline and riboflavin, remains to be understood. In this study, the effects of low dietary choline and low dietary riboflavin, with or without MTHFR deficiency, were examined in murine embryos and placentae. Female *Mthfr* +/+ and *Mthfr* +/- mice were fed either control diet (CD), choline-deficient diet (ChDD) or riboflavin-deficient diet (RbDD) prior to mating with male *Mthfr* +/- mice. Embryos were collected at day 14.5 and examined for gross abnormalities, reproductive outcomes and heart defects. A significant decrease in the number of viable embryos and a trend toward decreased number of eggs released was observed in ChDD mice when compared to CD groups. When RbDD mice were compared with those fed CD, a significant increase in delay rate was seen, which was reflected in significant decreases in both embryonic weight and crown-rump length. Ventricular septal defects (VSDs) were observed in embryos of all 6 groups, with a general trend toward increased VSD incidence in embryos from ChDD and RbDD groups when compared to those of the CD. A decrease due to *Mthfr* genotype within the CD group was observed for both right and left ventricular compact wall thickness, with the latter reaching significance. Additional litters are being examined, but these preliminary data suggest that disturbances in folate, choline or riboflavin metabolism may influence reproductive outcomes and cardiac development.

Adult Phenotype of Mulvihill-Smith Syndrome: Early-onset tumor and sleep disorder. *K. Kosaki[1], T. Yagihashi[1], M. Kato[2], K. Izumi[1,3], R. Kosaki[1,4], T. Takahashi[1]* 1) Dept Pediatrics, Keio Univ, Tokyo, Japan; 2) Dept Neuropsychiatry, Keio Univ, Tokyo, Japan; 3) Dept Genet, Case Western Reserve University, Cleveland, OH; 4) Dept Clin Genet & Mol Med, Natl Ctr for Child Health & Dev, Tokyo, Japan;.

Mulvihill-Smith syndrome (MSS) is characterized by premature aging, multiple pigmented nevi, lack of facial subcutaneous fat, microcephaly, short stature, mental retardation and recurrent infections, however the adult phenotype of MSS has yet to be delineated. We report a 28-year-old woman with Mulvihill-Smith syndrome, who suffered from a pancreatic tumor at age 17 years. Her distinctive sleep pattern includes severe insomnia with disappearance of sleep spindles and K-complexes, persisting muscle tone, and loss of slow wave sleep. The clinical and neurophysiological studies are compatible with Agrypnia excitata, which is ascribed to a dysfunction of the thalamo-limbic system. Brain MRI and SPECT studies revealed structural and functional deficits in the dorsomedial region of thalamus and indicated that the alteration of thalamo-limbic system may underlie the sleep disturbances with MSS. Furthermore the rapid and severe decline in acquired cognitive function showed the distinct cognitive impairments like dementia including intellectual deficits, memory disorder and executive dysfunction. We posit that an early onset tumor, sleep disorder and cognitive decline are unique adult manifestations of Mulvihill-Smith syndrome.

Disease gene mapping of young-onset hypertension in the Taiwanese population. *H.-C. Yang[1], K.-M. Chiang[2], Y.-J. Liang[1], J.-W. Chen[3], Y.-T. Chen[2], W.-H. Pan[2]* 1) Inst. Statistical Science, Academia Sinica; 2) Inst. Biomedical Sciences, Academia Sinica; 3) National Yang-Ming University, Taipei, Taiwan.

[**Introduction**] Young-onset hypertension (YOH) has been demonstrated to have stronger genetic component than its older counterpart. [**Materials**] We collected information and biospecimen from 1039 YOH patients with age-of-onset < 51 in the Academia Sinica Multi-Centered Hypertension Genetic Study. A two-stage association scan was carried out. In the 1st stage (genomewide association study, GWAS), 175 YOH patients with normal BMI, triglyceride and HDL-C levels were selected, and 175 age and sex-matched normotensive controls were selected from the Taiwan Han Chinese Cell and Genome Bank. All samples were genotyped with Affymetrix Human Mapping 100K Set. In the 2nd stage (confirmatory association study), a total of 1024 patients and 1023 controls were genotyped for the SNPs identified in GWAS with Sequenom MassArray. [**Methods**] Genomewide single-point association tests (exact conditional logistic regression), multipoint association tests (haplotype association test and p-value combination test) and pairwise gene-gene interaction tests (odds ratio difference test and conditional logistic regression) were carried out. Multiplicity of testing was adjusted using false discovery rate. The identified SNPs were further examined using the identical statistical tests based on large samples. [**Results**] GWAS in the 1st stage identified nine single SNPs, seven triplets of contiguous SNPs, six triplets of haplotypes and the top 32 pairs of interactive SNPs. In total, 35 identified SNPs in known or hypothetical genes were further examined. Among them, 10 SNPs on chromosomes 2, 4, 6 and 20 obtained verification in the 2nd stage. Interestingly, four SNPs in a hypothetical gene of chromosome 2 and three SNPs in *FSTL5* of chromosome 4 were confirmed by multiple association tests. One SNP in *IMPG1* of chromosome 6 interacted with two SNPs on chromosome 20 and jointly contributed to YOH. *FSTL5* functions as a calcium-ion binder and *IMPG1* is particularly over-expressed in cardiac myocytes. Their roles on YOH were not reported by other authors and are being examined in our replication and functional studies.

Association of five candidate gene polymorphisms in Type 2 Diabetes and Diabetic Nephropathy. *Q. Hasan[1,2,4], S. Movva[2], S. Mubigonda[3], S. Saharia[3], Y. R. Ahuja[4]* 1) Department of Genetics , Kamineni Hospitals, Hyderabad, Andhra Pradesh, India; 2) Department of Genetics, Bhagwan Mahavir Hospital & Research Centre, A.C.Guards, Hyderabad; 3) Renal Unit, Bhagwan Mahavir Hospital & Research Centre, A.C.Guards, Hyderabad; 4) Department of Genetics, Vasavi Hospital & Research Centre, Lakdi-ka-pool, Hyderabad.

Type 2 Diabetes Mellitus (DM) is a chronic metabolic disorder that has a significant impact on the health, quality of life and life expectancy. Renal failure is a common and serious complication of longstanding type 2 DM. Asian Indians, an ethnically distinct population, lead the world in the number of people with type 2 DM and have a consequent epidemic of diabetes associated micro- and macro-vascular complications. There is no simple genetic model adequately explaining risk for diabetes and its complications, there are likely to be multiple genes with small to modest effects that interact with each other and with the environmental factors to affect susceptibility. A total of 336 individuals including 236 Type 2 DM (136 with and 100 without Nephropathy) and 100 healthy volunteers were assessed for polymorphism in five candidate genes: ACE (I/D), MTHFR (rs1801133), eNOS (exon7, NM_000603.3), MMP9 (rs3918240) and IGF2 (exon7, NM_000612.3). Individually MTHFR (p= 0.0003, OR= 4.0423), eNOS (P= 0.0073, OR= 7.3218) and MMP9 (P= 0.0111, OR= 2.1801) gene polymorphisms were associated with type 2 DM while ACE (p=0.027, OR=1.87) and IGF2 ($p<0.05$) were significantly linked to DN. Results of Multiple regression analysis indicated an interaction of ACE, MMP9 and IGF2 (t-value of 3.2374, 3.24414 and 2.79313 with a $p<0.05$) genes in increasing the risk of diabetic patients to develop DN. Individuals with impaired glucose tolerance, a positive family history of DM or other risk factors should be screened for MTHFR C677T, eNOS T1187G, and MMP9 C1562T as biomarkers while individuals with type 2 DM should be assessed for ACE D allele and IGF2 857 del A to identify diabetic patients with higher chance of developing DN. This will help in devising appropriate presentation and management strategies.

Severity Transmission Test: An approach to detect modifier genes affecting severity of disease. *z. zaheer[1,2], M. Devoto[2]* 1) Dept. of Statistics, Univ. of Peshawar, Pakistan; 2) The Childrens Hospital of Philadelphia, Univ. of Pennsylvania, Philadelphia, PA.

Many Mendelian disorders are characterized by an enormous variability in the expressivity of the phenotype in different individuals even in the presence of the same mutation at the major disease-causing gene, or by reduced penetrance. In the case of autosomal dominant disease, parents of severely affected children sometime are identified as asymptomatic carriers of a disease mutation only after the child is diagnosed. One explanation for reduced penetrance or variable expressivity of a disease phenotype is the presence of modifier genes. When one parent has a dominant mutation but is mildly or not affected and a child with the same mutation is severely affected, a possible interpretation is that the mildly affected or unaffected carrier parent and the severely affected child carry a different allele at a modifier gene. If this is true, then the modifier gene allele causing a more severe disease phenotype in the affected child must have been inherited from the non-carrier parent. Based on this hypothesis, we developed the Severity Transmission Test (STT), which can be used for the detection of modifier genes when unaffected carrier parent/affected child pairs are available. The test is designed to distinguish between the transmission from the carrier and non-carrier parents to the affected child.Under the assumption that the modifier gene allele in the affected child must be transmitted from the non-carrier parent, we define our statistic as a test of the null hypothesis that the number of times an allele is transmitted by the non-carrier parents is the same as the number of times that allele is not transmitted by the carrier parents. We conducted a simulation to evaluate the type I error and calculate the power of STT for different disease models. The power of STT was also compared to that of the Transmission Disequilibrium Test (TDT). We show that the STT maintains the nominal level of significance and is as powerful as the TDT, with the additional advantage that it can be used in the absence of the non-carrier parents, when only DNA from the carrier parents is available.

Alu-related 5q35 microdeletions in Sotos syndrome. *N. Matsumoto[1], J. Mochizuki[1,2]* 1) Dept Hum Genet, Yokohama City Univ Grad Sch Med, Yokohama, Japan; 2) Dept Obtet Gynecol, Kitasato Univ Sch Med, Sagamihara, Japan.

Haploinsufficiency of the NSD1 gene due to 5q35 microdeletions or intragenic mutations causes Sotos syndrome (SoS). In 46 of the 49 Japanese deletion-cases, common deletion breakpoints were located at two flanking low copy repeats (LCRs), implying that non-allelic homologous recombination (NAHR) between LCRs is the major mechanism for the common deletion. In the other three cases of atypical deletions, the mechanism(s) of deletions remains unanswered. We characterized the atypical microdeletions using fluorescence in situ hybridization (FISH), quantitative real-time PCR (qPCR), and Southern blot hybridization. All the deletion breakpoints in the three cases were successfully determined at the nucleotide level. Two deletions are 1.07 Mb (SoS19) and 1.23 Mb (SoS109) in size, and another consisted of two deletions with sizes of 28 kb and 0.72 Mb, intervened by an intact 29-kb segment (SoS44). All deletions were smaller than a typical 1.9-Mb common deletion. Alu elements were identified in both deletion breakpoints in SoS19, one of deletion breakpoints in SoS109, and both deletion breakpoints of the proximal 28-kb deletion in SoS44. Alu-mediated NAHR is strongly suggested at least in two of atypical deletions. Finally, qPCR is a very useful method to determine deletion breakpoints even in repeat-related regions.

Systematic Identification of Functional Networks in Human Heart Development. *L. A. Larsen[1,3], K. Lage[2], K. Møllgård[3], C. T. Workman[2], E. Bendsen[4], N. Tommerup[1,3], S. Brunak[2]* 1) Wilhelm Johannsen Centre for Functional Genome Research, Univ. of Copenhagen, Copenhagen, Denmark; 2) Center for Biological Sequence Analysis, Technical University of Denmark, Lyngby, Denmark; 3) Department of Cellular and Molecular Medicine, Univ. of Copenhagen, Copenhagen, Denmark; 4) Department of Obstetrics and Gynaecology, Univ. Hospital of Odense, Odense, Denmark.

Development of the human heart is tightly controlled in time and space by coordination of several molecular networks. Central players in cardiac development (CD) have been identified but the nature of molecular network and the degree of communication between the networks remains largely unknown. An experimentally derived network of 8855 human proteins generated by integrating data from thousands of protein-protein interaction (PPI) screens reported in the literature was used to identify functional network modules in CD and investigate how these modules interact.The functional modules were identified using a phenotypic ranking of protein complexes. We investigated the PPIs of 259 proteins known to be involved in CD from targeted mutations in mice. These 259 proteins can be assigned to 20 different morphological subcategories based on the cardiac phenotype of each mutation. The data showed that the CD proteins were significantly interconnected compared to random sets of proteins (P= 6.5e-07). We have identified a set of 49 novel CD candidates significantly interacting with proteins from the input set (adjusted p-values <0.051). The CD candidate genes were more differentially expressed during heart development compared to controls (P<0.006) and expression of selected candidates in tissue sections from human embryonic hearts correlate with their deduced function. Functional assignment of PPI subclusters within the 20 morphological subcategories supports that the heart is developed in a modular fashion. Furthermore our data show that there is extensive communication between different signalling pathways during heart development, and indicate a high degree of recycling of specific functional modules in a combinatorial fashion during the different stages of organogenesis.

Candidate of biomarkers for Fabry disease mouse model. *J. O. Choi, E. S. Park, J. S. Hong, H. Y. Park, S. C. Jung*
Department of Biochemistry, School of Medicine Ewha Womans University, Seoul, Korea.

Fabry disease is the lysosomal storage disease deficient for the alpha-galactosidase A, leading to alter glycosphingolipid metabolism and accumulate Gb3. Intravenous infusion of alpha-galactosidase A is used for curing patient with Fabry disease as enzyme replacement therapy (ERT). Gene expression in liver and kidney of male alpha-galactosidase A deficient mice of age were compared with that of wild type mice. Microarray analyses were performed before and after injections of alpha-galactosidase A. The identified genes were validated using quantitative real-time PCR and Western blot assay. Serum Amyloid A1(Saa1), S100 Calcium-binding protein A8 (S100a8), S100 Calcium-binding protein A9 (S100a9) and Lipocalin 2 (Lcn2) in liver and Neuropeptide Y (Npy) in kidney were significantly up-regulated compared with wild mice. The gene- expression was normalized after enzyme replacement therapy. Saa1 can be induced in mice with inflammatory stimulus. Lcn2 protein plays a role as a modulator of inflammation. This finding have been shown to modulate inflammation by saa1, S100a8, S100a9 and Lcn2. Npy also have been shown to regulate renal function. These genes could play an important role in pathogenesis of Fabry disease and provide promising targets for develop biomarkers to monitor disease progression and therapeutic efficacy in patients with Fabry disease.

Single nucleotide variations upstream of CHRNB3 affect reporter gene expression. *N. Hoft[1], J. Stitzel[1,2], J. Miyamoto[1], M. Ehringer[1,2]* 1) Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 2) Department of Integrative Physiology, University of Colorado, Boulder, CO.

Recently single nucleotide polymorphisms (SNPs) in the upstream region of CHRNB3 have been associated with nicotine dependence (Bierut et al 2007, Saccone et al 2007) and early subjective effects of smoking (Zeiger et al 2008). The aim of this work is to assess whether these SNPs have a functional effect on gene expression. Promoter activity of fragments 3kb and 1.5kb immediately upstream of the CHRNB3 start codon has been characterized by cloning this region upstream of the luciferase gene in the promoterless reporter vector pGL3basic. Two constructs for each fragment length, representing both the major and minor haplotypes were compared. Promoter activity was tested in three cell types HEK293T, SH-SY5Y, and P19S18O1A1. Only P19S18O1A1 cells transfected with the 3kb constructs showed expression different than background. Lack of expression in the other two cell types suggests these may lack the transcriptional machinery necessary to express CHRNB3. Preliminary data indicate that the haplotype of minor alleles show an almost two fold increase (1.87 +/- 0.40) in promoter activity compared to the common haplotype. This difference indicates SNPs in this region may lead to functional differences in mRNA expression. Current efforts are now focused on examining individual SNPs on different haplotype background to characterize which SNPs in this region primarily account for this change in expression.

Identifying and Visualizing Complex Tumor Alterations through Integration of Diverse Data from The Cancer Genome Atlas (TCGA) Project. *J. Zhang[1], R. Finney[1], M. Edmonson[2], C. Schaefer[1], W. Rowe[1], C. Yan[1], R. Clifford[2], S. Greenblum[1], G. Wu[1], H. Zhang[2], H. Liu[2], C. Nguyen[2], K. Buetow[1,2]* 1) Center for Bioinformatics, NCI, Rockville, MD; 2) Laboratory of Population Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20892.

Cancer is a complex disease driven by networks of altered genes. The Cancer Genome Atlas (TCGA) project is a large-scale comprehensive investigation into various mechanisms that lead to gene dysfunction in tumors. The first cancer studied by the TCGA project is glioblastoma multiforme (GBM). Genome-wide assays of somatic sequence mutations, copy number changes, gene and microRNA expression, and methylation data of GBM have been generated using multiple experimental platforms (http://tcga-data.nci.nih.gov/tcga/findArchives.htm). To facilitate the identification and visualization of the complex mechanisms that can lead to gene dysfunction, we have developed a web-based application, The Cancer Genome WorkBench (CGWB, http://cgwb.nci.nih.gov), to display the diverse, multi-dimensional TCGA data in an integrated form. CGWB presents a high-level summary view of the recurrently altered genes/regions in tumor and a high-resolution, detailed, expert view for analysis of the relationships between the various genomic data sets. A user can toggle between an interactive heat map view for gene, genome and pathway-orientated display of somatic sequence mutations, copy number changes, gene expression and methylation status data, and a genome-browser view which provides the association between the reference genome annotation with tumor aberrations. The workbench enables a user to evaluate correlation between somatic genetic alterations and gene expression. More importantly, it permits researchers to discover the complex molecular mechanisms underlying cancer from large volumes of diverse, multiple-platform, high-resolution data.

Requirement of Bardet-Biedl Syndrome Proteins for Leptin Receptor Signaling. *S. Seo[1,2], D.-F. Guo[3], K. Bugge[1,2], D. A. Morgan[3], K. Rahmouni[3], V. C. Sheffield[1,2]* 1) Dept. of Pediatrics, Univ. of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute; 3) Dept. of Internal Medicine, Univ. of Iowa, Iowa City, IA.

Obesity is a major public health problem in most developed countries and a major risk factor for hypertension and diabetes. Emerging evidence indicates that ciliary dysfunction contributes to human obesity but the underlying molecular and cellular mechanisms are unknown. Bardet-Biedl syndrome (BBS) is a genetically heterogeneous human obesity syndrome. BBS proteins are thought to play a role in cilia function and intracellular trafficking. Here, we show that BBS proteins are required for leptin receptor (LepR) signaling in the hypothalamus. Physiological data indicate that *Bbs2*, *Bbs4*, and *Bbs6* null mice are resistant to exogenous leptin even when serum leptin levels are normalized. In contrast, downstream melanocortin receptor signaling is unaffected, suggesting that obesity in BBS animals is due to defect(s) downstream or at the level of LepR but upstream of melanocortin receptors in the hypothalamic leptin-melanocortin axis. Reduced STAT3 phosphorylation upon leptin administration indicates that LepR signaling is attenuated in *Bbs2*, *Bbs4*, and *Bbs6* null mice. Impaired LepR signaling in BBS mice results in decreased *POMC* expression, which consequently leads to hyperphagia. Furthermore, we found that BBS1 protein physically interacts with the LepR and that loss of BBS proteins alters LepR trafficking. Our data indicate that BBS proteins mediate LepR trafficking and that impaired LepR signaling underlies energy imbalance in BBS. These findings represent a novel mechanism for leptin resistance and obesity.

Role of non-B DNA conformations in initiating the non-allelic homologous recombination-derived *Se^{fus}* allele and the interlocus gene conversion-derived *Sec1-FUT2-Sec1* hybrid allele. *J. M. Chen, C. Férec* Etablissement Français du Sang (EFS) - Bretagne; INSERM, U613; Université de Bretagne Occidentale (UBO), Brest, France. Jian-Min.Chen@univ-brest.fr.

A *Sec1-FUT2-Sec1* hybrid allele that apparently resulted from a gene conversion event has recently been reported. This allele is more appropriately termed *Sec1-Se^{428}-Sec1* because it is the *Se^{428}* mutant allele of the *FUT2* gene that acts as the donor sequence. Interestingly, the 5 half of the maximal converted tract (MaxCT) of this interlocus gene conversion event overlaps with the crossover region of the previously reported *Se^{fus}* mutant allele. The *Se^{fus}* allele was generated from non-allelic homologous recombination (NAHR), through which the 3-part of the *FUT2* gene was fused to the 5-part of the *Sec1* gene. Homologous recombination, including NAHR and gene conversion, is generally thought to be initiated by double strand breaks (DSBs). Recent studies have demonstrated that non-B DNA conformations (e.g. triplexes, hairpins and tetraplexes), rather than the DNA sequence *per se* in the orthodox right-handed Watson-Crick B-form, serve as recognition signals to induce chromosomal DSBs. That the MaxCT of *Sec1-Se^{428}-Sec1* overlaps with the crossover region of *Se^{fus}* may not be a mere coincidence; rather, it suggests that the initiating DSBs might have occurred within the overlapping sequence tract. Were this to be the case, the overlapping sequence tract should be capable of adopting non-B conformation(s). Indeed, four GGG repeats within the overlapping sequence tract may fold into a tetraplex structure. In addition, we identified a hairpin structure that can be formed by a pair of imperfect inverted repeats, by means of the previously established method for predicting local secondary structure of nucleotide sequences. These non-B DNA structures may act individually or synergistically to promote the formation of DSBs, which in turn initiated the process of homologous recombination. In summary, our findings provide a reasonable explanation for the occurrence of two different homologous recombination events within a short sequence tract.

Development of zebrafish model for Diamond-Blackfan anemia by antisense oligo-mediated knockdown of ribosomal protein S19 gene. *N. Kenmochi, T. Uechi, Y. Nakajima, A. Chakraborty, H. Torihara, S. Higa* Frontier Sci Research Ctr, Univ Miyazaki, Miyazaki, Japan.

Although the ribosome is essential for cell growth and development, the effects of ribosomal mutations and their role in human diseases has largely been ignored. Most people might think that defects in ribosomal components would cause serious problems with the translational apparatus and result in early embryonic death. However, recent study has revealed that the gene encoding ribosomal protein S19 (*RPS19*) is mutated in 25% of patients with Diamond-Blackfan anemia. Moreover, in mouse, Tail-short (*Ts*) and Belly spots and tail (*bst*) mutants have been identified as genetic abnormalities within *Rpl38* and *Rpl24* genes, respectively.

In this study, we developed an RPS19-deficient zebrafish by knocking down *rps19* using a Morpholino antisense oligo. The RPS19-deficient animals showed a dramatic decrease in blood cells as well as deformities in the head and tail regions at early developmental stages. These phenotypes were rescued by injection of zebrafish r*ps19* mRNA, but not by injection of *rps19* mRNAs with mutations that have been identified in DBA patients. Our results indicate that *rps19* is essential for hematopoietic differentiation during early embryogenesis. The effects were specific to *rps19*, but knocking down the genes for three other ribosomal proteins, *rpl35*, *rpl35a*, and *rplp2*, produced similar phenotypes, suggesting that these genes might have a common function in zebrafish erythropoiesis. The RPS19-deficient zebrafish will provide a valuable tool for investigating the molecular mechanisms of DBA development in humans.

SNPs at the Intelectin 1 gene confer risks for metabolic syndrome in a southern Taiwan population. *Y. Li[1], Y. Liao[1], M. Yu[4], S. Juo[1,2,3]* 1) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan, Taiwan; 2) Department of Neurology, Kaohsiung Medical University, Kaohsiung, Taiwan, Taiwan; 3) Center of Excellence for Environmental Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Hepatobiliary Division, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background and Purpose Dysregulation of the production of adipokines plays a pivotal role in the development of metabolic syndrome and cardiovascular comorbidity. Omentin, is able to enhance insulin-stimulated glucose uptake in adipocytes and consequently leads to obesity and insulin resistance. The purpose of present study is to investigate whether the polymorphisms at the gene encoding omentin (ITLN1) confer risks for metabolic syndrome in a southern Taiwan population.

Methods The diagnosis of metabolic syndrome is based on the modified version of NCEP ATPIII. We conducted a case-control association study using subjects with at least three of the five components of metabolic syndrome as cases and those with zero or one feature as controls. Five tagging SNPs and one additional non-synonymous SNP at ITLN1 gene were genotyped.

Results A total of 159 cases and 414 controls were included in the present study. Men were accounted for 47.8 % and the average age was 48.512.9 year-old. One SNP (rs952804) showed a borderline significance for metabolic syndrome. Compared to the common homozygotes CC (n=230), the rare allele carriers (CT: n=223 and TT: n=94) were associated with increased risks of metabolic syndrome (OR=1.50 and 1.38, p=0.057 and 0.245 respectively). We further evaluated the genetic effect on each of the five components of metabolic syndrome. SNP rs952804 appeared to have a dominant effect and was associated with elevated levels of fasting plasma glucose (p=0.010). We did not find any significant association between metabolic syndrome and the other five SNPs.

Conclusions The present study demonstrated that polymorphisms at the ITLN1 gene may influence fasting plasma glucose and predispose to the development of metabolic syndrome.

Makes-it sense to propose *CFTR* and *SPINK1* gene testing in patient with recurrent pancreatitis? A Belgian 8 years experience! *X. Pepermans[1], P. Deprez[2], A. Bosmans[1], K. Dahan[1]* 1) Center of Human Genetics, Cliniques Universitaires St-Luc, Bruxelles, Belgium; 2) Department of Gastroenterology, Cliniques Universitaires Saint-Luc, Bruxelles, Belgium.

Hereditary Pancreatitis (HP) is an autosomal dominant disease typically consisting of recurrent episodes of acute pancreatitis, progression to chronic pancreatitis and an increased risk of pancreatic cancer. Mutations in the cationic trypsinogen gene (*PRSS1*) cause the disease in 60% of the kindred while the roles of other genes e.g. *SPINK1* and *CFTR* are still under evaluation, especially in determining chronic pancreatitis: chronic pancreatitis or acute recurrent pancreatitis is considered to be a complex multigenic disease. Here, we have performed genetic tests for recurrent pancreatitis in 331 probands referred to our center from 1999 until 2007. Whole coding region of *PRSS1* was analyzed while a specific exon 3 scanning for *SPINK1* and screening for a panel of 36 common *CFTR* causing mutations were done. Seventeen of 331 patients (5,1%) had a disease causing mutations in *PRSS1*. Another 9,8% (15/152) of the patients had a *SPINK1* gene substitutions -heterozygote p.N34S in 9/152 and homozygote p.N34S in 1/152 -. Thirteen-seven of 331 (11%) had mutations in *CFTR* by mutation targeted testing. The futher complete *CFTR* screening (sequencing and MLPA) revealed that 3 of them were compound heterozygote whereas, 16 heterozygotes (16/331) were carriers of a common *CFTR* haplotype c.869+11C>T(rs1800503)-c.1393-61A>G(rs34855237)-p.Met470Val(rs213950). Of 37 patients with *CFTR* mutations 1% (3/331) also carried a *PRSS1* mutations and 2% (3/152) carried a *SPINK1* mutation moreover one individual was trans-heterozygote *PRSS1/SPINK1*. In total, multi-step testing of *PRSS1*, *SPINK1* an *CFTR* genes identified genetic variants in 62 Belgian patients considered by there physicians as candidate for genetic testing. These data fully illustrate the importance of consensus guidelines for indications, regarding our apparent low rate of mutation detection.

CD40 ligand gene polymorphisms in Taiwanese women with cervical squamous cell carcinoma. *T. Y. Chang[1], Y. C. Yang[1,2,4], Y. J. Lee[1,3,5], T. H. Su[2,4], W. F. Chen[1], H. W. Chan[1], H. F. Liu[1], M. Lin[1]* 1) Medical Research Dept, Mackay Memorial Hosp, Taipei, Taiwan; 2) Dept of Gynecology and Obstetrics, Mackay Memorial Hosp, Taipei, Taiwan; 3) Dept of Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan; 4) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 5) College of Medicine, Taipei Medical University, Taipei, Taiwan.

Human papillomavirus (HPV) is considered to be a necessary but not sufficient cause for cervical cancer. It is now recognized that host immunogenetic background play an important role in the outcome of HPV infection and the subsequent development of cervical cancer. CD40 ligand (CD40L, also known as CD154 or gp39), a type II transmembrane protein, is expressed primarily on activated T cells and is indispensable to full and productive T cell activation. The aim of this study is to investigate if polymorphisms of the *CD40L* gene are associated with HPV-induced cervical cancer in the Taiwanese population. The *-3459 A/G* and *IVS4+121 A/G* polymorphisms were genotyped in 138 cervical squamous cell carcinoma (CSCC) patients and 519 age/sex matched healthy controls by using the Pre-Developed TaqMan Allelic Discrimination Assay. The presence and genotypes of HPV in CSCC patients were determined by PCR. We found no significant association between any polymorphisms or haplotypes examined and overall CSCC risk. In addition, no significant association was observed between HPV-16 positive CSCC patients and controls. Our findings provide no support for the hypothesis that *CD40L* polymorphisms are associated with increased risk for CSCC in the Taiwanese population.

New correction algorithms for multiple comparisons in case-control multilocus association studies based on haplotypes and diplotype configurations. *K. Misawa[1], S. Fujii[2,3], T. Yamazaki[2], A. Takahashi[2], J. Takasaki[2], M. Yanagisawa[3], Y. Ohnishi[2], Y. Nakamura[2], N. Kamatani[2,4]* 1) Research Program for Computational Science, RIKEN, Minato-ku, Tokyo, Japan; 2) SNP Research Center, RIKEN, Minato-ku, Tokyo, Japan; 3) Department of Computer Science, Waseda University, Tokyo; 4) Department of Advanced Biomedical Engineering and Science, and Institute of Rheumatology, Tokyo Womens Medical University, Tokyo.

The multiple comparison problem arises in population-based studies when the association between phenotypes and multilocus genotypes is examined. Although Bonferronis correction is often used to cope with such a problem, it may yield too conservative conclusions because all of the tests are assumed to be independent. We have developed new correction algorithms for the test of independence between phenotypes and multilocus genotypes at loci in linkage disequilibrium. In one of the algorithms, the exact type I error rate is calculated for the independency test. We found that such exact probabilities can be calculated using a 128 CPU PC cluster if the numbers of cases and controls are not more than 50. As an alternative method, we developed algorithms to calculate asymptotically the type I error rates using a Markov-chain Monte Carlo (MCMC) sampler which provided a good approximation to values calculated by the exact method. When the new algorithms were applied to both simulation and real data, the real overall type I error rates for the loci in linkage disequilibrium were from one-third to half as high as those obtained by Bonferronis correction. These algorithms are likely to be useful for multilocus association studies for data obtained by case-control and cohort studies.

Epigenetic variation in newborn twins. *M. Ollikainen[1], E. J. Joo[1], R. Andronikos[1], L. Gordon[2], R. Morley[1], R. Saffery[1], J. M. Craig[1]* 1) Developmental Epigenetics, Murdoch Childrens Research Institute, Melbourne, VIC, Australia; 2) Bioinformatics Department, Murdoch Childrens Researh Institute, Melbourne, VIC, Australia.

The phenotype of an individual is a result of a complex interplay between genome, epigenome and environment. The genotype of an individual is established at conception and only small changes occur later, whereas the epigenome is under constant environmental influence. Epimutations more common than genetic mutations and thereby contribute to phenotypic differences between individuals, whether genotypically different or identical (twins). To investigate the association between epigenetic variation and phenotypic discordance, we are examining the differences in DNA methylation in newborn twins. Our aim is to study the epigenetic profile in at least 20 newborn monozygotic twin pairs of at least 15% birth weight discordance. To establish a benchmark for the epigenetic variation between newborns we examined a dizygotic twin pair, sharing 50% of their genotype and most of their in utero environment. Methylated DNA Immunoprecipitation (MeDIP) was performed as described [Weber et al Nature Genetics 2005;37 853]. Validation of the MeDIP approach included locus-specific analysis of known methylated and unmethylated genes. We then compared signal intensities from the immunoprecipitated fraction to the input fraction following hybridisation to Affymetrix GeneChip Human Promoter Array. Hybridisation signals were analysed using the Model-based Analysis for Tiling arrays (MAT) algorithm. Promoter regions that were identified as methylated in two replicate experiments were divided into two categories: methylated in both twins and methylated in one twin only, and ranked according to MAT scores. We found several hundred highly methylated regions shared by both twins and a large number of regions methylated in one twin only. Current studies are aimed at examining epigenetic variation in monozygotic twins with a focus on methylation profile within birth weight discordant twin pairs. To our knowledge, this is the first study to assess epigenetic variation in newborn twins.

Association of Aphallia and Lung Agenesis. *M. Gerard-Blanluet[1], V. Lambert[2], S. Khung-Savatovsky[3], ML. Jaquemont[1], L. Perrin[1], C. Baumann[1], AL. Delezoide[3], A. Verloes[1]* 1) Medical Genetics, APHP Robert Debré Hospital, Paris, France; 2) Prenatal diagnosis, West Guyane Hospital Center, Saint Laurent du Maroni, Guyane, France; 3) Developmental Biology Department, APHP Robert Debré, Paris, France.

Aphallia, or congenital absence of the penis is a rare malformation, with an estimated frequency of 1/30 millions births. Aphallia is frequently associated with renal aplasia/dysplasia and imperforate anus. Absence of penis may be a part of severe malformation complexes that involve the perineal area, such as sirenomelia, cloacal extrophy or the anorectal septum malformation sequence. It has been associated with infants of diabetic mothers (Gripp et al., 1999). We report a patient with aphallia in a sequence of anorectal septum malformation associated with an unilateral lung agenesis. The fetus was the seventh child of non-consanguineous parents. Oligoanamnios was discovered at 32 weeks. Ultrasonography disclosed severe bilateral renal dysplasia with no residual renal function, and termination of the pregnancy was done at 35 weeks. No maternal diabetes was documented. Fetopathological examination showed the association of bilateral renal dysplasia, imperforate anus, aphallia with normal scrotal formation and testes, and right lung agenesis. Myocardic hypertrophy was present. X-rays showed thoracic hemivertebrae, and 14 ribs on the left side. Histological examination did not revealed any erectile tissue in pubic region. Karyotype was 46,XY normal. Aphallia and urogenital malformations are thought to be due to a defect of induction of the cloacal sequence during early embryogenesis. No lung agenesis are reported in the published cases of aphallia at our knowledge. Lung agenesis has been described in VACTERL association and oculo-auriculo-vertebral spectrum. The association of right lung agenesis, with presence of disorganization of the rib cage (hemivertebrae, 14 ribs on the left side), without maternal diabetes, integrate aphallia with imperforate anus and renal dysplasia in the larger group of blastogenesis disorders.

Three de novo deletions, one insertion, and one inversion of chromosome 6 in a patient with complete absence of expressive speech and reduced pain perception. *E. Passarge[3], M. Poot[1], R. van 't Slot[1], R. Leupert[2], V. Beyer[2], T. Haaf[2]* 1) Department of Medical Genetics, University Medical Centre Utrecht, Utrecht, Netherlands; 2) Institut für Humangenetik, Johannes Gutenberg-Universität Mainz, Mainz, Germany; 3) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany.

A known de novo deletion 6q(q13-q14) within a de novo pericentric inversion 6(p11.2q15) associated with a distinctive phenotype was re-investigated. A much more complex chromosomal rearrangement consisting of three non-contiguous deletions was found instead of a single deletion as determined by high resolution G-band analysis reported previously (E. Passarge, Cytogenet. Cell Genet. 91: 192-198, 2000). We employed the Infinium HumanHap300 Genotyping BeadChip SNP array and BAC-based FISH. This revealed three adjacent, but non-contiguous de novo deletions and one insertion. We confirmed the deletion 6q14 and determined its size to be 11.9 Mb. This deletion affects 27 genes, some of which are involved in growth regulation, tissue modeling, and pain sensation, and may be related to the patient's phenotype. The most distal deletion (towards the centromere) of two newly discovered deletions of 360 kb in 6p12.3 contains four genes, RHAG, CRISP1, -2, 3, and PGK2. The proximal new deletion on 6p12.2-p12.1 is 1.15 Mb in size and involves five genes, PKHD1, IL17, MCM3, EFHC1, and TRAM2. By combining the SNP array and FISH data we were able to completely map and to reconstruct this highly complex rearrangement in a single chromosome of paternal origin. The main clinical features of this 31-year-old women are dysmorphic facial features consisting of a broad face, prominent glabella, broad nose, and hypertelorism, non-progressive deficit of motor control, a broad-based slow-motion-like gait, absence of speech development, inability to acquire and comprehend theoretical knowledge, and reduced sensitivity to pain. This study shows that a complex chromosomal rearrangement disclosed by high resolution cytogenetic methods may be even more complex when analyzed at the molecular level.

Association of ITGAM and BLK polymorphisms with systemic lupus erythematosus (SLE) in Hong Kong Chinese. *MH. ZHAO, WL. YANG, YL. LAU* Department of Paediatrics and Adolescent Medicine, University of Hong Kong, Queen Mary Hospital, Hong Kong.

Systemic Lupus erythematosus (SLE) is an autoimmune disease characterized by high-level autoantibody production and immune complex deposition. Both genetic and environmental factors contribute to the etiology of SLE. In order to identify susceptibility genes associated with SLE risks in Chinese population, we have studied several SNPs in ITGAM and BLK, two genes found to be associated with the disease in Caucasians but with unknown effect in other populations. SNP rs1143682 and SNP rs1143683 of ITGAM, as well as SNP rs13277113 and SNP rs2248932 in BLK, were genotyped in this study by either TaqMan or direct sequencing of PCR products. We found that the risk allele A of rs13277113 in BLK is associated with SLE in Chinese (P=6.37×10-5, OR=1.39), and it is a major allele in our population while a minor allele in the Caucasians. It is enriched (77%) in SLE patients compared to healthy controls (71%). However, no significant difference was seen in ITGAM polymorphisms in Hong Kong Chinese. But when we separate the whole population by gender, for males, SNP rs1143682 has a G allele frequency of 46% in patients comparing to 34% in controls (P=0.009, OR=1.62). The conclusion is that BLK, but not ITGAM, is associated with Systemic Lupus Erythematosus (SLE) in Hong Kong Chinese. Whereas ITGAM seems to be a risk factor only in male patients, this finding needs to be verified by larger and independent sample collections, as male patient only constitute 10% of all the affected in our population.

Genetic variation and haplotypes of the *UGT1A1, 1A6* and *1A7* polymorphisms in Sao Miguel population (Azores, Portugal). *M. J. Brilhante[1], P. R. Pacheco[1,2], F. Sigallat[1], H. Polena[1], R. Cabral[1,2], C. C. Branco[1,2], L. Mota-Vieira[1,2]* 1) Molec Genetics & Pathol Unit, Hosp Divino Espirito Santo PD, EPE, Ponta Delgada, Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

Glucurodination reactions, catalysed by uridine-diphosphate glucuronosyltransferase (UGT) enzymes, are a detoxification process that transforms both endogenous and exogenous compounds into glucuronic acid, aiding their excretion. This study is a starting point for the evaluation of the impact of UGT genotypes and haplotypes in the individual susceptibility to chemical-induced diseases and responses to therapeutic drugs in Sao Miguel population (Azores). Here, we assess the genome of 469 individuals by determining the prevalence of the polymorphisms and haplotypes in *UGT1A1*, *UGT1A6* and *UGT1A7* and by calculating the extent of linkage disequilibrium (LD) in the genomic region encompassing these genes. Allelic analyses disclosed that *UGT1A1* presented the major frequency for *1 allele (70.7%), being *UGT1A*36* and *UGT1A*37* the two rare alleles. These last alleles, found only in African-ancestry individuals, confirm our previous results on Sao Miguel genetic background, an admixed population composed of European, Jews and Africans. For *UGT1A6*, the allele with major frequency was *1 (68.0%). In *UGT1A7* the three higher frequencies were observed for *1 (34.6%), *2 (28.1%) and *3 (35.5%). Concerning genotypic analyses, the frequencies detected for *UGT1A1*: *1*1 (50.5%) and *1*28 (39.7%); *UGT1A6*: *1*1 (47.5%) and *1*2 (36.2%); and *UGT1A7*: *1*3 (24.7%), *1*2 (19.6%) and *2*3 (19.2%). Haplotype analysis of the *UGT1A1*, *UGT1A6* and *UGT1A7* polymorphisms showed that three major haplotypes constituted 79.9% of the allelic variants in the cohort. We identified 21 haplotypes being *UGT1A1*28-UGT1A6*2-UGT1A7*3*, the second most frequent (23.8%), in which all three alleles codify for low function UGT isoforms. These highly prevalent polymorphisms and haplotypes result in modified expression and activity of UGTs, may influence susceptibility to cancers, and predispose to side effects of drugs. Currently, we are estimating the linkage disequilibrium between *UGT1A1*, *UGT1A6* and *UGT1A7*. (Azorean Government Funded).

The involvement of neuronal migration genes in developmental dyslexia. *J. A. Chapman, D. Harold, G. Hill, M. C. O'Donovan, J. Williams* Dept of Psychological Medicine, Cardiff University, Henry Wellcome Building, Heath Park, Cardiff, United Kingdom.

Neuronal migration is the process by which neurons in the brain are correctly positioned during development. It is achieved though the rearrangement of cytoskeletal components in response to extracellular cues, mediated by numerous intracellular signalling pathways. Through the use of RNA interference (RNAi), a number of genes that have shown an association with developmental dyslexia (DD) have also shown evidence for a role within neuronal migration. These include ROBO1, DYX1C1, DCDC2 and KIAA0319.

Other genes within DD linkage regions are plausible candidates for involvement in neuronal migration, and we aimed to investigate variants within these genes for an association with DD in our case/control sample. The most promising genes that have been identified so far are DCDC2b, (which shows homology to DCDC2), KIAA0319L (which shows homology to KIAA0319) and CDC42, within the replicated DD linkage region 1p34-36. A gene within the DD linkage region on chromosome 15q21 called Protogenin (PRTG) may also have a role within neuronal migration.

We genotyped tag SNPs for each of these 4 genes (71 SNPs in total) in our UK sample of 357 cases and 269 controls using the Sequenom platform. None of the variants show significant allelic, genotypic or haplotypic association with DD in our sample. However, these genes are not an exhaustive list of neuronal migration candidates, and impaired neuronal migration may still have a role to play within DD.

Paget's disease of bone in the Italian population: novel SQSTM1/p62 mutations and genotype-phenotype correlations. *F. Gianfrancesco[1], L. Gennari[2], P. Fusco[1], T. Esposito[1], D. Rendina[3], A. Ciccodicola[1], D. Merlotti[2], V. De Paola[2], G. De Filippo[4], G. Martini[2], P. Strazzullo[3], R. Nuti[2], G. Mossetti[3]* 1) Institute of Genetics and Biophysics, Italian National Research Council, Naples, Italy; 2) Internal Medicine, Endocrine-Metabolic Sciences and Biochemistry, University of Siena, Italy; 3) Clinical and Experimental Medicine, Federico II University of Naples, Italy; 4) Unit of Pediatric Endocrinology, Gaetano Rummo Hospital, Benevento, Italy.

Paget disease of bone (PDB) is a chronic disease of the skeleton that affects up to 2-3% of the population aged > 50 years. The PDB geographic distribution is not uniform, with a higher prevalence of the disease in in populations of British descent. We recently characterized an area of increased prevalence of PDB in the region of Campania, in Southern Italy. Patients from this region showed increased severity of disease with peculiar phenotypic characteristics and an increased number of familial cases. We examined the clinical characteristics, and the prevalence and type of SQSTM1 mutations in a large sample of 380 unrelated PDB subjects from several regions including 145 patients from Campania. Nine different mutations in SQSTM1 gene were observed in 35.2% and 11.3% of familial and sporadic PDB cases, respectively (equivalent to 15.6% of the overall cohort). Five of these mutations, were novel and have not been previously described. An higher prevalence of SQSTM1 mutations was observed in polyostotic than monostotic cases (7% vs 22%; $p<0.005$). In keeping with previous studies, the P392L was however the most common observed mutation in both sporadic and familial cases. Genotype-phenotype analysis confirmed an increased severity of disease and an earlier age of onset. Interestingly, in PDB subjects from Campania a different distribution and a significantly reduced prevalence of mutations was observed with respect to the other regions, despite an increase in disease severity and the higher prevalence of familial cases. This might imply the presence of mutations in different genes as well an increased persistence of a possible environmental trigger.

Towards the identification of a new gene for Andersons disease. *M. Varret[1], M. Sylvain[2], J.-P. Rabès[1,3], A. Grodet[4], A. Munnich[1], L. Ferkdadji[5], C. Boileau[1,3], L. Aggerbeck[2], J. Schmitz[6], M.-E. Samson-Bouma[1]* 1) INSERM U781, Hopital Necker, Université Paris Descartes, Paris; 2) CGM, CNRS, Avenue de la Terrasse, 91198 Gif-sur-Yvette; 3) Laboratoire de Biochimie et de Génétique Moléculaire, CHU Ambroise Paré (AP-HP & Université Versailles-Saint-Quentin-en-Yvelines), Boulogne; 4) Université Paris 7 Denis Diderot, Faculté de Médecine Xavier Bichat, Paris; 5) Service dAnatomie Pathologique, Hôpital R. Debré, Paris; 6) Departement de Pediatrie, Hopital Necker-Enfants Malades, Paris, France.

The study of naturally occurring mutations in hypocholesterolemic patients presenting with lipid malabsorption syndrome has been useful in identifying new target for lipid-lowering therapy. Andersons disease, is a very rare lipid malabsorption syndrome, usually diagnosed in early infancy, characterized by an inability to export dietary lipids as chylomicrons due to a recessive genetic defect in lipoprotein secretion. Recently, the molecular basis of this defect was show to be due to mutations in the SARA2 gene encoding the Sar1b protein. This protein is involved in the vesicular transport between the endoplasmic reticulum and the Golgi. We report here 4 patients from 2 families, clearly diagnosed as Andersons disease patients. They had low levels of cholesterol and of lipid soluble vitamins. No chylomicrons were secreted after a fat load, and alpha and betalipoproteins were 50% of normal. Endoscopy showed a typical white stippling-like hoar frosting covering the intestinal mucosal surface. Ultrastructural examination of intestinal biopsies showed an accumulation of free lipid and lipoprotein-like particles, reflecting the secretory defect. Direct sequencing of the 7 exons of the SARA 2 gene revealed no mutation. This result thus excludes, in these patients, SARA2 as the molecular basis of the lipoprotein secretory defect and suggests the existence of at least another gene. A genome scan, performed in the two families allowed us to identify four candidate locus that we are investigating at the moment. Proteins involved in the intracellular processing of chylomicron secretion would be good candidates.

Copy number variation and chronic pancreatitis. *C. Férec, E. Masson, C. Le Maréchal, J. M. Chen* INSERM, U613; Université de Bretagne Occidentale (UBO); Etablissement Français du Sang (EFS) - Bretagne; Centre Hospitalier Universitaire (CHU) Brest, Hôpital Morvan, Brest, France. claude.ferec@univ-brest.fr.

Although hereditary pancreatitis was described as an autosomal dominant disease in the early 1950s, only in the past decade has tremendous progress been made toward unraveling its molecular basis. In 1996, a gain-of-function missense mutation in the cationic trypsinogen gene (*PRSS1*) was identified by a candidate gene approach. Thereafter, search for chronic pancreatitis-associated genetic factors has been largely focused on one form of genetic variation viz. single-nucleotide substitutions. Recently, we have identified both duplication and triplication of a ~605-kb segment containing *PRSS1* and *PRSS2* (encoding anionic trypsinogen) on chromosome 7q34 in French Caucasians with hereditary or idiopathic chronic pancreatitis, by means of quantitative fluorescent multiplex PCR (Le Maréchal et al. Nat Genet 2006; Masson et al. Clin Gastroenterol Hepatol 2008). Thus, in the context of *PRSS1*, both qualitative missense mutations and quantitative copy number mutations independently contribute to the etiology of chronic pancreatitis. More recently, we have characterized an intriguing hybrid *PRSS2*/*PRSS1* gene, in which exons 1 and 2 are derived from *PRSS2* and exons 3 to 5 from *PRSS1* (Masson et al. Hum Genet 2008). Interestingly, this hybrid gene causes the disease through a combination of its inherent double gain-of-function effect, acting simultaneously as a quantitative copy number mutation and a qualitative missense mutation; this reveals a previously unknown mechanism causing human inherited disease, enriches the lexicon of human genetic variation and goes beyond the known interaction between copy number variations (CNVs) and single nucleotide substitutions in health and disease. It should also stimulate more interest in analyzing both types of genetic variation whenever one tries to determine the contribution of a specific locus to a given disease phenotype. In short, our findings made over the past two years represent a further demonstration of how studies of CNVs have altered the landscape of genetic research and offers a fresh glimpse into the exciting realm of human CNVs.

A Fourth Phenotype for Autosomal Dominant Hypercholesterolemia. *A. Marques[1], M. Marduel[1], J. Bonneau[1], M. Devillers[1], D. Erlich[1], K. Ouguerram[2], M. Krempf[2], M. Abifadel[1,3], J.-P. Rabès[1,4], C. Boileau[1,4], M. Varret[1]* 1) INSERM U781, Hosp Necker, Universtité Paris Descartes, Paris, France; 2) INSERM U539, University Hospital, Nantes, France; 3) Faculté de Pharmacie, Université Saint-Joseph, Beirut, Lebanon; 4) Laboratoire de Biochimie et de Génétique Moléculaire, CHU Ambroise Paré (AP-HP & Université Versailles-Saint-Quentin-en-Yvelines), Boulogne, France.

Autosomal Dominant Hypercholesterolemia (ADH) is due to defects in LDLR, APOB or PCSK9. Reports revealed the involvement of still unknown genes. We report an ADH family (HC6) excluding the 3 known genes and named the pathology HCHOLA4. We wish to identify HCHOAL4 and define the associated pathophysiology. A genome scan, performed in HC6 (11 affected), localized HCHOLA4 at 16q22.1. Functional candidate genes did not show any causal mutation. In vivo kinetics of apoB-100 showed a decrease in LDL catabolism. Q-PCR analysis of LDLR expression in EBV-transformed lymphoblasts showes that cells of 4 affected subjects do not reply to cholesterol deprivation by activating LDLR expression. These results suggest an alteration, direct or not, in LDL receptor endocytosis or intracellular traffic. We collected DNA from 25 small pedigree (63 affected) and excluded the 3 genes. Linkage to 16q is excluded in 8 families, the 17 other are being enlarged to allow reduction of the genetic interval. For 3 families, Q-PCR analysis of LDLR expression in lymphoblasts showed that 2 probands do not reply to cholesterol deprivation like affected subjects of HC6. One of these probands is from a familly (HC94) in wich linkage to 16q was excluded. A genome scan in HC94 (6 affected) with Illumina arrays began. We expect to redefine the HCHOLA4 interval with combined results from HC6 and HC94. Furthermore, 2-D electrophoresis for cytosolic proteins from lymphoblasts showed different profiles between affected and unaffected HC6 members. Mass spectrometry identified 120 proteins from the endocytosis, signaling or protein degradation pathway. These results will be confirmed by Q-PCR and westerns.

Effectiveness of enzyme replacement therapy in children: results from FOS - the Fabry Outcome Survey. *R. Hartung[1], C. Kampmann[1], R. Parini[2], G. Pintos-Morell[3], M. Beck[1], U. Ramaswami[4] on behalf of the FOS investigators*
1) University Children's Hospital, Mainz, Germany; 2) University Hospital San Gerardo, Monza, Italy; 3) University Hospital Germans Trias i Pujol, Badalona, Spain; 4) Addenbrookes University Teaching Hospital, Cambridge, UK.

Background: Fabry disease (FD), a progressive, X-linked lysosomal storage disease, leads to major organ failure and premature death. Enzyme replacement therapy (ERT) is now available but limited data exist on the long-term effectiveness of ERT in children. Methods: Effects of ERT with agalsidase alfa (Replagal; Shire HGT) were analysed at baseline, and after 12 and 24m of ERT in children aged 18y in FOS, a global database of patients with FD. Results: Of 257 children in FOS (120 boys, 137 girls), ERT data were available for: 49 boys, 26 girls at 12m; 31 boys, 21 girls at 24m. Diagnosis was delayed by 2y in both sexes. Onset of symptoms, diagnosis and treatment initiation occurred 2y later in girls than boys. Treatment for 24m reduced vomiting, fatigue, heat intolerance, abdominal pain, chronic pain and pain attacks. Renal function remained stable. Additional sign/symptom reductions included diarrhoea (boys), constipation, cold intolerance, tinnitus and microalbumin levels (girls). Results at 12m were similar. Cardiac structure was assessed by echocardiography in 12 boys and 9 girls (mean ages 13.2 and 14.8y, respectively) at baseline and 12m. Compared with a normal population of 2000 children, the mean z-score for left ventricular mass at baseline was 1.36 in girls (p0.01) and 0.73 (not significant; NS) in boys. After 12m of ERT the z-score was reduced in girls to 0.98 (NS) and was stable in boys (0.81; NS). Mean wall thickness z-scores decreased from 1.46 (p0.01 vs normal population) to 0.72 in girls (p0.05 vs baseline) and from 1.04 to 0.75 in boys (NS). Over 24m of ERT, 5 girls and 4 boys had reductions in cardiac dimensions (NS). Of the total cohort of treated children in FOS, 25 boys and 9 girls reported adverse events, the most common being mild, infusion-related reactions (n=50). Conclusions: ERT with agalsidase alfa for up to 24 months in children reduces or stabilizes the signs and symptoms of FD.

A new chromosomal translocation t(2q14;10p15.2) in a child with hypoparathyroidism. *L. TELVI[1], A. ROTHENBUHLER[2], J. GOGUSEV[3], M. MINZ[1], S. CHATAIGNIER[1], A. LINGLART[2], M. GARABEDIAN[2]* 1) Cytogenetics Laboratory, Hospital St Vincent de Paul, Paris, France; 2) Dept of Pediatric Endocrinology, Hospital St Vincent de Paul, Paris, France; 3) INSERM U567, Hospital Cochin, Paris, France.

Hypoparathyroidism (HPT) is an endocrine disorder in which hypocalcemia and hyperphosphatemia are the results of a deficiency of parathyroid hormone (PTH). We describe a case of idiopathic HPT in a 3 year-old girl showing a severe hypocalcemia (2.08 mmol/l) and a deficiency of the PTH (8 pg/ml). However, the clinical examination was normal including normal cardiac ultrasound either the immunological examinations with an IgA level at 1.04 g/l. During neonatal period, the patient had shown seizures and a low level of calcemia (1.4 mmol/l). The cytogenetics analysis using RHG banding showed a reciprocal translocation between chromosomes 2 and 10. FISH analysis confirmed the t(2q14;10p15.2) by using specific painting probes for chromosomes 2 and 10. We did not found deletion or duplication for the following genes : Tuple1(22q11),Shank3(22qter) and DGCR2(10p14). Otherwise, the DNA sequencing of calcium-sensing receptor gene (CASR) did not found any mutation. The diagnosis of idiopathic HPT was established and the patient was treated with calcitriol, which normalise the concentrations of calcemia and phosphatemia. The description of a new chromosomal translocation in a patient with HPT could lead to the location of susceptibility gene(s) involved in the pathogenesis of this disease. A candidate gene involved in the pathogenesis of HPT is underway by using array-CGH strategy and molecular analysis.

IN SILICO ANALYSIS OF PENDRIN. *E. Leonardi[1], S. Vanin[2], E. Orzan[3], A. Murgia[1], S. C. E. Tosatto[2]* 1) Department of Pediatrics, University of Padua, Padua, Italy; 2) Department of Biology University of Padua, Padua, Italy; 3) Pediatric Audiology Unit, Department of Otolaryngology and Otosurgery, University Hospital of Padua, Padua, Italy.

Mutations in SLC26A4 gene, which encode for pendrin, cause Pendred syndrome and hearing loss with enlarged vestibular acqueduct (EVA). The two disorders differ by the presence of thyroid defects. More than 150 SLC26A4 mutations have been reported but the genotype-phenotype correlation is not fully understood. We adopted an integrated approach for the study of pendrin combining available biological information, clinical data and bioinformatic results, to understand structure-function relationships and pathogenetic mechanisms. Family-based resources searches revealed that SLC26A4 contains three SLC26 family motifs: SLC26 sulfate transporter signature, sulfate transporter domain and STAS domain. Analysis of pendrin topology resulted in the prediction of 12 transmembrane domains. The program ZPRED predicts the second helix as a potential re-entrant region with a functional role in the anion selectivity. The identification of the GxxxG motifs in the last transmembrane helix, as a potential site of dimerization, provides structural support for the proposed model of dimeric quaternary structure of the SLC26 transporter. The 3D structure of the STAS domain, modeled with computational methods, was analyzed by structural comparison with similar folds to retrieve information on its possible role in the regulation of transport activity. A phylogenetic analysis was performed on the STAS domain sequence of the SLC26 transporter. We observed that the paralogs differ from each other by the length of the variable loop, which seems conserved in each member across species. This loop is suggested to function as an anion sensor and might be responsible for the conformational change in the STAS domain. The overall in silico characterization has lead to a structural model on which most mutations have been mapped. Together with a new hypothesis elucidating Pendrin structure-function relationships, we propose an explanation of the molecular effects of amino acid substitutions and their possible pathogenic role.

Clinical evaluation and molecular - genetic diagnosis of Wilson disease. *A. Krumina[1], J. Keiss[2], V. Sondore[2], G. Cernevska[3], A. Zarina[1], B. Lace[1]* 1) Dept Medical Biol & Genetics, Riga Stradins Univ, Riga, Latvia; 2) Infectology Center of Latvia, Riga, Latvia; 3) Children Clinical University Hospital, Riga, Latvia.

Wilson disease (WD) is an autosomal recessive disorder of copper metabolism caused by mutations in the gene *ATP7B*. As a consequence of enormous clinical variability of WD, the condition is commonly underdiagnosed. DNA analysis to identify defects in the *ATP7B* gene can provide unequivocal confirmation of WD in affected symptomatic or presymptomatic individuals. More than 300 mutations in the gene *ATP7B* causing WD have been reported. Among individuals of Northern European origin the most prevalent mutation is H1069Q. The data on correlation between WD patient genotypes and clinical presentation are controversial. Aims of the research were: 1) to perform mutation detection in seven exons of the gene *ATP7B* in the Latvian Wilsons disease patients; 2) to analyse the relationship between patients genotypes with mutation H1069Q and their clinical manifestation; 3) to analyse the predictive value of different clinical and biochemical data by comparing them with the results of DNA analysis. 40 patients with WD suggestive symptoms were included in the study. Laboratory confirmation of the clinical diagnosis included determination of serum copper, serum ceruloplasmin, liver function tests, 24-hour urinary copper excretion, and response to D-penicillamine. 157 unrelated healthy individuals were tested as controls for mutation H1069Q incidence analysis. Mutation H1069Q testing was performed by PCR Bi-PASA method. Seven exons of the gene *ATP7B* were sequenced. Five mutations (two previously described and three novel mutations) in the gene *ATP7B* were identified. The H1069Q mutation was present at 52.5% of the disease alleles. One individual among 157 healthy Latvians was found to be a mutation H1069Q carrier. Wide clinical variability was observed among individuals with the same *ATP7B* genotype. An algorithm for the diagnosis of WD, including testing for mutation H1069Q, is recommended for the populations where mutation H1069Q accounts for 50% of WD alleles or more.

An adult-onset autosomal dominant leukodystrophy linked to 5q23.2-q31.1 without duplication of the *LMNB1* gene. *A. Brussino[1], G. Vaula[2], C. Cagnoli[1], E. Panza[3], M. Seri[3], S. Leombruni[2], M. Bergui[2], G. B. Bradac[2], L. Pinessi[2], E. Di Gregorio[1], S. Scappaticci[4], S. Camanini[4], S. Cavalieri[1], E. Grosso[1], N. Migone[1], A. Brusco[1]* 1) Genetics Biology & Biochem, Univ Torino, Italy; 2) Neurosciences, A.O.U. S.Giovanni Battista, Torino; 3) Gynecological, Obstetric and Pediatric Sciences, Univ of Bologna, Italy; 4) Department of Biology and Medical Genetics, University of Pavia, Italy.

Adult-onset Autosomal Dominant LeukoDystrophy (ADLD, OMIM 169500) is a rare CNS demyelinating disease caused by duplication of the lamin B1 gene (*LMNB1*, 5q23). At present, five families, one recently identified by our group, are described with a homogenous phenotype. Other kindreds segregating an autosomal dominant form of leukodystrophy are reported, but their *LMNB1* gene status is at present unknown. We investigated the genetics of one such family in which affected members have a variant ADLD disease (vADLD). Patients become symptomatic in the 4th-5th decade, and in contrast with ADLD show mild involvement of the cerebellar white matter and no autonomic dysfunction at onset. An extensive search for *LMNB1*gene mutations was performed in this family using copy-number sensitive real-time PCR, coding region and cDNA direct sequencing, and Southern blot. No duplication/deletion and point-mutations were detected. A genome-wide scan identified two contiguous candidate regions in 5q23.2-q31.1: (1) between D5S2971-D5S2968 containing the Zinc finger 608 gene in which point mutations and genomic rearrangements were excluded by sequencing analysis and Southern blotting; and (2) between D5S804-D5S2115, a region comprising 67 transcripts, including *LMNB1*. Our preliminary results show the existence of a novel autosomal dominant adult-onset leukodystrophy linked to 5q23 and distinguishable from the ADLD phenotype both clinically (absence of dysautonomic initial symptoms) and genetically (absence of lamin B1 duplication). While our data tend to exclude *LMNB1* duplication as the cause of vADLD, we cannot rule out the possibility that *LMNB1* may harbor a mutation in an unknown regulatory region affecting mRNA expression or stability.

Quantitative MethylScreen DNA methylation analysis of the FXN gene. *S. Al-Mahdawi, R. Mouro Pinto, C. Sandi, M. A. Pook* Biosciences, Brunel University, Uxbridge, United Kingdom, School of Health and Social Care, Heinz Wolff building, Brunel University, Uxbridge, Middlesex, UB8 3PH, United Kingdom.

Friedreich ataxia (FRDA) is a neurodegenerative disorder caused by a homozygous GAA repeat expansion mutation within intron 1 of the FXN gene. The mutation causes reduced levels of the mitochondrial protein, frataxin, which is involved in iron-sulphur cluster and heme biosynthesis. Frataxin insufficiency leads to iron accumulation, oxidative stress and ultimately cell death. With the absence of effective treatment for this disorder, research in our laboratory has concentrated on the generation of an FRDA mouse model to investigate the effect of novel therapeutic agents. We have also established fibroblast and neuronal stem cell cultures derived from this model that can similarly be used to investigate novel therapies. With evidence that GAA repeat expansions produce a heterochromatin-mediated FXN gene silencing effect, epigenetic mechanisms, such as DNA methylation, have been investigated with a view to future epigenetic-based therapy. We have recently used bisulfite sequencing technology to assign differentially methylated CpG sites within the GAA upstream region of the FXN gene in human and mouse FRDA tissues. Although this technique is precise, it is also rather labour-intensive and time-consuming. Here we report the development of a MethylScreen technique as a more rapid approach to detecting quantitative DNA methylation changes in the FXN gene. This technique, which involves the digestion of DNA by methylation-sensitive and methylation-dependent restriction enzymes followed by quantitative PCR, has been validated by comparison with our previous bisulphite sequencing data. We further describe the use of this technique to analyse DNA methylation changes that are induced by epigenetic-based therapies within cultured cells and tissues from our FRDA mouse model.

MUTATIONAL ANALYSIS OF SLC26A4 AND FOXI1 IN INDIVIDUALS WITH HEARING LOSS AND INNER EAR MALFORMATIONS. *E. Orzan[1], E. Leonardi[2], M. Martella[2], C. Morando[2], A. Murgia[2]* 1) Pediatric Audiology Unit, Department of Otolaryngology and Otosurgery, University Hospital of Padua, Padua, Italy; 2) Department of Pediatrics, University of Padua, Padua, Italy.

Mutations in the SLC26A4 gene cause Pendred syndrome (PS) and hearing loss with inner ear malformations, mainly enlarged vestibular aqueduct (EVA) syndrome. Both disorders are recessive but many affected individuals show one or no SLC26A4 mutations. In a recent study EVA syndrome was found in a subject carrying a mutation of SLC26A4 in association with a mutation of FOXI1, gene encoding a transcriptional activator of SLC26A4. We have analyzed the SLC26A4 gene in a cohort of 29 unrelated subjects with age ranging from 3 to 43 years. All the selected individuals, only one subject with PS, presented prelingual sensorineural hearing loss often characterized by a progressive/fluctuating course. 14 had documented EVA, 1 had a Mondini dysplasia and 3 had other malformations. 17 different SLC26A4 variants were detected: 11 missense, 2 splice site and 1 frameshift mutation previously reported in other affected subjects, one known polymorphic variant and two new disease-causing mutations. Both the novel variants, c.600GA (p.Q200Q) and IVS9-1GT are believed to alter the splicing mechanisms. In 38% of the subjects, all but the PS case with EVA, at least one SLC26A4 mutation was present. Biallelic SLC26A4 mutations were found in 27,6% (11/29) of the tested subjects, while 10,3% (3/29) of them resulted to be heterozygote. To investigate other possible mechanisms or genetic causes of this condition in negative or heterozygote individuals we performed a gene dosage analysis on SLC26A4 and searched for mutations of the coding sequence of the FOXI1 gene. This analysis allowed detecting a single, putative disease-causing mutation of the coding sequence of the FOXI1 gene (p.161delN), in a subject with Mondini dysplasia, negative for the SLC26A4 analysis. Although signaling the likely presence of other genes involved in the phenotype, the data we report strengthen the importance of molecular analysis of SLC26A4 and FOXI1 in individuals with hearing loss and EVA syndrome.

***HIF1A* gene polymorphism association study in endometriosis and adenomyosis.** *C. Hu[1], W. Lin[2], M. Wu[5,7], J. Lee[6], E. Tsai[1,6], S. Juo[2,3,4]* 1) Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Department of Neurology, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Center of Excellence for Environmental Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan;; 5) Graduate Institute of Occupational Safety & Health, Kaohsiung Medical University, Kaohsiung, Taiwan; 6) Department of Obstetrics and Gynecology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 7) Department of Family Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Background: Endometriosis and adenomyosis are characterized by the presence of endometrial glands and stroma outside the uterine cavity. Hypoxia-inducible factor 1, alpha subunit (*HIF1A*) is a potent stimulant of angiogenesis potentially contributing to the pathogenesis of the two common gynecological disorders. The aim of this study sought to investigate whether the *HIF1A* gene polymorphism is associated with susceptibility to endometriosis and adenomyosis. Methods: We performed case-control studies. A total of eight SNPs were selected for genotyping including six common tSNPs and two functional SNPs. Logistic regression analyses were performed to evaluate the genetic effect with adjustment for age and parity. Results: This study recruited 185 patients with endometriosis, 162 patients with adenomyosis, and 380 controls. We found two significant associations between rs1951795 (intron 1) and rs2301113 (intron 10) for adenomyosis. For rs1951795, the results indicated that genotypes AA carried a higher risk than the reference CC genotype (adjust OR=3.57, P=0.006). For rs2301113, genotypes CC carried a higher risk than the reference AA genotype (adjust OR = 2.39, P=0.015). None of the candidate genes were related to endometriosis. Conclusions: The *HIF1A* gene significantly influences the risk of adenomyosis but not endometriosis.

Career Development in Public Health Genomics. *E. Balkite[1,2], C. Lieber[2], R. Grob[2]* 1) ABQ Associates, Inc, Durham, NC; 2) School of Graduate Studies, Sarah Lawrence College, Bronxville, NY.

Healthcare professionals with education and experience in both public health and genomics now have increasingly diverse career opportunities. Purpose: Yet, how does one create positions in a new field or integrate genomics into a current professional role? Many healthcare professionals are unsure of how to initiate this professional challenge. Methods: To meet this need, the Public Health Genomics (PHG) Certificate Program in the Graduate School of Sarah Lawrence College, Bronxville, NY established a model for career development in Public Health Genomics and made it integral to the curriculum of the certificate program. The PHG curriculum in career development is led by an experienced healthcare professional who is also a Career Development Specialist. The curriculum consists of five facets (1) identification of job topology with a searchable database of Public Health Genomics job categories (2) education in job search skills (3) networking with professional role models and mentors, (4) exercises in professional growth and development, and (5) individual career counseling, virtually and in person. Results: The curriculum has varied success with healthcare professionals depending on their professional roles and career status. Professionals whose goal was to integrate genomics into a current role found (3), (4), and (5) most valuable in meeting their needs. Others, seeking to establish a new role for themselves or a new position evaluated (1), (2), and (5) as most valuable. Conclusions: Healthcare professionals benefit from a flexible framework in career development that allows them to customize the components of the framework to meet their needs. Customization leads to the creation of new fields in Public Health Genomics as well as the integration of genomics into current professional roles.

Unbiased estimation of odds ratios combining genomewide association scans with replication studies. *F. Dudbridge, J. Bowden* Boistatistics Unit, Medical Research Council, Cambridge, United Kingdom.

Odds ratios or other effect sizes estimated from genome scans are upwardly biased, because only the top-ranking associations are reported, and moreover only if they reach a defined level of significance. No unbiased estimate exists based on data selected in this fashion, but replication studies are routinely performed that allow unbiased estimation of the effect sizes. Estimation based on replication data alone is inefficient in the sense that the initial scan could, in principle, contribute information on the effect size. We propose an unbiased estimator combining information from both the initial scan and the replication study, which is more efficient than that based just on the replication. Specifically, we adjust the standard combined estimate to allow for selection by rank and significance in the initial scan. Our approach explicitly allows for multiple associations arising from a scan, and is robust to mis-specification of a significance threshold. We require replication data to be available but argue that, in most applications, estimates of effect sizes are only useful when associations have been replicated. We illustrate our approach on some recently completed scans and explore its efficiency by simulation.

A novel mutation of EXT1 gene in a Korean family with multiple exostoses. *S. Shim[1], S. Sung[1], J. Park[1], D. Cha[1, 2], T. Yoon[1], D. Choi[1]* 1) Genetic Lab Fertil Center, CHA Genaral Hospital, College Med Pochon CHA Univ, Seoul, Korea; 2) Dep. of Ob and Gyn, CHA General Hospital, Pochon CHA University, Seoul, Korea.

A 35-year-old female patient diagnosed clinically as multiple exostosis visited the hospital for infertility evaluation and treatment. She had an operation in pelvis, humerus, tibia and femur in 1993. Extended pedigree analysis showed three out of 4 her siblings and several cousins have suffered from the same disease with a typical autosomal dominant pattern of inheritance. So she wanted a genetic test for her disease before having a child. For mutation analysis, DNAs were extracted from the patient and her brother. All exons and exon-intron boundaries of EXT1 and EXT2 gene were amplified by polymerase chain reactions. The PCR products were directly sequenced and analyzed by ABI genetic analyzer. A single base pair deletion [(2236_2241)delC] in the exon 6 of EXT1 gene was detected in both patient and her brother. Generation of a premature stop codon resulting from frameshift of codons might be a causative of the disease. According to the human genome mutation data base (HGMD), the mutation detected is not previously documented.

Natural history of Machado-Joseph disease: a 10 years observational study described through a Markovian method. *L. Jardim[1, 3], C. Kieling[4], A. Vigo[2], S. Camey[2]* 1) Department of Internal Medicine, Universidade Federal do Rio Grande do Sul, Brazil; 2) Department of Statistics, Universidade Federal do Rio Grande do Sul, Brazil; 3) Medical Genetics Service, Hosp de Clínicas, Porto Alegre, Brazil; 4) Psychiatry Service, Hosp de Clínicas, Porto Alegre, Brazil.

Machado-Joseph Disease (SCA3) is a rare autosomal dominant disorder, affecting 3:100.000 individuals in our region. A progressive motor disability supervenes, with a survival of 21 years after the disease onset. Natural history (NH) studies are hard to be done, since patients enter the study with variable disease durations, and are followed-up at irregular intervals. AIMS: show how the long-term progression of a disease, using all the available data, can be done through a Markovian method, and, by using it, describe the progression of gait ataxia (GA), from a SCA3 long-term cohort. METHODS: SCA3 patients were recruited from 1998 to 2005, and were invited to annual neurological follow-ups up to 2007. GA was described through both a MSG (Zilber et al, 98) and a markovian matrix and graph, called Mean Trajectory Graph (MTG). RESULTS: 156 patients were included: at baseline, age and disease duration were of 40.5 12.6 and 7.7 5.8 years (y); age at onset was of 32.8 10.6. There were 28 losses, 27 deaths and 315 neurological evaluations. Patients were seen during 5 2.4 years, with intervals between follow-ups of 2.5 1.5 years. With the MSG and MTG, GA progressed to stages 1, 2, 3 and 4 in, respectively, 2, 8.5, 19 and 25.5 (MSG) or 21 (MTG) years of disease duration. MSG was unsmooth, showing several unlikely ups and downs partially corrected by a posteriori adjustments. MTG produced a continuous curve without any aid. Markovian matrixes of two subgroups, stratified by their CAGn, showed no differences in GA progression ($^2(10)= 9.14$; $p=0.519$). CONCLUSION: The markovian method described the NH of gait ataxia without any a posteriori adjustment of data, and allowed statistical comparisons between subgroups. Using it, we verified that the CAGn did not interfere with this aspect of NH. We believe that Markovian method will probably be useful in future clinical trials in this disease.

***TBX22* promoter haplotypes influence gene expression and are associated with the prevalence of X-linked cleft palate.** *P. Stanier, G. E. Moore, E. Pauws* Institute of Child Health, University College London, London, United Kingdom.

Cleft palate (CP) is a common birth defect that can occur either as an isolated defect or as part of a syndrome. Whilst there is strong evidence for a genetic basis, environmental factors can influence risk, often making a molecular diagnosis difficult. It has proven easier to identify genetic defects in CP patients with additional recognisable features such as ankyloglossia, which is found in about 80% of X-linked CP (CPX) individuals carrying a *TBX22* mutation. In previous studies we have identified apparently classic CPX families with ankyloglossia but no identifiable mutation. Here we report a new investigation of the *TBX22* promoter region and a previously unsequenced 5 non-coding exon for potentially causative sequence changes in this cohort. Unique sequence variants were not present, although, 5 SNPs and one variable dinucleotide repeat were identified. We investigated the frequency of these polymorphisms in CP only (CPO=80), CP & ankyloglossia (CPA=53) and control (n=296) cohorts. We found significant associations for rs6523677 (OR=2.7, $p<0.01$) and rs41307258 (OR=18.3, $p<0.001$) between CPA patients and controls but not between CPO patients and controls. The other variants showed a similar trend but did not reach significance. The polymorphisms were present as three distinct haplotypes. Haplotype 3 was strongly associated with the CPA group (OR=10.1, $p<0.001$) but not CPO or controls. To investigate the functional significance of the different promoter haplotypes, luciferase reporter constructs for each were tested in transient transfection assays. A statistically significant ($p<0.001$) decrease in promoter activity (approximating empty vector) was found for haplotype 3. We therefore report a strong link between the regulation of *TBX22* gene expression and a pathogenic role for reduced *TBX22* transcript levels, potentially explaining many idiopathic cases with CPX like features. As expected, a proportion of the CPO patients also share the risk haplotype, but this was not sufficient to reach significance. This study therefore, highlights the value of ankyloglossia as a predictive diagnostic feature in X-linked cleft palate patients.

Long Term Imapact of Genetic Testing for Deafness: Phenotypic v/s Genotypic Marital Selection. *A. Pandya[1], K. S. Arnos[2], K. Withrow[1], V. Norris[2], S. H. Blanton[3], W. E. Nance[1]* 1) Dept Human & Molecular Genetics, VCU, VA; 2) Gallaudet University, Washington DC; 3) University of Miami, FL.

Hearing loss (HL) is a common neuro-sensory deficit affecting nearly 3/1000 children. The presence of relaxed selection and intense assortative mating among the deaf, have increased the frequency of the commonest form of recessive deafness in the population (Nance and Kearsey, 2004). In the past, assortative mating has been based on phenotype. However, with the advent of molecular testing, the potential exists for replacing phenotypic with genotypic assortative mating. To assess the impact of genetic testing on spouse selection, we compared 303 deaf probands married before counseling and testing for the connexin (Cx) gene, with 413 unmarried students who are followed longitudinally until they select a partner to determine if knowledge about their own Cx status has any impact on their choice of a partner. We present the comparison of frequency of Cx deafness, phenotypic assortative mating and genotypic assortative mating in 303 married probands with a small number of students (N=49) who have married after genetic testing and counseling. The frequency of phenotypic assortative mating was slightly but not significantly higher in students who married after being tested & counseled. Similarly, among students who have married, the proportion of Cx (+) probands with Cx (+) spouses was higher, even though the frequency of connexin deafness was slightly higher in the probands married before 1997. To test for genotypic assortative mating we compared the observed to expected frequencies of Cx (+) by Cx(+) matings in each group assuming random mating, and given the Cx frequency in each group. Interestingly, an excess of genotypic assortative mating was observed in both groups, but did not reach significance in the student group. A 30% excess in observed frequency of genotypic assortative mating compared to the expected in probands married before Cx was discovered must reflect the results of indirect genotypic assortative mating, in addition to the trend towards direct genotypic assortative mating in the students.

Molecular Analysis of Candidate Genes in Keratoconus Patients from the European Population. *DP. Dash[1], S. George[2], AE. Hughes[3], G. Silvestri[2], J. Jackson[2], D. Frazer[2], E. Heon[4], CE. Willoughby[1]* 1) Centre for Vision Sciences, Queen's University Belfast, UK; 2) Royal Victoria Hospital, UK; 3) Dept. of Medical Genetics, Queen's University Belfast, UK; 4) Dept. of Ophthalmology & Vision Sciences, Hospital for Sick Children, University of Toronto, Canada.

Purposes: Keratoconus (KC; MIM#148300) affects ~1/2000 people worldwide and is a common indication for corneal transplantation. At least 9 chromosomal loci have been reported with mutations detected in visual system homeobox 1 (VSX1; MIM#605020) and superoxide dismutase 1 (SOD1; MIM#147450). There are no studies on SOD1 screening in KC cohort except one reported potential mutation IVS2+50 DEL 7. The purpose of the study was to comprehensively screen SOD1 and VSX1 (including two newly identified exons) in keratoconus patients of European ethnicity. Methods: The patient cohort consisted of 66 unrelated KC patients (40 sporadic KC patients and 26 probands with familial KC) of European ethnicity. Mutational analysis of SOD1 and VSX1 including two newly identified exons (6 and 7) was performed by PCR based direct sequencing methods. Results: In total 12 VSX1 sequence variants were detected in KC patients of which c.432C>G (p.D144E), c.479G>A (p.G160D), c.789C>T (p.S263S) were not seen in 200 control chromosomes. The change p.G160D was seen in two sporadic KC patients. Segregation was not detected for p.D144E which represents a polymorphism. Although predicted to alter VSX1 splicing p.S263S had no effect on transcript processing. Two affected members in a KC family showed a novel silent mutation c.180T>C (S60S) in SOD1 gene which was absent in 200 control chromosomes. Bioinformatics testing predicts this sequence variant could be a potential splicing mutation and further RNA studies are ongoing. We did not find the previously reported deletion in SOD1 gene or any other pathological variants. Conclusions: This is the first study to report the complete screening of SOD1 in sporadic and familial keratoconus. The novel silent mutation (S60S) in SOD1 gene in a keratoconus family requires further characterisation at the RNA level. Mutations in VSX1 and SOD1 play a minor role in the pathogenesis of KC in the European population.

Therapeutic response after two years of Galsulfase enzyme replacement therapy (ERT) in five adult patients with Maroteaux-Lamy Syndrome. *C. Lampe, E. Miebach, L. Arash, E. Mengel, M. Beck* Children`s Hospital, University of Mainz, MAINZ, Germany.

Aims: 2006 Galsulfase (Naglazyme) was approved by the FDA and EMEA as enzyme replacement therapy for patients with mucopolysaccharidosis VI (MPS VI). The objective of this study was to proof safety and efficacy of Galsulfase treatment for adult MPS VI patients. **Methods/Patients:** We studied 5 adult MPS VI patients with attenuated presentation, age 27 to 34 years (median: 32), 2 male and 3 female. Before starting enzyme replacement therapy (ERT), all patients underwent an extensive baseline evaluation, they were re-evaluated after 1 and 2 years of treatment. To obtain consensus on contemporary therapeutic aims we used two goals of treatment to confirm therapeutic response: 1. 6 minute-walk test: improvement of at least 54 mtrs. 2. VC-in (inspiratory vital capacity): Improvement of at least 5% above the baseline value. **Results:** Baseline results: Height 135 to 160 cm (median 152), weight 42 to 70 kg (median: 56). Organomegaly in 4/5. Hearing impairment in 0/5, visual impairment and corneal clouding in 3/5. VC-in 42,2% to 85,4% (median 70,1%), thereof 1 patient had a normal lung function. Abnormalities of cardiac valves in 5/5, no cardiomyopathy. Pathological ECG in 2/5 (LVH). Reduced passive shoulder flexion in 4/5. Walking distance evaluated by 6 minute-walk-test varied between 210 and 492 mtrs (median 390). Stenosis of cervical spine in medical history in 2/5. Audiometric, ophthalmological, and cardiologic results showed no changes within two years of treatment. Organomegaly resolved in 3/4. Orthopaedic results did not improve. After 1 year treatment 3/5 achieved an improvement of 6 minute-walk-test. Our 4 patients with abnormal VC-in reached the therapeutic goal. Consequentially, 4/5 patients showed therapeutic response under ERT. In summary, a number of measures of clinical problems were stable or improved over the 2-year period, though there are some aspects of the disease that may be irreversible or difficult to treat, such as joint stiffness and bone disease. ERT was tolerated well, only 1 mild infusion-associated reaction with urticaria was observed.

Role of GABRG2 gene polymorphism in seizure reoccurrence. *S. Ponnala[1,2], J. R. Chaudhari[3], M. A. Jaleel[3], B. Dilnawaz[3], K. P. Rao[1], Q. Hasan[2]* 1) Dept of Genetics, Osmania University, Hyderabad - 500 007, Andhra Pradesh, India; 2) Dept of Cytogenetics and Molecular Medicine, Kamineni Hospitals, L B Nagar, Hyderabad - 500 068, Andhra Pradesh, India; 3) Dept of Neurology and Neurosuegery, Kamineni Hospitals, L B Nagar, Hyderabad - 500 068, Andhra Pradesh, India.

Gamma aminobutyric acid receptor (GABR) are anion-selective ligand-gated channels and occur in 30-40% of all synapses and use Gamma aminobutyric acid (GABA) as their transmitter. Disruption of GABAergic neurotransmission mediated by GABA has been implicated in epilepsy and the nature of the mutant channel may modulate the response to a given treatment. Major anti epileptic drugs used clinically act as GABAergic neurotransmission enhancers. The present study was conducted to evaluate the GABRG2 C588T gene polymorphism in generalized seizure (GS) and febrile seizure (FS) patients to assess whether it confers any susceptibility to seizures in a cohort of patients. 127 cases of seizures, which included 86 GS and 41 FS patients, who were analyzed in this study for GABRG2 C588T gene polymorphism using PCR RFLP. The allele distribution was statistically significant with T allele being associated with GS in our population (OR=2.0508 (95% CI= 1.0205 to 4.1234); X2 $p<0.05$). When the allele frequencies of GS and FS were combined and compared with controls, it showed significant association of T allele with seizures (OR=2.19 (95% CI=1.02 to 4.68); X2 $p<0.05$). In the present study, TT genotype carriers were high in recurrent seizure group of GS compared to well control GS. Compared to GS, in FS, CT genotype carriers were high in recurrent seizure group. Our data shows GABRG2 588T allele carriers have 2 fold increased risk of developing seizures compared to others, TT and CT genotype carriers of seizure reoccurrence group of GS and FS respectively, are at a higher risk of developing recurrent seizure. As yet, there are no studies reporting the role of GABRG2 C588T gene polymorphism in association with seizure reoccurrence.

Whole-Genome Linkage Analysis of High Grade Myopia in a U.S. Asian Family Dataset. *K. N. Tran-Viet[1], A. Bulusu[1], R. Metlapally[1,2], Y. J. Li[1], T. L. Young[1,2]* 1) Duke Ctr Human Genetics, Duke Medical Ctr, Durham, NC; 2) Duke Eye Center, Durham, NC.

Purpose: Myopia or nearsightedness is caused by excessive axial elongation of the globe. High-grade myopia can predispose individuals to premature cataracts, retinal detachment, and glaucoma. Myopia is highly prevalent in Asian countries, and is considered a serious public health issue in these populations. This study focused on U.S. Asian populations and used a whole-genome linkage panel to confirm existing or map novel high-grade myopia loci. **Methods:** A cohort of 10 U.S. families of Asian descent participated in the study with at least two affected (spherical refractive error of -5.00 diopters (D)) siblings per family. Subject refractive errors of -5.00 D were defined as unaffected. Whole genome single nucleotide polymorphism (SNP) genotyping was performed using the Illumina Linkage IVb Marker Panel (6008 SNPs). Genotype data were checked for Mendelian inconsistencies, and linkage analysis was conducted using high myopia as a qualitative trait. Both two-point and multipoint linkage analyses were conducted using the FASTLINK and MERLIN programs, respectively. **Results:** Parametric multipoint analysis demonstrated an HLOD score > 1.00 on chromosomes 1p, 2p, 5q, 10q, 12q, and 22q with corresponding peak HLOD scores of 1.533, 1.424, 1.344, 1.263, 1.553, and 1.269, respectively. Two-point linkage analyses revealed 32 SNPs with HLOD > 1.3. The highest two-point HLOD scores were recorded for SNPs on chromosomes 5q (rs307195, 1.439) and 12q (rs1163016, 1.434). While loci on chromosomes 1, 2, and 10 are suggestive novel linkage regions, loci on chromosomes 5q (Asian), 12q (Caucasian), and 22q (Ashkenazi Jews) have been previously reported. **Conclusion:** Our results show novel suggestive linkage peaks on chromosomes 1p21.20-1p13.2 (14.9 centimorgan (cM)), 2p13.3-2q12.3 (25cM), and 10q25.1-10q26.13 (27.4cM). Previous reported loci on chromosomes 5, 12, and 22 were replicated. These findings further substantiate genetic heterogeneity for myopia predisposition.

Telomeric Unbalanced Chromosomal Translocation t(9,14)(q34, qter)with Progressive Microcephaly, White Matter Lesions and Virschow-Robin Spaces Dilatation. *L. Perrin[1], A. Aboura[2], E. Pipiras[3], C. Baumann[1], C. Dupont[2], AC. Tabet[2], M. Tardieu[4], A. Verloes[1], B. Benzacken[2], M. Gérard-Blanluet[1]* 1) Clinical Genetics, APHP Robert Debré Hospital, Paris, France; 2) Cytogenetics, APHP Robert Debré Hospital, Paris, France; 3) Cytogenetics, APHP Jean Verdier Hospital, Bondy, France; 4) Neuropediatrics, APHP, Kremlin Bicêtre Hospital, Le Kremlin-Bicêtre, France.

The Virchow Robin Spaces (VRS) are invaginations of the subarachnoid spaces which contain spinal fluid that accompany small vessels as they perforate the surface of the brain. Dilated Virchow-Robin spaces are more frequently found in mental retardation (Rollins et al., 1993; Sotos-Ares et al., 2003). We were not able to any find reports of chromosomic abnormality and dilated VRS. We report the case of a child who presents first with neurological features (progressive microcephaly, delayed milestones, cystic Virchow Robin spaces and white matter lesions) in whom we secondary discovered an unbalanced chromosomal anomaly with deletion 9q34 and trisomy 14qter by telomeric screening. The child had neonatal hypotonia and mental retardation. The walk was achieved after 3 years and the language was severely delayed. Minor malformations were present: cryptorchidia, unilateral megauretere and severe gastro-oesophageal reflux. The dysmorphia was not obvious in early age, but was more characteristic of 9q34 microdeletion later on : flat midface, anteversed nares, tendancy to tongue protuding and prognathism. In this patient, the additional trisomy 14qter does not seem to alter the 9qter deletion phenotype. Unusual neurological presentations of 9q34 deletion have already been reported, periventricular leukomalacia and thin corpus callosum (Stewart et al., 2004; Stewart and Kleefstra, 2007), generalized atrophy with marked deep white matter changes (Dawson et al., 2002). We add a new neurological presentation of 9q34 deletion, with progressive microcephaly, cystic Virchow Robin spaces and severe leukomalacia. This observation reminds us that periventricular leukomalacia can be seen in chromosomal anomalies.

Effect of enzyme replacement therapy on gastrointestinal symptoms in children with Fabry disease: results from FOS - the Fabry Outcome Survey. *R. Parini[1], M. Beck[2], R. Hartung[2], G. Kalkum[2], G. Pintos-Morell[3], U. Ramaswami[4] on behalf of the FOS investigators* 1) Metabolic Diseases Unit, San Gerardo Hosp, Monza, Italy; 2) University Childrens Hospital, Mainz, Germany; 3) University Hospital Germans Trias i Pujol, Badalona, Spain; 4) Addenbrookes University Teaching Hospital, Cambridge, UK.

Background: Gastrointestinal (GI) symptoms are an early and common manifestation of Fabry disease, a progressive, X-linked lysosomal storage disorder that leads to major organ failure and premature death. Currently, there are few long-term data on the effect of enzyme replacement therapy (ERT) on GI symptoms in children. Methods: GI symptoms were assessed in children aged 18 years at entry into the Fabry Outcome Survey (FOS), a large database of patients with Fabry disease. For each symptom, the same cohort of children was evaluated at baseline and after 24 months of ERT with agalsidase alfa (Replagal; Shire HGT). Results: In total, 38 children (24 boys, 14 girls) from 8 countries in FOS were assessed. Mean age (range) at onset of symptoms was 6.9 (1-13) years for boys and 7.6 (2-17) years for girls while mean age (range) at start of ERT was 12.1 (3-18) years for boys and 14.7 (4-18) years for girls. At baseline, the most commonly reported symptom was abdominal pain (73%; 19 of 26 children), followed by diarrhoea (35%; 9 of 26 children), nausea (31%; 8 of 26 children), constipation (28%; 7 of 25 children) and vomiting (23%; 6 of 26 children). After 24 months of ERT, prevalence was markedly reduced compared with baseline for abdominal pain (54% vs 73%, respectively) and vomiting (12% vs 23%, respectively). The prevalence of nausea also decreased from 31% at baseline to 27% after 24 months of ERT. Conclusions: ERT with agalsidase alfa has previously been shown to be beneficial in stabilizing the major manifestations of Fabry disease in adults. The present study confirms that GI symptoms are an early manifestation of the condition, with abdominal pain being the most commonly reported symptom in children. However, these symptoms, which have a major impact on quality of life in children, are reduced or stabilized by ERT.

Association of PDE4D with Asthma. *B. E. Himes[1,2,3,4], A. J. Murphy[2], B. Klanderman[2], R. Lazarus[2], J. Lasky-Su[2], M. F. Ramoni[1,3,4], S. T. Weiss[2,4]* 1) Harvard-MIT Division of Health Sciences and Technology, Harvard Medical School, Boston, MA; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 3) Children's Hospital Informatics Program, Boston, MA; 4) Harvard Partners Center for Genetics and Genomics, Boston, MA.

Asthma is a common inflammatory airway disease with well-established heritability, affecting over 300 million people around the world. More than 100 genes have been individually associated with asthma or a related phenotype. We genotyped over 500,000 single nucleotide polymorphisms (SNPs) in DNA samples from 359 asthma cases and compared them to genotypes from 846 controls. Cases were part of the Childhood Asthma Management Program (CAMP), a clinical trial of asthma treatment in children. Controls were from the Illumina ICONdb public resource. Only SNPs that passed stringent quality-control filters were used for association analysis (n=516,617). Cases and controls, who were all reported to be Caucasian, were matched using genomic ancestry matching (GEM) to reduce population stratification. Association between asthma and each SNP was measured using the Cochran-Armitage trend test as implemented in Plink. The region of strongest association was in and near the phosphodiesterase 4D (PDE4D) gene in chromosome 5q12. The top SNP in this region had an odds ratio of 0.58 (p-value of 1.5E-07), and nine additional linked SNPs in this region had p-values less than 0.001. These case-control analysis findings were supported by family-based association tests using 387 CAMP cases and their parents. Six of the 10 SNPs that were significant in the case-control analysis had additive model FBAT p-values less than 0.05. Despite the limited number of subjects, two lines of evidence suggest that further studies of the potential role of PDE4D in asthma are warranted.

Mutant heat shock protein HSPB8 induces aggregation and a pro-apoptotic phenotype in distal motor neuropathy. *J. Irobi-Devolder[1], J. Krishnan[2], LC. Almeida-Souza[1], I. Dierick[1], C. Ceuterick-de Groote[3], L. Van Den Bosch[2], JP. Timmermans[4], W. Robberecht[2], P. De Jonghe[5,6], S. Janssens[1], V. Timmerman[1]* 1) Peripheral Neuropathy Group, Molecular Genetics Department, VIB, University of Antwerp, Universiteitsplein 1 B-2610 Antwerpen, Belgium; 2) Laboratory of Neurobiology and Experimental Neurology, University of Leuven; 3) Laboratory of Ultrastructural Neuropathology, Institute Born-Bunge, University of Antwerp; 4) Laboratory of Cell Biology and Histology, Department of Veterinary Sciences, University of Antwerp; 5) Neurogenetics Groups, Department of Molecular Genetics, VIB; Neurogenetics Laboratory, Institute Born-Bunge, University of Antwerp; 6) Division of Neurology, University Hospital of Antwerp, Antwerpen, Belgium.

Missense mutations in the small heat shock protein HSPB8 cause distal hereditary motor neuropathy (distal HMN), a motor disorder of the peripheral nerve resulting in severe atrophy and wasting of distal limb muscles. We previously demonstrated that distal HMN mutations target a conserved hot spot residue in the HSPB8 protein and promote formation of aggregates. We now show evidence of axonal degeneration in patients' skin and nerve biopsy. In patient fibroblasts we found multi-foci aggregation of mutant HSPB8 precipitating into aggresomes upon thermal stress. Rat motor neurons and glial cells transfected with mutant constructs show aggregates and degeneration of neurites. Immunostaining using cell death markers demonstrate that non-neuronal cells appear morphologically normal compared to motor neurons. Our findings also demonstrate that mutant HSPB8 induces subtle cell death, which appears to be less dramatic for dividing cells than for postmitotic neurons. Accumulation of mutant HSPB8 could hamper axonal transport and the overall survival of peripheral neurons.

Identification of STRA6 and SKI Mutations and Sequence Variants in Patients with Anophthalmia and Microphthalmia. *T. R. White[1], T. Lu[1], J. Zhou[1], T. Wang[1], K. N. Tran-Viet[1], R. Metlapally[1], T. L. Young[1,2]* 1) Duke Ctr Human Genetics, Duke Medical Ctr, Durham, NC; 2) Duke University Eye Center, Durham, NC.

Purpose: Anophthalmia and microphthalmia (A/M) are rare congenital ocular malformations presenting with absence of eye structure or abnormally small eyes. A/M can be isolated or syndromic. The genes Stimulated by retinoic acid gene 6 (STRA6) and Sloan-Kettering viral oncogene homolog (SKI) are involved in the retinoic acid pathway, and are implicated with A/M in human and animal studies. The retinoic acid pathway is vital to normal eye development and growth. This study explores the association of these genes in a cohort of subjects with A/M. **Methods:** STRA6 and SKI were screened for sequence variants by direct sequencing of genomic DNA samples from 18 patient subjects with A/M. Four external controls were also screened. Coding regions, intron-exon boundaries, and untranslated exons of the genes screened were sequenced by standard techniques. Derived DNA sequences were compared to known reference sequences from public genomic databases. **Results:** For STRA6, a novel coding non-synonymous single nucleotide polymorphism (SNP) was found in one patient, which results in an amino acid change from glycine to glutamic acid in residue 208. One novel nonsense mutation was found in the same patient. These SNPs were not detected in 89 control DNA samples. For SKI, a known coding non-synonymous SNP (rs28384811) was found in 3 patients, which results in an amino acid change from alanine to glycine in residue 62. However, this SNP was also found in 11/89 controls screened. Four novel coding-synonymous SNPs were observed in the SKI gene. **Conclusions:** The STRA6 mutations reported in this study could play a role in the pathogenesis of A/M development, potentially via the retinoic acid pathway. We can attribute 4% A/M incidence in this cohort to these mutations. Although no SKI mutations were found in this cohort, SKI should not be ruled out as a candidate gene for A/M due to the small cohort size.

Gorlin Syndrome: A substantial proportion of previously missing mutations are large PTCH deletions. *S. Benhamed, S. J. Bale* GeneDx, Gaithersburg, MD.

Gorlin Syndrome (GS), also known as basal cell nevus syndrome, is a rare, autosomal dominant multi-system disorder characterized by large numbers of basal cell carcinomas, keratocysts of the jaw, palmar and plantar pits, typical facial features, and other malformations. Mutations in PTCH cause the disorder, with those leading to premature termination of protein translation strongly predominating. Gene rearrangement, presumably resulting in deletion or disruption of PTCH, has been reported in a few patients. Sequencing of the PTCH gene has been the standard method for mutation identification, with sensitivity found to be no higher than 60% in most studies of patients with a diagnosis of GS. We report results of a systematic search for whole or partial PTCH gene deletion in patients referred to a clinical diagnostic lab with suspected Gorlin Syndrome where direct sequencing failed to detect either a pathogenic mutation or any heterozygous positions. We used multiplex ligation-dependent probe amplification (MLPA) to screen for whole gene and single/multi exon deletion in 51 patients. Of these, 13 were found to be deleted for the entire PTCH gene. In addition, one patient had partial gene deletion involving exons 3 to 24. Deletions were confirmed by real-time quantitative PCR or by oligoarray CGH. Two patients were analyzed by array and each showed a large deletion (4.2Mb and 2.7Mb, respectively) that did not appear to result from rearrangement between segmental duplication loci. In each case, the deleted region included the PTCH gene and other genes involved in recessive disorders (e.g. FANCC). These findings confirm that screening by MLPA or arrayCGH is expected to identify at least an additional 28% patients with GS previously missed by sequence analysis. Oligonucleotide arrayCGH analysis using an array with appropriate probe placement should be recommended in patients meeting criteria for GS, but where sequence analysis fails to identify the causative mutation.

Genotype-Phenotype correlations in Scottish Lonq QT syndrome families. *J. Dean[1], C. Brown[1], D. Walker[1], K. Kelly[1], C. Clark[1], P. Broadhurst[2], A. Choy[3], I. Findlay[4], D. Goudie[5], J. Grieve[1], N. Grubb[6], W. Lam[7], V. Murday[8], M. Porteous[7], T. Pringle[3]* 1) Dept Medical Genetics, Argyll House, Aberdeen, UK; 2) Dept Cardiology, Aberdeen Royal Infirmary, Aberdeen, UK; 3) Dept Cardiology, Ninewells Hospital, Dundee, UK; 4) Dept Cardiology, Royal Alexandra Hospital, Paisley, UK; 5) Dept Medical Genetics, Ninewells Hospital, Dundee, UK; 6) Dept Cardiology, Royal Infirmary of Edinburgh, Edinburgh, UK; 7) Dept Medical Genetics, Western General Hospital, Edinburgh, UK; 8) Dept Medical Genetics, Yorkhill Hospital, Glasgow, UK.

We present genotype and phenotype information for 89 Scottish probands with confirmed or suspected long QT syndrome presenting with presumed arrhythmia or sudden cardiac death without deafness. The Familial Arrhythmia Network Scotland, a new organisation of cardiologists, geneticists and pathologists caring for such patients and their families undertakes clinical assessments in each region. DNA samples are analysed in Aberdeen, where initial genotyping involves screening of KCNQ1 exons 3,5,6,7,8,12,13,15, KCNH2 exons 2,6,7,9,10 and SCN5A exons 23-28, which account for 67% of reported Long QT mutations. Of 89 probands, 44 were excluded from analysis because genotyping was incomplete on the cut-off date 30th April 2008. Of 45 whose initial genetic screening was complete, 25 (55.6%) had mutations, including 2 compound heterozygotes and 1 homozygote. There were 17 KCNQ1 and 10 KCNH2 mutations. Phenotype data (QTc, T wave morphology, symptoms, precipitants and age at onset of first event) were analysed for each proband with a mutation. Information on relatives sharing the same mutation was sought to assess further genotype-phenotype correlations. In heterozygous relatives, fewer symptoms were reported and the corrected QT interval was normal in 6/28 (21%). Certain precipitants of arrhythmia (cold water, noise, sleep) are reported to be associated with mutation in specific genes. This correlation was not universal in our cohort. Our data suggest that genotype cannot be reliably predicted from phenotype, and the occurrence of compound heterozygotes necessitates screening of all three genes in every case.

Genetic susceptibility to invasive pneumococcal disease (IPD). *L. Dumitrescu[1], D. Crawford[1], S. Zimmer[2], R. Lynfield[3], N. Messonnier[4], C. Whitney[4], J. McNicholl[4], J. Lingappa[5]* 1) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Department of Medicine, Division of Infectious Disease, Emory Univ, Atlanta, GA; 3) Emerging Infections Unit, Minnesota Department of Health, St. Paul, MN; 4) Centers for Disease Control and Prevention, Atlanta, GA; 5) Department of Medicine, University of Washington, Seattle, WA.

Invasive pneumococcal disease (IPD) is a leading cause of meningitis, pneumonia and blood-stream infection in children and the elderly. A combination of host genetic, pathogen and environmental factors likely determines host susceptibility. We used population-based Active Bacterial Core Surveillance in Minnesota to identify IPD cases in children 5 years of age, occurring between 1997-2000. The de-identified newborn blood spots of 367 (82%) IPD cases and 734 anonymous age, race and hospital of birth-matched controls were used. DNA extracted from 1,101 stored blood spots was whole genome amplified and 967 usable DNA samples (330 cases) were genotyped for 384 tagSNPs in candidate genes. Half the cases were female (52%) and the majority of cases were either European-American (EA; 73%) or African-American (AA; 17%). Population stratification was evaluated using STRUCTURE prior to testing for allelic association; the final stratified cohort consisted of 179/334 and 53/100 EA and AA cases/controls, respectively. Among EAs, one tagSNP (IL12B intronic rs919766) was significantly associated with IPD at p0.01 (OR=1.9; 95% CI:1.2-3.0). Among AAs, two tagSNPs (3' flanking PTAFR rs905907 and 5' flanking SFTPD rs12219080) were associated with IPD at p0.005 (OR=2.6; 95% CI:1.4-4.9 and OR=0.3; 95% CI:0.1-0.7, respectively). rs919766 and rs905907 are in strong linkage disequilibrium (LD) with intronic SNPs while rs12219080 is in strong LD with nonsynonymous rs4469829, which is monomorphic in EA reference populations. This study has identified putative causal SNPs associated with IPD in AAs; however, replication studies are needed to further evaluate the clinical significance of these genetic associations with IPD.

Differing clinical presentation between a mother and son with the same inherited 22q11.21q11.23 microduplication. *V. Siu*[1], *J. Xu*[2] 1) Division of Medical Genetics, Dept of Pediatrics, London Health Sciences Centre and University of Western Ontario, Canada; 2) Cytogenetics, London Health Sciences Centre and University of Western Ontario, Canada.

A 7 ½ year old boy was referred for medical assessment by an orthodontist with regards to multiple dental anomalies. He had fusion of the primary right central incisor to a supernumerary primary central incisor, bilateral posterior and anterior crossbite, overjet of -5 mm, skeletal class III malocclusion, and retrognathia. He also had moderate developmental delay, hyperopia, and astigmatism. There was no history of nasal regurgitation or hypernasal speech. Physical examination revealed normal growth parameters, heavy eyelids with slightly upslanting palpebral fissures, right epicanthal fold, midfacial hypoplasia, downturned corners of the mouth, and relative brachydactyly. The palate was unusual, described as an ogival palate with retropositioned uvula. G-banding analysis at ~700 band level of the boys peripheral blood showed a subtle duplication of 22q11.21-q11.23. This duplication was confirmed by FISH using the probe D22S75 (Vysis) for DiGeorge/VCF critical region at 22q11.2. The father had a normal karyotype. The mother has apparently the same 22q duplication by G-banding and FISH. She had a history of mild learning disability but had completed a regular high school program. Both parents have a history of oligodontia involving one or more molars, but have none of the orthodontic problems or dysmorphic features seen in their son. Microduplication 22q11.2 has been reported in ~40 cases and is emerging as a new syndrome with variable phenotype. This 22q11.2 region is characterized by the presence of multiple low copy repeats and is prone to recombination. Our case emphasizes the need for caution in clinical prediction and genetic counselling for an inherited cytogenetic finding, in view of the possibility of different phenotypes between a carrier parent and child.

Interest in predictive testing for type 1 diabetes among adults. *J. Silver[1, 2], C. Shuman[2], D. Chitayat[2], A. Moore[3]* 1) Molecular Genetics, University of Toronto, Toronto, ON; 2) Clinical and Metabolic Genetics, SickKids, Toronto, ON; 3) Neonatology, SickKids, Toronto, ON.

Objectives: Susceptibility testing for type 1 diabetes (T1D) using a combined genetic and immunological approach is currently available through research studies. Such testing is offered in the context of population-based newborn screening as well as through cascade testing within TID families. It is conceivable that predictive testing for T1D may eventually become available clinically as a public health initiative. Although 1/3 of diagnoses of T1D are made after age 20, little research has been undertaken on the attitudes of adults toward predictive testing for T1D. The aim of this study was to assess interest in T1D testing among those with and without a family history of this condition. Methodology: A self-reporting questionnaire was distributed among two adult cohorts; 203 first-degree relatives (FDRs) of T1D patients and 87 members of the general population (GP) were surveyed. Questions included interest in a test with 100%, 75% and 50% certainty of predicting T1D, perceived risk to develop the disease, and interest in prenatal diagnosis. Results: For a test that has 100% certainty of prediction, 78% of the FDRs and 85% of the GP expressed interest. Interest declined to 51% and 48% respectively if the test was 50% certain. Unexpectedly, self-perceived risk to develop T1D was higher among the GP than the FDRs; a significantly greater proportion felt that they were at higher than 1% risk to develop T1D ($p = 0.005$). Among all subjects, those with higher risk perception ($p = 0.045$) and less education ($p = 0.047$) were more likely to be interested in a 75% certain predictive test. Finally, 48% of the FDRs and 50% of the GP were interested in prenatal diagnosis for T1D. Conclusion: These results suggest that uptake for widespread predictive testing for T1D may be high if the test offers a high positive predictive value. The need for genetic counselling is also highlighted, given that the decision to test oneself or a pregnancy may be mediated by appropriate risk counselling, education regarding test accuracy and exploration of testing motivation.

Public Attitudes about Large Cohort Genetic Research. *D. Kaufman, J. Murphy, K. Hudson, J. Scott* Genetics & Public Policy Center, Johns Hopkins University, Washington, DC.

Introduction: Large cohort studies focusing on interactions between genes, environment, and lifestyle require a large representative sample of the population. In order to recruit and retain participants, it is critical to understand what factors influence support for such a study, and the relative importance of these factors in people's decisions to participate. We surveyed 4,659 Americans aged 18+ about their support for and potential participation in a large prospective cohort study. Methods: A survey instrument, informed by focus groups and community leader interviews that identified key issues, was administered to a representative sample of US residents. To measure the influence of study burden, compensation, and return of research results, respondents were randomized to one of eight study scenarios and then asked whether they would participate. Results: Most respondents (84%) said the study should definitely or probably be done, and overall, 60% would definitely or probably participate given the scenario they were presented. Returning research results to participants (OR=1.6, 95% CI 1.3-1.8, $p<0.0001$) and increasing financial compensation (OR=1.5, 95% CI 1.3-1.7, $p<0.0001$) were both strongly and significantly associated with increased willingness to participate, while a lower study burden was less important (OR=1.2, 95% CI 1.0-1.4, $p=0.015$). The importance of obtaining individual research results was echoed in other survey questions: 75% of respondents would be less likely to participate if research results were not returned and 91% wanted their research results even if there was no immediate clinical value. Support and overall likelihood of participation varied little by demographic group, although the influence of study scenarios on participation differed. Conclusion: Widespread public support exists for a large national cohort study. The prospect of obtaining personal research results can strongly motivate participation, but compensating participants for their time may increase participation by a similar amount. Incentives and recruitment may be tailored to meet different demographics groups interests. This work was funded by a grant from NHGRI.

The proximal and distal human globin CACCC box: a different effect in the hemoglobin switching of the -87 and -101 thalassemia mutations. *M. F. Marongiu[1], S. Porcu[1], D. Poddie[1], D. Drabek[2], T. DeWit[2], A. Cao[1], M. S. Ristaldi[1]*
1) INN-CNR, Cagliari, Italy, Monserrato (CA), Cagliari, Italy; 2) Department of Cell Biology, Erasmus University of Rotterdam, (NL).

The distal CACCC box has been reported not to bind EKLF in vitro. A minor role of the distal CACCC element in globin gene promoter function is suggested by the observation that naturally occurring thalassemia mutations affecting the proximal CACCC box are more severe than those affecting the distal element. Nevertheless recent evidences demonstrate that EKLF binds to the distal CACCC motif, although with low affinity;that the CCTCACCC is required for maximal stimulation of the globin gene by EKLF and that silent thalassemia due to mutations of the distal CACCC box affects the binding to EKLF of the globin gene promoter.We have analyzed in vivo the effect of mutations at the proximal and distal element. We engineered, by site specific mutagenesis, the -101 (distal CACCC element) and -87 (proximal CACCC element) mutations inside the / minilocus construct which contains the full globin LCR, the A globin gene, the globin gene and the 3HS of the globin cluster and produced three mice transgenic lines. The pattern of versus globin switching has been analyzed by S1 analysis and real time PCR. We have dissected the yolk sac at 10 days pc; the fetal liver at 12, 14 and 16 days pc; and the adult blood to assess the embryonic and fetal stages of erythropoiesis. Both mutations appear to be more severe in the adulthood than in the fetal liver stage of development. In addition the pattern of expression of the 101 mutation appears to worsen at day 12 pc than at day 14 pc while the opposite happens in the 87 mutation. This observation is in agreement with the age related pattern of expression of the 101 mutation. In summary the two mutations have a different effect on the activation pattern of the globin gene during the fetal stage of development in transgenic mice highlighting a possible role of the distal globin CACCC box in hemoglobin switching. Our data are in agreement with the observation that both CACCC elements are necessary for optimal globin gene expression.

IL-12B and MCP1 (CCL2) genomic variation associate with pulmonary tuberculosis in two independent West African populations. *D. R. Velez[1,2], G. A. J. Morris[3], C. Wejse[6,7], P. C. Hill[3,4], C. Bisseye[3], R. Olesen[6], M. Sodemann[6], T. L. Edwards[1,2], A. Tacconelli[1], E. Brunetti[1], G. Novelli[1], P. Aaby[7], L. Østergaard[6], W. K. Scott[2], R. A. Adegbola[3], S. M. Williams[5], G. Sirugo[1,3]* 1) Ospedale San Pietro FBF, Rome, Italy; 2) Miami Institute of Human Genomics, University of Miami, Miami, FL; 3) MRC Laboratories, Banjul The Gambia; 4) University of Otago, School of Medicine, New Zealand; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 6) Department of Infectious Diseases, Aarhus University Hospital, Skejby, Denmark; 7) Bandim Health Project, Danish Epidemiology Science Centre and Statens Serum Institut, Guinea-Bissau.

Mycobacterium tuberculosis pulmonary disease (PTB) has a significant morbidity and mortality worldwide, particularly in sub-Saharan Africa. Immune responses to TB are known to include proinflammatory cytokines and chemokines. The purpose of this study was to examine whether polymorphisms in two of these, interleukin-12B (IL-12B) and monoctye chemoattractant protein 1 (MCP1), were associated with susceptibility to PTB in two West African populations (The Gambia and Guinea Bissau). Eight SNPs were examined in 321 PTB cases and 346 controls from Guinea Bissau and 286 PTB cases and 280 controls from The Gambia. Single locus tests revealed associations in both populations at the IL-12B locus at rs3212227 (OR = 0.78, CI [0.61-0.99], p = 0.05) in Guinea Bissau and rs11574790 (OR = 0.76, CI [0.58-1.00], p = 0.05) in The Gambia. IL-12B haplotypes also associated in Guinea Bissau (global p = 0.0014). The MCP1 promoter variant (rs1024611) only associated in Guinea Bissau (OR = 0.71, CI [0.52-0.97], p = 0.03); these results are concordant with differential susceptibility previously described by Flores-Villanueva et al. (2005) in Mexican and Korean subjects. MDR analyses revealed a significant 3-marker association between MCP1 and 2 markers in IL-12B in Guinea Bissau but not in The Gambia. These data provide evidence for the role of IL-12B in PTB in two distinct West African settings, confirm that an MCP1 promoter variant influences host susceptibility, and suggest an interaction between IL-12B and MCP1 affecting disease risk.

Somatic Second Hits Explain the Localized Nature of Dominantly Inherited Glomuvenous Malformations (GVMs). *M. Amyere[1], V. Aerts[1], P. Brouillard[1], L. Boon[1,2], O. Enjolras[3], M. Wassef[3], JB. Mulliken[4], M. Vikkula[1]* 1) Lab Human Molec Genetics, de Duve Institute, Brussels, Belgium; 2) Centre for Vascular Anomalies, Plastic Surgery, Cliniques Universitaires, UCL, Saint- Luc, Brussels, Belgium; 3) Consultation des angiomes et Cytologie pathologiques, Hôpital Lariboisière, Paris, France; 4) Vascular Anomalies Center, Childrens Hospital and Harvard Medical School, Boston, USA.

Glomuvenous malformations (GVMs) are localized cutaneous vascular lesions, often hereditary and transmitted as an autosomal dominant disorder. We mapped the causative gene to 1p22.1 and identified that the glomulin gene is mutated in almost all familial cases (Brouillard et al., 2002, 2005 and 2008). A second-hit, a 5-bp-deletion resulting in a premature stop codon, was identified in one GVM. This would lead to a complete localized loss of function of glomulin (Brouillard et al, 2002). In this study, pairwise LOH and copy number analyses were performed between blood and tissue using Affymetrix GeneChip 250K and sequencing. Ten somatic mutations were identified: six consisted of the complete deletion of the short arm of chromosome 1, one was a limited 1p22.1-22.2 deletion, one a small intragenic deletion and 2 were intragenic substitutions. In parallel, glomulin expression was examined during murine development using RNA in situ hybridization. Known vascular smooth muscle cell (vSMC) markers (desmin, h-caldesmon, smooth muscle myosin heavy chain and smoothelin-b) were analyzed. Expression of glomulin appeared in vSMCs after desmin, h-caldesmon and smooth muscle myosin heavy chain, but before smoothelin-b. All the markers were expressed in VMs, whereas in GVMs, glomus cells did not express glomulin or smoothelin-b, although smooth muscle myosin heavy chain and h-caldesmon were detected. These data demonstrate that GVMs are caused by a localized complete loss of glomulin, due to the combination of a germline and a somatic second-hit mutation, which cause a deviation in vascular smooth muscle cell differentiation. This explains the variable number, size and localization of lesions (Miikka.vikkula@uclouvain.be, www.icp.ucl.ac.be/vikkula).

Identification of the mutated gene responsible for a new form of Recessive Spastic Ataxia with frequent Leukoencephalopathy (ARSAL) in the French-Canadian Population. *I. Thiffault[1], M. Tetreault[1], V. Bayat[5], L. Loiselle[1], J. Mathieu[2], J. P. Bouchard[3], J. Lesage[4], H. J. Bellen[5], B. Brais[1]* 1) Neuromics Center for Excellence of Université de Montréal, Université de Montréal, CR-CHUM hopital Notre-Dame, Montreal, PQ, Canada; 2) Carrefour de la Santé de Jonquière, Saguenay, QC, Canada; 3) Department of Neurology, CHUL, Quebec City, QC, Canada; 4) Department of Radiology, CHUM-Notre-Dame, Montreal, QC, Canada; 5) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, USA.

Recessive ataxias are a heterogeneous group of neurodegenerative disorders characterized by progressive gait ataxia often associated with pyramidal spasticity. We have recruited a cohort of 28 affected individuals and their unaffected relatives belonging to 23 unrelated French-Canadian families with an original form of Autosomal Recessive Spastic Ataxia with frequent Leukoencephalopathy (ARSAL,SPAX3; OMIM611390). In 2005, using a linkage mapping strategy with a 7cM-genome wide scan (GWS) we mapped the disease locus to chromosome 2q33-35. In order to better define the candidate region, SNP mapping was undertaken using Illumina HAP300DUO microarrays. Homozygosity mapping and linkage analysis confirmed that all ARSAL families are linked to the same 0.54kb candidate region. Haplotype analysis suggests that at least four mutations are present in Quebec. Amplification and sequencing uncovered three insertion mutations in the ARSAL gene. These mutations lead to abnormal size protein on Western blots. The gene codes for a mitochondrial protein. The identification of the mutated gene responsible for ARSAL further underlies the importance of normal mitochondrial function in cerebellar neuron survival.

***Slc7a9* knockout mouse used for searching new potential antilithiasic thiol drugs to treat cystinuria.** *M. Font-Llitjós[1,2], M. Espino[1], L. Feliubadaló[1], R. Sillué[1,2], S. Mañas[1], J. Visa[3], M. Palacín[4,5,6], V. Nunes[1,2,7]* 1) Med & Molec Genetics Ctr, IDIBELL, L'Hospitalet de Llobregat, Spain; 2) CIBER de Enfermedades Raras (CIBERER-U730), Barcelona, Spain; 3) Animal Facility Service, IDIBELL, L'Hospitalet de Llobregat, Spain; 4) Department of Biochemistry and Molecular Biology, Universitat de Barcelona, Spain; 5) Parc Científic de Barcelona, Spain; 6) CIBERER-U731, Barcelona, Spain; 7) Genetic Unit, Department of Physiology II, Universitat de Barcelona, Spain.

Cystinuria is a hereditary disorder caused by a defect in the apical membrane transport system for cystine and dibasic amino acids in renal proximal tubules and intestine, resulting in recurrent urolithiasis. Mutations in *SLC3A1* and *SLC7A9* genes, that encode rBAT/$b^{0,+}$AT transporter subunits, cause cystinuria. In humans, cystinuria treatment is based on prevention of calculi formation and its dissolution or breakage. Persistent calculi are treated with thiol drugs, such as D-penicillamine and tiopronin, for cystine solubilisation. The *Slc7a9* knockout model was used to study the therapeutic effect of 6 potential antilithiasic drugs to treat cystine lithiasis. All drugs are already used for other prescriptions in humans: succimer, sodium thiosulfate, unithiol, uromitexan, tiopronin and D-penicillamine. An in vitro precipitation test and a palatability test were performed for all drugs before performing 3-week treatments of lithiasic mice. Lithiasis evolution throughout drug treatments was followed-up with a non-invasive indirect method of calculi quantification based on densitometry analysis of stones in X-ray plaques. Urine was collected in metabolic cages to quantify amino acid excretion in treated and untreated mice. Histopathological analysis showed that treated lithiasic mice had similar urinary system damage than untreated mice indicating that these drugs had no toxic effects at short exposures. In vivo treatment with all drugs except for STS significantly prevented calculi growth and lowered urinary cystine excretion. Further studies need to be done to assess efficacy and toxicity of these drugs. Acknowledgements: MEC (BFU2006-14600-C02-02); Laboratorios Rubió, SL.

Partial rescue of the adrenocortical dysplasia embryonic phenotype by p53 deficiency. *C. Keegan, B. O'Connor, M. Morley, C. Vlangos, A. Krause* Univ Michigan, Ann Arbor, MI.

Adrenocortical dysplasia (*acd*) is a spontaneous autosomal recessive mouse mutation that exhibits a pleiotropic phenotype with perinatal lethality. The embryonic *acd* phenotype consists of caudal truncation, vertebral segmentation defects, hydronephrosis, and limb anomalies, resembling malformations observed in humans with caudal regression syndrome and VACTERL association. The *Acd* gene encodes a telomeric protein (also known as TPP1) that functions in a multiprotein complex to maintain telomere integrity. Consistent with this function, *acd* mutant mice have evidence of telomere dysfunction and genomic instability. To further explore the relationship between telomere dysfunction and embryonic malformations, we have investigated potential mechanisms leading to caudal dysgenesis in *acd* mutant embryos. Based on the proposed function of Acd as a telomeric protein, we hypothesized that the loss of cells in the caudal region might be due to apoptosis or cell cycle arrest via activation of p53. We observed a significant increase in the number of apoptotic cells in *acd* embryos, but no gross differences in proliferation, suggesting that apoptosis is the predominant mechanism leading to caudal truncation. To determine whether the increased apoptosis is p53-dependent, we crossed *acd* mice to p53 null mice and analyzed the phenotype of progeny from double heterozygote intercrosses. We found that the p53-deficient state does not rescue the embryonic lethality of the *acd* mutation on the C57BL/6 strain. However, a Mendelian genotype distribution was observed at embryonic day 15.5-16.5, suggesting perinatal lethality. Interestingly, the vertebral anomalies were completely rescued in homozygous double mutant embryos. Moreover, the limb hypoplasia phenotype was rescued by p53 haploinsufficiency while complete p53 deficiency in *acd* mutant embryos resulted in preaxial polydactyly. These findings support the hypothesis that the skeletal anomalies in *acd* embryos are secondary to p53-dependent apoptosis. This work will shed important insights into the role of telomere stability during development. This work was supported by a March of Dimes Basil OConnor Award.

miR-93, miR-98 and miR-197 regulate expression of tumor suppressor gene FUS1. *L. Du[1], J. Schageman[1], L. Prudkin[3], I. Wistuba[3], S. Hammond[2], L. Ji[3], J. Roth[3], J. Minna[1], A. Pertsemlidis[1]* 1) The University of Texas Southwestern Medical Center, Dallas, TX; 2) The University of Texas M. D. Anderson Cancer Center, Houston, TX; 3) University of North Carolina, Chapel Hill, NC.

FUS1 is a tumor suppressor gene located on human chromosome 3p21.3. Over-expression of FUS1 significantly inhibits tumor growth and progression in mouse models of lung cancer. Here we show that the 3UTR of FUS1 play a significant role in regulating the Fus1 protein expression and function. Based on computational methods, we predicted that FUS1 is a target of three miRNAs, miR-93, miR-98 and miR-197. By luciferase reporter assay, we validated the interaction of the three miRNAs with the 3UTR region of the FUS1 transcript. By over-expressing FUS1 in NCI-H1299 cells, we demonstrated that individual deletion of the three miRNA target sites in the 3UTR restores the expression level of Fus1 protein. Furthermore, we found that two of the miRNAs, miR-93 and miR-98, are over-expressed across small cell lung cancer cell lines (SCLC) relative to non-small cell lung cancer cell lines (NSCLC) and immortalized human bronchial epithelial cells (HBECs). We also found that elevated miR-93 and miR-197 expression is correlated with reduced Fus1 expression in NSCLC tumor specimens. These results suggest that the three miRNAs play a role in the development of lung cancer by regulating expression of Fus1.

Confirmation of the X-linked "Pierre-Robin sequence and faciodigital anomalies" syndrome. *P. BLANCHET, J. PUECHBERTY, A. SCHNEIDER, M. TOURNAIRE, AM. CHAZE, G. LEFORT, P. SARDA* Service de Genetique, CHU Montpellier, Montpellier, Herault, France.

In 1991, Chitayat et al. described a new apparently X-linked recessive syndrome in 2 half brothers, aged 6 months and 4 years, with the same mother. Patients had Pierre-Robin sequence, facial dysmorphism (retrognathia, high and broad forehead, cleft palate and glossoptosis) and digital anomalies (tapering fingers, hyperconvex nails, clinodactyly of the fifth fingers, narrow distal phalanges, finger-like thumbs and easily subluxated first metacarpophalangeal joints). Both had normal psychomotor development. This entity is probably very rare as no other case has been reported to date. We describe a new patient with a similar phenotype. The boy was born with intra uterine growth retardation, Pierre-Robin sequence, digital anomalies and micropenis. Course was marked by respiratory and feeding difficulties and psychomotor delay. Cerebral MRI was normal. Chromosomal analysis showed an abnormal karyotype: 46,X,der(Y).ish der(Y)t(X;Y)(p22.3;q11.2)(wcpX+,wcpY+,subtelXp/Yp++,subtelXq/Yq-,SRY+,Yq12-),der(X)(p22.3;q11.2)(wcpX+,wcpY+,subtelXp/Yp+,subtelXq/Yq+,SRY-,Yq12-).The karyotype analyzed by classical and FISH methods suggested that the der(Y) chromosome was the unbalanced product of translocation of Xp material onto Yq. The der(X) chromosome was interpreted as the unbalanced product of translocation of Yp onto Xp. These anomalies lead to partial Ypter trisomy and partial Xp disomy in the male patient. Further characterization of this chomosome anomaly by FISH and microarray is ongoing. This observation of a second family with a boy with Pierre-Robin sequence and faciodigital anomalies and a translocation between the X and Y chromosomes confirms this rare X-linked recessive syndrome. Psychomotor delay and micropenis are probably related to the chromosome anomaly.

Experimental approaches to the Imprinted status of the murine *Atp10a* locus. *A. J. DuBose, K. A. Johnstone, J. L. Resnick* Molecular Genetics and Microbiology, College of Medicine, University of Florida, Gainesville, FL.

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) can each be caused by loss of parental contribution from a cluster of genes on chromosome 15. PWS is characterized by a loss of paternal gene expression from this cluster, while AS can be caused by a loss of maternal gene expression from the same region. Regulation of both maternal and paternal gene expression in this region is controlled by a bipartite regulatory element composed of the Angelman syndrome imprinting center (AS IC) and the Prader-Willi syndrome imprinting center (PWS IC). *ATP10A* encodes a putative phospholipid translocase and has been implicated in fat metabolism. The human *ATP10A* locus is a preferentially expressed from the maternal allele and is under the control of the Angelman Syndrome imprinting center. The imprinted status of the orthologous gene in mice, *Atp10a* (*Atp10c, pfatp*), remains uncertain. Deletions including *Atp10a* have been shown to cause increased body fat when inherited maternally, but have no effect when inherited paternally which is consistent with imprinted expression. Molecular studies examining allelic expression have yielded contradictory results. One study showed equal expression of both alleles in all tissues examined while another study found predominantly maternal expression in the olfactory bulb and hippocampus. We are using strain specific polymorphisms in combination with imprinting center mutations to investigate the potential imprinted status of the *Atp10a* locus as well as the role of PWS genes in *Atp10a* expression.

Case report: Cytogenetic abnormalities in a rare CD4+/CD56+ hematodermic neoplasm. *s. michalowski, A. Gerling, F. Johnson, C. Thompson, C. Rehder, M. Selim, B. Goodman* Pathology, Duke, Durham, NC.

CD4+/CD56+ hematodermic neoplasm is a rare and aggressive malignancy of controversial origin. Some research suggests that it is a version of blastic NK leukemia/lymphoma with a cutaneous presentation, while other studies indicate a monocytic, perhaps dendritic origin. The unusual, primary cutaneous presentation, good initial response to therapy and high rate of relapse are hallmarks of this neoplasm. In our case a 12 year old girl presented with a small bruise-like lesion on her lower leg that did not resolve over the course of several months. Immunohistochemistry on a punch biopsy was positive for CD4, CD43, CD56 and TdT, a finding consistent with hematodermic neoplasm. PCR for B cell and T cell clonality was negative, also consistent with this diagnosis. Chromosome analysis of a punch biopsy of the region showed a complex karyotype that included loss of material from 4q, 6q and 9q, plus a gain of chromosome 21 (47,XX,add(4)(q21),del(6)(q23),add(8)(q24.1),del(9)(q22q34),+21[cp3]). Further studies did not show involvement of the bone marrow or cerebrospinal fluid. Currently, there is a lack of, but accumulating chromosomal data on these cases in the literature. Our findings may help to further define genetic changes in this rare tumor.

Identifying a Diagnostic Classifier of CdLS by a Stepwise, Multi-platform Procedure. *Z. Zhang[1], J. Liu[2], D. Wilson[5], M. Kaur[2], M. Deardorff[2,4], D. Clark[2], E. Rappaport[3], M. Morrow[5], I. Krantz[2,4]* 1) Center for Biomedical Informatics, The Childrens Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, The Childrens Hospital of Philadelphia, Philadelphia, PA; 3) Nucleic Acid/Protein Core Facility, The Childrens Hospital of Philadelphia, Philadelphia, PA; 4) The University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Xceed Molecular, Toronto, Ontario.

Cornelia de Lange Syndrome (CdLS) (OMIM 122470) is a dominant disorder of multiple congenital anomalies including characteristic facial features, upper limb defects, growth and cognitive retardation and other systemic abnormalities. Although mutations in the NIPBL, SMC1A or SMC3 genes can be identified in about 60% of CdLS probands, molecular diagnosis is not available for the remaining patients. All three causative genes encode subunits or regulators of the Cohesin complex, indicating the existence of a general, Cohesin-related mechanism in CdLS. In this study, we performed a genome wide screen to identify a gene expression profile for CdLS under the hypothesis that defects in Cohesin complex may have a common effect at the gene expression level. We started the screen using comprehensive human genome microarrays (Affymetrix Inc.) and refined it using focused arrays (Xceed Molecular).

Massive parallel bisulfite sequencing of CG-rich DNA fragments. *M. Zeschnigk[1], M. Martin[2], G. Betzl[3], S. Gross[1], K. Buiting[1], B. Frey[3], S. Rahmann[2], B. Horsthemke[1]* 1) Institut für Humangenetik, Universitätsklinikum Essen, Germany; 2) Bioinformatics, Computer Science 11, TU Dortmund, Germany; 3) Roche Diagnostics GmbH, Penzberg, Germany.

Methylation of CpG islands (CGIs) plays an important role in gene silencing, both in normal and disease states. Although next generation sequencers allow massive parallel sequencing, the analysis of the complete human genome in a single run is not yet possible. Guided by *in silico* restriction digests, we used a mixture of four enzymes and a size selection step to generate pools of 350-800 bp DNA fragments enriched for CGIs from female white blood cells and from sperm. The fragments were ligated to adaptors, bisulfite treated and subjected to a modified Roche Genome Sequencer protocol. Using one plate, we obtained 163,034 and 129,620 reads from blood and sperm, respectively, with an average read length of 133 bp. Bioinformatic analysis by newly developed algorithms revealed that 12,358 (7.6%) blood library reads map to 6,167 different CGIs, of which 1,409 (23%) were partially or fully methylated. Almost the same proportion of reads (7.9%) from the sperm library maps to 5,796 different CGIs, of which 820 (14%) CGIs were methylated. CGIs that were hit by reads from methylated and unmethylated fragments are regarded as differentially methylated and were observed in 63 and 53 CGIs in the blood and sperm library, respectively. Significant differences between both samples were found for X chromosomal CGIs. Only 2 of 108 (2%) X chromosomal CGIs that were hit by reads from the sperm library, but 81 of 154 (53%) X chromosomal CGIs that were hit by blood library reads are methylated. We verified the results of eight fully methylated and three differentially methylated CGIs by conventional bisulfite sequencing and found complete concordance. Our results show that the extraction of CG-rich fragments and massive parallel sequencing make it possible to detect tissue and allele-specific methylation differences.

Rare Presentation of Familial Head and Neck Paraganglioma without Evidence of A Mutation in the SDH, RET and VHL genes: Towards Further Genetic Heterogeneity. *A. Persu[1], M. Amyere[2], I. Gutierrez-Roelens[2], P. Rustin[3], C. Sempoux[1], FE. Lecouvet[1], BE. Van beers[1], Y. Horsmans[1], JF. De Plaen[1], M. Hamoir[1], M. Vikkula[2]* 1) Nephrology, Pathology, Diagnostic Radiology, Gastroenterology and Otorhinolaryngology Dept, Cliniques Univ St Luc, Brussels, Belgium; 2) Laboratory of Human Molecular Genetics, de Duve Institute, UCL, Brussels, Belgium; 3) INSERM U676, Hôpital Robert Debré, Paris, France.

SDH mutations in genes encoding succinate dehydrogenase and its anchoring subunits (SDHgenes) are at the origin of hereditary head and neck paraganglioma (PGL) and a subset of apparently sporadic pheochromocytoma. We describe a family including three patients harbouring bilateral head and neck PGL diagnosed before 25 years of age. Multiple hypervascular hepatic lesions were subsequently discovered in two of them. In both, liver biopsy confirmed the diagnosis of PGL. In addition, in one patient, MRI disclosed multiple target-like lesions of the spine, highly suggestive of metastatic PGL. Family history was compatible with autosomal dominant inheritance with possible maternal imprinting. Combined SSCP and heteroduplex analysis followed by sequencing did not show any mutation of the coding parts of SDHB, SDHC, SDHD, RET or VHL genes. Furthermore, succinate dehydrogenase activity measured in a liver PGL sample was not significantly decreased in the affected patients as compared to controls, underscoring the exclusion of the SDH genes. Screening of copy number alterations and LOH using Affymetrix 250K SNP chips in the three affected family members showed no deletion or amplification of the SDH, RET and VHL genes either. No other linked copy number deviation was identified elsewhere in the genome. To our knowledge, this is the first reported family of hereditary head and neck paraganglioma with metastatic dissemination in the liver and the spine. A large body of evidence supports the absence of mutations in SDH, RET and VHL genes, which suggests the existence of a yet unknown gene at the origin of this particular form of familial paraganglioma. (Miikka.vikkula@uclouvain.be, www.icp.ucl.ac.be/vikkula).

Functional analysis of osteoporosis pseudoglioma associated missense mutations in *LRP5*. *A. Saarinen[1, 2], U. Lahtinen[1, 3], M. Somer[4], AE. Lehesjoki[1, 3], O. Mäkitie[1, 5]* 1) Folkhalsan Inst Genetics, Biomedicum Helsinki, Helsinki, Finland; 2) Dept of Medical Genetics, University of Helsinki, Finland; 3) Neuroscience Center, University of Helsinki, Finland; 4) Dept of Medical Genetics, The Family Federation of Finland, Helsinki, Finland; 5) Metabolic Bone Clinic, The Hospital for Children and Adolescents, Helsinki University Hospital, Helsinki, Finland.

Background: Mutations in the low density lipoprotein receptor-related protein 5 gene (*LRP5*) have been associated with high and low bone mass. While homozygous *LRP5* mutations cause osteoporosis-pseudoglioma syndrome (OPPG), characterized by severe osteoporosis and blindness, heterozygous mutations have been associated with reduced bone mass. LRP5 functions as a plasma membrane receptor in the Wnt signaling pathway. We previously described *LRP5* mutations in patients with OPPG and/or severe osteoporosis. In this study we further analyzed the role of these mutations in Wnt signal transduction and cellular localization. **Methods:** Mutations were introduced to full length human LRP5-pcDNA3.1 expression vector using site-directed mutagenesis. Wnt signal transduction assays were performed in 293HEK cells using a previously published Wnt-induced canonical signaling assay (Ai etal. 2005). Localization studies were performed in HeLa cells using immunofluorescence staining. **Results:** Three different missense mutations were identified and selected for further studies. Wnt signaling assays indicated that one of the mutations, R570W in exon 8, completely disrupted Wnt signal transduction. The second mutation, R1036Q in exon 14, resulted in partial disruption of Wnt signaling while the third mutation, R925C in exon 12, did not show any alteration in the signaling assays. Localization studies revealed that the R1036Q and R925C mutant proteins were able to reach plasma membrane where as the R570W could not be detected, suggesting that it might be post-translationally degraded. **Conclusions:** We were able to show that some *LRP5* mutations directly impair Wnt signal transduction and cellular transportation while other pathogenetic mechanisms are associated with some mutations.

Clinical and cellular correlations in Chediak Higashi Syndrome. *W. Westbroek, W. Introne, I. Manoli, G. Golas, D. Adams, D. Maynard, M. Huizing, W. A. Gahl* Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Chediak Higashi syndrome (CHS) is a rare autosomal recessive disorder caused by mutations in the CHS1 gene, encoding the 430-kDa CHS1 protein with unknown biological function. Many cell types in CHS manifest giant lysosomes and lysosome-related organelles (LRO). Clinical characteristics can include skin, hair and eye hypomelanosis, recurrent infections, a mild bleeding diathesis and late-onset progressive neurological impairment. The clinical spectrum of CHS varies widely; most patients manifest the severe childhood form, with fatal infections and the accelerated phase while only a few suffer milder infections or progressive neurological impairment. We have shown that the clinical phenotype of CHS varies in relation to the molecular genotype. To study the cellular phenotypes in CHS, we cultured fibroblasts and melanocytes from 5 unrelated patients with vastly different clinical presentations and genotypes. Laser scanning confocal microscopy of cultured primary epidermal fibroblasts stained with the lysosomal marker, LAMP2, showed a perinuclear distribution of a few large lysosomes in severely affected patients; fibroblasts from mildly affected patients contained only slightly enlarged lysosomes. Bright field light microscopy and laser scanning confocal microscopy were used to study the localization, morphology and pigmentation of melanosomes. In control melanocytes, melanosomes exhibited a peripheral distribution with accumulation in the dendritic tips while severely affected patients CHS melanocytes had enlarged melanosomes restricted to the perinuclear area; mild CHS melanosomes were much smaller, with a nearly normal dendritic distribution. Western blot analysis with an anti-CHS1 antibody revealed residual CHS1 protein expression in mild CHS cell lines and absent CHS1 expression in severe CHS-1 cell lines. We show for the first time that the cellular phenotype and CHS1 expression level in CHS patients correlate with the molecular genotype and the clinical phenotype.

Regulatory genetics in childhood leukemia. *J. Healy[1], J. Dionne[1], M. Larivière[1], M. Ouimet[1], V. Gagné[1], N. N'Daye[1], P. Beaulieu[1], D. Labuda[1,2], D. Sinnett[1,2]* 1) Div Hematology-Oncology, Sainte-Justine Hosp, Montreal, Qc, Canada; 2) Department of Pediatrics, University of Montreal, Montreal, Qc, Canada.

It is now widely appreciated that complete loss or gain of function of essential tumor suppressor genes and potent oncogenes may not be the only prerequisite for malignant transformation but rather that increased/decreased gene expression levels might be sufficient to disrupt normal cellular function and drive oncogenesis. Accordingly, sequence variation in gene regulatory sequences has gained much importance in the study of complex disorders due to the quantitative effect on gene expression. We proposed a comprehensive study of functional regulatory variation in genes involved in highly controlled cellular processes known to contribute to cancer susceptibility, such as the cell cycle. We focused on cis-acting regulatory polymorphisms (rSNPs) that could disrupt transcription factor (TF) binding and lead to abnormal expression and variation in gene dosage and therefore influence the risk of disease. The proximal promoter region of 197 candidate genes has been screened and a total of 1838 rSNPs were identified. Population genetic studies are being carried out to evaluate promoter genetic diversity worldwide and the functional impact of these rSNP/haplotypes is assessed combining in silico TF binding site prediction analysis and in vitro functional assays. Thus far, the influence of promoter variation on transcriptional activity has been tested for 17 cell cycle genes and 6 DNA repair genes and DNA-protein binding disruption has been validated for several of these rSNPs. Population- and family-based genetic association studies are performed in parallel to evaluate the impact of functional rSNPs in the risk of childhood acute lymphoblastic leukemia (ALL). Our findings demonstrate how the expected variability in expression levels due to regulatory polymorphisms in key metabolic genes can influence the risk of childhood leukemia and contribute to carcinogenesis, and reveal the functional relevance of the study of regulatory genetics in cancer research.

AXIN2, Orofacial clefts and positive family history for cancer. *R. Menezes[1], M. L. Marazita[1], T. G. McHenry[1], M. E. Cooper[1], K. Bardi[1], C. Brandon[1], A. Letra[1], R. A. Martin[2], A. R. Vieira[1]* 1) Dept of Oral Biology, Center for Craniofacial and Dental Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Dept of Pediatrics, Division of Medical Genetics, St. Louis University School of Medicine, St. Louis, Missouri.

Background: Cancer and congenital malformations may occasionally have a common etiology. We investigated if families segregating orofacial clefts (CL/P) presented increased cancer incidence when compared to control families. Methods: We assessed 75 CL/P families and 93 control families of Caucasian ethnicity from Pittsburgh with regards to positive history of cancer. Chi-square and Fisher exact tests were used to determine statistically significant differences between both groups with alpha of 0.05. Then, we performed molecular studies with genes in which mutations have been independently associated with both cancer and craniofacial anomalies in a total of 111 families presenting isolated CL/P from Pittsburgh and St. Louis. Thirteen SNPs in eight candidate genes (AXIN2, CDH1, FGF3, FGF7, FGF10, FGF18, FGFR1 and FGFR2) were genotyped using Taqman chemistry and transmission distortion was analyzed using the Family Based Association Test (FBAT). Results: CL/P families reported positive family history of cancer more often than control families (p=0.0002), and had higher rates of specific cancer types, including colon (p=0.0009), brain (p=0.003), leukemia (p=0.005), breast (p=0.009), prostate (p=0.01), skin (p=0.01), lung (p=0.02), and liver (0.02). Over transmission of a marker allele in AXIN2 was detected in CL/P probands (p=0.003). Conclusion: Families segregating CL/P may have an increased susceptibility for cancer, notably colon cancer. Further, AXIN2, a gene that when mutated increases susceptibility to colon cancer, is also associated with CL/P. Individuals detected at a higher risk for disease predisposition could be able to adopt a better lifestyle avoiding exposure to other risk factors that may interact with the individuals genotype. NIH grants: R21-DE016718, R01-DE016148 and P50-DE016215.

Genetic heterogeneity for hydrometrocolpos in Bardet-Biedl syndrome: about splitting and lumping with the Mac-Kusick Kauffman syndrome. *H. Dollfus[1,2], E. Schaefer[1], M. Durand[1], C. Stoetzel[2], A. Verloes[3], D. Bonneau[4], C. Hamel[5], P. Bitoun[6], S. Finck[7], A. Goldenberg[8], I. Nisand[9], B. Viville[9], S. Hellé[2], JM. Danse[2], B. Doray[1,2], JL. Mandel[10,11]* 1) Medical Genetics Department, Hôpitaux Universitaires de Strasbourg, France; 2) Laboratoire EA3949, AVENIR Inserm, Faculté de Médecine, Strasbourg, France; 3) Service de Génétique, Hôpital Robert Debré, Paris, France; 4) Service de Génétique, CHU, Angers, France; 5) Service d'Ophtalmologie, CHU, Montpellier, France; 6) Service de Génétique, Bondy, France; 7) CH de haguenau, Haguenau, farnce; 8) Unité de Génétique Clinique, CHU, Rouen, France; 9) Service de Gynécologie Obstétrique, CHU, Strasbourg, France; 10) Laboratoire de Diagnostic Génétique, CHU, Strasbourg, France; 11) Collège de France, Paris, France.

Hydrometrocolpos and polydactyly (and occasional heart malformation) diagnosed in the prenatal period or in infancy may raise diagnostic dilemmas especially in departing McKusick Kauffman syndrome (MKKS) and the Bardet Biedl syndrome (BBS). The two syndromes show clinical overlap that dilutes with time because of the additional features of BBS appearing during infancy such as retinitis pigmentosa, obesity, learning disabilities and progressive renal dysplasia. Genotypic overlap also exists as MKKS-BBS6 gene has been previously found mutated in both syndromes. Herein we report on 7 cases, presenting in the neonatal period as MKKS and who are mutated in various BBS genes and not exclusively to the MKKS-BBS6 gene. The other BBS genes found mutated in the patients presenting with hydrometrocolpos are the following: BBS2, BBS10, BBS8 and BBS12. These findings highlights the great value of genotyping patients with hydrometrocolpos and polydactyly for diagnosis, prognosis and genetic counselling purposes. This data raises also intriguing questions about the phenotypic variability of both syndromes especially for the presence (BBS) or not (MKKS) of retinal degeneration and potential link with genetic modifiers of the phenotype already described for BBS for which oligogenic inheritance is well recognized.

Clinical and biological data of a cohort of 70 patients with 22q11 deletion. *E. HAQUET, P. BLANCHET, C. COUBES, L. PINSON, C. CIANNI, C. LABORDE, G. LEFORT, P. SARDA* Service de Génétique, CHU Montpellier, Montpellier, Herault, France.

DiGeorge syndrome is characterised by the association of facial dysmorphy and several malformations : congenital conotruncal cardiopathy, cleft palate or velar insufficiency, kidney anomalies, hypoplastic thymus and parathyroid glands. Clinical course of the patients is marked by neonatal hypocalcemia, susceptibility to infection due to T-cell deficit, short stature and scoliosis. Language and learning difficulties are common. Psychiatric disorders including paranoid schizophrenia have been described in some adult patients. We report data of a cohort of 70 patients managed in the Reference Center of Montpellier in the South of France. Diagnosis was confirmed in all patients by FISH. Patients are aged from one month to 43 years. Congenital cardiopathies are present in 65% of patients, kidney anomalies in 15% and cleft palate or velar insufficiency in 50%. Hypocalcemia is noted in the neonatal period for 20% of patients, but neonatal hypocalcemia is probably underestimated. Severe or persisting hypocalcemia is noted in 6% of infants. T-cell deficit led to no major illness except frequent otitis and pharingitis in the first years of life. Velopharyngeal insufficiency resulted in nasal speech and language difficulties in the majority of patients and required early language therapy. Even if mental retardation is not present in half of the infants, learning difficulties are extremely frequent. Few patients achieve secondary degrees in school. In our cohort, no adults show paranoid schizophrenia.

Instrument for quality self-assessment in provision of genetic counselling. *H. Kaariainen[1], E. Rantanen[2], M. Hietala[2], U. Kristoffersson[3], I. Nippert[4], J. Schmidtke[5], J. Sequeiros[6], H. Skirton[7]* 1) Dept Mol Med, National Public Health Inst, Helsinki, Finland; 2) Med Bioch Genet, University of Turku, Finland; 3) Dept Clin Genet, University Hospital of Lund, Sweden; 4) Dept Hum Genet, Westfaelische Wilhelms-University Muenster, Germany; 5) Inst Hum Genet, Hannover Medical School, Germany; 6) ICBAS and IBMC, University of Porto, Portugal; 7) University of Plymouth, UK.

Assessment of healthcare services is essential to ensure quality. In genetic counselling, assessing the outcomes is a challenge as many of them (e.g. altered sense of control, peace of mind, or ability to plan for the future) are extremely difficult to measure. In Europe the diverse structures of health services create an additional challenge. However, if genetic healthcare is to be audited, appropriate standards and measurable outcomes need to be defined. The EuroGentest project is a 5 year collaboration between many European experts, with the aim to harmonise and standardise genetic testing in Europe. As genetic counselling is part of the testing process, the quality of counselling issues is also in focus. Recommendations have been made about the need for different types of genetic testing to be accompanied by appropriate genetic counselling, to safeguard those being tested. Patient information materials have been created in several European languages (www.eurogentest.org). We present a self assessment tool developed by EuroGentest Unit 3 for genetic services. The tool that can be applied in self assessment across different systems of genetic healthcare has been developed in expert group workshops and discussed in an open workshop during ESHG Conference 2008. The decision was to emphasize the process instead of the outcome. We have devised a set of standards and potential measurable outcomes for genetic counselling, including items from waiting times and physical clinical environment to access to peer support and continuing professional education, supervision of junior staff, and the actual communication with counsellees. During the pilot phase, the tool has turned out to be helpful in external auditing as well as internal quality assessment.

The Informed Consent Process in Genetic Family Studies. *N. Arar[1,2], L. Panoyan[1], S. Lee[1,2], M. Parchman[1,2], P. Noel[1,2], H. Abboud[1,2]* 1) Dept Medicine, Div Nephrology, Univ Texas Health Sci Ctr, San Antonio, TX; 2) South Texas Veterans Health Care System, Sa, TX.

We examined subjects comprehension of the risks, and benefits associated with their participation in genetic family study (GFS). A cross-sectional study design was employed. A short self-administrative questionnaire was provided to 246 participants who were recruited from families enrolled in the Extended Family Investigation of Nephropathy and Diabetes (EFIND) study conducted at UTHSCSA. Participants responded to the questionnaire directly after their enrollment in the EFIND study. The questionnaire consisted of multiple choice questions and focused on the purposes, procedures, benefits and risks associated with their participation in the EFIND study. These questions were formulated to reflect basic information presented to subjects through the consent process. Responses to questions were expressed as percentages placing equal weight on each response. Average comprehension score of individual subject for all questions was calculated. Then, the total average comprehension score of each question was calculated for all participants. The software package, SPSS (v9), was used to analyze quantitative data. Participants were 62.3% female and averaged 35.2 12.7 years old (range: 18-76). Our findings showed that the average comprehension score was 58. About 30% of the participants did not know the name of the study, and 70% did not identify all elements related to the study procedures. The most striking finding was the lack of understanding concerning the social risks associated with participation in EFIND. While 35.1% of participants identified all potential physical risks, only 1.3% could identify all of the social risks. Our findings showed that participants comprehension score was significantly associated with their level of education ($r=0.2216$, $p=0.0062$) and income ($r=0.2214$, $p=0.0156$). Examination of the current system used for protecting human subjects participating in genetic research has highlighted concerns about its overall effectiveness. Future research directed at improving the communication of risks to subjects of low socioeconomic levels is justified.

A common cytokine profile in Fabry, Gaucher and Hunter diseases. *P. Rozenfeld, N. De Francesco, C. Fossati* Dept Immunolgia, Univ Natl de La Plata, Buenos Aires, Argentina.

A common cytokine profile in Fabry, Gaucher and Hunter diseases Rozenfeld P, De Francesco N, Fossati C LISIN, Facultad de Ciencias Exactas, Universidad Nacional de La Plata. Argentina. The pathophysiology of lysosomal storage diseases (LSD) is not well understood, and it is not solely explained by the burden of storage material. Other concurrent pathological mechanisms are elicited, giving together the phenotypic expression of the diseases. Studies in a spectrum of lysosomal storage disorders showed the upregulation of proinflammatory cytokines. To our knowledge, no analysis of cytokine production by real time PCR in immune cells from Fabry, Gaucher and Hunter human patients has been reported. The aim of this work is to study the cytokine expression in these group of LSD. Blood samples from patients with Fabry (n=24), Gaucher (n= 8) Hunter (n= 8) and 20 normal controls were obtained. Mononuclear cells were separated by Ficoll and cytokine RNA expression by qPCR was determined. A significantly higher expression level of mRNA of IL-1 (p=0.02) and TNF (p=0.03) was observed in mononuclear cells from Fabry patients as compared to normal controls. An overexpression of IL-6 and TNF was detected in Gaucher and Hunter cells in comparison to control individuals. No signs of induction of the genes for IL-4 or IFN was observed in any of these disorders. In conclusion, the cytokine profile overexpressed in Fabry, Gaucher and Hunter immune cells is characteristic of an innate immune response and inflammation, however no signs of induction of an adaptive immune response were detected.

Definitive Diagnosis of Glycogen Storage Disease (GSD) by Molecular Analysis. *N. J. Beauchamp, A. Dalton, S. Tanner, M. Sharrard* Sheffield Children's NHS Foundation Trust, Sheffield, United Kingdom.

Background Hepatic GSDs can cause hypoglycaemia, hepatopathy, lactic acidosis and variable myopathy, requiring different treatment. We have established a diagnostic molecular analysis service for GSDs 0, Ia, Ib, III, IV, VI and IX.

Methods 214 patients were referred with a clinical suspicion of a hepatic GSD or with abnormal enzymology. All exons of the respective genes were sequenced from genomic DNA.

Results Molecular analysis confirmed the diagnosis in 136 (64%) patients. In 19 (14%) of these the analysis changed the diagnosis; with a change of inheritance pattern between X-linked and autosomal, in 16. Mutations were identified in 59 (79%) of 75 suspected GSD IX patients: 45 (76%) had X-linked, and 14 autosomal, GSD IX. Analysis of the 31 patients with suspected GSD VI confirmed 9 (29%) identifying mostly missense mutations in exons 16 and 17. The 11 patients analysed further all had GSD IX. GSD III was confirmed in 39 (83%) of 47 patients. 85% of mutations were null and were located throughout the gene. Patients without muscle symptoms all had exon 3 mutations. Three (18%) of 17 patients analysed had *GYS2* mutations confirming GSD0. GSD Ia was confirmed in 14 (78%) of 18 patients but 2 (11%) were re-diagnosed with GSD Ib. Of the 19 patients with suspected GSD Ib, 11 (58%) had mutations. GSD IV was confirmed in 2 (40%) of 5 patients allowing prenatal diagnosis for one couple.

Conclusions Diagnosis of GSD I can be routinely performed by molecular analysis avoiding liver biopsy and reclassifying between Ia and Ib. Enzymology is inaccurate in distinguishing GSD VI and IX and GSD IX inheritance. Molecular analysis has reassigned both suspected GSD VI patients and inheritance in a significant number of patients. Targeted analysis may be possible in GSD VI but not in GSD III. *GYS2* mutations are found in patients with ketotic hypoglycaemia, though rarely. Molecular analysis for GSD gives a definitive diagnosis and allows rapid, non invasive family studies, including prenatal diagnosis and thus has a first line role in the diagnosis of GSDs.

Towards a pharmacological therapy for Mandibuloacral Dysplasia sindrome. *A. Vielle-Canonge[1], F. Gullotta[2], S. Salvatori[2], P. Molinaro[2], F. Lombardi[1], S. Ciacci[2], M. D'Adamo[3], P. Sbraccia[3], A. M. Nardone[2], M. R. D'Apice[1,2], G. Lattanzi[4], N. M. Maraldi[4], G. Novelli[1,5]* 1) Department of Biopathology , University of Tor Vergata, Rome, Italy; 2) Department of Medical Genetics, A.O.U. Recently, different groups have demonstrated that the farnesyl transerase inhibitors (FTIs) were able to reverse in-vitro and in-vivo some phenotypic manifestations of progeroid syndromes secondary to LMNA and/or ZMPSTE24 mutations (Hutchinson-Gilford progeria syndrome and restrictive dermopathy). The rationale of this treatment is based on blockage of the toxic effect of the farnesylated forms of prelamin A which in turn is responsible of cellular morphology alterations and genomic instability. In order to verify if this treatment is reproducible also in the mandibuloacral dysplasia (MADA), we studied the cellular effects of FTIs treatment on primary fibroblasts cell lines after 72 hrs at different concentrations (10 - 500 nM) of the drug. We observed that this treatment induces in MADAs cells, an increase of abnormal nuclei in a dose-manner dependent effect. On the basis of these results, we decided to test the effect of two different drugs (bisphosphonates and statins) known to act on the same biochemical pathway at different levels. We treated MAD fibroblasts in a two steps model (24 hrs statins treatment and then 12hrs bisphosphonate in a single dose). This treatment, showed an improvement of the cellular phenotype (reduction of the number of misshapen nuclei and a partial rescue of the heterochromatin organization). Singularly, these drugs were ineffective. All together these results, suggest that FTI treatment is ineffectiveness versus MADA patients, while inhibitors of prenylation pathways could be considered as potential. This work was supported by the AIFA (Italy) and EURO-Laminopathies (Contract LSHM-CT-2005-018690).

A mouse model heterozygous for protein kinase A regulatory subunit type 1A and catalytic subunit A deficiency develops multiple bone lesions. *K. Tsang[1], M. Starost[2], M. Nesterova[1], S. Boikos[1], A. Li[1], M. Harran[1], C. A. Stratakis[1]*
1) SEGEN, PDEGEN, NICHD, NIH, Bethesda, MD; 2) ORS, DVR, NIH, Bethesda, MD.

Carney Complex is a multiple neoplasia syndrome caused by PRKAR1A-inactivating mutations; PRKAR1A is the type 1A regulatory subunit of protein kinase A (PKA). We have shown that prkar1a+/- mice developed a variety of tumors including tail osteotic lesions. We hypothesized that altered catalytic (C) subunit activity may cause PKA dysfunction that leads to these tumors. Prkar1a+/- mice were crossed with animals heterozygous for the main PKA C subunit (Ca) [Ca+/- mice]; 30 R1a/Ca mice were studied (up to 18 months of age) along with control heterozygote or normal animals. R1a/Ca mice had no endocrine or other tumors except an increased number of tail osteotic lesions. Cartilaginous metaplasia/chondromas were only observed in marrow cavities of long bones and vertebral bodies of R1a/Ca mice. Tail lesions from R1a/Ca mice showed higher PKA activity which was accompanied by a significant decrease in Ca expression; thus Ca was not the only C subunit responsible for increased PKA activity. Immunohistochemical and protein expression analysis implicated potential involvement of PKA catalytic subunit gamma (Cg) and x-linked protein kinase (Prkx) in these lesions. By qRT-PCR and immunohistochemical analysis, we demonstrated an increase in runt-related transcription factor 2 (Runx2), which has been shown to be a major factor in the development of osteoblastic cells and bone formation. It is speculated that increased Runx2 leads to uncontrolled proliferation and differentiation of osteoblasts, and results in the development of cartilaginous chondromas. We conclude that Ca deficiency in prkar1a+/- mice prevents the development of all other tumors but not those of the skeleton; the latter are in fact characterized by increased PKA activity that maybe due to alternate C subunits such as Cg and Prkx (and possibly other factors). Increase in Runx2 expression in these lesions suggests an uncontrolled differentiation of osteoblasts in the background of Ca deficiency; these data point to a previously unknown role of PKA C subunit in the control of osteoblastic proliferation and/or differentiation.

The systematic deficit of heterozygote genotypes in Illumina WGA genotyping is largely explained by null alleles.

G. J. te Meerman[1,2], A. de Vries[2], M. Niens[2], M. Bruinenberg[2], E. Oosterom[2], C. Wijmenga[2], P. Nürnberg[3], D. S. Postma[2], G. H. Koppelman[2], S. M. Leal[1], R. M. W. Hofstra[2], Center for Genomics (CCG) University of Cologne D-50674 Köln/Germany 1) Statistical Genetics and Genetic Epidemiology, Baylor College of Medicine, one Baylor plaza, 77030, Houston, TX USA; 2) University of Groningen and University Medical Center, Hanzeplein 1, 9713AZ Groningen, The Netherlands; 3) Center for Genomics (CCG) University of Cologne D-50674 Köln/Germany.

The signal quality for genotype cluster separation in Illumina genotyping arrays can be improved by taking array specific red/green variation into account. The resulting signal to noise ratio is then typically in a range between 9 and 14 and an improved copy number signal is obtained. The genotyping quality is so high that Mendelian errors, even rare ones appearing a single time in large scale investigations, should hardly occur by chance. In trio genotyping data, a null allele can cause a parent to appear homozygous for one allele and a child homozygous for the other allele. Using autosomal data of 320K Illumina WGA data from 460 trio's we identified 7650 loci with 30269 pairs of a parent homozygous for one allele and a child homozygous for the other allele. A clear signal deficit was observed in these loci, although less pronounced than for the male-female X chromosome difference, indicating that the null alleles have no complete loss of signal. Much longer haplotype sharing exists surrounding the haplotype carrying the putative null allele in contrast with control haplotypes, supporting a more recent origin of the null allele. Average Hardy-Weinberg statistics over all SNP's point to a systematic deficit of about 0.1 % or 386,000 heterozygote autosomal genotypes, possibly caused by null-alleles. Comparison of signal strength at the 7650 loci between case and control haplotypes suggests that null alleles explain most of the deficit in the observed systematic deviation from Hardy-Weinberg equilibrium. Based on haplotype similarity correction of genotypes by resetting the null allele to its original allele at detected loci is feasible.

Geographic Ancestry and Genetics Affect Distinct Pathophysiologic Pathways in Spontaneous Preterm Birth: An Explanation of Disparity. *R. Menon[1], D. Velez[2], S. Fortunato[1], S. Williams[2]* 1) Perinatal Research Ctr, Nashville, TN; 2) Ctr Hum Gen Res, Vanderbilt University, Nashville, TN.

Disparity of preterm birth (PTB) rate between African Americans (AA) and Caucasians (C) (18.5% vs. 12.7%, respectively) is unexplained. Genetic variation has been suspected, and in several genes single SNPs associated with PTB may explain some of the disparity. We performed a large-scale analysis of 1432 SNPs in 130 candidate genes from PTB pathways using a case (PTB)-control (normal term study delivery) design to test for patterns of association in AA and C. Maternal and fetal DNA from 370 (172 cases and 198 controls) C and 279 AA (82 PTB and 197 term) were studied. Single locus association analyses on both maternal and fetal samples were performed. Kyoto encyclopedia of genes and genomes (KEGG) was used to group genes into potential biological pathways. The strongest single locus associations differed in the two races in both maternal and fetal DNA samples. In C maternal DNA, the most significant association was in plasminogen activator tissue (PLAT) gene (rs879293) for both allele (p = 2.00x10-3) and genotype (p=2.0x10-6) association with an odds ratio (OR) of 2.80 [CI 1.77-4.44]. The strongest effect in C fetal DNA was observed in the interleukin-10 receptor antagonist gene (rs17121510) for both allele (p=0.01) and genotype (p=3.34x10-4, OR 1.92 [CI 1.15-3.19]). In AA, the most significant associations were in Interluekin-15 (rs10833, allele p=2.91x10-4, genotype p=2.0x10-3) in maternal DNA with an OR=0.30 [CI 0.14-0.62] and in fetal DNA Interleukin-2 receptor B (rs84460, allele p=1.4x10-4, genotype p=6.3x10-4) with an OR 2.32[CI 1.47-3.67]. Pathway analysis also revealed disparity in PTB by ancestry. In C maternal gene variants had a significant excess of associations in complement-coagulation pathway. Whereas, in AA fetal DNA the infection/inflammation pathway had significantly more associations than expected by chance. Overall, the data suggest that PTB in AA is driven by fetal genotype while in C it is maternal genotype. Therefore, although the terminal events leading to PTB may be the same, upstream pathways appear to differ between African Americans and Caucasians.

Glutaric Aciduria, Type 3: Genetic Mapping to Chromosome 7 and Identification of Mutations in *C7orf10*. *E. A. Sherman[1,2], K. A. Strauss[2], M. J. Bennett[3], D. H. Morton[2], E. G. Puffenberger[2]* 1) Ephrata High School, Ephrata, PA; 2) Clinic for Special Children, Strasburg, PA; 3) Children's Hospital of Philadelphia, Philadelphia, PA.

While screening Old Order Amish infants and newborns for glutaric aciduria type 1 (GA1), we identified three healthy children who excreted abnormal quantities of glutaric acid but low or no 3-hydroxyglutaric acid, a pattern consistent with glutaric aciduria type 3 (GA3). None of the three children harbored the *GCDH* c.1262C>T mutation for GA1 that is known to segregate in the Old Order Amish population. We initiated a genome-wide mapping study using Affymetrix 10K SNP Mapping Arrays and identified a homozygous 4.7 Mb region on chromosome 7 common to all three children. This region contained 25 known genes, including *C7orf10*, an open reading frame predicted to contain a mitochondrial targeting sequence and a coenzyme-A transferase domain. PCR and sequencing of the 15 coding exons of *C7orf10* revealed that all three Amish individuals were homozygous for a non-synonymous sequence variant, c.895C>T (Arg299Trp). An additional non-Amish GA3 patient was sequenced for *C7orf10* and was found to be a compound heterozygote for the Amish variant and a second nonsense mutation, c.424C>T (Arg142Ter). Subsequently, a DNA sample from the original GA3 patient described by Bennett et al. (1991) revealed homozygosity for a novel nonsense variant, c.322C>T (Arg108Ter). This small-scale mapping study firmly establishes *C7orf10* as the causative gene for glutaric aciduria, type 3. Future studies that determine the exact biochemical relationship between *C7orf10* and *GCDH* may establish a foundation for more effective treatment of GA1.

Characterization of N-terminal huntingtin Fragments that Accumulate in the Nucleus. *L. R. Smith[1,2], S. H. Li[1], X. J. Li[1]* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Graduate Program in Genetics and Molecular Biology, Emory Univ, Atlanta GA.

Huntingtons disease (HD) is an autosomal dominant, late-onset neurodegenerative disorder characterized by the expansion of a polyglutamine (polyQ) repeat located in the N-terminal region of the huntingtin (htt) protein. Wild-type htt consists of less than 36 glutamine repeats whereas the mutant version of the protein has an expanded polyQ repeat of greater than 37 glutamines. Htt is normally a cytoplasmic protein but in HD, N-terminal fragments of mutant htt localize to the nucleus to form inclusions. In the nucleus, mutant htt has been shown to aberrantly interact with various proteins such as the transcription factors Sp1 and TAFII130. The nuclear toxicity of mutant htt is indicated by the fact that mutant htt preferentially accumulates in the nuclei of striatal neurons, which are most vulnerable in HD. However, the mechanism for the nuclear accumulation of mutant htt remains to be investigated. We first aimed to identify the size of the mutant htt fragment that can accumulate in striatal nuclei. We transfected HEK 293 cells with N-terminal htt fragments of various lengths (212, 300 and 500 amino acids). Using immunocytochemistry and nuclear fractionation techniques, we analyzed whether each of the fragments could accumulate in the nuclei. We found that the smaller fragment of 212 amino acids showed more nuclear accumulation than larger fragments of 300 and 500 amino acids. Next we aimed to identify nuclear proteins whose expression is altered by mutant N-terminal htt expression. To this end, we are using an approach known as SILAC (Stable Isotope Labeling in Cell Culture) to compare nuclear protein profiles in HEK 293 cells transfected with N212-htt containing 150Q and 23Q. These studies aim to reveal how mutant htt accumulates in the nucleus and affects nuclear function. Supported by NIH grants NS 045016 and NS41669.

Computing power and sample size for case-control association studies with copy number polymorphism: application of mixture-based likelihood ratio test. *S. Finch[1], W. Kim[2], D. Gordon[3], J. Sebat[4], K. Ye[5]* 1) Dept Applied Math, Stony Brook Univ, Stony Brook, NY; 2) Dept Math and Stat, Univ S Florida, Tampa, FL; 3) Dept Genetics, Rutgers Univ, Piscataway, NJ; 4) Cold Spring Harbor Labs, Cold Spring Harbor, NY; 5) Albert Einstein College Medicine, Bronx, NY.

Background: Recent studies suggest that copy number polymorphisms (CNPs) may play an important role in disease susceptibility and onset. Currently, the detection of CNPs mainly depends on microarray technology. For case-control studies, conventionally, subjects are assigned to a specific CNP category based on the continuous quantitative measure produced by microarray experiments, and cases and controls are then compared using a chi-square test of independence.

Methods/Results: The purpose of this work is to specify the likelihood ratio test statistic (LRTS) for case-control sampling design based on the underlying continuous quantitative measurement, and to assess its power and relative efficiency (as compared to the chi-square test of independence on CNP counts). The sample size and power formulas of both methods are given. For the latter, the CNPs are classified using the Bayesian classification rule. The LRTS is more powerful than this chi-square test for the alternatives considered, especially alternatives in which the at-risk CNP categories have low frequencies. An example of the application of the LRTS is given for a comparison of CNP distributions in individuals of Caucasian or Taiwanese ethnicity, where the LRTS appears to be more powerful than the chi-square test, due to misclassification of the most common CNP category into a less common category.

Conclusions/Significance: Substantial power may be gained by performing case-control analyses on the underlying CNP quantitative measures rather than on categorical data derived from these measures. Our method quantifies this power increase.

P14 GENOMIC AND EPIGENETIC CHANGES: NO CORRELATION WITH DNA MISMATCH REPAIR DEFICIENCY IN COLORECTAL CANCER. *C. Nyiraneza[1], C. Sempoux[2], A. Kartheuser[3], R. Detry[3], K. Dahan[1]* 1) Human Genetics Unit, Université Catholique de Louvain; 2) Department of Pathology, Cliniques Universitaires St Luc, Brussels; 3) Department of Colorectal Surgery, Cliniques Universitaires St Luc, Brussels.

The tumor suppressor gene *p14* is a major sensor of oncogenic stress in mammalian cells. p14 antagonizes MDM2 protein Ub-ligase activity, thereby stabilizes p53 protein. *p14* promoter methylation has been involved in colorectal cancer (CRCs), particularly in microsatellite instability (MSI) CRCs. Here we correlated the genomic and epigenetic alterations at *p14* locus with the molecular nature of DNA mismatch repair system (MMR) defects resulting in MSI, and we compared these data with *p53* status. Ninety eight CRCs were tested for *p14* methylation using Methylation Specific PCR (MSP) completed by BSP cloning and sequencing, for gene dosage and mutations (exon 1 and exon 2) in *p14* gene, as well as for p53 protein immunohistochemistry (IHC) and *p53* mutation analysis. MMR system sufficiency was assessed by MMR proteins IHC, MSI status and *MLH1*/*MSH2* germline mutation screening, *MLH1* promoter methylation and *BRAF* hot spot exon scanning. Overall, *p14* promoter hypermethylation was observed in 7 tumors (7/98; 7.1%). Of them, 3 were MSI-High CRCs due to MLH1 promoter silencing (1/3), and associated with p.V600E *BRAF* activating mutation (1/3), and 4 were microsatellite stable (MSS) CRCs showing a p53 protein overexpression, with two *p53* hotspot mutations [p.R158H, p.R267Q] (1/4). By contrast, both methylated and unmethylated alleles were detected in 91 CRCs (93%), 22 out them were MSI (MSI-High versus MSS, P>0.05), and the same profile was observed in all adjacent normal tissues (100%). Clonal bisulfite sequencing showed a mosaic state of *p14* promoter methylation in tumors and adjacent normal mucosa tested. The distribution of methylated CpG sites among clones was heterogeneous, showing no specific profile. No allelic imbalance was detected, and mutation analysis revealed one somatic mutation (p.A121V) in *p14* gene. Our data showed no significant correlation between *p14* hypermethylation and MSI status in CRCs. *p14* promoter silencing and somatic mutations appear as rare events in colorectal carcinogenesis.

Genetics variants in Sar1B gene associated with Chylomicron retention disease. *R. Sanchez[1], E. Levy[1,2], D. Sinnett[1,3]* 1) Research Center, CHU Sainte-Justine, University of Montreal, Montreal, Canada, H3T 1C5; 2) Department of Nutrition, University of Montreal, Canada, H3C 3J7; 3) Department of Pediatrics, University of Montreal, Canada, H3C 3J7.

Chylomicron retention disease (CMRD) is a rare, autosomic recessive disorder characterized by severe fat malabsorption associated with chronic diarrhea, failure to thrive, and hypocholesterolemia in childhood. The requirement of Sar1B for the intracellular CM transport has only recently been established in view of specific mutations in Sar1B gene. These mutations are directly associated with the disease-related phenotypes. Given the wide range of biochemical and clinical manifestation of CRMD, we suspect the presence of novel Sar1B mutations and/or DNA variants (SNPs). To address this issue we resequenced the Sar1B exons and promoter regions to detect new SNPs that could be associated with CRMD. Genomic DNA from peripheral blood cells was isolated from 14 CRMD patients that have been treated for a fat malabsorption syndrome associated with diarrhea and steatorrhea. PCR products corresponding to the proximal promoter region (2514 bp) and all 6 exons (763 bp) were directly sequenced to detect novel SNPs in Sar1B gene (Ref Seq NM_016103). We identified 10 known DNA variants including 7 promoter SNPs and 3 coding SNPs (cSNPs), two in exon 4 and one in exon 8. None of these SNPs were polymorphic in the group of patients (n=14) investigated. In addition, we also found four mutations (Glu122X, Asp137Asn, Ser179Arg and Gly185Val) known to be associated with CRMD phenotype. The SNP frequency and haplotype structure were also determined. More work is needed to investigate the impact of these Sar1B gene variants on lipid parameters, apolipoprotein profile and clinical features.

Allelic expression of the *MMACHC* gene and genotype-phenotype correlations in *cblC* disease. *N. Anastasio[1,2], J. P. Lerner-Ellis[1,2], T. M. Pastinen[1,2,3], J. Liu[1,2], D. Coelho[4,5], T. Suormala[4,5], M. Stucki[4,5], A. Loewy[1,2], S. Gurd[1,3], E. Grundberg[1,2,3], C. F. Morel[6], M. R. Baumgartner[4,5], D. Watkins[1,2], B. Fowler[4,5], D. S. Rosenblatt[1,2]* 1) Department Human Genetics, McGill University, Montreal, Canada; 2) Department of Medical Genetics, McGill University Health Centre, Montreal, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 4) Metabolic Unit, University Childrens Hospital, Basel, Switzerland; 5) Division of Metabolism and Molecular Pediatrics, University Childrens Hospital, Zürich, Switzerland; 6) Department of Medicine, University Health Network, University of Toronto, Canada.

Combined methylmalonic aciduria and homocystinuria, *cblC* type, caused by mutations in *MMACHC* located in chromosome region 1p34.1, results from the inability to convert intracellular vitamin B_{12} (cobalamin) into its two active coenzyme forms. Methylcobalamin is required by methionine synthase in the conversion of homocysteine to methionine, and adenosylcobalamin is required by methylmalonyl-CoA mutase in the conversion of methylmalonyl CoA to succinyl CoA. Individuals with *cblC* disease may present early in life or at a much later age. With regard to genotype-phenotype correlation, individuals with the c.394C>T (p.R132X) mutation generally have late onset of disease whereas patients with the c.331C>T (p.R111X) and c.271dupA (p.R91KfsX14) mutations usually present in infancy. Previous quantitative real-time RT-PCR studies showed increased *MMACHC* mRNA transcript levels in patients homozygous for the late-onset c.394C>T mutation when compared to both controls and patients homozygous for the early onset c.271dupA and c.331C>T mutations. Allele-specific expression analysis was carried out on human *cblC* fibroblasts with compound heterozygous mutations. Increased transcript levels were consistently observed from the c.394C>T allele when compared to the c.271dupA and c.331C>T alleles. Understanding the mechanisms underlying differential *MMACHC* transcript levels may provide a clue as to why individuals carrying the c.394C>T mutation generally present later in life.

Genetic interactions and vision defects of Bardet-Biedl Syndrome chaperonin-like genes in the zebrafish: pair-wise knockdown suppresses Kupffers vesicle phenotype. *L. Baye[1], E. M. Stone[2,3], V. C. Sheffield[3,4], D. C. Slusarski[1]*
1) Dept of Biology, Univ of Iowa, Iowa City, IA; 2) Dept of Ophthalmology, Univ of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute; 4) Dept of Pediatrics, Univ of Iowa, Iowa City, IA.

Bardet-Biedl Syndrome (BBS) is a pleiotropic, genetically heterogeneous autosomal recessive disease characterized by obesity, retinal degeneration, polydactyly, kidney malformations, hypogenitalism and learning disabilities. Twelve BBS genes have been identified to date and although the precise roles of the BBS proteins are yet to be elucidated, cilia and cilia-related functions appear to be central features of the disorder. To gain insight into the pathophysiology of BBS, as well as potential BBS gene interactions, we are utilizing the zebrafish model system. My work has focused on characterizing phenotypes associated with three identified chaperonin-like CCT family members that underlie approximately 25% of BBS cases: BBS 6, 10 and 12. Upon individual knockdown of these genes using antisense morpholinos, we found defects in the formation of a transient ciliated structure known as Kupffers vesicle as well as delays in melanosome transport. These two phenotypes are the cardinal features of BBS gene knockdown in zebrafish. Previously published work utilizing these two phenotypes determined genetic interactions in a subset of BBS genes, *bbs1-8*. Because members of the CCT family are known to interact as complexes, we tested genetic interactions among the BBS chaperonin-like genes. Interestingly, pair-wise co-injections of low dose BBS morpholinos suggest that BBS6 and BBS10 interact genetically to suppress the Kupffers vesicle defect. In addition, to examine the molecular and cellular pathways underlying vision loss in BBS, we are utilizing vision screening assays specific to the zebrafish. The first assay measures an adaptive response to light in which zebrafish contract pigment. The second assay measures cone visual function by examining a behavioral escape response to a visual stimulus. Vision analyses on morpholino injected embryos indicate reduced visual function with knockdown of BBS12.

EARLY-ONSET SEIZURE VARIANT OF RETT SYNDROME IN A 47,XXY BOY WITH A NOVEL CDKL5 MUTATION. *S. Sartori[1], R. Polli[2], G. Di Rosa[3], E. Bettella[2], G. Tricomi[3], G. Tortorella[3], A. Murgia[1,2]* 1) Pediatric Neurology Unit, Department of Pediatrics, University of Padua, Padua, Italy; 2) Rare Disease Laboratory, Department of Pediatrics, University of Padua, Padua Italy; 3) Infantile Neuropsychiatry, Department of Medical and Surgical Pediatrics, University Hospital of Messina, Messina Italy.

Mutations in the X-linked cyclin-dependent kinase-like 5 (CDKL5) gene have recently been found in patients with severe neurodevelopmental disorders, including infantile epileptic encephalophathy, severe X-linked infantile spasms (ISSX) and mental retardation, autism, and the early-onset seizure variant of Rett syndrome. As part of a clinical and molecular study we are conducting on encephalopaties of the first year of age associated with epilepsy, we have ascertained a child presenting with a severe early-onset epileptic encephalopathy, mild dysmorphic features, global developmental delay, and profound intellectual and motor impairment reminiscent of Rett syndrome. A standard karyotype analysis showed the presence of two copies of the X chromosome (47XXY by ICN 2005). A mutation scanning and quantitative analysis of the MECP2 gene coding sequence resulted negative, while the molecular analysis of the CDKL5 gene allowed the identification of a de novo heterozygous mutation at nucleotide 1675 of the coding sequence (c.1675C>T) resulting in the creation of a premature stop codon (p.Arg559Stop). The pattern of X chromosome inactivation was found to be balanced. This pathogenic CDKL5 mutation, never previously described, truncates the large COOH-terminal region of the gene, crucial for the proper subcellular localization of the CDKL5 protein. We report the second case of intragenic CDKL5 mutations found in a male subject, the first one detected in an individual with 47,XXY karyotype. We would like to draw attention on the importance of considering the causal involvement of CDKL5 in males showing early onset seizures and Rett-like clinical features, as well as other phenotypes that have been related to mutations of this gene in females.

SNP Discovery in High-throughput Resequenced Microarray-Enriched Human Genomic Loci. *A. A. Antipova, T. D. Sokolsky, C. R. Clouser, E. T. Dimalanta, C. L. Hendrickson, C. Kosnopo, C. C. Lee CC, S. S. Ranade, L. Zhang, K. J. McKernan* Applied Biosystems, Beverly, MA.

Identifying genetic variants and mutations that underlie human diseases requires development of robust, cost-effective tools for routine re-sequencing of the regions of interest in the human genome. Here we demonstrate that coupling Applied Biosystems SOLiD^{TM} System sequencing platform with microarray capture of targeted regions provides an efficient and robust method for high-coverage re-sequencing and single nucleotide polymorphism (SNP) discovery in human protein-coding exons. Utilizing high-density Agilent microarrays with a custom probe design to pull down 4.3 Mb target DNA sequence from a HapMap Yoruba sample, we obtained sequencing coverage averaging138 tags per base (median coverage is 59) with 91% of target sequence covered by at least one tag. This level of coverage enabled highly accurate and sensitive SNP detection. 99.9% of identified homozygous HapMap SNPs were called correctly, and 96.2% of heterozygous HapMap SNPs found de novo by us were correctly identified. Additional 35 SNPs, called unknown in HapMap (not defined as either homo- or heterozygous in HapMap), were Sanger-sequenced to verify their identity, and 96% of these SNPs were correctly called by SOLiD^{TM}. On the whole, 3526 SNPs were de novo discovered by SOLiD^{TM} in the target regions, with 73% of these SNPs overlapping positions in dbSNP database. The remaining 27% are novel SNPs. These results demonstrate that the combination of SOLiD^{TM} resequencing with microarray capture of the selected genomic regions provides a powerful tool for genetic analysis and will expedite the search for genes contributing to inherited common diseases and the diseases in which somatic mutations play a role, such as atherosclerosis and cancer.

Fragile X intermediate and small premutation alleles (45 - 69 repeats): Instability on transmission. *S. L. Nolin, A. Glicksman, T. Sukontasup, N. Hosmer, C. Dobkin, W. T. Brown* Human Genetics Dept, NYS Institute for Basic Research in Developmental Disabilties, Staten Island, NY.

We have examined the transmission of 210 alleles in 85 families with fragile X CGG repeats from 45 to 69 identified through population screening. Most (181) of the transmissions were maternal with the remaining 29 paternally transmitted. 40% (72/181) of maternal transmissions were unstable.

Maternal CGG Repeats	No. Unstable/total (%)	Average Repeat Change
45-49	6/26 (23)	1.7
50-54	11/47 (23)	3.1
55-59	30/69 (43)	2.2
60-64	11/22 (50)	5.2
65-69	14/17 (82)	14.4

For alleles with fewer than 65 repeats, most of the expansions were limited to 1 to 6 repeats. The most notable exceptions were an expansion from 54 to 85 repeats and a contraction from 53 to 33 repeats. Most alleles with 65-69 repeats increased by 20 to 27 repeats although some increased by 2 to 5 repeats. No expansions to full mutation were observed among the newly identified families. For the paternal transmissions 30% (9/29) were unstable; 8 were expansions ranging from 2 to 8 repeats and 1 was a contraction of 2 repeats. These results suggest that most alleles identified through population screening exhibit less instability than alleles with the same repeat size identified in families with affected individuals.

Age-related hearing loss is not caused by variants in the connexin genes that are implicated in prelingual deafness. *A. L. Souza[1], P. Libby[1], F. M. Mapes[2], S. T. Frisina[2], D. A. Eddins[2,3], R. D. Frisina[2,3], D. L. Newman[1]* 1) Biological Sciences, Rochester Institute of Technology, Rochester, NY; 2) International Center for Hearing and Speech Research, Rochester Institute of Technology, Rochester, NY; 3) Otolaryngology, University of Rochester Medical Center, Rochester, NY.

Mutations in the connexin genes, which are critical for cochlear gap junctions and K^+ cycling, are the most common cause of nonsyndromic sensorineural deafness. We investigated whether these genes are involved in the related phenotype of presbycusis (age-related hearing loss), a complex, progressive disorder that affects up to half of all elderly Americans. We targeted specifically *GJA1*, *GJB2*, *GJB3*, and *GJB6*, all of which code for connexins localized in the inner ear, and all of which have been associated with prelingual deafness. A screening set of 24 European-American subjects was sequenced for variants in the exon and upstream regulatory regions of each gene. No common amino acid changes were found, though three were observed at low (2%) frequency. We identified 13 variants in *GJA1*, 12 in *GJB2*, 22 in *GJB3*, and 7 in *GJB6*. In the 1 kb upstream region of *GJA1*, 9 rare variants were found, 7 of which were only observed in affected subjects and not in controls. To investigate whether or not variants in the *GJA1* promoter region are important, an additional 100 (50 best and 50 worst hearing) samples were sequenced. All SNPs were found at a low frequency, and there was no significant difference between the two groups. Genotyping of four SNPs in *GJB2* for ~600 European-American subjects indicates that there is no association between genotype and hearing phenotypes in our population. We are continuing to genotype additional SNPs in each of the four genes, but it appears that connexin gene variants do not play a significant role in the development of presbycusis.

Congenital Disorder of Glycosylation Type Ia Due to Paternal Uniparental Isodisomy 16. *G. E. Tiller[1], R. R. Mardach[1, 2], A. Still[3], T. C. Wood[3]* 1) Dept Genetics, Kaiser Permanente, Los Angeles, CA; 2) Dept Pediatrics, UCLA Medical Center, Los Angeles, CA; 3) Greenwood Genetic Center, Greenwood, SC.

Congenital disorders of glycosylation (CDG) are a genetically heterogenous group of inherited metabolic diseases, each affecting the posttranslational processing of glycoproteins. We describe an infant with CDG type Ia, the most common of these disorders, due to paternal uniparental isodisomy for chromosome 16. She was the second child born to a Mexican mother and Cambodian father. She presented at 5 months of age with acute respiratory failure due to bronchiolitis, hepatomegaly, and a history of neonatal apnea, hypotonia, failure to thrive, and microcephaly. Physical exam further revealed growth retardation, inverted nipples, and enlarged vulvar fat pads. Brain MRI revealed cerebral and cerebellar atrophy; liver biopsy revealed severe steatosis with moderate fibrosis. Spectroscopic analysis of serum transferrin exhibited increased asialo and disialo isoforms. Sequence analysis of the phosphomannomutase 2 (PMM2) gene revealed homozygosity for a c.G691A transition, resulting in amino acid substitution p.Val231Met. Due to the relative rarity of this allele and few reported cases of homozygosity for PMM2 mutations, analysis for uniparental disomy (UPD) was undertaken. Genotyping of the patient and parents at eight markers spanning all of chromosome 16 was consistent with paternal uniparental isodisomy. This case represents the first report of an individual with paternal UPD 16 and a clinically significant phenotype, as well as the first report of an individual with CDG Ia due to UPD. The apparent lack of clinical findings beyond the CDG phenotype supports the hypothesis that there are no areas of imprinting on human chromosome 16.

Global distribution of human progesterone receptor genetic variants. *L. C. Rockwell[1,2], K. Arnson[1], E. J. Rowe[1], F. Jackson[3], J. G. Lorenz[2,4]* 1) Temple University, Philadelphia, PA, 19122; 2) Central Washington University, Ellensburg, WA, 98926; 3) University of Maryland, College Park, MD, 20742; 4) Coriell Institute for Medical Research, Camden, NJ, 08103.

The progesterone receptor (PR) is a transcription factor that mediates the physiological actions of progesterone. Genetic variants of the PR gene have been investigated for associations with reproductive cancers (breast, ovarian, endometrial and prostrate) as well as other disorders and phenotypes (uterine fibroids, recurrent abortion, implantation failure following IVF, panic disorder, prolactin levels, and mammographic density) in several study populations self-identified as white/Caucasian. Little information exists about the frequency of potentially risk-conferring or protective variants in non-white populations. We genotyped 289 individuals from 21 populations derived from Europe, Asia, Africa, the Middle East, and North America, for 4 genetic variants of the PR (+331 G/A, PROGINS, rs561650, and rs608995). These populations include ethnic groups, geographically defined groups, and CEPH samples from Utah. Samples were obtained from Coriell Institute (Camden, NJ) or collected in the field with informed consent. +331 G/A, a single-base pair substitution in the promoter region which may increase transcription of the B isoform of the progesterone receptor protein, is polymorphic in all European populations but not elsewhere with the exception of one population in the Middle East (Druze) and one in Asia (Adygei). PROGINS, which includes an Alu insertion in intron G, occurs at highest frequency in the Middle East and European populations, lower frequency in the African-American population and CEPH samples, and is completely absent in the African and Asian populations excepting the Adygei. SNP rs561650 is polymorphic is all major geographic regions but absent in three populations: Senegal, Iberia and Cambodia. SNP rs608995 is polymorphic in all major geographic regions and all populations studied. The prevalence of progesterone-related reproductive cancers and disorders may differ among populations in part due to variable frequencies of these polymorphisms. (Support from Temple University.).

Genome-wide association study of vitamin D levels in Hispanic Americans: the IRAS Family Study. *C. D. Engelman[1], C. D. Langefeld[2], J. Ziegler[2], K. Taylor[3], J. I. Rotter[3], T. E. Fingerlin[4], J. M. Norris[4]* 1) University of Wisconsin, Madison, WI; 2) Wake Forest University, Winston-Salem, NC; 3) Cedars-Sinai Medical Center, Los Angeles, CA; 4) University of Colorado, Denver, CO.

Purpose: Vitamin D deficiency is associated with many adverse health outcomes, including several bone diseases, more than a dozen types of cancer, multiple autoimmune diseases, and type 2 diabetes. Two metabolites of vitamin D are commonly measured in blood, 25-hydroxyvitamin D (25[OH]D) and 1,25-dihydroxyvitamin D ($1,25[OH]_2D$). A few candidate gene association analyses and one linkage analysis of these vitamin D metabolites have been reported, however this is the first reported genome-wide association study. **Methods**: As part of the Insulin Resistance Atherosclerosis (IRAS) Family Study, 229 Hispanic Americans from 34 families in San Antonio, Texas were genotyped using the Illumina HumanHap300 BeadChip. Assuming an additive genetic model, SNPs were individually tested for association with 25[OH]D and $1,25[OH]_2D$ using variance components analysis implemented in SOLAR, adjusting for age, sex, body mass index, season of blood draw, and admixture for 25[OH]D and age, sex, 25[OH]D, and admixture for $1,25[OH]_2D$. **Results**: Of the 300,139 SNPs meeting all quality control criteria, three were significantly associated with 25[OH]D (p-value$5x10^{-6}$), two with unknown function on chromosome 1 (r^2=0.89) and the third on chromosome 9. Six SNPs were associated with $1,25[OH]_2D$ (p-value$5x10^{-6}$), four of which are all in the *DAB1* gene on chromosome 1 (r^2>0.58). The strongest overall signal was for an intronic SNP on chromosome 1 in *DAB1* (rs6680429) in association with 1,25[OH]2D (p-value=$6.63x10^{-9}$). **Conclusion**: We identified strong statistical evidence for three new SNPs associated with 25[OH]D and six new SNPs associated with $1,25[OH]_2D$ in an Hispanic American population that need to be further studied and replicated. These findings are important because 25[OH]D and $1,25[OH]_2D$ have a strong genetic component and serve as endophenotypes or biomarkers for multiple health outcomes. This study is also significant because Hispanics have been underrepresented in vitamin D research.

Evolutionary Forces Shape the Human RFPL1,2,3 Genes toward a Role in Neocortex Development. *S. I. Nikolaev[1], J. Bonnefont[1], A. L. Perrier[2], S. Guo[3], L. Cartier[1], S. Sorce[1], T. Laforge[1], L. Aubry[2], Ph. Khaitovich[3], M. Peschanski[2], S. E. Antonarakis[1], K.-H. Krause[1]* 1) Dept Genetic Med, Development, Univ Geneva, Geneva, Switzerland; 2) I-STEM, INSERM/UEVE UMR 861, Genopole Campus 1, 5 rue Henri Desbruères, 91030 Evry, France; 3) Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, 320 Yue Yang Road, 200031 Shanghai, China.

The size and organization of the brain neocortex dramatically changed during primate evolution. This is likely due to the emergence of novel genes after duplication events, evolutionary changes in gene expression, and/or acceleration in protein evolution. Here we describe a human Ret Finger Protein-Like (hRFPL)1,2,3 gene cluster on chromosome 22, which is transactivated by the corticogenic transcription factor Pax6. High hRFPL1,2,3 transcript levels were detected at the onset of neurogenesis in differentiating human embryonic stem cells and in the developing human neocortex, while the unique murine RFPL gene is expressed in liver but not in neural tissue. The history of the RFPL gene family revealed that the RFPL1,2,3 gene ancestor emerged after the Euarchonta-Glires split. Then, duplication events led to the apparition of multiple RFPL1,2,3 genes in Catarrhini (~34 mya), with an emphasis in the hominoid lineage as only human and orangutan kept the functionality of the three genes. In Catarrhini, RFPL1,2,3 expression diverged toward the neocortex and cerebellum over the liver. Importantly, humans showed a striking increase in cortical RFPL1,2,3 expression in comparison to their cerebellum and to chimpanzee and macaque neocortex. Acceleration in RFPL protein evolution was also observed with signs of positive selection in the RFPL1,2,3 cluster after the duplication events and two neofunctionalization events (acquisition of a specific RFPL-Defining Motif in all RFPLs and of a N-terminal 29 amino-acid sequence in catarrhinian RFPL1,2,3). Thus, we propose that the recent emergence and multiplication of RFPL1,2,3 genes contribute to changes in primate neocortex size and/or organization.

Hox genes are associated with clubfoot. *A. R. Ester[1], A. Burt[2], A. Scott[3], C. A. Gurnett[4], M. B. Dobbs[4,5], S. H. Blanton[2], J. T. Hecht[1,3]* 1) Univ Texas Medical School, Houston, TX; 2) Univ of Miami, FL; 3) Shriners Hospital for Children, Houston, TX; 4) Washington School of Medicine, St. Louis, MO; 5) Shriners Hospital for Children, St. Louis, MO.

Clubfoot is a common birth defect occurring in 1/700-1000 live births, and is a complex disease, with the environment, genetic variation and genetic-environmental interactions contributing to this birth defect. *HoxA* and *HoxD* gene clusters are involved in axial and limb patterning during embryonic development, and mutations in both *HoxA* and *HoxD* cause limb defects and syndromes with limb malformations. Because these genes regulate limb development, this study investigated the possibility that variations in *HoxA* and *HoxD* genes play a role in clubfoot. Twenty SNPs spanning these genes were genotyped in 160 nonHispanic white and 213 Hispanic trios and 121 nonHispanic white and 93 Hispanic families. A separate clubfoot population of 144 nonHispanic white trios was used in confirmation studies. Two SNPs in the 3 region of the *HoxD* gene cluster showed minimally significant altered transmission (p=0.02, p=0.04), but the closest *HoxD* genes are not expressed in the limb. Three SNPs in the *HoxA* cluster were significantly over-transmitted, and one of these was significantly over-transmitted in both the primary (p=0.0015) and secondary populations (p=0.028). This SNP is located in the basal promoter of *HoxA9* which is expressed during limb development. Gene-gene interactions were identified between variations in *HoxA* and *HoxD* with variations in apoptotic genes (*Apaf1*, *Bid*, *Casp3*, *Casp9* and *IGFBP3*) that were previously found to be associated with clubfoot. Interestingly, the most significant interactions were found between *Casp3* and *Bid* with both *HoxA* and *HoxD* variants. These interactions suggest a biologic model for clubfoot, with both *Hox* and apoptotic genes acting in a common mechanistic pathway. Interestingly, the SNP in the *HoxA9* promoter is 4kb downstream of a microRNA, miR196-b, which regulates both apoptotic and *Hox* genes. We have identified a previously unreported SNP that is two bases upstream of miR196-b. Together, this genetic variation may contribute to clubfoot.

Accounting for physical activity when testing for association of quantitative phenotypes with GWAS-derived candidate genes for diabetes: The IRAS Family Study. *S. Sibbel[1], J. Ziegler[2], N. Palmer[2], K. Young[1], D. Bowden[2], T. Fingerlin[1], R. Bergman[3], J. Norris[1]* 1) Colorado School of Public Health, Denver, CO; 2) Wake Forest University School of Medicine, Winston-Salem, NC; 3) Keck School of Medicine, University of Southern California, Los Angeles, CA.

Purpose: GWAS have identified several polymorphisms for type 2 diabetes. We recently published associations of these polymorphisms with 3 quantitative measures of diabetes phenotypes in the IRAS Family Study: insulin sensitivity (SI), acute insulin response (AIR), and disposition index (DI)(Palmer et al, 2008). Here, we tested for potential modifying effects of physical activity on these associations. Methods: Energy expenditure (EE) was collected at the time of the frequently-sampled IV glucose tolerance test, using a 1-year physical activity recall, in 989 Hispanic and 468 African-American non-diabetic participants from 134 families. We selected 13 SNPs in HHEX, SLC30A8, EXT2, IGFBP2, CDKAL1, FLJ39370, LOC387761, and an intragenic locus previously associated with our phenotypes for evaluation with EE. In SOLAR, we used a 2 df genotypic test to evaluate each SNP with and without adjusting for EE, to examine if EE explained variation in the phenotype, and whether accounting for EE modified the SNP association. We then tested for an interaction between EE and each SNP on our phenotypes to examine whether the genotypic association differed by levels of physical activity. Results: Adjusting for age, sex, body mass index, site and SNP, lower EE was significantly associated with lower SI and DI but not with AIR ($p<0.006$, <0.03, and $>>0.05$, respectively) in Hispanics. However, adjustment for EE did not appreciably alter the p-value of the SNP associations with SI, DI nor AIR. We also found no significant interactions between the SNPs and EE on SI, DI, nor AIR. Similar findings were observed in the African-American sample. Conclusions: In this example, accounting for physical activity did not alter the associations of these SNPs with SI, DI nor AIR. Regardless, we posit that in complex genetic traits, gene-environment interactions exist and formal testing of hypotheses of such interactions are critical next steps.

Identification of Seven Novel EIF2B Mutations in Chinese Patients with Vanishing White Matter Disease. *Y. Jiang, J. Wang, Y. Wu, Y. Yang, L. Du, J. Qin, X. Wu* Pediatrics, Peking Univ First Hospital, Beijing, Beijing, China.

[Purpose] Vanishing White Matter disease (VWM)is an AR transmitted leukoencephalopathy with specific abnormality in cranial MRI-almost all cerebral and partial cerebellar white matter became demyelination with partial replacement by cerebrospinal fluid (CSF). In 2001-2002, VWM was found to be caused by mutation in any of the five genes (EIF2B1, EIF2B2, EIF2B3, EIF2B4, EIF2B5) which encoding the subunits of eukaryotic translation initiation factor eIF2B (eIF2B~). This is the first hereditary human disease due to the direct defects in protein translation process. [Methods] Informed consents were obtained from all the families involved. Genomic DNA was extracted from peripheral leukocytes. Mutation screening for coding area and flanking introns of EIF2B5, EIF2B4, EIF2B2, EIF2B3 and EIF2B1 were performed in each patient sequential until mutation had been found. For novel mutations, the corresponding amplicons from fifty control samples were analyzed. [Results] Mutations were identified in 9 patients out of 11 patients with clinical diagnosis of VWM, including 5 patients with EIF2B5 mutations and the other 4 patients with EIF2B3 mutations, no EIF2B4, EIF2B2, and EIF2B1 mutation found. Totally 12 kinds of mutations were found, including 5 novel missense mutations: c.1126 A>G (p.N376D), c.1004 G>C (p.C335S), c.185 A>T (p.D62V), c.140 G>A (p.G47E), c.1037 T>C (p.I346T). 5 reported missense mutations: c.943 C>T (p.R315C), c.1340 C>T (p.S447L), c.674 G>A (p.R225Q), c.1016 G>C (p.R339P), c.1157 G>C (p.G386V), one novel nonsense mutation: c.805 C>T (p.R269X), one novel deletion mutation: c.1827_1838del (p.S610_D613del). Mutations of six patients had been proved inherited from their parents. [Conclusion] We identified 7 novel mutations in Chinese VWM patients. This is the first report of VWM in Chinese. 58% (7/12) mutations were novel mutations, and 44% (4/9) patients with EIF2B3 (much higher ratio than reported). This indicated that the mutation spectrum should be different in Chinese from other ethnic groups. The functional analysis of these novel mutations is ongoing now.

Clinical, neuropathological and genetic studies of Chinese patients with infantile neuroaxonal dystrophy. *Y. Wu[1], Y. Jiang[1], Z. Gao[1], J. Wang[1], Y. Yuan[2], H. Xiong[1], X. Chang[1], X. Bao[1], Y. Zhang[1], J. Xiao[3], X. Wu[1]* 1) Department of Pediatrics, Peking University First Hospital, Beijing, China; 2) Department of Neurology, Peking University First Hospital, Beijing, China; 3) Department of Radiology, Peking University First Hospital, Beijing, China.

Infantile neuroaxonal dystrophy (INAD) is a rare autosomal recessive neurodegenerative disorder.The clinical picture is characterized by progressive psychomotor regression with onset between 6 months to 2 years of age, usually leading to death by 10 years. The presence of axonal swelling is the most typical neuropathological finding. Before the identification of the mutations in PLA2G6 encoding iPLA2-VIA (cytosolic Ca2+-independent phospholipids A2, group VIA) in 2006, the neuropathological data was critical for definitive diagnosis. Only three genetic studies on INAD patients were published worldwide, with 44 mutations identified .Only two patients confirmed by neuropathology have been reported in China up till now. **Purpose** To delineate clinical, pathological and genetic characteristics of Chinese patients with INAD, we analyze ten cases. **Methods** Extensive clinical investigations were performed in ten patients with clinical diagnosis of INAD, as well as neuropathological analysis. All patients were screened for mutations in PLA2G6. **Results** All cases showed the typical clinical features of INAD. The presence of axonal swelling ,which is a hallmark of pathological finding in INAD,was found in biopsy specimens from three cases. 12 different PLA2G6 mutations were identified, consisted of 9 novel and 3 previously reported mutations. The 9 novel mutations include 6 missense mutations (R39Q, V371M, G373R, K545E, R591W and A657V), 1 abolishing the normal start codon (c.1A>G), 1 nonsense mutation (R70X) and 1 splice site mutation (IVS10+1G>A). **Conclusions** The clinical features of Chinese patients with INAD are consistent with those described in previous reports on patients from other races. 9 novel mutations identified in this study greatly broadened the spectrum of PLA2G6 mutations. In addition to pathological evidence, genetic analysis is an useful tool for definitive diagnosis of INAD.

Insulin-like Growth Factor Binding Protein-3 is associated with clubfoot. *K. S. Weymouth[1,2], A. R. Ester[1,2], A. Burt[3], S. H. Blanton[3], J. T. Hecht[1,2]* 1) University of Texas Medical School, Houston, TX; 2) Graduate School of Biomedical Sciences, Houston, TX; 3) University of Miami Miller School of Medicine, Miami, FL.

Clubfoot, a common birth defect affecting 1/1000 livebirths, is characterized by equinus of the ankle, varus of the hindfoot and adductus of the forefoot. Because both genetic and environmental factors have been causally implicated, a multifactorial etiology has been suggested for this complex disorder. In previous studies, we have shown that *HoxA* and *D* and mitochondrial-mediated apoptotic pathway genes are associated with clubfoot. Insulin-like growth factor binding protein-3 (*IGFBP3*) is of interest because it has a proapoptotic role in certain cancers and is underexpressed in mutant *HOXA13* mice. Because apoptosis and HOX genes play critical roles in limb development and were recently found to be associated with clubfoot, we hypothesized that *IGFBP3* may also have a causal role in clubfoot. This study was undertaken to investigate whether variation in *IGFBP3* contributes to clubfoot. Twelve SNPs spanning *IGFBP3* were genotyped in 160 nonHispanic white and 213 Hispanic simplex trios and 121 nonHispanic white and 93 Hispanic multiplex families. The data was analyzed in aggregate and, because allele frequencies were different, the data was stratified by ethnicity (nonHispanic white and Hispanic). In the combined sample, 5 SNPs had significantly altered transmission (0.007p-value0.05). The stratified data identified 4 significantly associated SNPs (rs3793345, p=0.0004) in the Hispanic population. Pairwise haplotype analysis detected significant overtransmission for 25 haplotypes with the strongest haplotype association identified for rs13223993 and rs3793345 (p=0.002). Gene-gene interaction was detected between SNPs in *IGFBP3* and *HOXA*, *HOXD* and mitochondrial-mediated apoptotic genes. These results suggest that genetic variation in *IGFBP3* plays a role in clubfoot and interacts with other genetic variants associated with clubfoot. It also provides the first evidence of gene-gene interaction and a common pathway leading to clubfoot.

A comparison of models used to predict *MLH1, MSH2* and *MSH6* mutation carriers. *C. J. Pouchet[1], M. Tischkowitz[2,3], N. Wong[1,4], W. Foulkes[2,3], G. Schneider[5], B. Rosen-Sheidley[5]* 1) Department of Human Genetics, SMBD-Jewish General Hospital, Montreal, Quebec, Canada; 2) Department of SMBD-Jewish General Hospital, Human Genetics, Oncology and Medicine, Montreal, Quebec, Canada; 3) Faculty of Medicine, McGill University, Montreal, Quebec, Canada; 4) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 5) Genetic Counseling Program, Brandeis University, Waltham, MA.

BACKGROUND: MMRpro, PREMM$_{1,2}$ and MMRpredict are three models which have been developed to predict the probability that an individual carries a Lynch syndrome-causing mutation. Each model utilizes data from both personal and family histories of cancer. To date, no studies have compared the performance of these models in a cancer genetics clinic. The purpose of this study was to determine each models ability to predict the probability of carrying a germline mismatch repair gene mutation in individuals with a family history of colorectal cancer, and to determine the clinical applicability of the models. METHODS: We obtained family pedigrees from 81 individuals who presented for HNPCC testing due to a personal and/or family history of cancer. Data from each pedigree were entered into MMRpredict, PREMM$_{1,2}$ and MMRpro, and were analyzed using SPSS. RESULTS: We found that MMRpredict, PREMM$_{1,2}$ and MMRpro showed similar performances with areas under the ROC curve of 0.731, 0.765 and 0.732 respectively. PREMM$_{1,2}$ showed the least dispersion of mutation probability estimates compared to the other two models with a p-value of 0.205, compared to 0.034 for MMRpro and 0.001 for MMRpredict. CONCLUSION: We found all three performed well in a cancer genetics setting, with PREMM$_{1,2}$ giving slightly better estimates. However, there were some significant discrepancies between the models in cases where the proband had both endometrial and colorectal cancer.

Evaluation of the QIAsymphony system with genetic research applications. *K. Beller[1], C. Homberg[1], S. Hammerschmidt[1], C. Kiss[1], P. Gohl[2], G. Wildhardt[3], K.-U. Lentes[3], C. Lenz[1]* 1) R&D Department, QIAGEN GmbH, Hilden, Germany; 2) Bioscientia, Institute for Medical Diagnostics, Ingelheim, Germany; 3) Bioscientia, Center for Human Genetics, Ingelheim, Germany.

Introduction: Blood is the most common sample material for genetic testing. In this study we determined if yield and quality of DNA purified from blood with the QIAsymphony system is suitable for use in genetic testing methods. Material and Methods: DNA was isolated from 200 l and 1000 l human whole blood in primary tubes with QIAsymphony DNA Mini or Midi Kits. DNA yield and quality were determined spectrophotometrically and by agarose gel electrophoresis. Performance of the purified DNA was tested with a set of 15 different genetic tests. Results: Yields of total DNA ranged from 3.9 - 12.8 g and 18.5 - 45.1 g from 200 and 1000 l blood, respectively. The DNA showed high integrity and was highly pure, with a mean A260/A280 ratio of 1.85 0.06. The DNA performed well in MLPA analyses (CAH and DMD) as well as with a commercially available cystic fibrosis assay, indicated by distinct and accurate electropherogramm profiles. SNP diagnostics by either real time PCR with melting curve analysis or pyrosequencing resulted in correct genotyping of Factor V, Factor II, HFE, MTHFR, LCT, PAI-1 and DPD alleles. HLA typing of loci A, B, C and DR for several individuals was successful. DNA purified with the 1000 l blood protocol was well suited for Fragile-X syndrome analyses by Southern blot. Conclusion: The QIAsymphony system enables fully automated purification of total genomic DNA of up to 96 human whole blood samples from primary blood tubes. Purified DNA shows high quality and is well suited for use in a broad range of genetic testing procedures. Disclaimer: The QIAsymphony SP is intended to be used only in combination with QIAsymphony kits indicated for use with the QIAsymphony SP for applications described in the respective QIAsymphony kit handbooks. The QIAsymphony DNA kits are intended for general laboratory use. No claim or representation is intended to provide information for the diagnosis, prevention, or treatment of a disease.

Interim results of a Phase II, multicenter, open-label study of sapropterin dihydrochloride in subjects with hyperphenylalaninemia related to primary BH_4 deficiency. *M. Wasserstein[1], B. Burton[2], S. Cederbaum[3], J. Munser[4], R. Scott[5], C. Harding[6], U. Wendel[7], C. Whitley[8], J. Wolf[9], A. Dorenbaum[10], E. Foehr[10], E. Kakkis[10]* 1) Mount Sinai Sch of Med, New York, NY; 2) Children's Memorial Hosp, Chicago, IL; 3) UCLA Med Ctr, Los Angeles, CA; 4) U N Carolina, Chapel Hill, NC; 5) U Washington, Seattle, WA; 6) Oregon Health & Sci Uni, Portland, OR; 7) Uni Childrens Hosp, Dusseldorf, Germany; 8) U Minnesota, Minneapolis, MN; 9) U Wisconsin, Madison, WI; 10) BioMarin Pharmaceutical Inc., Novato, CA.

We evaluated the safety and efficacy of sapropterin dihydrochloride (sapropterin) to manage blood Phe in subjects with primary BH_4-deficiency. Of the 12 subjects (5M/7F; mean age 13.59.6 [range: 3-35] years) with a history of Phe 180 mol/L, 6 had 6-pyruvoyl-tetrahydropterin synthetase, 3 had dihydropteridine reductase (DHPR), and 3 had unidentified BH_4 synthesis defects. All had normal ALT levels, were not taking investigational agents, and were not pregnant or breastfeeding. Subjects receiving non-registered BH_4 continued pre-study treatment for 2 wks. At Wk 3, they switched to sapropterin at the same dose and subjects not previously receiving BH_4 began sapropterin 5 mg/kg/day divided bid. Dose could be adjusted up to 20 mg/kg/day. Diet was unchanged. All subjects with BH_4-production defects and none with recycling defects were pre-treated with non-registered BH_4. MeanSD non-registered BH_4 dose at enrollment was 4.12.5 mg/kg/day. At Wk 10, 9 subjects received sapropterin 5 mg/kg/day and 3 received 10 mg/kg/day. Before sapropterin, mean blood Phe was 72.213.4 and 315.0180.9 mol/L for the BH_4 production- and recycling-defect groups, respectively; at Wk 10 on sapropterin, mean blood Phe was 75.011.5 and 347.7187.7 mol/L, respectively. Sapropterin was well tolerated. There were no deaths, serious adverse events (SAEs) or withdrawals caused by the drug; 9 subjects had AEs. Most frequently reported AEs were diarrhea (N=4) and vomiting (N=3). Dystonia unrelated to drug (N=1) was the only AE considered severe. Data from this interim report support a favorable profile for sapropterin in subjects with primary BH_4 deficiency caused by loss of a BH_4-production enzyme such as DHPR.

Analysis of the breakpoint junctions in six subjects with terminal deletions of 1p36. *C. S. D'Angelo[1], M. Gajecka[2], L. G. Shaffer[2,3], C. P. Koiffmann[1]* 1) Depto Genética, Universidade de São Paulo, SP, Brazil; 2) Washington State University, Spokane, WA, USA; 3) Signature Genomic Laboratories, Spokane, WA, USA.

Molecular characterization of subjects with monosomy 1p36 indicates these deletions have non-recurrent breakpoints; resulting in terminal truncations, interstitial deletions, complex rearrangements, and derivative chromosomes. In addition, cryptic interrupted inverted duplications have been observed at the end of terminally deleted chromosomes. Premeiotic breakage-fusion-bridge cycles appear to be an intermediate step in the process of generating and stabilizing these terminal deletions. Stabilization by telomere healing has been confirmed in one pure terminal truncation of 1p36. Telomeric acquisition from another chromosome most likely occurs by break-induced replication and nonhomologous end joining, appears to play a role in most rearrangements. Thus, the mechanisms are complex and no one mechanism is responsible for all rearrangements of this region. Six rearrangements of 1p36 were characterized. These included two apparently pure terminal truncations, three derivative chromosomes, and a complex rearrangement. Microarray analysis revealed a terminal deletion of ~2 Mb followed by a ~300 kb copy-number gain. Breakpoint junction analysis uncovered a cryptic interrupted inverted duplication at the end of the deleted chromosome. Array CGH and FISH analysis of unrelated der(1)t(1;1)(p36;q44) chromosomes from two subjects revealed variability at the breakpoint locations. In one case, no evidence for substantial homology between the 1p and the 1q breakpoints was observed. Preliminary data for the other case indicate the 1q breakpoint falls within a genomic gap. Sequence analysis of a der(1)t(1;4)(p36;q35) did not show any sequence homology at the 1p and 4q junctions. Characterization of two additional apparently pure terminal truncations narrowed the breakpoints to genomic intervals ~3 kb long containing a series of 1p36 specific segmental duplications. Collectively, these cases represent the complexity observed for most rearrangements of 1p36 and indicate that a variety of mechanisms result in the breakage and stabilization of these chromosome abnormalities. CEPID-FAPESP, CNPq.

Detection of variations in the p53 gene using True Single Molecule Sequencing™ Technology. *H. Gao[1], J. I. Colonell[2], C. Hart[2], D. Lipson[2], J. Sram[1], C. Fong[1], J.-S. Saldivar[1], P. M. Milos[2], W. E. Pierceall[2], J. Reifenberger[2], J. F. Thompson[2]* 1) City of Hope National Medical Center, Duarte, CA 91010, USA; 2) Helicos BioSciences, Cambridge, MA 02139, USA.

Somatic changes in DNA have been shown to play a large role in the initiation and development of cancer. Because these changes can occur throughout the course of tumorigenesis and metastasis, it is important to be able to detect novel variations once they occur to couple with an appropriate diagnosis. DNA samples for such analysis are now routinely collected via micro-dissection to remove the normal tissue or select particular tumor cells for tumor somatic mutation analysis. To address this issue, we sequenced individual and mixed DNA samples using True Single Molecule Sequencing (tSMS)TM technology in which individual templates of DNA were analyzed using a proprietary form of sequencing-by-synthesis. P53 was used as a model gene to investigate DNA samples from many patients with documented variations and insertions/deletions in the gene obtained through traditional Sanger sequencing. Bioinformatic tools were developed to detect SNPs and indels in the short read data produced by Helicos tSMSTM technology. Using these tools we detected variations in individual patient DNA samples, as well as in sample mixtures derived from multiple patients. A major benefit with the tSMSTM approach relies on our ability to directly sequence DNA samples without prior amplification thereby having the potential to eliminate a major source of artifactual results introduced by sample manipulation.

A novel missense mutation in the HAX1 gene and neutrophils apoptosis in severe congenital neutropenia (Kostmann disease) patients. *M. Faiyaz-Ul-Haque[1], A. Al-Jefri[2], H. A. Abalkhail[1], M. Toulimat[1], M. A. Al-Muallimi[1], M. S. Pulicat[3], A. Gaafar[3], A. A. Alaiya[3], F. Al-Dayel[1], S. H. E. Zaidi[4]* 1) Pathology and Laboratory Medicine, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 2) Pediatric Hematology/Oncology, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 3) Biological and Medical Research, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 4) Department of Medicine, University Health Network & University of Toronto, Ontario, Canada.

Autosomal recessive, severe congenital neutropenia (SCN) is caused by maturation arrest of granulopoiesis at the level of promyelocytes. This disorder is produced by mutations in the HAX1 gene. This gene encodes for the HAX1 (HCLS1-associated protein X1) protein which is indispensable for maintaining inner mitochondrial membrane potential and for protection against apoptosis in myeloid cells. SCN patients with HAX1 gene mutations display neutrophils apoptosis in addition to neurological symptoms which are manifested when mutation affects both transcript variants of the HAX1 gene. Here, we describe a consanguineous Saudi Arabian family in which patients were clinically diagnosed with the SCN. DNA sequencing identified a novel missense mutation in the HAX1 gene of these patients. This mutation is present in both transcript variants of the HAX1 gene. Interestingly these patients do not exhibit seizures, epilepsy, developmental delay or any other apparent neurological symptoms. On the other hand, consistent with the SCN phenotype, neutrophils form one of these patients exhibited massive apoptosis as assessed by flow cytometry analysis. This study suggests that the manifestations of neurological phenotype in SCN patients may depend upon the nature of mutation and that a complete absence of HAX1 protein may be required for expression of the neurological symptoms in the SCN patients.

Expression profiling and methylation-specific MLPA in uveal melanoma: markers for tumor progression and survival? *A. deKlein[1,4], H. Mensink[2], W. van Gils[1,3], J. Vaarwater[1,2], E. Kilic[3], D. Paridaens[2]* 1) Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 2) Ophthalmology, Rotterdam Eye Hospital, Rotterdam, Netherlands; 3) Ophthalmology, Erasmus MC, Rotterdam, Netherlands; 4) ROTTERDAM OCULAR MELANOMA STUDYGROUP.

Introduction: Uveal melanoma (UM) is the most common primary intra-ocular malignant tumour. Although chromosomal aberrations have prognostic significance, they result in classification errors in prediction of patient survival. Gene-expression profiling was performed and revealed sensitive prognostic markers and relevant genes in the carcinogenesis of UM. Besides genetic factors, epigenetic events, such as promoter silencing by methylation, play an important role in tumour progression. **Materials and Methods:** For expression profiling we analysed 49 tumour RNAs on Affymetrix GeneChips. Analyses was done with Omniviz and PAM software and validated with real-time PCR. Methylation of specific CpG islands or promoter regions was investigated using a methylation specific MLPA kit in 86 UM samples. **Results:** UM expression profiles classify in two distinct tumour classes with strong prognostic significance ($p<0.001$; hazard ratio 7.7). Using a locally adaptive statistical procedure (LAP) two regions on chromosome-arm 3p with decreased gene expression in tumours with shorter disease-free survival were identified. Promoter methylation of TIMP3, VHL, CDKN2A, CDKN2B and MLH1 was observed in several uveal melanomas and analysis of these data (e.g. correlation with patient survival) is in progress. **Conclusion:** Micro-array classification outperforms all known prognostic indicators for uveal melanomas. Methylation of promoter regions of genes in regions with decreased expression indicates a role for methylation in the aetiology of uveal melanoma.

Analysis of copy number variation in sporadic autism. *K. J. Meyer[1], L. K. Davis[1], D. S. Rudd[1], E. M. Stone[2,4], V. C. Sheffield[3,4], T. H. Wassink[1]* 1) Department of Psychiatry, University of Iowa, Iowa City, IA; 2) Department of Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 3) Department of Pediatrics, University of Iowa, Iowa City, IA; 4) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA.

Autism is a pervasive developmental disorder characterized by impairments in communication and social interaction as well as restricted interests and repetitive behaviors. Previous data has indicated de novo copy number variants (CNVs) are enriched in sporadic cases of autism. Therefore, we screened the DNA of 38 patients with sporadic autism and their parents (when available) for CNVs using the Affymetrix 250K SNP microarray. We identified two individuals with CNVs on chromosome 16p11.2, two individuals with duplications of chromosome 15q11.2-q13.1, two individuals with deletions on 2p16.3 in the NRXN1 gene, and two individuals with CNVs on chromosome 22q11.21 in the DiGeorge Syndrome region. Together, these CNVs account for 21% of sporadic autism in our sample. In addition, we identified multiple de novo and novel CNVs that may play a role in the pathogenesis of autism.

Socio-economic and spatial population structure in Northern Finland. *C. Hoggart[1], L. Coin[1], L. Peltonen[2], M. McCarthy[3], N. Freimer[4], P. Elliott[1], D. Balding[1], M. Järvelin[1]* 1) Epidemiology & Public Health, Imperial Col, London, UK; 2) Wellcome Trust Sanger Institute, Cambridge, UK; 3) Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK; 4) Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA.

Principal component (PC) analysis of genome-wide genotype data is widely used to summarise population structure. PCs from genotype data from the Northern Finnish Birth Cohort (NFBC), based on 4,763 individuals and 61,917 SNPs sampled from the Illumina 370K chip, show striking association with spatial location. In particular, the genetic variation described by the first two PCs is consistent with an east-west cline of genetic variation and with distinct early and late settlement patterns, as previously reported. However, the residuals of PCs after regression on latitude and longitude show association with socio-economic status (SES), which indicates patterns of assortative mating according to SES over many generations in a manner that cannot be captured by simple linear directional population gradients. The SES of each individuals parents was recorded in one of six categories, including two classifications for farmers (> 8 ha, and <= 8 ha). After adjustment for longitude and latitude, four of the first 10 PCs were significantly associated with mothers SES ($p < 10^{-7}$); and three with fathers SES. The PCs exhibited greatest variation between the large farmers, small farmers and professionals. A predictive model for SES using the PCs was able to predict 50% of individuals whose mothers were professionals, 49% of individuals whose mother or father were small farmers and 48% of individuals whose fathers were large farmers, at a false positive rate of 20%. Finally we explored the effect of population structure in the NFBC on the genome-wide association analysis (GWAS) of four phenotypes: height, LDL, total cholesterol and pulse pressure. All phenotypes showed significant associations with location, SES and the PCs; however, these associations could be adequately accounted for in these GWAS studies using PCs alone.

Organization of the 21-II region of human chromosome 21. *W. Ziccardi, R. Ennesser, M. Bozovsky, C. Zhao, J. Doering* Dept. of Biology, Loyola University Chicago.

The human genome sequence does not include the heterochromatic regions, although these sequences comprise 10-15% of the genome. We are constructing a detailed physical map of the HC21 centromere and short arm as a model for the organization of these regions. Our previous work showed that the alphoid DNA present on HC21 is found in two distinct regions: D21Z1 and 21-II. The D21Z1 cluster, required for centromere function, is 1 Mb long and consists of a homogeneous array of 11-mer higher order repeats (HOR). This alphoid array does contain substantial sequence heterogeneity at both its ends. We have now determined that the 21-II region on the p arm is comprised of five separate, distinct clusters (Mp1-Mp5) of monomeric -satellite repeats that extend at least 3.0 Mb away from D21Z1. Centromere-associated monomeric alphoid sequences extending this far from the centromere have not previously been described on other chromosomes. Interspersed between these monomeric alphoid clusters are satellite III clusters, multiple copies of the chAB4 duplicon, and other low copy number repeats that have not yet been fully characterized. The sizes for the Mp1-Mp5 clusters are highly heterogeneous, with size estimates of at least 94 kb, 25 kb, 126 kb, 30 kb and 50 kb, respectively. The respective distances of the clusters from the distal end of D21Z1 are approximately 1.0 Mb, 1.4 Mb, 1.7 Mb, 2.3 Mb, and at least 3.0 Mb. Detailed representative sequence information has been obtained for each of the 21-II alphoid clusters using 21p BACs already in GenBank as well as new clones we acquired. Analysis of this alphoid DNA shows no evidence of any of the regular repeating restriction sites or CENP-B boxes characteristic of higher-order alphoid repeats. Dot-plot analysis further indicates that this is monomeric alphoid DNA. These sequences show only 70-80% sequence identity to D21Z1 and to each other. The monomeric alphoid sequences form evolutionary clades distinct from D21Z1. Such multiple monomeric alphoid clusters are consistent with models suggesting that the functional centromere may move along the chromosome over evolutionary time.

Association of COMT Val158Met with autism spectrum disorders in Thai children. *P. Limprasert[1], W. Maisrikaw[1], T. Sripo[1], N. Ruangdaraganon[2], T. Hansakunachai[3], R. Roongpraiwan[2], T. Sombuntham[2], J. Cui[4], X. Guo[4]*
1) Human Genetics/Dept Pathology, Prince of Songkla Univ, Songkhla, Thailand; 2) Dept Pediatrics, Ramathibodi Hospital, Mahidol Univ, Bangkok, Thailand; 3) Dept Pediatrics, Fac Medicine, Thammasat Univ, Pathumthani, Thailand; 4) Cedars-Sinai Medical Center, Los Angeles, CA, USA.

Catechol-*O*-methyl-transferase (*COMT*) gene is located on chromosome 22q11.2. COMT enzyme catalyzes the inactivation of catecholamines including adrenaline, noradrenaline and dopamine. The Val (G allele) of SNP Val158Met at codon 158 of the *COMT* gene leads to higher COMT activity compared with Met (A allele). Exiting data suggest the involvement of *COMT* Val158Met with several psychiatric diseases including obsessive-compulsive disorder (OCD). Autism spectrum disorders (ASD) are complex neuropsychiatric disorders characterized by limited or absent verbal and nonverbal communication, a lack of reciprocal social interaction, and restricted interest and repetitive behaviors (OCD like symptoms). We investigate here the association between *COMT* Val158Met and Thai ASD children. One-hundred-and-fifty-one patients fulfilling the DSM-IV criteria for autistic disorder (128 Males, 23 females, mean age ~4 years) and 212 normal controls were recruited from two university hospitals in Bangkok. Parents of 130 out of the 151 patients were also recruited into this study. The *COMT* Val158Met polymorphisms were genotyped using allele specific PCR. Association analyses were carried out using PLINK. Significant association was first found under an additive genetic model ($P = 0.04$) in the case-control samples, and was further confirmed in the 130 family trios using the transmission disequilibrium test (TDT). The A allele was more common in patients (37%) than in controls (30%). The TDT test demonstrated a preferential transmission of the A allele to the affected children ($P = 0.04$). Our findings suggest that *COMT* Val158Met plays a role in the genetic predisposition to ASD in Thai children.

22q13.3 deletion syndrome: clinical and molecular analysis using array CGH. *S. U. Dhar[1], D. Del Gaudio[1], J. R. German[1], S. U. Peters[1], P. I. Bader[2], M. Blazo[1], C. W. Brown[1], B. H. Graham[1], T. A. Grebe[3], S. Lalani[1], D. Miller[4], S. Sparagana[5], J. A.III Phillips[6], A. L. Beaudet[1], S. W. Cheung[1], T. Sahoo[1]* 1) Molecular & Human Genetics, Baylor college of Medicine, Houston, TX; 2) Parkview Cytogenetic Laboratory, Fort Wayne, IN; 3) CHC Phoenix Genetics Program, St.Joseph's Hospital & medical center, Phoenix, AZ; 4) Children's Hospital, Boston, MA; 5) Pediatric Neurology, Texas Scottish Rite Hospital for Children, Dallas, TX; 6) Division of Medical Genetics, Vanderbilt University School of medicine, Nashville, TN.

22q13.3 deletion syndrome is a microdeletion syndrome resulting from loss of terminal segments of varying sizes at 22qter. Current data suggests a lack of correlation between the spectrum and severity of phenotype and the size and nature of the deletion. We carried out detailed clinical and molecular characterization of 12 patients. Developmental delay and speech abnormalities were common to all and comparable to previously reported cases. Hypotonia was recorded in 42% cases compared to over 85% in earlier cases. Array-based comparative genomic hybridization (aCGH) revealed the deletions to vary from 230 kb to 9.5 Mb. Five cases had a similar deletion (4.65 Mb) and might imply the recurrent nature of at least one deletion. Gene content and disruptions within the deleted segments were consistent with the size and included the three terminal genes (SHANK3, RAB1 and ACR) in the smallest deletion and over 50 genes in the largest. In the smallest deletion, a combination of aCGH and quantitative real-time PCR revealed the deletion breakpoint to be within the SHANK3 gene. These data support a crucial role for SHANK3 in the neuropsychiatric abnormalities seen in these patients. SHANK3 haploinsufficiency has been identified in some patients with idiopathic autism. Similar microdeletions, if identified, might elucidate additional genotype-phenotype correlations and highlights the use of aCGH as an important diagnostic tool. We recommend aCGH as a standard diagnostic test for patients with developmental delay, unexplained hypotonia and autism spectrum disorder with or without craniofacial dysmorphism.

Detection of 100 - 500 kb chromosome abnormalities: Utilization of a quantitative whole genome SNP array. *S. Schwartz, L. Henderson, D. Conrad, C. Ober, R. Nicolae, D. Waggoner, C. Tan, A. Murmann* Department of Human Genetics, University of Chicago, Chicago, IL.

The advent of array analysis, to detect small deletions and duplications, has created many new questions within the clinical community including: what array should be used?, how small can the changes be that can routinely be detected?, and what patients should be studied? These are complex questions that are not easily answered. To better understand these issues, we have tested a whole genome SNP array to study a series of phenotypically abnormal patients, some with known abnormalities, others were chromosomally normal. Of the 270 patients studied, 85 abnormalities that were not detected by routine G-banding were seen by array analysis; 35 additional cases were found to have more complex rearrangements than originally thought and could be clarified more precisely. In a recent study to explore the array's efficacy in 69 patients with phenotypic abnormalities and normal chromosomes, 19 patients (27.5%) had apparently clinically significant abnormalities. 29 different abnormalities could be detected, almost 35% of which involved less than 500 kb of DNA. This work has raised significant issues regarding the approach to employ when utilizing arrays and have provided interesting results including: (1) The importance of looking for and detecting abnormalities less than 500 kb, as 35% of the abnormalities detected were between 100 - 500 kb; (2) In 79% of cases specific genes related to the phenotype could be identified; (3) The complexity of abnormalities was greater than expected as 16% of the patients with abnormalities had more than one abnormality; (4) In many cases only one specific gene was involved; (5) 16% of the abnormalities had a carrier parent with an increased recurrence risk, indicating the importance of family studies; (6) The utilization of multiple analysis tools allowed a specificity of 97.6% and a sensitivity of 100% for any abnormality greater than 100 kb; and (7) The preliminary analysis of phenotypic abnormalities in our patients did not indicate that a specific phenotypic group, from those patients referred, was more associated with an abnormal array finding.

Functional characterization of *APOH* promoter and its variants. *S. Suresh[1], F. Y. Demirci[1], A. H. Kao[2], C. M. Kammerer[1], S. Manzi[2], M. I. Kamboh[1]* 1) Dept of Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) Lupus Center of Excellence, Univ of Pittsburgh, Pittsburgh, PA.

Apolipoprotein H (APOH), a.k.a. $_2$-glycoprotein I, is a major autoantigen for antiphospholipid antibodies involved in autoimmune diseases, such as systemic lupus erythematosus (SLE) and antiphospholipid syndrome. Sequence variation in the 5' regulatory element could directly affect gene expression and phenotypic variation. The purpose of this study was to characterize the *APOH* promoter and its variants by in vitro functional experiments and examining their relation with human plasma APOH levels. We examined (1) the individual effects of eight SNPs in the 5' flanking region of *APOH* (~1.4 kb) on luciferase activity in COS-1 cells and their impact on plasma APOH levels in 447 U.S. White females, (2) the DNA-binding properties of *APOH* promoter using electrophoretic mobility shift assay (EMSA) in HepG2 cells, and (3) the effects of serial deletion analysis of *APOH* 5' flanking region in COS-1 cells. Dual-luciferase experiments revealed that the variant alleles of three promoter SNPs (-1219G>A, -643T>C and -32C>A) showed significantly lower luciferase expression (51%, 40% and 37%, respectively) as compared to the wild-type allele. EMSA demonstrated that these three variants specifically bind with protein(s) from HepG2 cell nuclear extracts. In deletion experiments, the maximal promoter activity was observed on a fragment extending from position -325 to +43. Further deletion of sequences down to -65 decreased expression dramatically, suggesting the presence of essential elements between -325 and -65 positions of the *APOH* promoter. Three-site haplotype analysis (-1219G>A, -643T>C, and -32C>A) revealed one haplotype carrying -32A (freq: 0.075) to be significantly associated with decreased plasma APOH levels ($P < 0.001$). Another haplotype harboring the minor allele for -1219A (freq: 0.080) showed a significant albeit less pronounced association with plasma APOH levels ($P = 0.046$). In conclusion, we have characterized the functional promoter of *APOH* and identified functional variants that affect the transcriptional activity of the *APOH* promoter.

Patient with multifocal renal cell carcinoma, pancreatic neuroendocrine tumor and TSC1 Q343X mutation, TSC2 SNP and PTEN c.210-7~3del5. *S. Gustafson, C. Eng* Genomic Medicine Inst, Cleveland Clinic Fndn, Cleveland, OH.

A 29-year-old female with bilateral renal and pancreatic masses was referred for von Hippel-Lindau syndrome, an autosomal dominant disorder caused by VHL mutations, characterized by retinal and CNS hemangioblastomas, renal cell carcinoma (RCC), pheochromocytomas and pancreatic tumors. Abdominal CT confirmed solid renal neoplasms and a lobular pancreatic mass. CNS MRI reported subependymal nodules consistent with tuberous sclerosis complex (TSC). Ophthalmology exam was negative. Genetics evaluation revealed a history of learning delay, one partial seizure during adolescence, and un-biopsied skin lesions. Patient reported a brother with a possible spinal hemangioblastoma. Physical exam identified a 2-3 cm hypomelanotic patch and 8-10 cm shagreen patch on her back. A clinical diagnosis of TSC was made. TSC is an autosomal dominant hamartomatous disorder caused by mutations in TSC1 or TSC2, associated with typical skin findings, brain lesions, epilepsy and renal angiomyolipomas, with 2% progressing to renal malignancy. Radical right nephrectomy and distal pancreatectomy were performed. Pathology reported multiple foci of clear cell RCC, angiomyolipomas, a medullary fibroma and a non-functioning pancreatic neuroendocrine tumor. Concurrent molecular analysis of VHL, TSC1 and TSC2 identified a heterozygous Q343X TSC1 mutation and a heterozygous R1329H TSC2 polymorphism. PTEN analysis was performed as part of our cancer banking protocol and revealed a c.210-7~3del5 variant. VHL analysis was negative. TSC1 Q343X is likely deleterious due to its predicted truncating effects. PTEN c.210-7~3del5 has been classified as deleterious by a clinical lab but it is more likely a low penetrance modifier of cancer predisposition. TSC2 is downstream of the PTEN-AKT signaling pathway. TSC1 complexes with TSC2 to inhibit mTOR and HIF1 transcription. In this signaling context, one can visualize the interaction of the patients TSC1 truncating mutation with the PTEN variant leading to exaggerated mTOR signaling. Thus, a rational therapeutic choice should her clear cell carcinoma become metastatic or locally advanced would be combination mTOR inhibition and anti-angiogenic therapy.

LTBP2 mutation in autosomal recessive microspherophakia with marfanoid features. *M. Abramowicz[1,4], Y. Sznajer[2], F. Roulez[3], J. Desir[4]* 1) Dept Genetics, Hosp Erasme - ULB, Brussels, Belgium; 2) Pediatrics, HUDERF - ULB, Brussels, Belgium; 3) Ophthalmology, HUDERF - ULB, Brussels, Belgium; 4) Laboratory of Medical Genetics, ULB, Brussels, Belgium.

Microspherophakia is a lens malformation encountered in Marfan (MFS) and Weill-Marchesani (WMS) syndromes. We observed a large consanguineous family with three children affected with microspherophakia. The proband had tall stature with an arm span larger than his height, long slender fingers, and a high-arched palate. He did not meet the diagnostic criteria for MFS, nor WMS. No mutation was found in the MFS-associated gene *FBN1* (CMG, University of Gent, Belgium). We mapped the locus by homozygosity to a 12.6 cM region of chromosome 14q2 using a 10K GeneChip SNP array in the affected siblings, followed by microsatellite analysis, with a multipoint LOD of 2.87. The linkage interval contained one conspicuous candidate gene, *LTBP2*, encoding a latent transforming growth factor-beta binding protein. LTBPs are extracellular matrix proteins with multiple domain structures bearing strong homologies with fibrillins, and may play several roles, including finely controlling TGF- activity in the matrix, a structural role in microfibrils, and a role in cell adhesion. We found a truncating mutation, homozygous in the affected siblings, heterozygous in the parents, and absent from 100 unrelated control subjects from the same ethnic group. Using a polyclonal antibody, we found LTBP2 to be strongly expressed in the calf ciliary zonule. RT-PCR analysis of the proband's skin fibroblasts in primary culture showed absence of the LTBP2 cDNA with no evidence of exon skipping, consistent with nonsense-mediated mRNA decay, contrasting with normal LTBP2 transcript expression in control fibroblasts. We conclude that the *LTBP2* truncating mutation reported here is a rare cause of microspherophakia with marfanoid features. Of interest, LTBP2 has been shown not to bind TGF, and our patients did not show evidence of intense elastolysis or impaired tissue repair as they showed no heart, aortic, skin or lung involvement as encountered in Marfan syndrome.

PRENATAL FINDING OF PERICENTRIC INVERSIONS INVOLVING BOTH CHROMOSOMES 2 AND 9 IN THE SAME PATIENT: TWO CASES WITH NORMAL OUTCOME. *A. Singer[1], J. Rosensaft[2], C. Vinkler[3]* 1) Dept Clinical Gen Unit, Barzilai Med Ctr, Tel Aviv, Israel; 2) Genetic Institute, Kaplan Medical center Rehovot, Israel,; 3) Institute of Medical Genetics, Wolfson Medical Center Holon, Israel.

Pericentric inversion of chromosome 9 [inv(9)(p13;q13)] and pericentric inversion of chromosome 2 [inv(2)(p11;q13)], are both considered polymorphic variations and are the most common forms of autosomal inversion diagnosed prenatally in amniocytes. A small number of cases carrying pericentric inversion of chromosome 9 [inv(9)(p13;q13), were described in association with abnormal ultrasonic findings during pregnancy and rare cases were described with adverse outcome. The homozygote state, of each structural variation, on the other hand, is rarely encountered. In some reports a normal outcome was described while in a few others, an abnormal outcome has been reported. The combination of an inversion of both chromosome 9 and chromosome 2 in the same patient, is uncommon. We present two cases who were diagnosed in utero as carriers of both, the common pericentric inversion on chromosome 9 [inv(9)(p13;q13)] as well as the common pericentric inversion on chromosome 2 [inv(2)(p11;q13)]. In both cases normal babies were born and good outcome reported. One previous case, carrying both inversioms, has been reported and was associated with some fertility problems. Fertility problems have been previously attributed to the common pericentric inversion on chromosome 9 and should be discussed during counseling. Our cases demonstrate that carriers of two inversions are at no increased risk when compared to carriers of each inversion alone and are of generally good outcome.

Genes on chromosomes 1p, 2q, 5q and 6q modify nutritional status in CF. *S. M. Blackman[1,2], L. L. Vanscoy[3], J. M. Collaco[4], K. M. Naughton[2], G. R. Cutting[2]* 1) Pediatric Endocrinology, Johns Hopkins University, Baltimore, MD; 2) Institute of Genetic Medicine, JHU, Baltimore, MD; 3) Pediatrics, National Naval Medical Center, Bethesda, MD; 4) Pediatric Respiratory Sciences, JHU, Baltimore, MD.

Cystic fibrosis (CF) is a Mendelian disease caused by mutations in a chloride channel, CFTR, whose complications include lung disease and pancreatic insufficiency/malabsorption. Nutritional status, a key factor in prognosis, varies widely even among those with the same CFTR mutations, indicating a role for genetic or non-genetic modifiers. To estimate the contribution of genes, height/weight data for 1339 twins and siblings with CF (77,446 visits) were collected by the JHU Twin and Sibling Study. We derived traits reflecting nutrition overall (lifetime mean body mass index (BMI) Z-score; AvgBMI-Z) and before the onset of many CF complications (mean BMI-Z for ages 5 to 7 years; BMI-Z-5to7), and its rate of change (BMI-Z-rate). Concordance for AvgBMI-Z was high in 69 MZ twin pairs (r=0.81) and lower in 15 same-sex DZ twin pairs (r=0.51) and in 145 same-sex sibling pairs within 3 years of age used as a proxy for DZ twins (r=0.49), while trait variance was similar. These twins and siblings estimate heritability at 0.6, indicating that genetic modifiers play an important role in BMI variation among CF patients. Heritability was increased after adjusting for age, cohort, and CF complications (0.7) and was similar for other measures of BMI and for height and weight in CF (0.4-0.7). A subset of this sample (706 CF children, 461 parents) was genotyped with 402 STR markers. Genome-wide linkage analysis revealed evidence for linkage at chromosome 5q15 (LOD=3.78 for BMI-Z-5to7; LOD=1.8 for AvgBMI-Z), one of two loci previously linked to a trait reflecting both pulmonary and nutritional status (Vanscoy et al. 2007. Ped Pulm 42(S30):265 and unpublished data). Linkage was also detected to loci on chromosome 1p36.22 (LOD=4.2, BMI-Z-5to7), 2q33.3 (LOD=3.2, BMI-Z-rate), and 6q23.3 (LOD=3.78, AvgBMI-Z). These results demonstrate that genes other than CFTR play an important role in variation in nutritional status in CF. *Supported by NIH and CF Foundation*.

Hypothalamic-pituitary defects in *Chd7* deficient mice suggest critical roles for *CHD7* in endocrine tissues in human CHARGE syndrome. *D. M. Martin, E. A. Hurd, W. S. Layman* Pediatrics & Human Genetics, University of Michigan Medical Center, Ann Arbor, MI.

CHARGE syndrome is a multiple congenital anomaly condition characterized by ocular coloboma, heart defects, atresia of the choanae, retarded growth and development, genital hypoplasia, and characteristic ear abnormalities. CHARGE has variable phenotypic features which are incompletely penetrant. Many patients with CHARGE display delayed growth, which may be related to early feeding issues, cardiac disease, and/or endocrine dysfunction. Growth hormone (GH) deficiency and other endocrine defects including hypogonadotropic hypogonadism and hypothyroidism have been reported in children with CHARGE. Reduced testosterone levels and pubertal delay are common in boys with CHARGE, and girls display no luteinizing hormone (LH) or follicle-stimulating hormone (FSH) response to GnRH stimulation. CHD7, a member of the CHD family of chromatin remodeling proteins, is mutated in 60-80% of individuals with CHARGE. Members of the CHD family have pivotal roles in chromatin assembly and regulation of gene expression. Based on these observations, we hypothesized that loss of CHD7 disrupts hypothalamic-pituitary signaling during development. To analyze the roles of CHD7 in endocrine function, we generated mice carrying a $Chd7^{Gt}$ allele derived from *Chd7* deficient gene trapped *lacZ* reporter embryonic stem cells. $Chd7^{Gt/+}$ mice exhibit growth delays with onset around postnatal day 7. -galactosidase expression and immunohistochemistry in $Chd7^{Gt/+}$ mice showed *Chd7* expression in the embryonic pituitary and hypothalamus. We found no apparent defects in embryonic pituitary morphology of $Chd7^{Gt/+}$ mice. However, immunofluorescence showed increased GH-positive cells, decreased LH-positive cells, and variable expression of adrenocorticotropin (ACTH) and thyroid-stimulating hormone (TSH) in the late gestation (e18.5) $Chd7^{Gt/+}$ pituitary. Serum IGF-1 was significantly reduced in six week old male $Chd7^{Gt/+}$ mice. These studies suggest that primary defects in hypothalamic-pituitary signaling may underlie the endocrine dysfunction in human CHARGE syndrome.

Bayesian mixture models for case-control genome-wide association studies. *L. Li, A. G. Clark, C. D. Bustamante*
Cornell University, Ithaca, NY.

A fundamental challenge in genome-wide association (GWA) studies is to develop statistical methodology that maximizes power to identify genes responsible for human disease susceptibility while minimizing the number of false positives. Single marker analysis (SMA), involving independent testing of each SNP in a panel for association with a phenotype, has gained wide acceptance in GWA studies due to its simplicity. However, SMA is often limited for complex diseases, since SMA can be significantly biased in estimating effect sizes and significance when the disease is polygenic. We propose a new Bayesian approach to identify multiple quantitative trait loci (QTL) for human complex diseases in case-control GWA studies. The novel approach, based on the logistic or probit model with dimension reduction, simultaneously considers the influence of many SNPs on the disease. SNP effects are assumed to follow 3-component mixture priors, with different truncated normal distributions for positive and negative effects and a large point mass at 0. The point mass at 0 is derived from the assumption that only a small number of SNPs are associated with the disease. With such priors, only significantly nonzero effects have a high posterior probability of remaining nonzero, and modest or negligible effects shrink to 0 with high posteriors. To estimate posteriors, special Gibbs samplers have been developed: an adaptive independence sampler is proposed for the logistic model, and a liability-threshold method is used for the probit model. A score averaging method is proposed to accelerate dimension reduction, making large-scale studies practical. A desktop workstation took 4-6 hours to complete the analysis of human chromosome 1, and 2-4 days for a genome-wide study, while those without the score-averaging acceleration may take months. To compare our approach to SMA, case-control data, based on polygenic models, were simulated from 1,115 Swiss genotyped on the Affymetrix 500k SNP chip as part of the GSK-POPRES project, and Bayesian mixture models, both logistic and probit, as well as SMA were applied. Precision-recall curves suggest our approach is nearly always more powerful than SMA in identifying multiple QTLs, even with the presence of random errors.

Maternal Insulin Secretion or Sensitivity Genes are Associated with Offspring Size at Birth. *M. G. Hayes[1], M. Urbanek[1], L. P. Lowe[1], E. Hughes[1], C. Ackerman[1], N. J. Cox[2], D. B. Dunger[3], A. R. Dyer[1], A. T. Hattersley[4], B. E. Metzger[1], W. L. Lowe[1], HAPO Coop Research Group* 1) Northwestern Univ, Chicago, IL; 2) Univ Chicago, IL; 3) Univ Cambridge, UK; 4) Univ Exeter, UK.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study demonstrated a continuous relationship between maternal glucose measures and birth size or fetal adiposity. We hypothesize genetic factors also contribute to these phenotypes, and examined genetic variation in loci previously implicated in insulin secretion or sensitivity to determine associations with maternal glycemia and insulin secretion at ~28 weeks gestation and/or offspring size at birth for 2133 Thai HAPO mothers and their offspring. We investigated the association of fetal genotype with birth outcomes [birth weight (BW), birth length (BL), head circumference (HC), and sum of skinfolds (SSF)], and maternal genotype with these birth outcomes as well as maternal traits [fasting glucose (FG) and C-peptide (FCP) and 1-hr glucose (1hG) from the oral glucose tolerance test]. Associations were assessed through linear regressions with the single trait/outcome under an additive genetic model adjusting for known confounders. We found significant associations ($p<0.01$) between maternal FG or 1hG and maternal SNPs: *ABCC8* (best SNP is rs2073583; p=0.004 1hG), *GCK* (rs917793; p=0.002 FG), *HNF4A* (rs2071200; p=0.004 1hG), *PPARG* (rs4498025; p=0.009 FG), and *TCF7L2* (rs290484; p=0.009 FG). In a subset of these genes, fetal SNPs were associated with fetal BL (*PPARG* rs2972164, p=0.004), or SSF (*ABCC8* rs1055574, p=0.007). Further, several SNPs were associated with multiple maternal and/or fetal traits. Each maternal copy of the major G allele for *PPARG* rs4498025 was associated with increased FG (0.8mg; p=0.009) and FCP (0.06g; p=0.04), while each fetal copy of this allele was associated with decreased BW (43g; p=0.01). Each maternal copy of the minor G allele for *ABCC8* rs2237975 was associated with increased FG (0.5mg; p=0.04), SSF (0.2cm; p=0.009), HC (0.09cm; p=0.02), BL (0.1cm; p=0.009), and BW (42g; p=0.001). These results indicate genes involved in insulin secretion or sensitivity also impact birth size or fetal adiposity.

Worldwide genetic structure in 37 genes important for telomere maintenance using HGDP and HapMap data. *L. Mirabello[1], N. Xiao[2], X. Deng[2], L. Qi[2], Z. Wang[2], S. A. Savage[1]* 1) Clinical Genetics Branch, DCEG, NCI, National Institutes of Health; 2) SAIC-Frederick, and Core Genotyping Facility, DCEG, NCI, National Institutes of Health.

Telomeres form the ends of eukaryotic chromosomes and are vital in maintaining genetic integrity and function by keeping the chromosomes intact upon replication, preventing end-to-end fusion and atypical recombination. Telomere dysfunction has been linked to many diseases, including bladder and lung cancers, diabetes mellitus, cardiovascular disease, Alzheimers disease, and ulcerative colitis. We investigated patterns of differentiation and the haplotype structure of 37 genes important for telomere maintenance among 53 populations from sub-Saharan Africa, North Africa, the Middle East, Europe, Central/South Asia, East Asia, Oceania, and the Americas. Data from 1168 unrelated individuals was obtained from the genome-wide scan (650,000 common SNPs) of the Human Genome Diversity Panel (HGDP-CEPH) and from the HapMap database (Phase II) at 716 single-nucleotide polymorphism loci. Estimated haplotype frequencies, measures of genetic diversity, linkage disequilibrium (LD), population differentiation and structure were computed. The greatest gene diversity was observed in Africa, as anticipated. The majority of genes had low to moderate haplotype diversity; the lowest was observed in *DKC1*, *TERC*, *XRCC6* and the greatest in *RAD51L1*, *TEP1*, and *TERT*. Overall, there was significant differentiation between continental regions; the haplotype composition and LD patterns also varied among the regions. Structure analyses partitioned worldwide diversity into five genetic clusters that correspond to Sub-Saharan Africa, Eurasia, East Asia, America, and Oceania. The population of Utah residents from the USA partitioned into the Eurasia cluster. Although some telomere genes have higher than expected haplotype diversity (*e.g. TERT*), as a group there appears to be less diversity overall in these genes than in other sets of genes with different functions. Higher levels of genetic variation may not be tolerated in these genes, possibly due to their critical role in telomere maintenance and chromosomal stability.

Genetic factors contribute to dental caries in the primary and mixed dentitions in Appalachian children. *X. Wang[1], S. Wendell[1], G. Barkanic[1], R. J. Weyant[1], R. Crout[2], D. McNeil[2], M. L. Marazita[1]* 1) School of Dental Med, Univ Pitt, Pittsburgh, PA; 2) School of Dentistry, West Virginia Univ, WV.

The prevalence of dental caries (tooth decay) in children has dramatically increased in the past years, resulting in a major public health concern in children, and heavy economic burdens to society. Dental caries is a multifactorial complex disease, due to interactions between genetic, environmental and behavioral factors. We hypothesize that genetic factors play a crucial role in controlling both susceptibility and resistance to this disease. Two dental caries phenotypes based on the location of the decay (dmfs-pit/fissure, and dmfs-smooth surface) were assessed in 1382 participants (age15) from 618 families from the Center for Oral Health Research in Appalachia (COHRA). The Family Based Association Test (FBAT) was used to test associations with 29 SNPs from 24 caries candidate genes, in two non-overlapping subsets: primary dentition (age6) and mixed dentition (6age15). Further, we evaluated each caries phenotype twice for assessing caries susceptibility alleles (transmission patterns to children with caries) and caries resistance allele (transmission to children with no caries) separately. For caries scores of both pit/fissure and smooth surfaces (in both primary and mixed dentitions), 5 SNPs in 3 taste receptor genes (TAS1R1, TAS1R2 and TAS2R38), were consistently associated with protection against tooth decay (0.007P0.1). Similarly, one SNP from the cathepsin B gene (CTSB) demonstrated consistent association with risk for caries for both dentitions and phenotypes (0.05P0.1). In addition, SNPs from 2 genes (AMELX and CALR) were associated only with risk of pit/fissure caries (P0.05), but not with smooth surface caries. Notably, one allele (G allele) in CALR SNP was significantly associated with caries risk, while the opposite allele (T allele) showed borderline association with protection (p=0.07). Our results indicate that genetic factors are associated with caries risk and protection in children. Further, tooth decay on pit/fissure and smooth surfaces are associated with both common and unique sets of genes. NIH Grant # DE014899.

Defining UBE-1 Mutations and Ubiquitination Defects Underlying X-linked SMA (XL-SMA). *L. Baumbach[1], J. Ramser[2], M. E. Ahearn[1], K. O. Yariz[1], C. Lenski[2], B. Burnett[3], L. Wan[4], G. Dreyfuss[4], K. Fischbeck[3], A. Meindl[2]* 1) Univ Miami Sch Medicine, Miami, FL; 2) Technische Universitaet Muenchen, Munich, Germany; 3) NIH, Bethesda, MD; 4) Univ Penn Sch Medicine, Philadelphia, PA.

Our group has described an X-linked form of lethal infantile SMA (MIM 301830) with additional features of early onset/congenital contractures/fractures. We have identified the first human UBE-1 disease alleles in five unrelated X-linked SMA families. UBE-1 (Ubiquitin-Activating Enzyme E1) catalyzes the first step in the ubiquitin conjugation cascade. Two of the XL-SMA mutations are missense substitutions in highly conserved amino acids of UBE-1; the third mutation is a recurrent SNP which was shown to alter UBE1 expression (Meindl et al., this meeting). Co-segregation of these mutations with disease has been confirmed in the families, and not detected in control X chromosomes.. We have been investigating downstream effects on the ubiquitination-proteasome (UPP) pathway and SMN complex stability. SMN and other members of the SMN complex are quantitatively being measured in cell lines from XL-SMA, SMA Type I patients and controls using Western blots quantitative immunoassays, and a SMN complex activity assay. RNA expression levels of SMN and selected Gemins are being analyzed by Taqman assays. A series of related experiments are being completed which will predict in vivo effects of human UBE-1 mutations, including in vitro measurements of UBE-1 activity and downstream ubiquitination defects, evaluation of proteasome activity, and immunohistochemical analysis of UBE-1 protein. Western blot analyses and immunoassays suggest that UBE-1 protein is 20-30% reduced in XL-SMA patients, while SMN protein is 60% reduced due to an unidentified mechanism. SMN turnover and SMN complex assembly appear not to be affected in XL-SMA patients, and no direct effects of UBE-1 mutations have been demonstrated on ubiquitin activation or gross UPP activity.. Our evidence suggests that XL-SMA is part of a growing list of neurodegenerative disorders associated with defects in ubiquitination, and that XL-SMA and SMA share a common biological pathway which results in reduction of the SMN complex.

Renal phenotypes related to TCF2/HNFIB rearrangements diagnosed antenatally. *K. Dahan[1], N. Godefroid[2], L. Collard[3], A. Destree[4], M. Lizon[1], W. Courtens[1], O. Devuyst[2], Y. Pirson[2]* 1) Ctr Human Genetics, Univ Catholique Louvain, Brussels, Belgium; 2) Division of Nephrology, Université Catholique de Louvain, Brussels, Belgium; 3) CHC St Vincent Pediatric Nephrology, Rocourt, Belgium; 4) Centre de Génétique Humaine, Institut de Pathologie et de Génétique, Gosselies.

Mutations in TCF2 are known to be the cause of Maturity-Onset Diabetes of the Young type 5, a dominantly inherited multisystem developmental disorder with diabetes, pancreas atrophy, liver involvement, urogenital malformations. Whereas classical MODY5 is easily diagnosed, those apparently restricted to renal phenotype may be under recognized, especially in antenatal period. Although TCF2 genomic deletions are the most frequent cause of bilateral hyperechogenic kidneys, its impact on renal function remains unclear. Here, we summarize features of 9 children (6 girls;3 boys) and two adult relatives (2 males) from 8 families. The TCF2 mutation was whole gene deletion in 6/8, exon 6 deletion in 1/8 and exon 5 duplication in 1/8; de novo mutation was present in 6/8 families. All affected children had antenatally diagnosed hyperechogenic bilateral kidneys. After birth-median age at last follow was 28 mo (range 0 to 96mo)-, we found bilateral multicystic dysplasia in 1/9, renal cysts in 9/9 (bilaterally in 9/9), and renal dysplasia in 5/9 (bilaterally in 3/5). Three children had renal failure leading to ESRD at median age of 40 mo (range 0 to 92 mo). Of them, two were of low birth weight and one had prenatal renal failure with severe oligohydramnios diagnosed at 34wk of gestation. Pancreas size was normal by sonographic evaluation in the 8 tested and one had developed diabetes after renal transplantation. Extrarenal features compromised jejunum stenosis in 1/9, elevated liver enzymes in 3/4, hyperuricemia in 3/6 and macrocephalia in 1/8. Among the 2 adults (mean age of 31 y), we found bilateral medullary cysts in 1/2, dysplastic kidneys in 1/2, and progressive renal failure in 2/2 leading to ESRD in 1/2 at age 30. None had diabetes. These data illustrate the large clinical variability among TCF2 patients even in presence of identical molecular defect and common antenatal presentation.

Defects in neural stem cell proliferation in *Chd7* deficient mice suggest that olfactory epithelial dysfunction contributes to anosmia in human CHARGE syndrome. *W. S. Layman[1], D. P. McEwen[3], L. A. Beyer[4], S. R. Lalani[5], S. D. Fernbach[5], J. W. Belmont[5], Y. Raphael[4], J. R. Martens[3], D. M. Martin[1,2]* 1) Human Genetics, Univ of Michigan; 2) Pediatrics, Univ of Michigan; 3) Pharmacology, Univ of Michigan; 4) Otolaryngology, Univ of Michigan; 5) Genetics, Baylor College of Medicine.

Haploinsufficiency for CHD7, a chromodomain protein, causes CHARGE syndrome, a multiple anomaly disorder characterized by ocular coloboma, heart defects, atresia of the choanae, retarded growth and development, genital hypoplasia, and ear anomalies. The clinical features of CHARGE syndrome are highly variable and incompletely penetrant, but reduced olfaction and defects in the olfactory bulb have been reported. CHD7 is mutated in 60-80% of individuals with CHARGE. Members of the CHD family have pivotal roles in chromatin assembly and regulation of gene expression. Based on these observations, we hypothesized that loss of *Chd7* disrupts mammalian olfactory tissue development. We found severe defects in olfaction in children with *CHD7* mutations and CHARGE using the Basic Smell Identification Test (B-SIT). To analyze the role of CHD7 in olfaction, we generated mice carrying a $Chd7^{Gt}$ allele derived from *Chd7* deficient gene trapped *lacZ* reporter embryonic stem cells. Olfactory function analyzed by electro-olfactogram recordings in adult littermate mice showed that $Chd7^{Gt/+}$ mice have severely impaired olfaction independent of the olfactory bulb. -galactosidase expression in the $Chd7^{Gt/+}$ embryonic olfactory epithelium and immunofluorescence with an anti-CHD7 antibody in adult olfactory epithelium showed that *Chd7* is expressed in both sustentacular cells and basal (olfactory progenitor) cells but not olfactory sensory neurons. BrdU incorporation assays showed a significant (50%) reduction in proliferating CHD7-positive cells in the mature $Chd7^{Gt/+}$ olfactory epithelium. These studies suggest that olfactory dysfunction caused by reduced *Chd7* function in the mouse may be attributed to intrinsic defects in olfactory neural stem cell proliferation, which contribute to the olfactory defects associated with human CHARGE syndrome.

Variants in the ACAD10 Gene are Associated with Type 2 Diabetes, Insulin Resistance and Lipid Oxidation in Pima Indians. *L. Bian, Y. Muller, L. Ma, R. Hanson, S. Kobes, C. Bogardus, L. Baier* PECRB, NIDDK, NIH, Phoenix, AZ 85004.

A prior genome wide association (GWA) study in Pima Indians identified a single nucleotide polymorphism (SNP) within the ACAD10 gene that was associated with early-onset type 2 diabetes (T2D). ACAD10 encodes an acyl-CoA dehydrogenase that catalyzes mitochondrial fatty acid beta-oxidation, a key event responsible for insulin resistance and T2D. Therefore, ACAD10 was analyzed as a prior candidate gene for T2D. A total of 21 SNPs, identified by sequencing or selected from database, were genotyped in 895 case/control subjects for early-onset T2D as well as 415 non-diabetic individuals for predictors of T2D. All variants were further genotyped in 3501 full-heritage Pima Indians. Linkage-disequilibrium (LD) analysis showed that all of the 21 SNPs fell into one LD block and 3 representative SNPs (rs7136874, rs659964, rs601663) could capture all of the genetic information. SNPs represented by rs7136874 were associated with T2D (adjusted P = 0.003-0.006) among the case/control subjects. The diabetic risk alleles were associated with a decreased rate of insulin-stimulated glucose disposal at both physiological and maximally stimulating insulin concentrations during the clamp(adjusted P = 0.05-0.15 and 0.005-0.01, respectively), and a reduced rate of basal lipid oxidation (adjusted P = 0.02-0.03), among the non-diabetic individuals. SNPs represented by rs659964 showed the strongest associations with T2D (adjusted P = 0.000002-0.00001). Similarly, the diabetic risk alleles were significantly associated with reduced insulin sensitivity during the high dose insulin clamp (adjusted P = 0.002-0.01) and decreased basal lipid oxidation (adjusted P = 0.02-0.07) among the non-diabetic subjects. SNPs in perfect LD with rs601663 showed a marginal association with both T2D (adjusted P = 0.01-0.05) and reduced insulin sensitivity during the clamp (adjusted P = 0.01-0.06). In the population-based analysis of 3501 full-heritage Pima Indians, SNPs in perfect LD with rs659964 remained significantly associated with T2D (adjusted P = 0.0006-0.001). Our data indicate variants in ACAD10 may increase susceptibility to T2D by impairing insulin sensitivity via abnormal lipid oxidation.

CRISPLD1: Expanding the role of CRISPLD genes in Nonsyndromic Cleft Lip with or without Cleft Palate. *B. T. Chiquet[1,2], R. Henry[1], D. Ma[3], A. Burt[3], J. B. Mulliken[4], S. Stal[5], S. H. Blanton[3], J. T. Hecht[1]* 1) Dept Pediatrics, Univ Texas Med Sch, Houston, Houston, TX; 2) Univ Texas Dental Branch, Houston, TX; 3) Univ Miami Miller School of Medicine, Miami, FL; 4) Children's Hospital, Boston, MA; 5) Texas Children's Hospital, Houston, TX.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a common complex birth defect caused by genes and environmental factors. Despite having substantial genetic liability, less than 15 percent of the genetic contribution to NSCLP has been identified. We recently found that variation in CRISPLD2 (cysteine rich secretory protein LCCL domain 2) is associated with NSCLP and that CRISPLD2 is expressed in developing murine craniofacies. Our recent genome scan found suggestive linkage of NSCLP (LOD1.0) to 8q13.2-21.13, which contains the CRISPLD1 gene. Though little information is known about either CRISPLD gene, both protein products contain more cysteines than comparably sized proteins. The folate pathway is responsible for endogenous cysteine production; variation in four folate pathway genes have previously been associated with NSCLP. We hypothesized that variation in the CRISPLD1 gene contributes to NSCLP and that both CRISPLD genes interact with genetic variants in the folic acid pathway. CRISPLD1 SNPs were genotyped in nonHispanic white and Hispanic NSCLP families. Association was detected between NSCLP and CRISPLD1 in the total nonHispanic white sample (6 SNPs, 0.01p0.05) and in those without a family history of NSCLP (5 SNPs, 0.005p0.05). Altered transmission of CRISPLD1 haplotypes were found in both ethnicities (0.003p0.05). Evidence for a gene-gene interaction was not detected between the two CRISPLD genes; however, gene-gene interaction was detected between CRISPLD genes and folic acid pathway genes (0.002p0.05), including 5,10-methenyltetrahydrofolate synthetase, which was significant in both ethnicities. This data suggests that variation in both CRISPLD genes play a role in NSCLP, but not through a detectable interaction. Variation in each CRISPLD gene interacts with genetic variants in folic acid pathway genes. This is an important observation and may explain a novel etiologic NSCLP pathway.

Detailed Characterization of the Dyskeratosis Congenita Phenotypic Spectrum. *C. M. Mueller[1], N. Giri[1], G. Seratti[2], B. P. Alter[1], S. A. Savage[1]* 1) CGB/DCEG/NCI/NIH, Bethesda, MD; 2) MGB/NHGRI/NIH, Bethesda, MD.

Dyskeratosis congenital (DC) is characterized by the diagnostic triad of dysplastic nails, lacey skin pigmentation, and oral leukoplakia, but diverse clinical features have been reported. Individuals with DC are at high risk of developing aplastic anemia, myelodysplastic syndrome (MDS), leukemia and epithelial cancers. 5 telomere biology genes are known to cause DC; some individuals have no identifiable mutation. The unifying feature is extremely short telomere length, 1st%-ile; for age, in leukocyte subsets. Our objective was to comprehensively characterize the DC phenotype. We systematically evaluated 32 individuals(22 families) with either a known mutation in a DC gene, the classic DC phenotype or very short telomeres and a family member with classic DC from NCIs Inherited Bone Marrow Failure Syndromes protocol: including history, physical and dysmorphology examinations, as well as neuro-otology, dermatology, dental, otolaryngology and ophthalmology evaluations. We studied 25 males and 7 females, median diagnosis age 9 years (0-28). Mutation status: 5 DKC1(16%), 3 TERC(9%), 1 TERT(3%), 11 TINF2(34%), and 12 unknown(38%). 18(56%) had 2 features of the diagnostic triad; 20(63%) dysplastic nails, 16(50%) skin pigmentation and 19(59%)oral leukoplakia. 29(91%) had bone marrow failure, 1(3%)MDS and 2(6%)epithelial cancers. We found abnormalities in several systems more frequently than previously reported, including cerebellar hypoplasia(31%), ataxia(22%), developmental delay(50%); dental anomalies(56%); and pulmonary function abnormalities(56%). No distinct facies or skeletal dysplasias were observed. One subject had only pulmonary findings and another no clinical features. Preliminary analyses do not suggest genotype/phenotype correlations. The phenotypic spectrum of DC in our cohort ranges from severely affected to minimally affected. We observed a higher frequency of neurologic, dental and pulmonary abnormalities in our series. The DC phenotype is broader than is widely recognized. Comprehensive evaluation of all individuals, regardless of whether they meet the classic diagnostic triad, is necessary to better understand the clinical consequences of DC.

Mutation screening of CHD5 in melanoma-prone families linked to 1p36 revealed no pathologic changes. *D. Ng, X. Yang, M. Tucker, A. Goldstein* Genetic Epidemiology Branch, DCEG/NCI/NIH, Rockville, MD.

Background: A subset of cutaneous malignant melanoma and dysplastic nevi (CMM/DN) families is linked to 1p36. To date, no CMM/DN susceptibility gene has been identified at this locus. Data from mouse studies identified chromodomain helicase DNA binding protein 5 (CHD5) as a tumor suppressor gene affecting cellular proliferation and apoptosis via the CDKN2A/p53 pathway. Based on these findings, we felt it was important to screen CHD5 as a familial CMM/DN susceptibility gene. Methods: Eight unrelated CMM/DN families showing prior evidence of linkage to the 1p36 locus were identified for CHD5 mutation screening. One CMM/DN affected and one unaffected individual from each family were selected for sequencing of the coding exons and their respective intron-exon boundaries contained in CHD5. CHD5 variants that were identified solely among affecteds in the screening panel were further assessed by sequencing additional affected and unaffected members of these families to determine if the variant co-segregated with the CMM/DN phenotype. Results: Single nucleotide polymorphisms in the CHD5 intronic and coding regions were identified among affecteds in the screening panel. None of these variants completely co-segregated with CMM/DN affection status among these eight families. Conclusion: There is no evidence to support CHD5 as a major melanoma susceptibility gene among the eight CMM/DN families screened.

Feasibility and relevance of examining lymphoblastoid cell lines to study role of microRNAs in autism. *Z. Talebizadeh, M. Theodoro* Childrens Mercy Hospital and University of Missouri-Kansas City, Kansas City, MO.

Noncoding RNAs (ncRNAs) such as microRNAs do not code for protein but may regulate gene expression. microRNAs are small RNA molecules that regulate the expression of genes by binding to the 3-untranslated regions of specific mRNA directing translational repression or transcript degradation. Multiple classes of ncRNAs are highly represented in the nervous system, emphasizing the likelihood that nervous system development and function is heavily dependent on RNA regulatory network. Despite growing evidence for regulatory influence of ncRNAs in gene expression, particularly in brain function, this group of regulatory factors has not been evaluated in autism spectrum disorders (ASD), the most common childhood neurodevelopmental disease. To assess the feasibility and relevance of utilizing lymphoblastoid cell lines (LCL) to examine the role of microRNAs in autism, we performed a pilot study. Subjects were ascertained from the Autism Genetics Resource Exchange. Global expression profiling of 470 mature human microRNAs were examined using LCL derived RNA (LC Sciences, Houston, TX) from 6 subjects with autism compared with 6 age-gender matched unaffected subjects. Differential expression (either higher or lower) for 9 of the 470 microRNAs was observed in our autism samples compared with controls. Potential target genes for these microRNAs were identified using publicly available programs. Some microRNAs are tissue-specific while others are more abundant. Our pilot study represents an important first step in the possibility of utilizing LCL to identify at least a subset of microRNAs differentially expressed in autism subjects with a potential functional relevance. In the absence of having access to a large autism brain samples, evaluating LCL samples would still be informative in detecting changes for a subset of brain-expressed microRNAs implicated in autism. Subsequently, this model system should allow for detection of complex subtle changes in susceptibility genes/pathways contributing to autism. Genome-wide expression profiling is underway to examine the correlation between differentially expressed microRNAs and their potential target mRNAs.

Germline genetic variants associated with breast cancer survival in a genome-wide association study of breast cancer susceptibility. *E. Azzato[1,2], J. Tyrer[2], D. Greenberg[3], D. Easton[4], N. Caporaso[1], P. Pharoah[2], Breast Cancer Association Consortium* 1) Division of Cancer Epidemiology and Genetics, NCI, Rockville, MD; 2) Oncology Dept, Cambridge Univ, Cambridge, UK; 3) Eastern Cancer Registration and Information Centre, Cambridge, UK; 4) Cancer Research UK Genetic Epidemiology Unit, Cambridge, UK.

Somatic alterations correlate with breast cancer prognosis and survival, but less is known about the effects of common inherited genetic variation. We evaluated the association between survival after breast cancer diagnosis and 12,711 single nucleotide polymorphisms (SNPs) genotyped as part of a 2-stage genome-wide association study of breast cancer susceptibility. We obtained genotype data for 3,820 women with invasive breast cancer in SEARCH, a population-based case-control study. We tested polymorphisms for association with all-cause mortality (n=542) using Cox regression analysis and a one degree of freedom trend test. For replication, we obtained genotype and follow-up data for 11,161 women diagnosed with invasive breast cancer (1,432 deaths) from 13 studies in the international Breast Cancer Association Consortium and performed a fixed-effects meta-analysis. We genotyped two SNPs in the replication based on strong associations with survival in SEARCH ($p10^{-5}$). One SNP (rs4778137), located in the oculocutaneous albinism II gene (OCA2), showed a weak non-significant protective effect in the replication (replication HR=0.95, 95% CI: 0.87-1.04, p=0.26; pooled HR=0.89, 95% CI: 0.82-0.96, p=0.001). We found evidence that rs4778137 varies by ER status (p_{het}=0.01) and that the protective effect of this SNP appears limited to ER negative tumors (replication HR=0.83, 95% CI: 0.70-1.00, p=0.046; pooled HR=0.76, 95% CI: 0.65-0.89, p=0.001). The other SNP (rs6626269), located approximately 300 kilobase pairs upstream from the fragile X mental retardation 1 gene (FMR1), did not replicate (replication HR=0.99, 95% CI: 0.89-1.10, p=0.75; pooled HR=1.13, 95% CI: 1.04-1.23, p=0.004). There is some evidence that rs4778137 (OCA2) or a variant in linkage disequilibrium may be associated with prognosis after a diagnosis of ER negative breast cancer.

Molecular investigation of TBX1 gene in Midline Facial Defects with Hypertelorism. *M. Simioni, E. L. Freitas, I. Lopes-Cendes, V. L. Gil-da-Silva-Lopes* Medical Genetics, FCM/UNICAMP, Campinas, Brazil.

Midline facial defects with hypertelorism (MFDH) are a group of rare and heterogeneous condition involving anomalies of frontonasal process. Structural and functional anomalies of the central nervous system are also present. These CNS abnormalities have similarity with those found in patients with 22q11.2 deletion syndromes. Mutations in TBX1 gene (22q11.2 region) are also described in individuals with these conditions. There are some isolated reports of MFDH in which 22q11.2 deletion were detected. These facts suggested that some cases of MFDH may be part of the spectrum of these conditions and associated to sequence alterations in TBX1 gene. In order to verify this hypothesis, 10 individuals with MFDH were screened for mutations in this gene. All of them were previously investigated by clinical dysmorphologic and magnetic resonance of central nervous system. We selected individuals with normal karyotype (46,XX or 46,XY) and individuals that do not presented 22q11.2 deletion, previously investigated by FISH technique. Several alterations, classified as single nucleotide polymorphism (SNP) at databases such as NCBI, were found. A nucleotide substitution G A at position 297 (A99A), previously reported as a common polymorphism and as a rare variant, was found in one individual. A new alteration 1132G A that causes an amino acid substitution at codon G378S was found in one individual. Although the sample could be considered relevant as the rarity of these defects, in view of the size of the sample, the clinical-genetic heterogeneity and the new alteration found, we could not exclude neither associate the involvement of 22q11.2 region in the pathogenesis of MFDH. For these reasons, we consider that each situation of MFDH should be considerate individually in order to provide an adequate clinical follow-up for patients. Financial support: FAPESP.

Seeing the trees to understand the forest: array comparative genomic hybridization of 49 subjects with a Smith-Magenis-like phenotype. *S. Williams[1], S. Girirajan[1], D. Tegay[3], N. Nowak[4], E. Hatchwell[5], S. Elsea[1,2]* 1) Dept Human Genetics, Virginia Commonwealth University, Richmond, VA; 2) Dept of Pediatrics, Virginia Commonwealth University, Richmond, VA; 3) Dept of Medicine, New York College Osteopathic Medicine, Old Westbury, NY; 4) Dept of Cancer Prevention and Population Sciences, University of Buffalo, NY; 5) Depts of Genetics and Pathology, SUNY, Stony Brook, NY.

Smith-Magenis syndrome (SMS) is caused by del(17)p11.2, including the retinoic acid induced 1 gene (RAI1) or mutation of RAI1. Haploinsufficiency of RAI1 results in developmental delay, mental retardation, sleep disturbance, self-abusive behaviors, and most features commonly seen in SMS. Our lab has a cohort of ~60 subjects who were referred for molecular analysis due to an SMS-like phenotype. Within this cohort, deletion and mutation analyses of RAI1 were negative; thus, the clinical diagnosis of SMS cannot be confirmed and suggests that at least one other locus is responsible for the phenotype observed. Here we present whole-genome array comparative genomic hybridization of 49 subjects whose phenotypes have significant overlap with that of SMS. Specifically, this SMS-like cohort exhibits developmental delays, sleep disturbance, self-abusive behaviors, motor dysfunction, and hyperactivity of the same type and prevalence as that of SMS. From this study, we have discovered at least 19 new loci that are likely to contribute to the SMS-like phenotype. Genes in these regions contribute to development, neurological fidelity, and morphology, all of which are affected in SMS. In addition, as a result of the phenotypic overlap between SMS and SMS-like patients, these data may provide some insight into the function of RAI1, including the pathways in which it may be involved and the genes it may regulate. These data will improve diagnosis, understanding, and potentially treatment of these complex behavior and mental retardation syndromes.

Pre-B-Cell Leukemia Homeobox 1 (PBX1) Shows Genetic and Functional Association with Bone Mineral Density Variation. *C. L. Cheung[1,6], B. Y. Chan[1], V. Chan[1], S. Ikegawa[4], I. Kou[4], H. Ngai[1], D. K. Smith[2], Q. Y. Huang[1], S. Mori[5], P. C. Sham[3], A. W. Kung[1]* 1) Departments of Medicine; The University of Hong Kong, Pokfulam, Hong Kong; 2) Departments of Biochemistry; The University of Hong Kong, Pokfulam, Hong Kong; 3) Departments of Genome Research Centre; The University of Hong Kong, Pokfulam, Hong Kong; 4) Laboratory for Bone and Joint Disease, Center for Genomic Medicine, RIKEN, Tokyo, Japan; 5) Department of Internal Medicine, Tokyo Metropolitan Geriatric Hospital, Tokyo, Japan; 6) Current address: IFAR, Hebrew SeniorLife, Harvard Medical School, Boston, MA, USA.

Bone mineral density (BMD) is one of the major determinants of risk for osteoporotic fracture. Multiple studies reveal that peak bone mass is under strong genetic influence. One of the major susceptibility loci for peak spine BMD has been mapped to chromosome 1q21-q23 in the Caucasian population. We have previously replicated this finding in Southern Chinese pedigrees and detected a maximum multipoint LOD score of 2.36 at D1S196. To further fine-map this region, 380 single nucleotide polymorphic (SNP) markers were genotyped in 610 sibpairs from 231 families. Several markers were identified in the association analysis as important candidates underlying BMD variation. Among them, successful replication was demonstrated for SNPs in pre-B-cell leukemia homeobox 1 (PBX1) gene in two other unrelated Southern Chinese and Japanese case-control cohorts. The functional role of PBX1 in bone metabolism was examined in vitro using human bone derived cells (HBDC) and murine MC3T3-E1 pre-osteoblasts. PBX1 mRNA was constitutively expressed in both HBDC and MC3T3-E1 cells. Immunostaining revealed that PBX1 is localized in the nucleus compartment. Silencing of PBX1 by RNAi in MC3T3-E1 cells decreased the expression of Runx2 and Osterix, the critical transcription factors for osteogenesis, but accelerated cell proliferation and bone nodule formation. Overall our data support a genetic and functional association of PBX1 with BMD variation.

GKAP and GRIN2B are associated with full scale IQ in AD/HD families. *C. A. Markunas[1], K. Quinn[1], A. L. Collins[1], M. E. Garrett[1], S. Keatts[1], A. M. Lachiewicz[2], E. Morissey-Kane[3], S. H. Kollins[4], A. D. Anastopoulos[3], A. E. Ashley-Koch[1]* 1) Center for Human Genetics, Duke Medical Center, Durham, NC; 2) Department of Pediatrics, Duke Medical Center, Durham, NC; 3) Department of Psychology, University of North Carolina, Greensboro, NC; 4) Department of Psychology, Duke Medical Center, Durham, NC.

The postsynaptic density (PSD) is a cytoskeleton specialization attached to the postsynaptic membrane. It contains a complex protein signaling network, thought to be involved in information processing and memory formation. We evaluated a subset of PSD genes, including GKAP, SHANK3, NMDAR subunits 1-5, and AMPAR subunits 1-4, in a family-based association study. The dataset included 104 families with at least one child (5-12 yrs) meeting research criteria for AD/HD. Full scale IQ (FSIQ) and working memory indices (WMI) were obtained from the WAIS-III (parents) or the WISC-IV (affected and unaffected children) intelligence tests. Genotyping was performed using the Illumina Infinium HumanHap300 duo chip. A minimal number of tagging SNPs in each gene were selected for analysis (N_{total}=252). Using QTDT, each SNP was tested for association with FSIQ and WMI. One intronic SNP (rs11663827) in GKAP was significantly associated with FSIQ (nominal $p<0.0001$) and remained significant after applying an FDR-adjusted p-value threshold of 0.05. Using a less stringent FDR threshold of 0.20, 4 additional intronic GKAP SNPs flanking rs11663827 remained significantly associated with FSIQ, as well as 3 intronic SNPs in GRIN2B (NMDAR subunit). Two significant SNPs (GKAP: rs1791397, GRIN2B: rs1158541) were predicted by PupaSuite to be putative triplex disrupting SNPs and may affect gene expression. WGAViewer was used to evaluate the cis-effect of each significant SNP, and any SNP within the same HapMap LD bin ($r^2>0.7$), on GKAP or GRIN2B expression levels (GENEVAR dataset). In Caucasian children, but not parents, 75% of the SNPs present in the LD bin with rs1008619 were nominally associated ($p<0.05$) with GRIN2B expression levels. Our results support further investigation of GKAP, GRIN2B, and additional PSD genes in relation to learning and memory formation.

The autism phenotype in different racial-ethnic groups. *M. L. Cuccaro[1], J. Lee[1], K. Hamilton[1], R. K. Abramson[2], H. H. Wright[2], J. R. Gilbert[1], M. A. Pericak-Vance[1]* 1) Dept Medicine, Univ Miami Sch Med, Miami, FL; 2) School of Medicine, Univ South Carolina, Columbia, SC.

Autism is a complex disorder which affects individuals of all racial-ethnic groups. Using different populations has been successful in disentangling genetic complexity in complex diseases such as prostate cancer and asthma. We have established collections of African American (AA) and Hispanic American (HA) autism families for genetic analyses. In this study we compared our AA (n=75), HA (n=75), and Caucasian (CA n=171) autism samples on clinical-phenotypic measures including the Autism Diagnostic Interview-R (ADI-R), Aberrant Behavior Checklist (ABC), Vineland Adaptive Behavior Scales (VABS) and Social Responsiveness Scale (SRS). Most striking were group differences in ADI-R derived language traits including *age at first words* (p = 0.0005) and *age at phrase speech* (p 0.0001). Both the AA and HA groups were significantly delayed relative to the CA group. A clear relationship between functional language level and racial-ethnic group was identified as both the AA and HA groups had higher proportions of the individuals with no functional language (^{2}=29.22, df=2, p 0.0001). Group differences in adaptive level, another developmental indicator, were noted as well. No group differences were detected in the ADI-R domain scores, the SRS, or ABC scales suggesting that the language differences were not simply due to severity. Our findings are consistent with our previously published work suggesting a potential developmental language phenotype in AA and HA autism groups. This phenotypic variation may reflect differences in underlying autism risk genes in these racial-ethnic groups. These findings suggest that the autism phenotype in AA and HA families needs to be examined more closely as they may have implications for genetic analyses.

Contribution of a deep intronic mutation to Pelizaeus-Merzbacher disease. *J. Taube[1], L. Banser[1], S. Driscoll[1], G. Mancini[2], M. Meuwissen[2], C. Catsman[2], E. Sistermans[3], J. Garbern[4], G. Hobson[1]* 1) Nemours Biomedical Research, duPont Hosp Child, Wilmington, DE; 2) Erasmus University MC/Sophia Childrens Hospital, Rotterdam, Netherlands; 3) VU Univ Med Ctr Amsterdam, Amsterdam, Netherlands; 4) Wayne State University, Detroit, MI.

Pelizaeus-Merzbacher Disease (PMD) is a neurological disease often caused by duplication of the proteolipid protein 1 gene (*PLP1*) on the X-chromosome. PMD is also caused by complete deletion *PLP1*, as well as small deletions, insertions and single base mutations that affect the coding sequence of the protein or the splicing of the gene. The gene has two major spliced forms due to alternative 5' splice donor sites for intron 3: *PLP1* at c.453 and *DM20* at c.348. *PLP1* expression is largely restricted to oligodendrocytes in the brain, while *DM20* is more widely expressed. Our lab has demonstrated previously that mutations within the *PLP1* intron 3 donor site reduce expression of the *PLP1* splice form both in patient fibroblasts and in transfections of mini-gene constructs into cultured cells. Presently we are investigating the effects on the *PLP1/DM20* splicing ratio of two intronic mutations identified in PMD patients: IVS3+7A>G and IVS3-322G>A. We used site-directed mutagenesis to create these patient mutations in our mini-gene splicing construct and analyzed splicing by semi-quantitative RT-PCR after transfection into an oligodendrocyte-like cell line, Oli-neu. Both mutations significantly reduced the *PLP1/DM20* ratio, to less than 20% of normal, in the transfection experiments. Additionally, we analyzed RNA from patient fibroblasts, and found a reduction of the *PLP1 /DM20* ratio, but no aberrant splice forms. While the +7A>G mutation is just adjacent to the canonical donor site, the deep intronic point mutation is uniquely able to influence the choice of donor sites at a considerable distance, and may represent a new class of elements, FRISE, Far-Reaching Intronic Splicing Enhancers.

Integrating and visualizing human genome in a multi-Scale three dimensional model. *W. J. Zheng, T. M. Asbury*
Biostat, Bioinfo & Epi, Medical University of South Carolina, Charleston, SC.

A significant portion of genomic data that is currently being generated, such as histone modifications, extends beyond traditional primary sequence information. Nevertheless, genome browsers, such as the USCS Genome Database Browser, are specifically aimed at viewing primary sequence information. Although supplemental information can easily be annotated via new tracks, representing structural hierarchies and interactions is quite difficult, particularly across non-contiguous genomic segments. We present a multi-scale visualization framework to examine integrated epigenomic data within a three-dimensional model of the human genome. Our physical genome model is built using an object-oriented, hierarchical architecture and incorporates experimental data from atomic to nuclear scales. At the atomic level, we have modeled the human genome sequence with the atomic structure of each base. Genome-wide nucleosome positioning data were used from a recent high-throughput technique combining MNase digestion and ChIP-sequencing. The lower resolutions of our model, i.e., the 30nm chromatin and nuclear scales, contain data that are statistically derived. The model can provide unique insights into the interplay of various sources of genomic information. The complete model is a hybrid of rich detail in the atomic domain and progressively more statistically-based information in lower resolutions. The model is highly flexible in its ability to incorporate new data from different scales, while ensuring consistency at all levels. We view our model as a platform capable of integrating present and future data at the genomic scale. As more data becomes available, improved models should not only be able to provide the researchers with a foundation for genome visualization, but also with a comprehensive analytical platform to investigate sequential, structural and spatial details of the genome.

A Haplotype-free Approach for Cross Platform Imputation. *P. Lin, J. P. Rice* Washington University in St. Louis, St. Louis, MO.

For genome-wide association study, combining new samples with existing samples can increase power. The challenge to combine cross-platform samples is that different platforms have different choices of SNPs. One way to solve the problem is to impute unknown SNPs from known SNPs. Traditional methods for SNP imputation rely heavily on haplotype information from HapMap Project. However, haplotype information is not always available. Here, we propose a haplotype-free approach. Based on 423 individuals both genotyped by Illumina 500K chips and Affymetrix 500K chips, we predict SNPs in one platform by using logistical regression to forward select predictor SNPs among surrounding SNPs in the other platform. We demonstrate that our method has average concordance rate 97.6% (median 99.3%) on all SNPs of chr22, predicting from Illumina 500K chips to Affymetrix 500K chips, and 93.6% (median 99.1%) from Affymetrix to Illumina. The result is comparable to the program IMPUTE with average concordance rate 96.5% (median 99.2%) from Illumina 500K to Affymetrix, and 90.5% (median 95.2%) from Affymetrix to Illumina on the same data. In addition, we demonstrate that our method can predict better for more than half of SNPs. Our method is well calibrated in that the predicted probability is consistent with the observational probability distribution. We introduce a new statistic that quantifies the agreement between observed and inputed genotypes. This statistic can be used to assess the quality of the imputation (i.e., not all SNPs are amenable to imputation), and can be used to contrast different imputation methods.

Increased risk of monoclonal gammopathy of undetermined significance (MGUS) and lymphoid tumors among first-degree relatives of MGUS cases. *L. R. Goldin[1], S. Y. Kristinsson[2], N. E. Caporaso[1], M. Bjorkholm[2], I. Turesson[3], O. Landgren[1]* 1) Genetic Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD. USA; 2) Dept. of Medicine, Hematology Ctr, Karolinska U. Hospital, Stockholm, Sweden; 3) Department of Medicine, Section of Hematology, Malmo University Hospital, Malmo, Sweden.

MGUS is a generally asymptomatic plasma-cell disorder with an elevated monoclonal immunoglobulin of less than 3 g/dl in the absence of a lymphoproliferative (LP) malignancy. MGUS is a precursor to multiple myeloma (MM) and other lymphoid tumors, transforming at the rate of approximately 1% per yr. Genetic factors have been shown to be important for MM and other LP tumors but the genetic relationship to the precursor trait is not known. We identified 4488 MGUS cases diagnosed in major hematology outpatient units in Sweden (1967-2005) with linkable relatives. Using the population-based Multigenerational Registry, we obtained 17,628 controls and first-degree relatives of cases(n=14689) and controls (n=58698). Relatives were linked with hospital outpatient registries and the Cancer Registry to define occurrence of MGUS and other LP tumors. We applied a marginal survival model with a sandwich covariance estimator to take into account familial dependencies. Relatives of MGUS cases were at significantly increased risk for MGUS (HR=2.84,1.45-5.57), MM (HR=2.87,1.92-4.27), Waldenstrom macroglobulinemia (HR=4.94,1.32-18.46), and chronic lymphocytic leukemia (CLL) (HR=2.05,1.22-3.43) but not for other lymphomas. Thus, shared genes likely contribute to risk of MGUS and related LP tumors, MGUS being an early genetic lesion in the pathway to malignancy. Our candidate gene studies show possible associations of LP tumors with apoptosis genes.

ACUTE LYMPHOBLASTIC LEUKEMIA (ALL) IN A GIRL LATER DIAGNOSED WITH CARDIO-FACIO-CUTANEOUS SYNDROME. *C. Vinkler[1,2], M. Michelson-Kerman[1,2], M. Yanoov-Sharav[1,2], T. Lerman-Sagie[2,3], D. Lev[1,2]* 1) Inst Medical Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Metabolic Neurogenetic Clinic,Wolfson Medical Ctr, Holon, Israel; 3) pediatric Neurology Unit, Wolfson Medical Center, Holon. Israel.

Cardio-facio-cutaneous syndrome (CFC) is characterized by a heart defect, facial dysmormphism, and ectodermal abnormalities as well as mental retardation. Clinically it overlaps with Noonan syndrome and Costello syndrome which are caused by mutations in the proto-oncogenes PTPN11 and HRAS as well as other genes. These genes encode molecules in the RAS/RAF/MEK/ERK signaling pathway. Tumors were reported both in Noonan Syndrome and Costello syndrome. Malignancies were rarely reported in CFC. Two CFC patients have been previously reported with ALL and were associated with mutation in the BRAF gene. We report a case of ALL in an 18 months old girl who was later diagnosed with CFC. This 3 years old girl was followed in our clinic since her birth because of dysmorphic features and significant motor and language delay. She had sparse curly hair, prominent forehead, coarse facial features, hypertelorism, earlobe creases, bulbous nose, tented mouth, broad nasal bridge, hyperkeratosis in her hands and feet and hypermobility of the knees and hips joins. No cardiac involvement was identified yet. At the age of 3 years she did not walk or gain expressive language. The combination of ALL at the age of 18 months and the distinct clinical findings including her facial appearance as well as her ectodermal findings and developmental delay, support the diagnosis of CFC syndrome. Mutations screening in the BRAF, HRAS, KRAS, MEK1/2 and RAF-1 gene are currently ongoing. The risk of malignancies and type of tumors are different between syndromes of the RAS/RAF/MEK/ERK pathway. Very few patients were described with malignancies thus far. The two patients previously described with CFC and ALL carried a mutation in the BRAF gene. It is suggested that careful monitoring for malignancies should be considered as part of the regular management of CFC.

Identification of a novel missense mutation at an invariant position of the PROKR2 gene in a patient with Kallmann syndrome. *E. M. SHAH[1, 2], H. G. KIM[1, 2], L. P. CHORICH[1, 2], L. C. LAYMAN[1, 2]* 1) Dept. of OB/GYN, Section of Reproductive Endocrinology, Infertility & Genetics, The Medical College of Georgia Augusta, GA 30912; 2) Reproductive Medicine Program, Developmental Neurobiology Program, Neuroscience Program, Institute of Molecular Medicine & Genetics, The Medical College of Georgia Augusta,GA 30912.

Idiopathic hypogonadotropic hypogonadism (IHH) is a developmental disorder characterized by a derangement in hypothalamic gonadotropin releasing hormone (GnRH) secretion or action. Kallmann syndrome (KS) combines IHH with anosmia and results from impaired embryologic GnRH and olfactory neuron migration. Patients with IHH/KS present with absent or impaired pubertal development, low serum sex steroids, and low serum gonadotropin levels. Although mutations in the FGFR1, KAL1, and GNRHR genes have been reported in ~20-30% of IHH/KS patients, the molecular basis of most patients remains unknown. Heterozygous, homozygous, and compound heterozygous loss-of-function mutations in the gene encoding the prokineticin receptor 2 (PROKR2) have been reported recently in patients with IHH/KS. We wanted to determine the prevalence of PROKR2 mutations in our sample of patients with IHH/KS. To date, PCR and DNA sequencing have been performed on 53 IHH/KS (26 anosmic, 6 hyposmic, and 21 normosmic) patients using primers designed to amplify both protein encoding exons. DNA sequence was analyzed using the CodonCode Aligner program. No gene deletions were identified in any IHH/KS patient, but 1/53 (1.9%) patients had a heterozygous missense mutation (Arg135Cys) not reported in the SNP database. This novel missense mutation interrupts a highly conserved, invariant amino acid within the first extracellular loop (including amino acid residues 111-136) near the junction of the third transmembrane domain. Our findings indicate that mutations in the PROKR2 gene may be responsible for ~2% of KS patients, but additional normosmic IHH and KS patients need to be studied.

Association between IL17RD gene and Crohns disease and gene-gene interaction in the IL23-IL17 pathway. *L. Mei[1], K. Taylor[1], D. McGovern[2], S. Targan[2], J. Rotter[1]* 1) Medical Genetics, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Inflammatory Bowel Disease Center, Cedars-Sinai Medical Center, Los Angeles, CA.

Accumulating evidence has shown that the IL23-IL17 pathway is important in pathogenesis of Crohns disease (CD). We, and others, have shown that IL23-IL17 pathway genes including IL12b, IL12RB1, IL12RB2, IL17A, IL17RA are associated with CD. IL17RD, another member of IL17 receptor family, has been detected in various cells, but its role in human CD is not clear. The aim of our study was to determine whether IL17RD is associated with CD and whether there is a gene-gene interaction within IL23-IL17 pathway genes. Methods: 763 CD subjects and 254 controls were genotyped for single nucleotide polymorphisms in the IL23A, IL23R, IL17A, IL17RA, IL12B, IL12RB1, IL12RB2 and IL17RD genes using Illumina and ABI platforms. Haplotypes were assigned using Phase v2 and were tested for association with CD by chi square test. We utilized multidimensionality reduction (MDR) to explore gene-gene interactions. Results: Two Blocks (B) of IL17RD were associated with CD. CD patients had a higher frequency of haplotype2 in block2 (B2H2, 55.0% vs. 45.4%, OR=1.5, p=0.01) and a lower frequency of B1H2 (39.1% vs. 50.2%, OR=0.64, p=0.002) and B2H3 (37.8% vs. 47.4%, OR=0.68, p=0.01) when compared with controls. The results of other pathway genes have been previously reported by our group. Haplotypes with increased risk for CD were observed in the IL23R_ B2H1 and B3H1, IL17A_H2, IL17RA_B2H4, IL12RB1_H1 and IL12RB2_H3; haplotypes with decreased risk were observed in the IL23R_B2H2 and B3H2, IL17A_H4, IL17RA_B1H3, IL12B_H1 and IL12RB2_H4. MDR analysis suggested interaction between IL23R_B2H2, IL12RB2_H4 and IL17RD_B2H2 (CV consistency 10/10, tested accuracy 59.7%, p=0.002). The following logistic regression analysis confirmed the interaction (IL23R_B2H2*IL12RB2_H4, p<0.0001; IL23R_B2H2*IL17RD_B2H2, p=0.02). Conclusion: IL17RD is significantly associated with CD and is likely to interact with IL23R in the risk of developing CD. Gene-gene interactions in the IL23-IL17 pathway may play an important role in the pathophysiologic mechanisms of the disease.

Identifying epigenetic patterns that are associated with atherosclerosis. *J. J. Connelly[1], C. Markunas[1], D. R. Crosslin[1], D. Biscocho[1], S. Gadson[1], J. F. Doss[1], T. S. Furey[1], T. Wang[1], S. Nelson[1], P. D. Ellis[2], C. F. Langford[2], P. J. Goldschmidt-Clermont[3], D. Seo[3], S. H. Shah[1], W. E. Kraus[1], E. R. Hauser[1], S. G. Gregory[1]* 1) Duke University, Durham, NC; 2) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) University of Miami, Miami, FL.

DNA methylation plays a role in the transition of smooth muscle cells (SMCs) from a contractile, differentiated state to a migratory, proliferative, anti-apoptotic state. These etiological changes lead to atherosclerotic lesion formation and coronary artery disease (CAD). Passaging aortic SMCs in culture results in similar characteristics of migratory SMCs and differentially methylated loci can be detected in early versus late passages (*ESR1*, *ESR2*, *MCT3*). The same changes have also been detected in atherosclerotic lesions. These data suggest that changes in DNA methylation status of genes of proliferative SMCs could play a role in CAD initiation and progression. To identify these epigenetically regulated candidate genes we investigated the DNA methylation status of passaged aortic SMCs by comparative methylation hybridization using genomic tile path arrays. We identified 346 significantly differentially methylated regions in aortic SMCs at passage 5 versus passage 8 (p0.01). One of these regions contains a gene, collagen type XV, alpha 1 (*COL15A1*) that is hypomethylated, upregulated with passage (p=0.013), and responsive to decitabine treatment (p=0.003). SMCs secrete COL15A1, a molecule known to interact with LDL and to be enriched in plaques. We hypothesized that *COL15A1*, its expression level and its methylation status may play a role in atherosclerosis. We show that *COL15A1* gene expression is upregulated in diseased versus non-diseased aorta (p=0.02) and that a specific intronic polymorphism, rs4142986, within *COL15A1* leads to a dose dependant decrease in transcription of the gene in aorta samples (p=0.008). This G/C polymorphism is the only SNP in the linkage disequilibrium bin (r2 cutoff=0.7) and creates a CpG site within a region of putative differential methylation. We present this non-biased method as a novel cellular based approach to defining and characterizing polymorphisms associated with CAD.

First trimester sequential screen results which indicate a moderately increased risk of Down syndrome (1/50 - 1/270): How do patients respond to these results? *D. Wagner[1], C. Pargas[2], A. Donnenfeld[1]* 1) Genzyme Genetics, Philadelphia, PA; 2) Genzyme Genetics, Sante Fe, NM.

Background: The Genzyme Genetics first trimester sequential screening (SS1) program utilizes a Down syndrome (DS) risk cut-off of 1/50 as a screen positive result. This will detect 70% of DS pregnancies at a 1.2% screen positive rate. Following completion of the second trimester sequential screen (SS2), 90% of DS fetuses will be detected utilizing a risk cut-off of 1/270. **Objective:** To document patient decisions after being informed their SS1 results were within the normal range according to our protocol, but revealed a moderately increased risk of DS between 1/50-1/270. **Methods:** A query of our sequential screening database was performed on patients in the Philadelphia/South Jersey area seen from January, 2006-March, 2008. All patients with SS1 results in the 1/50-1/270 range were identified. Patient decisions regarding invasive testing (prior to completing SS2), completing the SS2 blood draw, or no additional testing were tabulated. Patients who had a spontaneous loss, a family history indication for a diagnostic procedure, an abnormal ultrasound, or a positive Trisomy 18 screen were excluded from the analysis. **Results:** A total of 10,850 patients underwent SS1 testing during this interval. 557 patients (5.1%) had risks between 1/50 - 1/270.

Total # of pts	Pts who had SS2	CVS	Amnio before SS2	No further tests
557	515 (93%)	5 (0.9%)	13 (2.3%)	24 (4.3%)

Conclusion: The majority (93%) of patients in the intermediate DS risk range completed the sequential screening process before making any decisions regarding invasive testing. Only 3.2 % of these patients and 0.16% of all patients decided to pursue a CVS or amniocentesis without completing the SS2 blood draw. Using a 1/50 risk cut-off in the first trimester is an effective screening policy for sequential screening.

Cystinosis: Novel Dental Findings Involving Enamel and Root Anomalies. *C. W. Bassim[1], D. L. Domingo[1], J. Z. Balog[2], JP. Guadagnini[1], W. A. Gahl[2], T. C. Hart[1]* 1) NIDCR, NIH, Bethesda, MD; 2) NHGRI, NIH, Bethesda, MD.

OBJECTIVE: Cystinosis is an autosomal recessive lysosomal storage disorder caused by loss-of-function mutations of the cystinosin gene (CTNS), leading to cellular damage from cystine accumulation. Clinical features include growth retardation, renal failure, and hypophosphatemic rickets. Oral manifestations remain poorly defined. This study characterized dental anomalies of enamel and root morphology, both derived from enamel epithelium, in cystinosis patients and unaffected controls. **METHODS:** Oral clinical and radiographic evaluations were performed on 44 nephropathic cystinosis patients (22 males, 22 females; mean age=17.21.0, range 10-41 years) and 93 healthy controls (36 males, 57 females, mean age=18.00.4, range=10-25 years). The Taurodontism Index (TI), measuring the size of the pulp chamber in multi-rooted teeth, was used to evaluate mature first and second molar pulp chamber size from radiographs. The Developmental Defects of Enamel (DDE) Index was used to determine the prevalence of enamel defects from clinical photographs of teeth, i.e., 104 maxillary incisors each from cystinosis patients and age- and gender- matched controls. **RESULTS:** All three classifications of taurodontism were significantly more prevalent in cystinosis patients than in controls, indicating increasing severities of pulpal enlargement. Hypotaurodontism was present in 71/252 molars (28%) vs. 114/652 molars (17%; $p<0.0001$); mesotaurodontism in 11/252 molars (4%) vs. 4/652 molars (1%; $p<0.0001$); and hypertaurodontism in 5/252 molars (2%) vs. 2/652 molars (0%; $p=0.020$). For every unit increase in TI Index, the odds of increasing pulpal enlargement being associated with cystinosis status increased by 8%, even when adjusted for age (OR=1.08, $p<0.0001$). Enamel defects (diffuse opacities or hypoplasia) were found in 42% (44/104 incisors) of the cystinosis group, significantly more than for controls (1/104 incisors, $p<0.0001$). **CONCLUSIONS:** Our findings indicate novel dental features in cystinosis. Cystinosis associated variations in tooth morphology may be part of the disease spectrum affecting mineralized tissues and may shed additional insight on this complex disease.

Living with Costello Syndrome: Quality of Life Issues in Older Individuals. *E. G. Hopkins[1], A. E. Lin[2], K. E. Krepkovich[3], L. Nicholson[1], M. E. Axelrad[4], K. Sol-Church[5], J. Hossain[6], K. W. Gripp[1]* 1) Medical Genetics, AI duPont Hospital, Wilmington, DE; 2) Genetics and Teratology Unit, MGH for Children, Boston, MA; 3) Center for Human Genetics, BMC, Boston, MA; 4) Texas Childrens, Child Psychology, BCM, Houston, TX; 5) Biomedical Research, Nemours Childrens Clinic, Wilmington, DE; 6) Nemours, Research Programs, Wilmington, DE.

Costello syndrome (CS), a rare condition due to mutations in the *HRAS* gene, consists of coarse facial features, mental retardation, cardiac abnormalities, musculoskeletal anomalies, and an increased incidence of neoplasia. We designed a two part Quality of Life (QoL) survey to obtain (1) objective information from caregivers regarding daily living skills and activities, and (2) subjective information from older individuals with CS assessing self-esteem, life satisfaction and interpersonal relations. Questionnaires were collected from 13 caregivers and 11 individuals with CS. RESULTS: Data was analyzed to describe day-to-day life, as well as potential impediments on QoL for older individuals. A Wilcoxon signed rank test demonstrated significant difference between the QoL total scores based on caregiver report and the QoL total scores based on self-report ($p<.008$). A Spearmans rho revealed an inverse relationship between caregiver QoL total scores and the number of major medical issues experienced by the individual with CS ($N = -.549$) and minimal correlation between QoL total scores based on self-report and the number of major medical issues ($N = -.107$). CONCLUSIONS: Four impediments to QoL for CS individuals include desire for close relationships, lack of independence, plans for the future, and medical issues. As the number of major medical issues an individual experiences increases, the QoL score determined by caregiver report decreases; however, there is little effect on QoL score based on self-report. Recommendations to maximize QoL include encouraging autonomy without compromising safety, discussing relationships and future plans, and continuing to practice preventative medicine. Genetic counselors must be aware of factors affecting QoL to provide appropriate psychosocial counseling and anticipatory guidance.

Population demographic history causes the appearance of recombination hotspots. *H. R. Johnston[1], D. J. Cutler[2]*
1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

The existence of human recombination hotspots is widely accepted. However, the vast majority of human hotspots have been identified only through inferences based on Linkage Disequilibrium (LD). These inferences are made using a model of human history with a constant effective population size. Relaxing this assumption, we show that models of human history with large ancestral populations, followed by long, shallow bottlenecks, and culminating in rapid population growth produce variation and LD patterns very similar to humans. When recombination rates are estimated on data produced by this model, LDHat infers tens of thousands of recombination hotspots, with ~50% of all recombination occurring in ~10% of the genome. This model gives the appearance of recombination hotspots due to variation in the time to most recent common ancestor. Apparent recombination hotspots are regions of the genome that are much older than their neighbors.

Our demographic model can be distinguished from true recombination rate variation by several predictions. First, our model predicts substantial variation in SNP density across the genome, and apparent hotspots ought to be associated with higher SNP density. There are 4.1 SNPs per 1,000 bases in hotspots, and 3.5 SNPs per 1000 bases elsewhere, as predicted. Second, the average recombination rate across all hotspots can be estimated from the correlation in SNP density on either side of the hotspot. Apparent hotspots have an average recombination rate of 1 cM/Mb, the genome-wide average. Finally, we reexamine published data by Coop, et al. that mapped recombination events in pedigrees. The hotspot model predicts that the center of windows containing known recombinations ought to be enriched for hotspots, while our model predicts that the edges of the recombination windows should show enrichment for apparent hotspots because apparent hotspots are rich in informative SNPs. We find that the centers of recombination windows have exactly the genome-wide average of apparent hotspots, while the edges are enriched by ~50%.

PREST-plus: detection of pedigree error and cryptic relatedness among individuals that allows for high-throughput genotype data and adjusts for large-scale multiple hypothesis testing. *L. Sun*[1,2,3], *T. Chiang*[4] 1) Dept Public Health Sci; 2) Dept Statistics, Univ of Toronto; 3) Genetics and Genomic Biology, Sickkids; 4) Centre for Computational Biology, Sickkids, Toronto, Canada.

Genetic studies collect both family and population data, and most statistical mapping methods are not robust to pedigree errors nor cryptic relatedness (e.g. Boehnke and Cox, 1997; Thornton and McPeek, 2007). However, pedigree errors are well documented in linkage analyses and more recently cryptic relatedness in association studies. PREST (Pedigree RElationship Statistical Test) is a C program for detection of pedigree errors by use of genetic marker data. PREST implements the EIBD, AIBS, IBS, and MLLR test statistics, as well as an EM-based estimator of IBD sharing by two individuals developed by McPeek and Sun (2000) and Sun et al. (2002). PREST has been shown to be an effective tool in identifying misspecified relationships using genome-wide (GW) linkage marker data (e.g. Keenan et al, 2008; Samudrala et al, 2008). However, a number of statistical and computational issues remain, and new challenges emerge as the ability for high-density genotyping increases. PREST-plus aims to increase the efficiency and interface of PREST. For example, to deal with the computational load of the MLLR test which requires simulation to assess significance, PREST-plus adopts a dynamic procedure that estimates the number of simulation replicates needed for each test, replacing the 2-stage screening procedure used by PREST. The computational saving is more than 10-fold. PREST-plus also allows users to specify a number of options in a script file including checking for errors across pedigrees. In addition, a R program is developed for post-PREST analyses that incorporates the False Discovery Rate (FDR) methodology (Benjamini and Hochberg, 1995) to adjust for the large-scale multiple hypothesis testing, as well as the Stratified FDR method (Sun et al. 2006) to improve power by utilizing the knowledge that the expected error rates are different for different types of putative relationship (e.g. full-sib vs. unrelated). We also present results of application of PREST-plus to existing GW linkage and association studies.

Sequence determinants of human microsatellite variability. *T. J. Pemberton, C. I. Sandefur, M. Jakobsson, N. A. Rosenberg* Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Microsatellite loci consist of short tandem repeats (STR) that vary in length between individuals and that generally have many distinct alleles within the human population. The high level of variability for microsatellites compared to other regions in the genome has led to their use as markers in linkage analysis and population-genetic studies. In this study we have used genotypes at 631 microsatellite loci in 1048 worldwide individuals from the HGDP-CEPH cell line panel to investigate the effect of sequence properties of microsatellites on their level of variability. We consider an STR to be a repeat unit of 2-5 nucleotides with four or more consecutive repeats; a microsatellite locus may contain one or more STR regions embedded between the PCR primers used to amplify the locus. The number of STRs in the microsatellite sequence, the sequences of their repeat units, and the numbers of repeats, were identified for each microsatellite from the DNA sequence in the human RefSeq database extracted using its PCR primer pair. Calibrating PCR fragment lengths in individual genotypes by using the RefSeq sequence enabled us to infer repeat number in the HGDP dataset and to calculate the mean number of repeats (as opposed to the mean PCR fragment length), under the assumption that differences in PCR fragment length are due to differences in the numbers of repeats in the embedded STRs. We find that the sequence of the repeat unit is an important factor in predicting microsatellite heterozygosity (e.g. $P = 6.01 \times 10^{-4}$ for tetranucleotide microsatellites with one embedded STR with repeat unit AAAT versus those with repeat unit AAGG, Wilcoxon test). The mean number of repeats is observed to be positively correlated with heterozygosity (e.g. Spearman's = 0.564 for dinucleotide microsatellites with one embedded STR, $P = 1.16 \times 10^{-3}$). Finally, we find that the number of STRs in a microsatellite's sequence increases its heterozygosity (e.g. $P = 2.69 \times 10^{-5}$ for tetranucleotide microsatellites with one STR versus those with two STRs, Wilcoxon test). These results further our knowledge of the sequence determinants of microsatellite variability.

/Foxl2/ functions in sex determination and histogenesis throughout mouse ovary development. *E. Pelosi[1], J. E. Garcia-Ortiz[1,2], S. Omari[1], T. Nedorezov[1], Y. Piao[1], J. Karmazin[1], M. Uda[3], A. Cao[3], A. Forabosco[4], D. Schlessinger[1], C. Ottolenghi[1]* 1) Laboratory of Genetics, NIA/NIH-IRP, Baltimore, USA; 2) División de Genética, Centro de Investigación Biomédica de Occidente, CMNO-IMSS, Guadalajara, México; 3) Istituto di Neurogenetica e Neurofarmacologia, Consiglio Nazionale delle Ricerche, Cittadella Universitaria di Monserrato, Monserrato, Cagliari, Italy; 4) Unità di Genetica Medica, Università di Modena, Italy.

Partial loss of function of the transcription factor /FOXL2/ leads to premature ovarian failure in women. In goats and mice, /Foxl2/ is required for maintenance, and possibly induction, of female sex determination. We have thus suggested that in all mammals, female sex determining gene(s) in the /Foxl2/ pathway may operate throughout development and postnatal life, both to mature the fetal ovary and to maintain female reproductive function. Here we investigated this possibility by expression profiling of mouse ovaries that lack /Foxl2/ or /Foxl2/ and /Wnt4/ (a second gene critical for gonadal development). Compared to wild-type, loss of one copy of /Foxl2/ showed strong gene dosage for a subset of ovarian developmental genes; and /Foxl2/-null ovaries were depleted of follicle formation markers and enriched for a number of testis tubule markers. Consistent with early anti-testis and pro-ovary actions, a /Foxl2/ transgene reduced the levels of key testis markers, including /Sox9/, in embryonic XY gonads, and increased the levels of ovarian somatic and meiotic factors, e.g. /Fst /and /Sycp3/, /in XX littermates. We used in silico approaches to identify novel candidate anti-testis genes and to infer that the mouse transcriptome progressively converges toward a testis-like signature, already notable at birth, in /Foxl2/- and /Wnt4/-null ovaries. These data 1) support the proposal of anti-testis, continued function of /Foxl2/ from the earliest steps of ovary differentiation to adult; and 2) identify additional candidate genes associated with sex determination and ovary histogenesis.

Duplication restricted to ICR2 (*KCNQ1, KCNQ1OT1* and *CDKN1C* genes) at 11p15 segregating in a family with five children affected by Silver-Russell syndrome. *A. M. Vianna-Morgante[1], A. Bonaldi[1], R. S. Honjo[2], D. R. Bertola[2], L. M. J. Albano[2], I. M. Furquim[2], C. A. Kim[2], J. F. Mazzeu[1]* 1) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil; 2) Unidade de Genética, Instituto da Criança, Hospital das Clínicas, Universidade de São Paulo, São Paulo, Brazil.

Silver-Russell syndrome (SRS, MIM180860) is a clinically and genetically heterogeneous syndrome characterized mainly by severe intrauterine and postnatal growth retardation, craniofacial features including frontal bossing and small triangular face with pointed chin, and body asymmetry. Imprinted regions on chromosomes 7 and 11 have been implicated in the aetiology of SRS: while maternal uniparental disomy of chromosome 7 has been identified in about 10% of patients, methylation defects at 11p15 have been described as a major cause of SRS, being present in 35-65% of patients. Hypomethylation on the telomeric imprinting center on chromosome 11 (ICR1) is the most frequent alteration, and a few maternal duplications of the segment including genes regulated by ICR1 have also been described. A single maternal duplication that encompasses ICR2, but not ICR1, has been reported. We found a similar duplication segregating in a family with five children affected by SRS, two boys and three girls born to two clinically normal sisters. The analysis of the ICR regions on 11p15 (*H19*, *IGF2*, *KCNQ1*, *KCNQ1OT1* and *CDKN1C* genes) was carried out by MS-MLPA (MRC-Holland). The duplicated region was restricted to the centromeric ICR2, and encompassed the *KCNQ1*, *KCNQ1OT1* and *CDKN1C* genes. This duplication was present in the five children affected by SRS, in their normal mothers and in a normal maternal uncle, but not in the maternal grandmother, indicating that the deceased maternal grandfather was the carrier. An aunt, an uncle and a sister of the SRS children, all clinically normal, did not carry the duplication. This family provides further evidence that ICR2 on 11p15 is involved in the etiology of SRS. In addition, it shows that duplication of the *KCNQ1*, *KCNQ1OT1* and *CDKN1C* genes does not have clinical effects when paternally transmitted.

Association study of phencyclidine-responsive genes with schizophrenia. *X. Deng[1], H. Shibata[1], T. Kuroki[2], T. Nakahara[2], K. Hashimoto[2], H. Ninomiya[3], N. Iwata[4], N. Ozaki[5], Y. Fukumaki[1]* 1) Div. Hum. Mole. Genet., Res. Ctr. Genet. Info., Med. Inst. Bioreg., Kyushu Univ., Japan; 2) National Hospital Organization Hizen Psych. Ctr., Japan; 3) Dazaifu Hospital, Japan; 4) Dept. Psych., Fujita Health Univ.,Japan; 5) Dept. Neuropsych., Nagoya Univ., Japan.

Since schizophrenia-like symptoms are produced by administration of phencyclidine (PCP), a noncompetitive antagonist of N-metyl-D-aspartate (NMDA) receptors, PCP-responsive genes could be involved in pathophysiology of schizophrenia. We have injected PCP (5mg/kg) to two groups of twelve Wistar rats and isolated 5 different parts of the brain of rats one hour and four hours, respectively, after the injection. The same number of rats treated with saline was also prepared as controls. We compared gene expression profiles of these tissues using AGILENT microarrays. Ninety annotated genes and 21 ESTs showed altered expression after the treatment. We have successfully identified ten genes of which expression was altered at least two folds after quantitative evaluation by real-time PCR. The PCP-responsive genes were subjected to the locus-wide association study to identify susceptibility genes for schizophrenia. To date six of them have been analyzed by the case-control association procedure. In single marker analysis, there was no association of SNPs of these genes with schizophrenia. However, in haplotype analysis, significant associations were detected in combinations of two SNPs of *BTG2* and *PLAT*($P = 1.4\times10^{-6}$, $P = 1\times10^{-3}$). These associations were still significant even after correction of multiple testing by False Discovery Rate. These results indicate that at least one susceptibility locus for schizophrenia may be located within or very close to the *BTG2* and *PLAT* regions in the Japanese population.

Characterization of Circulating Tumor Cells by Fluorescence In-Situ Hybridization. *J. F. Swennenhuis[2], A. G. J. Tibbe[2], R. Levink[2], R. C. J. Sipkema[2], L. W. M. M. Terstappen[1]* 1) Twente University, Enschede, Netherlands; 2) Immunicon Europe, Enschede, Netherlands.

Background: Tumor cells in blood of patients with metastatic carcinomas have been associated with poor survival prospects. Further characterization of these cells may provide further insights into the metastatic process. In this study we demonstrate feasibility of reproducible analysis of Fluorescent in situ hybridization (FISH) of CTC in patients with metastatic prostate cancer. Methods: CTC were enumerated in 7.5 mL of blood with the CellSearch system. After enumeration of Cytokeratin+, CD45-, nucleated cells, the cells are fixed in their original position and the fluid from the analysis cartridge is removed. Cartridges were hybridized with probes detecting chromosome 1, 7, 8 and 17 and placed on a fluorescent microscope. The previous identified CTCs are revisited and fluorescent images of the probes were acquired. Leukocytes surrounding the CTC were used as internal controls. Results: FISH was applied to 199 CTC containing blood samples from 70 metastatic prostate cancer patients. The 199 samples contained a total of 23,341 CTC (mean=11, average= 116, SD= 570). Of the 23,341 CTC, 6,068 (26%) were lost during the fixation and FISH. Of the remaining 17,273 CTC no FISH signals were detected in 51% of the CTC that were undergoing apoptosis. The 8,809 (49%) evaluable CTC contained on average 2.8 copies of chromosome 1, 2.7 copies of chromosome 7, 3.1 copies of chromosome 8 and 2.3 copies of chromosome 17. 80% of the CTC were aneuploid. In only 6 patients no aneuploid cells were detected and these patients only had 1 or 2 CTC. Heterogeneity in the chromosomal abnormalities was observed between CTC of different patients as well as among CTC of the same patient. Conclusions: Cytogenetic composition of CTC can be assessed after they have been identified by the CellSearch system. The relation between the presence of aneusomy, the extent of amplification and outcome can now be investigated.

Whole Genome Scan in the CARRIAGE Family Study: Evidence of Novel Quantitative Trait Loci (QTL) for Osteoarthritis Trait on Chromosome 8. *HC. Chen[1,4], SH. Shah[2,3], YJ. Li[2], S. Nelson[2], C. Haynes[2], J. Johnson[2], T. Stabler[1], ER. Hauser[2], SS. Gregory[2], WE. Kraus[3], VB. Kraus[1,4]* 1) Division of Rheumatology; 2) Center for Human Genetics; 3) Division of Cardiology; 4) Department of Pathology, Duke University Medical Center.

Background: Osteoarthritis (OA) is a multifactorial disorder associated with various risk factors. Recently, the genetic contribution to OA has been recognized. OA-related biomarkers have been proposed as sensitive and reliable markers to quantify OA burden. Therefore, finding genes associated with variation in OA-related biomarkers may provide distinctive insights into genetic determinants of OA. Methods: The extended CARRIAGE family consists of 3357 pedigreed members in the US. Ascertainment of 365 members was accomplished. We measured five OA-related biomarkers: HA (hyaluronan), COMP (cartilage oligomeric matrix protein), PIIANP (type IIA collagen N-propeptide), CPII (type II procollagen carboxy-propeptide), and C2C (neoepitope from cleavage of CII). Genotyping was performed using Illumina BeadChip with 6,090 SNP markers. Variance components as implemented in SOLAR were used to estimate heritabilities of quantitative traits, and probabilities of IBD using a polygenic model. Results: Four of five biomarkers showed significant heritability [PIIANP (h2r=0.57), HA (h2r=0.49), COMP (h2r=0.43), $p< 0.005$ for each; C2C (h2r=0.30), p=0.01] after adjusting for age and sex. The maximum multipoint LOD score of 3.90 was achieved for PIIANP on chromosome 8p23 (1-16 cM). For COMP, the strongest evidence of linkage was also on chromosome 8 (LOD=3.2, 61-69 cM and LOD=2.5, 146-153 cM). For HA and C2C, the maximum QTL were identified on chromosome 6q16 and 5q31, respectively. Additional QTL (LOD >2.0) were observed on chromosome 9, 13 and 15 for PIIANP and chromosome 14 for COMP. Conclusions: We report the first evidence of genetic contribution to OA-related biomarkers, identified in one extended family. We identified several new genetic loci for OA-related biomarkers. Further studies of the candidate genes at these loci may provide new insights for the mechanisms of cartilage metabolism, development and progression of OA.

Colorectal Cancer and *XRCC2*: A Three-center Meta Analysis. *K. Curtin[1], W.-Y. Lin[2], R. George[2], M. Katory[2], J. Shorto[2], D. T. Bishop[3], A. Cox[2], N. J. Camp[1]* 1) Genetic Epidemiology, University of Utah School of Medicine, Salt Lake City, UT, USA; 2) Inst. for Cancer Studies, Sheffield School of Medicine, UK; 3) Epidemiology and Biostatistics, Leeds Inst. of Molecular Medicine, UK.

Double-stranded DNA repair polymorphisms may play a role in cancer etiology. Associations of 17 SNPs in *XRCC2* and colorectal cancer (CRC) were investigated in a three center meta study including two UK case-control cohorts (Sheffield and Leeds) and family-based cases in high-risk Utah pedigrees and matched controls (total: 1132 cases, 1092 controls). The SNPs studied were 15 tagging-SNPs selected from an analysis using HapMap/NIEHS data. In addition, two novel variants were identified from sequencing of 125 Caucasian CRC cases chosen to represent multiple CRC groups (including familial, sporadic and metastatic disease). Meta-statistics and Monte Carlo significance testing using Genie software provided valid analyses of the total resource. Similar to reports in other cancer sites, the rs3218536 R188H allele was not associated with increased risk of CRC. However, two SNPs were observed to be associated with CRC. These SNPs were in linkage disequilibrium with each other and represented only a single association finding in overall CRC (OR 1.6, 95%CI 1.1-2.4), in women (OR 2.1, 95%CI 1.2-3.7), and in rectal colon tumors (OR 2.1, 95%CI 1.3-3.4). The association was highly significant in female rectal cases (OR 3.2, 95%CI 1.5-6.7; $p<0.001$). A significant difference was found in a case-case comparison of rectal vs. proximal/distal colon cancers ($p=0.02$). Our investigation offers support for a role of *XRCC2* in susceptibility to CRC, and more specifically for rectal cancer subsite, particularly in women.

Identifying Diabetic Nephropathy Genes on Chromosome 18 in African Americans: A Dense SNP Map. *C. W. McDonough[1], M. Bostrom[2], L. Liu[3], P. J. Anderson[2], C. D. Langefeld[3], J. Divers[3], B. I. Freedman[4], D. W. Bowden[1,2,4]*
1) Program in Molecular Medicine; 2) Dept of Biochemistry; 3) Dept of Public Health Sciences; 4) Dept of Medicine; Wake Forest Univ Sch Medicine, Winston-Salem, NC USA.

Genome wide linkage scans for diabetic nephropathy (DN) in Turkish, African Americans (AA), European Americans, and American Indians have mapped a susceptibility locus to 18q21.1-23. There is also evidence that a polymorphism in the *CNDP1* gene, located on 18q, is associated with DN in Europeans and European Americans. In order to examine this region comprehensively in AAs, we performed a dense SNP map of a 17.6 Mb region: 18q21-22.2. 3,072 SNPs were genotyped in 1080 AAs with type 2 diabetes and end stage renal disease and 1080 AA healthy controls. Seventy ancestry informative markers (AIMs) were included in the SNP set for admixture adjustment. 2,816 SNPs were used for data analysis. After admixture adjustment, 233 SNPs were significantly associated with DN ($P<0.05$) under an additive and/or dominant genetic model. Seven of the top 15 associated SNPs were located within or near known genes; two were located near hypothetical genes; and six were located within intergenic regions. After prioritizing the results, three candidate genes in the region: *DCC*, *NEDD4L*, and *SERPINB7* are noteworthy. In *DCC*, deleted in colorectal carcinoma, 17 of the 152 SNPs genotyped showed evidence of association (11.2%). The most associated SNP, rs1393330, was intronic and located at the 3 end of the gene ($P=0.002$, all genetic models). Eight percent of the SNPs genotyped in *NEDD4L*, neural precursor cell expressed, developmentally down-regulated 4-like, previously associated with hypertension, were associated with DN (6/75). Four of the associated SNPs clustered in intron 1 and intron 2. rs512099, located in intron 1, showed the strongest evidence of association ($P=0.0006$, dominant model). There were five SNPs that showed evidence of association in and near (within 30kb) *SERPINB7*. The most associated SNP, rs1720843, was intronic ($P=0.005$, additive model). Overall the results are consistent with multiple variants contributing to DN. These genes warrant further investigation in order to determine their role in DN in AAs.

Assessing the prognostic utility of pharmacogenetic biomarkers. *L. Li, M. Mosteller, M. G. Ehm, M. R. Nelson*
Genetics Division, GlaxoSmithKline, Research Triangle Park, NC.

The ultimate goal of many pharmacogenetic (PGx) studies is to identify markers that may be clinically useful for differentiating clinical response and risk of adverse drug reactions (ADRs). However, a PGx marker that is statistically significant may not demonstrate prognostic or clinical utility. Summarizing and communicating the potential utility of identified markers is an important step in the biomarker development process. Our initial work focuses on markers for ADRs. We first build up a marker utility profile using well-known statistics including: odds ratio, p value, accuracy, ADR prevalence, marker prevalence, sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV). From these we can derive additional relevant statistics if marker screening were to be implemented: number needed to screen to avoid one ADR, relative risk of ADR, absolute reduction in ADR rate, and fraction of patients who would not receive the drug, but who could safely take it. Through exploring these statistics for ADRs with known genetic risk factors, we conclude that the strength of association and commonly used descriptors of genetic effects are insufficient to assess and communicate the usefulness of a potential biomarker. One example is *HLA-B*1502* for Carbamazepine-induced Stevens-Johnson syndrome in Asians, which has an estimated odds ratio of infinity and a discovery p value of 10^{-33}. However, we find that for every 300 patients screened, 11 would be denied treatment while one ADR would be avoided. We also investigated the relationship between predictive values, ADR prevalence () and marker prevalence (*p*) to facilitate future study design. We find that the upper bounds of PPV and NPV are determined by min[*/p, 1*] and min[*(1-)/(1-p), 1*], respectively. Given these bounds, we confirm that common variants are capable of identifying prognostically useful PGx biomarkers for relatively common ADRs. However, it is important to recognize the limited prognostic utility of common variants for rare ADRs if NPV and PPV must be close to one.

A *CFH* haplotype that tags a deletion of *CFHR1* is over represented in individuals with coronary artery disease.

J. F. Doss[1], K. S. Chen[1], J. J. Connelly[1], D. R. Crosslin[1], S. Nelson[1], T. Wang[1], D. Seo[2], J. M. Vance[2], P. J. Goldschmidt-Clermont[2], S. H. Shah[1], W. E. Kraus[1], E. R. Hauser[1], S. G. Gregory[1] 1) Duke University, Durham, NC; 2) University of Miami, Miami, FL.

Immunity and inflammation have been shown to play a major role in the development of many chronic diseases, including cardiovascular disease. Tight regulation of the complement system is necessary to prevent excessive inflammation resulting in tissue damage and heightened disease progression. Recent studies suggest that the complement system is a key component in the progression of age-related macular degeneration and atypical hemolytic uremic syndrome. Based on convergent data, we propose that impaired regulation of the complement system is also a factor in the progression of coronary artery disease (CAD). First, a proteomics study from Duke University identified lower complement factor H related 1 (CFHR1) and higher complement C3 (C3b) blood plasma levels in CAD cases versus controls (Donahue *et al*. 2006). In the complement pathway, CFHR1 acts as a cofactor in the degradation of the complement response cell targeting protein C3b. Therefore, decreased CFHR1 levels may lead to excessive C3b activity and inflammation. Second, we show that mRNA expression levels of *CFHR1* in human aorta are significantly lower in diseased versus non-diseased samples (p=0.01). Third, the region containing *CFHR1* has been shown to be copy variable. Thus, we hypothesize that *CFHR1* gene expression is altered by deletion of a segment of DNA that contains *CFHR1* and that individuals that have CAD are more likely to harbor this copy number variant (CNV). To test this, we genotyped 1920 individuals from the CATHGEN study for a common haplotype (GTGTAAAG) that tags the *CFHR1* CNV (Hughes et al 2006). We found a significant association between the haplotype and CAD in young affected individuals (p=0.001). Two SNPs within the haplotype, rs1831281 and rs2284664, were also found to be independently associated with CAD (p= 0.024 and 0.028, respectively). We are currently assessing the CNV within this region to determine if mRNA and protein levels of *CFHR1* correlate with hemizygous deletion of *CFHR1*.

Analysis of apparent homozygous runs of SNPs in genome-wide association studies. *F. J. Boehm, T. S. Lumley, K. M. Rice, B. S. Weir* Biostatistics, University of Washington, Seattle, WA.

Within the context of genome-wide association studies, some investigators have reported apparent homozygous runs of SNPs of varying lengths. Our goals are to expand current methodology to aid in the analysis of apparent homozygous runs of SNPs with applications to data cleaning in genome-wide association studies. We analyzed apparent homozygous runs in multiple, high-density genome-wide association studies. We defined apparent homozygous runs in a manner that partially accounted for the possibility of genotyping errors within the run. At least four possible explanations for apparent homozygous runs need to be considered: 1) genuine homozygosity, 2) inherited hemizygous deletion, 3) de novo hemizygous deletion, and 4) for cell line data, loss of heterozygosity in the cell line. Towards this end, we used the genotyping intensity data to attempt to distinguish the first possibility from the other three. Using family data, when those were available, we attempted to distinguish the second possibility from the last two. Our preliminary analyses have identified long apparent homozygous runs in some HapMap study subjects. In some subjects, the longest apparent homozygous run accounts for up to 1% of the bases in the genome. Further analyses that incorporate probe intensity data are underway. We conclude that analyses of homozygous runs of SNPs may be useful as part of the data cleaning measures in genome-wide association studies.

***COL4A1* Polymorphism Is Associated With Pulse Wave Velocity By Genome Wide Association Scan.** *K. V. Tarasov[1,2], S. Sanna[3], A. Scuteri[4], J. B. Strait[1,2], M. Orrù[3], A. Parsa[5], P.-I. Lin[5], A. Maschio[3], W. Post[6], A. Cao[3], R. Nagaraja[2], B. Mitchell[5], G. Abecasis[7], A. R. Shuldiner[5], M. Uda[3], E. G. Lakatta[1], S. S. Najjar[1], D. Schlessinger[2]* 1) Laboratory of Cardiovascular Science, National Institute on Aging, Baltimore, USA; 2) Laboratory of Genetics, National Institute on Aging, Baltimore, USA; 3) Istituto di Neurogenetica e Neurofarmacologia (INN), Cagliari, Italy; 4) Unitá Operativa Geriatria, (INRCA), Rome, Italy; 5) Department of Medicine, University of Maryland School of Medicine, Baltimore, USA; 6) Department of Medicine, Johns Hopkins School of Medicine, Baltimore USA; 7) Center for Statistical Genetics, University of Michigan, Ann Arbor, USA.

Pulse wave velocity (PWV), a non-invasive index of central arterial stiffness, is a potent predictor of cardiovascular mortality and morbidity. Heritability and linkage studies have pointed toward a genetic component affecting PWV. We conducted a genome-wide association study (GWAS) to identify SNPs associated with PWV. The study cohort included participants from the SardiNIA study for whom PWV measures were available. Genotyping was performed in 4,221 individuals, using either the Affymetrix 500K or the Affymetrix 10K mapping array sets (with imputation of the missing genotypes). The associations with PWV were evaluated using an additive genetic model that included age, age^2 and sex as covariates. The findings were tested for replication in an independent internal Sardinian cohort of 1,828 individuals, using a custom-chip designed to include the top 43 non-redundant SNPs associated with PWV. Of the loci that were tested for association with PWV, a SNP in the *COL4A1* gene on chromosome 13 and a SNP in the *MAGI1* gene on chromosome 3 were successfully replicated ($p=2.0x10^{-7}$ and $p=4.5x10^{-6}$ respectively for the combined analyses). The association between SNP in *COL4A1* and PWV was also successfully replicated (p=0.02) in an independent population, the Old Order Amish, leading to an overall p-value of $1.43x10^{-8}$. Collagen type IV is the major structural component of basement membranes, suggesting that previously unrecognized cell-matrix interactions may exert an important role in regulating arterial stiffness.

Role of PALB2 in familial melanoma and pancreatic cancer. *N. Sabbaghian[1,2], N. Hamel[3], R. Kyle[1,2], H. Rothenmund[4], A. Hao[5], D. Hogg[5], S. Gallinger[4], W. Foulkes[1,2,3], M. Tischkowitz[1,2]* 1) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Segal Cancer Centre, Sir M.B.Davis Jewish General Hospital, Montreal, Quebec, Canada; 3) The Research Institute, McGill University Health Centre, Montreal, Quebec, Canada; 4) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario, Canada; 5) Department of Medical Biophysics, Institute of Medical Sciences, University of Toronto, Toronto, Ontario, Canada.

PALB2 is a recently identified breast cancer susceptibility gene whose protein is closely associated with BRCA2 and is essential for BRCA2 anchorage to nuclear structures. This functional relationship made PALB2 a candidate gene for susceptibility to BRCA2-related cancers such as melanoma and pancreas cancer. The purpose of this study was to screen for the presence of germline mutations in PALB2 in familial melanoma families and in families with pancreatic cancer, thus assessing its role in these cancers. Methods. We sequenced PALB2s exons and introns boundaries in probands from 53 families with familial melanoma where p16 mutations were absent and 80 individuals with pancreatic cancer and at least one first or second degree relative with pancreas cancer (n=48), breast (n=23) or prostate cancer (n=9) with no known mutations in BRCA2. We screened a further nine individuals with pancreas and other primary cancers. Results. No significant variants were found in the melanoma study and one unreported silent variant,V398V, was identified in one case from the pancreatic cancer cohort. No truncating mutations were identified in either group. Conclusions. These results indicate that deleterious PALB2 mutations are unlikely to play a significant role in familial melanoma or pancreatic cancer.

Interrogating genomic region containing major effect risk gene for renal disease for signatures of recent selection in human populations. *T. K. Oleksyk[1,2], G. W. Nelson[1,2], M. Jamba[1,2], C. A. Winkler[1,2], M. W. Smith[1,2]* 1) Laboratory of Genomic Diversity, NCI, Frederick, MD; 2) Basic Research Program, SAIC, Frederick, MD.

MYH9 encodes nonmuscle myosin IIA, and is widely expressed in most tissues. Mutations in MYH9 are associated with May-Heggalin, Sebastian, Fechtner, and Epstein syndromes that all involve autosomal dominant macrothrombocytopenia. In addition, recently MYH9 has been associated with focal segmental glomerulosclerosis and renal disease. Several recent whole-genome scans indicated that MYH9 has been the subject of natural selection during different periods of human evolution, starting from time of human-primate divergence, to the recent local adaptations. We investigated the role of population history and natural selection in shaping genetic diversity in the MYH9 gene region in a group of worldwide and ethnologically well-defined human populations. We first examined evolutionary history early in the human lineage by comparing sequence of the gene in humans to the sequences of its primate relatives (chimpanzee, orangutan, and rhesus macaque). Then, we determined sequence diversity patterns, linkage disequilibrium and haplotype divergence of the MYH9 gene in the Human Diversity Panel. Finally, we concentrated on the genomic neigborhood to evaluate (1) the extent of haplotype homozygosity, (2) patterns of sequence polymorphism and (3) population divergence in the gene as well as its neighboring region. Understanding haplotype structure, evolutionary history and the role of natural selection in shaping disease genes like MYH9 is a crucial next step in biomedical reseach.

Expanding the phenotype of 22q11.2 microduplication. *E. Prijoles[1], M. Sutcliffe[1,2], J. Ranells[1]* 1) Department of Pediatrics, Division of Medical Genetics, University of South Florida, Tampa, FL; 2) Department of Pathology, All Children's Hospital, Saint Petersburg, FL.

Clinical reports of 22q11.2 microduplication (OMIM #608363) are limited compared to the reciprocal 22q11.2 microdeletion syndrome. Chromosome 22q11.2 microduplication shows phenotypic overlap with DiGeorge/velocardiofacial syndrome, but the phenotypic spectrum is proving to be much broader. We present a patient with additional features. In infancy, large fontanelles, right frontal upsweep, prominent eyes with shallow orbits, preauricular pits, prominent maxilla, thin vermilion border with ill-defined philtrum, undescended testes, hypoplasia of the fourth and fifth toes,hoarse hypernasal cry, mild hearing loss, and neonatal hepatitis were noted. Optic atrophy, Duane anomaly type II, and bilateral lacrimal punctal atresia were detected on ophthalmology exam. Brain MRI revealed normal optic nerves and chiasm and partial interrupted pituitary stalk. Growth hormone stimulation studies showed low peak growth hormone response. At age 16 years, the patient had severe cognitive impairment, poor coordination, attention deficit hyperactivity disorder, short stature, hypertelorism, upslanted palpebral fissures, small low-set ears, bifid uvula, broad neck with low posterior hairline, squared fingertips, short fourth toes with distal hypoplasia, and pes planus. Chromosomal microarray analysis (CytoChip) showed a gain in copy number at chromosome 22q11.21, detected with 7 clones encompassing at least 0.66 Mb. All clones were within the DiGeorge syndrome locus. Parents were not available for testing, although family history was significant for learning problems in both parents and emotional difficulties, bilateral atresia of lacrimal puncta, cleft lip and short fourth toes in the mother. Lacrimal punctal atresia, Duane anomaly, and pituitary stalk abnormalities with growth hormone deficiency have not been previously reported in 22q11.2 microduplication. These characteristics further expand the highly variable phenotype seen in this condition. Additional research may ultimately provide a molecular basis for the broad range of clinical features observed in 22q11.2 microduplication.

Detection of a 3q29 microdeletion syndrome case diagnosed by CGH-array. *AL. Silva, J. L'Heureux, S. Daack-Hirsch, JC. Murray* Dept Pediatrics, Univ Iowa, Iowa City, IA.

The identification of microdeletions syndromes started with the recognition of syndromic phenotypes associated with mental retardation and have been evolving with the use of more advanced molecular technologies especially the use of microarrays. These comprehensive arrays make it possible to identify not only new syndromes, but also characterize new features for already described conditions. Here we report a case of 3q29 microdeletion syndrome identified with the use of Affymetrix Genome-Wide Human SNP Array 6.0 that includes more than 906,600 single nucleotide polymorphisms (SNPs) and more than 946,000 probes for the detection of copy number variation. The patient phenotype includes broad nasal root, cleft lip and palate, complete syndactyly of third and fourth toes on the right foot, cup shaped ears, thickened helices and developmental delay. The analysis shows a 1.5 Mb microdeletion at the 3q29 region; the same region reported previously by Willat et al. (2005). The deletion encompasses 22 genes including PAK1 and DLG1 that are the autosomal homologues of two known X-linked mental retardation genes, PAK3 and DLG3. The syndrome phenotype is variable despite the almost identical deletion size in all cases. Our study confirms that microarray analysis is a very important tool for screening and detection of submicroscopic chromosomal abnormalities that are undetectable by current cytogenetic and/or molecular methods. We report only the 7th case of the 3q29 microdeletion syndrome and add more description to its phenotype.

High Carrier Frequency of Founder Mutation Causing Severe/Lethal Recessive Type VIII Osteogenesis Imperfecta in West Africans and African-Americans. *W. A. Cabral[1], A. M. Barnes[1], C. N. Rotimi[2], L. Brody[3], J. Bailey-Wilson[3], S. R. Panny[4], D. Chitayat[5], F. D. Porter[6], J. C. Marini[1]* 1) Bone and Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD; 2) ICGHD, NHGRI, NIH, Bethesda, MD; 3) NHGRI, NIH, Bethesda, MD; 4) Maryland DHMH, Baltimore, MD; 5) Dept OB/Gyn, Mt Sinai Hosp, Toronto, Ontario; 6) HDB, NICHD, NIH, Bethesda, MD.

Type VIII OI (OMIM #610915) is a lethal or severe recessive form of OI caused by mutations in *LEPRE1*, the gene encoding prolyl 3-hydroxylase 1. We identified a recurring mutation, IVS5+1G>T, in 6 probands born to carrier parents of West African or African-American descent, suggesting an African founder mutation which had been transported to the Americas. We investigated the carrier frequency for this mutation in African-American and contemporary West African populations and the molecular anthropology of the mutation. We screened gDNA using PCR and RE digestion, or a custom SNP assay, followed by PCR confirmation of positive samples. The recurring mutation was identified in 5/995 Washington DC, 5/1429 Pennsylvania and 2/631 Maryland samples. Thus, Mid-Atlantic African-Americans have a carrier rate of 1/200-300 and a predicted incidence of homozygosity for this mutation of 1/160,000-380,000 births. Fifteen of 1097 unrelated individuals (1.37%) from Nigeria and Ghana were heterozygous for *LEPRE1* IVS5+1G>T, all but one from Kwa-speaking tribes. The high (>1%) carrier frequency for this founder mutation among West Africans predicts an incidence of recessive OI in West Africa of 1/21,000 births, which is equal to the incidence of *de novo* dominant OI, and an order of magnitude greater than the 5-7% proportion of all recessive OI in North America. To estimate mutation age, we used microsatellites and short tandem repeats covering 4.2 MB surrounding *LEPRE1* on chromosome 1p to characterize the conserved haplotype. Haplotype analysis of the founder mutation pedigrees has revealed a conserved region of <450Kb, consistent with a single mutation that arose over 300 years ago and was transported by the Atlantic slave trade. We estimate that 350 carriers were transported to the American colonies, preventing the occurrence of a secondary founder effect.

Non-recipient DNA in squamous cell carcinomas of transplant patients. *A. Toland*[1], *A. Dworkin*[1,2] 1) MVIMG/Human Cancer Genetics, Ohio State University, Columbus, OH; 2) IBGP Program.

Background: Organ transplant recipients (OTRs) have a 65-80 fold increased risk of cutaneous squamous cell carcinoma (SCC). There is a great deal of variability in SCC development in OTRs, suggesting genetic contributions to risk. For example, years post transplant some OTRs develop up to 20 tumors while others do not develop any, despite similarities between other risk factors. In previous studies, we showed that some tumor susceptibility loci demonstrate allelic selection during tumor development and that allelic imbalance studies can be used to identify these loci. To identify loci showing preferential imbalance in SCCs from OTR, we genotyped paired normal and tumor DNA from individuals with five or more SCCs using microsatellite markers from loci exhibiting frequent losses or gains in SCCs. In 11 of 44 individuals, we observed extra alleles in some tumors when comparing tumor genotypes to normal DNA genotypes from the recipient. We never observed extra alleles in any SCCs from non-OTRs. These data made us consider the possibility that the OTR SCCs contained DNA of donor origin. **Methods and Results:** To examine this possibility, we tested matched normal and tumor DNA from 5 females showing extra genotyping bands for the presence of Y-chromosome specific SRY markers. Tumors from 3 of the 5 females were PCR positive for SRY. All of the female controls and some other SCCs from these patients were negative for SRY. Next, we genotyped matched normal and tumor DNA from 6 males and the 2 females negative for SRY for X chromosome markers. Tumors from 2 of the 6 males and 1 of the 2 females showed 2 or more additional bands for X-specific markers suggesting they may have had an organ donation from a female donor. Quantitation of the levels of non-OTR versus OTR DNA by comparison of peak height of alleles suggests that the non-recipient DNA comprises 20-50% of the total DNA. **Conclusions:** SCCs from OTRs contain DNA of non-recipient origin. Ongoing studies are to confirm that the DNA is of donor origin and to identify the cell type of origin. This work has implications for the role of stem cells or immune cells from organ donors in cutaneous SCC development.

Nine years of experiences of Integrated Prenatal Screening at North York General Hospital, Toronto, Ontario, Canada. *A. M. Summers[1, 2], T. Huang[1], K. Boucher[1], S. Rashid[1]* 1) Genetics Program, North York General Hosp, Toronto, ON, Canada; 2) Department of Pediatrics, Faculty of Medicine, University of Toronto, Toronto, ON, Canada.

Integrated Prenatal Screening (IPS) was first started in Ontario at North York General Hospital (NYGH) in December 1999. The first step of IPS involves an ultrasound for nuchal translucency and a blood sample for maternal serum pregnancy-associated plasma protein A at 11-14 weeks gestation. The second step is a blood sample at 15 - 20 weeks for maternal serum AFP, uE3 and total hCG. The result is based on the integration of the two parts. Prior to the introduction of IPS, a screening protocol, patient brochure, counselling guideline and requisition were developed. Education sessions were organized to educate health care providers throughout the NYGH catchment area. Between December 1999 and June 2007, 81,779 women were enrolled in our IPS program. 68,026 women completed 5-marker IPS. Others had 6-marker IPS and serum IPS. Six percent of the women did not complete the second part of IPS. Of women who completed IPS, the detection rate for Down syndrome was 84.9 % and the false positive rate was 2.7 %, which is consistent with the literature. For every 14 women who were screen positive, one case of Down syndrome was diagnosed. IPS represented 62% of our current screening volume, followed by Quad test (22%) and First Trimester Screening (9%). IPS is now offered at all screening centres in Ontario as part of Enhanced Prenatal Screening funded by the Ontario Ministry of Health and Long-Term Care. As of April 2008, 214,819 women have IPS and over 700 sonographers have been enrolled into the Ontario program. Since the introduction of enhanced screening, the overall screening uptake rate in Ontario has increased from 47% in 2002 to 62% in 2007. Our experience shows that IPS is feasible and is acceptable to pregnant women and health care providers at NYGH and in Ontario.

Double mutant mouse for Dystrophin and Large proteins: a new model for neuromuscular diseases. *M. Vainzof[1], P. C. M. Martins[1], V. L. Ferreira[1], D. Ayub-Guerrieri[1], P. C. Onofre[1], C. M. C. Mori[2], L. U. Yamamoto[1]* 1) Hum Genome Res Ctr, IB-Univ Sao Paulo, Sao Paulo, Brazil; 2) Depto Patologia, Veterinary Inst. Univ Sao Paulo, SP, Brazil.

The muscular dystrophies (MD) represent some of the most common human genetic disorders yet few treatment options are available. Animal models are therefore a major tool for testing therapies. Several natural mice models for MD are recognized. The dystrophin-deficient *mdx* mouse is the most widely used model for Duchenne muscular dystrophy. However, because of its very mild phenotype, it is less informative in clinical trials. The myo-dystrophy mouse, the murine model of congenital CMD1D, harbors a mutation in the glycosyltransferase *large* gene, which leads to altered glycosylation of -DG, and a severe phenotype. Aiming the use of these animal models in therapeutic trials, we are defining the clinical natural history and standardizing tests for the analysis of muscle strength and motor ability. Additionally, to help to elucidate the role of the proteins dystrophin and large in the organization of the dystrophin-glycoprotein-complex in muscle sarcolemma, we generated through mendelian cross breads, double mutants mice for dystrophin/large proteins. Up to the present date, 78 animals from 9 litters were born from 6 mdx/double heterozygous couples: 15 (19%) normal, 43 (55%) heterozygous and 20 (26%) double affected puppies. Therefore, this double mutant is compatible with life, and no intrauterine dead apparently occurred. About 75% of the affected puppies died within the first 24 hours, suggesting a strong selection in the peri-natal period. Five animals remained alive and are showing a clinical course worst that the original Large model of the same age. Histological and histochemical and immunohistochemical analysis of the muscle are elucidating the involved histopathological alterations. These new animal models carrying two simultaneous mutations can be used as important tools for genetic, clinical studies, providing important clues to the understanding of the pathogenesis of these disorders. FAPESP-CEPID, CNPq, ABDIM-BR.

MYP3 Locus for High-grade Myopia: Association Analyses and Mutation Screening. *R. Metlapally[1,2], K. N. Tran-Viet[2], T. R. White[1,2], A. Bulusu[2], B. Zhao[2], J. Zhou[2], G. R. Czaja[2], Y.-J. Li[2], T. L. Young[1,2]* 1) Duke Univ Eye Center, Durham, NC; 2) Duke Ctr Human Gen, Durham, NC.

Purpose: The first MYP3 locus (12q21-23) for autosomal dominant high-grade myopia was mapped in a large family of German/Italian origin, and was replicated in two subsequent small family studies. Our recent whole genome linkage scan using single nucleotide polymorphisms (SNPs) in a 5-site international Caucasian dataset of 249 multiplex high-grade myopia families also confirmed this locus. To identify the implicated MYP3 gene, we employed a two-pronged approach that included SNP-based association analysis to refine the interval, and sequence variant screening. **Methods:** 239 SNPs (average spacing 33.8 kilobases) for an 8 megabase (Mb) region were selected for an Illumina Goldengate genotyping assay based on coding function, biological relevance, ranking score, validation, and frequency information. A total of 657 subjects from 146 multigenerational high-grade myopia families participated in the study. Genotype data were checked and corrected for Mendelian inconsistencies. Markers were checked for Hardy-Weinberg equilibrium and linkage disequilibrium between markers was calculated. Family-based pedigree disequilibrium test (PDT), GenoPDT, and association in the presence of linkage test were used for testing SNP association with high myopia. Eight genes were sequenced in 12 affected and unaffected subjects from 3 families that showed strongest linkage to MYP3 in our linkage study. **Results:** Family-based association analyses revealed significant association of several SNPs from the 91-94 Mb interval on chromosome 12 ($p<0.01$). Based on significant association values and expression in ocular tissues, we prioritized 8 candidate genes for mutation screening: ATP2B1, EEA1, MRPL42, PLXNC1, CCDC41, TMCC3, FGD6, and C12orf63. Sequence analysis did not reveal segregated variants with affection status. **Conclusions:** The SNP-based analyses revealed potential involvement of a 3 Mb region in the MYP3 locus. Mutation analysis of 8 candidate genes in this region did not identify sequence variants associated with the MYP3 high myopia phenotype. Further screening of candidate genes is underway.

Common Genetic Variants in Candidate Genes and Risk of Familial Lymphoma. *X. Liang, D. Ng, M. L. McMaster, O. Landgren, N. Caporaso, L. R. Goldin* Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD.

A role for genetic factors in chronic lymphocytic leukemia (CLL) is unequivocal based on evidence from multiply affected families, case series and twin, case-control and population-based registry studies. Similar findings have been reported for Hodgkin lymphoma (HL), non-Hodgkin lymphoma (NHL) and WaldenstrÖm macroglobulinemia (WM). Population-based studies have found CLL, HL, NHL, and WM to co-occur in families, suggesting that shared genetic pathways may contribute to risk for multiple lymphoproliferative malignancies. Using a custom-designed Illumina panel containing 1536 SNPs, we investigated the effect of common genetic variants in 152 candidate genes from several functional groups including apoptosis, DNA repair, immune response, and oxidative stress among 44, 50, 28, and 71 unrelated familial CLL, HL, NHL, and WM patients from high-risk families, respectively, and a control group consisting of 107 spouses from the same families. Several findings were notable. SNPs in BCL2 showed an association with all four phenotypes. SNP rs9989529/BCL2 was significant in both NHL and WM with ORs of 2.28 (95% CI: 1.19-4.37) in NHL and 1.66 (95% CI: 1.08-2.56) in WM. SNP rs4987827/BCL2 was significant in both NHL and HL. Polymorphisms in IL10 (including a variant in the promoter region previously reported to be associated with NHL), TRAIL and TRAILR1 were found associated with CLL and WM. Consistent with prior data, IL6 polymorphisms were associated with WM and HL. To our knowledge, this is the first large-scale dense-SNP candidate gene study in familial lymphomas. Our results highlight the importance of both extrinsic and intrinsic apoptosis pathways in lymphoma etiology. Future investigations are needed to replicate our findings and to define functional roles of genetic variants associated with the risk of developing lymphoproliferative malignancies.

Correlation of CpG Methylation with Gene Expression in Patients with Coronary Artery Disease. *H. Tao[1], P. L. Beineke[1], S. E. Daniels[1], W. E. Kraus[2], E. R. Hauser[2], S. Rosenberg[1], J. A. Wingrove[1]* 1) CardioDx, Palo Alto, CA; 2) Duke University, Durham, NC.

We have previously shown that gene expression in circulating blood cells significantly correlates with severity of coronary artery disease (CAD). Epigenetic modifications, including CpG methylation, are known to influence gene expression, prompting us to investigate whether CpG methylation might influence gene expression in relation to CAD. To study this possibility, we measured CpG methylation in two sets of samples, choosing five genes whose expression levels have previously been shown to correlate with CAD severity: TLR5, S100A9, CAPG, TNFSRF1b, and SERPINB6. A total of 17 amplicons were used to interrogate upstream promoter regions spaced in ~ 1 Kb increments beginning at the transcriptional start site of each gene. Amplicons averaged 180 bp in length and contained an average of 4 CpGs. Genomic DNA was purified in 2 sets from 231 patients obtained from the CATHGEN registry (a biorepository paired with clinical and angiographic data in the Duke Databank for Cardiovascular Disease) and was subjected to bisulfite modification. Quantitative High Resolution Melting (HRM) was then used to estimate the degree of methylation in each of the amplicons across the first set of 143 samples. After adjusting for age, gender, ethnicity and diabetes status in a multiple linear regression model, methylation in 3 amplicons was significantly associated with expression levels as determined by RT-PCR ($p < 0.05$). A region in the TLR5 promoter showed the strongest association ($p < 0.001$), leading us to examine 7 additional loci in the TLR5 gene, of which 1 locus showed significant correlation ($p < 0.01$). When re-assessed in the second set of 88 patient samples, both loci identified in the first set were again significantly associated with expression of TLR5 ($p < 0.01$). In conclusion, we have identified two regions in the TLR5 promoter that show significant correlation between gene expression and CpG methylation levels, across 2 sets of samples. This result suggests that epigenetic modifications may play a role in regulating gene expression in CAD.

Genome-wide targets of aberrant methylation in serous epithelial ovarian cancer cells. *D. Biscocho, J. J. Connelly, Z. Huang, S. K. Murphy, S. G. Gregory* Duke University, Durham, NC.

Ovarian cancer is an insidious disease that has usually metastasized prior to diagnosis. Abnormal DNA methylation is frequently found at specific loci in ovarian cancers and may provide opportunities to improve early disease detection and treatment. Unlike genetic mutations, aberrant DNA methylation is potentially reversible via epigenetic-based therapies. We have utilized DNA tiling path arrays to determine the genome-wide distribution of methylation in cell lines derived from spontaneously transformed normal ovarian surface epithelium (NOSE-06) and malignant ovarian cancer (SKOV4). 2414 regions of the genome were identified as differentially methylated (p0.01) in SKOV4 versus NOSE-06. Several regions contained genes known to be aberrantly methylated in ovarian cancer cells lines (*GSTP1*, *FLNC*, *CDH1*, *MAGEA3*, and *PYCARD*). Interestingly, loci previously identified as methylated in ovarian cancer cell lines were methylated in NOSE-06. It is not known how spontaneous immortalization and passaging in cell culture have influenced the methylation profiles of NOSE-06, but suggests the importance of defining normal methylation profiles of relevant tissues in order to serve as a basis for comparison to ovarian malignancy. We have validated the methylation state of several novel genes using methylation specific PCR (*CDH2*, *CDH4*, *PLAUR*, *CALCB*, *PLEK2*, *FN1*, *NR2E1*). Correlative gene expression analysis identified two genes that exhibit a decrease in gene expression and an increase in promoter methylation in two separate ovarian cancer cell lines. Interestingly, these genes, fibronectin 1 (*FN1*) and alpha-actinin 1 (*ACTN1*), both play a role in cell adhesion and migration. Pathway analysis of the genes contained within differentially methylated regions indicated enrichment of pathways involved in tight junction (p=0.01) and adherens junction (p=0.05) formation. Disturbance of the integrity of intercellular junctions promotes invasiveness and mobility of cancer cells. Taken together this information indicates the role DNA methylation may play in the integrity of intercellular junctions and implicates a reversible cellular process in the oncogenic transformation of a cell.

Somatic reversion? A case of mosaic dup(17)(p11.2p11.2) in a mother and child. *R. Yusupov[1,4], A. Roberts[1,2,4], R. V. Lacro[2,4], M. Sandstrom[3], A. H. Ligon[3,4]* 1) Division of Genetics, Children's Hospital Boston, MA; 2) Department of Cardiology, Children's Hospital, Boston, MA; 3) Department of Pathology, Brigham and Women's Hospital Boston, MA; 4) Harvard Medical School Boston, MA.

Low copy repeat (LCR) sequences in 17p11.2 predispose this region to genomic deletions and duplications. Duplication of 17p11.2, also known as Potocki-Lupski syndrome (PTLS), is a recently recognized contiguous gene syndrome featuring cognitive and language deficits, developmental delay, autistic behavior, structural cardiovascular anomalies, hypotonia, failure to thrive, apnea and dysmorphism. We present a mother and child, both mosaic for dup(17)(p11.2p11.2), who share dysmorphic features. At birth, the infant was noted to have microcephaly, prominent occiput, short and down-slanting palpebral fissures, deeply set eyes, epicanthal folds, micro and retrognathia, a long, bulbous nasal tip, hypotonia and a grade II/VI harsh systolic murmur. Echocardiogram showed hypoplastic left heart syndrome with mitral and aortic atresia, hypoplastic ascending aorta, and a large patent ductus arteriosus, confirming the prenatal diagnosis. Considerable oral motor and pharyngeal phase swallowing dysfunction was present. Mosaicism for the dup(17)(p11.2p11.2) was suspected initially by GTG-banded analysis of metaphase chromosomes from peripheral blood specimens of both individuals. This suspicion was subsequently confirmed by interphase fluorescence in situ hybridization (FISH) using a probe within the Smith-Magenis critical region (17p11.2)and a control probe mapping to 17p12. In both the child and mother, the dup(17) was identified in ~60-70% of nuclei. Confirmation of this cytogenetic duplication was supported by array comparative genomic hybridization (aCGH). The fact that this aberration was visible cytogenetically suggests that the duplicated region is greater than 5Mb. Here we provide a thorough description of the phenotypes of each affected individual, and propose a mechanism by which mosaicism for the duplication could exist in individuals from two successive generations.

Sequencing reveals low variability in human microRNA genes. *C. H. Lee[1], L. Pennachio[2], A. Pertsemlidis[1]* 1) The University of Texas Southwestern Medical Center, Dallas, TX; 2) DOE Joint Genome Institute, Walnut Creek, CA.

MicroRNAs (miRNAs) are short (~21 to 23 nucleotides) RNAs that regulate gene expression by binding to the 3' untranslated region (3'-UTR) of their target mRNAs, resulting in either modulation of translational efficiency or in degradation of the mRNAs. miRNAs have been shown to play important roles in embryonic development as well as human diseases, including cancer. We sequenced nine loci containing miRNAs predicted to target genes related to lipid and sterol homeostasis in 1,917 human subjects. These subjects were drawn from the Dallas Heart Study (DHS), a single-site, multi-ethnic, population-based probability sample. We sequenced a total of 7.2 kb of genomic DNA, covering 17 mature miRNAs and 13 miRNA passenger strands. We identified 115 single nucleotide polymorphisms (SNPs) and 8 insertion/deletion polymorphisms (indels); the majority (89 of 123) of these polymorphisms were extremely rare, with minor allele frequencies of less than 0.01 across all ethnicities. The density of SNPs within mature microRNAs and passenger strands (~3.5 SNPs per kb) is much lower than the density within other regions of the miRNA precursors and the flanking regions (~7 to 12 SNPs per kb, depending on ethnicity), as is , the average per nucleotide heterozygosity (on the order of 10^{-5} for mature miRNAs and passenger strands and 10^{-4} for other precursor and flanking regions). Sequencing of approximately 100 other miRNA loci across a smaller sample of 32 African American subjects from the DHS confirmed the rarity of SNPs in mature miRNAs and their passenger strands. Several of the SNPs typed in this study showed associations with measured levels of plasma lipids, suggesting a role for miRNAs in lipid and sterol homeostasis; these associations match observations made in other published genome-wide association studies (GWAS). Together, these data provide evidence of selective pressure imposing sequence constraints on miRNAs and their precursors, as variation may affect overall miRNA expression, thereby altering the regulation of specific target genes.

Identification of a novel mutation in *LAMIN A/C* in a family with atrial fibrillation, progressive conduction system disease and dilated cardiomyopathy. *H. Pan[1], A. A. Richards[1], J. Chen[2], J. A. Joglar[2], H. L. Yin[3], V. Garg[1, 4], UT Southwestern, Dallas, TX* 1) Department of Pediatrics; 2) Department of Internal Medicine; 3) Department of Physiology; 4) Department of Molecular Biology.

Atrial fibrillation (AF) is the most common type of arrhythmia in adults, and it infrequently occurs in association with conduction abnormalities and dilated cardiomyopathy (DCM). We identified a family spanning 3 generations with autosomal dominant cardiac disease that had 15 affected members. Clinical histories were obtained by review of available medical records. Specifically, 12 subjects had AF, 12 had atrioventricular block (AVB), 10 had DCM and 8 experienced sudden cardiac death (SCD). In the majority of cases, the first symptom of disease in affected family members was a cardiac conduction abnormality, either AF or AVB, occurring between 30 and 55 years of age. DCM was always diagnosed after the initial presentation and in 5 cases with a delay of at least 8 years. Similarly, SCD occurred 5 to 30 years after the initial presentation. The subjects were studied to determine the genetic etiology of their cardiac disease. Genomic DNA was collected from available family members after obtaining informed consent. Genetic studies excluded linkage to all previously described AF loci except for the lamin A/C (*LMNA*) locus. Direct sequencing of the *LMNA* gene in affected members identified a heterozygous single base pair insertion after nucleotide 348 (c348_349insG). Consistent with the mutation being disease-causing, it segregated with affected members and resulted in a frameshift that predicted premature truncation of the protein. The observed K117fs mutation in *LMNA* is novel and highly penetrant. Mutations in *LMNA* have been described in a group of heterogeneous diseases, termed laminopathies, which affect multiple organ systems. The identification of a novel mutation in *LMNA* in this pedigree with isolated cardiac disease highlights the importance of screening for mutations in *LMNA* in patients with isolated AF, especially those with a positive family history for DCM or SCD. Additional studies of this *LMNA* mutation may suggest a mechanism for the development of AF, AVB and DCM in affected individuals.

Waved with open eyes (*woe*) phenotype caused by a mutation in *Adam17*. *E. L. Hassemer[1], R. R. Dubielzig[2], C. Zeiss[3], B. Chang[4], D. J. Sidjanin[1]* 1) The Department of Cell Biology, Neurobiology and Antomy, Medical College of Wisconsin, Milwaukee, WI 53226; 2) School of Veterinary Medicine, University of Wisconsin-Madison, Madison, WI 53706; 3) School of Medicine, Yale University, New Haven, CT 06520; 4) The Jackson Laboratories, Bar Harbor, ME 04609.

Waved with open eyes (*woe*) is an autosomal recessive mouse mutant that arose spontaneously on the C57BL/6J background. Phenotypically, the woe mice have a wavy coat, microphthalmia/anophthalmia and corneal opacities. In order to map the *woe* locus, homozygote woe mice were backcrossed to C3H mice to generate 138 F2 progeny. A genome wide scan mapped the woe locus to the proximal arm of mouse chromosome 12. Evaluation of the *woe* critical region identified *Adam17* as a candidate gene. The role of Adam17 is in shedding the soluble forms of TNF-, TGF- and other proteins from their membrane-bound precursors. The $Adam17^{-/-}$ mice are phenotypically similar to the *woe* mice; however, $Adam17^{-/-}$ mice die shortly after birth. The Adam17 sequence analysis in *woe* mice revealed a C794T substitution that leads to a Thr265Met change in an evolutionary conserved residue. To prove that the $Adam17^{Thr265Met}$ substitution is responsible for the woe phenotype, a complementation breeding was set up with an $Adam17^{+/-}$ mouse. The Adam17 null allele rescued the lethality seen in the $Adam17^{-/-}$ mouse, but did not rescue the eye and fur phenotype proving the mutation. Western blot analysis did not detect different levels of Adam17 in wild-type and woe tissues. *In-vitro* expression and subcellular localization of $Adam17^{Thr265Met}$ in COS-7 cells showed no difference in the subcellular localization between $Adam17^{Thr265}$ and $Adam17^{Thr265Met}$; however, evaluation of the free TNF- in sera of woe and wild-type mice via ELISA showed a slight decrease in $Adam17^{Thr265Met}$ shedding activity indicating that the mutation might be affecting other Adam17 specific substrates (e.g. TGF-). Our data suggest that *woe* is a hypomorphic mutation in Adam17 where the Thr265Met substitution results in lowering the metalloprotease enzymatic function. Evaluation of the role of Adam17 in ocular development is currently in progress.

Psoriasis Association with ZNF313-SPATA2 Region on Chromosome 20q13 Replicated. *R. P. Nair[1], P. E. Stuart[1], T. Tejasvi[1], H. W. Lim[2], E. Christophers[3], J. J. Voorhees[1], J. T. Elder[1]* 1) Department of Dermatology, University of Michigan, Ann Arbor, MI; 2) Henry Ford Hospital, Detroit, MI; 3) University of Kiel, Kiel, Germany.

Psoriasis is a common inflammatory skin disease with genetic, immunological and environmental inputs. Several linkage studies and recent genome-wide association studies have mapped the major genetic determinant of psoriasis susceptibility to the vicinity of HLA-C. Replicated association studies have confirmed the involvement of IL12B and IL23R in psoriasis, providing an additional genetic basis for inflammatory and immune processes in psoriasis. Recently Capon et al. (Hum Mol Genet 13:1938, 2008) reported a novel association of psoriasis to rs495337, a synonymous coding SNP located in SPATA2, which is in absolute linkage disequilibrium with ZNF313 on chromosome 20q13. Unlike SPATA2, ZNF313 is abundantly expressed in skin, T cells and dendritic cells, leading the authors to suggest that ZNF313 may be the causal genetic determinant at this locus. In the present study, we attempted to replicate this association in two large psoriasis cohorts: a collection of 686 pedigrees of varying sizes (2744 individuals), and a case/control collection of 1588 cases and 1921 controls, all of Caucasian ancestry. While the pedigrees showed no association (FBAT S* = 0.017, p = 0.68), the case/control sample showed confirmatory evidence for association (OR = 1.19, p = 3.2E-04) for the same the risk allele described by Capon et al. (G). When the case control sample was enhanced using one case per family of US Caucasians (552 individuals) for a total of 2140 cases, the association results modestly improved with no change in odds ratio (OR = 1.19, p = 8.9E-05). These results confirm the association of psoriasis with the ZNF313 - SPATA2 region. Further studies of large cohorts are needed to fine map the associated haplotype(s) and identify the causal variant(s) at this locus.

The Mouse Genome Informatics (MGI) Database: A resource for genetic and phenotypic information for mutant mice as models of human disease. *H. Onda, A. Anagnostopoulos, R. Babiuk, S. Bello, D. L. Burkart, H. Dene, M. Knowlton, I. Lu, T. Meehan, B. Richards-Smith, C. L. Smith, M. Tomczuk, L. L. Washburn, J. T. Eppig, the Mouse Genome Informatics Group* Mouse Genome Informatics, The Jackson Laboratory, Bar Harbor, ME.

Mouse models of human diseases are invaluable tools for researchers for understanding disease processes and developing potential new therapies. Physiological and genetic similarities between human and mouse make the laboratory mouse a premier model for the study of human genetic disease. With the wealth of available experimental tools for the mouse, including a high-resolution genetic map, complete genome sequence, myriad inbred and mutant strains and the technologies to alter the genome, the mouse has become an essential surrogate for exploring human disease. The Mouse Genome Informatics Database (MGI, http://www.informatics.jax.org) supports biological knowledge building for the laboratory mouse by integrating and providing access to a wide range of data including phenotype and disease associations and their underlying genetic cause; gene function and genome location; gene and protein sequence; and expression data. Currently, MGI contains almost 24,000 mouse phenotypic alleles including QTL. Over 23,000 genotypes are annotated with one or more phenotypic terms; and more than 2,200 genotypic mouse models are associated with 800+ human diseases or syndromes. Phenotypic abnormalities of mutant mice and their similarities to human disease are curated using a structured vocabulary of mouse anomalies (the Mammalian Phenotype Ontology) and human disease terms from the Online Mendelian Inheritance in Man (OMIM). These standard terms provide a backbone for robust annotation, allowing comprehensive queries and supporting web-based and computational access to phenotype and disease data. The Mouse Genome Informatics Database is supported by NIH grant HG000330.

Contribution of mtDNA to the expression profiles of human cells grown in culture and in xenografts. *P. K. Dranchak[1], D. Magda[2], P. Lecane[2], J. Prescott[2], P. Thiemann[2], X. Ma[2], D. M. Toleno[1], K. D. Siegmund[3], J. G. Hacia[1]*
1) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA; 2) Pharmacyclics, Inc., Sunnyvale, CA; 3) Department of Preventive Medicine, University of Southern California, Los Angeles, CA.

Interactions between the gene products encoded by the mitochondrial and nuclear genomes play critical roles in eukaryotic cellular function. Here, we characterized metabolic properties and gene expression profiles of A549 lung cancer cells and their isogenic mitochondrial DNA (mtDNA)-depleted ^{0} counterparts grown in culture and as tumor xenografts in immune-deficient mice. Cultured A549 ^{0} cells were respiration-deficient and showed enhanced levels of transcripts relevant to metal homeostasis, initiation of the epithelial-mesenchymal transition, and glucuronidation pathways. Intriguingly, subsets of well-established HIF-regulated transcripts were both up- and down-regulated relative to the parental cell line, implying a higher complexity in HIF-mediated gene regulation than previously reported. Surprisingly, growth in culture versus xenograft has a significantly greater influence on expression profiles, including transcripts involved in mitochondria structure, aerobic and anaerobic respiration, and splicing. However, both *in vitro* and *in vivo*, mtDNA levels explained the majority of the variance observed in the expression of transcripts in glucuronidation, heat shock response, and immune surveillance related pathways. Overall, ^{0} xenografts and cell cultures provide two distinct, yet complementary, means to investigate the role of mitochondrial function in normal and pathological cellular processes under physiological and controlled growth conditions.

The CC2D2A gene is mutated in Joubert syndrome and implicated in the function of the primary cilium/basal body. *D. Doherty[1], N. Gorden[1], H. Arts[2], M. Parisi[1], S. van Beersum[2], A. Hikida[1], A. Alswaid[3], H. Ozyurek[4], E. Otto[5], C. Hutter[6], F. Farin[7], M. Dorschner[8], N. Katsanis[9], K. Owens[10], D. Raible[10], N. Knoers[2], P. Chance[1], R. Roepman[2], C. Moens[11], I. Glass[1]* 1) Dept Pediatrics, Univ Washington, Seattle, WA; 2) Dept Human Genetics, Radboud Univ Nijmegen Med Cntr, Nijmegen, Netherlands; 3) Dept Pediatrics, King Abdulaziz Med City, Riyadh, Saudi Arabia; 4) Dept Pediatrics, Ondokuz Mayis Univ, Samsun, Turkey; 5) Dept Pediatrics, Univ of Michigan, Ann Arbor, MI; 6) Dept Epidemiology, Univ of Washington, Seattle, WA; 7) Dept Environmental & Occupational Health Sciences, Univ of Washington, Seattle, WA; 8) Dept Medicine, Univ of Washington, Seattle, WA; 9) Mc-Kusick-Nathan Inst of Genetics, John Hopkins Univ School of Med, Baltimore, MD; 10) Dept Biological Structure, Univ of Washington, Seattle WA; 11) Fred Hutchinson Cancer Research Cntr, Seattle, WA.

Joubert syndrome and related disorders (JSRD) are autosomal recessive conditions characterized by hypotonia, ataxia, abnormal eye movements, intellectual disability and a distinctive mid-hindbrain malformation. Variable features include retinal dystrophy, cystic kidney disease and liver fibrosis. JSRD are included in the rapidly expanding group of disorders called ciliopathies, as 4 of the 5 gene products implicated in JSRD (NPHP1, CEP290, RPGRIP1L and TMEM67) function in the primary cilium/basal body organelle. Using homozygosity mapping in consanguineous families, we identified loss of function mutations in the CC2D2A gene in JSRD patients with and without retinal, kidney and liver disease. CC2D2A is expressed in all fetal and adult tissues tested. A nonsense mutation in the zebrafish CC2D2A ortholog (sentinel) results in pronephric cysts, a hallmark of ciliary dysfunction analogous to human cystic kidney disease. Using a yeast two-hybrid approach, we identified a physical interaction between CC2D2A and CEP290. Knockdown of CEP290 function in sentinel fish resulted in a synergistic phenotype, highlighting the functional importance of the physical interaction. This work implicates CC2D2A in cilium/basal body function and provides a model for the role of extragenic modifiers in JSRD.

PLAC1 gene structure and transcription response elements. *Y. Chen[1], M. Zalzman[1], S. L. Lee[2], J. G. Yoo[1], D. Schlessinger[1], M. S. H. Ko[1], R. Nagaraja[1]* 1) Laboratory of Genetics, National Institute on Aging, NIH, Baltimore, MD 21234; 2) College of Veterinary Medicine, Gyeongsang National University, 900 Gazwa, Jinju, Gyeongnam, Republic of Korea 660701.

PLAC1 is an X-linked placental specific gene that is conserved in both human and mouse. Large deletions encompassing the Plac1 region in mouse cause runty phenotype or stillbirths, hinting that the gene is involved in growth control; and recent studies find PLAC1 derepressed in multiple cancer tissues and linked to tumor cell proliferation. To understand the mechanism of tissue specificity and effects on growth we characterized the genomic DNA structure and defined promoter elements. Based on 5 RACE reaction we conclude that the gene contains a total of 6 exons, 3 of which are newly defined; the lie well upstream of the known exons. The 5.2 kb sequence between the newly identified exon 1 and the next gene shows strong promoter activity when fused to a luciferase reporter gene and transfected into Bewo cells, a choriocarcinoma-derived cell-line that expresses PLAC1 endogenously. This promoter fragment was fused to a fluorescent reporter, injected into fertilized oocytes and were then allowed to differentiate into blastocysts. In an outgrowth assay of these blastocysts, expression is restricted to the cells outside the outgrowth. We are currently testing the PLAC1-positive cells for trophoblast lineage markers. Sequential deletion of the 5.2 Kb DNA indicate that 500bp 5 of exon 1 contains essential elements to yield high promoter activity Several transcription factor binding sites are included in the putative promoter region, and we are further testing the inference that they are both necessary and sufficient to provide high-level specific expression in the placenta and cancer cells.

High Fidelity of Whole-Genome Amplified DNA on High-Density Single Nucleotide Polymorphism Arrays. *Y. Zhang, J. Xing, W. S. Watkins, D. J. Witherspoon, L. B. Jorde* Dept Human Genetics, Univ. of Utah, Salt Lake City, UT.

Current microarray technology allows researchers to genotype a large number of SNPs with relatively small amounts of DNA. Nevertheless, researchers and clinicians still frequently face the problem of acquiring enough high-quality DNA for analysis. Whole-genome amplification (WGA) methods offer a solution for this problem, and earlier studies showed that WGA samples perform reasonably well in small-scale genetic analyses (e.g. Affymetrix 10K array). To determine the performance of WGA products on a large-scale genotyping array, we compared the Affymetrix 250K array genotyping results of genomic DNA and its WGA products from four individuals. Our results indicate that WGA product performs well on the 250K array compared to genomic DNA, especially when using the BRLMM calling algorithm. WGA samples have high call rates (97.5% on average, compared to 99.4% for genomic DNA) and excellent concordance rates with their corresponding genomic DNA samples (98.7% on average). In addition, no apparent systematic genomic amplification bias can be detected. This study demonstrates that, although there is a slight decrease in the total call rates, WGA methods provide a reliable approach for increasing the amount of DNA samples for a commonly used SNP genotyping array.

Chromosome 22q13.3 deletion syndrome with a *de novo* interstitial 22q13.3 cryptic deletion disrupting *SHANK3*.

A. Delahaye[1,2], A. Toutain[3], A. Aboura[2], C. Dupont[1,2], A. C. Tabet[2], B. Benzacken[1,2], J. Elion[2], A. Verloes[2], E. Pipiras[1], S. Drunat[2] 1) Cytogenetics Department, APHP-Jean Verdier University Hospital, Bondy, France; 2) Genetics Department, APHP-Robert Debré University Hospital and INSERM U676, Paris, France; 3) Genetics Department, CH Tours-Bretonneau University Hospital, Tours, France.

Background: The 22q13.3 deletion syndrome (MIM 606232) is characterized by developmental delay, absent or severely delayed speech, autistic behavior, normal to accelerated growth, and minor dysmorphic facial features. Among the three genes of the minimal critical region (from centromere to telomere: *SHANK3*, *ACR* and *RABL2B*), *SHANK3* is considered to be at the origin of the neurobehavioral symptoms. **Objective:** We describe the molecular characterization of a *de novo* interstitial del(22)(q13.3q13.3) disrupting the *SHANK3* gene in a child with a phenotype compatible with the deletion 22q13.3 syndrome. **Methods:** Clinical work up included clinical histories, physical, neurological, and ophthalmologic examinations, and imaging of the brain. Commercially available MLPA for subtelomeric analysis, FISH and quantitative real time PCR were used to characterize the rearrangement. **Results:** Subtelomeres analysis by MLPA showed a discrepancy between the P036B and P070 kits (MCR Holland): P070 MLPA probe (targeting *ARSA* gene) showed a deletion but P036B (targeting *RABL2B* gene) showed a normal result. FISH analysis using LSI TUPLE1/LSI ARSA (Vysis) probes confirmed deletion of *ARSA*, whereas FISH with N25/N85A3 (Cytocell) probes, targeting *SHANK3* locus was normal. Supplemented FISH analysis using BAC clones allowed to specify the centromeric breakpoint region of the interstitial deletion at less than 2Mb from the telomere. Quantitative real time PCR of exon 5, 22 and 24 and intron 9 of *SHANK3* showed the telomeric breakpoint occurred between intron 9 and exon 22. **Conclusions:** These data highlight the difficulty of performing an appropriate test aimed at looking for cryptic 22q13.3 deletion. Furthermore the molecular characterization of this interstitial 22q13.3 deletion contributes to clinical and genetic delineation of the 22q13.3 deletion syndrome.

Patterns of genetic differentiation between Mexican-Americans and three HapMap ethnic populations in candidate genes for depressive disorder and antidepressant response. *C. Dong, M.-L. Wong, J. Licinio* Dept Psychiatry, Univ of Miami, Miami, FL.

While major depressive disorder (MDD) is one of the most common diseases, the basis for ethnic differences in MDD susceptibility or antidepressant response is not well understood. To investigate the patterns of population differentiation of candidate genes for MDD and antidepressant response, we compared the allele frequencies of a panel of 956 SNPs in 270 candidate genes with genotypes in all four ethnic samples: 320 healthy Mexican-Americans (MA) recruited in our genetic study and three HapMap samples (CEU, CHB+JPT, YRI). F_{st} values were used to assess the population differentiation between Mexican-Americans and each of the three HapMap ethnic groups. Biological processes were determined on the basis of PANTHER classification. Overall, the greatest F_{st} was found between MA and YRI with an average value of 0.150, compared to 0.066 between MA and CHB+JPT and 0.043 between MA and CEU. The similar patterns were found by minor allele frequency, SNP type and biological process classification. General linear regression analysis showed a significant variation of F_{st} for population ($F_{(2, 3637)} = 152.84$, p 0.0001), minor allele frequency ($F_{(4, 3637)} = 19.04$, p 0.0001, SNP type ($F_{(3, 3637)} = 4.05$, p=0.0069) and biological process classification ($F_{(7, 3637)} = 3.01$, p=0.0037). A greater differentiation was also observed for coding SNPs (mean F_{st}=0.109), compared to intronic variants (mean F_{st}=0.060), in the genes in biological process of proteolysis. Our findings suggest a greater genetic differentiation between Mexican-Americans and Africans and a smaller differentiation between Mexican-Americans and Caucasians, and provide a possible basis for understanding of the genetic differentiation in susceptibility to MDD and antidepressant response across ethnic groups.

Identification of candidate transcription factors involved in human obesity. *J. Lane[1], L. Parnell[1], JP. Fortin[2], A. Kopin[2], J. Ordovas[1]* 1) Nutrition & Genomics, Tufts Univ, Boston, MA; 2) Molecular Cardiology Research Institute, Tufts Medical Center, Boston, MA.

Obesity is a complex disease that involves multiple tissues. Research in human populations is especially difficult, because of gene-by-environment interactions. We show that starting with data from a fat storage candidate gene screen in C.elegans, a novel bioinformatics approach can be used to generate candidate transcription factors (TFs) involved in obesity. In brief, human homologs of genes involved in fat storage in C.Elegans were identified. The homologs were grouped according to function and biological process, based on evidence that TFs can control groups of genes with similar function. To determine if the genes in each functional group are coordinately regulated, the upstream region of each gene in the group was scanned for common transcription factor binding sites (TFBS). TFBS that occurred in genes from the groups, but not in random sets of genes are candidates. The transcription factors (TFs) that bound to the TFBS of interest then became candidate TFs for involvement in obesity. The 46 mouse, rat, and human TFs identified as candidates were validated by searching databases of mouse knock-out data, quantitative trait loci, literature, and microarray data for evidence linking each TF back to obesity. The results highlights several promising candidates, such as CEBPB, ESR1, STAT5A, and THRB. The evidence also suggests the need for an in vitro validation of the candidates to assist in adjusting parameters in the bioinformatics screen. As an in vitro validation, during differentiation of mouse preadipocyte OP9 cells into adipocytes, measures of changes in gene expression were taken. The 46 genes will be measured for expression changes during adipocyte differentiation using a mouse microarray. Candidate transcription factors that show changes in expression level during adipocyte differentiation will be examined for single nucleotide polymorphisms (SNPs) that associate with obesity in human populations. This approach demonstrates that one can gain insight into complex diseases, such as obesity, by using publicly available data from model organisms.

Mutation analysis of the PMP22 and MPZ genes in Chinese patients with Charcot-Marie-Tooth disease. *W. Luo, Z. Ouyang* Neurology, Second Affiliated Hospital, Zhejiang University, Hangzhou, zhejiang, China.

Objective: To establish a technical platform in peripheral myelin protein 22 (PMP22) and myelin protein zero (MPZ) genes diagnosis by combining PCR based polymorphic short tandem repeats (STR) with denaturing high-performance liquid chromatography (DHPLC), and to detect the mutation of PMP22 and MPZ genes in 23 probands of Chinese patients with Charcot-Marie-Tooth disease (CMT) by using DHPLC. Methods: We detected the duplication mutation of PMP22 by PCR based polymorphic short tandem repeats, the PMP22 and MPZ point mutation by DHPLC in patients without PMP22 duplication mutation. The abnormal amplifications detected by DHPLC were sequenced. Further analysis was made to investigate whether the base variation was a polymorphism or a pathogenic mutation. Results: Seven cases of 23 CMT patients had PMP22 duplication analysis (30.4%). By using DHPLC to the mutation analysis of ten coding exons of the PMP22 and MPZ, we found eleven abnormal peak forms in nine patients. There were two in exon 4, 5 of MPZ, two in exon 5, 6 of MPZ, seven in exon 4 of PMP22. Furthermore, the amplifications with abnormal peak form were sequenced. We found two synonymous mutations in MPZ which were 657GA (Gly219Gly) in exon 5, 511AG (Pro171Pro) in exon 4, and one basic changes in the intron of PMP22 IVS4+32(CT)in seven patients. Conclusion: Established a technical platform in PMP22 and MPZ genes mutation analysis by combining PCR based polymorphic STR with DHPLC. Established the technology for mutation analysis of PMP22 and MPZ by DHPLC first in China. PCR based polymorphic STR can be used as a primary screening in the detection of PMP22 duplication analysis. Discovered a new synonymous mutations in MPZ, 511AG (Pro171Pro). Preliminarily test the reliability for the mutation analysis by DHPLC in PMP22 and MPZ. This study was funded by the grants from the National Natural Science Foundation of China (Grant No. 30672264), Health Bureau of Zhejiang Province(Grant No. 2005QN005) and Pao Yu-kong and Pao Zhao-long Scholarship.

Genomic organization of human satellite. *R. Ennesser[1], S. McCutcheon[2], M. Cummings[2], J. Doering[1]* 1) Dept. of Biology, Loyola Univ. Chicago; 2) Dept. of Bio. Sci., Univ. of Illinois at Chicago.

Beta satellite is a family of tandemly repeated 68-69 bp monomers located throughout the genome, including a 6.2 kb cluster distal to the FSHD-associated D4Z4 3.3 kb repeat array at 4q35. satellite clusters may be composed exclusively of monomers and exhibit a higher order repeat (HOR) structure or contain interspersed sequences similar to 3.3 kb repeats, which we have termed core. In order to elucidate the organization of satellite and core elements in the genome, we searched the NCBI database for core using sequence obtained from an isolated HC21p core element as well as for satellite using a sequence reported to be part of an HOR. We found both core and satellite on many chromosomes, but interestingly only two of the clusters are not associated with core, and both lacked any HOR. This finding suggests the NCBI database is underrepresented for satellite arrays. All 44 core sequences present in the NCBI database were examined and most were found to be 2.8 kb, but smaller, truncated copies also exist. The core sequences have only an 85-87% sequence similarity to each other as well to D4Z4 3.3 kb repeats. Sequence analysis identified four types of core-like element organizations, including 3.3 kb repeat arrays, classic elements flanked on both sides by satellite, junction elements flanked on only one side by satellite, and island elements not associated with satellite. The 3.3 kb arrays can also be subdivided into three groups based on distal organization. Analysis of satellite clusters flanking core has revealed high sequence similarity to regions of the 6.2 kb satellite cluster distal to 3.3 kb repeat arrays. We propose a model in which 2.8 kb core elements, including full-length LSau domains, were formed from D4Z4 via two recombinational steps with a third step producing truncations and resulting in the observed complex genomic organization. This study has provided the first high-resolution analysis of satellite and interspersed core sequences and clarified their organization at many loci.

Detection of copy number variation in mental retardation using high-density arrays. *P. Fortina[1,2], V. Alesi[1,3], L. Bernardini[3], S. Loddo[3], A. Novelli[3], I. Bottillo[3], A. Battaglia[4], M. C. Digilio[5], S. Surrey[6], B. Dallapiccola[2,3]* 1) Department of Cancer Biology, Thomas Jefferson University, Jefferson Medical College, Philadelphia, PA; 2) Department of Experimental Medicine, University La Sapienza, Rome, Italy; 3) CSS Hospital, IRCSS, San Giovanni Rotondo and CSS-Mendel Institute, Roma Italy; 4) IRCCS Istituto Scientifico per la Neuropsichiatria dell'Infanzia e dell'Adolescenza Stella Maris, Pisa, Italy; 5) Ospedale Pediatrico Bambino Gesù, Rome, Italy; 6) Cardeza Foundation for Hematological Research, Thomas Jefferson University, Jefferson Medical College, Philadelphia, PA.

Forty patients with moderate to severe mental retardation with at least one major malformation and/or dysmorphism and/or multiple minor anomalies were analyzed for pathogenic genomic changes using an oligonucleotide array with ~75 Kb spacing (Agilent Human Genome CGH 44K array), and a SNP array with ~5 Kb spacing (Affymetrix GeneChip 250K Nsp array). Copy number variations (CNVs) ranging from 0.2-22.5 Mb were identified in 11 patients (27.5%) using the Agilent array while CNVs from 0.1-23.0 Mb were identified in 16 different patients with the SNP array. CNVs were confirmed using FISH or qPCR, and 14 overlapped (74%) comparing oligonucleotide and SNP data. In both analyses, 8 patients had a deletion, 1 two non-contiguous duplications on the same chromosome, and 2 had a deletion and duplication on a single chromosome. The CNVs are presumed to be causally related to the phenotypes because of their extent and the genes involved. The SNP array showed 5 additional CNVs, including 3 deletions and 2 duplications ranging in size from 0.152-0.393 Mb confirming the higher density array is more sensitive in detecting smaller changes. An additional 32 patients with CNVs identified by other techniques were typed on the 250K Nsp, and showed agreement with previous results. The SNP array detected all changes identified by other techniques as well as a 9.5 Mb duplication not previously known. In summary, array-based platforms facilitate detection of CNVs but results must be confirmed independently and software settings must used to reduce false positives and identification of CNVs devoid of a pathogenic role.

Complement Factor H (CFH) and ARMS2/LOC387715 as Risk Factors for Age-Related Macular Degeneration in the French-Canadian Population. *M. Lanthier-Veilleux[1], P. Belleau[1], E. Deilhes[1], R. Arseneault[1], S. Dubois[1], M. Malenfant[3], N. Gaudreault[2], M.-A. Rodrigue[2], V. Raymond[1,2]* 1) Ocular Genetics & Genomic, CRCHUL, Québec City, QC, Canada; 2) Genomes Sequencing & Genotyping Platform, CRCHUL, QC, Canada; 3) Ophthalmology, Laval University Hospital (CHUL), QC, Canada.

Age-related macular degeneration (AMD), a leading cause of blindness, is a genetically complex disorder. In several Caucasian populations, variations in the genes of the alternate complement cascade represent major risk factors for AMD. However, this contribution still remains to be established in French-Canadians. To assess these genes on susceptibility to AMD in French-Canadians patients, we tested if SNPs in CFH, ARMS2/LOC387715, C-reactive protein pentraxin-related (CRP) or complement factor B (CFB)/complement component 2 (C2) were associated with the disorder. 111 unrelated FC patients and 113 controls matched for age and sex were genotyped using DNA sequencing or Sequenom mass array. AMD diagnosis was made according to the International Age-Related Maculopathy Epidemiological Study. PLINK was used to reconstruct haplotypes, Armitage tests to estimate associations. Within CFH, 2 SNPs in complete LD, rs10465586 and rs1410996, showed strong association with AMD. When carried in the TA homozygotic state, these 2 SNPs decreased by 3 fold risk for AMD. Five CFH haplotypes (17 SNPs) displayed a prevalence > 5 %. Two of these were strongly associated with AMD. The QCAMD1 haplotype was associated with an increased risk for the disorder and encompassed Y402H. On the other hand, the QCAMD2 haplotype, harboring H402H, decreased this risk. The 3rd haplotype, QCAMD3, was the only one containing the G allele at rs419137. Although it carried Y402H, its prevalence was similar between patients and controls. Among ARMS2 haplotypes, only the 1 harboring A69S increased risk for AMD. Variations in CRP and CFB/C2 were not associated with the disorder. This study demonstrates that variants of the CFH and ARMS2 genes represent major risk factors for AMD in French-Canadians. It is the 1st study to extend previous findings to 1 of the several Canadian populations.

Californias experience with a statewide prenatal screening program for chromosomal abnormalities. *M. Roberson, B. Currier, A. Davis, L. Malm, S. Smith, S. Riggle, C. Hodgkinson, C. Tempelis, L. Jellife-Pawlowski, L. Walton-Haynes, F. Lorey, N. Kazerouni* Genetic Disease Screening Program, California Department of Public Health, Richmond, CA.

Aim: Examine screening performance of Californias triple-marker screening program, utilizing data from a statewide registry for chromosomal defects. **Methods:** A total of 378,751 women who had successful screening and had an expected date of delivery in 2006 are included in the study. Follow-up diagnostic services for screen positive women were performed at State-approved centers. Data on diagnostic outcomes from these visits were entered into the statewide registry. Other registry sources include mandatory reporting by all cytogenetic labs, hospitals, State newborn screening records, and outcome data forms submitted by prenatal care providers. **Results:** The observed detection rate (DR) for Down syndrome (N=601) was 77%. It varied significantly by gestational dating method and maternal age. The rates for women under 35, and 35 and over were 61% and 95%, respectively. The DRs were 80% for ultrasound dated pregnancies and 69% for LMP-dated pregnancies. For Turners, trisomy 18, triploidy and trisomy 13, the DRs were 75%, 83%, 96%, and 39%, respectively. The Programs cut-off was a risk of 1:190 or greater for Down syndrome (DS) and 1:100 for trisomy 18 at mid-trimester, resulting in an overall program screen positive rate of 6.5%. The positive rate for DS was 5.3%. Of the women with a DS fetus that were screen positive, only 59% chose to have amniocentesis. Of the women who obtained results from amniocentesis indicating a DS fetus, 65.8 % had an elective termination, 22.4% had a live birth, 5.1 % had a demise or miscarriage, and 6.6% had an unknown outcome. **Conclusions:** The observed performance of this large triple-marker screening program exceeds generally predicted detection rates for DS. California added inhibin to its screening program in July of 2007 and will be adding first trimester markers in January of 2009. This study methodology will be used to measure the performance of these subsequent screening enhancements in this large interventional program.

Two cases of Mucolipidosis II presenting in the newborn period as a skeletal dysplasia consistent with Pacman Dysplasia. *J. Lester[1,3], T. Del Moral[2], M. Buch[2], M. Diaz-Barbosa[2], M. Fajardo[2], K. Wierenga[3], P. Jayakar[1,3], D. Barbouth[3], S. Sacharow[3]* 1) Medical Genetics, Miami Children's Hospital, Miami, FL; 2) Division of Neonatology, University of Miami, Miami, FL; 3) Division of Medical Genetics, University of Miami, Miami, FL.

Pacman dysplasia is a rare skeletal dysplasia with epiphyseal stippling and osteoclast overactivity. Mucolipidosis II (ML-II) is a condition caused by abnormal lysosomal enzyme transport due to N-acetylglucosamine-1-phosphotransferase deficiency, and results in multi-organ dysfunction, skeletal disease and cognitive decline. The proposition that Pacman dysplasia and ML-II are allelic has been controversial. We report two patients with skeletal dysplasia, consistent with Pacman dysplasia, diagnosed with ML-II by lysosomal studies. Baby A, a Hispanic male, was born to consanguineous parents at 39 weeks gestation by caesarean section because of failure to dilate. Birth weight was 2.5kg, length 46cm, and head circumference 32.5cm. At birth he had rhizomelic shortening, severe demineralization with fractures of several ribs, humeri, tibiae, and fibulae, and hypoplasia of the pelvis, rib shortening and a C7 compression fracture. Punctate calcifications of calcanei were noted. Physical exam showed micrognathia and hypertrophic gums. He required tracheostomy and gastrostomy placement. Baby B, an African-American male, was born by normal vaginal delivery at 30 weeks gestation. Birth weight was 1.5kg, length 39.5cm, and head circumference 28cm. At birth he had severe demineralization with fractures of several ribs, humeri, femora, tibiae and fibulae. Punctate calcifications of the calcanei and orbital bones were noted. Exam revealed a small mouth, contractures involving several fingers and toes, and hypertrophic gums. Since tracheal intubation, he has remained ventilator-dependent. Parathyroid hormone was elevated in both patients. Lysosomal enzymes showed high elevations of several enzymes in plasma with normal enzyme levels in leukocytes confirming the diagnosis of ML-II in both patients. These two cases add to the increasing body of evidence that Pacman dysplasia represents the severe end of the spectrum of ML-II.

Mobile elements create copy number variation in an individual human genome. *J. Xing[1], Y. Zhang[1], S. Levy[2], E. F. Kirkness[2], M. A. Batzer[3], L. B. Jorde[1]* 1) Dept Human Genetics, Univ of Utah, Salt Lake City, UT; 2) J. Craig Venter Institute, Rockville, MD; 3) Dept of Biological Sciences, Louisiana State University, Baton Rouge, LA.

Copy number variation has been the subject of much recent research. Because approximately half of the human genome consists of mobile, repetitive DNA sequences such as Alu and LINE1 elements, it is plausible that these elements play an important role in generating copy number variation. Sequencing of the diploid genome of one individual human (HuRef) affords us the opportunity to assess, for the first time, the impact of mobile elements on copy number variation in a thorough and unbiased fashion. In this study, we systematically examined more than 720,000 indels between the HuRef assembly and the Human Genome reference sequence. Combining computational analysis and PCR experiments, we identified and validated more than 600 mobile element insertion events (including Alu, L1 and SVA elements), which added ~270Kb new DNA sequence to the HuRef genome compared to the Human Genome reference sequence. We also identified more than 150 mobile element recombination-mediated deletions (RMDs) in the HuRef sequence. These events removed ~200Kb sequence from the HuRef genome. About half of the insertion/deletion events occurred in genic regions, and at least one deletion removed part of coding region of a predicted human gene. Most of these insertion/deletion events are polymorphic in human populations and have a higher frequency in European populations, in agreement with the HuRef donors ancestry. This study presents the first comprehensive analysis of mobile element variation in the complete DNA sequence of an individual and demonstrates that mobile elements play an important role in generating inter-individual indel variation. In addition, newly identified polymorphic mobile element insertions in the HuRef genome are useful tools for human population genetic studies.

A *SOD1* missense mutation in dogs with degenerative myelopathy: a spontaneous amyotrophic lateral sclerosis model. *G. S. Johnson[1], T. Awano[1], C. M. Wade[2,3], M. L. Katz[1,4], G. C. Johnson[1], J. F. Taylor[5], M. Perloski[2], T. Biagi[2], S. Long[6], S. Khan[1], D. P. O'Brien[7], K. Lindblad-Toh[2,8], J. R. Coates[7]* 1) Dept. of Veterinary Pathobiology, Univ. Missouri, Columbia, MO; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Center for Human Genetic Research, Massachusetts General Hospital, Boston MA; 4) Mason Eye Institute, Univ. Missouri, Columbia, MO; 5) Division of Animal Sciences, Univ. Missouri, Columbia, MO; 6) Section of Neurology and Neurosurgery, Univ. Pennsylvania, Philadelphia PA; 7) Dept. of Veterinary Medicine and Surgery, Univ. Missouri, Columbia, MO; 8) Dept. of Medical Biochemistry and Microbiology, Uppsala Univ., Sweden.

Canine degenerative myelopathy (DM) is a fatal neurodegenerative disease prevalent in several dog breeds. The initial signs usually occur at 8 years of age or older and are characterized by progressive upper motor neuron pelvic limb paresis and ataxia. If euthanasia is delayed, the clinical signs will ascend causing flaccid quadraparesis and other lower motor neuron signs. DNA samples from 38 DM-affected Pembroke Welsh corgi cases and 17 related clinically normal controls were used for genome-wide association mapping which produced the strongest association with markers on CFA31 in a region containing the canine *SOD1* gene. *SOD1* was considered a regional candidate gene because mutations in human *SOD1* can cause amyotrophic lateral sclerosis (ALS), an adult-onset fatal paralytic neurodegenerative disease with both upper and lower motor neuron involvement. Resequencing of *SOD1* in normal and affected dogs revealed a G to A transition, resulting in an E40K missense mutation. Homozygosity for the A allele was associated with degenerative myelopathy in five dog breeds ($p = 2.93E-19$). Microscopic examination of spinal cords from affected dogs revealed myelin and axon loss affecting the lateral white matter and neuronal cytoplasmic inclusions that bind anti-superoxide dismutase 1 antibodies. These inclusions are similar to those seen in spinal cord sections from ALS patients and transgenic rodents with *SOD1* mutations. Our findings identify canine DM to be the first recognized spontaneously occurring animal model for ALS.

Factors Impacting Transformation Efficiency of B Cells by Epstein Bar Virus in the NINDS Human Genetics DNA and Cell Line Repository. *R. A. Corriveau[1], K. P. Reeves[1], J. L. Andrews[1], C. M. Ziccardi[1], M. A. Keller[1], K. Gwinn[2], L. A. Mamounas[2], R. Zhang[2], C. M. Beiswanger[1], A. B. Ansbach[1]* 1) Coriell Institute for Medical Research, Camden, NJ; 2) National Institute of Neurological Disorders and Stroke, Bethesda, MD.

The NINDS Human Genetics DNA and Cell Line Repository was established in 2002 to support discovery of genetic risk for complex neurological diseases. To date the NINDS Repository has banked biospecimens and associated clinical data from more than 22,000 unique individuals. Samples are from donors with amyotrophic lateral sclerosis (ALS) and other motor neuron diseases, epilepsy, Parkinsons disease and related disorders, ischemic stroke, hemorrhagic stroke, aneurysm, and Tourettes syndrome, as well as from control individuals. To create a renewable biospecimen resource, B lymphocytes obtained from gradient-separated peripheral blood mononuclear cells are transformed with Epstein Barr virus (EBV) to establish lymphoblastoid cell lines. Here we evaluate the efficiency of B cell transformation by EBV. Variables evaluated include: age of subject, race, ethnicity, gender, diagnosis, smoking status, volume of blood collected, time between blood collection and processing, and type and concentration of anticoagulant. For ALS, we also analyze the relationship between disease treatment and transformation efficiency (riluzole versus no treatment). Preliminary data indicate that for 8.5 ml ACD blood collection tubes, blood specimens with volumes less than 4 ml or time to processing of more than eight days have decreased incidence of transformation. Additionally, samples submitted from younger subjects are more likely to transform successfully than samples from older subjects, with the exception of the very oldest subjects (over 90 years old), which display transformation efficiencies comparable to subjects aged 46 to 50 years (~94%). Finally, samples from subjects with the neurological diseases banked by the NINDS Repository do not appear to differ in their transformation efficiency as compared to control subjects.

Shorter telomeres in metaphase, interphase, and individual chromosomes 21, 1, 2, and 16, may indicate dementia and mild cognitive impairment in older adults with Down syndrome. *E. Jenkins[1], L. Ye[1], H. Gu[1], S. Ni[1], M. Velinov[1], D. Pang[1,2], S. Krinsky-McHale[1], W. Zigman[1], N. Schupf[1,2], W. Silverman[1,3]* 1) Dept. Hum. Genet., NYS Inst. for Basic Res. in Development. Disabil., Staten Island, NY; 2) Taub Inst. for Res. on Alz. Disease and the Aging Brain, Columbia University, 630 West 168th St., New York, NY; 3) The Kennedy Krieger Inst. and The Johns Hopkins Univ. School of Medicine, Suite 222s, 707 Broadway, Baltimore MD.

We have reported shorter telomeres (indicated by reduced fluorescence light intensities from a PNA telomere probe) in T lymphocytes of older adults with Down syndrome (DS) and dementia due to Alzheimers disease (AD; Jenkins et al., 2006). We have now extended that study by discovering that adults with DS and mild cognitive impairment (MCI-DS) also have shorter telomeres than adults with DS without MCI-DS. Cumulatively, these findings have been observed in 15 older adults with DS and dementia compared to 15 adults with DS without dementia and 8 adults with MCI-DS compared to 8 age-matched adults with DS without MCI. Additionally, new findings have shown that fluorescence light intensity measurements from chromosome 21 alone, or in combination with chromosomes 1, 2, and 16, exhibited reduced light intensities in telomeres from adults with DS with either dementia or MCI-DS compared to non-demented adults with DS only. Chromosome 21 measurements appear to be promising for use as a biomarker because there was no overlap in light intensities between demented or MCI-DS and non-demented participants with DS without MCI. Since early clinical symptoms of AD can be very difficult to recognize in this population of adults due to their pre-existing cognitive impairments, a valid biomarker would be of great value. Early detection of AD is especially important because it would allow treatments to begin before the occurrence of significant damage to the central nervous system. Our findings suggest the feasibility of using telomere shortening as a biomarker for accurately indicating dementia status. Supported in part by NYS OMRDD, Alz. Assoc. grants IIRG-07-60558, IIRG-99-1598 and IIRG-96-077; NIH grants PO1-HD35897, RO1-HD37425, and RO1-AG014673.

Screening Small Molecules for Rescue of Peroxisome Assembly Defects. *N. Braverman[1], R. Zhang[2], S. Steinberg[3]* 1) Dept Human Gen & Pediatrics, McGill Univ, MCH Res Inst, Montreal, PQ, Canada; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Medical Ctr, Baltimore MD; 3) Dept Neurogenetics, Kennedy Krieger Institute, Baltimore, MD.

Zellweger spectrum disorder (ZSD) is a heterogeneous group of autosomal recessive diseases with high morbidity and mortality caused by a failure to assemble normal peroxisomes. There are no therapies for ZSD and management is supportive. Nevertheless about half of the patients have a phenotype milder than classic Zellweger syndrome and exhibit a progressive disease course. Thus patients would benefit if therapies become available and are instituted early. Recent observations suggest that improving the conformation of a defective Pex protein, increasing its expression, or increasing peroxisome numbers results in partial recovery of peroxisome function in ZSD fibroblasts. We utilized a patient cell line with a common genotype, containing the *PEX1*-Gly843Asp and Ile700fs alleles, and engineered this to over-express a GFP-tagged PTS1 matrix protein that remains cytosolic at baseline. 2400 compounds from two small molecule libraries containing known bioactive chemicals were screened first. The cells were cultured in each compound in duplicate for two days, fixed and imaged using epifluorescent microscopy on a high content imaging platform. Redistribution of the GFP tagged matrix protein from the cytosol to the peroxisome membranes was scored visually and compared to both positive and negative controls. Currently we have identified four compounds that recover peroxisome matrix protein import and confirmatory studies are in progress. Initial studies indicate that *PEX1*-G843D homozygous and compound heterozygous primary fibroblasts attain similar functional improvement. This will be a robust platform for drug identification because analysis is based on recovery of downstream function, and is not biased toward mechanism.

Characterization and Linkage Analysis of a Large Amish Family with an Increased Prevalence of Multiple Sclerosis and Hodgkins Lymphoma. *C. A. Gurnett[1], L. Kruse[2], D. M. Desruisseau[1], W. J. Linz[3], C. E. Jackson[3]* 1) Dept Neurology, Washington University, St Louis, MO; 2) Washington University School of Medicine, St Louis, MO; 3) Scott and White Hospital, Temple, TX.

Multiple sclerosis (MS) is a multifactorial neurological disorder that is influenced by complex interactions between genetic and environmental factors. Recent genome wide association studies have identified numerous risk factors associated with MS though these only explain a small proportion of the risk for disease. We identified a four-generation Amish family from Daviess County, Indiana that consisted of ten individuals with multiple sclerosis (nine females, one male). Eight were diagnosed with clinically definite and two with clinically probable multiple sclerosis. The phenotype varied with regard to age of onset (20-50 yr) and clinical course (six relapsing remitting, two secondary progressive, and two primary progressive). Included in the family is a pair of identical twins concordant with similar clinical course (relapsing-remitting) and age of onset (23 and 30 yr). There were also four closely related males with Hodgkins lymphoma. All but one individual with multiple sclerosis had at least one copy of the HLA DRB1*1501 high-risk allele (rs3135388 A allele). Affymetrix 250K StyI genotype data were obtained and genome wide linkage analysis was performed with GENEHUNTER. Three chromosomal regions were identified with NPL scores >4 (11p14.2, NPL=7.86; 1p36.22, NPL=4.91; 6p22, NPL=4.87). Haplotype analysis enabled mapping of these regions to 6.5 cM on chromosome 1p36.22 and 3 cM on chromosome 11p14.2; the region on chr 6p22 contains HLA-DRB1. These regions, along with the high-risk HLA DRB1*1501 polymorphism, were a strong predictor of disease in this cohort. Resequencing of candidate genes (TNFRSF9, TNFRSF25, RPL22, KLHL21, and BDNF) in these regions of chromosome 1 and 11 did not reveal any novel mutations. This study identified two loci that, when inherited with HLA DRB1*1501, are a strong predictor of disease presence in this Indiana Amish family.

Further evidence of modifier gene(s) for glaucoma. *P. Belleau[1], S. Dubois[1], R. Arseneault[1], J. L. Anctil[2], E. Shink[1], M. A. Rodrigue[1], G. Côté[2], M. Amyot[3], V. Raymond[1,2], The Québec Glaucoma Network* 1) Ocular Genetics & Genomics, CREMO, Laval University Hospital (CHUL) Res Ctr, Québec City, PQ, Canada; 2) Ophthalmology, Laval Univ, Québec City; 3) Ophthalmology, Univ of Montréal, Montréal, PQ, Canada.

Primary open-angle glaucoma (POAG) is a complex disorder characterized by an optic neuropathy and visual field loss. We reported 2 huge autosomal dominant glaucoma families in which the deleterious genes were associated with wide phenotypic variabilities. In the CA family, POAG was caused by the $MYOC^{K423E}$ mutation while, in the BV kindred, the disorder was due to a *FOXC1* duplication. In the CA pedigree, $MYOC^{K423E}$ carriers clustered into large groups with extreme ages at onset (AAO). This finding supported the presence of 1 modifier altering glaucoma severity. To investigate if this variability in the BV pedigree was also caused by modifier gene(s) interacting with the primary mutation, we assessed if sub-phenotypes for the disorder clustered in particular branches of the kindred. Of the 201 BV individuals studied, 41 were carriers of the *FOXC1* duplication. Among those, 20 carriers were POAG, 12 were suspects and 9 were asymptomatics. AAO varied from 5 to 75 years old in these carriers with a mean of 34 years of age. Clusters were built using a neighboring approach in which the neighborhood of each carrier was defined as a set of pedigree members in which the kingship coefficient between the carrier and other members was 0.0625. For each carrier of the duplication, we next calculated the median of AAO for his/her neighborhood and each carrier was classified into 1 of 3 groups according to this median: group 1, 25 years old; group 2, between 26 and 38; and group 3, 39. Using this approach, 5 distinct clusters were detected in the BV pedigree; 3 were in group 3 while the other 2 clusters were in the group 1. In conclusion, in the BV family, carriers of the *FOXC1* duplication clustered into 5 large groups with extreme ages at onset for glaucoma. This observation confirms our previous finding of the presence of modifier gene(s) that alters glaucoma severity when the disorder is caused by a primary mutation.

Cardio-facio-cutaneous syndrome (CFCS) due to a novel MEK2 mutation involving four generations: Clinical delineation and natural history. *Y. Lacassie[1], S. Sampath[2], H. M. Peltier[3], S. Bale[4], K. A. Rauen[5]* 1) Dept Ped/Div Clin Genetics, LSUHSC and Children's Hospital, New Orleans, LA; 2) Dept of Genetics, LSUHSC, New Orleans; 3) The Ctr for Pediatric and Adolescent Medicine, Thibodaux, LA; 4) GeneDx, Gaithersburg, MD; 5) Div of Medical Genetics, Dept of Pediatrics, San Francisco, CA.

CFCS is a rare AD disorder characterized by cardiac abnormalities, distinctive craniofacial appearance and ectodermal anomalies. Learning disability, short stature and other findings have been reported. All cases reported are due to *de novo* mutations mainly in the BRAF but also in the MEK1, MEK2 and KRAS genes. We report 9 affected relatives spanning 4 generations detected through the diagnosis of a 7½ mo WM referred for evaluation of short stature and pulmonic stenosis (PS). The proband had a history of pyloric stenosis and had curly hair, a distinctive face with large forehead, absence of eyebrows and hypertelorism. A cavernous hemangioma, a CALS, penoscrotal inversion, ridge dysplasia and low TRC were also noted. His mother had a history of PS and learning difficulties and presented with short stature and similar CF features. From a previous union, mom had a 7-yo son with history of pyloric stenosis, lazy eye, inguinal hernia and ADHD, who on PE had prominent forehead, sparse, curly hair, absence of eyebrows, strabismus, pointed lateral incisors, a CALS, a hemangioma, pectus excavatum, minor penoscrotal inversion, a CPL in F4 and low TRC. In follow up at 1yo, along with an old family picture, it became evident that his condition was CFCS with 9 affected relatives involving 4 generations. Molecular testing showed a novel P128Q mutation in the MEK2 gene segregating with the disorder. The clinical evaluation of the family showed an evolving phenotype. All affected relatives had evident absence of the eyebrows, curly hair and prominent forehead. Most affected members had sparse hair. Learning disability and strabismus were common. PS was only seen in the proband and his mother. This large family allows the delineation of clinical features and natural history and has important implications in current genetic counseling.

Study of families with discordant/concordant sibling pairs for comgenitally missing teeth. *E. Severin[1], C. Albu[1], D. Stanciu[2], D. Albu[1]* 1) Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania; 2) Dept Orthodontics, Carol Davila Univ Med Pharm, Buharest, Romania.

Background: There is evidence that genetic factors control the phenotypic variation of dental number abnormalities and autosomal dominant forms of congenitally missing teeth are caused by different mutations in human MSX1, PAX9 and AXIN2 genes. Objective: The aim of the study is to ascertain the occurrence and characteristics of tooth agenesis in sibling pairs and to compare the findings in different families. Patients and Methods: Data from seven Caucasian sibling pairs with a family history of non-syndromic permanent missing teeth, ranging in age from 10 to 27 years, were used for analysis. Clinical, radiographic and genetic examinations were carried out. Results: Clinical examinations revealed five families in which one sibling of the sibling pair has tooth agenesis and the other has not and two families in which siblings are concordant for hypodontia but discordant for the pattern of congenitally missing teeth. There are three main groups of sibling pairs: female pairs, male pairs and female-male pairs. In all cases, one of the parents shows the clinical phenotype of hypodontia. Hypodontia is inherited as a dominant trait with autosomal transmission, complete penetrance and highly variable expression. Conclusions: Phenotypic evaluations have revealed that expression of tooth agenesis varies widely not only among, but also within families.A comparison of interfamilial and intrafamilial variability in expressivity found significantly greater interfamilial variability, suggesting that more than one gene or allele might be involved.

MAST3: a Novel IBD Risk Factor that Modulates TLR4 Signaling. *C. Labbe[1], P. Goyette[1], C. Lefebvre[1], C. Stevens[2], T. Green[2], M. K. Tello-Ruiz[2], Z. Cao[3], A. Landry[3], J. Stempak[4], V. Annese[5], A. Latiano[5], S. Brant[6], R. Duerr[7], K. Taylor[8], J. Cho[9], A. H. Steinhart[4], M. Daly[2], M. Silverberg[4], R. Xavier[3], J. D. Rioux[1]* 1) Université de Montréal, Montreal Heart Inst, Montreal, Canada; 2) The Broad Institute of MIT and Harvard, Cambridge, MA; 3) Center for Computational and Integrative Biology and Gastrointestinal Unit, MGH, Harvard, Boston, MA; 4) Mount Sinai Hospital IBD Center, U. of Toronto, Toronto, On, Canada; 5) Gastrointestinal and Endoscopy Units, I.R.C.C.S. Hospital, San Giovanni Rotondo, Italy; 6) Meyerhoff Inflammatory Disease center, Johns Hopkins University School of Medicine, Baltimore, MD; 7) School of Medicine, University of Pittsburgh, Pittsburgh, PA; 8) IBD Center, Cedars-Sinai Medical Center, Los Angeles, CA, USA; 9) IBD Center, Department of Medicine, Yale University, New Haven, CT.

Inflammatory bowel disease (IBD) is a chronic disorder caused by multiple factors in a genetically susceptible host. Significant advances in the study of genetic susceptibility have highlighted the importance of the innate immune system in this disease. We previously completed a genomewide linkage study and found a significant locus (IBD6) on chromosome 19p. We were interested in identifying the causal variant in IBD6. We performed a two-stage association mapping study. In stage one, 1530 SNPs were selected from the HapMap database and genotyped in 761 patients with IBD. Among the SNPs that passed the threshold for replication, 26 were successfully genotyped in 754 additional patients (stage two). One intronic variant, rs273506 located in the MAST3 gene was found to be associated in both stages (pooled $P=2x10^{-4}$). We identified four MAST3 coding variants, including a non-synonymous SNP rs8108738, correlated to rs273506 and associated to IBD. To test whether MAST3 was expressed in cells of interest, we performed expression assays which showed abundant expression of MAST3 in antigen presenting cells and in lymphocytes. The knockdown of MAST3 specifically decreased TLR4 dependent NF-B activity. Our findings are additional proof of the pivotal role played by modulators of NF-B activity in IBD pathogenesis.

Novel systems-based endophenotypes spanning psychosocial stress, hormones, and vascular damage for genome wide linkage and association analyses in the Jackson Heart Study. *S. G. Buxbaum[1], M. Sims[2], E. Fox[2], L. Ekunwe[1], K. T.Cuenco[3]* 1) Jackson Heart Study, Jackson State Univ, Jackson, MS; 2) Jackson Heart Study, School of Medicine, University of Mississippi, Jackson, MS; 3) School of Dentistry, University of Pittsburgh, Pittsburgh, PA.

Earlier studies have shown that the risk for accumulating vascular damage leading to disease is elevated in African Americans (AA), and that psychological stress and hormone levels may play an important role in influencing vascular outcomes. Using extensive pedigree, biologic, and psychosocial data in the Jackson Heart Study (JHS),a population-based study that has a primary goal of identifying underlying causes of AA vascular disease, we are conducting genomewide studies of novel endophenotypes that incorporate vascular, endocrine, and psychosocial measures. 2108 JHS AA(including 539 family members) have provided psychosocial stress and biologic data on hormones and inflammation in addition to vascular disease outcomes during 2004-8. Psychosocial stress levels were assessed by responses to questions regarding negative life events, feelings of hopelessness, negative societal interactions, anger, violence, social support, and SES. Hormone and endocrine measures included cortisol, insulin, endothelin, and aldosterone as well as reproductive history. Vascular damage was assessed through inflammation and cell adhesion measures. Factor analyses identified a system of correlated stress and vascular measures. Genomewide linkage analysis and family-based transmission disequilibrium tests for association were conducted on multiallelic markers. Preliminary results suggest that vascular and psychosocial stress are quantifiable using a system of five multivariate factor scores (heritability ranging from 0.25 to 0.51). Initial inkage peaks mapped to regions of chromosomes 1p34.1-p32 (p=7.9 x 10-5), 3p25.3 (p=3.7 x 10-6), 10p12 (p=1.2 x 10-6), and 15q12 (p=6.0 x 10-5). Single marker associations of nuclear families suggest that AVSD2 and EIG5 (susceptibilities to atrioventricular septal defect and idiopathic general epilepsy) may be correlated with systems-based vascular damage measures (p-values=0.01 and 0.044, respectively).

Novel Copy Number Variants in Children with Autism and Additional Developmental Anomalies. *L. Davis[1, 2], K. Meyer[1, 2], D. Rudd[1, 2], A. Librant[1], E. Epping[1], V. Sheffield[2, 3, 4], T. Wassink[1, 2]* 1) Dept Psychiatry, Univ Iowa, Iowa City, IA; 2) Interdepartmental Genetics Program; 3) Dept Pediactrics, Univ Iowa, Iowa City, IA; 4) Howard Hughes Medical Institute, Univ Iowa, Iowa City, IA.

Autism is a neurodevelopmental disorder characterized by three core symptom domains: ritualistic-repetitive behaviors, impaired social interaction, and impaired communication and language development. Recent studies have highlighted recurrent copy number changes in autism, such as 16p11.2 deletions and duplications (Christian et al. 2008; Marshall et al. 2008; Weiss et al. 2008), as well as a significant role for unique, novel variants (Christian et al. 2008; Davis et al. 2008; Roohi et al. 2008). We used Affymetrix 500K GeneChip Microarray technology to detect these smaller microdeletions and duplications in a subset of children from the Autism Genetic Resource Exchange (AGRE). In order to enrich our sample for potentially pathogenic CNVs we selected children with autism who had additional phenotypic features suggestive of a developmental disturbance (positive criteria filter) but who had normal cytogenetic testing (negative criteria filter). We identified families with the following features: two or more children with autism, at least one of whom also had facial dysmorphology, limb or digit abnormalities, or ocular abnormalities. To detect changes in copy number we used a publicly available program, Copy Number Analyser for GeneChip (CNAG) Ver. 2.0, developed at The University of Tokyo (Nannya et al. 2005). We identified novel deletions and duplications on chromosomes 1q24.2, 2q37.3, 3p26.1, 3p26.2, 4q34.2, and 6q24.3. Several of these deletions and duplications include new and interesting potential candidate genes for autism such as syntaxin binding protein 5 (STXBP5 also known as tomosyn) and leucine rich repeat neuronal 1 (LRRN1 also known as NLRR1). Lastly, our data suggest that rare pathogenic microdeletions and duplications may have a substantially higher prevalence in children with autism plus additional developmental anomalies.

Dysregulation of *p63* (*TP73L*) Expression and Desmosomal Assembly as Etiologic Factors for Bladder Exstrophy-Epispadias Complex. *B. Ching[1], G. Yagnik[1], L. Qi[2], C. Nauta[1], A. Hata[1], M. Ludwig[3], H. Reutter[4], C. Naydenov[5], J. P. Gearhart[6], S. A. Boyadjiev Boyd[1,6]* 1) Dept of Pediatrics, Section of Genetics, Univ California Davis, Sacramento, CA; 2) Rowe Program in Human Genetics, Dept Public Health Sciences, Univ California Davis, Davis, CA; 3) Dept of Clinical Chemistry and Pharmacology, University of Bonn, Bonn, Germany; 4) Dept of Human Genetics, University of Bonn, Bonn, Germany; 5) Dept of Chemistry and Biochemistry, Medical Univ Sofia, Sofia, Bulgaria; 6) Dept of Urology, The James Buchanan Brady Urological Institute, Johns Hopkins University, Baltimore, MD.

The bladder exstrophy-epispadias complex (BEEC) is a spectrum of congenital anomalies of the abdominal wall, bladder, bony pelvis, and genitalia, ranging from isolated epispadias, to its most severe form, cloacal exstrophy (OEIS complex). The etiology of BEEC is unknown, but there are indications that genetic factors contribute to this birth defect. Loss of function of *p63*, a *p53* homolog, causes developmental defects of skin and limbs in transgenic mice. Bladder exstrophy and related urogenital defects are also present in a proportion of the knockouts. Furthermore, *p63* gain of function mutations in humans cause at least 5 different genetic syndromes that present with urogenital anomalies. We have performed detailed *p63* sequencing and expression analysis in a cohort of BEEC patients. Although no obvious mutations have been detected thus far, we observed reproducible dysregulation of variable p63 isoforms in eight of fourteen blood- or bladder- derived cDNA samples. Independently, microarray expression analysis of normal vs. exstrophic bladder samples was carried out to identify differentially expressed genes. A higher than expected proportion of the differentially expressed genes were related to desmosomal assembly and function, suggesting an association of BEEC with desmosomal dysregulation. Interestingly, the downstream target of *p63*, *PERP*, encodes a tetraspan protein that is an integral part of the desmosome. Consistent with the suggested multifactorial inheritance of this birth defect, we suggest that *p63* defects lead to dysregulation of desmosomal assembly, thus contributing to the etiology of BEEC.

Reduced expression of integrin v8 is associated with brain arteriovenous malformation (BAVM) pathogenesis. *H. Kim[1,2], H. Su[1], L. Pawlikowska[1,2], H. Kitamura[3], F. Shen[1], S. Cambier[3], J. Markovics[3], M. T. Lawton[4], S. Sidney[5], A. Bollen[3], P.-Y. Kwok[2], L. Reichardt[6], W. L. Young[1,4], G.-Y. Yang[1,4], S. L. Nishimura[3]* 1) Dept Anesthesia, UCSF, San Francisco, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA; 3) Dept Anatomic Pathology, UCSF, San Francisco, CA; 4) Dept Neurological Surgery, UCSF, San Francisco, CA; 5) Division of Research, Kaiser Permanente Northern California, Oakland, CA; 6) Dept Physiology, UCSF, San Francisco, CA.

Background: Brain arteriovenous malformations (BAVMs) are a potentially devastating hemorrhagic disease with little known of their pathogenesis. TGF- signaling is required for proper vessel development, and defective TGF- signaling has been implicated in BAVM pathogenesis. We hypothesized that expression of the TGF- activating integrin, v8, might be reduced in BAVMs and that decreased 8 expression might lead to defective neoangiogenesis. **Methods:** We tested integrin v8 involvement in BAVM pathogenesis by: 1) determining 8 protein expression in perivascular astrocytes by immunostaining BAVM lesional tissue and controls, 2) measuring angiogenic response to focal vascular endothelial growth factor (VEGF) stimulation in adult brains of conditional itgb8 knock-out mice, 3) evaluating association of common genetic variants in ITGB8 with BAVM susceptibility in 194 BAVM cases and 127 healthy controls of Caucasian ancestry, and 4) correlating ITGB8 genotypes with 8 immunostaining in a subset of 28 patients. **Results:** Integrin 8 expression was significantly decreased in perivascular astrocytes of BAVM tissue compared to controls (P=0.002). Adenoviral Cre-mediated deletion of 8 in adult mouse brain resulted in enlarged dysplastic vessels in response to focal VEGF stimulation. Two ITGB8 SNPs (rs10486391 and rs11982847) and their haplotypes in the 5' region were associated with BAVM in Caucasians. BAVM-associated SNP genotypes were also associated with 60% decreased expression of integrin 8 in BAVM tissue (P=0.016). **Conclusion:** Reduced expression of integrin 8 is involved in the pathogenesis of sporadic BAVMs.

Development and evaluation of new mask protocols for gene expression profiling in humans and chimpanzees. *D. Toleno[1], G. Renaud[2], T. Wolfsberg[2], K. Siegmund[3], J. Hacia[1]* 1) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA, USA; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland, USA; 3) Department of Preventive Medicine, University of Southern California, Los Angeles, CA, USA.

Gene expression oligonucleotide microarrays are typically designed to detect the abundance of specific transcripts based on a reference genome sequence. Consequently, sequence differences between the arrayed oligonucleotide probes and transcriptome under consideration can lead to spurious estimates of transcript abundance. Here, we developed new methods for probe masking based on the most recent releases of human and chimpanzee genome sequences. Using publicly available tools from Bioconductor, data from probes predicted to have poor hybridization sensitivity and specificity to human and/or chimpanzee transcriptomes are discarded, followed by the removal of data from probe tilings with limited numbers of remaining probes. We investigated the effects of varying probe number on estimation of gene expression scores from five tissues derived from six humans and five chimpanzees. We consistently found that probe sampling has a significant effect on the variation of gene expression scores across samples, with fewer sampled probes resulting in more apparent expression variation for a probe tiling. The effect of probe number is greater when probe tilings have less than six probes remaining relative to the effect observed for gene expression estimated from between six probes and the full complement of eleven probes. Based on replicate probe sampling analyses, we found that the false positive and false negative rates for identifying cross-species gene expression difference increase with decreasing probe number. Overall, we provide a new resource for the analysis of human and chimpanzee transcriptomes and novel guidelines for probe masking.

Mutations in SPG11 and SPG15 account for the majority of cases with autosomal recessive complicated spastic paraplegia with thin corpus callosum. *G. Stevanin[1,15], C. Goizet[1,14], A. Boukhris[1,12], S. Hanein[1], P. Denora[1,13], H. Azzedine[1], P. Coutinho[2], A. Lossos[3], M. Tazir[4], A. Hamri[5], A. Benomar[6], M. Huntchinson[7], A. L. Rosa[8], M. Tada[9], J. Vale[10], C. Tallaksen[11], A. Durr[1,15], C. Mhiri[12], F. M. Santorelli[13], A. Brice[1,15], SPATAX network* 1) INSERM / UPMC U679 - NEB, Paris, France; 2) Hosp. S. Autosomal recessive hereditary spastic paraplegias (ARHSP) with thin corpus callosum (TCC) are neurodegenerative diseases characterized by lower limb spasticity and mental impairment. Recently, we identified mutations in the SPG11 and SPG15 genes in patients. Their expression patterns are very similar in rat adult brain and expression is also detected in embryos. In a large series of index patients (n=127, 74 with AR-HSP, 53 sporadic cases) with this condition, we have identified 51 mutations in the SPG11 gene segregating in 111 cases (44 families) and in 17 apparently isolated cases, from 16 Countries. In SPG15, 16 different truncating mutations have been identified in 15 families (in progress). Overall, the phenotype of the SPG11 or SPG15 patients is severe and includes mental retardation or cognitive decline, lower motor neuron degeneration and slight cerebellar signs. In addition to TCC, brain MRI reveals frequently white matter alterations and cortical atrophy that worsen with disease duration. Disease onset occurs during the first to the third decade by problems with gait and/or mental impairment. Our study reveals the high frequency of SPG11 and SPG15 mutations in patients with HSP, TCC and mental/cognitive impairment, including isolated patients with this clinical profile.

A novel susceptibility locus for type 1 diabetes maps to human chromosome 21q22.3. *S. Onengut-Gumuscu[1], P. Concannon[1], J. A. Todd[2], D. J. Smyth[2], F. Pociot[3], R. Bergholdt[3], B. Akolkar[4], H. A. Erlich[5], J. E. Hilner[6], C. Julier[7], G. Morahan[8], J. Nerup[3], C. Nierras[9], WM. Chen[1], S. S. Rich[1], Type 1 Diabetes Genetics Consortium* 1) Ctr for Public Health Genomics, Univ of Virginia, VA, USA; 2) JDRF/WT DIL, Cambridge Inst for Medical Research, Univ of Cambridge, UK; 3) Steno Diabetes Ctr, Denmark; 4) Div of Diabetes, Endocrinology and Metabolic Diseases, NIDDK, NIH, MD, USA; 5) Roche Molecular Systems, CA, USA; 6) Wake Forest Univ, Health Sciences, NC, USA; 7) Inst de Genomique CNG, France; 8) WA Inst for Medical Research, Univ of Western Australia, Australia; 9) JDRF, NY, USA.

In an effort to map genomic regions linked to Type 1 diabetes (T1D), the Type 1 Diabetes Genetics Consortium (T1DGC) has genotyped 6,090 single nucleotide polymorphisms (SNPs) in 2,496 affected sib pair families. In the current study, we exploited the genome-wide linkage scan data to test for evidence of family-based association to T1D, using the pedigree disequilibrium test (PDT). P-values for each SNP were ranked, the top three SNPs localized to previously identified T1D risk loci INS (11p15), IFIH1 (2q24), and KIAA0350 (16p13). The fourth most strongly associated SNP is rs876498 ($P= 1.0\times10^{-4}$), which maps to 21q22.3, in a region that previously was not associated with T1D risk. rs876498 is located within the 'Ubiquitin associated and SH3 domain containing protein 3A' (UBASH3A) gene. UBASH3A is expressed primarily in lymphoid cells where it interacts with c-CBL and may help to down-regulate protein tyrosine kinases that are activated upon T-cell receptor stimulation. The association of T1D with rs876498 was replicated in two independent sets of samples, 2,214 trio T1D families from USA and Denmark and 17,400 British cases and controls. Overall the minor allele of rs876498 is significantly associated with T1D ($P= 6.4 \times 10^{-12}$; OR= 1.10; 95% CI[1.07-1.13]). This study provides compelling support for a novel T1D risk locus on chromosome 21, and suggests further genetic and functional studies are warranted to identify the causative variant(s) within this region.

BFAST: Blat-like fast alignment search tool. *N. Homer, S. F. Nelson, B. Merriman* University of California Los Angeles 5554 Gonda, 695 Young Drive South David Geffen School of Medicine at UCLA Los Angeles, CA 90095-7088.

Recently developed high-throughput next-generation sequencing technologies have begun to replace the previously dominant Sanger sequencing technology in terms of cost and throughput. Technologies like Illumina's Genome Analyzer, Roche's 454, and ABI's SOLiD are able sequence billions of bases in a matter of days. These technologies rely on producing short reads making the alignment of these reads to a reference genome difficult. Additionally, these technologies allow for paired-end reads, which further increases the capacity and also the potential accuracy when considered during alignment. Nevertheless, the number of reads generated by these high-throughput systems overwhelms current algorithms in the context of whole-genome sequencing. Additionally, these algorithms encounter difficulty when aligning reads that include sequence variants. Therefore we have developed a new sequence alignment tool for whole-genome sequencing called BFAST, or Blat-like Fast Alignment Search Tool. BFAST uses various subsets of bases for a given read to search corresponding index of the reference genome. In this fashion, the search space is significantly reduced giving a set of Candidate Alignment Locations (CALs) for the read, which can be subsequently aligned using standard dynamic programming techniques. BFAST is fully generalizable as to be robust against common variants such as mismatches, insertions and deletions as well as sequencing errors. We have implemented a multi-threaded and parallelizable software suite that can now be used to quickly and accurately perform whole-genome sequencing.

Identification of Autism candidate gene through proteomic profiling in Drosophila melanogaster heads. *S. Sarkardei[1], E. Cummings[2], G. Hilliard[2], L. Reiter[1]* 1) Neurology, UTHSC, Memphis, TN; 2) Department of Mol Sci, UTHSC, Memphis, TN.

Autism is an enigmatic childhood disorder of unknown origin, characterized by developmental, language and social deficits, ranging in severity from patients with profound deficits to individuals that are high functioning. Autism spectrum disorders (ASD) affect almost 1 in 150 children, males 3-4 times more than females, but in only 10% of these individuals is autism associated with a recognized cause. Understanding the molecular pathways dysregulated in Angelman syndrome (AS), a disorder related to autism, can provide key insights leading to identification of autism susceptibility genes and pathways. Approximately 3% of all autism cases result from maternal duplications of the region containing the AS gene *UBE3A*. The protein targets of *UBE3A* which cause the neurological defects observed in patients with AS are still largely unidentified. We have been using a novel strategy to identify these protein targets using over-expression and protein profiling in the brains of Drosophila melanogaster. In this approach we express high levels of both human and Drosophila *UBE3A* proteins in fly head using the GAL4/UAS system. To identify these potential protein targets, *UBE3A* is over-expressed in the brains of flies ubiquitously using the *Heatshock*-GAL4 driver. The targets are then identified by Rotofor-assisted proteomic profiling and followed by MALDI-ReTOF protein identification. We will discuss the neurologically relevant targets identified so far, which are involved in energy metabolism; dopamine biosynthesis; cell motility and neuromuscular development. Some of these targets include: GTP cyclohydrolase I; arginine kinase; tropomyosin; sodium pump alpha subunit; UBQLN1; calreticulin and synapse associated protein.

Creatine deficiency due to a novel nonsense mutation in the arginine:glycine amidinotransferase gene. *R. K. Bai[1], K. J. Wierenga[2], D. P. Dimmock[1], L. Y. Tang[1], L. J. C. Wong[1]* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Medical Genetics, University of Miami, Miami, FL.

Arginine:glycine amidinotransferase (AGAT) catalyzes the first step of creatine synthesis by combining arginine and glycine to form guanidinoacetate (GAA) and ornithine. AGAT is encoded by GATM gene, which has nine coding exons and has been mapped to 15q21.1. The cDNA is 1272 bp long encoding a protein of 423 amino acids. GAA is subsequently converted to creatine by the action of guanidinoacetate methyltransferase (GAMT). To date, only one affected family has been described with this disorder. In this kindred, two affected siblings, and subsequently their second cousin and another sibling were found to be homozygous for a nonsense mutation, c.446G>A, p.W149X, resulting in an undetectable mRNA by RT-PCR, and undetectable AGAT activity. The two female siblings, aged 4 and 6 years, had presented with mental retardation and severe brain creatine deficiency detected by NMR Spectroscopy. Cerebral deficiency was reversed by oral creatine supplementation, with favorable clinical response. Here we report a novel homozygous nonsense mutation, c.505C>T, p. R169X in two adult siblings, a 26 year old female and a 23 year old male, children of a first-cousin relationship. Both had significant developmental delay in early childhood without diagnosis, and adult-onset of proximal muscle weakness with undetectable GAA levels in plasma and urine as part of a genetic evaluation. The p.R169X mutation results in a truncated protein lacking all three important amino acid residues, C407, H303 and D254, that form the proposed catalytic triad. Evaluation of the parents revealed that each is a carrier for the p. R169X mutation. Consistent with the previously reported truncating mutation, both siblings have extremely low levels of AGAT mRNA by quantitative RT-PCR (~5% of the controls). The mothers AGAT mRNA level is ~45% of the controls. This is the second mutation found in the GATM (AGAT) gene and the second kindred described with arginine:glycine amidinotransferase (AGAT) deficiency.

***In vitro* and *in vivo* analysis of the AMP-activated protein kinase alpha subunit (AMPK) carboxyl-terminus reveals vital roles in both localization and function.** *T. Williams, N. Kazgan, LJ. Forsberg, JE. Brenman*
Neuroscience, UNC CHAPEL HILL, Chapel Hill, NC.

Often referred to as an energy sensor, AMP-activated protein kinase (AMPK) is a serine-theronine kinase whose function has been implicated in cell polarity and cell division, in addition to energy metabolism. AMPK is a heterotrimer composed of a catalytic subunit and two regulatory subunits, and . There are regions within each subunit that have considerable conservation across species. Specifically, the amino acid sequence of the kinase domain within AMPK is highly conserved. However, the carboxyl-terminus lacks conservation with the exception of the last 20 amino acids. We hypothesize that the last 20 amino acids are vital to the structure, function, and/or localization of AMPK. To test this hypothesis we generated mammalian constructs, GFP tagged full length AMPK (pGFP-AMPKwt) and Truncated AMPK (pGFP-AMPKtrunc) missing the last 20 amino acids, and performed transient transfection in HeLa cells. *In vivo*, we utilized transgenic Drosophila fruit flies expressing either full length AMPK or the truncated version. Both *in vitro* and *in vivo* experiments demonstrated AMPK localization in both the cytoplasm and nucleus, with the truncated version enriched in the nucleus. HeLa cells transfected with pGFP-AMPKwt and pGFP-AMPK-trunc were treated with leptomycin B (LMB) in order to determine if the observed nuclear localization was due to a block in CRM1 mediated nuclear export. Post LMB treatment pGFP-AMPKwt expression localized to the nucleus suggesting AMPK nuclear export is CRM1 mediated. In addition, the last 20 amino acids appear to be vital for AMPK function *in vivo*. AMPK null flies are 2nd instar larval lethal and have neuronal phenotypes. Furthermore, while wildtype AMPK is able to rescue both the neuronal phenotypes and lethality, the truncated transgenic flies lacking the final 20 amino acids are unable to rescue any of the AMPK null phenotypes in flies. In conclusion, our studies indicate that the last 20 amino acids of AMPK are important for localization and function. We intend to investigate whether the truncated function is altered, reduced, or completely diminished.

BAC-FISH assay for FGFR1 rearrangement in 8p12-MPD and report of a new patient with t(8;9)(p12;q33). *R. Fraser[1], M. Nicola[1], J. Suttle[1], N. Patton[2], S. Moore[1]* 1) Division of Molecular Pathology, Institute of Medical and Veterinary Science, Adelaide, Australia; 2) Division of Haematology, Institute of Medical and Veterinary Science, Adelaide, Australia.

Fibroblast Growth Factor Receptor 1 (FGFR1) gene rearrangement is the molecular hallmark of a recently recognised group of myeloproliferative disorders (MPD) that affect the hemopoietic stem cell. This disease mimics CML in that it has an early chronic phase and a more aggressive blastic phase, which is usually fatal within 12 months of diagnosis. A new small molecule tyrosine kinase inhibitor, PKC412, has been demonstrated to inhibit the proliferation of FGFR1-rearranged cells and clinical trials are underway to determine its therapeutic efficacy. Since FGFR1 is a promiscuous gene, with rearrangement at 8 different chromosomal loci reported so far, detection of FGFR1 rearrangement by BAC-FISH is of obvious use in the identification of patients who may benefit from treatment with PKC412. A 63 year old woman presented to our Unit in July 2007 with MPD showing marked bone marrow eosinophilia and the cytogenetic finding of t(8;9)(p12;q33). Utilising BACs from the Childrens Hospital Oakland Research Institute we demonstrated that the FGFR1 gene was disrupted in this patients malignant cells and that she was therefore a candidate for treatment with PKC412. She commenced therapy in January 2008 and showed a reduction in white cell count. Dose escalation resulted in further improvement, although her response has now plateaued. We have used BAC-FISH as a rapid and sensitive method to provide an individualised FISH result within 48 hours. Since new targeted therapies are under constant development, fast confirmation of chromosomal breakpoints and resultant gene disruption is required to identify those patients who may obtain clinical benefit from these novel therapies. This technique also allows monitoring each patients responses to therapy should their tumor burden fall below the level detectable by classical cytogenetic evaluation.

Recurrent 1q21.1 microdeletions associated with variable disease phenotypes. *H. Mefford[1], A. Sharp[2], B. Conrad[3], T. Walsh[4], S. Antonarakis[2], C. Chen[5], G. Gimelli[6], S. Schwartz[7], J. Sutcliffe[8], S. Knight[9], J. Sebat[10], C. Romano[11], C. Schwartz[12], J. Veltman[13], B. de Vries[13], J. Vermeesch[14], J. Barber[15], L. Willatt[16], M. Tassabehji[17], E. Eichler[1,18], The 1q21.1 Deletion Consortium* 1) Genome Sciences, Univ of Washington, Seattle, WA; 2) Genetic Medicine & Development, Univ of Geneva, Switzerland; 3) Human Genetics, Bern Univ Children's Hospital, Switzerland; 4) Medicine, Univ of Washington, Seattle, WA; 5) Applied Biosystems, Foster City, CA; 6) Instituto G. Gaslini, Genova, Italy; 7) Univ of Chicago, Chicago, IL; 8) Vanderbilt Univ, Nashville, TN; 9) Wellcome Trust Centre for Human Genetics, Oxford, UK; 10) CSHL, Cold Spring Harbor, NY; 11) IRCCS Assoc. Oasi Maria Santissima, Troina, Italy; 12) Greenwood Genetic Center, Greenwood, SC; 13) Radboud Univ Nijmegen Medical Centre, The Netherlands; 14) Human Genetics, Catholic Univ of Leuven, Belgium; 15) Salisbury District Hospital, Salisbury, UK; 16) Medical Genetics, Univ of Cambridge, UK; 17) Medical Genetics, Univ of Manchester, UK; 18) HHMI, Seattle, WA.

We present a series of patients with recurrent reciprocal rearrangements of chromosome 1q21.1 associated with a variable spectrum of phenotypes. We identified 20 individuals with a recurrent 1.35-Mb deletion from a screen of 5243 patients with mental retardation and/or congenital anomalies. The deletions are *de novo* in five cases, inherited from an apparently unaffected parent in seven cases, and of unknown inheritance in eight cases. The deletion was absent in 4737 controls, representing a significant association with disease ($p<3x10^{-6}$). Considerable variability in expressivity was observed among probands including mental retardation, microcephaly, cardiac abnormalities and cataracts. The reciprocal duplication seems enriched in affected individuals but too few cases (8/5243) were observed to conclude statistical significance. We predict that screens for structural variants across large patient pools with diverse and complex phenotypes will reveal other recurrent molecular lesions that elude syndromic classification. Clinical recognition of these patients may be most effective by diagnosis based on genotype rather than phenotype.

FGFR2 SNPs are associated with contralateral breast cancer in the WECARE Study. *S. Teraoka[1], A. Reiner[2], J. L. Bernstein[2], R. W. Haile[3], P. Concannon[1], The WECARE Study Consortium* 1) University of Virginia, Charlottesville, VA; 2) Memorial Sloan Kettering Cancer Center, NY, NY; 3) University of Southern California, LA, CA.

Recent genome-wide association studies have identified single nucleotide polymorphisms (SNPs) in the *FGFR2* gene that are associated with breast cancer risk. To assess the role of variation at *FGFR2* in risk of developing second primary breast cancer, we genotyped 6 SNPs in *FGFR2* intron 2 in all 2105 subjects in the WECARE Study. The WECARE Study is a multi-center, population-based, case-control study designed to examine gene-environment interactions and risk of contralateral breast cancer (CBC). The study population included 708 women with CBC (cases), and 1397 women with unilateral breast cancer (UBC) (matched controls), all of whom were ascertained through five population-based cancer registries in the U.S. and in Denmark. Controls were matched 2:1 on birth year, year of breast cancer diagnosis, registry, race, and counter-matched on registry-reported radiation exposure. Minor alleles at three of the *FGFR2* SNPs were associated with CBC; rs2981582 (rate ratio (RR) = 1.3, 95% confidence interval (CI) = 1.1-1.7), rs2981578 (RR = 1.4, 95% CI = 1.1-1.8), and rs1078806 (RR = 1.3, 95% CI = 1.0-1.6). No significant interactions were observed for any of these SNPs with either radiation dose or age at onset. A consideration of haplotypes formed from these SNPs suggests that the association between *FGFR2* and CBC is haplotype-based. These findings further support a role for variation at the *FGFR2* locus in modifying risk for breast cancer.

PAX3 and MITF oppositely regulate a melanogenesis nodal point in metastatic melanoma cell lines. *M. Eccles[1], S. He[1], A. Jeffs[1], C. Li[1], A. Glover[1], J. Ineson[1], E. Marshall[2], H.-S. Yoon[1], B. Baguley[2]* 1) Dept of Pathology, Dunedin School of Medicine, University of Otago, Dunedin, New Zealand; 2) Auckland Cancer Society Research Centre, The University of Auckland, Auckland, New Zealand.

PAX3 and MITF are markers of the neural crest cell lineage. These two proteins form part of a network of proteins that regulate neural crest and melanocyte developmental pathways. We are interested in whether PAX3 and MITF proteins control a gene regulatory nodal point in melanoma cells, just as in melanocytes, and whether this has gone awry in melanomas, thereby providing a mechanism for failure of proper differentiation in melanoma onset. In this research we found that PAX3 and MITF were expressed in skin melanocytes, nevi, and primary and metastatic melanomas, but they were not necessarily expressed together. That developmental pathways could be part of subsequent progressive oncogenic changes is suggested, as there was a progressive acquisition of PAX3, or MITF and co-expression of the proliferation marker Ki67 with increasing malignancy in melanoma. Using a panel of metastatic melanoma cell lines, we found that PAX3 and MITF were relatively infrequently expressed together, and in knock down experiments in melanoma cells, neither *PAX3* nor *MITF* were dependent on the other genes expression. Melanogenesis (synthesis of melanin pigment) typifies melanocyte differentiation and is present in most melanomas. In representative melanoma cell lines, we found that the knockdown of *PAX3* or *MITF* led to reciprocal effects on melanogenesis and other morphological features, without induction of cell death. However, in other melanoma cell lines, *PAX3* or *MITF* knockdown did lead to significant apoptotic cell death, and concomitant decrease in *BCL-2* and/or *CDK2*expression. Taken together, our data suggest that the integrity of the melanogenic pathway and its regulation is an important feature in the proliferation and survival of melanoma cells. We also show that the *PAX3/MITF* gene regulatory nodal point is present in melanoma, but appears to malfunction in terminal differentiation. A proportion of melanoma cell lines were not dependent on melanogenic pathways or regulation for their proliferation and survival.

Utility of 3D Imaging for Genetic Counseling and Perinatal Planning for Maxillonasal Dysplasia: In Utero Natural History of Binder Syndrome Phenotype. *J. Wente[1], R. F. Hume, Jr.[3], K. Norris[2, 3], L. Zak[4], M. Estes[3], S. Kerger[3], T. Kuperberg[3], D. C. Willis[3], L. S. Martin[5]* 1) Family and Child Sciences Prog, Florida State University, Tallahassee, FL; 2) Diagnostic Medical Sonographer Program, Tallahassee Community College; Tallahassee, FL; 3) Center for Maternal Fetal Medicine; Tallahassee Memorial Healthcare; Tallahassee, FL; 4) Neonatal Intensive Care Unit, Tallahassee Memorial Healthcare, Tallahassee, FL; 5) Nemours Children's Clinic; Division of Genetics; Jacksonville, FL.

Case Report: 25 yo G2 P1001, routine obstetrical sonography at 18 weeks failed to visualize fetal nose. TARGET US identified severe midfacial hypoplasia and absent nasal bone. Differential diagnosis includes lobar holoprosencephaly syndromes and aneuploidy. After genetic counseling and repeat fetal imaging (3D Facial Mask), family chose amnio; 46 XY. Fetal echocardiography and subsequent serial fetal imaging confirmed isolated midfacial defect consistent with Maxillonasal Dysplasia (Binder). Perinatal genetic counseling was enhanced by the perceived clarity of 3D facial imaging. Serial multidimensional fetal sonography from 18 through 37 weeks gestational age provides the earliest 3D images of the in utero natural history of maxillonasal dysplasia which significantly facilitated family understanding of issues and risks for their son, even with apparently normal chromosomes. Continued fetal care addressed evolving phenotype: no evidence of holoprosencephaly, normal fetal echocardiography, transient polyhydramnios, and progressive but hypoplastic growth of nose. Choanal atresia could not be excluded. Neonatal management plans were facilitated by clarity of fetal images. Cesarean section at 37 weeks due to Intrauterine growth failure (IUGR), 2 kg 5%tile SGA, APGAR 8/8, choanal atresia was excluded, neonatal imaging confirmed isolated maxillonasal dysplasia, and neonatal course was uncomplicated. Conclusion: Our case provides further evidence for the benefit of advanced imaging for prenatal diagnosis and the enhanced understanding of fetal condition, the Binder Phenotype. More important for our patient was her better understanding of fetal disorder due to 3D findings.

Development of Genome Wide Association Database in Japanese Integrated Database Project. *A. Koike[1], N. Nishida[2], I. Inoue[3], S. Tsuji[4], K. Tokunaga[2]* 1) Cent. Res. Lab., Hitachi, Ltd., Japan; 2) Graduate School of Medicine, University of Tokyo; 3) Tokai University School of Medicine; 4) Department of Neurology, Graduate School of Medicine, University of Tokyo.

The recent progress in the large-scale and high-density genome wide association studies (GWAS) has brought us valuable clues to elucidate genetic factors associated with various complex diseases. The management of vast amounts of data and analysis results produced by GWAS projects and schematics of their data sharing among researchers are becoming concerns. In NCBI, the dbGAP has been launched in 2006 as a GWAS repository system, while in EBI, the EGA has been created in 2007 as a repository system for phenotype-genotype relationships. Our organizations (Univ. of Tokyo, Univ. of Tokyo Hospital, Univ. of Tokai, and Hitachi, Ltd.) involved in the integrated database project supported by Ministry of Education, Culture, Sports, Science and Technology (MEXT) has created GWAS database (https://gwas.lifesciencedb.jp/) to achieve continuous and intensive management of GWAS data and data sharing among researchers, and widely call for data-deposit of GWAS data. In the GWAS database, information on the study design, quality control protocols, allelic and genotypic frequencies, and statistical results are stored as freely accessible data, while individual genotyping data and raw data are stored as restricted data and cannot be accessed without special permission. The graphic viewer to display statistical results along with other information such as copy number variations and exon information has also been provided to facilitate identification of disease-related SNPs. Furthermore, comparisons among various study results produced by different institutions and different platforms, and meta-analysis for these results are available. The database is designed to be friendly for researchers not familiar with GWAS to promote disease related studies. In this presentation, we introduce the overview of database structure and methods for SNP quality control and for statistical genetic analysis and data management policies. Acknowledgements: This study was supported by the integrated database project of MEXT.

Evaluation of Imputation-based Association in and around Integrin--M (ITGAM) gene and Replication of Robust Association between a Non-synonymous Functional variant in ITGAM and Systemic lupus erythematosus (SLE). *SK. Nath[1], X. Kim-Howard[1], H. Deshmukh[1], S. Han[1], P. Viswanathan[1], J. Guthridge[1], P. Guffney[1], K. Moser[1], R. Kimberly[1], K. Kaufman[1], C. Jacob[1], J. James[1], S. Bae[4], J. Anaya[3], K. Matsuda[2], M. Alarcon-Riquelme[6], T. Vyse[5], J. Harley[1]* 1) USA; 2) Japan; 3) Colombia; 4) Korea; 5) UK; 6) Sweden.

Recently, we identified (Nat Genet. 40:152-154, 2008) a novel non-synonymous variant (R77H substitution), rs1143679, at exon-3 of ITGAM associated with SLE. The objectives of the present study are to (a) assess whether single or multiple causal variants from the same gene or any nearby gene(s) are involved in SLE susceptibility using an imputation-based association test, (b) assess the robustness of the genetic association across 9 ethnically diverged samples (~12000), including European-American (EA), Hispanics (HI), Korean, Japanese, United kingdom (UK), Colombian and Mexican, and (c) resequence exon-3 to identify novel variants and reassess the causal association. Our imputation-based association analysis confirms the ITGAM is the major susceptibility gene for SLE (log 10 Bayes factor = 20 for European-American). The association between rs1143679 and SLE is reconfirmed and replicated in 5 case-control samples including EA ($P = 1.0 \times 10^{-8}$, OR = 1.7, 95% CI = 1.4-2.1), HA ($P = 2.8 \times 10^{-5}$, OR = 2.1,CI = 1.4-2.9), UK ($P = 3.0 \times 10^{-6}$, OR = 2.1,CI = 1.5-2.8), Mexican (P = 0.002, OR = 1.6, CI = 1.2-2.3) and Colombian ($P = 3.6 \times 10^{-7}$, OR = 2.2, CI = 1.6-3.1), and 2 trios including UK (P = 0.003, OR = 1.6, CI = 1.2-2.4) and Mexican (P = 0.01, OR = 1.7, CI = 1.2-2.6). A meta-analysis combing all data greatly reinforces the association ($P = 1.7 \times 10^{-45}$, OR = 1.8, CI = 1.6-1.9). However, ITGAM association is not observed in the Korean and Japanese samples, in which the rs1143679 is monomorphic (risk allele A). Finally, resequencing exon-3 did not identify any novel variant. Therefore, taken together with our earlier findings, our results demonstrate the $_{M2}$-integrin adhesion pathway in disease development, especially in the European- and African-derived populations, but probably not in Asian derived populations.

Severe Neonatal Complications in an Infant Girl with Jansen's Metaphyseal Chondrodysplasia. *C. Kozma[1], N. Scribanu[1], K. Abubakar[1], R. Lachman[2]* 1) Dept Pediatrics, Georgetown Univ Hosp, Washington, DC; 2) Cedars-Sinai Medical Center, Los Angeles.

Jansens metaphyseal chondrodysplasia is a severe rare form of short-limbed dwarfism. It is caused by mutations in the PTH/PTHrP receptor gene. The disorder is inherited in an autosomal dominant fashion. Case reports describing neonatal complications associated with the syndrome are very few. We report an affected girl who experienced respiratory distress, severe feeding difficulties, and significant hypotonia as well as motor deficits. She was the product of the second pregnancy to 27-year-old Salvadoran woman whose pregnancy was complicated by polyhydramnios and short femur. The family history was unremarkable. Genetic amniocentesis done at 32 weeks of gestation revealed normal karyotype. The baby was born vaginally at 36 weeks of gestation. Her head circumference was 32.5 cm (60th centile); weight 2903 gms (60th centile), length 43 cm (3rd -10th centile). Physical examination showed flat supra orbital ridge, small mouth, small thorax, moderate pectus carinatum, and a slight bowing of the legs. The nails and fingers were normal. She required brief mechanical ventilation and oxygen treatment for a few days. Due to her short stature, X rays were done revealing the long bones to be proportionately short and to have a moth-eaten appearance with diffuse osteoporosis. There was bilateral hip dislocation. The proximal ends of the humeri as well as the distal ends of the ribs had a severe flared and raggy appearance. The ribs appeared shortened. The metaphyseal ends of the major long bones showed irregularity, slight cupping and slight splaying of the metaphyses in addition to a celery stalked appearance. The talus and calcaneus demonstrated focal areas of bone sclerosis and osteoporosis as well as popcorn density. Throughout her stay, she had significant generalized hypotonia, absent suck and very decreased neonatal reflexes. Feeding was done by gavage. Her calcium and phosphorus level were normal. She died at the age of 5 weeks of wide spread necrotizing enterocolitis. This case adds to the further documentation of the natural history of this disorder.

A New de novo Balanced Translocation Breakpoint Truncating the Autism Susceptibility Candidate 2 (AUTS2) Gene in an Autistic Patient. *X. Huang[1], Y. S. Zou[1,2], T. A. Maher1[1], S. Newton[1], J. M. Milunsky[1,2,3]* 1) Dept Human Gen, Boston Univ Sch Med, Boston, MA; 2) Dept Pediatrics, Boston Univ Sch Med, Boston, MA; 3) Dept Genet and Genom, Boston Univ Sch Med, Boston, MA.

Autism Spectrum Disorder (ASD) is a developmental disorder of the central nervous system of largely unknown etiology. Truncated AUTS2 at 7q11.2 by a translocation breakpoint has been reported in four unrelated ASD/mentally disabled patients. Here we present a new patient carrying a new de novo balanced translocation that truncates the AUTS2 gene. He is a mildly dysmorphic 5-year old boy with delays in language, finemotor, and visual receptive skills who has been diagnosed with pervasive developmental disorder - not otherwise specified (PDD-NOS). His score on the childhood autism rating scale (30.5) indicates mild-moderate autism. Chromosome analysis revealed a translocation: t(6;7)(q14;q11.2)dn. Affymetrix 500K SNP array analysis was normal, thus supporting a balanced reciprocal translocation. Simultaneous molecular genetic testing of Fragile X syndrome, as well as NLGN3 and NLGN4 were normal. BAC-FISH mapping revealed that the chromosome7 breakpoint is within intron 1 of AUTS2. The breakpoint of 6q14.1 is between RP11-352K16 and RP11-213K12, where there are abundant retrotransposon long interspersed element-1 (LINE-1) elements and no reported genes. The mild-moderate autism seen in our patient with truncated AUTS2 gene is consistent (probably milder) with previous reports. It indicates that the AUTS2 gene, originally identified as KIAA0442 from a library of large brain-expressed transcripts previously linked to autism and mental retardation, plays a critical role in the etiology of ASD.

Characterization of the immune response to Helper Dependent Adenovirus for Gene Therapy of Hemophilia A.

M. Suzuki[1], V. Cerullo[1], N. Bruetti-Pierri[1], M. Seiler[1], V. Mane[1], C. Clarke[1], R. Cela[1], L. Medima-Kauwe[3], B. Lee[1,2] 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Houston Tx; 3) Cedars-Sinai Medical Center, University of California Los Angeles, Los Angeles CA.

Hemophilia A is a common inherited coagulopathy caused by deficiency of factor VIII (FVIII) activity. Previously, we focused on gene therapy of hemophilia A using helper dependent adenovirus (HDAd) encoding B-domain deleted human FVIII in both dog and mouse models. However, host antibody response to hFVIII has been a limitation of these therapies. We hypothesized that the innate immune response to HDAd may correlate with the induction of adaptive immune response to transgene product delivered with these vectors. In the present study, we investigated the cellular and molecular mechanisms related to induction of the innate immune to infection with HDAd using genetically modified mice deficient in components of this system. Toll-like receptors (TLRs) are innate receptors that sense microbial products. We first asked whether the class of TLRs is involved in the immune response following the intravenous injection of HDAd. To test this, we injected the HDAd encoding LacZ transgene into Myd88 knock-out (Myd88-KO) mice. Myd88 is a well characterized key signal mediator of TLRs signals. We measured cytokine and chemokine production in serum of mice injected with HDAd at early time points. Myd88-KO mice showed significant reduction of proinflammation molecules compared with WT C57Bl/6 mice after HDAd treatment. Similarly, surface TLR2 and endosomal TLR9-KO mice injected with HDAd exhibited significant reduction of expression of these cytokines albeit less so then that observed in Myd88-KO mice. These results indicated that systemic administration of HDAd activates the immunity through TLR-dependent pathways leading to the induction of innate immune response. Myd88-KO mice injected with HDAd exhibited high and long-term expression of transgenes compared with WT mice. By modulating signaling via these receptors we may be able to decrease the innate and adaptive immune response to HDAd and/or transgene products.

Functional characteristics of a 4.5kb non-coding DNA found to be associated with acute graft-verse-host disease.

J. Li[1], B. Zhang[1], X. Zhang[1], L. Tabellini[1], W. Fan[1], P. Martin[1], J. Chien[1,2], H. Warren[1], B. Storer[1], L. Zhao[1,2], J. Hansen[1,2] 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) University of Washington, Seattle, WA.

Acute graft-versus-host disease (aGvHD) following allogeneic hematopoietic cell transplantation (HCT) is the major cause of morbidity and mortality. The genetic determinants modulating the incidence and intensity of aGvHD are largely unknown. Recently, we have genotyped 1425 HCT recipients and 1506 donors using Affymetrix 5.0 GeneChip. A total of 130 copy number polymorphisms (CNPs) were identified in our study population. A CNP association analysis with aGvHD revealed one signal consisting of 4.5 KB deletion mapping to an intergenic region on chromosome 8. This CNP was initially identified by Hinds *et al.* (Nat Genet. 2006, 38:82-5) and independently validated by Kidd *et al.*(Nature. 2008, 453:56-64). We performed a detailed sequence analysis of this CNP region using the consensus sequence from the Human Genome. Three well-conserved regions were identified which contain several known motifs including TATA box (TATAAA), and a 300bp down-stream sequence harboring part of an ORF sequence which overlaps with sequences encoding components of ten unique zinc finger proteins as well as several other transcriptional/translation regulators. Several ESTs , a zinc finger transcription factor, a eukaryotic translation initiation factor and a zinc transporter locate immediately downstream of the identified CNP. Preliminary results from gene expression profiles of aGvHD patients indicate the involvement of a group of genes encoding zinc finger proteins and transcriptional/translation regulators as seen in our CNP sequence analysis, supporting our hypothesis of a novel functional component in this identified non-coding region on chromosome 8. Further validation of this association is planned. Besides gaining insight into the biology in acute GvHD, we believe this analysis, coupled with the experimental validation strategy would be useful to study other genetic discoveries, which locate within gene desert regions. * Corresponding authors: jhansen@fhcrc.org and lzhao@fhcrc.org.

Complex epigenetic abnormalities are not detected by targeted methylation analysis. *S. Horike[1,7], M. Meguro-Horike[1,7], J. C. Ferreira[1], A. C. Smith[1,4], C. Shuman[1,2,3], W. Meschino[5], S. W. Scherer[1], E. Zackai[6], R. Weksberg[1,2,3,4]*
1) Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 3) Department of Molecular and Medical Genetics, University of Toronto, Toronto, Canada; 4) Institute of Medical Sciences, University of Toronto, Toronto, Canada; 5) Division of Clinical and Metabolic Genetics, North York General Hospital, Toronto, Canada; 6) Division of Human Genetics and Molecular Biology, Childrens Hospital of Philadelphia; 7) Frontier Science Organization, Kanazawa University, Kanazawa, Ishikawa, Japan.

Over a 10 year period blood samples from 63 individuals with growth restriction and RSS-like features were collected. Our goal was to identify causal epigenetic abnormalities e.g. UPD 7 (mat), methylation changes at 11p15, and new epigenetic alterations. We evaluated the methylation status of 6 imprinted loci, on chromosomes 7, 11, 14 & 15 including ICR1, ICR2, *H19* promoter (at 11p15), *PEG1/MEST*, *MEG3/GTL2*, *SNRPN* CpG islands. We previously reported UPD 7 (mat) in 3 cases. Epigenetic alterations on chromosome 11p15.5 were identified in 10 cases. This included one set of MZ twins discordant for both IUGR & for 11p15.5 loss of methylation. In addition, in one case we detected methylation changes across all 4 chromosomes tested consistent with maternal UPD and prompting consideration of more complex diagnoses. The newborn clinical presentation for this case included birthweight 3%, head circumference 50%, hemiatrophy and hypospadias. Although this patient is phenotypically male, we did not detect any Y-specific PCR product. Follow-up clinical information included karyotype: 46, XY (and 1/100 69, XXY). No further blood/tissue samples could be obtained. We present this case to demonstrate that complex epigenetic abnormalities will not be detected if testing is limited to single targeted assays.

Congenital aural atresia type I, report 3 Mexican patients. *L. Hernandez[1], G. Juarez[2], D. Gomez[3], E. Hernandez[4]* 1) AUDIOLOGIA, INSTITUTO NACIONAL DE REHABILITACION, MEXICO D.F; 2) NEUROPSICOLOGIA, INSTITUTO NACIONAL DE REHABILITACION, MEXICO D.F; 3) INSTITUTO NACIONAL DE REHABILITACION; 4) FACULTAD DE ESTUDIOS SUPERIORES IZTACALA BIOLOGIA.

Is a rare anomaly, occurring in approximately 1 in 10,000 live births. In only about 5% of cases does one find atresia without concomitant Microtia. The CAA (congenital aural atresia) phenotype varies from mild manifestations, has been divided into three forms based on increasing severity. Type I, with narrowing of the external auditory canal and hypoplasia of the tympanic membrane and middle ear cavity. Type II, to severe manifestations, including absence of the middle ear in combination with anotia. Type III, bony atresia of the external auditory canal, and hypoplasia of inner ear structures. We report 3 Mexican patients Case I: female patient 6 year old, both hearing loss, onset at 5 years old, examination physical both normal pinna , right aural atresia, left narrowing of the external auditory canal. Audiometric test showed mild conductive hearing loss. Speech audiometric test showed conductive deficit. Report computed tomography right aural atresia, left narrowing of the external auditory canal. Case II: male patient 10 year old, right hearing loss, onset at 1 years old, examination physical both normal pinna , right aural atresia. Audiometric test showed right mild conductive hearing loss. Speech audiometric test showed right conductive deficit. Left Normal audition. Report computed tomography right aural atresia. Case III: male patient 6 year old, left hearing loss, onset at 3 years old, examination physical both normal pinna , left aural atresia. Audiometric test showed left mild conductive hearing loss. Speech audiometric test showed left conductive deficit. Right Normal audition. Report computed tomography left aural atresia .

International Patient Survey of Treatment Satisfaction for Mucopolysaccharidosis I. *W. Harris[1], K. Harkins[2], B. Wedehase[3], C. Lavery[4], N. Durkin[4], G. F. Cox[1]* 1) Genzyme, Cambridge MA; 2) Canadian MPS Society, North Vancouver, BC; 3) National MPS Society, Durham, NC; 4) Society for Mucopolysaccharide Diseases, Amersham, Buckinghamshire, UK.

Background: Patient satisfaction is an important gauge of treatment success. We asked patients with mucopolysaccharidosis I (MPS I) and their parents/guardians how treatment with enzyme replacement therapy (ERT, laronidase, Aldurazyme) and/or hematopoietic stem cell transplantation (HSCT) met their expectations. Methods: With MPS societies, Genzyme designed and distributed an 8-page questionnaire between 9/06 to 11/07 in the UK, US, Brazil, Canada, Germany, Poland, Netherlands, Japan, and Australia. Results: Response rate was 45% (238 completed surveys). Gender ratio was equal; phenotype distribution was 60% Hurler, 21% Hurler-Scheie, and 18% Scheie; 25% were <6 y; 45%,6-17 y, and 29% 18 y; 43% had HSCT (years since HSCT: <3: 22%, 3-5: 27%; >5: 52%), 58% received ERT (11% short-term peri-HSCT, 20% for <3 y, 27% for >3 y) and 8% received neither. Independent of treatment expectations, quality of life was rated as excellent/very good by 81% of respondents. The lowest rated symptom was musculoskeletal, rated by 60% as fair/poor. Mental development was rated by 39% as fair/poor; 60% reported learning difficulties and 49% reported mood disorders (anxiety, stress, depression). Among HSCT patients, 60% reported complications and 26% repeat procedures; however, 84% rated HSCT performance highly favorably (mean score 8.95 on a 1-10 scale) and 75% reported some/a lot of improvement on mental development. The earlier the HSCT, the greater the satisfaction. Lowest satisfaction was with cardiac, visual, and musculoskeletal symptoms. Among ERT patients, 63% rated performance highly favorably (mean score 8.14), with best ratings for quality of life, gastrointestinal, sleep, and musculoskeletal symptoms and lowest ratings for mental development, cardiac, craniofacial, and visual symptoms. The longer patients were on ERT, the greater the satisfaction. Conclusions: MPS I patients receiving therapy give overall positive reports on physical and emotional health and high satisfaction rates for both HSCT and ERT.

Use of multiple ethnic groups to identify causal breast cancer risk variants in the *FGFR2* and *TNRC9* loci. *M. Udler[1,3], S. Ahmed[2], M. Maranian[2], K. Gregory[2], K. A. Pooley[2], J. Tyrer[2], P. D. Pharoah[2], J. P. Struewing[3], R. Luben[1], C. A. Haiman[4], A. Wu[4], H. Anton-Culver[5], C. Y. Shen[6], D. Kang[7], A. Lindblom[8], B. A. J. Ponder[9], K. Malone[10], E. A. Ostrander[3], A. M. Dunning[2], D. F. Easton[1]* 1) Dept of Public Health & Primary Care, Univ. of Cambridge, UK; 2) Dept of Oncology, Univ. of Cambridge, UK; 3) NHGRI/NIH, MD; 4) Dept of Preventive Medicine, Keck School of Medicine, USC, CA; 5) Dept of Epidemiology, Univ of California Irvine, CA; 6) Inst of Biomedical Sciences, Academia Sinica, Taiwan; 7) Seoul National Univ College of Medicine, Korea; 8) Karolinska Inst, Sweden; 9) CR-UK Cambridge Research Inst, UK; 10) Fred Hutchinson Cancer Research Ctr, WA.

Genome-wide association studies (GWAS) have identified new breast cancer (BC) loci. We utilized data from European, Asian and African American (AA) BC case-control studies to facilitate fine-mapping of the *FGFR2* and *TNRC9* gene regions. Associated LD blocks were resequenced in 45 European individuals, creating a catalogue of genetic variation (*FGFR2*: 25kb, 117 variants; *TNRC9*: 133kb, 175 variants). For each locus, SNPs highly correlated with the best tagSNP (rs2981582 in *FGFR2*, rs3803662 in *TNRC9*) were genotyped in BC cases and controls of European (n=14,000), Asian (n=7,000) and AA (n=2,500) ethnicity. Likelihood ratio tests (LRTs) were used to exclude SNPs with likelihoods 100 times worse than the best candidate. For *FGFR2*, we identified 28 candidate SNPs. Based on the European data alone, 3 SNPs could be eliminated by LRT. Using the Asian and AA data allowed exclusion of a further 17. SNPs showed effects in the same direction in all 3 populations (P-heterogeneity 0.05). For *TNRC9*, we identified 24 candidate SNPs. Two were excluded using European data alone and 9 more using the Asian data. Candidate SNPs had effects in the opposite direction in AAs compared to Europeans and Asians. Haplotype analysis suggested there were 2 risk haplotypes in AAs, only 1 of which also conferred risk in Europeans and Asians. These results illustrate the importance of using diverse ethnic groups in fine-mapping studies to 1) eliminate candidate SNPs and 2) replicate GWAS hits as SNP alleles may affect risk differently in distinct populations.

Homozygous deletions in pedigrees with autism and recent shared ancestry implicate heterogeneous loci and genes. *E. Morrow[1,2,3,4], N. M. Mukaddes[5], S. Balkhy[6], G. Gascon[6], S. Y. Yoo[1,2,4], J. N. Partlow[1,2,4], B. Barry[1,2,4], K. Markianos[1], C. A. Walsh[1,2,4], Homozygosity Mapping Collaborative for Autism (HMCA)* 1) Division of Genetics, Children's Hospital Boston, Harvard Medical School, Boston, MA; 2) Department of Neurology and Howard Hughes Medical Institute, Beth Israel Deaconess Medical Center, Boston, MA; 3) Department of Psychiatry, Massachusetts General Hospital, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 5) Department of Child Psychiatry, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey; 6) Department of Neurosciences and Pediatrics, King Faisal Specialist Hospital and Research Centre, Jeddah, Kingdom of Saudi Arabia.

To find inherited causes of autism-spectrum disorders, we studied families in which parents share ancestors, enhancing the role of inherited factors. Using high-density SNP microarrays, we conducted genome-wide, pedigree-based copy number analysis and homozygosity mapping. We mapped several loci, some containing large, inherited, homozygous deletions that are likely mutations. These deletions affected both coding and non-coding genomic elements. The largest deletions implicated genes, including PCDH10 (protocadherin 10) and a novel gene DIA1 (deleted in autism1, a.k.a c3orf58). A subset of genes showed additional putative mutations in patients with unrelated parents. Our findings highlight the utility of homozygosity mapping in heterogeneous neurodevelopmental disorders like autism. Finally, our results offer traction for studying the potential role of non-coding mutation in neurodevelopmental disease.

Result of the bioethics questionnaire survey of Japanese university students on genetic testings. *H. Numabe[1,2], S. Kosugi[1,2]* 1) Department of Medical Ethics, Kyoto University Gradiate School of Medicine, Kyoto, Japan; 2) Department of Clinical Genetics, Kyoto University Hospital, Kyoto, Japan.

We made the questionnaire survey of Japanese university students on genetic diagnoses. The survey was done during the course of Introduction to clinical medicine and Prejudice, human rights, and discrimination in 2007. The questionnaire was consist of properties of the student, considerations to spiritual matters, acceptability of an artificial abortion, the time of the beginning of human life, and considerations to various genetic testing. Total number of students was 223 and the mean age was 19.4 years. The result was as follows. 1. Genetic testing to confirm an existing clinical diagnosis: acceptable 176 (78.9%), not acceptable 13 (5.8%) 2. Predictive genetic testing for disorders in which clinical management may not affected by the test result: acceptable 165 (74.0%), not acceptable 14 (6.3%) 3. Genetic testing for carrier status: acceptable 152 (68.2%), not acceptable 21 (9.4%) 4. Prenatal genetic testing: acceptable 96 (43.0%), not acceptable 68 (30.5%) 5. Pre-implantation genetic testing: acceptable 77 (34.5%), not acceptable (35.9%) Acceptability of genetic testing correlates closely with students recognition of the time of the beginning of human life. Students who recognize the life start from the fertilization or within 15 days after fertilization are not acceptable to prenatal and pre-implantation tests. On the other hand, students who recognize the life start after 22 weeks of gestational age or after birth are acceptable to them. Acceptability of an artificial abortion has a similar tendency, but over 50% of students who recognize the life start from the fertilization or within 15 days after fertilization are acceptable to an artificial abortion.

Melanoma and Hirschsprung's Disease in a Family: Coincidence or Shared Susceptibility? *R. S. Wildin[1,2], J. Eichmeyer[2]* 1) Idaho State Genetic Services Program, Boise, ID; 2) St. Lukes Regional Medical Center, Boise, ID.

One heritable form of Hirschsprungs Disease (HSCR) is Waardenburg-Shah (Waardenburg, type IV) Syndrome. Three genes have been reported responsible: EDN3, EDNRB, and SOX10, with some evidence in all for either recessive or occasionally multigenic inheritance. An increased frequency of EDNRB non-synonymous variations has been observed in Malignant Melanoma (MM) patients (Soufir, et al., J NCI 2005) and an ENDRB mutation has been found in an individual with a CDK-4-positive melanoma (Soufir, et al., J Dermatol Sci 2007). The EDNRB gene product interacts with SOX10, plays a role in melanocyte growth and differentiation, and genetic and epigenetic variations in it have been observed in a range of cancers. We report a young boy with apparently isolated HSCR whose paternal uncle has a lock of white hair and whose father has a history of malignant melanoma at age 30. No one in the family has deafness, iris heterochromia, or dystopia canthorum. We hypothesize that this family harbors an endothelin receptor pathway mutation that predisposes to MM, pigment anomalies, and/or HSCR, with expression depending, perhaps, on the presence of other interacting predisposing genes. Testing is underway. If true, this would alter the genetic counseling and preventative management provided for both HSCR and MM in this context.

Nonpathogenic clonal chromosome abnormalities in donor cells post transplant. *J. Meck[1], A. Meloni-Ehrig[1], G. Erdag[2], P. Mowrey[1], J. Kelly[1], L. Matyakhina[1], T. Donohue[3], R. Srinivasan[3], R. Childs[3]* 1) Quest Diagnostics/Nichols Inst, Chantilly, VA; 2) Georgetown U Med Ctr, Washington, DC; 3) NHLBI/NIH, Bethesda, MD.

Although rare, chromosome abnormalities resulting in hematologic neoplasms in donor cells after allogeneic bone marrow or peripheral blood stem cell transplantation (PBSCT) have been reported. We describe 2 patients, one with chronic myeloid leukemia (CML) and the other with chronic lymphocytic leukemia (CLL), who showed persistence for years of a chromosomally abnormal clone that appeared in donor cells several months after PBSCT, but was not associated with disease in recipient or donor. Both patients underwent PBSCT from HLA-matched opposite sex siblings. Early post-transplant studies showed full engraftment with normal donor metaphases. Subsequent studies of both patients, however, revealed a population of karyotypically abnormal, but apparently balanced, donor cells that persisted at a low level for years without apparent clinical effect. The CLL patients donor is karyotypically normal. The CML patient donor studies are pending; however, since the initial study post-transplant showed a normal donor karyotype, it suggests that the abnormalities occurred subsequent to transplant. The CLL patient has been in remission for 5 1/2 yrs. The CML patient suffered relapse of CML with karyotypic evolution in recipient cells and simultaneous appearance of the chromosomally abnormal donor clone several months after PBSCT. He was treated successfully, and was healthy until his recent accidental death. The abnormal donor cell clone persisted for 7 years. Donor cell rearrangements in our patients are not recurrent in neoplasia except for an 11q23 rearrangement, shown by FISH not to involve the MLL gene, and a t(X;20) with breakpoints similar to ones reported infrequently in MDS. To our knowledge this is the first report of a persistent, complex chromosomally abnormal clone in donor cells with no known malignancy association. We speculate that the abnormal donor clone possibly arose due to host-related factors such as the microenvironment, residual effects of chemotherapy, or faulty DNA repair mechanisms.

Genetic Variants in the Lipoprotein Lipase Gene Are Confirmed to Be Associated with Liver Enzyme Levels in Hispanic Americans. *X. Guo[1], Y.-D. I. Chen[1], M. O. Goodarzi[1], B. Fang[1], A. Xiang[2], X. Su[1], Y. Liu[1], K. D. Taylor[1], T. A. Buchanan[2], L. J. Raffel[1], J. I. Rotter[1]* 1) Medical Genetics Inst, Cedars-Sinai Medical Ctr, Los Angeles, CA; 2) USC, Los Angeles, CA.

Elevated liver enzyme (LE) levels have been associated with the insulin resistance syndrome (IRS), but the common genetic basis underlying IRS and LE has not been well established. Heritability analyses indicate significant evidence for a genetic contribution to LE levels, and co-heritability analyses showed that LE levels share common genetic determinants with IRS in several studies. The lipoprotein lipase (LPL) gene has been shown to be associated with IR in two different cohorts of Hispanic Americans (HA). The fact that the LPL gene was associated with both Gamma-glutamyl transferase (GGT) and IR in HA families recruited through the Insulin Resistance Atherosclerosis Study (IRAS) Family Study has suggested LPL as a common gene underlying GGT levels and IR. We study here the role of genetic variants in the LPL gene on GGT levels using 618 non-diabetic offspring from 160 HA families ascertained through a proband with hypertension. GGT was measured by enzymatic colorimetry. Six single nucleotide polymorphisms (SNPs) known to be in the same block in the LPL gene were genotyped in these samples. The generalized transmission disequilibrium test as implemented in the QTDT program was used in the association analysis. To avoid false positives derived from population stratification, the within family variance component was used for the association testing. After adjusting for age, sex, and body mass index, significant association with GGT was found for SNP Ser447Stop/rs328 ($p = 0.019$). Haplotype analysis revealed that the SNP was located at the fourth most common haplotype (GAGGGG), which was also significantly associated with decreased GGT (28.52.6 vs 32.21.2U/L, $p=0.009$). This haplotype has been previously reported as significantly associated with IRS in HA families recruited through CAD probands (Goodarzi et al., Diabetes, 53:214-220, 2004). These results confirmed that the LPL gene is a common genetic determinant for LEs and IRS in the Hispanic American population.

Effects of CYP2D6*10 on recurrence-free survival in breast cancer patients receiving adjuvant tamoxifen therapy. *K. Kiyotani[1], H. Zembutsu[2], T. Mushiroda[1], M. Sasa[3], K. Hirata[4], M. Okazaki[5], Y. Takatsuka[6], Y. Bando[7], I. Sumitomo[3], N. Hosono[8], M. Kubo[8], Y. Nakamura[1,2]* 1) Laboratory for Pharmacogenetics, Center for Genomic Medicine, The Institute of Physical and Chemical Research, Yokohama; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo; 3) Department of Surgery, Tokushima Breast Care Clinic, Tokushima; 4) First Department of Surgery, Sapporo Medical University, School of Medicine, Sapporo; 5) Department of Surgery, Sapporo Nyusen Clinic, Sapporo; 6) Department of Surgery, Kansai Rousai Hospital, Amagasaki; 7) Department of Molecular and Environmental Pathology, Institute of Health Biosciences, The University of Tokushima Graduate School, Tokushima; 8) Laboratory for Genotyping, Center for Genomic Medicine, The Institute of Physical and Chemical Research, Yokohama, Japan.

The clinical outcomes of breast cancer patients treated with tamoxifen may be influenced by the activity of cytochrome P450 2D6 (CYP2D6) enzyme because tamoxifen is metabolized by CYP2D6 to its active forms of antiestrogenic metabolite, 4-hydroxytamoxifen and endoxifen. We investigated the predictive value of the CYP2D6*10 allele, which decreased CYP2D6 activity, for clinical outcomes of patients that received adjuvant tamoxifen monotherapy after surgical operation on breast cancer. Among 124 patients examined, those homozygous for the CYP2D6*10 alleles revealed a significantly shorter recurrence-free survival compared with those homozygous for the wild-type CYP2D6*1 alleles (P = 0.0052), or compared with CYP2D6*1/*1 + *1/*10 (P = 0.017). Cox proportional hazard analysis demonstrated that the CYP2D6 genotype and tumor size were independent factors affecting recurrence-free survival. Patients with the CYP2D6*10/*10 genotype showed a significantly shorter recurrence-free survival period (P = 0.017; adjusted hazard ratio, 6.58; 95% confidence interval, 1.41-30.77) compared to patients with CYP2D6*1/*1 after adjustment of other prognosis factors. The present study suggests that the CYP2D6 genotype should be considered when selecting adjuvant hormonal therapy for breast cancer patients.

Downregulation of sodium channel 4 subunit in Huntington Disease transgenic mice. *F. Oyama, H. Miyazaki, M. Kurosawa, M. Yamada, N. Nukina* Lab Structural Neuropathology, RIKEN Brain Science Inst, Saitama, Japan.

Sodium channel 4 (4) is a recently identified auxiliary subunit of the voltage gated-sodium channels. We identified 4 as an EST that was significantly downregulated in the striatum of Huntington Disease (HD) model mice and patients. To define the molecular mechanism underlying the reduction of 4 expression, we generated transgenic mouse line expressing Venus under the control of mouse 4 promoter in brain. We established six mice lines exhibiting Venus expression primarily in striatum, cortex or both striatum and cortex. The mouse line exhibiting predominant Venus expression in striatum was crossed with HD model mice to generated double transgenic mice. The expression of Venus transcribed from 4 promoter-Venus transgene lacking exon-intron structure and 3-UTR as well as endogenous 4 was downregulated in the striatum of double transgenic mice. These results indicate that downregulation of 4 in HD model mice is dependent on its promoter.

Intrathecal (IT) enzyme replacement therapy (ERT) for symptomatic spinal cord compression (SCC) in a MPS VI child: safety, efficacy and pitfalls. *D. Horovitz[1], M. V. R. Munoz[2], M. A. Lima[1], T. Magalhaes[1], R. Costa[2], A. Pena Costa[1], L. Jardim[2], L. E. Carelli[3], J. Llerena Jr.[1], R. Giugliani[2]* 1) Instituto Fernandes Figueira, Rio de Janeiro, Brazil; 2) Hospital de Clinicas de Porto Alegre, RS, Brazil; 3) Into, RJ, Brazil.

SCC is a known complication of MPS VI, caused by bone disease and meningeal GAG storage. We present the experience with IT treatment with recombinant human Galsulfase (rhASB) in a child with SCC. To our knowledge, this is the first MPS VI patient with such therapeutic approach. At baseline the patient, ERT naive, presented walking difficulty and neurogenic bladder. Surgery was refused by the mother. 4 IT infusions (1.5mL of rhASB dilluted on 3mL of Elliotts B solution, total volume 4.5mL) were administered monthly via lumbar puncture. Evaluation 3 months after IT 4 showed improved sensitivity, reflexes, and correction of the incontinence in urodynamic studies; walking capacity worsened. Intravenous (IV) ERT was then introduced. A 5th IT was performed 5 months after IT 4. Over the next 2 weeks he developed hypotonia, loss of voluntary movements in the limbs, neck and trunk instability. CSF analysis ruled out inflammatory reaction, infection or monoclonal bands. Lifesaving spinal surgery with cervical decompression and fixation was performed. He is regaining motor function, with better muscle tone, strength and diminished hyperreflexia; sensitivity remains preserved. Despite urodynamics and sensitivity improvements, suggesting a positive response to IT ERT, motor function worsened. We believe motor loss was due to an increased cranio-cervical junction mobility secondary to ERT (IT and IV) associated to cervical instability related to MPS VI bone disease (partially compensated before ERT due to joint restriction), leading to a physical effect compressing motor pathways. Decompressive surgery remains the gold standard for SCC in MPS. In situations of high surgical risk or less advanced bone disease, however, the IT approach must be taken into account, as therapeutic or as adjunct therapy. Even with the observed motor complications, we believe IT ERT can be safe and may be used as an alternative for MPS VI patients.

Cornelia de Lange (CdL) Syndrome - Prenatal findings and autopsy review. *K. Chong[1], D. Chitayat[1], S. Keating[2], S. Hurst[3], A. Summers[3], H. Berger[4]* 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, ON, Canada; 2) Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada; 3) Lakeridge Health Corporation, Toronto, ON, Canada; 4) St. Michael's Hospital, Toronto, ON, Canada.

Objective: Low PAPP-A levels (0.3 MoM) and cystic hygroma in the first trimester as well as increased nuchal fold and limb abnormalities in the second trimester can be associated with CdL syndrome.

Design: Three women presented for genetic counseling following abnormal fetal ultrasounds: one in the first trimester with cystic hygroma followed by bilateral limb anomalies at 20 weeks gestation (case 1), two in the second trimester with multiple fetal anomalies. Case 2 had low PAPP-A as well as a fetal right hand malformation and intra-abdominal cyst. At 27 weeks gestation, intrauterine growth retardation was noted. Case 3 presented with increased nuchal fold, Dandy Walker variant, congenital heart disease, echogenic kidneys, ambiguous genitalia and clenched left hand.

Results: Amniocentesis for all cases revealed normal karyotypes. Due to the multiple fetal anomalies and suspicion of CdL syndrome, all 3 pregnancies were terminated. Autopsy findings were consistent with CdL syndrome. Genetic testing for the NIPBL gene demonstrated a base pair change in the gene, resulting in a premature stop codon/splice site change and a truncated protein in all three cases.

Conclusions: Severe phenotypes of CdL syndrome may present with low PAPP-A and cystic hygroma in the first trimester of pregnancy. First trimester screening with biochemistry and nuchal translucency ultrasound should be recommended for at risk couples with family/previous history of this condition.

Treatment of 654-Thalassemia in Mice with Delivery of siRNA and Antisense RNA Plasmids. *S. Xie, J. Zhang, Z. Ren, F. Zeng, S. Huang* Shanghai Inst Med Genet , Shanghai Children's Hospital, School of Medicine, Shanghai Jiao Tong University, 24/1400 West Beijing Road, Shanghai 20040, China.

To explore the feasibility of a molecular therapy strategy for 654-thalassemia, small interfering RNA vectors (siRNA, mi 1, mi 2), homologous to -globin transcripts and antisense RNA vector which targeted the specific portion of 654 aberrant pre-mRNA were constructed, followed by delivering into 654-thalassemia mice via an intravenous injection to investigate the impact on the treatment. A significant improvement of RBC counts and Hb levels were observed in the treated mice. We also found an obvious reduction of poikilocytosis plus reticulocyte counts in periphoreal blood under treatment and decreased nucleated cells in bone marrow. Histopathological analysis showed that red pulp decreased and clear white pulp marginal zone occurred in the spleens of the treated mice, as wells as the intrasinusoidal EMH loci reduced and iron accumulation ameliorated in the livers. RT-PCR and real-time quantitative RNA analysis showed that above 50% amount of -globin mRNA was down-expressed as well as the normally spliced -globin transcripts were present after transfection of siRNA and/or antisense RNA vectors into MEL and HeLa 654 cells, suggesting that the improvement of the anemic phenotype in 654-thalassemia mice may result from the restoration of the balance in /-globin biosynthesis by RNA interference and antisence RNA treatment. The results provide a potential way for -thalassemia therapy by using RNAi and antisense RNA approaches.

Avellino Corneal Dystrophy in a Korean population. *E. J. Lee[1], H. N. Kim[1], B. J. Ha[2], S. W. Kim[2], E. K. Kim[2], H. L. Kim[1,3]* 1) Dept Biochemistry, Ewha WOmans Univ, Seoul, Korea; 2) The Institute of Vision Research, Department of Ophthalmology, Yonsei University College of Medicine, Seoul, Korea; 3) Division of Center for Genome Science, Korea National Institute of Health, Korea Centers for Disease Control, Seoul, Korea.

Avellino Corneal Dystrophy (ACD) is autosomal dominant corneal dystrophy that presents to coexistence of granular and lattice deposits. Mutation (R124H) in TGF beta induced gene human clone 3, (bigh3) on chromosome 5q31 causes autosomal dominant corneal dystrophy including ACD, is only on identified in ACD (allelic homogeneity). On the other hand, bigh3 gene is known to a candidate gene of osteoporosis and diabetes. But, this is no report that bigh3 induced systemic disease of ACD patients so far. Therefore, we observed other phenotypes of ACD patients. We analyzed epidemiologic character in 58 Korean families, including 212 ACD patients and 339 unaffected relatives of ACD patients. In this study, heights, glucose levels, insulin levels, bone density were not different from normal population. But, uncorrected visual acuity is significantly different among women over 40 years-old with avellino, as compared to the normal population. Further investigation is needed to identify the correlation between genotype and phenotypes in Avellino and normal population using whole genome-wide scan or SNPs. This work was supported by the intramural grant from the Korea National Institute of Health, Korea Center for Disease Control, Republic of Korea (Project number 4845301-260).

Molecular, Cytogenetic and Immunohistochemical Analysis of a Complete Molar Pregnancy with Isodisomic Chromosome 9 Inversion. *M. Wick[1], N. Hoppman-Chaney[2], C. Runke[2], M. Parkman[2], G. V. Velagaleti[2]* 1) Dept OB/GYN, Mayo Clinic & Foundation, Rochester MN; 2) Dept Lab Genetics, Mayo Clinic & Foundation, Rochester MN.

Hydatidiform moles (HM) arise from an abnormal fertilization event, resulting in abnormal development of fetal and trophoblastic tissue. HM are subcategorized as Partial hydatidiform moles (PHM) and complete hydatidiform moles (CHM) based on clinical features, histopathology, karyotype and malignant potential. CHM have diffuse trophoblastic hyperplasia, hydropic villi, and lack of embryonic tissue. CHM are diploid, arising from the fertilization of an empty ovum with either a haploid sperm with subsequent duplication of chromosomes, or by two haploid sperm. Risk for gestational trophoblastic neoplasia is 18-28%. Given the clinical/prognostic importance of distinguishing PHM from CHM and the role of imprinting in HM, there has been increased interest in the use of molecular and immunohistochemical characterization. Here we report characterization of a complete molar pregnancy isodisomic for chromosome 9 inversion. Parenteral chromosome analysis revealed paternal 46,XY,inv(9)(p13q13). Microsatellite analysis of six chromosome 9 markers revealed 4 informative markers, with products of conception (POC) homozygous for all four markers. Microsatellite analysis of POC tissue for seven markers on chromosomes 6,7,8,10, 14, 15 and 17 revealed homozygosity at all markers; markers on 6 and 15 were informative and also homozygous for the paternal allele. These results are consistent with paternal isodisomy as the molecular mechanism for the molar pregnancy. Additionally, immunohistochemical analysis with p57, an imprinted gene with maternal expression, was negative. These studies confirm that the complete molar pregnancy resulted from fertilization of an empty ovum with a haploid sperm followed by duplication of paternal chromosomes. Although CHM is known to result from androgenic conception, very few cases have been reported where chromosome polymorphisms indicated the pathologic basis. Our results indicate the importance of chromosome polymorphisms in the diagnosis of uniparental disomy, especially in those cases where the karyotype is normal.

Detection of the Common Chromosomal Abnormalities Using Array-based MLPA Approach. *F. Zeng, Z. Ren, J. Yan, M. Chen, Y. Huang, Y. Wu* Shanghai Inst Med Genet , Shanghai Children's Hospital, Shanghai Jiao Tong University, Shanghai, China.

Aneuploidies are the most frequent chromosome abnormalities. Currently, the diagnosis of aneuploidies usually relies on karotyping analysis, which is labor- extensive, time-consuming and inefficient. Recently, we developed array-based MLPA method. It can detect more than 100 DNA sites or copy information within two days. We previously applied array-MLPA to detect DNA deletions and duplications in DMD gene, which proved the stability and reliability of the method. The present study is committed to apply array-MLPA to detect aneuploidies in clinical patients and to assess the accuracy in diagnose of aneuploidies as compared to karotyping analysis. Probes on several key gene sites on five chromosomes (13, 18, 21, X, Y) were designed, followed by detecting the copy number of each site to check the number of the chromosomes. A total of 200 clinical samples including 188 blood cell and 12 amnionic cell DNA samples were tested. 103 were checked out to be aneuploidis except 2 mosaicisms, that were completely in accordance with karotyping analysis. The results demonstrated that the array-MLPA takes on a high rate for detecting number changes in chromosomes. As a method of gene-scanning, array-MLPA has the advantages in detecting micro-chromosome changes at submicroscopic level, and some small changes were tested in part of samples with a normal karotype. It also has a significant help for checking the accurate sites of some unknown markers. With great advantage in simple operation, high efficiency and reliability, array-MLPA has a practical value and potential in the application of molecular and prenantal diagnosis for aneuploidies.

Regulatorygenomics.org: An ENSEMBL/BIOMART environment for the analysis of regulatory regions and their involvement in complex diseases. *P. Beaulieu[1], A. Graziani[1], R. Hamon[1], T. Pastinen[3], E. Harmsen[3], D. Sinnett[1,2]* 1) Centre de recherche, CHU Sainte-Justine, Montréal, QC, Canada; 2) Departement de Pédiatrie, Université de Montréal, Montreal, QC, Canada; 3) McGill University and Genome Quebec Innovation Center, Montreal, QC, Canada.

Previous efforts to identify functional disease-causing DNA variants were essentially oriented towards the coding regions (cSNPs) of candidate genes since these variants have a direct impact on the structure (qualitative changes) and function of the affected proteins. However, abnormal expression of finely regulated genes can also lead to disequilibria (quantitative changes) in different metabolic pathways and/or biological processes. Thus, investigation of the functional impact of SNPs as well as the determination of the importance of evolutionary conservation in the regulatory regions of candidate genes should improve our knowledge of complex disease aetiologies. As part of the Gene Regulators in Disease (GRID) project, we have to integrate layers of information including gene structure, SNP content, genomic patterns (i.e. CpG islands, conserved regions) and in silico analysis together with experimental results from electrophoretic mobility shift assays (EMSA) and several types of in vitro and in vivo promoter activity assays. Here, we present a web-based environment to combine, analyse and distribute the results generated by the GRID project as well as external sources of regulatory genomics and genomic-phenotype association data. Our software takes advantage of the ENSEMBL genome browser package combined with the BIOMART data management and query system. This allows an efficient integration of data collected from the various wet-labs and in silico platforms and therefore a better functional annotation of the regulatory regions of human genes.

GAPO syndrome or Cranioectodermal dysplasia? Three affected Egyptian sibs with overlapping features. *H. H. Mostafa, M. H. Zeineldin* Molecular Biosciences, University of Kansas, lawrence, KS.

GAPO and cranioectodermal dysplasia are rare genetic syndromes with relatively few world-wide reported cases. Both syndromes affect, with other systems, ectodermal, mainly hair and teeth, and skeletal tissues. In this report we describe 2 brothers and a sister from an Egyptian family with features of both GAPO syndrome and cranioectodermal dysplasia. We also describe features that have not been reported before in either of both syndromes including structural and functional CNS and connective tissues anomalies. We suggest that both cranioectodermal dysplasia and GAPO syndrome might be variable expression of one condition.

A model system of methylation establishment and unmethylation maintenance in the PWS-imprinting center region. *T. Ohta, N. Sosonkina, D. Starenki, N. Niikawa* Res Inst, Personal Hlth, Univ Hokkaido Hlth Sci, Ishikari-gun, Japan.

The human 15q11-q13 region has an imprinting domain consisting of two imprinting control centers, ASIC and PWSIC. PWSIC functions as a maternal and a paternal mark for the maintenance of the methylated and the unmethylated regions, respectively. This maternal methylation is supposed to be established in the maternal oocyte or at an early embryonic stage with a cis-factor from ASIC located at the upstream region of PWSIC. The paternal unmethylation and maternal methylation at PWSIC are maintained stably in all tissues through developmental stages and also in cultured cells. To confirm the stable maintenance, we generated several transgene (Tg) constracts including human genomic DNA of PWSIC to transfect and integrate into mouse ES cells with a positive selection marker. All positive mixed cell clones were harvested at 1 week, and at 4 weeks after one-week selection with subculture treatments in undifferentiation medium. Consequently, no new methylation at PWSIC was observed in any one-week cultured cells. In 4-week cultured cells, the control Tg constract [ACTB promoter-exon 1-SV40 polyA (PA)] showed that the CpG island of the ACTB promoter is partially methylated, while neither of two Tg constracts, PWSIC-SV40PA and ASIC-PWSIC-SV40PA, showed methylation at PWSIC. In contrast, PWSIC was highly methylated in cells with three Tg constracts, SV40 promoter-intron-PWSIC-SV40PA, SV40 promoter-intron-ASIC-PWSIC-SV40PA, and SV40PA-PWSIC-SN40PA. These results indicate that PWSIC is easily methylated with an alternative SV40 promoter, but suggest that PWSIC has its own factor to prevent new methylation as seen in chromatin boundaries.

Fast and accurate genotype imputation and trio phasing: new methods and applications to genome-wide association studies. *B. Browning, S. Browning* Department of Statistics, The University of Auckland, Auckland, New Zealand.

There is widespread interest in imputing genotypes for markers that are not genotyped in a sample of interest, but that are genotyped in a reference panel. Early applications of imputation have used a reference panel of phased haplotypes from the HapMap phase 2. The HapMap is an extremely valuable resource, but it is limited in both markers and samples. Copy number variants and many SNPs are not in the HapMap, and accuracy of genotype imputation is limited by the HapMaps small sample size.

We have developed new methods for phasing parent-offspring trios and for imputing genotypes. These methods enable imputation of genotypes at additional markers and the use of large reference panels with thousands of trios or unrelated individuals. Our methods can be used to:

1) Impute variants that are not in the phased HapMap data, but that have been genotyped on HapMap samples using high density arrays.

2) Impute variants by using trio data in a reference panel. Use of trio data directly, instead of phased haplotypes derived from trios, provides a way to account for haplotype uncertainty in the reference panel.

3) Combine data across studies that have used different high density arrays by using imputation with a large reference panel that has been genotyped on each array.

4) Phase and impute genotypes simultaneously using a mixture of unrelated individuals, parent-offspring trios, and phase-known haplotypes.

We have phased >2.5 million markers genotyped on 30 HapMap trios in <5 hours. Our trio phasing method is several orders of magnitude faster than the gold standard PHASE method, yet the proportion of heterozygous genotypes phased differently between the two methods is only 0.0081 (CEU) and 0.0038 (YRI).

Our new methods are implemented in Beagle 3.0, which is freely available from www.stat.auckland.ac.nz/~browning/beagle/beagle.html.

A Powerful Gene-Based Association Test using Optimally Weighted Markers. *M. Li[1], K. Wang[2], S. F. A. Grant[3], H. Harkonarson[3], C. Li[4]* 1) Department of Biostatistics and Epidemiology, Univ Pennsylvania; 2) Department of Genetics, Univ Pennsylvania; 3) Center for Applied Genomics, Children's Hospital of Philadelphia; 4) Department of Biostatistics, Vanderbilt University.

Large-scale candidate-gene and genome-wide association (GWA) studies genotype multiple SNPs within or surrounding a gene, including both tag and functional SNPs. The immense amount of data generated in these studies poses new challenges to analysis. One particularly challenging yet important question is how to best use all genetic information to test whether a gene or a region is associated with the trait of interest. We propose a powerful gene-based Association Test using Optimally weighted Markers (ATOM) within a gene or a region. Due to variation in linkage disequilibrium, different markers often associate with the trait at different levels. To appropriately apportion their contributions, we assign a weight to each marker that is proportional to the amount of information it captures about the trait locus. We analytically derive the optimal weights for both quantitative and binary traits, and describe a procedure for estimating the weights from a reference data set such as the HapMap. Compared to existing approaches, our method has several distinct advantages, including 1) the ability to borrow information from external data set to increase power, 2) the theoretical derivation of optimal marker weights, and 3) the scalability to simultaneous analysis of all SNPs in candidate genes/pathways. Through extensive simulations and analysis of the FTO gene in our ongoing GWA study on childhood obesity, we demonstrate that ATOM is robust and consistently increases the power to detect genetic association as compared to several commonly used multipoint association tests. The power improvement is even more pronounced when allelic heterogeneity exists. With the wide availability of genotyping arrays with increasing marker density, our method will provide a powerful approach to identifying disease loci from multiple genotyped markers.

Robust Multifactor Dimensionality Reduction Method for Detecting Gene-Gene Interaction in Bladder Cancer.

J. Gui[1], *J. H. Moore*[1,2,3], *A. S. Andrew*[1] 1) Community & Family Medicine, Dartmouth Medical Sch, Hanover, NH; 2) Dept. of Genetics, Dartmouth Medical Sch, Hanover, NH; 3) Norris-Cotton Cancer Center, Dartmouth Medical Sch, Lebanon, NH.

The central goal of human genetics is to identify and characterize susceptible genes for common complex human diseases. In 2001, Ritchie, et al proposed the Multifactor Dimensionality Reduction (MDR) method in American Journal of Human Genetics that successfully reduced the high dimensionality caused by combining multi-locus genotypes and provided a key step to facilitate detection of important gene-gene and gene-environment interactions. However, MDR classifies the combination of multi-locus genotypes into high-risk and low-risk groups based on a simple comparison of the ratios of the number of cases and controls to that in the entire data. This may cause false-positive findings when the two ratios are very close to each other. To tackle this problem, we propose the Robust Multifactor Dimensionality Reduction (RMDR) method that performs Fishers Exact Test on the case-control ratio in all possible genotype combinations. We classify the combination in the high or low risk group when the test is significant; otherwise we classify it to the unknown group. In this way, only genotypes with significant case-control ratios are considered. We expect that this approach will increase the power when heritability is low. In the simulation study, with 400 samples and a heritability of 0.025, we show that RMDR has 70% power to detect the true interaction as compared to 50% from MDR. We then apply the RMDR method to detect interactions in genotype data from a population-based study of bladder cancer.

Whole Genome Mapping Identifies Multiple Quantitative Trait Loci (QTL) for Novel Cardiovascular Disease Biomarkers. *S. Shah[1, 2], H. Chen[1], D. Thompson[1], S. Nelson[2], C. Haynes[2], J. Johnson[2], T. Stabler[1], Z. Dowdy[1], E. Hauser[2], S. Gregory[2], V. Kraus[1], W. Kraus[1]* 1) Dept Medicine, Duke Univ Med Ctr, Durham, NC; 2) Center for Human Genetics, Duke University Med Ctr, Durham, NC.

Background. Cardiovascular disease (CVD) has a strong genetic component and is heritable. We have shown that novel CVD biomarkers are also heritable. We hypothesized that genome mapping would identify quantitative trait loci (QTL) underlying these traits. **Methods.** Samples and clinical data were obtained on 365 members from a large, multi-generational, multiethnic family (N=3000). Commercial assays were used to measure paraoxonase, D-dimer, C-reactive protein (hsCRP) and glycated serum protein (GSP) from frozen serum. Genotyping was done using the Illumina linkage chip with ~5700 SNPs. Variance components implemented in SOLAR was used to calculate linkage odds (LOD) scores using a polygenic model adjusted for age and sex. **Results.** We identified multiple QTL for novel CVD biomarkers. For paraoxonase, a QTL was identified on chromosome 7q22-q31 (108-119 cM, maximum twopoint LOD=2.39, multipoint LOD=2.76); chromosome 8p12-p11 (51-59 cM, twopoint LOD=1.94, multipoint LOD=2.77); and chromosome 19p13-q12 (46-51 cM, twopoint LOD=0.91, multipoint LOD 2.18). Two of these QTL (7q, 19p) have been identified previously; the chromosome 8p locus is novel. For D-dimer, a QTL was identified on chromosome 9q33-q34 (128-149 cM, twopoint LOD=1.38, multipoint LOD=2.31), chromosome 15q12 (8-15 cM, twopoint LOD=0.65, multipoint LOD=2.00) and chromosome 3q22-q24 (140-152 cM, twopoint LOD=1.18, multipoint LOD=1.68). For GSP, two QTL were identified: chromosome 13q12-q13 (17-38 cM, twopoint 0.26, multipoint LOD 2.00) and chromosome 3p14 (84-94 cM, twopoint 0.53, multipoint 1.46). For CRP, modest QTL were identified on chromosomes 3q26-q27, 7q31-q34, 14q31-q32, 19p12-q13, and 22q11-q12 (LOD 1.55-1.85). **Conclusions.** We report multiple QTL for novel cardiovascular biomarkers in a large family with a burden of CVD reflective of the average United States population. Several strong candidate genes underlie these QTL and could be contributing to variability of these CVD-related biomarkers, thus mediating CVD risk.

Identification of osteoporosis susceptibility genes by computational disease gene identification strategy. *Q. Huang, G. Li, A. Kung* Dept Medicine, Univ Hong Kong, Hong Kong, Hong Kong.

We previously used five freely available bioinformatics tools (Prioritizer, Geneseeker, PROSPECTR and SUSPECTS, Disease Gene Prediction and Endeavour) to analyze the thirteen well replicated osteoporosis susceptibility loci and identify a subset of most likely candidate osteoporosis susceptibility genes (Huang et al. 2008). In current study, we experimentally tested the association between osteoporosis and the 9 most likely candidate genes [LAMC2(1q25-q31), MATN3(2p24-p23), ITGAV(2q31-q32), ACVR1(2q23-q24), TDGF1(3p21.31), EGF(4q25), IGF1(12q22-q23), ZIC2(13q32), BMP2(20p12)] which were pinpointed by all of 5 tools. Tag SNPs-based and gene-wide association studies were conducted in 1, 810 case-control Hong Kong Chinese. The cases were subjects with low bone mineral density (BMD) (Z-scores -1.28, equivalent to the lowest 10 percent of the population) at either the L1-4 lumbar spine or femoral neck. Control subjects had high BMD (Z-score +1.0) at the corresponding sites. A total of 40 tag SNPs were identified from the CHB panel of the phase II HapMap project, and genotyped using the high-throughput Sequenom genotyping platform. Allelic/genotypic and haplotypic associations were evaluated by Haploview and binary logistic regression. The SNP rs9585308 in the ZIC2 gene showed consistent genotypic/allelic associations with BMD at all sites measured ($p = 0.04$-0.002). The SNP rs10178256 in the MATN3 gene showed significant genotypic/allelic associations with total hip BMD and troancher BMD ($p = 0.05$-0.01). Interestingly, mutations in the MATN3 gene have been reported in a variety of skeletal diseases and a functional knockout of the MATN3 gene increases BMD in mice (van der Weyden, et al. 2006). Our results thus demonstrated the feasibility of a computational disease gene identification strategy for prediction of susceptibility genes that affect complex diseases such as osteoporosis.

Interstitial lung disease in two patients with Rubinstein-Taybi syndrome. *R. Kosaki[1], S. Kikuchi[2], G. Koinuma[2], M. Higuchi[2], K. Kawasaki[2], K. Kosaki[3]* 1) Div.Clin Genet & Mol Med, Natl Ctr Child Health & Dev, Tokyo, Japan; 2) Div. Pul , Natl Ctr Child Health & Dev, Tokyo, Japan; 3) Dept Ped, Keio Univ Sch Med, Tokyo, Japan.

Rubinstein-Taybi syndrome (RTS) is characterized by broad thumbs and great toes, short stature, mental retardation, and distinctive facial features including downslanting palpebral fissures, columella extending below the nares. CREBBP and EP300 are the causative genes for RTS. Here we report on two patients with RTS who developed interstitial lung disease. [Case 1] The patient was born after 38 weeks of gestation with a birth weight of 2840g. At age 6 weeks, he started to develop tachypnea and cyanosis. Based on a hazy ground glass appearance on the chest X-ray and elevated serum marker KL-6, he was diagnosed as having interstitial lung disease. After treatment with corticosteroids, his respiratory status improved. He had typical RTS phenotype and a complex CREBBP mutation involving a 6-base deletion and an 11-base insertion that truncates protein [Case 2] The patient was born after 37 weeks of gestation with a birth weight of 1943g. At birth he had PDA, congestive heart failure, and pulmonary hypertension. PDA was ligated at age 1 month. After age 4 months, he experienced several episodes of pneumonia that required occasional ventilatory support. At age 12 months, X-ray revealed a hazy ground glass appearance. Based on elevated serum KL-6, he was diagnosed as having interstitial lung disease. He died because of irespiratory failure. Dysmorphic features of the patient were compatible with RTS. To the best of our knowledge, development of interstitial lung disease has never been reported previously in relation to RTS. Nevertheless, the similarity of the clinical course of two patients herein reported suggests that patients with RTS may be susceptible to interstitial lung disease. Recurrent pulmonary infection, a relatively common complication of RTS, may have contributed to fibrotic process of the lung. Alternatively, mutations in CREBBP, a transcoactivator of various transcriptional factors, may have direct impact on the structural integrity of the alveolar wall.

Variation of gene silencing contributes in a variety of gene expression in mammalian cells. *H. Hohjoh, Y. Tamura*
Natl Inst Neuroscience, NCNP, Tokyo, Japan.

Gene expression complexity is required for gaining a variety of biological functions, regulations and morphology in organisms. MicroRNAs (miRNAs) are small noncoding RNA and play a role in gene expression regulation by inhibiting translation of their target messenger RNAs (mRNAs). In this study, we indicate contributions of endogenous miRNAs, as well as target mRNAs, in the generation of a variety of gene expressions. We investigated the effects of endogenous let-7 miRNA on the expression of target genes in various mammalian cells. The results indicate that different cells had different levels of gene silencing against the target genes, depending upon the level of let-7. In addition, we also identified the intriguing regulation of the High Mobility Group A2 (Hmga2) gene expression involving endogenous let-7 during neuronal differentiation of mouse embryonal carcinoma P19 and human teratocarcinoma NTera2D1 cells, where the mouse Hmga2 underwent gene silencing and the human HMGA2 escaped gene silencing by its alternative splicing. The evidence presented here suggests that various levels of gene silencing involving endogenous miRNAs and target mRNAs most likely yields immensely various and complex gene expression.

Molecular mechanisms for subtelomeric rearrangements associated with the 9q34.3 microdeletion syndrome. *S. A. Yatsenko[1], E. Brundage[1], E. K. Roney[1], S. W. Cheung[1], A. C. Chinault[1], J. R. Lupski[1,2,3]* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Pediatrics, Baylor College of Medicine; 3) Texas Children Hospital, Houston, TX.

We characterized genomic rearrangements in 28 unrelated patients with 9q34.3 deletions using a custom designed high-resolution microarray. Four distinct rearrangement categories were delineated: terminal deletions, interstitial deletions, derivative chromosomes, and complex rearrangements; each results in haploinsufficiency of the *EHMT1* gene and a characteristic phenotype. Interestingly, 25% of our patients had *de novo* interstitial deletions, 25% were found with derivative chromosomes and complex rearrangements, and only 50% were bona fide terminal deletions. In contrast to genomic disorders that are often associated with recurrent rearrangements, breakpoints involving the 9q34.3 subtelomere region are highly variable producing nonrecurrent rearrangements. Molecular studies identified 3 potential breakpoint cluster regions. Interspersed repetitive elements such as *Alu*, LINE, long terminal repeats and simple tandem repeats are frequently observed at the breakpoints. Such repetitive elements may play an important role by providing substrates with a specific DNA secondary structure that stabilize broken chromosome or assist in DNA DSB repair. Sequence analyses of the junction fragments suggest that subtelomere deletions can be stabilized by both homologous and nonhomologous recombination mechanisms, through a telomere-capture event, by *de novo* telomere synthesis, or multistep breakage-fusion-bridge cycles.

Genome Wide Linkage and Admixture Scans in African American Families from the American Diabetes Association GENNID Cohort. *S. C. Elbein[1], S. K. Das[1], D. M. Hallman[3], C. L. Hanis[3], S. J. Hasstedt[2]* 1) Endocrinology, Dept of Medicine, CAVHS and Univ Arkansas Med Sci, Little Rock, AR; 2) Dept of Human Genetics, University of Utah Health Sciences Center, Salt Lake City, UT; 3) Human Genetics Center, School of Public Health, Univ. of Texas Health Science Center , Houston, TX.

We examined 1496 individuals from 580 African American families ascertained from 10 centers. Participants were evaluated at 5,958 single nucleotide polymorphisms (SNPs). After data cleaning and removal of singleton and problematic pedigrees, analyses were conducted on 1344 individuals from 530 families (1293 affected sib pairs; 1021 full siblings, 306 parent-offspring pairs, 267 half sibs, 43 avuncular pairs, and 14 grandparent/grandchild pairs) using variance components analysis for type 2 diabetes (T2D), age of diagnosis (AOD), and BMI at 5619 SNPs. Ordered subsets were investigated based on AOD, BMI, waist circumference, waist:hip ratio, and European Admixture using nonparametric linkage (NPL)scores. The strongest signal for T2D was on chrm 2 at 127 cM and 108 cM (lod 4.53 and 2.98, resp), where AOD also showed suggestive linkage(1.66 at 115 cM). Chromosome 13p likewise showed linkage for both T2D and AOD (3 cM - 22 cM; lod 2.42 for T2D;2.46 for AOD). Suggestive T2D regions were chrms 4 (135 cM; lod 2.26), 7 (79 cM, 2.93), 11 (123 cM, 2.36), and 16 (56 cM, 2.43). The best AOD score lod 2.96 (chrm 18, 66 cM). Suggestive ordered subset scores included chrm 1 (30 cM; admixture), chrm 3 (11 cM; AOD), chrm 7 (131 cM; WHR); and chrm 14 (57 cM; T2D duration. Multipoint admixture linkage disequilibrium was calculated from 4486 markers spaced at >0.05 cM. The best admixture signal was found on chrm 12 at 90 cM (p=0.0003), which approached but did not meet genome-wide significance. The regions of best linkage (chrm 2, 13, 18) are gene rich (122, 27, and 47 genes, resp), and include candidate genes LIPG (18q), PDX1(13q), PAX8 (2q), IL18R1 (2q), and MAP4K4(2q). Secondary peaks on chrms 4 (125 - 135 cM), 7 (27-78 cM), and 22 (33 cM)overlapped with previous reports. Our results suggest several novel T2DM susceptibility genes, and particularly support a recent report on chromosome 7 in African-Americans.

Information-Theory methods for analyzing Gene-Gene and Gene-Environment Interactions involving quantitative traits. *L. Sucheston[1, 2], P. Chanda[1], S. Liu[1,2], A. Zhang[1], M. Ramanathan[1]* 1) State Univ New York, Buffalo, Buffalo, NY; 2) Roswell Park Cancer Institute, Buffalo, NY.

We developed two information theoretic metrics and a computationally efficient algorithm for analyzing genome wide data for evidence of gene-gene (GGI) and gene environment interactions (GEI) associated with quantitative traits (QT). The approach can be employed for case-control and case designs. We evaluated the power and type I error of the phenotype-associated information (PAI), which is obtained from the total correlation information (TCI) by removing the contributions for inter-variable dependencies (resulting from factors such as linkage disequilibrium) and the KWII, which is defined in terms entropies of both the individual variables and the entropies the combinations of the variables, using a series of controlled numerical experiments. In addition to these simulations, we examined the ability of the metrics when used in a greedy search algorithm to efficiently analyze genetic association with QT on a genome wide level using GAW15 data (generated by complex simulations based on a rheumatoid arthritis data). The metrics and search algorithm were also applied to a QTL mouse mapping study of HDL levels and atherosclerotic lesion size. The results of this analysis were compared to existing literature and a comparative genomics approach was used to evaluate the ability of the PAI and greedy search to replicate other study results, narrow regions and generate additional regions of interest. In addition to good power and type I error in the simulations, involving only a few SNPs, the information metrics were found to have excellent sensitivity at the genome level for identifying the GEI in the GAW15 data. Results from the mouse QTL analyses when used in a comparative genomics analysis showed that our method was capable of successfully identifying all published regions associated with HDL and atheroscelortic disease in humans and several that have only been found using fine mapping studies following a genome scan. These metrics and the algorithm provide a promising approach for analyzing the GGI and GEI associated with QT in an increasingly data rich age.

pHCR: A Parallel Haplotype Configuration Reduction Algorithm for Haplotype Interaction Analysis. *W. Makarasara[1,2,4], A. Assawamakin[3], A. Intarapanich[3], S. Fucharoen[2,4], N. Chaiyaratana[5], N. Kamatani[1], S. Tongsima[3]*
1) Center for Genomic Medicine, Institute of Physical And Chemical Research, RIKEN, Minato-ku, Tokyo, Japan; 2) Thalassemia Research Center, Institute of Science and Technology for Research and Development, Mahidol University, Nakornpathom, Thailand; 3) Biostatistics and Informatics Laboratory, Genome Institute, National Center for Genetic Engineering and Biotechnology, National Science and Technology Development Agency, Pathumthani, Thailand; 4) Department of Biochemistry, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand; 5) Department of Electrical Engineering, Faculty of Engineering, King Mongkuts Institute of Technology North Bangkok, Bangkok, Thailand.

Multiple genes and their interactions are believed to underlie most of complex diseases. Within the last decade, extensive studies have successfully identified disease-associated genetic variants. However, the lack of the knowledge for modeling the gene-gene interaction has led to the failure in the full explanation of the genotype-phenotype relationship. To overcome such an obstacle, we here introduce a novel algorithm for modeling the gene-gene interaction via haplotype interaction called Parallel Haplotype Configuration Reduction (pHCR). This technique extends the original multifactor dimensionality reduction (MDR) algorithm by utilizing haplotype contribution values (c-values) and a haplotype interaction scheme to achieve the goal of specifying the haplotype combination which best classified cases and controls. The parallel computing technology is introduced to handle the large scale analysis. Results using simulation data sets of twelve two-locus disease models suggested that pHCR can predict the gene-gene interaction correctly in most epistasis models. In addition, incorporation of haplotype which includes the linkage disequilibrium (LD) information showed an increase in power for detecting true interactions when susceptibility loci are not present in the data set and other SNPs are in weak LD with the susceptibility loci.

Meta-analysis of genome-wide association scans reveals new loci for body mass index in early adulthood. *S. I. Berndt[1], L. Qi[2], A. U. Jackson[3], M. Garcia-Closas[1], M. Boehnke[3], F. Hu[2], D. J. Hunter[2], S. J. Chanock[1], R. B. Hayes[1]*
1) Division of Cancer Epidemiology & Genetics, National Cancer Institute, Bethesda, MD; 2) Departments of Nutrition and Epidemiology, Harvard School of Public Health, Boston, MA; 3) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Obesity is an important risk factor for a multitude of diseases. Although obesity has high heritability, efforts to detect genetic loci associated with the trait have yielded a limited number of susceptibility genes. Considering the heterogeneity in obesity and that genetic determinants may be important particularly in early onset obesity, we conducted a meta-analysis of genome-wide association (GWA) scans from three studies (Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial, Nurses Health Study, and Finland-United States Investigation of NIDDM Study) including ~ 5,400 individuals of European ancestry to identify genetic loci associated with body mass index (BMI) in early adulthood (ages 18-20 years). Based on scans of 300-500K SNPs, each study imputed genotypes for the ~2.5 million common SNPs in the CEU HapMap and tested the association under an additive genetic model (1 d.f.). SNPs with a minor allele frequency <1% or low imputation quality score ($r^2 < 0.3$) were excluded, and a meta-analysis of the associations using the square root of the sample size as weights was performed. The recently identified variants in *FTO* and near *MC4R* were associated with BMI in early adulthood ($p = 0.01$ and $p = 0.02$, respectively). We discovered one novel locus on chromosome 4 with a p-value $< 1 \times 10^{-6}$, and nine loci not previously implicated in obesity showed nominally significant associations with p-values $< 1 \times 10^{-5}$. Some of these loci are located near genes related to metabolism or growth factors, which are promising candidates for obesity. We are currently replicating the top findings in an additional 10,000 persons of European ancestry. In conclusion, our study identified several new promising genetic variants associated with BMI in early adulthood and will hopefully shed additional insight into the complex etiology of obesity.

In-silico pharmacokinetic and cellular simulation of pharmacological chaperone therapy for GM2 gangliosidosis.
J. G. Keimel Biomedical Engineering, University of Minnesota, Minneapolis, MN.

Background: Inadequate -hexosaminidase A (HexA) activity results in an over-accumulation of GM2 ganglioside in neuronal lysosomes (lys) and disruption of normal cell function. G269S, the primary mutation associated with Adult Tay-Sachs Disease (ATSD), does not impact the viability of the HexA active site, but is believed to cause post-translation misfolding, instability of the HexA constituent monomers, and premature routing for degradation from the endoplasmic reticulum (ER). Pharmacological chaperone (PC) therapy has been proposed to improve HexA monomer stability in the ER and thereby increase the HexA dimer transport to the lys. Prior in-vitro studies have shown pyrimethamine (pyr) to be a potential PC therapy for ATSD, but being a HexA inhibitor, it also poses possible safety risks. **Model Description:** In lieu of a suitable animal model, a computer simulation has been developed to provide insight on pyr pharmacokinetics (PK) and GM2 response that might be observed in ATSD patients. The simulation uses three interlinked models. The PK model uses classical two compartment theory to estimate neuronal pyr concentration. An ER model modulates the enzyme stability based on the pyr level and predicts the relative amount of HexA transported to the lys. The third model simulates lysosomal GM2 degradation and HexA inhibition caused by pyr. The models are based on simultaneous solution of 18 ordinary differential equations and use previously published parameter values, when available. The lysosomal model incorporates an algorithm that increases HexA half-life as a function of GM2 substrate. It is hypothesized that this simple regulatory mechanism allows ATSD patients to remain in a rather stable disease state for decades. **Simulation Results:** Simulations of continuous daily pyr therapy results in a 40 day transient HexA increase but with a persistent decrease in GM2. The transient HexA level response suggests that an alternative measurement of GM2 levels may be required to assess long-term clinical efficacy. **Conclusions:** The simulation provides a means of creating hypotheses on PC mechanisms, but clinical studies are required for validation.

Crossing-over satellite and jumping SRY. *C. C. Lin[1,2], Y.-C. Li[3], S.-C. Chien[4,5], L.-J. Hsieh[1], F.-J. Tsai[5,6]* 1) Lab for Chromosome Research, Dept Medical Research, China Medical Univ & Hosp, Taichung, Taiwan; 2) Graduate Institute of Basic Medical Sciences, China Medical Univ, Taichung, Taiwan; 3) Dept Biomedical Sciences, Chung Shan Medical University, Taichung, Taiwan; 4) Dept Obstetrics and Gynecology, China Medical Univ Hosp, Taichung, Taiwan; 5) Dept Medical Genetics, China Medical Univ, Taichung, Taiwan; 6) Dept Pediatrics, China Medical University Hosp, Taichung, Taiwan.

We report here two extreme rare and unique prenatal diagnostic cases. The first case is a phenotypically normal male fetus with a satellited short arm of the Y chromosome, 46,XYps. Amniocentesis was performed due to advanced maternal age and parental chromosome study revealed that the father has a normal Y and a satellited short arm X chromosome, 46,XpsY. The mother has normal female karyotype. The couple has another son with normal male karyotype. This is the second documented case of Yps, while it is the first time to demonstrate the likely mechanism that a crossing-over between Xps and terminal short arm of the Y occurred during spermatogenesis, for production of Yps in this case. In the second case, amniocentesis revealed a male fetus with apparently normal female karyotype,46,XX. Surprisingly, FISH study with SRY probe detected a hybridization signal on the terminal short arm of a chromosome 3 of the fetus. An apparently normal male newborn was delivered. Both parents have the normal karyotype and the SRY locus located on the terminal short arm of the fathers Y chromosome. We hypothesize that instead of the more common translocation between Xpter and Ypter, a jumping translocation between Ypter involving the SRY locus and terminal 3p occurred during paternal meiosis. The fetus in this case had received a normal X and a SRY translocated chromosome 3 from a paternal gamete. To our knowledge, it is the first such a case reported.

A novel six nucleotide insertion and a novel nonsense mutation in the fructose-1,6-bisphosphatase 1 gene of patients with clinical diagnosis of the fructose-1,6-bisphosphatase deficiency. *H. Abalkhail[1], M. Faiyaz-Ul-Haque[1], M. Al-Owain[2], Z. Al-Hassnan[2], H. Al-Zaidan[2], Z. Rahbeeni[2], M. Al-Sayed[2], A. Balobaid[2], A. Cluntun[1], M. Toulimat[1], F. Al-Dayel[1], S. H. E. Zaidi[3]* 1) Pathology & Lab Med (MBC 10), King Faisal Special Hosp, Riyadh, Saudi Arabia; 2) Dept of Medical Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 3) Dept of Medicine, University Health Network & University of Toronto, Toronto, Ontario, Canada.

Fructose-1,6-bisphosphatase 1 (FBP1) is an important regulator of gluconeogenesis which catalyzes the hydrolysis of fructose 1,6-bisphosphate to fructose 6-phosphate and inorganic phosphate. FBP1 deficiency results in impaired gluconeogenesis which produces episodes of hyperventilation, apnea, hypoglycemia, and metabolic and lactic acidosis in patients. This autosomal recessive disorder is caused by mutations in the FBP1 gene which encodes for the fructose-1,6-bisphosphatase 1 protein. Although mutations in FBP1 gene have been reported in Japanese, European and North American populations, genetic causes of fructose-1,6-bisphosphatase deficiency in the Arab population have not been investigated. Here, we describe five consanguineous families in which patients were clinically diagnosed with the deficiency of fructose-1,6-bisphosphatase. Mutation analyses of the FBP1 gene identified a novel six nucleotide insertion in three families, and a novel stop codon mutation in two other families. The insertion mutation which encodes for two additional amino acids, may affect the FBP1 enzyme activity by altering its structure or allosteric regulation. The stop codon encoding mutation is expected to produce protein truncation in the active site region of the FBP1 protein. These novel mutations in the FBP1 gene are the first known genetic causes of the FBP1 deficiency in patients of Arab ethnicity. Reoccurrence of these mutations in other unrelated families provides a strong justification for analysis of Arab patients with clinical diagnosis of fructose-1,6-bisphosphatase deficiency for these mutations.

Canine polydactyl mutations with heterogeneous origin in the conserved intronic sequence of LMBR1. *C. Kim[1], K. Park[1], J. Kang[1], K. Subedi[1], J. H. Ha[2], C. Park[1]* 1) Biological Science, Korea Advanced Institute of Science and Technology, Daejeon, Korea; 2) Genetic Engineering, college of Natural Sciences, Kyungpook National University, Daegu, Korea.

Canine preaxial polydactyly (PPD) in the hind limb is a developmental trait that restores the first digit lost during canine evolution. Using a linkage analysis, we demonstrated previously that the affected gene in a Korean breed is located on canine chromosome 16. The candidate locus was further limited to a linkage disequilibrium (LD) block of less than 213 kb comprising the single gene, LMBR1, by LD mapping with single-nucleotide polymorphisms (SNPs) for affected individuals from both Korean and Western breeds. The ZPA regulatory sequence (ZRS) in intron 5 of LMBR1 was implicated in mammalian polydactyly. An analysis of the LD haplotypes around the ZRS for various dog breeds revealed that only a subset is assigned to Western breeds. Furthermore, two distinct affected haplotypes for Asian and Western breeds were found, each containing different single-base changes in the upstream sequence (pZRS) of the ZRS. Unlike the previously characterized cases of PPD identified in the mouse and human ZRS regions, the canine mutations in pZRS lacked the ectopic expression of sonic hedgehog in the anterior limb bud, distinguishing its role in limb development from that of the ZRS.

A Common Intronic Variant of *CXCR3* is Functionally Associated with Gene Expression Levels and the Polymorphic Immune-cell Responses to Stimuli. *Y. Kim[1], C. Choi[1], M. Hwang[2], C. Park[3], H. Nam[1], H. Chang[3], B. Han[1], K. Kimm[4], H. Kim[1], B. Oh[1]* 1) Ctr Genome Science,3rd Fl, KNIH, Seoul, Korea; 2) Graduate School of Medicine, Korea University, Seoul, Korea; 3) Genome Research Center for Allergy and Respiratory Diseases, Soonchunhyang University, Bucheon Hospital, Bucheon, Korea; 4) Merck Research Laboratories/WWL & ER/MSD Korea, Korea.

Background: Asthma is a complex trait disese, which renders the task of identifying its etiologic factors difficult. CXCR3 is a chemokine receptor that plays important roles in mediating chemotactic signals, and modulating the activation of lymphocytes. We have previously conducted a case-control study using a candidate gene approach to investigate the association of CXCR3 polymorphisms with the risk of asthma. Results from the epidemiological study showed that a common nucleotide variant in the CXCR3 intron (rs2280964G>A) was associated with disease susceptibility (1006 cases & 384 controls, OR=0.81 (0.69-0.94), P=0.007). Objective: The aim of our study was to evaluate the epidemiological study and provide functional evidence for the association of rs2280964G>A with asthma by investigating the effects of intronic variant on chemokine-mediated phenotypes of human-derived T cells. Methods: We used cell line-based in vitro and human primary T cell-based ex vivo studies to examine functional consequences of the intronic polymorphism with respect to the regulation of gene expression, splicing as well as immune responsiveness toward activating signals. Results: We present functional evidence indicating that the rs2280964A allele significantly correlates with decreased CXCR3 gene expression, which would lead to variation in immune cell responses to chemokine-cytokine signals in vitro and ex vivo, including a decrease in chemotactic activity. Conclusion: These findings, in conjunction with our previous epidemiological studies, may implicate a functional link between a common nucleotide variant of a chemokine receptor gene, CXCR3 and an etiology for a complex-trait disease, asthma.

Two mutations at the opposite sites in anticodon stem of mitochondrial tRNA-Trp gene cause different phenotypes on cytochrome c oxidase activity. *H. Hatakeyama, H. Komaki, Y. Goto* Dept. 2, Natl. Inst. Neurosci., Natl. Ctr. Neuro. & Psychiatry, Kodaira, Tokyo, Japan.

Various mutations have been found in mtDNA-encoded tRNA genes, and some frequently cause severe phenotypes with morphological and physiological alterations of mitochondria such as a3243g in tRNA-Leu(UUR) gene in MELAS. Here, we report homoplastic mtDNA mutations of c5541t and g5549a in the independent Japanese patients with mitochondrial disorders. The c5541t mutation was detected, for the first time, in the present study, these two mutations sit facing each other in the anticodon stem of tRNA-Trp gene. To identify the pathogenesis of these two mutations and the difference in phenotypic severity, we introduced cell-based functional screening system to patients mitochondria. Primary cultures from these two patients muscle were subjected to various biochemical and cell biological examinations. In comparison with a control group (n10), no significant differences were found in cellular ATP production and oxygen-consuming mitochondrial respiration. However, enzymatic analyses for mitochondrial respiratory chain complexes indicated the significantly decreased activities of both cytochrome c reductase and cytochrome c oxidase (COX) than those of controls. In addition, the normalized activity of COX by citrate synthase revealed the difference between these two mutations: c5541t mutation showed significantly reduced activity of normalized COX than that of controls, whereas g5549a mutation did not. We also confirmed the decreased activity of COX by histochemical staining; diffuse COX deficiency in the patient with c5541t mutation but only one COX-negative ragged-red fiber in the patient with g5549a mutation. If the disruption of base pair complementarity in the stem structure might be associated with tRNA dysfunction, our finding seems paradoxical because G-T base pair has more profound effect than A-C base pair. In summary, our newly found mutation of c5541t in tRNA-Trp gene would be causative to diffuse COX deficiency, and the g5549a mutation at the opposite site of c5541t mutation, which was previously described in only one patient, would also be milder effect on COX activity.

Molecular analysis of glucose-6-phosphate dehydrogenase deficiency in Saudi Arabian patients. *J. A. K. M. Bhuiyan[1], M. Faiyaz-Ul-Haque[1], R. Al-Nounou[1], A. Al-Abdullatif[1], A. Cluntun[1], T. Gonzales[1], M. Toulimat[1], F. Al-Dayel[1], S. H. E. Zaidi[2]* 1) Pathology & Lab. Medicine, King Faisal Specialist Hospital & Research Centre, Riyadh, Riyadh, Saudi Arabia; 2) Dept of Medicine, University Health Network & University of Toronto, Toronto, Ontario, Canada.

Glucose-6-Phosphate Dehydrogenase (G6PD) catalyzes an important step during conversion of glucose-6-phosphate to pentose phosphate. Deficiency of this enzyme produces hemolytic anemia in affected individuals. Other symptoms include neonatal jaundice, abdominal and/or back pain, dizziness, headache, dyspnea, and palpitations. G6PD deficiency is the most common human enzyme deficiency with an estimated 400 million peoples affected worldwide. This disorder is caused by mutations in the G6PD gene. More than 140 mutations have been identified with considerable variations in G6PD enzyme activities among various ethnic populations. Because of impaired malaria parasite growth in G6PD deficient red blood cells, G6PD deficiency confers a selective advantage in the geographical regions where malaria is common. Due to this beneficial effect and frequent consanguineous marriages, there is a higher incidence (15-26%) of G6PD deficiency in Saudi Arabia. The three G6PD mutations which are found in the Middle Eastern countries include the Mediterranean (S188F), the A- (V68M) and the Aures (I48T) variants. In the present study we have recruited approximately 1700 randomly selected individuals from Saudi Arabia. From this large group, 210 patients (133 men and 77 women) were confirmed for G6PD deficiency by enzyme assay. Their DNA was analyzed for the three mutations, which are common in this geographical region, by sequencing of the exons 3-7 of the G6PD gene. This study shows that the Mediterranean variant accounts for ~54% of the G6PD deficiency cases followed by the Aures variant in ~20% of the patients. The A- variant was rare (5%) in our cohort of patients. The 21% of G6PD deficient patients who were negative for these three mutations may carry less common variants in other regions of the G6PD gene. It is also possible that G6PD deficiency in these subjects is caused by mechanisms other than the G6PD gene mutation.

The common 677CT MTHFR and 66AG MTRR polymorphisms involved in folate metabolism are not risk factors for Down syndrome in a Danish population-based study. *M. Grigoriadou[1], H. Kokotas[1], A. Giannoulia-Karantana[2], M. B. Petersen[1]* 1) Department of Genetics, Institute of Child Health, Athens, Greece; 2) Department of Pediatrics, Athens University Medical School, Athens, Greece.

Chromosomal aneuploidy consists the leading cause of fetal death in our species. Around 50% of spontaneous abortions until 15 weeks of gestational age are chromosomally aneupoid, with trisomies accounting for 50% of the aneuploid abortions. Trisomy 21 is the most common chromosome abnormality in liveborns and is usually the result of nondisjunction of chromosome 21 in meiosis in either oogenesis or spermatogenesis. To investigate a possible relationship between folate metabolism and Down syndrome (DS), genetic polymorphisms in the methylenetetrahydrofolate reductase (MTHFR) and the methionine synthetase reductase (MTRR) genes were analyzed in the Danish population. Our cohort consisted of 181 mothers of children with DS versus 1,084 healthy controls. Polymerase chain reaction (PCR) and restriction fragment length polymorphism (RFLP) were used to examine the MTHFR 677CT and MTRR 66AG polymorphisms. No significant association between the two polymorphisms and the risk for DS was found. We conclude that the two common MTHFR 667TC and MTRR 66AG polymorphisms are not likely to be maternal risk factors for DS in our cohort and that the difference to previous studies is probably due to small sample size or geographic variation in gene polymorphisms involving gene-nutritional or gene-gene or gene-nutritional-environmental factors.

Strong linkage disequilibrium for the frequent GJB2 35delG mutation in the Greek population. *H. Kokotas[1], L. Van Laer[2], M. Grigoriadou[1], V. Iliadou[3], J. Economides[4], E. Ferekidou[5], S. Korres[5], A. Giannoulia-Karantana[6], G. Van Camp[2], M. B. Petersen[1]* 1) Department of Genetics, Institute of Child Health, Athens, Greece; 2) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 3) Department of Psychoacoustics-Neurootology, AHEPA Hospital, 3rd Psychiatric Clinic, Aristotle University of Thessaloniki, Thessaloniki, Greece; 4) Department of Audiology-Neurootology, Aghia Sophia Childrens Hospital, Athens, Greece; 5) Department of Otorhinolaryngology, Athens University, Hippokration Hospital, Athens, Greece; 6) Department of Pediatrics, Athens University Medical School, Athens, Greece.

Up to forty percent of autosomal recessive, congenital, severe to profound hearing impairment cases result from mutations in the GJB2 gene. The 35delG mutation accounts for the majority of mutations detected in Caucasian populations and represents one of the most frequent disease mutations identified so far. Some previous studies have assumed that the high frequency of the 35delG mutation reflects the presence of a mutational hot spot, whilst other studies support the theory of a common founder. Greece is amongst the countries presenting the highest frequency of the 35delG mutation (3.5%), and a recent study raised the hypothesis of the origin of this mutation in ancient Greece. We genotyped 60 Greek deafness patients homozygous for the 35delG mutation for six single nucleotide polymorphisms (SNPs) and two microsatellite markers, mapping within or flanking the GJB2 gene, as compared to 60 Greek hearing controls. A strong linkage disequilibrium was found between the 35delG mutation and the DNA markers at distances of 34 kb on the centromeric and 90 kb on the telomeric side of the gene, respectively. A comparison of the present findings with those of a previous study from Belgium, UK and USA, demonstrated a common haplotype reflecting the common founder. Our study supports the hypothesis of a founder effect and we further propose that ethnic groups of Greek ancestry could have propagated the 35delG mutation, as evidenced by historical data beginning from the 15th century BC.

Sudden hearing loss in a family with GJB2 related progressive deafness. *M. Petersen[1], H. Kokotas[1], M. Theodosiou[2], M. Grigoriadou[1], G. Korres[2], E. Ferekidou[2], A. Giannoulia-Karantana[3], S. Korres[2]* 1) Department of Genetics, Institute of Child Health, Athens, Greece; 2) Department of Otorhinolaryngology - Head and Neck Surgery, Athens University, Hippokration Hospital, Athens, Greece; 3) Department of Pediatrics, Athens University Medical School, Athens, Greece.

Approximately one in 1,000 children suffers from severe to profound hearing loss (HL) at birth or during early childhood (prelingual deafness). Around fifty percent of prelingual deafness has been related to genetic causes. Among genetic non-syndromic deafness, autosomal recessive inheritance predominates, accounting for about 80% of the cases, and up to date about 50 genes have been identified. Mutations in the GJB2 gene are responsible for up to 40% of such cases in many populations. Around 90 GJB2 mutations have so far been reported to be associated with recessive, non-syndromic HL. One specific mutation, 35delG, has accounted for the majority of mutations detected in the GJB2 gene in Caucasian populations and consists of a deletion of guanine (G) in a sequence of six Gs leading to a frameshift and truncation of connexin 26, the GJB2 gap junction protein. Recent studies have described progression of HL in a proportion of cases with GJB2 deafness. We report an unusual family with four 35delG homozygous members, in which the parents were deaf-mute whilst both children had a postlingual progressive HL. Furthermore, the son suffered from an episode of sudden HL.

Analysis of OLR1 Polymorphisms across Human Populations. *I. M. Predazzi[1], C. Martínez-Labarga[2], L. Vecchione[1], R. Mango[3], C. Ciccacci[1], F. Amati[1], M. Crawford[4], O. Rickards[2], F. Romeo[3], G. Novelli[1]* 1) Univerisity of Rome Tor Vergata, Department of Biopathology; 2) Univerisity of Rome Tor Vergata, Department of Biology; 3) Univerisity of Rome Tor Vergata, Department of Internal Medicine; 4) University of Kansas, Lawrence, Laboratory of Biological Anthropology.

Genetic variants predisposing to complex diseases are an open question in medical and population genetics. Several studies demonstrated a correlation between cardiovascular disease (CVD) susceptibility and the genetic background of ethnic groups. Since different populations are subject to distinct environments, natural selection may produce population-specific allele frequencies. The human oxidized low density lipoprotein (lectin-like) receptor 1 (OLR1) gene is involved in the uptake of oxidised low density lipoproteins (ox-LDL) and in the pathogenesis of atherosclerosis. We have previously identified 7 different Single Nucleotide Polymorphisms (SNPs), 6 of them located within introns 4, 5, and 3' UTR (untranslated region), comprised in a linkage disequilibrium (LD) block strongly associated with the elevated risk to develop Myocardial Infarction (MI). In the present study we analyze the frequency distribution of two variants of OLR1 gene (rs3736235 and rs11053646) in 17 different populations from Europe, Asia, Africa and North America at genotypic and haplotypic level and we measure the apportionment of genetic diversity. The multivariate analysis of molecular variance (AMOVA), the correspondence analysis and the multidimensional scaling (MDS) representation of genetic distance matrix performed between the studied population samples highlight that the African populations are closer to the Asian populations, clearly separated from the Europeans. These results suggest a possible basis for varying susceptibility to CVD among groups correlated with the Out-of-Africa expansion or different level of stress.

Nonsense-mediated mRNA decay may be involved in the down-regulation of the *Alu*-containing splicing variants.
K. Inoue, K. Takano, Y. Goto Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan.

Although thousands of intronic *Alu* elements, the most abundant interspersed elements in human genome, have predicted capability to become alternative exons, only a small number of genes actually incorporate *Alu* elements as expressed splicing variants by unknown genomic basis. Here we tested our hypothesis that nonsense-mediated mRNA decay (NMD), an mRNA surveillance system by which mRNAs containing premature termination codons (PTCs) are selectively detected and disrupted, can serve as post-transcriptional eliminator of *Alu*-containing splicing variants (ASVs). Examination of the expression level of ASVs in 21 human genes revealed that ASVs are generally present as minor alleles in multiple human tissues as well as in HeLa and SH-SY5Y cells. Suppression of NMD in these cell lines resulted in upregulation of ASVs in some genes, suggesting a partial role of NMD in downregulation of the ASV expression. However, a serial introduction of PTCs in the non-truncating high-expresser ASV of the *ADARB1* gene failed to trigger NMD, suggesting that the efficiency of NMD on PTC-containing ASV can be variable and modulated by other factors. Computational prediction suggested that ASVs may possess the strength of splice sites comparable to other alternative exons and less number of exoninc splicing enhancers than constitutive or alternative exons. At individual gene level, no association between these predicted splicing scores with ASV expression level or sensitivity to NMD inhibition was noted. Together, our findings suggested that NMD may be involved in the down-regulation of the of the ASV expression together with other undetermined factors.

No evidence for skewed X-inactivation in fragile X syndrome premutation carriers. *L. Rodriguez-Revenga[1,2], I. Madrigal[1,2], C. Badenas[2], M. Milà[2]* 1) Centre for Biomedical Research on Rare Diseases (CIBERER), ISCIII, Barcelona, Spain; 2) Biochemistry and Molecular Genetics, Hospital Clinic, Barcelona, Spain.

X-Chromosome inactivation (XCI) is the mechanism by which gene dosage equivalence is achieved between female (XX) and male (XY) mammals. In the general female population, the X-inactivation process is random, and therefore XCI ratios have a normal distribution (with average of 50:50) with only a small percentage of females (5-8%) showing a skewed X-inactivation ratio (>90:10). Fragile X syndrome (FXS) premutation carriers (55-200 CGG repeats) do not present FXS symptoms but it has been shown that they have a higher risk of developing premature ovarian failure (POF) and/or fragile X associated tremor/ataxia syndrome (FXTAS). About 20% of the FXS female premutation carriers present POF and around 15% FXTAS. In order to evaluate if these pathologies are associated with skewed XCI patterns, we have studied the X-inactivation pattern in 270 FXS females carriers (41 POF, 2 FXTAS, 3 POF and FXTAS, and 224 no POF no FXTAS). Results showed that FXS permutation female carriers have a normal distribution and that there is no correlation with the CGG repeat number. On the basis of these observations we conclude that FXS female premutation carriers with or without POF and/or FXTAS do not present skewed X-inactivation and therefore, other molecular or environmental factors may predispose to these conditions. Acknowledgments: Marató TV3 (TV06-0810).

Genotype-phenotype correlations in two PWS patients carrying atypical deletions: additional evidence for a causative role of the HBII-85 C/D box snoRNA cluster. *L. Larizza[1,2], F. Malvestiti[1], L. Ballarati[1], G. Grugni[3], R. Pignatti[3], D. Giardino[1], M. T. Bonati[1]* 1) Lab. Citogenetica Medica e Genetica Molecolare, IRCCS Istituto Auxologico Italiano, Milano, Italia; 2) Lab. Genetica Medica, Ospedale S. Paolo, Universita di Milano, Italia; 3) Ospedale S. Giuseppe, IRCCS Istituto Auxologico Italiano, Piancavallo, Italia.

Prader-Willi syndrome (PWS) is a complex neurodevelopmental disorder clinically characterized by hypotonia and feeding difficulties in the neonatal period, failure to thrive in the postnatal period, hyperphagia in early childhood resulting in obesity, hypogonadism, mental retardation and behavioural difficulties. It is caused by the loss of function of genes mapped in 15q11-13 that are subject to genomic imprinting and expressed by the paternal allele only. Different genetic/epigenetic mechanisms can lead to PWS: approximately 70% of the patients carry a de novo deletion of paternal chromosome 15, 25% show maternal uniparental disomy 15, and the remaining 5% have imprinting defects or structural abnormalities involving chromosome 15. The vast majority of the 15q11-13 deletions shows recurrent breakpoints (bkps), with a single distal bkp and two proximal bkps. Refined bkps mapping allows to group the patients into two main common deletion classes: type I (TPI) and type II (TPII). We report on two patients carrying two different atypical deletions characterized by BAC FISH and array CGH (244K, Agilent). Both have been thoroughly analysed for clinical and behavioural characteristics using Wechsler Adult Intelligence Scale-Revised (WAIS-R) and Autism Diagnostic Observation Schedule (ADOS). Both patients show a classical PWS phenotype according to the clinical diagnostic criteria of Holm and a mild cognitive impairment. They carry yet unreported deletions smaller than TPI and TPII, sized about 4,3 Mb and 372 Kb. Within the latter deletion part of SNURF-SNRPN gene is mapped together with several C/D box snoRNA genes, among which the HBII-85 snoRNA cluster, that seems a likely candidate gene for PWS. This is the second reported PWS atypical deletion showing the potential causative role of HBII-85 genes in the PWS phenotype.

Molecular characterization by aCGH of a 2,8 Mb duplication at Xq26.3 in a male with mental retardation. *I. Madrigal[1,2], M. Fernandez-Burriel[3], L. Rodriguez-Bodi[1,2], M. Milà[1,2]* 1) Biochemistry and Molecular Gen, Hospital Clinic, Barcelona, Barcelona, Spain; 2) Unidad de Investigación. Hospital de Mérida. Badajoz; 3) Biochemistry and Molecular Genetics Department, Hospital Clínic and IDIBAPS.

Males with duplications in the distal long arm of the X chromosome are rare and in most cases are inherited from a carrier phenotypically normal. We report the clinical and molecular characterization of a Xq26.3 duplication in two brothers affected by MR. Chromosome analysis was normal and Multiplex Ligation Probe Amplification (MLPA) analysis detected a duplication of the ARHGEF6 gene inherited from a carrier mother. Both affected brothers presented moderate mental retardation and displayed dysmorphic features. Further characterization of the duplication by array CGH and FISH experiments with specific BAC probes, revealed a deletion of 28 contiguous BAC clones, spanning a region of 2,8 Mb in Xq26.3. X-inactivation studies in the mother showed a skewed X-inactivation (90/10) inactivating the X-chromosome inherited by the patient. Among the 20 genes included within the duplicated region we discuss the implication of ARHGEF6, PHF6, SLC9A6 and HPRT1 in the phenotype of the patient. Mutations or deletions in these four genes are responsible for syndromic and non-syndromic forms of mental retardation. Nowadays high-resolution technologies such as array CGH allow the detection of copy number aberrations in patients with MR. The characterization of these cryptic rearrangements is of clinical importance in order to provide a genetic counselling in carrier women for future pregnancies.

Fine delineated comparative genome mapping between Indian muntjac and human by cross-species BAC-FISH.

Y. C. Li[1], T. S. Li[2], P. C. Hsu[1], C. C. Lin[2] 1) Dept Biomedical Sci, Chung Shan Medical Univ, Taichung, Taiwan; 2) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan.

Indian muntjac is a unique mammalian species with 2n=6/7 (the lowest chromosome number in mammals). The chromosome of this species was thought to have evolved through extensive chromosomal rearrangements by recent molecular cytogenetic studies. However, the molecular mechanism of chromosome restructure and gene order alteration during karyotypic evolution are not clearly elucidated so far. To clarify these issues, we established the highly resolution comparative map of the Indian muntjac-human using cross-species BAC-FISH mapping strategy in this study. We had previously constructed an Indian muntjacs BAC library with 4X genome coverage and established the highest density BAC-FISH map with 2081 muntjacs BAC clones on the Indian muntjac genome. In the present study, we selected 280 Indian muntjacs BAC clones to map onto the metaphase chromosomes of human and selected 300 human RPCI BAC clones to map onto Indian muntjac chromosomes. This mutual comparative FISH map would provide (1) the high resolution of the Indian muntjac-human comparative map, (2) the gene orders in the homologous synteny block to further deduce the rate of chromosome evolution, (3) more information on the accurate location of the evolutionary breakpoints and identifying the numbers of those breakpoints, and (4) shed more light on the genome organization of the species-specific genes.

Frequency of fragile X tremor ataxia syndrome in fragile X syndrome families. *M. Mila[1,2,3], I. Madrigal[1,3], J. Kulisevsky[4], J. Pagonabarraga[4], B. Gomez[5], L. Rodriguez-Revenga[1,3]* 1) Biochemistry and MolecularGenetics Department, Hospital Clinic, Barcelona, Spain; 2) IDIBAPS, Barcelona, Spain; 3) Centre for Biomedical Research on Rare Diseases (CIBERER), ISCIII, Barcelona, Spain; 4) Neurology Service, Hospital Sant Pau, Barcelona, Spain Centre for Biomedical Research on Neurodegenerative disease(CIBERNED), ISCIII, Barcelona, Spain; 5) Radiodiagnostic Service, Hospital Sant Pau, Barcelona, Spain.

Fragile X syndrome (FXS), which is caused by a CGG triplet expansion in the first exon of FMR1 gene, is the leading cause of familial mental retardation. Premutated individuals (55-200 CGG) do not present FXS symptoms, but approximately one third on them can present other manifestations such as a late onset ataxia /tremor syndrome (called FXTAS) or premature ovarian failure (POF).In order to determine the frequency of FXTAS among FXS grandparents, we have contacted by telephone with 151 families from 398 registered in our Service. These results evidence that FXTAS frequency among FXS families is around 12 per cent;. FXTAS frequency among permutated woman is 11 per cent; and FXTAS frequency among NTM is 25 per cent;. We obtain also information about thyroid dysfunction and fibromyalgia, about 20 per cent; of carrier women present at least one of them. We are now evaluating these patients psychologically, neurological and with magnetic resonance imaging. Molecular studies confirm a slight reduction of FMRP protein and increased levels of mRNA in these patients (x2-x5 folds). The description of associated pathologies (FXTAS and POF) to premutation carriers has modified genetic counseling for FXS, these two disorders and their consequences have to be taken into account by genetic counselor. Acknowledgements (Marató TV06-0810).

Paternal Isodisomy chromosome 6: clinical report. *A. Mur[1], L. Perez-Jurado[2], O. Garcia[1], M. Bonet[3]* 1) Sección Neonatología.Servicio de Peditria. Hospital del Mar UAB. Barcelona Spain; 2) Genetics Unit, Universitat Pompeu Fabra, Program in Molecular Medicine and Genetics, Hospital Vall dHebron, Barcelona, Spain. Transient neonatal diabetes (TND; MIM 601410) is a developmental disease of insulin production with an incidence about 1 in 500,000 in Europe. TND is characterized by hyperglicemia occurring in the first days of life, glycosuria, dehydratation, severe intrauterine grow retardation and decreased adipose tissue. In about approximately 90% TND cases, chromosome 6 is involved, including paternal disomy, paternal duplications, or loss of maternal imprinting in 6p24. Mutations in ABCC8 and KCNJ11 genes located in chromosome 11 are also responsible for TND. No significant differences in clinical characteristics between patients with ABCC8 and KCNJ11 mutations are detected, whereas patients with a 6q24 abnormality have a significantly lower birth weight. We present here, a neonate female born after 37.4 week pregnancy to a healthy primipara. Familial antecedents show diabetes on fathers side. Neonate birth weight was 1,955g and she was 43cm long. Physical examination showed bilateral palpebral edema, macroglossia, umbilical hernia and abdominal distension. At 29hours of life she presented hyperglycemia without acidosis or ketosis. The patient presented anemia the second day of life, which required iron therapy and blood transfusion one moth after birth. Insulin treatment was started and maintained intermittently until 38 days of life. At 12 months she was normoglucemic with normal levels of insulin and peptide C. Genetic studies show a complete paternal uniparental isodisomy of chromosome 6.

***IronXS*: an Australian high school screening program for haemochromatosis.** *S. Metcalfe[1,2], M. Wolthuizen[1], E. Varley[1], V. Collins[1], I. Macciocca[3], MA. Aitken[1], L. Bond[1,2], K. Allen[1,4], M. Delatycki[1,3]* 1) Murdoch Childrens Research Institute, Melbourne, Australia; 2) Dept Paediatrics, The University of Melbourne, Melbourne, Australia; 3) Genetic Health Services Victoria, Melbourne, Australia; 4) The Royal Children's Hospital, Melbourne, Australia.

New research suggests that population genetic screening for hereditary haemochromatosis (HH), an easily preventable iron overload condition, should be reconsidered.[1] In the *HaemScreen* workplace-based study,[2] we found high uptake of screening (>90%) for people attending the information session, but only 6% of those eligible actually attended. This led us to consider other strategies for offering screening. We report our first year of data from *IronXS*, a screening program for the C282Y *HFE* mutation in high schools. A DVD-based information session was presented to 3840 year 10 and year 11 students at 19 schools. 1533 students had parental consent to participate (40% of eligible students; males:females = 45:55; mean age=15.7yr) of whom 1359 chose testing (35.4% overall uptake; 89% of attenders). This revealed 7 C282Y homozygotes (1 in 194), who were invited to clinic for genetic counselling, and 148 C282Y heterozygotes (1 in 9), who received their result in the mail. Students completed a baseline questionnaire (Q1). More than 90% of students answered all the knowledge questions correctly. A second questionnaire (Q2) was sent one month after results were received to all homozygotes and heterozygotes and a sample of wild-types (74% response rate). Knowledge retention was generally very high. There were no significant differences in general health perception scores, risk perception and anxiety levels between the three groups. Follow-up includes Q3 at 12 months and interviews with students, parents and teachers. Our first year data show that the education is highly effective and there have been no significant effects on psychological well-being and health risk perception of students who have been tested. Testing uptake is high for students with consent from parents, but this requirement appears to be a barrier to participation. We aim to screen 9000 students in total. Copper supplementation restores Cytochrome c oxidase activity in a C.elegans model of COX deficiency. *E. Trevisson[1], C. Asencio[2], J. C. Rodriguez Aguilera[2], P. Navas[2], L. Salviati[1]* 1) Pediatrics - Genetics Unit, University of Padova, Italy; 2) Centro Andaluz de Biología del Desarrollo, Universidad Pablo de Olavide Sevilla,Spain.

Cytochrome c oxidase (COX) deficiency is one of the most frequent mitochondrial respiratory chain (MRC) defects in infancy and causes severe encephalomyopathy. Although it can be due to both mtDNA and nDNA mutations, most of these forms are inherited as autosomal recessive traits and are generally caused by mutations in nuclear genes encoding the ancillary proteins required for the assembly of the holoenzyme. COX19 and COX17 encode two closely related metallochaperones involved in copper delivery to the mitochondrial inner membrane that are required for COX assembly. We aimed at generating a multicellular model of COX deficiency using the nematode C.elegans. We down-regulated the expression of these copper chaperones through RNA interference in worms and analyzed their phenotype: the animals display a COX-dependent decrease in respiration and an increase in lactate production, recapitulating the phenotype observed in patients with mutations in other COX-assembly genes. They also show an increase in lifespan and reduced fertility, as it has been reported with other Mit mutants, nematodes carrying defects in genes involved in the biogenesis of the MRC. We analyzed whether copper supplementation could rescue the phenotype, as it has been demonstrated in fibroblasts of patients with mutations in the SCO2 copper chaperone. Our results indicate that in interfered nematodes, copper allows a partial recovery of the pathological phenotypes. In this work we showed that C.elegans proves to be a useful tool to investigate mitochondrial dysfunction observed in patients with MRC defects that often presents in a tissue-specific fashion; moreover, it allows studying potential pharmacological therapeutic strategies. We investigated the effect of copper supplementation on COX-deficient animals, which is specific for this kind of defect and could represent a realistic therapeutic option. To our knowledge, this is the first demonstration of the efficacy of copper supplementation in a multicellular system.

Assessment of polymorphic variation within VEGF and retinal angiomatous proliferation in neovascular age-related macular degeneration. *G. J. McKay[1], G. Silvestri[1], N. Orr[2], U. Chakravarthy[1], A. E. Hughes[2]* 1) Vision Science, Queen's University Belfast, N. Ireland, United Kingdom; 2) Medical Genetics, Queen's University Belfast, N. Ireland, United Kingdom.

Purpose. Recent development and use of VEGF inhibition therapy has been shown to offer improved treatment for those with neovascular AMD (nvAMD) and in particular, those with retinal angiomatous proliferation (RAP). This study seeks to determine whether VEGF is likely to be a major genetic contributor to nvAMD or specifically within a subset of patients with observed RAP lesions.

Methods. Haplotypic structure of the *VEGF* gene region was elucidated using HapMap data and tagged SNPs were identified. Polymorphisms were genotyped using SNaPshot technology (ABI) or by conventional DNA sequencing in an association study of 211 patients with end-stage nvAMD, which included a subset of 51 individuals identified with a RAP lesion and 238 age-matched disease-free controls. Association of polymorphic variation was assessed through logistic regression also measuring the effect of smoking status and variation within the genes *CFH* and *LOC387715* and RAP nvAMD.

Results. Logistic regression modelling, measuring the effect exerted by *CFH, LOC387715*, and smoking status, demonstrated significant association between rs3024994 and RAP nvAMD (Odds Ratio=3.0; 95% CI: 1.02-8.86; P value=0.046). This SNP was not associated with nvAMD where RAP lesions were undetected.

Conclusions. Previous studies have conflicted on the significance of variation within *VEGF* as a genetic contributor to the nvAMD disease process. Our results suggest that *VEGF* is not a major genetic initiator of AMD, but there is evidence to suggest that it may contribute to the formation of RAP lesions which appear to be more amenable to treatment with anti-VEGF therapies. While this study is the first to try and dissect the neovascular AMD phenotype in relation to association with genetic variation, the authors recognise that the sample numbers examined in this study are low and analysis of a much larger sub-phenotyped neovascular cohort is required.

An Imprinting Map of the Human Genome. *A. J. Sharp[1], H. Holster[2], E. Kriventseva[1], U. Surti[3], L. Iniguez[2], S. E. Antonarakis[1]* 1) Department of Genetic Medicine and Development, University of Geneva, Switzerland; 2) Roche NimbleGen, Inc., Madison, WI; 3) Department of Pathology, University of Pittsburgh, PA.

One of the major features associated with imprinting is the presence of parent-of-origin specific Differentially Methylated Regions (DMRs). Thus, the maternal and paternal genomes possess distinct epigenetic marks which distinguish them at imprinted loci. In order to construct an imprinting map of the human genome, we have profiled DNA methylation patterns genome-wide in rare uniparental tissues, utilizing a panel of Complete Hydatidiform Moles (CHMs), which have an exclusively paternal genetic contribution, and Ovarian Teratomas (OTs), which have an exclusively maternal genetic contribution. Methylated DNA was immunoprecipitated using anti 5-methyl cytidine and hybridized to Nimblegen high-density oligonucleotide tiling arrays composed of 21 million probes distributed throughout the genome, generating complete profiles of the paternal and maternal methylomes. Comparison of these profiles identifies numerous sites of parent-of-origin specific methylation, revealing a genome-wide imprinting map. Examination of known imprinted genes showed that the majority are associated with DMRs, validating this as an optimal system for the detection of imprinting. Furthermore, numerous candidate imprinted loci identified by previous sequence analysis were also associated with DMRs (Luedi et al. 2007 Genome Res 17:1723). Many novel putative imprinted regions on nearly every human chromosome were also identified. These include novel DMRs within known imprinted gene clusters, as well as chromosomal regions not previously thought to be imprinted, including several regions of common human aneuploidy. To validate our array data we performed bisulfite sequencing of putative DMRs, giving base-pair resolution of these imprints and confirming the presence of parent-of-origin specific methylation marks in multiple independent CHM and OT samples. Our data provides the first imprinting map of the human genome, demonstrates that the number of imprinted loci in the human genome is much higher than previously thought, and suggests that imprinting may influence the phenotypes of many human diseases.

The Currarino syndrome : two previously unreported nonsense mutations. *V. Benoit[1], S. Gaillez[2], T. Wester[3], Ch. Verellen-Dumoulin[1], P. Hilbert[1]* 1) Human Genetics Center, Institute of Pathology and Genetics, charleroi, Belgium; 2) Human Genetics Center, CHU, Liege, Belgium; 3) Akademiska Barnsjukhuset, Uppsala, Sweden.

The Currarino syndrome (CS) is characterized by 3 main clinical features : total or partial sacral agenesis with intact first sacral vertebra (sickle-shaped sacrum), anorectal malformation and a presacral mass (meningocoele or teratoma). This triad occurs as an autosomal dominant trait and is caused by mutations in the HLXB9 homeobox gene. If mutations are detected in only 50% of sporadic cases, the detection rate reaches 90% in familial cases. So far, 66 different mutations has been described, most of them being truncating mutations (57%). Only 7 nonsense mutations have been reported. In this study, sequence analysis of the HLXB9 gene was performed in 5 unrelated patients showing the clinical features of CS. No mutation was found in 2 patients, a known mutation (c.336dupG, p.P113fsX224) was identified in one patient and two previously unreported nonsense mutations were detected in the 2 last patients. The first, c.634C>T (p.Q212X), is sporadic and has been identified in a 2.5 year-old boy with anal stenosis, megarectum, anterior sacral myelomeningocoele and scimitar sacrum. The second, c.55C>T (p.R19X) is familial and affects 3 generations : a 6 month-old girl with anal stenosis, sacral dysplasia and presacral mass; her father, diagnosed at 8 months of age with presacral teratoma and anorectal stenosis and her paternal grandmother with sacral arachnoid cyst, operated at the age of 34 years. Phenotypic expression of the mutation varies within the family members, which is consistent with previous observations. These 2 novel truncating mutations confirm that haploinsufficiency is causing Currarino syndrome and indicate that patients with the triad should undergo genetic evaluation.

Genomic Sequence Analysis of the HMSN-P region on human chromosome 3q13. *S. Makino[1], K. Maeda[2], J. Jamiyansuren[1,2], K. Yasuno[3,4], R. Kaji[2], G. Tamiya[1]* 1) Division of Human Molecular Genetics, Department of Neurology and Neuroscience, The University of Tokushima Institute of Health Biosciences, Graduate School, Japan; 2) Department of Neurology and Neuroscience, The University of Tokushima Graduate School of Medicine, Japan; 3) Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Agency, Japan; 4) Department of Molecular Life Science, Tokai University School of Medicine, Japan.

Hereditary motor and sensory neuropathy with proximal dominancy (HMSN-P; MIM 604484) is endemic to Okinawa Islands, the most southern part of Japan, which is characterized by autosomal dominant inheritance, slowly progressive proximal muscle atrophy and weakness, sensory disturbance such as paresthesia and vibration loss, leading to be bedridden. The disease locus of HMSN-P has been mapped to 3q13-14. We previously reported our linkage study in a newly-found large family with many members developed the similar symptoms of HMSN-P in a western part of Japan around the HMSN-P locus identified in 3p13. However, the HMSN-P gene and an obvious causative mutation is still undiscovered. To find all variants within the HMSN-P region, we employed a genomic sequence analysis. We first constructed a BAC library using HMSN-P patient's genomic DNA. The insert size ranged from 35 to 175 kb with an average insert size of 102.0 kb. We screened the BAC library and obtained a chromosome-specific contig which covered 590 kb HMSN-P critical region also includes 7 genes and ESTs. Subsequently, we determined the entire genomic sequence of the HMSN-P region by the shotgun sequencing strategy with an average 5-fold redundancy. A comparison with reference sequence showed over 100 variants in the HMSN-P region, including many base substitutions, small indels and some chromosome rearrangements. This was twenty times as many as the number of variants reported previously. After listing these variants, we performed expression analyses, by northern hybridization and quantitative RT-PCR, for several candidate genes in which some desease-specific mutations of these variants were located. We would like to show these results in the presentation.

Two brothers presenting Early Infantile Epileptic Encephalopathy (EIEE) with the recently described mutation in the ARX gene. *S. Boulanger[1], L. Mariage[1], A. Destree[1], M. Foulon[2], P. Hilbert[1]* 1) Human Genetics Center, Institute of Pathology and Genetics, Charleroi, Belgium; 2) Department of neuropediatrics, CHU, Charleroi, Belgium.

Aristaless-related homeobox gene (ARX), is located within the human chromosome Xp22 region and is essential for the development of cerebral interneurons.Two recurrent polyalanine expansions in ARX are responsible for mental retardation and epilepsy in males. Recently, a new larger polyalanine expansion has been described - a 33-bp duplication in exon 2 of ARX gene expanding the original 16 alanine to 27 in the first poly A tract of the protein - it appeared de novo in two unrelated patients and caused Early Infantile Epileptic Encephalopathy (EIEE) with suppression-burst pattern. EIEE (also known as Ohtahara syndrome) is a severe and early form of epilepsy. The 33-bp duplication in exon 2 is the first gene alteration involved in idiopathic EIEE. We report two brothers presenting the same duplication with a typical phenotype of EIEE. Their parents are not bearing the mutation suggesting germinal mosaicism.

Meta-analysis of rheumatoid arthritis genome-wide association studies identifies common variants at *CD40* and five other gene loci. *R. M. Plenge[1,4], S. Raychaudhuri[1,4], E. F. Remmers[2], A. T. Lee[3], L. Gianniny[4], L. Padyukov[5], L. A. Criswell[6], C. I. Amos[7], M. F. Seldin[8], D. L. Kastner[2], T. W. J. Huizinga[9], N. de Vries[10], J. Worthington[11], M. Seielstad[12], R. E. M. Toes[9], E. W. Karlson[1], A. B. Begovich[13], L. Klareskog[5], P. K. Gregersen[4], M. J. Daly[4], BRASS, EIRA, GENRA, NARAC, WTCCC* 1) Harvard Medical School; 2) NIAMS, NIH; 3) Feinstein Institute; 4) Broad Institute; 5) Karolinska Institutet; 6) UCSF; 7) M.D. Anderson Cancer Center; 8) University of California, Davis; 9) Leiden University Medical Centre; 10) AMC/University of Amsterdam; 11) The University of Manchester; 12) Genome Institute of Singapore; 13) Celera.

BACKGROUND: Previous genetic studies have identified and validated risk alleles for autoantibody positive rheumatoid arthritis (RA): the MHC region, *PTPN22*, 6q23/*TNFAIP3*, *STAT4*, and *TRAF1-C5*. We hypothesize that additional common alleles of modest effect size remain to be discovered, and that these alleles can be identified through combining genome-wide association studies (GWAS) followed by large-scale replication. **METHODS**: We performed a meta-analysis of three recently published GWAS totaling 3,393 cases and 12,462 controls. We examined a set of 340,000 SNPs genotyped on the Affymetrix 500K platform as part of the WTCCC and imputed with Illumina case-control GWAS data from Sweden (EIRA) and North America (NARAC). The top 31 SNPs with P0.0001 but not previously associated with RA were genotyped in 3,929 autoantibody positive RA cases and 5,807 matched controls. **RESULTS**: We identified a reproducible and highly significant association to a common variant at the *CD40* gene locus (rs4810485, P=0.0032 replication, P=8.2x10^{-9} overall, OR=0.87). We also identified significant associations at five additional loci containing genes of immunological relevance: 9p13/*CCL21* (P=2.8 x 10^{-7}), 12q13/*PIP4K2C* (P=8.8 x 10^{-8}), 1p36/*TNFRSF14* (P=1.1 x 10^{-7}), 7q21/*CDK6* (P=4.0 x 10^{-6}), and 10p15/*PRKCQ* (P=4.4 x 10^{-6}). **CONCLUSIONS**: A novel variant at the *CD40* locus is definitively associated with RA. Along with other confirmed associations near *TRAF1* and *TNFAIP3*, this implies a central role for the *CD40* signaling pathway in RA pathogenesis.

The Human Genetics Historical Library: an International Resource. *P. S. Harper[1], K. Pierce[2], P. Keelan[2]* 1) Inst Medical Genetics, Cardiff University, Cardiff, United Kingdom; 2) Special Collections Cardiff University Library, Cardiff University, Cardiff, United Kingdom.

Historical and non-current scientific books are increasingly often dispersed or destroyed, even though, unlike journals, digitisation does not provide a satisfactory alternative for their preservation and is unlikely to do so in the near future. The Human Genetics Historical Library, initiated in 2003, provides a definitive collection of books on and related to human and medical genetics. Curated by Cardiff University Special Collections, it now contains over 2000 volumes, almost all donated by individual workers or institutions. A continuously updated list is available on www.genmedhist.org/HumanHistLib. The collection, as it grows, will provide an increasingly complete backdrop to the development of human genetics internationally during the past century, as well as a source for specific books. Detailed cataloguing, funded by Wellcome Trust, allows searching by category and is accessible on the web through the Voyager Library Catalogue (http://library.cardiff.ac.uk/). Further donations are welcome; please contact PSH or PK by email (above).

FLJ human cDNAs cloned focusing on mRNA variations and found some genes which predicted to have close relations between mRNA variations and diseases. *T. Isogai[1,2], A. Wakamatsu[1], J. Yamamoto[2], K. Kimura[3]* 1) Grad Sch Pharmaceutical Sci, Univ Tokyo, Tokyo, Japan; 2) Reverse Proteomics Research Institute, Tokyo, Japan; 3) Central Research Laboratory, Hitachi Ltd., Tokyo, Japan.

Human gene number was predicted to be about 20 thousand. But the number of the mRNA was predicted to be several times of gene number. Those varieties were thought to be caused by variations of splicing and transcription start site (TSS). In our NEDO human cDNA project, we sequenced about 44 thousand of human full-length cDNAs (FLJ cDNAs) and also obtained about 1.5 million of 5'-end onepass sequences (5'-EST), about 500 base length, of full-length cDNAs from about 100 kinds of cDNA libraries consist of human tissues and cells constructed by oligo-capping method. The majority of the insert size of those was over 2 kb and the full-length rate of 5'-end of those was 90%. All sequences of those were deposited to DDBJ/GenBank/EMBL and we constructed FLJ Human cDNA database, http://flj.hinv.jp/. Then about 11 thousand of full-length sequenced FLJ cDNAs, which was selected focusing on variations of splicing and TSS, was obtained from our cDNA resources described above. The sequences will be publicly available in a few months. In addition, we found some splicing and TSS variations which showed specific expression from newly isolated cDNAs. In order to search mRNA diversity, we analyzed gene expression profiles with the about 1.5 million of 5'-EST by oligo-capping method and then selected two types of genes mainly. The first: specific expression profiles; the second: variations of motifs and/or domains in coding regions. Using 8,313 cDNAs of 5,530 clusters from about 11 thousand of the newly isolated cDNAs, we selected 316 cDNAs of 144 clusters for further expression analyses by realtime PCR. As a result, 13 cDNAs of 8 clusters were shown tumor tissue specific expressions, and 20 cDNAs of 13 clusters were shown synovial, osteoclast, and/or blood cell specific expressions. This work was supported by a grant from New Energy and Industrial Technology Developmental Organization (NEDO) project of the Ministry of Economy, Trade and Industry of Japan.

Heritable somatic methylation and inactivation of *MSH2* in families with Lynch syndrome due to deletion of the 3 exons of *TACSTD1*. *M. J. L. Ligtenberg[1,2], R. P. Kuiper[1], T. L. Chan[3,4], M. Goossens[2], K. M. Hebeda[2], M. Voorendt[1], T. Y. H. Lee[3], D. Bodmer[1], E. Hoenselaar[1], H. G. Brunner[1], A. Geurts van Kessel[1], S. T. Yuen[3,4], J. H. J. M. van Krieken[2], S. Y. Leung[3,4], N. Hoogerbrugge[1]* 1) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Department of Pathology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Hereditary Gastrointestinal Cancer Genetic Diagnosis Laboratory, Department of Pathology, The University of Hong Kong, Pokfulam, Hong Kong; 4) Hereditary Gastrointestinal Cancer Registry, Department of Pathology, St. Pauls Hospital, No 2 Eastern Hospital Road, Causeway Bay, Hong Kong.

Lynch syndrome patients are susceptible to colorectal and endometrial cancers due to inactivating germline mutations in mismatch repair genes, including *MSH2*. Here we describe patients from Dutch and Chinese families with MSH2-deficient tumors carrying heterozygous germline deletions of the last exons of *TACSTD1*, a gene directly upstream of *MSH2* encoding the epithelial cell adhesion molecule Ep-CAM. The smallest deletion, which is detected in 9 patients from 4 families, encompasses only 4.9 kb and is located 14.5 kb upstream of *MSH2*. Due to the deletions transcription of *TACSTD1* extends into *MSH2*. The *MSH2* promoter *in cis* with the deletion is methylated in Ep-CAM positive, but not in Ep-CAM negative, normal tissues, thus revealing a correlation between activity of the mutated *TACSTD1* allele and epigenetic inactivation of the corresponding *MSH2* allele. Gene-silencing by transcriptional read-through of a neighboring gene as demonstrated here for *MSH2*, appears to represent a general mutational mechanism. Depending on the expression pattern of the neighboring gene that lacks its normal polyadenylation signal, this may cause either generalized or mosaic patterns of epigenetic inactivation, that are inherited over generations.

Exploration of Pathophysiological Mechanisms in Lamin A/C Associated Charcot-Marie-Tooth Disease (CMT2B1). *Y. Poitelon, C. Baudot, T. Hamadouche, N. Levy, V. Delague* Inserm UMR_S 910, Faculté de la Timone, Marseille cedex 05, France.

Lamins, a class of intermediate filaments, are major components of the nuclear lamina, a filamentous network underlying the inner face of the nuclear membrane. A-type Lamins are encoded by the same gene: LMNA, regulated by the AP1 complex (c-Fos & c-Jun). Up to date, eleven pathologies, described as laminopathies, have been associated with mutations in LMNA. One of these, Charcot-Marie-Tooth disease (CMT), type 2B1, is an autosomal recessive form of axonal CMT caused by the c.892C>T transition in LMNA exon 5. (p.Arg298Cys). In order to progress towards understanding of the pathophysiological mechanisms underlying CMT2B1, we studied two different models for the disease: human cells from patients homozygous for the c.892C>T mutation, and a Knock-In LmnaR298C/R298C mouse model. Gene expression studies performed on human microfluidic plates (Low Density Arrays) evidenced significant decrease in expression levels of several genes, including LMNA. These observations were confirmed in mouse brain, skeletal and cardiac muscle, sciatic nerve and spinal cord at the transcriptional level, as well as on lymphoblastoid human cell lines at the protein level. The p.Arg298Cys mutation lies within a coil-coiled domain, an important functional domain for intermediate filament polymerization. In silico predictions are in favor of a potential destabilizing effect of the mutation. Moreover, previous publications have shown that Lamins interact with c-Fos, a Leucine Zipper transcription factor, through their coiled-coil domain.We therefore propose a two-hit pathophysiological mechanism model: - The pArg298Cys mutation might destabilize complexes between A-type Lamins and transcription factors: the latter might be either components of the AP1 complex, or some nerve specific transcription factors, which remain to be identified. - LMNA seems to be autoregulated through an A_type Lamins - AP1 complex, which might be disrupted at the DNA level by the presence of the mutation. We are actually conducting further experiments in order to confirm these hypotheses.

A Haplotype-Specific Developmental Shift in Bitter Taste Sensitivity. *F. Duke, D. Reed, Y. Pepino, J. Mennella*
Monell Chemical Senses Center, Philadelphia, PA.

The purpose of this study was to define the effects of alleles within the haplotypes of the bitter receptor gene TAS2R38 and to investigate the interaction of haplotype and age on human bitter taste perception. A racially diverse sample of 980 people, ranging in age from 3 to 55 years old, were phenotyped for taste thresholds of a bitter compound (6-n-propylthiouracil; PROP) using methodologies that were validated for use with young children. DNA was extracted from cheek cells and genotyped for the three common alleles of the TAS2R38 gene (A49P, V262A, I296V). Subjects were grouped by diplotype and age (children, adolescents and adults) and compared for PROP thresholds. Eighty-five percent of all haplotypes observed were of one of two configurations, AVI (bitter insensitive) or PAV (bitter sensitive) while 15% were rarer haplotypes (i.e., AAI, AAV). The frequencies of some haplotypes differed between racial/ethnic groups, specifically, the AAI haplotype was found more often in Blacks whereas the AVI and AAV haplotypes were found more often in Whites. However, no differences between Black and White subjects within a diplotype or between males and females in PROP sensitivity were observed (all p-values >0.05). We found that children were more sensitive to PROP than adults but this observation was dependent upon diplotype. In particular, heterozygous children could perceive a bitter taste at lower PROP concentrations than could adults with the same diplotype, and the thresholds of adolescents were intermediate between adults and children (AVI/PAV; N=358; $p<0.001$). However these age differences were not apparent for subjects with either of the other common homozygous diplotypes (N=342; $p>0.05$; PAV/PAV and AVI/AVI). Biter sensitivity to the compound PROP is determined by the combination of the three alleles within the TAS2R38 gene and is also influenced by age, with children being more sensitive than adults. However not all diplotypes were affected to the same extent by development. The timing of the shift from child-like to adult-like bitter perception for groups with age-sensitive diplotypes occurred during adolescence.

A case of Recurrent Spontaneous Abortions with centric fission of chromosome 5. *M. Tanwar[1], M. Kumar[1], S. Mittal[2], D. Pathak[1], S. Venkatesh[1], M. B. Shamsi[1], R. Kumar[1], R. Dada[1]* 1) Lab. for Molecular Reproduction and Genetics, Deptt. of Anatomy, AIIMS, New Delhi, India; 2) Deptt. of Obs. & Gynae. AIIMS, New Delhi, India.

Centric fission is a rarely reported chromosomal abnormality in humans. Centric fission results when metacentric or submetacentric chromosome splits at the centromere giving rise to two stable telomeric products. We report a centric fission of chromosome 5 in a healthy female suffering from recurrent miscarriages. A couple was referred for cytogenetic analysis with bad obstetric history. Pregnancy history, age, occupation, disease information and all other medical records were reviewed. The wife had history of three abortions. The etiology of recurrent abortions is often unclear and may be multifactorial. Couples having multiple miscarriages are at risk for carrying chromosomal abnormalities. Majority of the studies have shown that most of the chromosomal abnormalities associated with recurrent abortions are numerical and structural which may adversely affect embryonic development but there are reports of recurrent miscarriages due to centric fission of the chromosomes. Peripheral blood was collected and lymphocyte cultures were set up for chromosomal analysis. Atleast 20 metaphases were analysed using GTG banding. The husband was cytogenetically normal and wife had 46,XX,-5,+fis(5)(p10),+fis(5)(q10) chromosomal complement. Both fission products were mitotically stable. To the best of our knowledge this is the first report on centric fission of chromosome 5 as the individuals with stable centric fission products have rarely been documented in humans. In this case, the centric fission does not cause any significant dysmorphic features and mental handicap. But heterozygous individuals for centric fission appear to be at increased risk for production of unbalanced gametes which consequently increased risks for spontaneous abortion, stillbirth and live born infants. However, even between homologous chromosomes, the size of centromeres is different from each other. A further study including more such cases is required to understand the etiology of recurrent spontaneous abortions in detail.

Accurate determination of copy-number-variations (CNVs): application to the alpha- and beta-defensin repeat region. *H. Nuytten[1], I. Wlodarska[1], S. Vermeire[2], JJ. Cassiman[1], H. Cuppens[1]* 1) Human Genetics, K.U.Leuven, Leuven, Belgium; 2) Gastroenterology, K.U.Leuven, Leuven, Belgium.

In the human genome, a considerable large number of genomic regions are found which are repeated several times. These regions are known as CNVs (Copy-Number-Variations) and may be polymorphic. There is an interest in determining the number of repeats in CNVs in individuals. We therefore developed a strategy that accurately determines the number of repeats in a CNV. Specifically, we developed an assay for the alpha- and beta-defensin repeat region, but any CNV can be characterized in an analogous way. For an accurate determination of the number of repeats, appropriate controls are needed, which are generally obtained by mixing different amounts of the (repeated) fragment under investigation and a reference fragment. Pipetting errors, and variable DNA concentration determinations, may interfere in such assays. We therefore developed concatemeric control constructs: each of these constructs contains 1 copy of a reference fragment in concatenation with a fragment of the repeated region. Different concatemeric control constructs were developed, each of them having a different number of the repeated region in concatenation. These concatemeric control constructs are then used for the generation of a standard curve, e.g. in a real-time PCR assay. We developed 4 concatemeric constructs with 1 copy of *DEFB1* and 1-4 copies of *DEFB4*. We analogously developed constructs for *DEFB104* and *DEFA1A3*. *DEFB4* and *DEFB104* are both located in the same CNV. In a real-time PCR assay, a correlation of R^2=0.98 was found between the number of repeats and the PCR yield. Using these controls as standards, the number of defensin repeats could then be accurately determined in DNA samples of 427 individuals. Each individual was tested three times, and each of these 3 experiments was performed in duplo. The copy number determined with the *DEFB4* and *DEFB104* was the same (SD = 0.2). We also validated the Real-Time PCR assay with interphase FISH. In conclusion, we have developed an accurate method to determine large scale copy number variation.

The Pompe Registry: Tracking Pompe Disease Symptoms in a Broad Patient Population. *B. Byrne[1], L. Case[2], P. S. Kishnani[3]* 1) Congenital Heart Center University of Florida, College of Medicine Gainesville, FL; 2) Div. of Physical Therapy, School of Medicine, Duke University Medical Center, Durham, NC; 3) Div. of Medical Genetics, Duke University Medical Center, Durham, NC.

Pompe disease (acid maltase deficiency) is a rare, progressive, and often fatal metabolic myopathy, which manifests as a clinical spectrum that varies with respect to age at onset, rate of disease progression, and extent of organ involvement. The underlying pathology is a deficiency of acid alpha-glucosidase (GAA). To gain a better understand of the natural course of Pompe disease, a global, voluntary, observational Registry was developed to collect anonymous, longitudinal data. As of September 2007, 400 patients from 23 countries are enrolled; 71% are Caucasian. Europe and North America enroll 85% of patients. For infants (n=78, 20%), the median age at symptom onset was 2.0 months and median age at diagnosis was 4.0 months. For adults (n=238, 60%), the median age at symptom onset was 26.3 years and median age at diagnosis was 34.5 years. Patients currently 18 years old (n=259) report the following symptoms most frequently: muscle weakness [lower extremities (81%), upper extremities (71%), trunk (57%)]; shortness of breath after exercise (61%) and at rest (33%); dependence on respiratory support (39%); sleep disturbance/apnea (37%); orthopnea (34%); and scapular winging (31%). Of the patients genotyped, 54% (76/140) expressed the IVS1-13T>>G mutation. These results show a significant delay from symptom onset to diagnosis in adult patients and highlight the need for greater disease awareness. As the Pompe Registry matures, data on prevalence and age at onset of symptoms in various patient subgroups may allow physicians to identify patients at earlier stages of disease progression; thus enabling therapeutic intervention before irreversible muscle damage occurs.

C4 gene copy number correlates to C4 protein levels and associates with development of SLE: results from Swedish study. *E. Lundstrom[1], Y. L. Wu[2], E. Svenungsson[1], I. Gunnarsson[1], A. Larsson[3], C. Y. Yu[2], L. Padyukov[1]* 1) Dept Medicine, Karolinska Inst & Hosp, Stockholm, Sweden; 2) Pediatrics; Molecular Virology, Immunology and Medical Genetics, The Ohio State University, and Center for Molecular and Human Genetics, The Research Institute at Nationwide Children's Hospital, Columbus, Ohio, USA; 3) Department of Clinical Chemistry and Pharmacology, Inst Med Sci, Akademiska Hospital, Uppsala, Sweden.

Objective: Copy number polymorphism (CNP) is one of many possible sources of phenotypic heterogeneity and susceptibility to human complex diseases. We analyzed association between CNP of the C4A and C4B genes at human chromosome 6p22 and systemic lupus erythematosus (SLE) in a Swedish cohort and investigated the correlation of the CNP with serum levels of C3, C3d and C4 in patients with SLE. Methods: 160 SLE patients and 180 controls matched on sex and age were included in the study. C4 CNP was discriminated by using RT-PCR and serum levels of C3, C3d as well as C4 were measured in patients by rate nephelometry. Correlation between the number of gene copies and the disease was analyzed by Chi-square test and complement factors levels were compared by Mann-Whitney test. Results: Our data show an increased odds ratio (OR) for SLE in carriers of 2 copies of C4A (OR: 2.26 95% CI: 1.37-3.74) or 4 copies of C4 total (C4A+C4B) (OR: 2.28 95% CI: 1.44-3.62). No association between C4B CNP and SLE was observed. Further analyses revealed a correlation between low copy numbers (4 copies) and low serum levels of C4 (p-value: 0.018). However, individual levels of C4 protein in serum of SLE patients with normal number of copies of C4 genes are in common range of concentration. No correlation between C4 CNP and serum levels of C3 and C3d was observed. Conclusion: Our data confirm, in Swedish population, previous findings of correlation between low copy number of C4 with low concentrations of C4 protein in serum and confer susceptibility to SLE in these individuals. Thus, a subgroup of SLE could be determined by C4 deficiency and further functional studies of mechanisms related to complement system are warranted for such subgroup.

Paraoxonase (PON1) gene polymorphisms in Fabry disease: Correlation with renal disease. *T. Shemesh[1], C. Whybra[3], S. Delgado-Sanchez[3], M. Beck[3], D. Elstein[2], G. Altarescu[1]* 1) Medical Genetic Unit, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 3) Metabolic Unit, the Universitäts-Kinderklinik2, Mainz, Germany.

Background: Fabry disease, an X-linked disorder due to decreased alpha-galactosidase-A activity, is associated with early-onset stroke, cardiomyopathy, and renal failure. There are very few markers to predict disease progression and hence we have attempted to develop polymorphic genotypes of symptomatic patients using genes that are predictive of specific disease signs. The two common polymorphisms of paraoxonase gene (PON1), Leu(55)Met and Gln(192)Arg are hypothesized to modulate cardiovascular risk as well as prognosis of stroke and deterioration of renal function in other diseases. PON1 is a high-density-lipoprotein-associated enzyme that apparently mitigates oxidative damage. Methods: DNA was extracted and PON1 polymorphisms performed by restriction enzyme analysis. The disease-specific Mainz Severity Score Index (MSSI) was calculated for patients. Results: Eighty patients (58 female) and 46 healthy controls (23 female) were evaluated for these 2 polymorphisms. There was a significant difference by chi-square analysis (p=.04) of the PON55 LL genotype among patients but no significant differences were noted with any PON 192 polymorphic genotypes. The PON55 LL genotype was strongly correlated with the MSSI renal sub-score categorized for more severe manifestations (p=.003); the omnibus test of model coefficients (p=.004) and the 2-way ANOVA (p=.0001) between groups for the LL genotype of PON55 were also predictive of more severe renal MSSI sub-scores, but not for cardiac, neurological, or general manifestations. Although there was no statistically significant difference between groups in levels of alpha-galactosidase-A activity, the LL genotype, which is correlated with higher PON1 activity, had the lowest levels. Conclusion: The PON55 LL genotype, i.e. higher PON1 activity, was significantly more common among patients with Fabry disease than controls and was correlated with more severe clinically relevant renal sub-scores as seen in other kidney diseases.

Polymorphisms and mutational analysis of the NOTCH3 gene in a large cohort of patients affected by leukoencephalopathy. *C. Ungaro[1,2], F. L. Conforti[1], T. Sprovieri[1], P. Servillo[1], M. Liguori[1], L. Citrigno[1], A. L. Gabriele[1], A. Magariello[1], A. Patitucci[1], M. Muglia[1], R. Mazzei[1]* 1) ISN-CNR, Mangone (CS), Italy; 2) Department of Neurosciences, Psychiatric and Anesthesiological Sciences, University of Messina, Messina, Italy.

CADASIL is a cerebrovascular disease caused by mutations in the NOTCH3 gene. Most CADASIL associated mutations result in a gain or loss of a cysteine residue in one of the 34 EGF-like repeats in the extracellular domain of the Notch3 protein, thus sparing the number of cysteine residues within a domain. To date, more than 130 different mutations in the NOTCH3 gene have been reported in CADASIL patients, the 95% being missense point mutations. Many polymorphisms have also been identified in the NOTCH3 coding sequence some of them leading to amino acid substitutions. The aim of the present study was to analyze the coding region and intron-exon boundaries of the NOTCH3 gene in a large cohort of patients affected by leukoencephalopathy to investigate the presence of genetic variants. We analyzed exons 3-4, exons 3-4-6-8 and exons from 2 to 23, respectively in 684, 542 and 157 patients affected by leukoencephalopathy. The molecular analysis revealed several nucleotide alterations in comparison to the wild type sequence; in particular, we identified 20 different mutations in 47 subjects from 30 families, 22 polymorphisms, 7 of them were novel, and 8 genetic variants of unknown pathological significance never been reported previously. In conclusion, this NOTCH3 gene mutational analysis performed in such a significant number of unrelated and related patients may help in molecular screening for NOTCH3 gene and may contribute to enlarge the NOTCH3 gene variation database. Acknowledgements We thank Drs G Guidetti, D Consoli, A Gambardella, A Toscano, for helping identify patients. The work was in part supported by the Italian Ministero dell'Istruzione, dellUniversità e della Ricerca Grants MIUR-FIRB2006-RBIP06PMF2_006.

-thalassemia trait in immigrants from Southeast Asia in Korea. *H. N. Kim[1], E. J. Lee[1], H. L. Kim[1,5], S. C. Jung[1], S. Y. Yi[2], E. A. Park[3], H. W. Chung[4]* 1) Dept Biochemistry; 2) Dept Internal Medicine; 3) Dept Pediatrics; 4) Dept Obstetrics and Gynecology, School of Medicine, Ewha Womans University, Seoul 158-710, Korea; 5) Korea National Institute of Health, Korea Centers for Disease Control, Seoul 122-701, Korea.

Beta-thalassemia is one of the most common hemoglobinopathy in many part of the world but rare in Korea. In the past 10 years, a dramatic increase in the number of immigrants from Southeast Asia into Korea led to have insight in the thalassemia. To detect -thalassemia trait, asymptomatic 635 Southeast Asian women immigrated to Korea were screened by using complete blood counts (CBC), Shine and Lal indices (MCV^2*MCH*0.01), Ricerca index (RDW/RBC) and peripheral blood smearing. Initially high risk group of -thalassemia trait was screened by two indices, either less than 79 fl mean corpuscular volume (MCV) or less than 26 pg mean corpuscular volume (MCH). Among 635 women, 72 were within the criteria. As a standard diagnostic marker for -thalassemia, the level of Hemoglobin (Hb) A_2 was measured by high performance liquid chromotography (HPLC). Among those 72 women, 13 women showed elevated Hb A_2 (> 3.5%), MCV 76 fl, MCH < 25 pg, Shine and Lal indices < 1530, Ricerca index < 4.4 and microcytic hypochromic red blood cell without anemia. These results implied they were -thalassemia tait. As immigrants from these countries increases, estimating allele frequencies of -thalassemia among them would be helpful to genetic counseling. This study was supported by the Center for Genome Science, Korea, National Institute of Health research contract (budgets: 2007-090-091-4854-300, 2008-E00157-00).

The genetic control of microRNA expression in Humans. *C. Borel, S. Deutsch, H. Attar, M. Gagnebin, C. Gehrig, E. Falconnet, Y. Dupré, S. E. Antonarakis* Dept Genetic Medicine, Univ Geneva Medical Sch, Geneva, Switzerland.

MicroRNAs (miRNAs) are small non-coding RNAs that regulate the expression of protein-coding transcripts. Each miRNA is thought to have multiple target genes that are regulated at the post-transcriptional level. Inter-individual variation of miRNA gene expression is likely to influence the levels of target transcripts, and may therefore contribute to some phenotypic differences, including susceptibility to common disorders. The aim of this study was to characterize the natural variation in miRNA expression levels present in different individuals, and to identify loci that control this variation. We established primary fibroblasts from 200 unrelated umbilical cord samples of Caucasian origin (GenCord collection). All of these samples have been genotyped using the Illumina Hap550 SNP array. After multiple filtering steps 417820 SNPs were retained for statistical analyses. Taqman real-time PCR in all cell lines was used to measure the expression of 365 known mature miRNAs in each sample. This revealed that 108 miRNAs are expressed in fibroblasts and that their expression levels are highly variable between individuals. Normalized miRNA levels for each individual were used to perform quantitative whole genome association studies using the Plink software. We will present the detailed genome-wide association analysis of SNPs that control in *cis*- or *trans*- miRNA expression. We identified around 5% of microRNAs with cis eQTLs and 16% with *trans* eQTLs that remain significant after multiple testing correction. *Cis* eQTLs are located quite far away from miRNA (200-700 kb) and a large fraction of *trans* eQTLs are intronic (13 out of 18). This is the first attempt to characterize the genetic regulation of miRNA expression levels. Loci identified through this approach are likely to be important determinants of human phenotypes. *C.B and S.D contributed equally to this work.*.

L-2-Hydroxyglutaric aciduria: clinical, genetic and neuroradiological findings in an Italian patient. *R. Mazzei[1], C. Ungaro[1,2], F. L. Conforti[1], T. Sprovieri[1], V. Blasi[1], A. Mollo[3], O. Gallo[1], P. L. Lanza[1]* 1) ISN-CNR, C.da Burga, Mangone (CS), Italy; 2) Department of Neurosciences, Psychiatric and Anesthesiological Sciences, University of Messina, Messina, Italy; 3) ASP 4, Cosenza, Italy.

In our report we describe clinical, genetic and neuroradiological features in an Italian patient with L-2-Hydroxyglutaric aciduria (L-2-HGA), in whom L-2-HGA was diagnosed at an adult age. L-2-HGA is an autosomal recessive inherited neurometabolic disease, belonging to the group of organic acidurias, whose biochemical hallmark is represented by increased levels of 2-hydroxyglutaric acid in urine, blood and cerobrospinal fluid, with 90% of isoforms representing the L-form. The gene causing L-2-HGA, designed as L2HGDH, encodes for a L-2-hydroxyglutarate dehydrogenase, a putative mitocondrial protein converting L-2-hydroxyglutarate to alpha-ketoglutarate. The mutations found in L-2-HGA patients abolish the activity of this enzyme, therefore the symptoms are most likely due to the toxic effects of the accumulating metabolite L-2-hydroxyglutarate; in fact, L-2-hydroxyglutarate has been shown to induce oxidative stress and to inhibit mitochondrial creatine kinase in the cerebellum. The proband underwent to the screening of the full L2HGDH gene by direct sequencing. Patients MRI scanning of the brain revealed hyperintense signal on T2W and FLAIR images of the subcortical white matter and basal ganglia. The symptoms were represented by mental deficiency, cerebellar ataxia, pyramidal and extrapyramidal signs and dysarthria. Molecular analysis showed a sequence variation in the exons 8, highlighting the presence of a homozygous nucleotide variation at position c.1082 (c.1082 CT) that leads to substitution of a CGA codon encoding for an arginine residue with a TGA codon predicting for a stop codon at position 335 (Arg335Stop) in the protein. In conclusion, in the current study we report the first evidence of a mutation in the L2HGDH gene in an Italian patient affected by L-2-HGA, reinforcing the previously described phenotype of this rare metabolic disease and reaffirming the data that mutations in the L-2-Hydroxyglutaric dehydrogenase gene cause L-2-Hydroxyglutaric aciduria.

Identification of the allelic architecture of *NNMT* gene as a genetic determinant for Homocysteine levels. *M. Sabater-Lleal[1], J. Martín[2], A. Buil[1], M. Chillón[3], JC. Souto[4], J. Blangero[5], J. Fontcuberta[4], F. Blanco-Vaca[2], JM. Soria[1], L. UAB. Barcelona; 4) Unity of Thrombosis and Hemostasia, HSCSP, Barcelona; 5) Southwest Foundation for Biomedical Research. San Antonio (TX).

Homocysteine (Hcy) plasma level is an independent risk marker for venous thrombosis, myocardial infarction, stroke, congestive heart failure, osteoporotic fractures and Alzheimer disease. Previous results from the GAIT Project allowed the identification of a region in chromosome 11q23, which was completely linked (Lod score =3.01;p=0.0001) Hcy levels. The most probable candidate gene in that region was the *NNMT* gene, a methyl-transferase involved in Hcy metabolism. A study of 17 SNPs in this gene reveled the presence of a haplotype strongly associated with Hcy levels (p=0.00031). To identify the most likely functional variants responsible for this association, we now have resequenced this candidate gene. We amplified the *NNMT* gene (75Kb) in two haplotype carriers. The fragments were cloned in TOPO XL vectors. We fully sequenced four clones of each individual and four clones from a control haplotype to obtain the complete sequence of the gene. The identified genetic variants have been analyzed in a sample of 398 GAIT participants using Bayesian QTN analysis. Sixty-six polymorphisms were identified in both carriers of the Hcy-associated haplotype. Preliminary multivariant results from the full GAIT sample show that four of these SNPs exhibit a strong probability of affecting Hcy levels (posterior probability >0.9). Using a novel strategy, we have identified four SNPs in the *NNMT* gene that present a strong probability of affecting Hcy levels. We are now analyzing the functional effect of these allelic variants. These results represent a relevant advance in the knowledge of the genetic factors that determine Hcy levels, an important intermediate phenotype for thromboembolic disease.

Population Genetics and Genomics of Human Gene Expression. *B. E. Stranger[1], S. B. Montgomery[1], C. E. Ingle[1], M. Sekowska[1], C. Beazley[1], C. Barnes[1], S. McCarroll[2], S. Tavaré[3,4], M. E. Hurles[1], P. Deloukas[1], E. T. Dermitzakis[1]* 1) Wellcome Trust Sanger Institute, Hinxton, UK; 2) Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA; 3) Department of Oncology, University of Cambridge, Cancer Research UK, Cambridge Research Institute, Li Ka Shing Centre, Cambridge, UK; 4) Program in Molecular and Computational Biology, University of Southern California, CA.

Gene expression is a heritable, quantitative phenotype that can be used to assess the impact of naturally occurring functional genetic variation. It is increasingly used to assist in the interpretation of disease association signals. We previously described a comprehensive analysis of the genetic basis of gene expression variation in the original 270 individuals of the HapMap project using both SNPs and CNVs (Stranger et al. Science 2007 and Nat Genet 2007). We have now extended this analysis to 830 unrelated individuals from 8 global populations of the extended HapMap samples. We interrogated whole-genome gene expression in lymphoblastoid cell lines, and performed association analyses with these expression data and 1.6M SNP genotypes from the HapMap3 Consortium and thousands of high resolution CNV calls, with the goal of identifying and characterizing cis eQTLs in these populations. The increased power from analyzing nearly double the sample size of each of the initial four HapMap populations allows us to detect approximately 2.5 times the number of previously-reported genes with SNP-expression eQTLs in each of these populations, corresponding to a cis-eQTL for approximately 6% of expressed genes from samples of around 100 unrelated individuals. In total we detect cis-eQTLs for approximately 20% of expressed genes, with 34% of detected eQTL observed in at least two populations. We identify strong CNV-expression associations and observe that only 7-14% (depending on population) of CNV associations are also detectable with SNPs. We present analyses of population differentiation and natural selection on variants that influence gene expression using haplotype-based methodologies designed to detect recent selection.

Genome-wide association studies on multiple system atrophy (MSA). *Y. Nakahara[1], Y. Momose[2], Y. Ichikawa[1], Y. Takahashi[1], K. Yamamoto[3], J. Goto[1], S. Tsuji[1], JAMSAC (Japan Multiple System Atrophy research Consortium)* 1) Department of Neurology, Univ. of Tokyo, Tokyo, Japan; 2) Neurology, KITAHARA Nerurosurgical Institute, Tokyo, Japan; 3) Division of Molecular Population Genetics Department of Molecular Genetics Medical Institute of Bioregulation, Univ. of Kyushu, Fukuoka, Japan.

Background: Multiple system atrophy (MSA) is a sporadic neurodegenerative disorder characterized by various combinations of autonomic failure, cerebellar symptoms, parkinsonism and pyramidal signs. Although the discovery of alpha -synuclein has been identified as a major component of the glial cytoplasmic inclusions (GCIs), a pathologic hallmark for MSA, the etiologies of MSA remain to be elucidated. To obtain clues as to the genetic factors for MSA, we have conducted genome-wide association studies on MSA cases and controls. Design/Methods: We have established a consortium focusing on multiple system atrophy (JAMSAC; JApan MSA Research Consortium), to obtain longitudinal clinical information and genomic DNA. We genotyped 209 patients with MSA and 220 neurologically normal controls, using Illumina HumanHap 550K Genotyping BeadChip. Results: Genotype data (544,148 SNPs) fulfilling the following conditions are processed for statistical analyses; the call rate exceeding 0.98 in MSA patients and controls, p value for Hardy-Weinberg equilibrium exceeding 1E-6. The number of the SNPs with significant p values of 2 test are as follows; (p0.05: 24,024 SNPs, p0.01: 4,748 SNPs, p0.001: 482 SNPs, and p0.0001: 47 SNPs). To identify susceptibility genes for MSA further replication with independent data set will be required.

PALB2 and BRCA2 mutations in Finnish prostate cancer cases - Co-occurrence of mutations in a family with multiple types of cancer. *T. Wahlfors[1], S. Pakkanen[1], S. Siltanen[1], MP. Matikainen[2], TLJ. Tammela[2], J. Schleutker[1]* 1) Laboratory of Cancer Genetics, IMT, University of Tampere, Tampere, Finland; 2) Division of Urology, Tampere University Hospital and Medical School, University of Tampere, Tampere, Finland.

A truncating mutation (1592delT) in the recently found Fanconi anemia gene, PALB2 (BRCA2 cofactor), is associated with an increased breast cancer risk in Finland, but also may be correlated with an increased risk of other cancers including prostate cancer (PRCA). Besides breast cancer, mutations in the BRCA2 gene predispose carriers to PRCA in some population but PRCA-associated mutations in BRCA2 have not previously been identified in the Finnish PRCA patients. We explored the contribution of PALB2 and the BRCA2 PALB2-binding site mutations to the clinical characteristics of Finnish PRCA patients. Finnish families with two or more PRCA-affected males (178) and 285 unselected cases with complete clinical data were initially screened for mutations in the coding region and splice sites of PALB2. Additionally, we analyzed BRCA2 exon 2 and 3, which code for the PALB2 binding site, to address the implication of the BRCA2-PALB2 interaction on PRCA patient clinical parameters. We identified six variants in the PALB2 and five variants in the BRCA2 genes. No novel truncating mutations were found in either gene, but three novel variants were characterized in BRCA2. One family with multiple cancer cases, including four PRCA, two breast, one gastric and one skin, carried PALB2 1592delT, a BRCA2 missense mutation and two novel intronic BRCA2 variants. PALB2 1592delT showed complete penetrance in this family and clinical characteristics among the mutation carriers in this family revealed a trend towards aggressive disease. Aggressive fenotype associating with 1592delT also applied to a few non-familial cases. All together, our results indicate that, in Finland, PALB2 truncating mutations and potentially functional variants in BRCA2 exons 2 and 3 are rare at the population level. However, cancer incidence among mutation carriers is moderate to high and a trend towards aggressive disease is observed.

Novel Homozygous 4bp Deletion in LAMB2 Causing Pierson Syndrome. *M. Al-Owain[1], M. Faiyaz Al-Haque[2], H. Al-Zaidanl[1], H. Al-Muallimi[2], J. Nelson[3], H. Abalkhail[2]* 1) Dept Medical Genetics, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 2) Dept of Pathology and Molecular Medicine, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 3) Genetic Services of Western Australia, King Edward Memorial Hospital, Australaia.

Pierson Syndrome (Microcoria-Congenital Nephrosis Syndrome, MIM # 609049) has been recently delineated as an autosomal recessive disease causing congenital nephrotic syndrome and distinct eye abnormalities. The renal disease is classically due to diffuse mesangial sclerosis. The Microcoria (fixed narrowing of the pupils) is due to maldevelopement of the eye including hypoplasia of the iris, lens, and ciliary body. Pierson syndrome is caused by a defect in laminin beta 2, an integral component of basement membranes. We report two brothers who died in the infantile period with Pierson syndrome. During the pregnancy of the first affected child to consanguineous parents, the fetus was noted to have enlarged echogenic kidneys and markedly elevated amniotic fluid alpha-fetoprotein suggesting congenital nephrosis. After delivery, the newborn had massive proteinuria and had to undergo bilateral nephrectomy. The microscopic finding was consistent with diffuse mesangial sclerosis and diffuse dilatation of the renal tubules. The patient additionally had hypotonia, seizures, and microcephaly. Examination of the eyes revealed that the left eye was larger than the right and the pupils remained small despite administration of dilating drops with only glimpses of the fundi being apparent. The MRI of the brain showed areas of infarction in the parieto-occiptal lobe and the occipital lobe with dilatation of the lateral ventricles. The diagnosis of Pierson syndrome was made, however no mutation analysis of the gene was available. The family had subsequently another boy who was also affected with Pierson syndrome. LAMB2 gene sequencing revealed that he was homozygous for a novel 4 bp deletion in exon 26. Both parents were heterozygous carriers of this deletion. Based on this finding we have referred the family for preimplantation genetic diagnosis.

Identification of a mutation causing encasement of fetus. *J. Lahtela[1], H. O. Nousiainen[1], J. Tallila[1], H. Honkala[1], M. Gentile[2], V. Stefanovic[3], VM. Ulander[3], R. Karikoski[4], R. Salonen[5], M. Kestila[1]* 1) National Pub Hlth Institu, Helsinki, Finland; 2) Genome Informatics Unit, University of Helsinki, Helsinki, Finland; 3) Department of Obstetrics and Gynaecology, Helsinki University Hospital, Helsinki, Finland; 4) HUSLAB Central Pathology Laboratory, Helsinki University Hospital, Helsinki, Finland; 5) Department of Medical Genetics, Väestöliitto, Helsinki, Finland.

We describe a Finnish family with two affected fetuses with identical severe malformations. Both upper and lower limbs seemed to be absent because they were totally encased under the skin. The skull was small, and the nose and the mouth were replaced by a single orifice with a septum dividing it vertically into two spaces resembling open choanae. There were hypoplastic eyes on both sides of the orifice, and an abnormal large cyst in the middle of the neck. The pregnancies were terminated at 13+6 and 12+5 gestational weeks, respectively, based on ultrasound findings. Assuming recessive mode of inheritance, we performed a genome-wide scan with microsatellite markers using DNA samples of parents, affected fetuses and a healthy sibling. The linkage analysis provided several putative loci. We also performed genome-wide gene expression analysis from fibroblast RNA of affected fetuses and observed several differentially expressed transcripts compared to age-matched controls. Based on these findings and additional information from public databases, we sequenced a selected candidate gene from the affected fetuses. This study revealed a pathogenic mutation that creates a premature stop codon and co-segregates with the phenotype within the family. We are currently sequencing control samples to define the carrier frequency of the variant in the Finnish population. We are also performing functional studies to identify the actual consequences of the mutation on protein level. The findings of this study provide strong evidence about the role of this gene and protein in epidermal differentiation during human embryonic development and also add essential knowledge about the early fetal stages in general.

Segmental copy number variation shapes tissue transcriptomes. *A. Reymond[1], C. N. Henrichsen[1], N. Vinckenbosch[1], S. Zollner[2], E. Chaignat[1], S. Pradervand[1], M. Ruedi[3], H. Kaessmann[1]* 1) The Center for Integrative Genomics, University of Lausanne, Switzerland; 2) University of Michigan, Ann Arbor, MI; 3) Natural History Museum, Geneva, Switzerland.

Copy number variation (CNV) of DNA segments has recently been identified as a major source of genetic diversity, but a comprehensive understanding of the phenotypic effect of this type of variation is only beginning to emerge. We have generated an extensive map of CNV in wild mice and classical inbred strains. Copy number variable regions cover a total of ~340 megabases (~11%) of their autosomal genome. Genome-wide expression data from 6 major organs and 4 developmental times in six different strains reveal that expression levels of genes within CNVs positively or negatively correlate with copy number changes in approximatively 35 and 15% of the cases, respectively. Our experiments also show that CNVs influence the expression of genes in their vicinity - an effect that extends up to half a megabase. These controls over expression are effective throughout mouse development, however some genes appear to be under compensatory loops at specific time point. Interestingly, genes within CNVs show lower expression levels and more specific spatial expression patterns than genes mapping elsewhere in the genome. Furthermore, genes expressed in the brain are significantly underrepresented in CNVs compared to genes with expression in other tissues, suggesting differential selective constraint on copy number changes of genes expressed in different tissues. Our study provides initial evidence that CNVs shape tissue transcriptomes on a global scale and thus represent a significant source for within-species phenotypic variation.

Effect of enzyme replacement therapy on growth in patients with Hunter syndrome: results from the Hunter Outcome Survey. *M. Beck[1], J. Muenzer[2], M. Scarpa[3], G. Schulze Frenking[1], E. Wraith[4] on behalf of the HOS investigators* 1) Pediatric Dept, Univ Mainz, Mainz, Germany; 2) Pediatric Dept, Univ North Carolina, USA; 3) Pediatric Dept, Univ Padova, Padova, Italy; 4) Willink Biochemical Genetics Unit, Royal Manchester Children's Hosp, Manchester, UK.

Introduction: The Hunter Outcome Survey (HOS) is a global database covering the natural history of Hunter syndrome (MPS II) and the safety and effectiveness of enzyme replacement therapy (ERT) with idursulfase (ElapraseTM; Shire HGT). Untreated patients with MPS II have markedly reduced growth after 5-8y of age. The first data on the effects of ERT on the growth of patients with MPS II are provided here. Methods: On 15 May 2008, there were 421 prospective patients in HOS (i.e. alive when enrolled); 221 were receiving ERT. This analysis included all patients with available height data 1y before and 1y after ERT. Results: Height data were available for 29 patients; 2 were excluded because they were aged 20y at the start of ERT (baseline). Of the 27 eligible patients, 17 were aged 12y (3-11) and 10 were aged 12y (12-18) at baseline. Mean (SD) changes in height were: 2.9 (2.3) cm before and 4.7 (3.0) cm after ERT for patients aged 12y; 1.8 (2.3) cm before and 3.2 (2.7) cm after ERT for patients aged 12y; and 2.5 (2.3) cm before and 4.1 (2.9) cm after ERT for all patients. Mean (SD) change in height velocity 1y before to 1y after ERT was +1.6 (3.1) cm/y, and mean changes in z-scores were -0.5 (0.3) before and -0.1 (0.5) after ERT. Changes were more notable in patients aged 12y at baseline. Mean (SD) changes in height velocity for patients 12y and 12y were +1.8 (3.4) and +1.4 (2.5) cm/y, respectively. Mean changes in z-scores for patients 12y before and after ERT were -0.4 (0.2) and 0.0 (0.4), respectively, and for patients 12y were -0.5 (0.5) and -0.3 (0.5), respectively. Conclusions: In a non-age-stratified analysis of outcome survey data, we observed an acceleration of growth in patients with MPS II given ERT with idursulfase for 1y. Ongoing collection of data in HOS, including analysis of ERT and pubertal development status (Tanner stage), will further elucidate the effect of idursulfase ERT on growth.

Mechanisms of loss of heterozygosity in neurofibromatosis type 1-associated plexiform neurofibromas. *H. Kehrer-Sawatzki[1], K. Steinmann[1], L. Kluwe[2], R. Friedrich[2], D. N. Cooper[3], V.-F. Mautner[2]* 1) Human Genetics, Univ Ulm, Ulm, Germany; 2) Department of Maxillofacial Surgery, University Hospital Eppendorf, Hamburg, Germany; 3) Institute of Medical Genetics, School of Medicine, Cardiff University, Cardiff, UK.

Plexiform neurofibromas constitute a serious burden for patients with neurofibromatosis type 1 (NF1), a common autosomal dominant disorder characterised by pigmentary changes and tumorous skin lesions (neurofibromas). Despite the prominence of these benign tumours in NF1 patients, the mechanisms underlying the tumour-associated loss of heterozygosity (LOH) in plexiform neurofibromas have not been extensively studied. We performed LOH analysis on 43 plexiform neurofibromas from 31 NF1 patients, the largest study of its kind to date. A total of 14 (33%) plexiform neurofibromas exhibited LOH involving 17q markers. In four tumours, LOH was found to be confined to the NF1 gene region. However, in none of the tumours was a somatic NF1 microdeletion, mediated by non-allelic homologous recombination (NAHR) between either NF1-REPs or SUZ12 genes, detected. Thus, NF1 microdeletions do not appear to be frequent somatic events in plexiform neurofibromas. Determination of NF1 gene copy number by multiplex ligation-dependent probe amplification (MLPA) indicated that although tumours with smaller regions of LOH were characterized by 17q deletions, no NF1 gene copy number changes were detected in seven plexiform neurofibromas with more extensive LOH. This is the first indication that mitotic recombination is a frequent cause of LOH in plexiform neurofibromas.

Genes relating synapse in 7q31 as Candidate genes for Autism. *N. Nakashima, T. Yamagata, Z. Yu, M. Saito, M. Mori, M. Y. Momoi* Dept Pediatrics, Jichi Medical Univ, Tochigi, Japan.

Because genes working on synapse such as *NLGN3, 4, SHANK3* and *GABRB3* were identified as causative genes for Autism spectrum disorder (ASD), genes relating to synaptogenesis and function can be candidate genes. In linkage analysis, 7q31 was reported to be one of the locus for ASD. Therefore, we analyzed genes relating to synapse on 7q31, *NRCAM* and *GRM8*, and also *POT1* on ASD patients for mutation. *NRCAM* is expressed in neurons in the mature brain, and is considered to play a role in synapse formation and neuronal plasticity regulating cell-cell interactions. *NRCAM* was reported to associate with ASD. GRM8 is a member of metabotropic glutamate receptors that is a family of G-protein coupled receptors. *GRM8* is expressed in the brain especially cerebellum and fetal brain, and regulates glutamate transmission and maturation of synapse. *GRM8* was reported as an autism causative gene. POT1 is a conserved single-stranded DNA binding protein with the crucial function of the protection of telomeres and also the maintenance of overall genomic stability. *SHANK3* is located in the minimal telomeric region that rationalized *POT1* to be a candidate for ASD. (Methods)Genomic DNA was extracted from leukocytes/lymphoblasts from 63 Japanese patients obtained with the informed consent of their parents, and 100 Caucasian patients from AGRE (the Autism Genetic Resource Exchange). Each exon and introns nearby was amplified by PCR and sequenced. (Results) In *NRCAM*, we detected 22 sequence variations and 8 were in the coding region. One base change that induced amino acid change was detected in 20 patients and reported as SNP previously. Three SNPs were not reported previously. In *GRM8*, we detected 4 intronic base changes and one base substitution in the coding region that did not induce amino acid change. In *POT1*, we detected 18 sequence variations, and 5 of them were in the coding region. Three induced amino acid change, however, they were also detected in the controls. (Discussion) We did not detect causative mutation in *NRCAM*, *GRM8* and *POT1*. These results suggested that the causative genes should carry additional or much specified biological functions besides synaptogenesis.

Novel IRF6 mutations associated with nonsyndromic Cleft Lip or Cleft Palate: Who should be eligible for IRF6 screening? *K. M. Rocha[1], B. Burin[1], F. S. Jehee[1], L. Brito[1], P. S. Costa[1], R. Zechi-Ceide[2], N. Alonso[3], L. Dalva-Lopes[4], J. Souza[5], M. R. Passos-Bueno[1]* 1) Centro de Estudos do Genoma Humano, IB, USP; 2) Centro de Reabilitação, Bauru, USP; 3) Faculdade de Medicina, USP; 4) Defeitos da Face; 5) CAIF, PA, Brasil.

Nonsyndromic Cleft Lip with or without Cleft Palate (NSCLP), one of the most common human congenital malformations, is a multifactorial disorder. Recurrence risk varies from 4-10%. In contrast, Van der Woude syndrome (VWS), the most common syndromic form of CLP is an autosomal dominant condition with high penetrance caused by null mutations in IRF6. Lower-lip pits, present in about 85% of the VWS cases, allow the clinical distinction between VWS and NSCLP or NS Cleft Palate (CP). , Misdiagnosis of VWS can lead to incorrect recurrence risk calculation for the patients and their family. In order to test the proportion of NSCLP or NSCP with mutations in the IRF6, we have directed sequenced exons 3, 4 and 7 of IRF6 in 108 probands with CLP or CP (76 with CL/P, 24 CL, 6 CP and 2 congenital healed cleft lip) with at least one other affected relative with orofacial cleft. None of them had lower lip pits. Four missense mutations were detected: R9W, Q17P, V113L and D354N (c.1060G>A). These mutations were not detected in 200 control chromosomes and, except for the R9W mutation, were not previously described. Arg9, Gln17 and Val113 are located in evolutionary conserved amino acids at the DNA-binding domain and c.1060G is an evolutionary conserved guanine residue located 1 nucleotide upstream of the exon 7 donor site and they are probably pathogenic. We observed that three of these 4 mutations occurred in families segregating both CLP and CP. Therefore, these results are showing for the first time that CLP or CP in the absence of lower lip-pits can be associated with mutations in the IRF6 gene and we recommend that familial cases (1st degree affected relative), particularly those segregating CLP and CP, should be tested for IRF6 mutations CEPID/FAPESP, CNPq.

Genomic DNA duplications associated with complex polysyndactyly. *M. Sun[1], F. Ma[1], X. Zeng[2], Q. Liu[2], XL. Zhao[1], X. Zhang[1]* 1) Department of Medical Genetics, Peking Union Medical College, Beijing, China; 2) Peking Union Medical College Hospital, Beijing, China.

Triphalangeal thumb-polysyndactyly syndrome (TPTPS; OMIM 190605), syndactyly type IV (SD4; OMIM 186200) and tibial hemimelia-polysyndactyly-triphalangeal thumb syndrome (THPTTS; OMIM 188770) are congenital limb malformations all mapped to chromosome 7q36 and have various limb phenotypes including triphalangeal thumb, syndactyly and polydactyly. Unlike preaxial polydactyly types II (PPD2; OMIM 174500) and III (PPD3; OMIM 174600), which map to the same chromosome 7q36 region, no point mutation within the ZRS (ZPA regulatory sequence) was found in these complex polysyndactylies. We recently ascertained six Han Chinese families, including three with TPTPS, two with TPTPS and SD4, and one with SD4. We found that the pathogenic mutations underlying TPTPS/ SD4 were genomic DNA duplications involving ZRS. Using quantitative real-time PCR (qPCR) and Affymetrix-Genome-Wide Human SNP Array 6.0, we refined the extent of duplications, ranging from 144 kb to 398 kb. Sequence analysis of the breakpoints in three families suggested that the molecular mechanism underlying the genomic duplications might be non-homologous end joining (NHEJ). Our molecular findings suggest that severe syndactyly and complete thumb duplication seen in TPTPS and SD4 might be associated with unknown regulatory elements centromeric to the ZRS. The fact that two members in one of our TPTPS/SD4 families had limb phenotype similar to PPD2 also suggests that the ZRS duplication is probably responsible for those PPD in which point mutations were not discovered in ZRS. We predict that THPTTS could also be involved in the abnormal ZRS. Further genetic studies in more families may help to establish the correlation between the phenotypic severity and the extent of duplications.

Major loci determining lipid levels and coronary heart disease risk in 16 population-based European cohorts. *S. Ripatti[1,2], Y. Aulchenko[3], I. Lindqvist[1,2], CM. van Duijn[3], L. Peltonen[1,2,4,5] for the ENGAGE Consortium* 1) FIMM, Helsinki, Finland; 2) NPHI, Helsinki, Finland; 3) Dept of Epidemiology and Biostatistics, Erasmus University, Netherlands; 4) The Broad Institute, Massachusetts Institute of Technology, MA; 5) Wellcome Trust Sanger Institute, Hinxton, UK.

The recent flood of genome wide association (GWA) studies of lipid metabolism are based on heterogeneous samples of patients and controls derived from studies of diabetes and other disorders. Here we report the first GWA analysis of loci affecting lipid levels, major cardiovascular risk factors in 16 European population cohorts, not ascertained or collected based on any specific trait or disease outcome but sampled from the general population. Our study included a total of 17,798-22,562 persons (depending on the outcome studied), with age distributions ranging from 18 to 104 years and the geographic region of origin spanning from the Nordic countries to Southern European populations. We established 22 genomic regions consistently and significantly associated with serum lipid levels at a genome wide significance level (p5 x 10^{-8}), including 16 loci identified earlier by previous GWA studies. The six new loci with genome wide significance identified in our cohort samples are: ABCG5 (TC, p=1.5 x 10^{-11}; LDL, p=2.6 x 10^{-10}), TMEM57 (TC, p=5.4 x 10^{-10}), CTCF-PRMT8 region (HDL, p=8.3 x 10^{-16}), DNAH11 (LDL, p=6.1 x 10^{-9}), FADS3/FADS2 (TC, p=1.5 x 10^{-10}; LDL, p=4.4 x 10^{-13}) and MADD-FOLH1 region (HDL, p=6 x 10^{-11}). Jointly these 22 loci explain up to 5.6% of variation in lipids at the population level, the impact of some loci being different for males than females. When the impact of these loci was estimated for coronary heart disease risk in the Dutch cohort with individuals over 55 years of age, each risk allele increased the risk by 2%.

DNA methylation plasticity in the muscle tissue under disuse stress. *T. Kubota[1], K. Endoh[1], K. Ohori[1], K. Koyama[2]*
1) Fac Med, Epigenetic Medicine, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Fac Edu and Hum Sci, Univ Yamanashi,Kofu, Yamanashi, Japan.

The pattern of DNA methylation is faithfully maintained after DNA replication, and thus it has been thought that DNA methylation will not be changed for ones lifetime long. However, it has recently known that DNA methylation can be changed in short term by some factors such as malnutrition, mental stress, and some drugs as well as methylation supplements. To know the methylation plasticity, we investigate whether DNA methylation is changed by stress in rats muscle tissue. We examined DNA methylation in the upstream-regulatory regions of the three genes related to muscle differentiation in the soleus (lower limb) muscle tissues in acute-exercise (30 min on treadmill, 9 weeks of age) rat group (n=6, control=6), and those in chronic-disuse (3 weeks tail-suspension, 18 weeks of age) rat group (n=5, control=5) using bisulfite sequencing and COBRA methods. As a result, the percentages of methylated-CpGs in acute-exercise group were similar to the control group [57% and 42% in MyoD, 25% and 35% in Myogenin, 49% and 50% in Myostatin]. However, the percentages of methylated-CpGs in chronic-disuse group were different to the control group [60% and 27% in MyoD, 58% and 37% (24% and 17% (p=0.02) by COBRA) in Myogenin, 70% and 36% in Myostatin]. These results suggest that not acute-exercise but chronic-disuse stress changes DNA methylation in muscle tissue, and indicate that muscle tissue has DNA methylation plasticity. This observed hypomethylation in the muscles under the chronic-disuse stress may not only caused by proliferation of myoblast-like satellite cell induced by lower-limb muscle atrophy with tail-suspension (since these genes are hypomethylated in myoblasts), but also caused by demethylation change in the muscle cells in the atrophic muscle tissue without cell division (since the hypomethylation change is larger than the expected increase of the satellite cells).

Mutations in TMC1 are Relatively Frequent Among Families with Nonsyndromic Autosomal Recessive Deafness in Turkey. *M. Tekin[1], A. Sirmaci[1], H. Ozdag[2], D. Duman[1], H. Ozturkmen-Akay[3], S. Erbek[4], S. Tasir-Yilmaz[2], A. Incesulu[5], B. Ozturk-Hismi[1], Z. S. Arici[1], B. Yuksel-Konuk[1], F. B. Cengiz[1], I. Aslan[1]* 1) Division of Pediatric Molecular Pathology and Genetics, Ankara University School of Medicine, Ankara, Turkey; 2) Biotechnology Institute, Ankara University, Turkey; 3) Department of Radiodiagnostics, Dicle University School of Medicine, Diyarbakir, Turkey; 4) Department of Otorhinolaryngology, Baskent University School of Medicine Hospital, Konya, Turkey; 5) Department of Otorhinolaryngology, Eskisehir Osmangazi University School of Medicine, Eskisehir, Turkey.

Biallelic mutations in TMC1 have been reported to cause profound prelingual deafness, DFNB7/11. We screened TMC1 mutations in 86 unrelated Turkish families, in which 2-15 individuals with nonsyndromic severe to profound congenital or prelingual onset sensorineural hearing loss were born to normal hearing and consanguineous parents. GJB2 and mtDNA A1555G mutations were negative in probands from each family. Affected members in each family were initially genotyped for SNP or microsatellite markers linked with the TMC1 gene. Mutation analysis was performed in families showing co-segregation of deafness with haplotypes at the DFNB7/11 locus. A total of 6 different mutations in 7 families were identified, including previously undescribed three missense alterations, p.G444R (c.1330G>A), p.R445C (c.1333C>T), and p.I677T (c.2030T>C); one splice site mutation IVS6+2 T>A (c.64+2T>A); and a large deletion including exons 19-24; as well as a previously reported nonsense mutation, p.R34X (c.100C>T). All identified mutations co-segregated with deafness in all families and were not found in Turkish hearing controls. These results confirm the significant contribution of TMC1 mutations in deafness in Turkey.

Sign-dependent linkage disequilibrium estimation. *C. Zapata* Departamento de Genética, Centro de Investigaciones Biológicas Universidad de Santiago de Compostela, 15782 Santiago de Compostela, A Coruña, Spain.

Knowledge on the frequency and strength of non-random associations of alleles at different loci (LD, linkage disequilibrium) across genomes is very useful to explore their multilocus genetic architecture and to locate genetic factors underlying phenotype by positional cloning. In practice, most studies on LD follow estimation procedures which ignore the sign of deviations from random association. However, it is known that the sign of LD can affect seriously its estimation. The aim of the present work is to evaluate whether advantageous statistical properties to reliably estimate the frequency and intensity of LD between diallelic locus pairs concentrate on haplotype configurations exhibiting the same sign of LD. For this purpose, sign-dependent comparisons were performed by Monte Carlo simulation with respect to the power of the chi-square test to detect LD and the sampling variance and bias of estimates of the strength of LD obtained by the measure D'. The study included a wide variety of population conditions (different levels of LD intensity and combinations of allele frequencies at loci) and haplotype sample sizes. Sign-dependent LD analyses require the application of a uniform criterion to determine the allele composition of haplotype classes. Here, coupling haplotypes were designated as those carrying the most and the least frequent allele variants. Simulations showed that the power of the chi-square test was generally much higher for positive than for negative LD ($P < 0.01$). In addition, the precision of D'-estimates was also sign-dependent being the sampling variance generally much smaller for positive than for negative LD ($P < 0.01$). By contrast, no statistically significant differences in bias were found between D'-estimates with different sign over population conditions and sample sizes ($P= 0.32$). Overall, the present study shows that haplotype configurations with positive deviations from random association offer clear statistical advantages to reliably assess the frequency and intensity of LD across genomes with respect to sign-independent estimation procedures.

Folate Pathway Genes and Biochemical Studies in Orofacial Clefts. *S. Brustolin[1], M. E. Cooper[2], A. Silva[3], M. L. Marazita[2], M. M. Santos[1], R. Giugliani[1], J. C. Murray[3], T. M. Felix[1]* 1) Federal University of Rio Grande do Sul, Porto Alegre, RS, Brazil; 2) University of Pittsburgh, Pittsburgh,PA; 3) University of Iowa, Iowa City, IA.

Background: Non-syndromic cleft lip with or without cleft palate (CLP) is one of the most common birth defects with multiple genetic and environmental components. Studies have indicated that folate and vitamin consumption are environmental factors. Sample: Using 27 SNPs in 14 folate pathway genes, we analyzed 2 Brazilian samples consisting of 140 women (113 unaffected, 27 affected with CLP), their folate-related biochemical measures(vitamin B12, homocysteine, serum folate, red blood cell folate (RBC), hematocrit and hemoglobin) and 247 genotyped cleft proband trios where only some of the mothers have biochemical data. Results: NNMTrs2852447 shows significant differences in the means of the vitamin B12 among the 16 clefted mothers genotyped (ANOVA p=0.01) but not among all 140 mothers (ANOVA p=0.96). The means of all the biochemical measures do not differ by cleft status of the mothers (all t-test p>0.094). In chi-square tests of genotypes, the A allele of MTHFD1rs1950902 (p=0.01) and the CC genotype of CBSrs1789953 (p=0.01) are associated with clefted mothers. The TDT association tests on the trio family data revealed significant associations between clefting and: 1) The C alleles of MTRRrs1532268 (p=0.04), NNMTrs694539 (p=0.003) and BHMTrs651852 (p=0.04); 2) the CC genotypes of MTRRrs1532268 (p=0.02) and NNMTrs694539 (p=0.001); and 3) the haplotypes for the 4 SNPs in the BHMT gene (p=0.06) and the NNMT gene (p=0.03).The gene-gene interaction in each of these 3 SNPs with all the other SNPs was significant for MTRR rs1532268 versus 2 other SNPs within the same gene (rs10925235, p=0.03 and rs1801394, p=0.003) and NNMTrs694539 versus DHFRrs1643638 (P= <0.0001). Conclusion: The analysis indicates that the NNMT gene may be involved with both clefting and vitamin B12 and that both the MTRR and BHMT genes are involved with clefting. Further investigation with a larger sample will further illuminate the gene-environmental involvement with orofacial clefting. Grant NIH DE-08559, FIRCA TW007644-02 and CNPq.

The entire HFE gene deletion does not cause symptom of hemochromatosis in a homozygous woman of 47 years-old. *G. Le Gac, I. Gourlaouen, C. Ronsin, V. Géromel, A. Bourgarit, N. Parquet, S. Quemener, C. Le Maréchal, J.-M. Chen, C. Férec* Inserm U613, EFS-Bretagne, Université de Bretagne Occidentale, F-29200 France.

Hemochromatosis is predominantly associated with the HFE p.C282Y homozygous genotype, which is found in approximately 1 person in 200 in Northern European populations. Rarely, the disease also refers to point mutations in HJV, HAMP, TFR2 or SLC40A1 (namely the non-HFE hemochromatosis genes). Here, we identified an Alu element-mediated deletion of the entire HFE gene sequence, detected and further characterized using a range of PCR-based methods, and confirmed using array-comparative genomic hybrization (array-CGH). Although being homozygous for the HFE knocked-down allele, the woman did not present symptoms of hemochromatosis at 47 years-old. Our study illustrates the importance of including chromosomal rearrangement screening in the hemochromatosis diagnosis setting. But, it also supports the idea that not all individuals having a homozygous genetic alteration in HFE will be concern by clinical complications and especially the women.

Genotype and Phenotype Heterogeneity in MUTYH Associated Polyposis. *F. J. Hes[1], M. C. Joerink - van de Beld[1], M. Nielsen[1], N. Jones[2], S. Vogt[3], C. M. J. Tops[1], H. F. A. Vasen[4], S. Aretz[3], J. R. Sampson[2]* 1) Department of Clinical Genetics, Leiden University Meidcal Center, Leiden, Netherlands; 2) Institute of Medical Genetics, School of Medicine, Cardiff University, Wales, UK; 3) Institute of Human Genetics, University of Bonn, Germany; 4) Department of Gastroenterology & Medical Oncology, Leiden University Medical Center, Netherlands.

Background and aim: Bi-allelic mutations in the base excision DNA repair gene MUTYH lead to MUTYH associated polyposis (MAP) and thereby predispose to colorectal cancer (CRC). Functional studies have demonstrated significant differences in base recognition and glycosylase activity between various MUTYH mutations, notably for the two mutations most frequently reported in MAP patients: Y179C and G396D (previously annotated as Y165C and G382D). Our aim was to unravel correlations between genotype and their phenotypic expression of MAP. Methods: In this multicentre study we analyzed genotype and phenotype data including age at presentation of MAP, polyp count and the occurrence, location and age at presentation of CRC in 257 MAP patients. Results: The three possible bi-allelic combinations of truncating and non-truncating mutations showed no significant phenotypic differences. In contrast, both G396D homozygotes and G396D/Y179C compound heterozygotes presented later with MAP and had a significantly lower CRC hazard than Y165C homozygotes ($p<0,001$). The median age of developing CRC was 60 years and 51 years versus 48 years respectively. Conclusions: Our clinical study corroborated earlier functional assays and identified Y179C as a relatively severe and G396D as a relatively mild MUTYH mutation. Genotypic stratification may be useful in the development of guidelines for counseling, screening and management of families with MAP.

Dietary Intervention in Patients Receiving Substrate Reduction Therapy with Miglustat. *U. Ramaswami[1], H. Champion[1], J. Imrie[2], R. Lachmann[3], TM. CoX[4], JE. Wraith[2]* 1) Paediatric Metabolic Unit, Addenbrooke's University Hospital, Cambridge, United Kingdom; 2) Royal Manchester Childrens Hospital, UK; 3) Charles Dent Metabolic Unit, London, UK; 4) Department of Medicine, University of Cambridge, UK.

Background The iminosugar, miglustat, inhibits glucosylceramide synthase, the initial enzyme in the formation of glycosphingolipids: offering an alternative therapeutic approach in Type 1 Gaucher Disease and investigation into related lipidoses. Miglustat inhibits sucrase-isomaltase and other disaccharidases in the small intestine resulting in gastrointestinal (GI) side effects. Methods We analysed retrospectively the effect of dietary modification over a 6 month period in patients with related lipidoses. Patients were divided into Groups A, B, C as described in table below. Patients on low disaccharide diet commenced their modified diet 2-4 weeks prior to starting miglustat. Neurological outcome is not discussed for this presentation. Results 29 patients were included. Mean age 17 years(range 1-39). The results of mean change from base line in body weights are shown below. *

	Group A: Milk based; n=5	Group B: Low lactose; n=5	Group C Low Disaccharide; n=19
Mean Weight Change	-6.2	-1.7	+8.8
Mean Change in Weight in Line with Growth	-10	-4.3	+2.1

In Group A, frequent loose stools were controlled with loperamide; Group B had mild to moderate diarrhoea. Group C had occasional loose stools only. Conclusion Analysis of the data from 29 patients receiving therapy with miglustat shows that with dietary modification, weight gain during treatment can be maintained in line with weight gain potential and episodes of GI disturbances significantly reduced. A diet low in disaccharides was most effective especially when started before treatment commenced.

Transcriptome sequencing of human ESC. *G. Kolle[1], B. Gardiner[1], N. Cloonan[1], H. S. Chy[2], G. Q. Zhou[2], A. L. Laslett[2], S. M. Grimmond[1]* 1) Institute for Molecular Bioscience, University of Queensland, Brisbane, Qld, 4072, Australia; 2) Australian Stem Cell Centre, Clayton, Vic, 3800, Australia.

We have previously characterized the full polyadenylated transcriptome of mouse embryonic stem cells using Short Quantitative RNA Library (SQRL) sequencing (Cloonan et al., 2008)[1]. Here we present a comprehensive and complementary analysis of the transcriptome of human embryonic stem cells (hESC). To assess the full protein coding transcriptome, the polyadenylated fraction of hESC was isolated. To complement this, the membrane bound and free ribosome fractions of hESC were isolated using the method of (Diehn et al., 2000)[2]. This fractionation procedure permits a sensitive and accurate ability to distinguish all integral membrane and secreted proteins (extracellular space) that are translated by hESC. These three fractions were sequenced using the AB SOLiD next generation sequencing platform. A complete and quantitative estimation of gene expression level, spliced variant expression, novel transcription, non-coding RNA and transcribed sequence variants (SNPs, Indels) was performed. We were able to characterize all transcribed genes that encode integral membrane or secreted proteins, define spliced variants that result in switching from the membrane to the cytosolic fraction and reveal a set of novel genes not previously associated with the extracellular space in hESC. This is the highest resolution analysis of both the transcriptome of hESC and the membrane-polysome associated transcriptome of any mammalian cell type. References: 1. Indentification of genome wide targets of the UPF3B dependent nonsense-mediated mRNA surveillance pathway by exon array expression profiling and their relevance to the pathogenesis of intellectual disability. *J. Gecz[1], L. S. Nguyen[1], A. Gardner[1], L. Vandeleur[1], C. Shoubridge[1], J. Rodriguez[2], C.-F. Chen[3], L. Wang[2,3], A. Srivastava[2,3], M. Corbett[1]* 1) Dept Genetic Medicine, Women's & Children's Hospital, Adelaide, Australia; 2) J.C.Self Research Institute, Greenwood Genetic Center, Greenwood, South Carolina, USA; 3) Department of Genetics and Biochemistry, Clemson University, Clemson, South Carolina, USA.

Non-sense mediated mRNA decay (NMD) is a universal RNA surveillance pathway that also targets for degradation mRNAs bearing premature termination codons (PTC). We showed that mutations in UPF3B cause different forms of learning disability (Nature Genet, 39:1127-33, 2007). To assess the impact of UPF3B null mutations we performed expression profiling of control and patient lymphoblastoid cells using Human Exon 1.0 ST arrays. We found 633 deregulated genes (30% up, 70% down). One of these genes was UPF3B itself, which carriers PTC mutations in our patients. Applying KEGG pathway analysis we found disruption in regulation of cytoskeleton (PAK4, RHOA, FGFR4) and axon guidance (NFATC4, CFL2, NGEF), as well as purine and pyrimidine metabolism in the patients. Our data also demonstrated, that NMD is only partially compromised in the absence of UPF3B. Surprisingly, comparison with previous studies from UPF1, UPF2 or UPF3B knock down models in human, fly and yeast generated minimal overlap. Such low correspondence might be explained by tissue specificity of NMD, array platforms used or complexities of in vitro knockdown models versus naturally occurring human UPF3B KO situation. We also identified consequences of UPF3B KO on the level and type of alternative splicing and mRNA processing. At FDR=0.01 ($p<0.0006$), 1047 genes made the list. We manually picked and analysed 133 genes, which fell into two categories: 3 processing (34 genes, 25%; LMO2, XRN2, RPS8 and GARNL4); and internal splicing (100 genes, 75%; EIF4E3, UBAP2, PAPOLA and TBP). In summary, we have identified for the first time the bona fide targets of the UPF3B dependent NMD pathway and glimpsed into the complexities of NMD pathways and the molecular pathogenesis of UPF3B associated learning disability.

Linkage and Candidate Gene Studies of Autism in EU Populations. *R. Holt[1], G. Barnby[1], E. Maestrini[2], E. Bacchelli[2], D. Brocklebank[1], A. J. Bailey[3], A. P. Monaco[1], EU Autism MOLGEN Consortium* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Dipartimento di Biologia, Università di Bologna, Italy; 3) University Department of Psychiatry, Park Hospital for Children, Oxford, UK.

Autism is a strongly genetic childhood onset psychiatric disorder; however, genes underlying its susceptibility remain elusive. As part of an EU collaboration, we used linkage and haplotype analyses to refine previously identified regions of linkage with autism. We also examined variants in candidate genes for association with autism. The Autism Genome Project (AGP) have genotyped families, including 311 from the EU, using the Affymetrix 10k array. A total of 384 SNPs from this array within regions of linkage with autism on chromosomes 2, 3, 6, 7, 16 and 17 were genotyped using the Illumina GoldenGate BeadArray platform on 92 new EU multiplex families. The data from these new genotypes were pooled with those of the 311 EU families from the AGP study and used to perform a meta-analysis of linkage and to search for parent-of-origin effects. Also, 281 trios were genotyped to narrow critical regions by searching for extended haplotypes. For the candidate gene study, seven genes previously reported to be involved in autism, *ASMT*, *SHANK3*, *GRIK2*, *SLC6A4*, *NOSTRIN*, *PRKCB1* and *RELN*, were investigated. A total of 384 SNPs were selected to cover all variation in the genes. Genotyping was performed with the Illumina BeadArray platform on one proband and both parents from 387 multiplex families. Association was sought using the TDT. The highest LOD score in the linkage analysis was 1.64 (rs2862479, chromosome 3), increasing to 1.87 (rs2885116, chromosome 2) when a subset of Finnish families were excluded. Parent-of-origin and haplotype analyses are ongoing. In the candidate gene study, the most significant result was for rs362780 (*RELN*, $P = 0.00079$), although this does not reach significance after correction for multiple testing. While continuing to demonstrate the difficulties in identifying autism susceptibility loci, these results help highlight the possible importance of chromosomes 2 and 3, and *RELN* in autism susceptibility.

Breast cancer risk not only was not associated with CYP17/ A2 allele but also was related to A1 allele. *M. Hosseini[1], M. Houshmand[2,3], A. Ebrahimi[2,3]* 1) Dept Science, Islamshahr Branch,Islamic Azad University, Tehran,Iran, Asia; 2) National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 3) Special Medical Center, Tehran, Iran.

Breast cancer is the second common cancer in rate in world and the first common cancer in Iranian women. The Cytochrome P-450c17 (CYP17) gene, located on chromosome 10q24.3, encodes the enzyme Cytochrome P-450c17, which functions as susceptibility factor in breast cancer. Three common polymorphisms have been described in the CYP17 gene [1, 2]. The variant creates a recognition site for the MspAI restriction enzyme, the common allele as A1 and the variant alleles A2 (-34TC). Totally 53 Iranian sporadic breast cancer affected women compare to control group were studied by PCR-RFLP for CYP17 variant. Even the A2/A2 were reported as risk factors for breast cancer our results showed that the A1/A1 were most risk factor in our population. A2/A2 had inhibition effect in our patients. [A1/A1 / A2/A2 odds ratio, 5.57 (95% confidence interval, 1.514-20.506) p=0.008]. We conclude that not only A2/A2 in our patients was not associated with breast cancer risk but also there is a reverse relation between presence of A1/A1 and increasing of breast cancer risk. Keywords: CYP17 gene, polymorphism, breast cancer, MSPA1, PCR-RFLP, susceptibility factor.

***Vax2* regulates retinoic acid distribution and cone opsin expression in the mouse eye.** *G. Alfano[1], T. Caramico[1], P. Dollè[2], S. Banfi[1]* 1) TIGEM, Fondazione Telethon, Rome, Rome, Italy; 2) Institut de Genetique et de Biologie Moleculaire et Cellulaire, Illkirch, France.

Vax2 is a homeobox gene expressed in the ventral developing eye. The inactivation of this gene in mouse determines an incompletely penetrant eye coloboma as well as abnormal axonal projections of ventral retinal ganglion cells to the superior colliculus. In order to dissect the molecular pathways in which *Vax2* is involved, we performed a transcriptome analysis of *Vax2-/-* mice starting from early stages of eye development until adult stages. By microarray studies, we found that some genes encoding enzymes involved in the metabolism of retinoic acid (RA) show significant variations of their expression levels in *Vax2-/-* mice. RA plays an important role at early stages of eye development and displays a peculiar distribution in the developing eye, as it is present only in its dorsal and ventral parts while it is absent in an intermediate region (RA-free zone). We found, in *Vax2-/-* mutants, an expansion of the expression domain of the genes encoding the RA-degrading enzymes *Cyp26a1* and *Cyp26c1* and a down-regulation of the RA-synthesizing enzyme *Raldh3*. This leads to an abnormal distribution of RA in the developing eye of *Vax2-/-* mice with a significant expansion of the RA-free zone in the ventral part of the eye. In addition, this analysis allowed us to detect, in *Vax2-/-* mice, an altered expression of two cone-specific genes, *S-Opsin* and *M-Opsin*, which plays a key role in color vision. These two genes normally display an asymmetric dorsal-ventral distribution in the eye. In our mutant animals, we observed a significant alteration of the expression gradient of these two genes, which may underline impairment in visual function. These data demonstrate that *Vax2* plays a key role in the determination of the distribution of RA in the developing eye and in the establishment of a physiological asymmetric expression of genes not only at early stages of development but also in adult stages and in mature photoreceptors. We propose that the expression alterations determined by *Vax2* in cone photoreceptors are mediated by the abnormal distribution of RA at earlier stages of eye development.

Analysis of candidate SNPs for high Hb F in thalassemia intermedia patients. *F. Anni[1,2], L. Perseu[3], S. Satta[1], M. Bowser[4], P. Fortina[2,5], M. Devoto[4,5], S. Surrey[6], R. Galanello[1]* 1) Ospedale Regionale Microcitemie, ASL Cagliari, II Clinica Pediatrica, Universita` degli Studi di Cagliari Cagliari, Italy; 2) Dept of Cancer Biology, Thomas Jefferson University, Philadelphia, PA; 3) INN-CNR, Cagliari, Italy; 4) The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Dept of Experimental Medicine, University La Sapienza, Rome, Italy; 6) Cardeza Foundation for Hematological Research, Thomas Jefferson University, Philadelphia, PA.

Raising fetal globin levels in adult life could eliminate the need for transfusion in thalassemia and decrease painful crises in sickle cell disease. Since the population from the island of Sardinia is genetically homogeneous, identification of high Hb F determinants might be more straightforward compared to other populations. In this study, 43 transfusion-dependent (TD) and 29 non-transfusion dependent (NTD) or thalassemia intermedia individuals all homozygous for the 39 C->T chain termination mutation inherited on I, II or IX -globin haplotype backgrounds were evaluated for SNPs associated with the high Hb F phenotype. All were Xmn I negative at -158 G and no additional promoter variants or indel were detected in -like globin gene clusters. Initial focus was on sequence analysis of SNPs previously shown to be associated with high Hb F on chromosomes 2 and 6. rs6732518 located in the BCL11A gene on 2p16.1 showed highly significant association, with a frequency of the C allele of 0.52 in the NTD group and of 0.20 in the TD group ($p = 0.00006$). Less significant association was detected for rs1320963 on 6q23.3 ($p = 0.02$). Whole-genome association studies are ongoing using the Affymetrix GeneChip 6.0 array to elucidate other high Hb F determinants in this unique population.

Clinical and molecular investigation in an unusual Rett Syndrome case. *T. Sprovieri[1], R. Mazzei[1], C. Ungaro[1,2], A. Fiumara[3], A. Magariello[1], A. Patitucci[1], L. Citrigno[1,2], A. Arena[3], A. L. Gabriele[1], M. Muglia[1], F. L. Conforti[1]* 1) ISN/CNR, Mangone(CS), Italy; 2) Department of Neurosciences, Psychiatric and Anesthesiological Sciences, University of Messina, Messina, Italy; 3) Department of Paediatrics University of Catania, Catania, Italy.

Here we report the clinical and X-linked cyclin-dependent kinase-like 5 (CDKL5) molecular investigation in a very unusual Rett Syndrome (RTT) case, with severe, early-neurological involvement. Mutations in the CDKL5 gene have recently been reported in patients with severe neurodevelopmental disorder characterized by early-onset seizures, infantile spasms, severe psychomotor impairment and very recently, in Rett syndrome-like phenotype. Although the involvement of CDKL5 in specific biological pathways and its neurodevelopmental role have not been completely elucidated, CDKL5 appears to be physiologically related to the MECP2 gene. We investigated a 13-year-old girl affected by early convulsion onset who fulfilled the revised criteria for RTT variant phenotypes. Samples were also taken from more than 150 controls, matched for geographical region. DNA extraction and molecular investigation were performed by standard protocols. The screening of the whole coding sequence of the CDKL5 gene by DHPLC revealed an abnormal chromatographic pattern in exon 12 of the patient. Direct sequencing of the amplicon identified a CDKL5 missense mutation AACACC; c.1417 AC (GenBank accession No. Y15057), causing the aminoacidic change of asparagine in threonine (p.N399T). This sequence variation was not found both in the patients family and in more than 300 normal chromosomes. In conclusion, in our study we have identified a novel CDKL5 pathogenic mutation N399T that contributes to enlarge the CDKL5 gene variation database. Nonetheless, this finding reinforces the idea that altered CDKL5-regulation of MECP2 is responsible for a specific RTT phenotype and suggests that CDKL5 mutation screening should be performed in RTT patients, mainly females, presenting a history of early onset of a severe intractable seizure disorder.

Genome-wide association and meta-analysis for bipolar disorder in European ancestry samples. *L. J. Scott[1], P. Muglia[2], W. Guan[1], R. Upmanyu[3], M. Flickenger[1], X. Kong[4], F. Tozzi[2], J. Li[5], M. Burmeister[5, 6], D. Absher[7], R. C. Thompson[6], F. Meng[6], A. Farmer[8], J. Vincent[9], A. D. Roses[10], R. M. Myers[7], D. Burns[2], M. Boehnke[1] for GSK R&D and the Pritzker Neuropsychiatric Disorders Research Consortium & Site Directors* 1) Biostatistics, U Michigan, Ann Arbor, MI; 2) Genetics, GSK R & D, Verona, Italy; 3) GSK, Harlow, UK; 4) GSK, Research Triangle Park, NC; 5) Human Genetics, U Michigan, Ann Arbor, MI; 6) MBNI, U Michigan, Ann Arbor, MI; 7) HudsonAlpha Inst Biotechnology, Huntsville, Alabama; 8) IoP, King's Coll London, London, UK; 9) Psychiatry, U Toronto, ON, Canada; 10) Duke U Med Ctr, Durham, NC.

Bipolar disorder (BD) is a disabling and often life-threatening disorder that affects ~1% of the population worldwide. To identify genetic variants that increase the risk of BD, we genotyped 2 sample sets on the Illumina 550K Beadchip: (1) NIMH/Pritzker: 1195 BD 1 cases and 777 controls collected through the NIMH Genetic Initiative and the Prechter Repository and (2) GSK: 899 BD cases and 904 controls from London, Toronto, and Scotland. We tested for SNP-BD association in each sample and performed meta-analysis across samples. The NIMH/Pritzker-GSK meta-analysis yielded a top association p-value of 2.4×10^{-6}. We next imputed and analyzed data using the publicly available Affymetrix 500K genotype data from the Wellcome Trust Case Control Consortium (WTCCC) for 1,868 BD cases and 12,813 controls comprised of individuals from the National Blood Sample and from six non-BD case groups. After elimination of overlap of 261 cases present in both the WTCCC and GSK data, we performed a 3-study meta-analysis of 3,926 cases and 14,594 controls genotyped or imputed on 485,604 SNPs. A non-synonymous SNP on chromosome 3 showed the strongest 3-study meta-analysis association (p-value = 2.4×10^{-8}) and was associated in the NIMH/Pritzker, GSK, and WTCCC studies with p-values of .003, .001, and .00005, respectively. Genotyping and analyzing additional samples will be required to confirm that variant(s) in this region increase BD risk.

Comprehensive resequencing of *ABCD1, ABCD2, ABCD3* and *ABCD4* genes in patients with X-linked adrenoleukodystrophy (ALD) and association studies with the phenotypes of ALD. *T. Matsukawa[1], M. Asheuer[2], Y. Takahashi[1], J. Goto[1], Y. Suzuki[3], N. Shimozawa[3], H. Takano[4], O. Onodera[4], M. Nishizawa[4], P. Aubourg[2], S. Tsuji[1]*
1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) UMR Inserm 745, University Paris-Descartes, Hôpital Saint-Vincent de Paul, Paris, France; 3) Univ Gifu, Gifu, Japan; 4) Univ Niigata, Niigata, Japan.

Background: Adrenoleukodystrophy (ALD) is an X-linked disorder affecting primarily the white matter of the central nervous system occasionally accompanied with adrenal insufficiency. Despite the discovery of the causative gene, *ABCD1*, clear genotype-phenotype correlations have not been established. Association studies based on SNPs identified by comprehensive resequencing of gene related to *ABCD1* may reveal genes modifying the phenotypes of ALD. **Methods:** We analyzed 40 Japanese patients with ALD (childhood cerebral CCALD 16, adult with cerebral AdultCer ALD 6, AMN with cerebral AMN-Cer ALD 2, AMN 13, asymptomatic 1 and Unknown 2). *ABCD1* and *ABCD2* were analyzed by newly developed microarray-based resequencing system. *ABCD3* and *ABCD4* were analyzed by direct nucleotide sequence analysis. Replication studies were conducted on an independent french ALD cohort with extreme phenotypes (CCALD 118 and pure AMN 71) **Result:** All the mutations of *ABCD1* were identified and there was no correlation with the ALD phenotypes. SNPs identified by comprehensive resequencing of *ABCD2*, *ABCD3* and *ABCD4* were used for association studies. There were no significant associations between these SNPs and ALD phenotypes, except for the 5 SNPs of *ABCD4* that are in complete disequilibrium in the Japanese population. These 5 SNPs were significantly less frequently represented in the patients with AMN compared to controls in the Japanese population ($p<0.05$), while there were no significant differences in patients with CCALD. The replication study employing these 5 SNPs on an independent french ALD cohort, however, did not show any significant associations with CCALD or pure AMN. **Conclusion:** The present study indicates that *ABCD2*, *ABCD3* and *ABCD4*, are less likely the disease modifying genes, necessitating further studies to identify genes modifying the phenotypes of ALD.

Haplotypic investigation of SNPs at the NOS2A locus in relapsing-remitting Multiple Sclerosis. *I. Manna[1], M. Liguori[1], P. Valentino[2], F. Condino[1], R. Nisticò[2], P. Spadafora[1], G. Di Palma[1], A. Quattrone[1,2]* 1) Institute of Neurological Science - CNR, Cosenza, Italy; 2) Institute of Neurology, University "Magna Graecia", Catanzaro, Italy.

The aim of this study is to investigate the contribution of the gene encoding the inducible form of Nitric Oxide Synthase (NOS2A) in Relapsing-Remitting Multiple Sclerosis (RRMS). This study enrolled 250 selected RRMS patients from Southern Italy and 250 ethnically matched healthy subjects. We decided to approach the NOS2A gene study with the SNPlex methodology, an efficient and reliable tool for a broad range of genotyping applications which uses oligonucleotide ligation, polymerase chain reaction and capillary electrophoresis to analyze bi-allelic single nucleotide polymorphism (SNP) genotypes. Thirteen SNPs spanning throughout the entire NOS2A gene have been selected. Genotyping was performed by the SNPlex platform and data was analyzed by GeneMapper v4.0 (Applied Biosystems), using the SPSS 12.0 software for the statistical evaluation. Genomic DNA was extracted from the peripheral blood samples of all the subjects recruited for the study, and the NOS2A genotypes of 56 RRMS patients and 40 controls have been analized. The distribution analysis of the SNPs frequencies showed that two of them (rs1137933 and rs2297518) seemed to be more frequently associated to the MS disease ($p= 0.0053$ and $p= 0.046$, respectively). Although derived from a limited sample of the study population, these data seem to confirm that NOS2A gene might be involved in the MS susceptibility; the evaluation of the remaining samples is in progress, also to eventually identify a disease-related NOS2A haplotype. Acknowledgement: The Authors thank dr. Letizia Gerace (Applied Biosystems Europe) for the technical support in the SNPlex methodology.

AMPD1 knock-out mice: A murine model for myoadenylate deaminase deficiency. *T. Morisaki[1,2], J. Cheng[1], N. Sugimoto[1,2], A. Dohi[1,2], E. Kimura[1], T. Shintani[1,2], M. Ikawa[3], M. Okabe[3], H. Morisaki[1]* 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Molecular Pathophysiology, Osaka University Graduate School of Pharmaceutical Sciences, Suita, Osaka, Japan; 3) Genome Information Research Center, Osaka University.

AMP deaminase (AMPD)is an enzyme playing an important role in purine nucleotide interconversion in eukaryotic cells. AMPD1 gene, a member of the AMPD gene family in vertebrates, is specifically expressed in skeletal muscles, and its deficiency was reported in patients with metabolic myopathy, though it is controversial whether AMPD deficiency is indeed associated with exercise-induced muscle dysfunction. Also, it was reported that AMPD1 mutant allele have an improved clinical outcome of congestive heart failure but the mechanism for that has not been verified. To answer those questions, we generated a murine model for myoadenylate deaminase deficiency by establishing AMPD1 knock-out (KO) mice. Homozygous AMPD1 KO mice showed almost complete loss of AMPD activities only in skeletal muscles, though there were no abnormal histological findings in skeletal muscles. Physiological levels of exercise did not apparently alter the nucleotide levels in skeletal muscles nor showed different muscle performance in AMPD1 KO mice, while the electrostimulation of isolated muscle revealed elevated AMP and decreased ATP in muscle of those mice. Moreover, more phosphorylated AMP activated protein kinase (AMPK) was determined after electrostimulation in muscle of AMPD1 KO mice. In this study, we established a murine model of myoadenylate deaminase deficiency, and confirmed altered nucleotide metabolism and changed AMPK phosphorylation status in AMPD1 deficiency. Further functional analysis of this model is being in progress.

Hybrid SNPing provides a rapid technology to identify chromosome abnormalities, including balanced translocations, and genome-wide characterization of a species genome in the context of a different species genome. *R. D. Nicholls[1,2], S. Li[1], D. Lewis[2], S. M. Gollin[2], D. N. Finegold[1,2]* 1) Children's Hospital of Pittsburgh, Pittsburgh, PA; 2) University of Pittsburgh, Pittsburgh, PA.

We developed a genome-wide technology using single nucleotide polymorphism (SNP) genotyping microarrays and DNA from somatic cell hybrids, termed hybrid SNPing. This process allows the rapid, specific and complete characterization of the genome of one species in the context of another species genome, illustrated using two applications on a set of rodent-human somatic cell hybrids retaining one or more human chromosomes and chromosome fragments. First, hybrid SNPing provides a complete human genome molecular karyotype of somatic hybrid cells, to 1-50 kb resolution, which we verified by PCR and FISH methodologies. Second, hybrid SNPing provides high-resolution definition of chromosomal rearrangements such as balanced translocations associated with birth defects and other congenital disease. The average resolution of chromosome fragment and translocation breakpoint mapping from hybrid SNPing using Illumina 300K SNP genotyping arrays was 25.1 kb, with a range of 1.47 kb to 51.3 kb for the nine breakpoints that we characterized. Use of Illumina 550K SNP arrays resolved reciprocal balanced translocation breakpoints to 4.2 kb and 4.7 kb. To date, breakpoints of three balanced translocations [t(15;17), t(14;18, t(3;14)] were directly cloned by PCR and DNA sequencing. With 300K arrays, a maximum of 3% of human SNP probes are potentially conserved in rodents, which decreases to 1.5% with a more stringent cutoff and phylogenetic sequence analyses. In conclusion, hybrid SNPing identifies to near nucleotide resolution the DNA content and breakpoints of balanced translocations and chromosome fragments, with envisaged applications in somatic cell genetics to identify oncogenes, tumor suppressor genes, cell senescence genes, stem cell markers, or any functional sequence that can be screened for by cellular phenotypic assays. Other novel applications of the technology include identification of disease-associated SNPs and large DNA fragments in transgenic or gene therapy applications.

Syntrophin-2 that interacts with neuroligins is not related with autism. *M. Saito, T. Yamagata, N. Nakashima, M. Mori, M. Y. Momoi* Pediatrics, Jichi Medical University, Shimotsuke, Tochigi, Japan.

Neuroligin (NL) 3 and 4 were identified as responsible genes for autism spectrum disorder (ASD). NLs are cell adhesion molecule which are essential components of synaptogenesis, and the binding of NLs to -neurexin induces both pre- and postsynaptic maturation. Addition to that, NLs were reported to interact with syntrophin-2 (SNTG2), and the mutations of NLs detected in the autistic patients were reported to impair interaction between NLs and SNTG2. The syntrophin family is considered as adapter proteins that interact with dystrophin and the dystrophin-related proteins in both neuromuscular junctions and the CNS. ASD is more common in Duchenne and Becker muscular dystrophy than in the general population. From these points, we analyzed coding regions of SNTG2 for possible direct link between SNTG2 and ASD. Materials and Methods: Genomic DNA was extracted from the peripheral blood leukocytes/lymphoblasts from 143 ASD patients. Patients included 65 Japanese patients obtained with the informed consent of their parents, and 78 Caucasian patients from AGRE (the Autism Genetic Resource Exchange). Each exon and introns nearby were amplified by PCR and the PCR products were sequenced. Detected sequence variations were compared with control samples. Results: We detected 32 kinds of sequence variants and 12 of them were in the coding region. Ten base substitutions induced amino acid change and 4 of them were already reported as SNPs. The other 6 base changes were detected in 1 to 4 patients each, but also in the controls. Therefore, they were considered as rare SNPs. No association was detected in each SNPs between ASD and controls. Discussion: We did not detect any mutations or ASD-associated SNPs in STNG2. Our result suggested that SNTG2 was not one of the major causative genes for ASD.

Role of Optineurin Sequence Variations in the Ghana Patients with Primary Open-Angle Glaucoma. *MA. Hauser[1], Y. Liu[1], CS. Cohen[2], K. LaRocque-Abramson[1], X. Qin[1], C. Santiago-Turla[2], LW. Herndon[2], P. Challa[2], D. Budenz[3], S. Schmidt[1], S. Akafo[4], RR. Allingham[1,2]* 1) Ctr Human Genetics, Duke Univ Medical Ctr, Durham, NC; 2) Department of Ophthalmology, Duke University Eye Center, Duke University Medical Center, Durham, NC; 3) Bascom Palmer Eye Institute, Miami, FL; 4) Unit of Ophthalmology, Department of Surgery, University of Ghana Medical School, Korle Bu, Ghana.

Glaucoma is a heterogeneous group of disorders that cause retinal ganglion cell loss resulting in optic nerve degeneration. Glaucoma is the leading cause for irreversible blindness worldwide. Primary open-angle glaucoma (POAG) is the most common type and is highly prevalent in persons of West African descent. Optineurin (OPTN, GLC1E) was initially identified as the causative gene in a set of pedigrees displaying autosomal dominant normal-tension glaucoma (NTG). Subsequently, variants of this gene have been shown to be associated with POAG in Indian, German, and Japanese populations, while playing a much less significant role in US Caucasians. In this study, we have explored the role of OPTN in a population collected in the western African country Ghana. Entry criteria for this study included glaucomatous optic nerve damage, associated visual field loss, and elevated intraocular pressure (>22 mm Hg in both eyes). Unaffected controls were also collected. All exons of the OPTN gene were sequenced in 190 Ghanaian POAG patients and 140 controls. Several coding variants were identified, including the E322K variant (rs523747) in exon 10, which is significantly associated with POAG (Chi-square $p = 0.04$). There were no significant differences on the frequencies of other identified variants between POAG cases and controls in this population. Our study represents the first OPTN screening with POAG patients from western Africa and suggests that variants in OPTN may play a role in POAG from those of West African descent.

A Functional *MMP12* Promoter Polymorphism is Associated with Increased Lung Function and Delayed Onset of COPD. *G. Hunninghake[1], M. Cho[1], M. Soto-Quiros[2], L. Avila[2], J. Lasky-Su[1,3], C. Lange[1,3], D. Demeo[1], C. Hersh[1], B. Klanderman[1], B. Raby[1], D. Sparrow[4], S. Shapiro[5], E. Silverman[1], A. Litonjua[1], S. Weiss[1], J. Celedón[1]* 1) Channing Lab, Brigham and Women's Hospital, Boston, MA; 2) Hospital Nacional de Niños, San José, Costa Rica; 3) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 4) VA Healthcare System and Department of Medicine, Boston University School of Medicine, Boston, MA; 5) Department of Medicine, University of Pittsburgh, Pittsburgh, PA.

Background: Genetic variants that influence lung function in children might ultimately contribute to the development of chronic obstructive pulmonary disease (COPD) in adults. Methods: We tested for association between single nucleotide polymorphisms (SNPs) in the gene for matrix metalloproteinase 12 (MMP12) and a measure of lung function (pre-bronchodilator FEV1) in over 5,400 subjects in five cohorts in: two family-based studies of childhood asthma, and three populations of adults including populations of individuals and families recruited on the basis of a subject with COPD, and a prospective study of initially healthy men in the Normative Aging Study (NAS). Within NAS, we also tested for association between SNPs associated with FEV1 and time to onset of COPD, and replicated findings in adults with severe, early-onset COPD. Results: Two correlated SNPs (rs737693 and rs2276109 [a known functional promoter variant]) were significantly associated with pre-bronchodilator FEV1, in populations of both children and adults, and in a combined analysis of all cohorts (P values=7.0 x 10-5 and 5.0 x 10-4, respectively). These SNPs were associated with a significantly reduced risk of COPD in subjects from the NAS (e.g., hazard ratio for rs2276109= 0.65, 95% confidence interval=0.46-0.92, P=0.02) and explained 28% of the population attributable risk of COPD. Similar associations with COPD were noted in a family-based study of subjects with early-onset COPD (P = 0.04 rs2276109). Conclusions: SNPs in MMP12 are associated with a reduced risk of COPD in adulthood, likely through a positive effect on FEV1 level in early life.

Transmission of KID syndrome by a mosaic parent for a *GJB2* mutation. *M. Titeux[1], V. Mendonça[3], A. Décha[1], E. Moreira[3], S. Magina[3,4], A. Maia[3], L. Lacaze-Buzy[2,5], J. E. Mejía[1], L. Torrão[3,4], F. Carvalho[4], J. Eça-Guimarães[3,4], A. Hovnanian[1,2,5]* 1) INSERM U563, Toulouse, France; 2) Reference Centre for Rare Skin Diseases, Toulouse, France; 3) Hospital de São João do Porto, Porto, Portugal; 4) University of Porto School of Medicine, Porto, Portugal; 5) Purpan Hospital, Department of Medical Genetics, Toulouse, F-31000 France.

KID syndrome associates keratitis, ichthyosiform lesions and neurosensory deafness. This is an autosomal, dominant disorder caused by specific, often sporadic mutations in the genes encoding connexin-26 and connexin-30 of gap junctions (*GJB2*, *GJB6*). Over 80% of known cases are caused by the recurrent c.148G>A (p.Asp50Asn) mutation of *GJB2*. We describe the first instance of KID syndrome transmission from a mosaic parent. The proband was a 27-month-old Portuguese boy born to non-consanguineous parents. He developed generalized keratotic plaques of the skin more prominent on the scalp and face, had no hair, eyebrows and eyelashes, showed dystrophic nails and palmoplantar hyperkeratosis. Deafness was clinically detected, and he developed bilateral corneal opacification. Cerebellar hypoplasia was observed by magnetic resonance imaging, in association with neuromuscular defects. The father was healthy, while the mother displayed hyperkeratotic, pigmented, segmental lesions on the chest and back along the Blaschko lines. Leukocyte DNA showed heterozygosity for the p.Asp50Asn mutation of *GJB2* in the patient but not in his parents. The mutation, however, was weakly detectable in the mothers lesional skin DNA, suggesting mosaicism, and its presence was confirmed by molecular cloning of the PCR amplimers. KID syndrome is thus a member of a growing group of disorders which can present with segmental cutaneous manifestations arising from mosaicism. It argues for systematic careful clinical assessment of parents of KID patients, and has consequences for genetic counseling due to the risk for their offspring of inheriting a generalized form of the disorder.

The association between genetic polymorphism of INSIG2 and obesity in Central Taiwan. *K.-Y. Tung[1], R.-Y. Wang[2], K.-T. Chen[1], C.-J. Lin[3], M.-C. Hung[3], W.-C. Shy[3], C.-Y. Chen[2], T.-N. Wu[1], F.-Y. Wu[1]* 1) China Medical University, Environmental Health, Taichung, Taiwan; 2) China Medical University, Public Health, Taichung, Taiwan; 3) China Medical University, Nursing, Taichung, Taiwan.

In recently, diet change on food increasing rate of obesity prevalence in the world. The lipid metabolic gene, insulin-induced gene 2 (INSIG2), is putatively involved in the transcription of genes associated with regulating the lipid metabolism, and may play a key role in lipid metabolism. Our study aims are to investigate putative associations between genetic polymorphism of INSIG2 and obesity related indices. A total of 691 subjects participate our study. Subjects were recruited in 2007 from Central-western; Hsin-yi village in Nantou country (240 aboriginal subjects) and Taichung city (447 non-aboriginal subjects) in Taiwan. All subjects were adult recipients of national health insurance screening examination. Data on demographics, lifestyle habits and medical history were collected using a structural questionnaire. The subjects with a BMI 27 were classified as obese (n = 213). The rs7566605 polymorphism in the INSIG2 gene was genotyped by TaqMan assay. SAS statistical software was used to analysis the distribution of INSIG2 genotypes between the obese and non-obese groups. The results demonstrated that aborigines had a higher BMI than non-aborigines (28.5 kg/m2 vs. 24.3 kg/m2, p 0.0001). The subjects that carried GG genotype of INSIG2 had a higher BMI than GC or CC genotypes (26.3 kg/m2 vs. 25.5 kg/m2, 25.2 kg/m2; p = 0.03). After adjusting for confounding factors such as age, gender, ethnicity and waist circumference, the odds ratio for obesity that carriers the GC or CC genotype compared to the GG genotype was 0.55 and 0.33 (95% CI: 0.34 - 0.9 ; 95% CI: 0.15 - 0.7), respectively. In conclusion, our study showed that the GG genotype of rs7566605 on INSIG2 may as a risk factor for obesity. These findings may provide potential preventions or therapeutic strategies.

Relationship between the thrombophilic mutations or single nucleotide polymorphisms and pulmonary thromboembolism. *F. Atac[1], H. Verdi[1], AC. Yazici[2], A. Simsek[3], F. Eyupoglu[3], N. Ozbek[4]* 1) Dept Medical Biol & Genetics, Baskent Univ Fac Medicine, Ankara, Turkey; 2) Dept Biostatistcs,Baskent Univ Fac Medicine, Ankara, Turkey; 3) Dept Chest Disease and Tuberculosis, Baskent Univ Fac Medicine, Ankara, Turkey; 4) Dept Pediatric Heamotology, Baskent Univ Fac Medicine, Ankara, Turkey.

Thrombosis, is a complex and multifactorial disease that results from the interaction between predisposing of both inherited and acquired risk factors. There has been considerable interest in identifying molecular risk factors that predispose to thrombosis. The disequilibrium in haemostatic system is the key mechanism that enrolles at types of thrombosis. The point mutations and/or polymorphisms in the genes encoding coagulation factors shifts the delicate balance in haemostatic system toward thrombosis. Several genetic risk factors, especially factor V Leiden and prothrombin G20210A mutations have been reported to be related to VTE in Caucasians, but the relationship remains controversial in other populations. Since the prevalence of molecular risk factors for thrombosis varies greatly in different parts of the world, both in patients with thrombosis and in the general population, we felt it was prudent to evaluate further the relation between the thrombophilic mutations / single nucleotide polymorphisms and pulmonary thromboembolism phenotype in our population. 95 patients that are diagnosed as pulmonary thromboembolism by thorax CT or ventilation-perfusion scan were included in our study. Restriction fragment size analysis were performed by visualizing digested PCR products for Factor V Leiden (FVL G1691A), Factor V Cambridge (A1090G), Factor V A1299G, prothrombin G20210A, methylene tetrahydropholate reductase C677T . and Plasminogen activator inhibitor 1 4G/5G. The results of this study indicate that FVL (0.001) , Prt G20210A (0.001) and MTHFR C677T (0.001) may be suggested as risk factors for pulmonary thromboembolism in our population.

MATERNALLY DERIVED CHROMOSOME 1 IN A SIBLING PAIR WITH MENTAL RETARDATION, MICROCEPHALY, HYPOTONIA, EPILEPSY, FACIAL DYSMORPHISM, ATAXIA AND IMPAIRED SPEECH: CLINICAL AND MOLECULAR FINDINGS. *D. Aktas[1], GE. Utine[1], A. Aydin[1], K. Mrasek[2], A. Weise[2], N. Akarsu[1], T. Liehr[2], M. Alikasifoglu[1], E. Tuncbilek[1]* 1) Dept Genetics, Hacettepe Univ, Ankara, Turkey; 2) Universitatsklinikum Jena, Institut für Humangenetik und Anthropologie, Jena, Germany.

Whole-genome analysis using SNP oligonucleotide arrays allows identification of microdeletions, duplications and uniparental disorders. Here, we report on a sibling pair with mental retardation, microcephaly, hypotonia, epilepsy, facial dysmorphism, ataxia and impaired speech. GTG-banded chromosome analysis revealed as 46,XX,der(1)(:p34.2-q43~44::p34.2->pter). FISH and MCB analysis showed that the deletions were at 1p34.2 and 1q44. SNP oligonucleotide array analysis also detected these deletions as 2.9 Mb in size at 1p34.2 and 2.7 Mb in size at 1q44. The deleted region on 1p34.2 encompasses 33 genes, among them is GLUT1 gene (SLC2A1) (MIM*606777). Haploinsufficiency of GLUT1 leads to GLUT1 deficieny syndrome, which is characterised by epilepsy, developmental delay, microcephaly, hypotonia, ataxia and impaired speech. GLUT1 gene deficiency seemed to be most relevant in relation to phenotype of our patients. On the other hand, deleted region on 1q44 contains zinc finger protein and olfactory receptor genes. Since zinc finger genes have previously been shown to be involved in mental retardation, these zinc finger genes (SMYD3, ZNF695, ZNF670, ZNF669, ZNF124, ZNF496 and ZNF672) which are located at 1q44 may be related with mental retardation in our patients. The clinical phenotype of our individuals have clear similarities with previous cases, suggesting a specific phenotype of patients with 1q deletions. During the parental evaluation, the paternal karyotype was found normal. However, the maternal karyotype with GTG-banding as 46,XX,t(1;1)(p34.2;q44),del(6)(q16.1q21). To the best of our knowledge, this is the first report of a phenotypically normal woman with an interstitial deletion of region 6q16.1q21. With SNP array, breakpoint-associated imbalance on chromosome 1 was not identified; however, a deletion at 6q16.1q21 15.9 Mb in size was detected in the mother.

Changes in global DNA methylation in response to chronic consumption and withdrawal of folic acid is dependent on the MTHFR 677CT polymorphism. *K. Crider[1], E. Quinlivan[2], R. J. Berry[1], L. Hao[3], Z. Li[3], D. Maneval[2], T. Yang[2], S. Rasmussen[1], Q. Yang[1], J. Zhu[2,3], L. Bailey[2]* 1) NCBDDD, Division of Birth Defects and Developmental Disabilities, CDC, Atlanta, GA; 2) University of Florida, Gainesville, Fl; 3) Peking University Health Science Center, Beijing, China.

We evaluated the effect of the MTHFR CT polymorphism on global DNA methylation from a double-blind randomized trial in which Chinese women of reproductive age took supplements of folic acid (100, 400, 4000 g/day). DNA methylation was expressed as a % of methylated cytosines (measured by a novel LC-MS/MS assay) at enrollment, 1, 3, 6 months of supplementation, and after a 3 month washout period, stratified by MTHFR genotype (CC, CT, TT) (n=135; ~15 subjects/genotype x 3 treatment groups). Baseline methylation levels (4.4 0.12) were similar (p>0.25) across the MTFHR genotypes. Folic acid supplementation resulted in a 13.5% (p< 0.0001) decrease in global methylation after 1 month of exposure, independently of genotype and dose. After 6 months of supplementation, DNA methylation had returned to baseline in the TT-subjects taking 100 g, but not in CC-subjects, or in any subject receiving 4 mg/d. During the 3 month washout period DNA methylation decreased further in CC (40%) and CT (20%), but not significantly in the TT-subjects. This post-intervention decrease in methylation was both genotype and dose dependent. In conclusion, global DNA methylation response to folic acid supplementation and withdrawal varied by MTHFR genotype with a complex genotype-dose interaction.

New preimplantation genetic diagnosis for fatal surfactant deficiency caused by ABCA3 mutations. *B. Tazon-Vega, C. Zhang, K. Amoroso, Z. Rosenwaks, KP. Xu* CRMI, Weill Cornell Medical College, New York, NY.

Mutations in the ABCA3 gene can lead to lethal conditions caused by a deficiency in pulmonary surfactant. Our objective was to provide PGD to a couple with two specific ABCA3 mutations (intron 6: 613+4 a>g and exon 10: 1132g>a) together with linkage markers that would reduce the risk of misdiagnosis due to allele dropout (ADO) and could be applicable to other patients in the future. The couple had an affected neonate who died of surfactant deficiency. DNA was extracted from paraffin embedded tissue obtained from the deceased neonate. Four microsatellite markers flanking the ABCA3 gene were selected defining a 0.8 Mb region: D16S3024 - 0.68 Mb - D16S291 - 0.01 Mb - ABCA3 - 0.02 Mb - D16S664 - 0.09 Mb - D16S663. To detect the parental mutations, two restriction enzyme reactions were set up (HphI for intron 6 and AcuI for exon 10). Linkage and mutation analysis were performed for the family to determine haplotypes linked to the ABCA3 mutations. Markers and mutations were co-amplified in a pentaplex PCR from single lymphocytes to validate the method. Overall amplification efficiency was 83.4% and markers showed 10.3% of ADO. In this family markers D16S3024, D16S291 and D16S663 indicated the paternal and maternal carrier and normal alleles. For marker D16S291 the couple did not share any of the possible alleles allowing assessment of ADO. Marker D16S664 was not informative. Two IVF-PGD cycles were performed. Overall 17 eggs were retrieved, 15 were fertilized and all were biopsied obtaining 16 blastomeres. Two embryos were diagnosed as unaffected, 5 carriers (maternal) and 6 affected. Inconclusive results were obtained in two embryos showing the maternal normal haplotype and absence of the paternal haplotype. One recombination was detected between markers D16S3024 and D16S291. Unaffected embryos were not transferable due to poor development. Two embryos were transferred in both cycles resulting in a biochemical pregnancy the first time and no pregnancy the second time. One carrier embryo was cryopreserved. A new indication for molecular PGD is now available to reliably detect ABCA3 mutations causing fatal surfactant deficiency.

CA/TG-repeat instability as a factor impeding branch migration in Holliday junctions during homologous recombination. *M. G. Yakubovskaya[1], V. K. Gasanova[1], N. V. Ryadninskaya[1], G. A. Belitsky[1], V. I. Popenko[2], C. Gaillard[3], F. Struass[3]* 1) Institute of Carcinogenesis, Blokhin Cancer Rsearch Center RAMS, Moscow, Russia; 2) Engelgardt Institute of Molecular Biology, RAS, Vavilova 32, Moscow 117984, Russia; 3) Centre de Recherche des Cordeliers, 15 rue de l'Ecole de Medecine, 75006 Paris, France.

Homologous recombination provides an error-free way for double-strand break repair. However, its role in carcinogenesis of inherited cancer via loss of heterozygosity was demonstrated to exceed impacts of point mutagenesis. Homologous recombination can be modulated by a variety of factors, and deep knowledge of its molecular background is essential to control this type of genetic rearrangements. Some microsatellites represent hot-spots of homologous recombination. CA/TG-repeats, the most abundant microsatellites in the human genome, affect homologous recombination. One of the possible mechanisms is by the formation of noncanonical DNA structures impeding branch migration in Holliday junctions. We have studied this hypothesis with Holliday junctions formed by two PCR products, which sequences were identical except for an internal region containing either a random sequence or a (CA)31-repeat. A comparative electron microscopy analysis of the Holliday Junctions revealed a statistically larger number of cross points in the internal regions of structures with repeats. Internal CA-regions of different duplexes were shown not to interact. Using native polyacrylamide gel electrophoresis in combination with restriction fragment length polymorphism analysis, one-side or one-round amplifications and electrophoresis in denaturing conditions, we showed CA-repeat instability in PCR causing formation of homo- and heteroduplexes. As CA-repeat instability greatly exceeds DNA-polymerase error both in vitro and in vivo, and since microsatellite heterozygosity by several repeat units is widely spread in eukaryotes, this repetitive sequence heterology appears to be a structural background for formation of Holliday junctions with repetitive sequences at the cross-points, that enhances probability of homologous recombination termination in the repeat region.

Further Explorations in the Genetics of Age-related Maculopathy (ARM). *D. E. Weeks[1,2], J. Jakobsdottir[2], Y. P. Conley[1,3], R. E. Ferrell[1], M. B. Gorin[4]* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA, USA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, PA, USA; 3) Department of Health Promotion and Development, School of Nursing, University of Pittsburgh, PA, USA; 4) Department of Ophthalmology and Jules Stein Eye Institute, The David Geffen School of Medicine, UCLA, CA, USA.

A combination of strategies have been used to successfully identify susceptibility genes for ARM including family-based linkage studies, locus-specific and genome-wide SNP, and candidate-based genotyping. We have integrated the results of multiple linkage studies and the AREDS public genome-wide association findings with an extensive set of 587 genes based on known and hypothesized biological pathways in the etiology of ARM. We created a prioritization strategy to develop a panel of 1381 SNPs for association studies with the Center for Inherited Disease Research. A gene was selected if 1) AREDS associated P-value 0.005, 2) AREDS associated P-value 0.05 and ranked among top 50 genes based on HLOD or S_{all} ranks from our local linkage scan, 3) AREDS associated P-value 0.05 and located in a region supported by the meta-analysis of ARM linkage scans, 4) ranked among top 50 genes based on local linkage scan and located in a region supported by at least one other scan, 5) AREDS associated P-value 0.05 and located in a region supported by at least one linkage scan other than ours, and 6) located in a region supported by at least two linkage scans other than ours. This left 111 genes of interest, 73 of those are known to be expressed in the eye. SNPs were tested for allelic associations using the MQLS statistic. We successfully replicated known associations for SNPs linked to CFH, C2, C3, and HTRA1/LOC387715 with P-values 10^{-28}, 10^{-6}, 10^{-5}, and 10^{-12}, respectively. We also found several complement factor H related loci and a few novel genes that do not appear to be directly related to the complement activation pathway. We are pursuing replication studies of these new loci in a separate cohort.

The diploid genome sequence of an Asian individual. *J. Wang* Beijing Genomics Institute at Shenzhen, Shenzhen, 518083, Huada Genomics Institute, Shenzhen University Medical School, Shenzhen, 518083, China.

We present the diploid genome sequence of the first Asian individual. The genome was sequenced to 36-fold average coverage, using massive parallel sequencing technology. By aligning the short reads onto the NCBI reference genome, 99.6% of the genome has been covered, and variations, detected using the assembled high-quality consensus sequence, covered 92% of the whole genome. Approximately 3 million SNPs were identified, of which 13.6% were not in dbSNP. SNP detection accuracy was measured by comparing the assembly with the genotyping analysis and showed that 99.2% of the 1M genotyped alleles have been covered at a 99.9% consistency. The majority of the remaining unconfirmed SNPs were validated using PCR amplification and Sanger sequencing. The high amount of consistency in the alleles of the assembly with those identified via genotyping indicates that this sequence is the highest quality of all currently available human genome sequences. The heterozygotes were phased, and haplotypes were predicted against HapMap CHB/JPT haplotypes. Paired-end reads were used to discover structural variations and short indels. We carried out further analysis on identified variations that might potentially change gene function or be associated with known diseases or phenotypes. Our data and characterization of the variations demonstrated the usefulness of next-generation sequencing technologies for personal genomics.

Polymorphisms of plasminogen activator inhibitor 1 gene associated with diffuse type gastric cancer susceptibility. *H. Ju, C. Kang* Biological Sciences, KAIST, Daejeon, Korea.

Plasminogen activator inhibitor 1 (PAI1) regulates physiological thrombotic and fibrinolytic processes by inhibiting plasminogen activator. It also has roles in regulating tumor invasion, angiogenesis and metastasis, and many clinical studies have found that high levels of PAI1 are correlated with poor prognosis for cancers. In this case-control association study using 250 Korean gastric-cancer patients and 400 non-patient controls, we found that several single-nucleotide polymorphisms (SNPs) in PAI1 were significantly associated with susceptibility to diffuse-type gastric cancer. The most significant association was found for a SNP in the intron 7 region and the risk variant increased the susceptibility to diffuse-type gastric cancer by 1.4-fold (P = 0.0019) versus the non-risk variant, but not the susceptibility to intestinal-type gastric cancer. When fused to the luciferase gene, the intron 7 sequence reduced the luciferase activity by 4-fold. No significant difference was found, however, between the risk and non-risk variants. Further studies are in progress towards identifying functional polymorphisms affecting the susceptibility to diffuse-type gastric cancer.

Analysis of IRF6 gene in Van der Woude syndrome from an Indian population. *A. Ali[1], S. Singh[2], R. Raman[1]* 1) Department of Zoology, Banaras Hindu University, Varanasi, India; 2) G S Memorial Hospital, Varanasi, India.

One of the most common congenital malformations, the cleft lip and/or cleft palate (CL/P) when associated with lower lip pits is known as Van der Woude syndrome (VWS), the most common form of CL/P. Till now 2 loci have been mapped for VWS; 1q32-41 and 1p34. Only one gene IRF6 which resides in 1q32-41 region is known to cause VWS in various populations. Mutations were found in 70% of VWS cases. More than 70 mutations have been reported to date in IRF6 in VWS cases. There is no report of genetic study of VWS on Indian population. To screen for mutations in IRF6 gene in VWS cases from an Indian population, resequencing of all coding regions and exon-intron boundaries of IRF6 gene in 13 individuals (9 affected and 4 unaffected) from 7 Van der Woude syndrome families as well as 5 normal controls was performed. We have detected 5 novel variants; IVS1+ 3900 A>G, 191 T>C, IVS4+ 775 C>T, IVS8+218 C>T, 1511 T>A (Ser 416 Arg) and 2 known variants; IVS6+27 C>G, 1083G>A (V274I). Except one, all were in non-coding regions either in 3 UTR or in introns, while one was in coding region detected in a normal control. In this cohort, we report lack of any mutation in the coding region of the affected individuals. All but one of the variants obtained in probands were also found in one or other unaffected family members and/or controls. In an independent case-control study from this population, on the association of IRF6 820G>A SNP with nonsyndromic cleft lip with or without cleft palate (NSCLP) on 761 individuals including probands, their parents and normal controls, we have found the frequency of putative risk allele G in the probands (0.88) to be higher than the normal controls (0.81) but lower than mothers (0.89), and fathers (0.92). This study showed a statistically significant difference of IRF6 820G allele between the case and controls but this appears to be only a weak risk factor for NSCLP in this population. Though screening a larger number of VWS samples will allow a more reliable view, the present report indicates that point mutations in IRF6 gene may not be a major cause of VWS in Indian population from the eastern region.

Broad clinical spectrum in Silver-Russell syndrome and consequences for genetic testing. *N. Schoenherr[1], S. Spengler[1], D. Gonzalez[2], M. Arslan-Kirchner[2], G. Binder[3], T. Eggermann[1]* 1) RWTH Aachen; 2) MH Hannover; 3) University Tübingen.

Silver-Russell syndrome (SRS) is a heterogenous disorder characterised by severe intrauterine growth restriction, lack of catch-up after birth (IUGR/PNGR) and specific dysmorphisms. In ~10% of patients maternal uniparental disomy of chromosome 7 (UPD(7)mat) is detectable. Hypomethylation of the ICR1 in 11p15 can be discovered in ~63% of typical SRS patients fulfilling strict criteria defined by Netchine et al. (JCEM 2007:92:3148-54) (length/weight at birth -2SD; 3/5 of the following criteria: PNGR, relative macrocephaly, asymmetry, prominent forehead, feeding difficulties). Single patients carry chromosomal aberrations. Due to the heterogeneity of SRS the clinical diagnosis is difficult and the detection rate for disturbances is relatively low. We tested 161 SRS patients from routine diagnostics and 20 patients referred as isolated IUGR/PNGR for 11p15 (epi)mutation and UPD(7)mat. In the SRS group ICR1 hypomethylation was identified in 23 and UPD(7)mat in 4 patients. None of the patients with isolated IUGR had a 11p15 (epi)mutation but two carried a UPD(7)mat. Interestingly some SRS patients with a ICR1 hypomethylation showed only slight IUGR (>-2SD) while the two isolated IUGR/PNGR patients with UPD(7)mat were retrospectively identified as mild SRS. Despite the scarce clinical data we can show that the phenotypic spectrum is broad and that several (epi)mutation or UPD(7)mat carriers would be missed if we consider strict diagnostic criteria. Based on our experience we propose to test (a) severely growth retarded patients (-2SD) even when only minimal SRS features are present and (b) probands with isolated asymmetry and mild growth retardation. Testing should include: (1) Methylation-specific (MS) MLPA for detection of 11p15 (epi)mutations. (2) MS-PCR for the PEG1/MEST locus. In case of UPD(7)mat the results should be confirmed by microsatellite typing to exclude (so far unreported) isolated imprinting defects. Although the MS-PCR test is restricted to a narrow region in 7q it would detect all reported segmental UPD(7)mat cases. (3) Cytogenetic analyses should be done.

Description of a four-generation family with autosomal dominant cerebellar ataxia: clinical and genetic analysis.

F. Annesi[1], D. Italiano[2], G. Provenzano[1,3], P. Tarantino[1,3], E. V. De Marco[1], D. Civitelli[1], A. Laganà[3], A. Gambardella[1,4], P. Bramanti[2], G. Annesi[1], A. Quattrone[1,4] 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) IRCCS Centro Neurolesi Bonino-Pulejo, Messina, Italy; 3) Department of Neurosciences, of Psychiatric and Anaesthesiological Sciences, First Neurology Clinic, University of Messina, Italy; 4) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

SCAs are a heterogeneous group of neurodegenerative disorders, principally characterized by imbalance, dysarthria. To date, about 29 genetic loci associated to Mendelian forms of SCA are known, and a number of SCA genes have been identified. We performed a genetic analysis of a family from southern Italy, with a form of slowly progressive SCA. 14 subjects (7 affected) from a SCA family with 15 affected members in 4 generations have been evaluated. The disease seems to display an autosomal dominant pattern of inheritance with elevated penetrance. The mean age at onset was 34 years with a strong evidence of anticipation across generations. The first symptoms were invariably legs heaviness, imbalance, or dysartria. We performed mutational analysis by PCR searching for the most common SCA mutations. Two-point linkage analysis for known SCA genetic loci was calculated with the LINKAGE program package. Mutational analysis excluded pathological repeat expansions in the SCA 1, 2, 3, 6, 7, 8, 12, 17 and DRPLA genes. Linkage exclusion tests showed no evidence of association with most of known mapped SCA loci (SCA4, SCA5, SCA13-16, SCA19-22, SCA25 and SCA27-29). SCA prevalence in Italy significantly differs from European countries because of the very low prevalence of SCA 3 and SCA 6. 45% of the Italian families are associated with SCA1 and SCA2 genotypes, and only a small percentage of cases exhibited expansions in SCA3, SCA6, SCA7, SCA17 and DRPLA genes. In this large family, mutational analysis excluded the presence of all the main common SCA gene mutations, and linkage analysis ruled out the association with most of the so far reported SCA genetic loci. This could suggests a genetically distinct form of SCA.

Characteristics of SNPs Associated with Complex Traits in Genome-Wide Association (GWA) Studies: The NHGRI GWA Catalog. *L. A. Hindorff, J. P. Struewing, E. M. Ramos, H. A. Junkins, T. A. Manolio* Office of Population Genomics, NHGRI, NIH, Bethesda MD.

Over 150 GWA studies have implicated SNPs influencing a wide array of common diseases and traits, but characteristics of these SNPs have not been systematically examined. For GWA studies published through May 8, 2008 and attempting to assay at least 100,000 SNPs, we identified up to five replicated but previously unreported SNP-trait associations at $p < 9.5 \times 10\text{-}6$. Estimates of risk allele frequencies, sample sizes, and odds ratios (OR) were extracted from the published reports; attributable risk percents (AR%) were calculated from published ORs. Genomic characteristics of these SNPs were retrieved from dbSNP, the HapMap website, and the UCSC Genome Browser. Genetic distances were estimated for each SNP for the three main HapMap populations. Of 284 unique SNPs identified, 139 (49%) were in genic regions. Fourteen SNPs (5%) were missense variants, 3 (1%) were synonymous coding variants, 2 were in a 5 UTR, 2 in a 3 UTR, and 118 (42%) were intronic. Median genetic distances between the HapMap YRI and CEU populations, and between YRI and JPT+CHB, were 0.023 and 0.028, respectively; 95th percentile values were 0.16 and 0.192, respectively. Reported risk allele frequencies ranged from 5%-97% (median 41%); only 3.5% of risk alleles were present at frequencies of 10% or lower. For SNPs associated with binary outcomes, reported ORs ranged from 0.43 to 20.1 (median 1.27), which translated into AR% of 3%-95% (median 22%). Several complex traits of public health interest were represented among those with AR% > 50%, including diabetes and stroke. Though SNPs assayed on genotyping platforms are likely to be overrepresented here, these results suggest that a systematic review of SNPs implicated in GWA studies may yield useful insights into the nature of genetic variation influencing complex traits. Additionally, the modest to strong increase in disease risk attributable to several genetic variants may guide future studies that assess whether these variants, or variants in linkage disequilibrium, are of clinical or public health significance.

Primary torsion dystonia due to Tor1A GAG deletion in 3 Turkish Patients. *U. Yilmaz[1], FB. Atac[2], D. Yuksel[1], H. Verdi[2], D. Yilmaz[1], N. Senbil[1]* 1) Dr.Sami Ulus Pediatrics Hospital, Ankara, Turkey; 2) Dept Medical Bio and Genetics, Baskent Univ Fac Medicine Ankara, Turkey.

Primary torsion dystonia (PTD) is a clinically and genetically heterogeneous movement disorder which is characterized by involuntary sustained muscle contractions. The 3-bp (GAG) deletion in the TOR1A (DYT1) gene was found in patients with PTD linked to 9q34. In this study, 3 patients who have attended to our clinic with dystonic symptoms and have demonstrated GAG deletion in DYT1 gene have been described. In these 3 patients although the diagnosis have been done when they were in 9, 9 and 12 year-old, their symptoms started respectively at the age of 3, 7 and 2. The symptoms began focally at the right hand in two patients and multifocally in both hands in the third patient. None of the patients had a family history and their parents were not relatives. In their initial examination, except dystonia there was not any other pathologic finding. All the patients cranial magnetic resonance imagings, serum copper - ceruloplasmin levels, urine - blood aminoascites and urine organic ascite levels were normal.The results of the molecular analyisis reveals the existance of GAG deletion in TOR1A gene. Their fundoscopic examination were also normal. During two year follow-up period, the patient with multifocal beginning had no progression in his symptoms and had benefit from anticholinergic therapy. In one of the patients who had a focal beginning at the right hand, the dystonia spread to the left arm and in the other patient spread to the right leg and inspite of various therapies these patients didnt show any significant improvement. This finding is in harmony with the articles reporting that the primary dystonia with juvenile onset has a more rapid progression than the adult onset primary dystonias. Although there have not been large case series in DYT1 primary torsion dystonia, the average beginning age have been reported as 11. In our patients it has been observed that the beginning age of the dystonic symptoms were younger.

Development of specific biologic tests for B and T immune response against type VII collagen: tools for gene therapy in RDEB patients. *V. Pendaries[1], G. Alberola[1], M. Titeux[1], C. Leroux[2], Z. G. Vitezica[1], J. Mejia[1], A. Décha[1], C. Prost[2], A. Hovnanian[1,3]* 1) U563, Inserm, Toulouse, France; 2) Avicenne Hospital, Bobigny, France; 3) Purpan Hospital, Toulouse, France.

Dystrophic epidermolysis bullosa (DEB) is a severe inherited skin disorder caused by loss-of-function mutations in COL7A1 encoding type VII collagen, the component of anchoring fibrils. In the auto-immune blistering disease, epidermolysis bullosa acquisita (EBA), circulating autoantibodies are produced against type VII collagen, while patients with vesiculobullous systemic lupus erythematosus (VBSLE) also display antibodies against this protein. To assess the immunologic risk in recessive DEB patients during gene therapy restoring type VII collagen expression, we developed ELISA and ELISPOT assays using the full-length type VII collagen molecule. Biochemical analysis of secreted type VII collagen demonstrated that this protein assembled into trimers and adopted a triple-helical conformation. The ELISA and ELISPOT assays were performed on a cohort of 44 untreated EBA and VBSLE patients. The ELISA assay detected type VII collagen circulating antibodies with high specificity (95%), sensitivity (65%) and predictive positive value (91%). The ELISPOT assay detected a Th1 immune response against type VII collagen, which correlated with disease activity. We subsequently tested 4 RDEB patients. The ELISA assay was positive for anti-type VII collagen antibodies in one of the 2 patients who did not express detectable type VII collagen. The two patients who expressed low levels or a truncated form of type VII collagen were non-responsive in the ELISPOT assay. Conversely, a positive Th1 immune response was observed in the 2 RDEB patients who expressed no type VII collagen. HLA typing of EBA and RDEB patients is in progress to determine if a specific HLA subtype is a risk for developing an immune response against type VII collagen. The immunologic tests for the B and T immune response to type VII collagen that we have developed will be useful to select candidates for clinical trials of gene therapy for RDEB. They will also be essential to the immunological follow-up of treated RDEB patients during these trials.

Fetal Constraint as a Potential Risk Factor for Craniosynostosis. *P. A. Sanchez-Lara[1], S. L. Carmichael[2], J. M. Graham, Jr.[3], E. J. Lammer[4], S. A. Rasmussen[5]* 1) Childrens Hospital Los Angeles, Los Angeles, CA; 2) California Research Division, March of Dimes, Oakland, CA; 3) Medical Genetics Institute, Cedars-Sinai Medical Center; 4) Childrens Hospital Oakland Research Institute, Oakland, CA; 5) Centers for Disease Control and Prevention, Atlanta, GA.

Fetal head constraint has been hypothesized to contribute to the risk of craniosynostosis(CS). We used data from the National Birth Defects Prevention Study to evaluate for an association between CS and factors potentially indicative of fetal constraint which included multiple gestation (twins or higher), macrosomia (birth weight >4000 g), post-term gestational age (>42 weeks), and parity (nulli- or primiparity). Case infants (n=677) had CS documented either by radiographic evidence or by surgical intervention, excluding those with known or suspected genetic conditions. Control infants (n=5,958) had no major birth defects and were randomly selected from the same population as case infants. Logistic regression estimated the odds ratios for association, while adjusting for several covariates (maternal age, race-ethnicity, education, body mass index, fertility treatments and parity, paternal age, and infant sex). The reported adjusted odds ratios (aOR) includes adjustment for the above covariates and exclusion of certain subjects. Specifically, for plurality, we excluded subjects whose mothers had fertility treatments or pre-pregnancy or gestational diabetes, and for the remaining exposure variables, we excluded subjects from multiple gestations and subjects whose mothers had pre-pregnancy or gestational diabetes. Results: multiple gestation (compared to singletons), aOR 1.7, 95% CI 0.9-3.0;, macrosomia (compared to normal birth weight), aOR 1.1 95%, CI 0.9-1.5; prolonged compared to term gestation, aOR 1.1, 95% CI 0.6-2.3; and no and one previous live birth, compared to two or more, aOR 0.9, 95% CI 0.7-1.2, and aOR 0.9, 95% CI 0.7-1.2, respectively. A lack of dural stretch has been proposed as a mechanical signal for premature suture closure. We found that the studied factors- multiple gestation, macrosomia, prolonged gestation and nulliparity-were not associated with CS, after adjusting for potential confounders.

Genetic variation in folate pathway enzymes exhibit sex-specific association in cases of Down syndrome-associated congenital heart defects. *A. E. Locke[1], E. G. Allen[1], S. W. Tinker[1], K. J. Dooley[2], G. Capone[3], C. Cua[4], E. Feingold[5], S. L. Sherman[1], L. J. H. Bean[1]* 1) Dept of Human Genetics, Emory University, Atlanta, GA; 2) Sibley Heart Center Cardiology, Children's Hospital of Atlanta, Atlanta, GA; 3) Division of Neurology and Developmental Medicine, Kennedy Krieger Institute, Baltimore, MD; 4) Nationwide Children's Hospital, Columbus, OH; 5) Depts of Human Genetics and Biostatistics, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA.

Folate is a nutrient vital for nucleotide synthesis, DNA and protein methylation, and homocysteine to methionine conversion. Maternal folate deficiency has been associated primarily with neural tube defects, but also with other birth defects including heart defects. Additionally, numerous studies have associated maternal polymorphisms in folate pathway genes with the risk of having a child with Down syndrome (DS). We hypothesized that folate pathway polymorphisms contribute to the high incidence of heart defects observed in fetuses with Down syndrome. These effects could be exaggerated in females with DS who have a higher methylation burden and, as we have shown, an increased risk of AVSD. Cases defined as individuals with DS and complete atrioventicular septal defect (AVSD) (93 white, 29 black) were compared to controls, defined as individuals with DS with no heart defect (94 white, 28 black). SNPs in the folate pathway genes MTHFR, MTR, MTRR, and CBS as well as the reduced folate carrier gene SLC19A1 were gentoyped. Consistent with our hypothesis transmission of the c.2756AG MTR G allele (rs1805087) was significantly associated with the risk of AVSD in families with a female, but not a male proband ($p = .002$). Transmission of SNPs within the MTHFR gene show evidence for complex survival factors that will be further investigated. Statistical methods to make genotype calls from Illumina data on trisomic chromosome 21 SNPs in CBS and SLC19A1 have been developed and the potential role of polymorphisms in these genes contributing to the risk of AVSD is being evaluated. Epidemiologic data will be used to explore the relationship between dietary folate, genotype, and AVSD susceptibility.

Potential interactors of PHOX2B as candidate genes for orphan central hypoventilation and companion disorders. *S. Parodi[1,2], T. Bachetti[1], S. M. Kooistra[3], R. Ravazzolo[1,2], I. Ceccherini[1], B. J. L. Eggen[3]* 1) Lab di Genetica Molecolare, Istituto Giannina Gaslini, Genova, Italy; 2) Dipartimento di Pediatria, Università degli Studi di Genova, Genova, Italy; 3) Developmental Genetics, Groningen Biomolecular Sciences and Biotechnology Institute,University of Groningen, Haren, Netherlands.

The PHOX2B gene encodes a 314 amino acids paired box homeodomain transcription factor known to play a key role in the development of the central and peripheral autonomic nervous system. Accordingly, Phox2b-/- mice die in utero with absent autonomic nervous system circuits, as those neurons either fail to form or degenerate. In particular, Phox2b has been implicated in the specification of neuronal subtypes, acting as determinant of the noradrenergic phenotype. Mutations of the PHOX2B gene have recently been associated with Congenital Central Hypoventilation Syndrome (CCHS or Ondines curse), a life-threatening disorder characterized by impaired autonomous breathing and other autonomic dysfunctions such as neuroblastoma and Hirschsprung disease. Although the function of this trascription factor in the noradrenergic neuron differentiation is well studied, the PHOX2B pathway remains poorly understood. In order to identify interaction partners of PHOX2B, we carried out a yeast two-hybrid screen using a 11 day mouse embryo pretransformed cDNA Library. Among many interacting clones obtained, we focused on proteins known to localize in the nucleus, to modulate transcriptional activities or to act as chromatin remodelling factors. In particular, we are evaluating, by co-immunoprecipitation and co-localization assays, an actin related protein, specifically expressed in the brain and in differentiated neurons and a nuclear factor whose knockout mouse model dies at postnatal day 1 exhibiting failure to suckle, cyanosis and respiratory distress. Indentification of PHOX2B interactors represents an useful step towards the reconstruction of a full genotype-phenotype correlation in CCHS as well as an alternative way to discover new candidate genes for orphan central hypoventilation and companion disorders.

GENETIC ANALYSIS AND EPIDEMIOLOGICAL DISTRIBUTION OF SPANISH SPINOCEREBELLAR ATAXIAS. *V. Volpini[1], J. Corral[1], I. Banchs[1], L. De Jorge[1], H. San Nicolas[1], O. Combarros[2], J. Berciano[2], C. Serrano[3], M. Calopa[4], A. Matilla[5], D. Genís[6]* 1) Center for Molecular Genetic Diagnosis of Hereditary Diseases, CDGM-IDIBELL, L'Hospitalet de Llobregat, Spain; 2) Dept. of Neurology, Hosp.Univ. Marqués de Valdecilla, Santander, Spain; 3) Dept. of Neurology, Hosp. Sant Joan de Déu, Martorell, Spain; 4) Dept. of Neurology, Hosp. Univ. de Bellvitge, L'Hospitalet de Llobregat, Spain; 5) Health Sciences Research Institute Germans Trias i Pujol, Badalona, Spain; 6) Dept. of Neurology, Hosp. Univ. Josep Trueta, Girona, Spain.

Autosomal dominant cerebellar ataxias (ADCA) are a clinically and genetically heterogeneous group of neurodegenerative disorders in which several spinocerebellar ataxia (SCA) genes have been cloned: SCAs1-3, SCAs6-7, SCA12 and SCA17; sharing a CAG repeat expansion mutations which generally encodes a polyglutamine tract. In SCA8 the mutation is an untranslated CTG repeat. We have analyzed 353 unrelated familial and 1,043 sporadic and idiopathic cases of SCA. Over the familial cases 6.00% were SCA1; 26.67% SCA2; 33.33% SCA3; 7.33% SCA6; 6.67% SCA7; 14.67% SCA8 and 1.33% SCA17. In 22 familial index cases with SCA8 expansions the allele range goes from 85 to 470 repeats (129.32%67.55%; Pearson Coef.=52.24%). Maternal transmissions presented elongations of the CTG combined sequence ranging from +2 to +11 repeats (5.334.93; Pearson Coef.=92.49%). In contrast, paternal transmissions presented contractions ranging from -1 to -17 repeats (-9.756.89; Pearson Coef.=-70.75%). Several giant SCA8 expansions ranges from 401 to 1126 (N= 9), carried by unaffected adult individuals and being originated from homozygous SCA8 females with alleles of moderate size. In contrast,the homozygous males have transmitted contracted alleles, as in heterozygous cases occurs. We have tested 90 individuals from general population and the distribution of SCA8 alleles could be classified in two groups: 15 to 34 CTGs with frequency 98% and 77 to 86 CTGs with frequency 2%. About 60% of familial ADCA cases remained genetically unclassified. No SCA mutations were detected in the 1,043 isolated and idiopathic cases of spinocerebellar ataxia.

GENETIC INTERACTIONS BETWEEN 2 OLIGOGENIC DISEASES: BARDET-BIELD SYNDROME AND HIRSCHSPRUNG DISEASE. *L. de Pontual[1], S. Thomas[1], H. Dolffus[2], C. Baumann[3], S. Audollent[1], A. Pelet[1], N. Katsanis[4], P. Beales[5], A. Munnich[1], H. Etchevers[1], S. Lyonnet[1], T. Attie-Bitach[1], J. Amiel[1]* 1) Dept Genetics, Hosp Necker-enfants Malades, Paris, France; 2) Service de Génétique, Hôpital de Haute-Pierre, Strasbourg, France; 3) Service de Génétique, Hôpital Robert Debré, Paris, France; 4) McKusick-Nathans Institute of Genetic Medicine, Baltimore, Maryland; 5) Molecular Medicine Unit, London, United Kingdom.

Bardet-Biedl syndrome (BBS, MIM 209900) is an autosomal recessive multisystemic disorder genetically heterogeneous with 13 BBS genes hitherto identified. BBS proteins are involved in primary ciliary and basal body function, affecting both transport and signalling of the planar cell polarity pathways. BBS patients are predispose to Hirschsprung disease (HSCR, MIM 164761) as it is reported in 5 to 10% of the cases versus 1/5000 in the general population.RET is the major gene in HSCR. We genotyped the hypomorphic allele located in a conserved non-coding sequence in intron 1 of the RET gene in 54 BBS patients with or without HSCR. In this series, mutations in BBS 1- 2- 4- 5- 7 and 10 have been identified, and no correlation between the genotype and the phenotype could be drawn as espected by the observation of intrafamilial variability of expression. We report an over-transmission of the RET hypomorphic allele in sporadic BBS+HSCR cases and we show that the RET hypomorphic T allele can account for the variability of HSCR expression within BBS families. We then demonstrated co-segregation of both BBS gene mutations and the RET hypomorphic allele HSCR patients only within BBS familial cases. Moreover, we identified a 11bp deletion encompassing a DNA binding site for the transcription factor SNAIL (will be confirmed by ChiP) in a RET enhancer in a sporadic case of BBS+HSCR. These data strengthen the role of the RET gene in the co-occurrence of BBS and HSCR and, suggest genetic interactions between two oligogenic disorders. Functional studies have been undertaken to demonstrate a possible role of BBS proteins on human neural crest cells migration.

Pure partial trisomy 19p : identified by MLPA subtelomeric screening. *H. Yoshihashi, N. Furuya, K. Kurosawa*
Dept Med Gen, Kanagawa Children's Med Ctr, Yokohama, Japan.

Submicroscopic subtelomeric chromosomal rearrangements are considered to be a significant cause of idiopathic mental retardation (MR). Unbalanced rearrangements involving chromosome 19, which has a greater density of genes than any other human chromosome, are expected to have serious clinical implications. Reports of rearrangements involving chromosome 19 are quite uncommon. In particular, few malformed individuals with partial trisomy 19p accompanying partial monosomy of different chromosomes have been reported. Both participating choromosomes contribute to the phenotype, producing complex malformation patterns. Here, we report on an infant with pure partial trisomy 19p. Case: The propositus was a 3-year-old girl. At 30 weeks of gestation, she was born by Cesarean delivery due to fetal asphyxia. Birth weight was 826 g (-2.7SD), length 32 cm (-2.9SD), and head circumference 23 cm (-2.7SD). She had growth retardation(IUGR), developmental delay, and distinctive facial appearance (telecanthus, sparse hair, micrognathia, long philtrum, bulbous nose). Standard karyotype was normal. Cytogenetic study: Multiplex-Ligation Probe Amplification (MLPA) has come into wide use for subtelomeric screening as a new molecular cytogenetic technique. Subtelomeric assay using MLPA with SALSA P036B and P070 kits (MRC-Holland) revealed only gain of the short arm of chromosome 19. The metaphase FISH with a telomere probe specific for 19p and 19q (Vysis, Downers, Grove, IL) showed that the extra 19ptel signal was present at the short arm of chromosome 13. Based on our FISH mapping analysis, we estimate the size of trisomic region from 19p13.3 to be approximately 3.0-3.8Mb. The parents had normal karyotype and showed no abnormal hybridization results. The duplication of 19ptel was confirmed as de novo subetelomeric imbalance. Summary: We review four reports of individuals with partial trisomy for terminal 19p rearrangements (Byrne et al.,1980; Salbert et al.,1992; Brown et al., 2000; Quigley et al., 2004). To our knowledge, the present case is the first report of pure partial trisomy 19p and contributes to a bettter clinical characterization of duplication of 19ptel.

Lethal hypophosphatasia with spina bifida, a diagnostic delimma. *H. I. Alzaidan[1], M. Alowain[1], D. Arafah[1], H. Abalkhail[2]* 1) Medical Genetics, King Faisal Specialist Hospital and Research ctr, Riyadh, Riyadh-11211, Saudi Arabia; 2) Pathology department, King Faisal Specialist Hospital and Research ctr, Riyadh, Riyadh-11211, Saudi Arabia.

Hypophosphatasia is an autosomal recessive disorder characterized by a defect in mineralization of bone with low activity of serum and bone alkaline phosphatase (ALP). There are different forms of clinical presentation according to the age of onset and severity of the disease. We report a newborn of a consanguineous couple who died shortly after birth because of severe pulmonary insufficiency. He was labeled initially by prenatal U/S to have (lethal skeletal dysplasia). examination revealed dysmorphic newborn with large head, absence of the skull bones, short thick extremities and lumbosacral myelomeningocoele. The diagnostic thinking process represents a great prototype of the diagnostic challenge that dysmorphologist and skeletal dysplasia experts face while approaching such cases. Chromosomal analysis showed normal male karyotyping; babygram revealed very abnormal limbs with short, poorly formed and demineralized bones, large head with deficient ossification of the skull vault. Appearance was suggestive of lethal osteogenesis imperficta(OI) as per our radiologist. Skin biopsy was sent initially for COL1A1 and COL1A2 the only known genes for autosomal dominant OI and came back negative for mutations. Then we considered cartilage associated protein CRTAP as a potential cause at that stage which is rarer, recently described cause for AR lethal OI. however discussing the X rays findings with the experts in the field of dysplasia raise the possibility of AR Hypophosphatasia as cause. this turned to be the case when we found a homozygous previously reported c.977GT transversion in exon 9 of alkaline phosphatase ALPL gene. It take us more than a year to diagnose the case. We report this case to document the association between Myelomeningocoele and hypophosphatasia which is "up to my knowledge" not reported before. Furthermore, we want to stress the need to include alkaline phosphatase in any case of lethal dysplasia. This probably will save the physician a lot of precious time and effort.

Difficulty of clinical diagnosis of Japanese children with Marfan syndrome. *H. Kawame[1], S. Yasukochi[2]* 1) Div Medical Genetics,; 2) Dep Cardiology, Nagano Children's Hospital, Nagano, Japan.

Marfan syndrome (MFS) is a systemic connective tissue disorders caused by mutations in the FBN1 gene. It is characterized with variety of skeletal, cardiovascular, ocular manifestations. Aortic root aneurysm and dissection are major cause of mortality. Early diagnosis is crucial for appropriate management including medical therapy of beta-adrenergic blocker and potential drug, Losartan, and prophylactic surgical procedures. The diagnosis of MFS is based clinical ground according to the Ghent criteria. But application to childhood MFS is challenging, because of age-dependent nature of manifestations. Also standards for clinical features such as dolichostenomelia have not been applicable for Asian ethnic population. In order to evaluate the phonotypic spectrum and value of Ghent criteria for Japanese children with MFS, we reviewed 13 children (age range: 2 - 16 years) with MFS or suspected MFS referred to our Genetic clinics in Nagano Childrens Hospital from 2002 to 2007. Seven were familial cases.

Four (5, 7, 11, 11 years) familial cases and one sporadic case (16 years) (38%) fulfilled the Ghent criteria. In skeletal system, all had involvement and no patient presented major criteria. None had arm span-to-height ratio more than 1.05. All had joint hypermobility and no reduced extension at the elbows. In cardiovascular system, 4 (30%: 5, 11, 11, 13 years) had major criteria and 2 (15%) had involvement. One patient had ectopia lentis (7 years). No patient had pelvic X-ray for protrusio acetabuli, and MRI or CT for dual ectasia. Although three patients had only involvement in the skeletal system, all were diagnosed as emerging MFS and offered repeat evaluations. In summary, Ghent criteria has serious limitations in the diagnosis of Japanese children with MFS. It seems appropriate to consider children with Marfan-like features as emerging MFS, and offer them periodical evaluations with psychosocial supports to the parents. These findings indicated genetic testing including FBN1, TGFR1 and TGFR2 genes is recommended in children with suspected MFS.

Molecular modeling of NIPBL missense mutations: an adjunct tool for the comprehension of genotype-phenotype correlations. *S. Ferraiuolo[1], M. Masciadri[1], C. Gervasini[2], P. Castronovo[2], A. Selicorni[3], D. Milani[3], L. Larizza[2], S. Russo[1]* 1) Molecular Laboratory, Istituto Auxologico Italiano, Milano, MI, Italy; 2) University di Milano - Osp San Paolo- MI-Italy; 3) Clinica De Marchi- University of Milano - Italy.

Cornelia de Lange syndrome (CdLS) is a rare multisystem disorder characterized by facial dysmorphisms, upper limb abnormalities, growth and cognitive retardation. The main causative gene, NIBPL, is responsible for CdLS in about 50% of patients; the encoded protein,delangin,belongs to the adherin family and is involved in sister chromatid cohesion, DNA repair and long range gene regulation. Within a cohort of 97 CdLS patients with a phenotype scored as severe, moderate or mild, we identified 46 NIPBL mutations, including 8 missense mutations. Genotype-phenotype correlation is not clearly defined for NIPBL mutations, in particular the missense ones,which appear to be associated with a variable phenotype. Aiming at establishing if a molecular modeling approach might be in keeping with the clinical presentation of carriers of missense mutations, we addressed the modelling of NIPBL protein. Indeed the X-ray structure has been deposited in PDB only for the second part of the protein. We built up a 3D model of the human NIPBL protein using the Fold Recognition approach. Several different structural and evolutionary criteria enabled us to choose as model the QBK1 Rod-like C-shape structure as it showed the best score following validation (VERIFY3D) and energetic minimization (GROMACS). Up to day in silico mutagenesis of three substitutions was carried on by this model: p.Arg1856Gly associated with a very severe clinical score, p.Arg2298Leu and p.Arg2298Cys both affecting the same residue and underlying a moderate clinical phenotype. Only Arg1856Gly affects the folding region, losing crucial intramolecular interactions and exposure to the solvent, while the other two variants cause mild conformation changes.These preliminary results indicate the usefulness of bioinformatic tools in the comprehension of genotype-phenotype correlation. Evaluation of other missense mutations mapping within the modeled region is in progress.

Estimating The Coefficient Of Linkage Disequilibrium Between A QTL And A Marker Locus. *S. Ghosh* Human Genetics Unit, Indian Statistical Inst, Kolkata, India.

Although statistical methods based on case-control designs are the most popular and extensively used approach for genetic association mapping of binary traits, development of such methods for quantitative traits is currently an active area of interest. While there are some classical approaches like analysis of variance as well as novel approaches based on quantiles of the quantitative trait for testing for association, these methods do not involve the estimation of the coefficient of linkage disequilibrium between the putative QTL and the marker locus. We propose an estimation procedure of this parameter based on the Expectation-Maximization (EM) algorithm and simultaneously develop a test for association. We assume that the quantitative trait is controlled by a biallelic QTL and is distributed as normal conditioned on the genotypes of the QTL. The estimation involves a two-stage procedure. In the first stage, we estimate the posterior probabilities of the QTL genotypes conditioned on the quantitative trait values from a mixture of three normal populations. In the second stage, we estimate the two-locus haplotype frequencies based on the QTL and the marker genotypes using the posterior probabilities of the QTL genotypes obtained in the first stage. We test for association using the resultant estimate of the coefficient of linkage disequilibrium using permutation principles. We note that the parameters of the component normal distributions in the mixture are nuisance parameters and are not used in either the second stage of our estimation procedure or for testing for association. We perform Monte-Carlo simulations for different genetic parameters and probability distributions of the quantitative trait to assess the efficiency of the estimator and the power to detect association. We find that method is sufficiently robust to lack of normality of the quantitative trait values, although one can improve the efficiency by classical transformations like logarithmic or square root.

Miglustat in patients with Niemann-Pick Type C disease (NPC): a multicentre retrospective survey. *J. E. Wraith[1], M. Pineda[2], F. Sedel[3], W. L. Hwu[4], M. Rohrbach[5], B. Bembi[6], G. C. Korenke[7], R. Giorgino[8], P. Schieber[8], M. C. Patterson[9]* 1) Royal Manchester Children's Hospital, UK; 2) Hospital Sant Joan de Deu, Barcelona, Spain; 3) Hopital Pitié Salpêtrière, Paris, France; 4) National Taiwan University Hospital, Taipei, Taiwan; 5) Kinderspital, Zürich, Switzerland; 6) Regional Coordinator Centre for Rare Diseases, University Hospital, Udine, Italy; 7) Elisabeth Kinderkrankenhaus, Oldenburg, Germany; 8) Actelion Pharmaceuticals Ltd, Allschwil, Switzerland; 9) Mayo Clinic, Rochester, USA.

A clinical trial indicated that miglustat is able to slow disease progression in patients with NPC.[1] We present the interim results from an ongoing international, retrospective survey assessing neurological disease progression in NPC patients treated with miglustat. All NPC patients prescribed miglustat in 17 selected expert centres are included. Treating physicians complete a questionnaire on patient demographics, treatment history, disease progression and general health. A disease-specific disability scale[2] evaluates dysphagia, dystonia, ataxia and dysarthria severity at diagnosis, treatment initiation and last visit. As of 17 December 2007, 44 patients were included. Median (range) miglustat exposure was 17.4 (0.6-40.2) months. Of 43 evaluable patients (meanSD age: 9.97.2 years at diagnosis, 14.29.5 years at miglustat initiation), most remained at least stable after treatment as regards dysphagia (n=36; 84%), dystonia (n=33; 77%), ataxia (n=31; 72%) and dysarthria (n=31; 72%). Thirty-two (74%) patients were classified as good responders, with at least 3 out of the 4 scale parameters rated as stable or improved. According to physician global assessments, 16/41 (39%) patients improved in general health, and 30/38 (79%) patients experienced good/fair benefit. Physicians' intention to maintain patients on therapy was recorded for 31/33 (94%) patients. Miglustat appears to provide clinically relevant benefits on neurological disease progression in patients with NPC. These data are consistent with results from a previous clinical trial[1] in the same patient population. [1]Patterson et al. Lancet Neurol 2007;6:765-72. [2]Iturriaga et al. J Neurol Sci 2006; 249:1-6.

Active chromatin marks on ultraconserved non-coding elements. *U. Choudhury[1,3], F. Parisi[2], F. Naef[2], SE. Antonarakis[1]* 1) Gen Med, Univ Geneva Medical School, Geneva, Switzerland; 2) School of Life Sciences, Polytechnic Federal School of Lausanne, Lausanne, Switzerland; 3) NCCR Frontiers-in-Genetics Doctoral School, University of Geneva, Geneva, Switzerland.

Identifying gene regulatory elements and unraveling their mechanisms of action is a major challenge in the field of genomics. Sequence conservation between species is an efficient criterion for finding such elements. Ultraconserved elements (UCEs) are sequences with extreme conservation levels between mammals. They are 100% identical between human, mouse and rat over at least 200 bp. About 2/3 of UCEs are non-coding and map in the vicinity of genes that are key regulators of vertebrate development. Regulatory elements are known to possess specific chromatin signatures. We analyzed the chromatin state of 286 non-coding UCEs by ChIP-on-chip using antibodies against histone H3 modifications that mark either active chromatin (K4-dimethyl/trimethyl) or repressed chromatin (K27-trimethyl and K9-dimethyl) in different human cell types (lymphoblastoids, fetal lung and neuroblasts). Immunoprecipitates were hybridized to a custom tiling array containing a 2kb region around each UCE, promoter regions of the genes nearby and control sequences located upstream and downstream of each UCE. A statistically significant fraction of the UCE regions showed enrichments for H3 K4-dimethyl and K4-trimethyl modifications (30 and 10%, respectively). Interestingly, the modified histones were generally positioned close to rather than over the UCE sequence. In most cases, enrichment for K4-trimethyl was not linked to the presence of a known transcriptional start site (26 versus 9 regions), although this mark is reported to be tightly associated to the 5 end of actively transcribed genes. The presence of active chromatin marks on UCE regions strengthens the hypothesis of a gene regulatory activity of these elements and sheds light on their profile of activity. Our results provide a framework for further investigating their mechanisms of action and testing for the presence of non-coding RNAs in the relevant cell lines.

Mutations in *Frem1* yield an animal model of retrosternal diaphragmatic hernia. *D. A. Scott[1], M. Wat[1], B.-J. Kim[1], O. Shchelochkov[1], D. W. Stockton[2], M. J. Justice[1], B. Lee[1,3]* 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept Pediatrics, Wayne State University School of Medicine, Detroit, MI; 3) Howard Hughes Medical Institute.

Congenital diaphragmatic hernia (CDH) is a common sporadic birth defect that affects ~1:3000 newborns. Anterior diaphragmatic hernias account for approximately 10% of CDH cases. These hernias are often referred to as Morgagni hernias since the majority involve herniation through the foramina of Morgagni, two small parasternal regions between the costal and sternal attachments of the diaphragm. However, some hernias affect the region directly behind the sternum and are best described as retrosternal in nature. In a recessive ENU mutagenesis screen we identified a mouse strain with several congenital anomalies including retrosternal diaphragmatic hernia, lung segmentation defects and unilateral kidney agenesis. All cases of CDH involved herniation of a portion of the liver and, in some cases, a hernial sac consisting of a thin adherent membrane was also present. Traditional linkage mapping followed by sequencing of positional candidate genes revealed a homozygous 1687A>T (I563F) change in the extracellular matrix protein *Frem1*. This *Frem1* mutation is likely to be causal since these mice showed failure of complementation when crossed to mice carrying an L826X mutation in the same gene. Further studies revealed that the penetrance of both the retrosternal CDH and the lung segmentation defects were highly dependant on genetic background. We note that incomplete penetrance has also been a hallmark of human CDH suggesting the importance of genetic modifiers. Although human CDH can affect any portion of the diaphragm, data from this and other recently identified CDH mouse models*Gata4*, anterior CDH; *Slit3*, central CDH; *Coup-TFII*, posterolateral CDHsuggest that abnormal formation of one region of the diaphragm may be associated with defects in genes and/or genetic pathways that are distinct from those affecting other regions. Future studies will be aimed at understanding the mechanisms by which *Frem1* affects retrosternal diaphragm development and identifying genes that modify the *Frem1* phenotype.

Use of Public Genotype Data from Multiple Platforms to Increase Power of a Genome-wide Association Study of Parkinson's Disease. *A. J. Oudes, E.Sasha Paegle* Application Science, Rosetta Biosoftware, Seattle, WA.

Recently, genome-wide association (GWA) studies have been conducted to investigate several diseases including type 1 and 2 diabetes, prostate cancer, breast cancer, and heart disease. These studies identified numerous loci associated with predisposition for these diseases. Other GWA studies investigating asthma and Parkinson's disease have found few if any significantly associated loci. An important consideration when designing a GWA is study power. One way to increase study power is to add genotype data from unaffected individuals. Repositories such as dbGAP and the Illumina iControl database are sources of genotype data that may be used to increase power of GWA studies. However, the use of these data in a secondary analysis is challenging due to issues such as population stratification, cryptic relatedness, and lack of corresponding markers between genotyping platforms. We used Parkinson's disease GWA data from Fung et al. in combination with Illumina iControl data studies 64 and 67 to increase the power of the original study. To assess the structure of the composite control population, we used multi-dimensional scaling to identify and subsequently remove outlier individuals. Analysis of the powered study revealed previously unidentified loci on chromosome 2 that were associated with the disease state. To address the lack of corresponding markers between data sets, a linkage-disequilibrium based "clumping" analysis of association results was performed between our powered results and those from the LEAPS Parkinson's GWA (Maraganore et. al.). Clumping analysis identified differing disease associated SNPs within 250 Kb windows, which corresponded between the studies at a p-value of <0.01. In conclusion, we used public genotype data to increase the power of an existing GWA study and identified novel Parkinson's disease associated alleles. Comparison of the powered results with those from a previously published study identified corresponding disease associated alleles.

G-protein-coupled receptor kinase 5 and dementia in Parkinsons disease. *P. Tarantino[1,2], E. V. De Marco[1], F. E. Rocca[1,3], F. Annesi[1], D. Civitelli[1], G. Provenzano[1,2], V. Scornaienchi[1], V. Greco[1], G. Annesi[1]* 1) Inst Neurological Sci, National Research Council, Mangone, Cosenza, Italy; 2) Departement of Neurosciences, Psychiatry and Anaesthesiology University of Messina, Messina-Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro-Italy.

Parkinsons Disease (PD) is characterized by selective degeneration of dopaminergic neurons in the substantia nigra. Dementia is a common complication of PD. Although the pathogenesis of the disease is unclear, phosphorylation of alpha-synuclein and its oligomer formation seem to play a key role. G-protein coupled receptor kinase (GRKs) constitute a serine/threonine kinase family. It has recently been demonstrated that GRK5 promotes the formation of soluble oligomers and aggregates of -synuclein. We have performed a case control study to investigate whether genetic variability in the GRK5 gene may predispose to dementia in PD. A total of 114 demented patients and 114 non demented patients with sporadic PD were included in the study. Two polymorphic loci in the GRK5 gene were examined. Cognitive conditions were assessed by Mini Mental State Examination. SNP genotyping was performed by using allelic discrimination on ABI PRISM 7900-HT. All SNPs showed high genotyping quality and were in Hardy-Weinberg equilibrium in both demented and non-demented groups. The haplotype analysis was performed using the software Unphased. We observed association with the two polymorphisms. There were significant differences in the genotype or allele frequencies between the demented and non-demented patients. Furthermore we found significant differences in the inferred haplotype frequencies of the two groups ($p<0.001$). The substrate of dementia in PD is Lewy bodies, mainly costituited of alpha-synuclein. Quite recently, GRK5 have been demonstrated to phosphorilate alpha-synuclein at Ser 129 and other synuclein isoforms. Here, we report genetic evidence of significant association of GRK5 polymorphisms with dementia in PD and therefore it is possible to speculate that the gene has a crucial role in the development of this PD complication. Further studies of other regions of the GRK5 gene are in progress to confirm this association.

Cardiac Transplantation in a Child with Recurrent Thrombosis due to Congenital Thrombophilic Mutations. *S. Ozkan[1], FB. Atac[2], H. Verdi[2], S. Ozcobanoglu[1], E. Uguz[1], A. Sezgin[1], N. Ozbek[3]* 1) Dept Cardiovascular Surgery, Baskent Univ, Ankara, Turkey; 2) Dept Medical Biol and Genetics, Baskent Univ, Fac Medicine, Ankara, Turkey; 3) Dept Pediatric Hematology, Baskent Univ, Fac Medicine, Ankara, Turkey.

Thrombosis is known to be one of the most serious complications leading to increased morbidity and graft dysfunction after solid organ transplantation. Therefore predicting the risk of thrombosis before the operation is important for preventing the complications during posttransplantation follow up. Here we report a cardiac transplantation patient who had Blalock-Taussig (BT) shunt three times. He was heterozygous for two thrombophilic mutations; MTHFR C677T and FV A4070G. We believe, congenital risk factors should be bear in mind in patients who had thromboembolic event(s) before cardiac surgery. Careful application of routine anticoagulation during and after surgery is essential.

A new mitochondrial cytochrome b (MTCYB) gene mutation responsible for a polyvisceral neonatal failure. *K. Fragaki[1,2], V. Procaccio[3], S. Bannwarth[1,2], V. Serre[4], G. Augé[1], A. Figueroa[1,2], F. Casagrande[5], J.-C. Lambert[1], V. Paquis-Flucklinger[1,2]* 1) Service de Génétique Médicale CHU de Nice, France; 2) IGMRC FRE CNRS/UNSA 3086 Faculté de Médecine Nice, France; 3) Department of Pharmacology University of California Irvine, USA; 4) Service de Génétique and INSERM U781 Hôpital Necker Enfants Malades Paris, France; 5) Service de Pédiatrie CHU de Nice, France.

To date, the majority of MTCYB mutations have been reported in patients with severe exercise intolerance. Here we report a child born to non consanguineous parents with no family antecedent. At birth, he presented with hypotonia, respiratory distress and hypertrophic cardiomyopathy. He developed seizures and died 24h later of a polyvisceral failure. Biochemical analysis showed major lactic acidosis and hepatocellular insufficiency. We first proceeded by enzymatic analysis of respiratory chain activity which showed isolated complex III deficiency in liver, whereas all respiratory chain complexes activities were normal in muscle. Western blotting also demonstrated isolated severe loss of complex III expression in liver, whereas all subunits levels in muscle were unaffected. Sequencing of the MTCYB gene, revealed a previously unreported 15635 T>C transition leading to a highly-conserved amino-acid substitution (S297P) located in a transmembrane hydrophobic helix of cytochrome b. RFLP analysis showed that this transition was homoplasmic in all patients tissues studied and undetectable in various cellular types of patients mother. Modelling of this transition showed interruption of the helix due to geometrical constraints induced by proline. Finally, cell fusion experiments between rho0 lymphoblastoid cells, fully depleted of mtDNA, and patients fibroblasts did not led to respiratory chain defect complementation in mitochondria of the resulting cybrid cells, thus demonstrating the mitochondrial origin of the defect initially observed. All these biochemical and molecular elements demonstrate the extreme pathogenic character of this new mutation, which likely occured de novo. These findings also have a major interest for genetic counselling in this family.

Hyperdiploidy with trisomy 9 and deletion of the p16 locus in precursor T-cell acute lymphoblastic leukemia. *J. Morrissette[1], K. Healey[1], A. McKenzie[2], G. Halligan[2], JP. de Chadarévian[1]* 1) Department of Pathology, St Christopher's Hospital for Children, Philadelphia, PA; 2) Department of Pediatrics, Section of Oncology, St Christopher's Hospital for Children, Philadelphia, PA.

We describe the rare finding of a 4 year-old male who presented with T-cell acute lymphoblastic leukemia (T-ALL) and a pre-treatment bone marrow karyotype mosaic for four distinct cell lines. G-band analysis of metaphase cells identified a hyperdiploid cell line (52 chromosomes) in 11/19 cells studied, which were trisomic for chromosomes 6, 9, 11, 13, 19, and 22. Fluorescence in situ hybridization (FISH) analysis demonstrated that these hyperdiploid cells were missing all three copies of the p16 locus at 9p21. FISH analysis of the interphase nuclei also identified cells with homozygous deletions of the p16 locus at 9p21, and containing two chromosome 9 centromere signals in 88/100 cells; another cell line demonstrated a heterozygous deletion with one p16 locus intact in 6/100 cells. A normal signal pattern was found in 6/100 cells. This suggests the presenting bone marrow had undergone clonal evolution, with the most evolved clone seen in the G-banded karyotype hyperdiploid line. Although a non-random pattern of hyperdiploidy, with trisomy for chromosomes 4, 10, 17 and 21, is commonly seen in childhood pre-B ALL cases, the hyperdiploid cell line observed in this patient did not fit this pattern. This case represents a rare case of hyperdiploidy in T-cell ALL, and identifies clonal evolution of the 9p21 deletion.

The importance of gender-specific and non-additive effects in complex traits: insights from a 33000 person genome-wide association study of height. *H. Lango[1], G. Lettre[2], M. N. Weedon[1], GIANT (Genetic Investigation of ANthropometric Traits) Consortium* 1) Genetics of Complex Traits, Peninsula College of Medicine and Dentistry, Exeter, UK; 2) Broad Institute of MIT and Harvard, Cambridge, USA.

Recent genome-wide association studies have identified 43 independent loci where common variation influences human height. The identified loci explain only around 5% of the population variation of height, which is up to 90% heritable. These studies were based on additive, gender-combined analyses. However, final adult height is highly dichotomized by gender, and it is one of the polygenic traits most likely to have gender-specific SNP effects. In this study, we assessed the importance of gender-specific and non-additive effects in a height genome-wide association study.

As part of the GIANT consortium we meta-analysed ~2.4 million autosomal, directly genotyped or imputed, SNPs against Z-score (age-adjusted) height in 33000 (50% male) individuals from 13 studies. We performed gender-specific analyses under additive, dominant and recessive models. For the additive model, we tested if there was a differential effect between males and females.

Overall, there was no strong evidence for gender-specific effects, as the most highly gender-differentiated SNP had a gender difference $P=1x10^{-6}$, no better than expected by chance based on the number of tests performed. Similarly, there were no notable gender-specific associations when we limited the analysis to SNPs with overall $P<0.0001$ (best gender difference $P=5x10^{-3}$). When we looked for gender differences in SNPs that had $P<5x10^{-7}$ in either males or females, we found one potential gender-specific association (females $P=2x10^{-7}$; males $P=0.3$; difference $P=8x10^{-6}$). The associated SNP is in the *SYNE1* gene region, mutations of which cause recessively inherited cerebellar ataxia. Preliminary data from the recessive and dominant models have not identified any novel height associated loci.

In conclusion, gender-specific and non-additive effects appear to be of limited importance for genome-wide association studies of height, a model complex trait.

Principal Component Analysis and Hierarchical Clustering in 500K and 6.0 Genome Wide Association Datasets.
T. Drgon, C. Johnson, G. R. Uhl Dept Molecular Neurobiology, NIDA-IRP/NIH, Baltimore, MD.

Genome wide association (GWA) is a method of choice for elucidating polygenic influences in complex genetic disorders. However, the large numbers of repeated comparisons characteristic of GWA and the small anticipated sizes of the case/control allele frequency differences that are likely to be found in polygenic disorders motivate use of a variety of techniques for evaluating association signals. Principal Component Analysis (PCA) and Hierarchical Clustering (HC) array the variance found in multidimensional GWA datasets in matrices based on covariance (PCA) or geometric distance (HC). Variance components identified using these methods can be tested against the null hypothesis that no such component (or at least no component that explains certain threshold amount of the overall variance) can distinguish cases from controls using methods that are a priori agnostic to the structure in the data. We have used these approaches to analyze SNP and copy number variant (CNV) data from 500k and 6.0 array sets from samples of substance dependent and control individuals of European-American, African American and Asian origin studied as pools of DNA from 20 individuals. In these samples, both SNP and CNV datasets identified principal components that appear to capture much of the variance attributable to 1) ethnicity and 2) substance dependence. Using data from candidate genes, HC identifies significant clustering of a) pools of different ethnicities and of b) abuser and control pools within one ethnicity. We test the significance of such findings using permutation and Monte Carlo methods. These top down approaches provide assurance of overall genetic differences between case and control groups, and remind us of the modest sizes of these differences in comparison to racial/ethnic differences.

Familial longevity is not dependent of disease risk alleles identified in recent genome-wide association studies. *M. Beekman[1], B. T. Heijmans[1], C. Nederstigt[1], R. Van der Breggen[1], N. Lakenberg[1], J. J. Houwing-Duistermaat[2], R. G. J. Westendorp[3], P. E. Slagboom[1]* 1) Molecular Epidemiology, LUMC, Leiden, Netherlands; 2) Dept of Medical Statistics and Bioinformatics, LUMC, Leiden, Netherlands; 3) Dept of Gerontology and Geriatrics, LUMC, Leiden, Netherlands.

Ageing is the main risk factor for the major common human diseases that contribute to human mortality such as cardiovascular disease, cancer and type 2 diabetes. Centenarians show delayed ageing and among their offspring the prevalence of these age-related diseases is markedly decreased. Although partly heritable, genetic variation underlying familial longevity is as yet unknown. Long-lived families could by chance carry very few disease risk alleles, leading to their extreme survival. Alternatively, they may carry protective alleles, diminishing the effect of risk alleles. The first hypothesis can now be tested, using the robust associations with common age-related diseases published in the recent wave of genome-wide association studies (GWAs). We reviewed GWAs until May 31th 2008 on cardiovascular disease, cancer and type 2 diabetes. We selected 26 associated loci ($p<10^{-4}$) showing at least replication in one study or a second disease. At least one top SNP in each locus was tested for association with familial longevity in the Leiden Longevity Study, consisting of 959 long-lived siblings (mean age 93 yrs), 1765 of their offspring and the 758 partners of the offspring serving as population controls. None of the 26 loci from recent GWAs was associated with familial longevity. The estimated odds ratios were closer to 1 than in the published GWAs and the lowest observed p-value without adjustment for multiple testing was 0.055 (rs6922269). Next, we tested whether the total number of risk alleles was different between long-lived siblings and the controls, but this was not the case (p=0.256). These results indicate that long-lived families from the Leiden Longevity Study achieve high ages irrespective of the presence of the latest published common risk alleles. The deleterious effect of these alleles may be too small to affect mortality, or alternatively, longevity families may be protected against their effect.

Interstitial Deletion 6q25.2-q25.3 - A Novel Syndrome Associated With Microcephaly, Developmental Delay, Dysmorphic Features And Hearing Loss. *SC. Sreenath Nagamani[1], A. Erez[1], C. Eng[1], Z. Ou[1], C. Chinault[1], L. Workman[4], J. Coldwell[5], P. Stankiewicz[1], A. Patel[1], JR. Lupski[1,2,3], SW. Cheung[1]* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Dept of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Childrens Hospital, Houston, TX; 4) Sutter Medical Center, Sacramento, CA; 5) Children's Medical Center, Tulsa, OK.

Interstitial deletions of 6q are rare. We characterized the size, extent and genomic content of four interstitial deletions involving 6q25. Using a clinical targeted BAC or oligonucleotide array-CGH (Agilent, 44K), we identified submicroscopic deletions in 6q25.2-q25.3 in two patients and confirmed the cytogenetically visible 6q deletions in two patients. Genomic DNA from these patients was subsequently analyzed using an Agilent 244K oligonucleotide array. The deletions varied from 3.77 Mb to 13.81 Mb. All four patients had a common deleted segment in 6q25.2-q25.3, with the smallest region of overlap (SRO) spanning 3.52 Mb and containing fifteen genes mapping from TIAM1 to TULP4. As there was grouping of the proximal breakpoints in three of our patients in 6q25.2, we suggest that an underlying genomic architecture (e.g. palindrome or cruciform structures) important to the rearrangement is present in the vicinity of the deleted regions. Common clinical features seen in all four patients included microcephaly, developmental delay, dysmorphic features such as plagiocephaly, hypertelorism, abnormal nasal root, posteriorly rotated auricles and hearing loss. Hearing loss was of sensorineural type in three patients and conductive in one. Agenesis of corpus callosum was seen in two of the three patients who had imaging studies. We hypothesize that a subset of genes in the SRO are dosage sensitive and that their haploinsufficieny impairs normal development of the brain and hearing. We recommend that MRI of the brain and a formal hearing evaluation be done as a part of clinical assessment in patients with interstitial 6q25 deletions.

Family based association study for bipolar affective disorder identifies a candidate region on chromosome 1p31.3. *R. Secolin[1], C. E. M. Banzato[2], M. C. M. Oliveira[2], M. F. R. Bittar[1], P. Dalgalarrondo[2], I. Lopes-Cendes[1]* 1) Dept Medical Genetics, Univ Campinas - UNICAMP, Campinas, SP, Brazil; 2) Dept Medical Psychology and Psychiatry, Univ Campinas - UNICAMP, Campinas, SP, Brazil.

Bipolar affective disorder (BPAD) is a common psychiatric illness, with a prevalence of 0.8-2.6% in the general population. Clinical features include episodes of mania or hypomania, interspersed with periods of depression. Genetic factors are known to contribute to the etiology of BPAD. A recent large genome-wide population based association study performed in the British population identified 21 candidate loci across the genome. However, in order to confirm and strength these findings, further replication studies in different populations are needed. In the present study we aimed to evaluate the candidate loci previously reported using a family-based association approach. We evaluated 74 pedigrees with BPAD, with a total of 411 individuals, including 95 patients who fulfilled clinical criteria for BPAD according to ICD-10. We genotyped SNPs surrounding the candidate loci using real-time PCR by ABI 7500, TaqMan System (Applied Biosystems). We used TDT POWER CALCULATOR program in order to verify statistical power of our sample. Genotype data were processed by the LINKGEN program, which also estimates minor allele frequency (MAF). Mendelian inconsistencies and Hardy-Weinberg Equilibrium (HWE) were evaluated by PEDCHECK and HAPLOVIEW softwares, respectively. Family-based association analysis was performed by the UNPHASED software. Our sample has statistical power higher then 80% to detect association. To date, seven SNPs were analyzed and presented MAF 0.05. We found no Mendelian inconsistencies and HWE 0.001 for all SNPs genotyped. Only one single SNP (rs2989476) showed statistically significant association with BPAD (p 0.05). In conclusion, we demonstrated that SNP rs2989476, located on chromosome 1p31.3, is associated with the disease phenotype in our BAPD pedigrees. Additional SNPs are been genotyped in the candidate region in order to estimate haplotype association and to identify the putative causal variant associated with BPAD on chromosome 1p31.3. Supported by FAPESP.

Does raised adiposity increase blood pressure? The use of FTO and Mendelian randomisation in a large cohort study of causality. *N. Timpson[1], G. Davey Smith[1], J. Zacho[2], R. Harbord[1], A. Tybjærg-Hansen[2], B. Nordestgaard[2]* 1) CAiTE Ctr/Social Medicine, Univ of Bristol, Bristol, United Kingdom; 2) Herlev University Hospital, Denmark.

High body mass index (BMI) is associated with blood pressure (BP) and cardiovascular disease risk. If this association is causal, elevated BMI is a key target for intervention for BP reduction. Given the confirmed relationship between FTO (rs9939609) and BMI, we ultilised instrumental variable methods to estimate the strength and direction of the unconfounded association between BMI and BP. Within the Copenhagen General Population Study (n=37033), the correlation coefficients between systolic/diastolic BP and BMI were 0.21 and 0.24 (p=<0.001) respectively. In those not taking anti-hypertensive treatment where average BMI was 26.22kg/m2 (SD 4.27), the relationship between tertile of BMI and standardised BP was 0.17SD(0.16, 0.19) for systolic and 0.23SD(0.22, 0.24) for diastolic (p=<0.001) BP when adjusting for age, income, education, smoking and drinking. Using the FTO locus as an instrument for BMI in efforts to avoid confounding/reverse causation, equivalent estimates were revised to 0.36SD(0.18, 0.55) systolic and 0.27SD(0.07, 0.46) diastolic (p<0.001, 0.007) indicating that for each tertile of BMI, we predict an approximate causal change in BP of 1.5 and 1.2mmHg respectively. First stage F statistics confirm the strength of rs9939609 as an instrument for fat mass and a test for difference between observational and instrumental analyses showed there to be no consistent disparity between estimates (Wu-Hausman p>0.05). In a large, cross sectional, cohort of Europeans, a Mendelian randomisation approach yielded strong evidence for a causal relationship between BMI and BP as implicated by observational studies. Furthermore, estimates of life long exposure to elevated fat mass (derived from rs9939609), if anything, suggest a larger effect on blood pressure than basic analyses. These observations confirm BMI as an important target for therapeutic intervention aimed at lowering BP in concert with pharmaceutical approaches.

Aberrant activation of Rho GTPases in Smith-Lemli-Opitz syndrome: Neurodevelopmental and clinical implications. *X. Jiang[1], C. A. Wassif[1], L. Song[1], P. S. Backlund[2], A. L. Yergey[2], Z. Li[3], F. D. Porter[1]* 1) PDGEN, NICHD, NIH, DHHS, Bethesda, MD; 2) OSD, NICHD, NIH, DHHS, Bethesda, MD; 3) GCAP, NIMH, NIH, DHHS, Bethesda, MD.

Smith-Lemli-Opitz syndrome (SLOS) is a malformation syndrome with neurocognitive deficits due to mutations of *DHCR7* that impair synthesis of cholesterol. To investigate the pathological processes underlying the neurocognitive deficits found in SLOS, we performed proteomic analysis comparing protein expression in E18.5 *Dhcr7*+/+ and *Dhcr7*-/- mouse brains. Combining 2D-PAGE analysis and mass spectrometry techniques we identified 52 proteins with differential expression. One of these proteins was cofilin. Cofilin regulates depolymerization of actin, and plays a major role in regulation of cytoskeletal structure. Western blot analysis showed that the apparent differential expression of cofilin was due to increased phosphorylation. Phosphorylation of cofilin alters its activity, and is regulated by Rho GTPases through both the Rho-Rock-Limk-Cofilin and Rac/Cdc42-Pak-Limk-Cofilin pathways. Rho GTPases cycle between inactive GDP-bound and active GTP-bound states. We used GST-pull-down assays to demonstrate increased activation of RhoA, Rac1, and Cdc42 in *Dhcr7-/-* brains. Consistent with increased activation of Rho GTPases, we also found increased phosphorylation (activation) of Limk and Pak in mutant brain tissue. This explains altered cofilin phosphorylation. Rho GTPases play a central role in the regulation of axonal and dendrite growth. Altered Rho/Rac signaling impairs normal dendrite and axon formation, and mutations in genes encoding regulators and effectors of the Rho GTPases have been found to underlie other human mental retardation syndromes. Thus, we hypothesized that aberrant activation of Rho/Rac could have functional consequences for dendrite and axonal growth. *In vitro* functional analysis of *Dhcr7-/-* hippocampal neurons demonstrated significant abnormalities of both axon and dendrite growth. Thus, developmental abnormalities of neuronal process formation may contribute to the neurocognitive deficits found in SLOS, and may represent a potential target for therapeutic intervention.

Identification of a putative association between a common variant in the Thyroid stimulating hormone receptor (TSHR) gene, known to predispose to autoimmune thyroid disease, and preterm birth. *T. M. Frayling[1], R. M. Freathy[1], D. Velez[2], J. Bartlett[2], S. Fortunato[3], S. M. Ring[4], B. Shields[1], A. T. Hattersley[1], S. M. Williams[2], G. Davey Smith[4], R. Menon[3], C. Relton[5]* 1) Peninsula Medical School, Exeter, UK; 2) Vanderbilt University, Nashville, TN, USA; 3) The Perinatal Research Center, Nashville, USA; 4) Bristol University, UK; 5) Newcastle University, UK.

Preterm birth, defined as a gestational age <37 weeks, is one of the leading causes of neonatal morbidity and mortality. There is strong evidence that preterm birth has a genetic component, but the genes involved, and the extent to which offspring and maternal genotypes play a role, are not known. We performed the largest preterm birth genetic association study to date, consisting of 729 offspring cases, 593 maternal cases, 920 offspring controls and 772 maternal controls. We analysed ~930 SNPs in 134 candidate genes from pathways thought to play key roles in preterm birth. The most strongly associated offspring genotypes were those in the thyroid stimulating hormone receptor (TSHR) gene. A cluster of SNPs from across the TSHR gene, were associated with preterm birth. The strongest association was with rs2075173, with an odds ratio of 1.38 (95%CIs:1.11-1.72; p=0.003). This and other SNPs representing the signal were in linkage disequilibrium (r2=0.12 to 0.7) with a non-synonymous SNP, S248R, known to predispose to autoimmune thyroid disease. The strongest maternal association was with rs3211719 in the Factor VII gene, with an odds ratios of 1.33 (95%CIs:1.11-1.59; p=0.002). The most common variant known to alter the risk of thrombosis, R353Q, in Factor VII, was not associated with pre-term birth (odds ratios of 0.97 (95%CIs:0.75-1.26; p=0.19) using an r2=0.93 proxy. SNPs in another gene involved in the coagulation-complement pathway, Plasminogen activator tissue (PLAT), were the fourth strongest maternal signal (rs879293, p=0.006). Thyroid function is known to be altered in preterm infants. Our results need to be followed up in additional samples but provide the first evidence that altered thyroid function may be causal to preterm birth.

Assessing Public and Biobank Participant Attitudes toward Data Sharing for Genome Wide Association Studies: A Community Consultation Approach. *A. A. Lemke[1], W. A. Wolf[1], J. Hebert-Beirne[2], R. L. Chisholm[1], M. E. Smith[1]*
1) Northwestern University, Chicago, IL; 2) Women's Health Foundation, Chicago, IL.

Recent policies requiring sharing of research data on participants included in genome-wide association studies have not been fully assessed. This study utilizes a community consultation process to elicit feedback and opinions from participants in the NUgene, a hospital-based biorepository, and a diverse group of community members. The study objectives are: 1) to obtain in participants own words their attitudes toward collecting, analyzing and sharing genetic research data; 2) to compare attitudes between biorepository participants and the public; and 3) to offer recommendations for the consent process and sharing of genetic research data. Forty-nine individuals participated in six focus groups; 21 in three NUgene biorepository focus groups and 28 in three public focus groups. All participants completed a brief background information survey. In the NUgene focus groups, 67% of participants were women, 95% had some college education or more, and the majority (80%) of participants were Caucasian (20% African-American). In the public focus groups, 75% of participants were women, 75% had some college education or more, 29% were Hispanic, and the majority (46%) were African-American (29% Caucasian, 21% other). More than half (56%) of the NUgene focus group participants were somewhat or very concerned about the confidentiality and privacy of medical information compared to 46% of the public group participants. Overall, approximately 75% of focus group participants were neutral or somewhat trusting of medical research. Preliminary themes identified in both focus group types include: barriers and incentives toward participating in genetic research; conditions necessary to consent to participation in genetic research; concerns about the privacy of individual research data, and apprehension regarding the role of institutions and the government in the protection of genetic research data. Findings from this research will be used to inform key professional groups regarding concerns and potential changes needed in the consent and genetic research data sharing process.

Nuclear architecture alterations in a patient with a novel heterozygous missense LMNA mutation. *F. Gullotta[1], D. Postorivo[1], F. Lombardi[2], S. Latini[2], A. Vielle-Canonge[2], K. Petrilli[1], A. M. Nardone[1], M. R. D'Apice[1,2], M. Bertoli[2], M. D'Adamo[3], P. Sbraccia[3], S. Servidei[4], G. Novelli[1,2,5]* 1) Department of Medical Genetics, A.O.U. Policlinico Tor Vergata, Rome, Italy; 2) Department of Biopathology and Diagnostic Imaging, University of Rome Tor Vergata, Rome, Italy; 3) Department of Internal Medicine University of Rome Tor Vergata, Rome, Italy; 4) Department of Neuroscience, Catholic University, Rome, Italy; 5) University of Arkansas for Medical Sciences, Little Rock, Arkansas.

We report a 27-yr-old Italian girl with a complex disorder characterized by extreme leanness, severe insulin resistance, mixed calcific valvulopathy involving both mitral and aortic valves, slight facial dismorphism, low femoral bone mass. LMNA sequencing evidenced a novel heterozygous missense mutation in exon 4 that replaces well-conserved residue glutamic acid at position 262 to lysine (p.E262K, c.784 GA). Her parents, not consanguineous, were negative for the same mutation, suggesting its de novo origin. Genetic screening of additional genes mutated in laminophatic or lipodistrophyc disorders (ZMPSTE24, PPAR, BSCL2) showed a wild type sequence. In order to investigate the effects of this mutation on the nuclear architecture, we examined the nucleus morphology, the unprocessed precursor pre-lamin A protein, and the chromatin organization through the study of heterochromatin protein trimethyl histone H3 (Lys9). Patients fibroblasts showed numerous and eterogeneous nuclear shape alterations and pre-lamin A accumulation at the nuclear rim but also, in a lower percentage of cells, in intranuclear foci. Heterochromatin disorganization was observed resulting in loss of trimethyl histone H3 (Lys9) clustering. The three markers selected to check the cellular phenotype in our patient have already been described altered in fibroblasts of patients whit Mandibuloacral dysplasia type A [MADA; OMIM # 248370], a rare autosomal recessive disorder caused by an homozygous missense mutation (p.R527H) in C-terminal tail domain of LMNA gene.

Reconsidering reproductive benefit: A systematic review of guidelines on preconception, prenatal and newborn screening. *Y. Bombard[1], F. A. Miller[1], R. Hayeems[1], D. Avard[2], B. M. Knoppers[2]* 1) U. Toronto; 2) U. Montréal.

Introduction: Traditionally newborn screening (NBS) aimed to reduce morbidity and mortality among screened infants. Its mandatory nature was justified by the primary benefit of improved clinical outcomes in affected babies. Expanded NBS programs identify conditions for which treatment is not established as well as benign carrier states or variants of uncertain clinical significance. In consequence, expansion is accompanied by debates about the nature of benefit and the appropriateness of a mandatory program. Chief among secondary benefits is the opportunity to inform parents and infants of future reproductive risks (RR). However, in the absence of clinical benefit, pursuit of RR information through NBS requires consideration. Although their historical contexts and value systems differ, preconceptual screening (PCS) & prenatal screening (PNS) programs may be informative paradigms for considering how to pursue reproductive benefit through NBS. **Purpose:** To explore how PCS & PNS guidance can inform NBS guidelines, we investigated: 1.Whether the generation of RR information is pursued as a benefit of screening; 2.How this benefit is to be realized (e.g. voluntarism). **Methods:** All available English guidelines on NBS, PCS & PNS from inter-, national and regional governmental and non-governmental health organizations were retrieved using HUMGEN and other sources. **Results:** All PCS & PNS guidelines pursue the generation of RR information as a benefit of screening, and a majority requires that individuals be given the choice to learn of their RR. By contrast, few NBS guidelines identify the generation of RR information as a benefit and for most, this is a secondary goal. While many NBS guidelines stress the importance of educating parents about NBS, few require consent. **Discussion:** Insights gleaned from PCS & PNS guidance suggest that mandatory NBS may be ethically untenable in its expanded form. If what constitutes benefit widens to include ascertaining RR information some form of voluntarism becomes a fundamental condition. Alternatively, achieving reproductive benefit in the absence of clinical benefit may be better pursued through antenatal screening programs.

A comprehensive evaluation of the Interferon Induced with helicase C domain 1 gene (IFIH1) reveals further evidence for association in families with type 1 diabetes. *K. Keene, S. Onengut-Gumuscu, P. Concannon* Center for Public Health Genomics, University of Virginia, Charlottesville, VA.

Type 1 diabetes (T1D) is a complex autoimmune disease that involves both genetic and environmental risk factors. Genome wide association studies have recently provided a new list of potential T1D predisposing genes including the Interferon Induced with helicase C domain 1 gene (IFIH1), a putative RNA helicase that has been implicated in innate immune defense against viruses. A nonsynonymous single nucleotide polymorphism (SNP), rs1990760, has been shown to be associated with T1D in case-control and family studies. However, the subsequent association with rs3788964 and relatively low correlation (r^2= 0.26) between the two SNPs suggests that multiple variants within IFIH1 may contribute to T1D risk. In order to fully understand the functional role of IFIH1 in T1D susceptibility, it is imperative that the causal variants are identified and characterized. Using sequencing and fine-mapping approaches, we aimed to identify and subsequently perform tests of association for variants within the IFIH1 gene region. We re-sequenced all 16 exons and intron/exon boundaries of IFIH1 in 48 individuals, confirming 16 previously identified SNPs and three novel SNPs. Thirteen SNPs were genotyped, using the Eclipse genotyping platform, in 382 multiplex T1D families from the Type 1 Diabetes Genetics Consortium. Single SNP and haplotype association was performed using Family Based Association Tests (FBAT). Eight SNPs and three haplotypes provided evidence for association (P< 0.05) with T1D. The most significant single SNP associations were observed with rs12479043 (P= 0.00516), rs1990760 (P= 0.00569), rs3747517 (P= 0.00756), and rs3747518 (P= 0.00796), while rs3788964 provided modest evidence of association (P= 0.0404). One common risk haplotype (45% frequency; Z= 2.624; P= 0.00868), and two uncommon protective haplotypes (7.6% frequency; Z= -2.115; P= 0.0344 and 1.4% frequency; Z= -2.364; P= 0.0181) were significantly associated with T1D. These results suggest that the association between IFIH1 and T1D may be more haplotype-based rather than specific to one particular SNP.

Routine application of an extended prenatal diagnosis panel (EPP) for the targeted detection of known microdeletion syndromes and subtelomeric deletions/duplications by MLPA analysis. *C. Pangalos[1,2], B. Hagnefelt[2], S. Karapanou[2], C. Konialis[2]* 1) Clinical Genetics, Diagnostic Genetic Ctr, Athens, Greece; 2) Molecular Genetics, Diagnostic Genetic Ctr, Athens, Greece.

There are a relatively large number of known genetic syndromes, as well as newly discovered ones, now described as genomic disorders, involving gain or loss of genetic material at a level not detectable by routine karyotype analysis. Although individually rare, these genetic syndromes may occur collectively in ~1 in 1,200 live births. Subtelomeric rearrangements are recognized as the underlying cause of idiopathic mental retardation, with or without congenital abnormalities, in 5-12% of patients studied. Prenatal ultrasound examination and karyotype analysis will typically fail to detect most, if not all, of the above anomalies in the fetus. We describe the application of a multiplex ligation-dependent probe amplification (MLPA) approach for the simultaneous targeted detection of 19 known microdeletion syndromes (1p-deletion syndrome, Williams-Beuren, Smith Magenis, Miller-Dieker, DiGeorge, VCFS, Cat Eye, Prader-Willi/Angelman, Sotos, Wolf-Hishhorn, Cri du Chat, Langer-Giedon, WAGR, 2p16, 3q29, 9q22, 15q24,17q21, 22q13) as well as subtelomeric copy number assessment for all chromosomes, as an extension to routine prenatal karyotype analysis in a diagnostic service laboratory. Using MLPA probe sets P064, P096, P245, P036D and P070 (MRC-Holland, The Netherlands) and analysis with GeneMarker software (Softgenetics LLC), the detection sensitivity for the selected syndromes is 50-98%, coupled to reliable detection of all subtelomeric deletions/duplications. This panel has been applied in 520 random chorionic villi and amniotic fluid samples referred for routine prenatal karyotype analysis, with or without U/S findings. We identified one unsuspected case for DiGeorge syndrome in a 17 week fetus, referred only because of advanced maternal age, and the result was further confirmed by FISH analysis. The protocol is relatively cheap, robust, rapid, targeted and sensitive, while genetic counseling in case of abnormal results is fairly uncomplicated compared to abnormal arrayCGH results in prenatal samples.

Capacity Building for the Transfer of Genetic/Genomic Knowledge into Practice and Prevention: The CAPABILITY International Collaborative Network. *I. Nippert[1], U. Kristoffersson[2], J. Schmidtke[3], A. Kent[4], A. Christianson[5], R. Raouf[6], C. Barreiro[7]* 1) Women's Hlth Res, Univ Muenster, Muenster, Germany; 2) Dept Clin Gen, Univ Hosp Lund, Lund, Sweden; 3) Inst Hum Gen, MHH, Hannover, Germany; 4) GIG, London, UK; 5) Div Hum Gen, Univ Witwatersrand, Johannesburg, South Africa; 6) Children with special needs Dep, Ministry of Health, Cairo, Egypt; 7) Hospital de Pediatria Garrahan, SAMIC, Buenos Aires, Argentina.

The number of genetic tests is growing each year and increasing knowledge about gene-disease associations will lead to new opportunities to apply genetic/genomic knowledge in practice and prevention. Before genetic tests are introduced into general practice the benefits of their use must be evaluated. Worldwide, health care systems are facing the same challenges: 1) The need to develop an evidence-based evaluation process for genetic tests or other applications of genomic knowledge in transition from research into practice. 2) The need for capacity building to enable health care systems to make effective use of genetic/genomic applications with proven clinical utility. CAPABILITY (http://www.capabilitynet.eu) is a 3-year model project developed by the European Network of Excellence: Genetic Testing in Europe - Network for test development, harmonization, validation and standardization of services (EuroGentest) (http://www.eurogentest.org) and by leading experts from emerging economies: Argentina, Egypt and South Africa, the latter being currently engaged in major development projects to integrate genetic services in primary care and prevention in their countries. CAPABILITY methods: develop an analytic framework for evidence-based genetic test evaluation identify priorities for capacity building by a systematic needs assessment survey and validate the project's approach by means of a demonstration project. CAPABILITY's overall objectives are to contribute to the efforts to establish and sustain a worldwide harmonisation process for quality standards for the integration of genetic test/genomic knowledge applications into practice and prevention and to serve as a model project for successful, sustainable international collaboration.

Identification of a novel mutation homozygous mutation in the SIL1 gene in Marinesco-Sjögren syndrome (MSS). *G. Annesi[1], C. Cerami[2], C. Cupidi[2], P. Tarantino[1,4], E. V. De Marco[1], F. Annesi[1], V. Lo Re[2], E. Mannarino[1,4], G. Provenzano[1,4], A. Quattrone[1,3]* 1) Inst Neurological Sci, National Res Council, Cosenza, Italy; 2) Dept. Clinical Neurosciences, University of Palermo, Palermo, Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 4) Departement of Neurosciences, Psychiatry and Anaesthesiology University of Messina, Messina-Italy.

MSS is an autosomal recessive disorder, characterised by cataracts, ataxia, and growth and mental retardation. Chronic myopaty is a common feature, and peripheral neuropathy has also been described. Recently, Anthonen et al showed the linkage of the MSS phenotype to 5q31 chromosome in a Finnish family, and identified mutations of the SIL1 gene in all investigated MSS patients. Senderek et al, using homozygosity mapping in three small consanguineous families with typical MSS, narrowed a critical region on 5q31. In this region the authors identified 9 distinct mutations in SIL1 gene in individuals from eight small families with MSS . In this study we analyzed the SIL1 gene in a small pedigree from Sicily with one patient clinically definite MSS . He shows classical MSS with psychomotor delay, hypergonadotrophic hypogonadism and distinct cerebellar symptoms.He showed poor vision and the early infantile period, which was diagnosed as cataract and was surgically removed later on. Brain MRI of the patient showed marked cerebellar atrophy. We sequenced all 10 exons of the BAP/SIL1 gene in our MSS pedigree (heterozygote parent and affected individual). Sequencing of the SIL1 gene revealed a novel homozygous mutation in exon 10 (1207delG) and a new homozygous mutation in the same exon (1209delC). Both mutations cosegregate with the disease and were detected in a heterozygous state in the patientmother and father. We did not find the same mutation in 100 chromosomes from healthy individuals from Sicily. This mutation causes a frameshift in translation and premature termination of SIL1 protein (V403fsX427), deleting 24 amino acids from the end of the protein. Our study strengthen the previous findings of loss-of-function mutations in SIL1 being the major cause of MSS.

Identifying Gene X Gene Interactions for phenotypes in Genome-wide Association Studies. *J. Wu, K. Roeder*
Statistics, Carnegie Mellon University, Pittsburgh, PA.

More and more studies have confirmed that interactive effects, or epistasis, of two or more genetic variants plays a key role in the understanding of liability to complex disease. We explore a procedure called screen and clean by Roeder and Wasserman (2008) for identifying liability loci, including interactions, in genome-wide association studies. Instead of testing each locus marginally, we identify the most promising SNPs and interactions simultaneously using the lasso procedure (Effron et. al 2004). Because the class of models including all interactions is too large to be practical we approach the problem using a varying dictionary. In the first step the lasso dictionary includes only main effects. The most promising SNPs are identified using a screening procedure designed to identify SNPs involved in interactions as well as main effects. Next the lasso dictionary is adjusted to include these main effects and the corresponding interaction terms. Again, promising terms are identified using a lasso screening procedure. Only those SNPs identified by the stage 1 screening process are genotyped in stage 2. Significant terms are identified through the cleaning process. We applied our procedure on both simulated data and data simulated with linkage disequilibrium and allele frequencies identical to a panel of SNPs from a candidate gene study. We compared our results with marginal two stage tests such as Lin (2006) and LeBlanc and Kooperberg (2008). Our method has comparable or higher power than the marginal two stage tests. Moreover, our method provides an accurate control of the type I error and false discovery rate when the markers are correlated. The R code is available at www.stat.cmu/~jwu/screenNclean/.

Effect of Fibrinolysis on Bronchopulmonary Dysplasia in Newborns. *H. Verdi[1], FB. Atac[1], D. Ince[2], A. Taneri[1], E. Sezgin[1], AC. Yazici[3], A. Tarcan[2], N. Ozbek[2]* 1) Dept Medical Biol and Genetics,Baskent Univ, Ankara, Turkey; 2) Dept Pediatric, Baskent Univ,Ankara,Turkey; 3) Dept Biostatistics, Baskent Univ, Ankara, Turkey.

Bronchopulmonary dysplasia (BPD) is a chronic disease that affects premature babies and contributes to their morbidity and mortality. A new BPD has been characterized in preterm infants that may begin in utero, then progress postnatally, resulting in arrested lung development and alveolar hypoplasia. It is defined as oxygen therapy requirement at the age of 28 days for premature infants. The severity of BPD is defined in infants born at <32nd gestational week based on their oxygen requirement on the 36th gestational week or at the time of discharge to home, and in infants born on >32nd gestational week based on their oxygen requirement on the 56th postnatal day or at the time of discharge to home. Factor XIII (F13) Val34Leu, angiotensin-converting enzyme insertion/deletion (ACE I/D) and the plasminogen activator inhibitor-1 gene (SERPINE1, also known as PAI1) 4G/5G are the three hypofibrinolytic gene variants that may enroll a cumulative effect in the development of BPD phenotype. To test this hypothesis a total of 192 newborn infants (98 BPD cases and 94 controls) were included. The obtained genomic DNA was used as a template for the investigation of F13 Val34Leu, ACE I/D and PAI-1 4G/5G genotypes. The preliminary results of our study indicates that ACE D, SERPINE1 4G and F13 34Leu alleles did not have a cumulative effect on the development BPD in our population.

Overexpression of microRNA-206 in the skeletal muscle from myotonic dystrophy type 1 patients. *S. Gambardella[1], F. Rinaldi[1], A. Viola[1], L. Vergani[2], E. Loro[2], V. Romeo[2], C. Angelini[2], G. Novelli[1], A. Botta[1]* 1) Dept Biopathology, Tor Vergata Univ, Rome, Italy; 2) Dept of Neurology, University of Padoa, Padoa, Italy.

MicroRNAs are highly conserved, noncoding RNAs involved in post-transcriptional gene silencing. They have been shown to participate in a wide range of biological processes, including myogenesis and muscle regeneration. The goal of this study is to test the hypothesis that myo-miRs (myo=muscle+miR=miRNA) expression is altered in muscle from patients affected by myotonic dystrophy type 1 (DM1), the most frequently inherited neuromuscular disease in adults. To this aim, we have profiled the expression miR-133 (miR-133a-1, miR-133a-2, miR-133b), miR-1 (miR-1-1, miR-1-2), miR-181 (miR-181a, miR-181b, miR-181c) and miR-206, that are specifically induced during myogenesis in the heart and skeletal tissues. QRT-PCR experiments have been performed on RNA from vastus lateralis biopsies of DM1 patients (n=7) and control subjects (n=4). Only miR-206 showed an over-expression in 5 of 7 DM1 patients (threshold=1.5, fold change between 1.68 and 13.51, average= 5.02) compared to control group. This result has been further confirmed by Northern blot analysis (4.2-fold overexpression). The misregulation of miR-206 in DM1 is consistent with what observed in the affected diaphragm of mdx mouse (an animal model of Duchenne muscular dystrophy). Since the vastus lateralis from DM1 patients exhibits all the pathological hallmarks of a dystrophic tissue, miR-206 may contribute to the chronic course of both muscular dystrophies. Further investigation are in progress to characterize the protein level of miR-206 targets and to understand if the excess of this miR colocalized with the ribonuclear foci observed in DM1 cells. This study is supported by Telethon (GGP07250).

Multivariate genetic analysis of specific language impairment (SLI) in extended pedigrees: The relationship between reading and language measures on 13q21. *T. R. Simmons[1], P. J. Weaver[1], T. Andrews-Bryant[1], J. F. Flax[2,3], P. Tallal[2], C. W. Bartlett[1], L. M. Brzustowicz[3]* 1) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Childrens Hospital, Columbus, OH; 2) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ; 3) Department of Genetics, Rutgers University, Piscataway, NJ.

SLI is a heritable developmental language disorder occurring in absence of frank neurological or cognitive impairment. It is characterized by significant problems of comprehension and/or expression of spoken language. However, the difficulty defining SLI and the complex relationship between language and reading (in SLI) requires us to understand phenotypic and genetic heterogeneity in the context of the different phenotypic pathways to language impairment. Previously, we found compelling evidence for an SLI susceptibility locus using a reading impairment (RI) variable on 13q21-22 with a PPL of 53% (LOD=3.92). This finding was followed up with a replication PPL of 17% (LOD=2.62); joint analysis of both datasets shows strong evidence for linkage to 13q21 with a PPL of 96.9% (LOD=7.86). Despite the overwhelming evidence for a susceptibility allele in 13q21, prima fascia, it is unclear how reading impairment relates to either SLI or quantitative measures of language at this locus. In order to elucidate the relationship, we performed a joint analysis where persons affected with RI are left coded as affected while the remainder of the individuals retain their quantitative language scores in the analysis. Our model implicitly assumes that RI is at the low end of the language score distribution. The PPLs for this model were 65%, 37% and 15% using three different language measures. We also performed the complimentary linkage analysis where language impairment was analyzed with several quantitative reading measures (all PPLs < 5%). This dissociation is consistent with our hypothesis that, in our sample selected for language deficits, RI is due to either an underlying language impairment or both reading and language deficits are caused by the same (similar) underlying factors.

Parkin, Pink1 and DJ-1 heterozygous mutations in southern italian patients with early-onset parkinsonism. *F. Rocca[1,2], F. Annesi[1], E. V. De Marco[1], D. Civitelli[1], P. Tarantino[1,3], G. Provenzano[1,3], V. Scornaienchi[1], V. Greco[1], G. Annesi[1]* 1) Inst Neurological Sci, National Research Council, Cosenza, Italy; 2) Institute of Neurology, University Magna Graecia, Catanzaro; 3) Departement of Neurosciences, Psychiatry and Anaesthesiology University of Messina, Messina Italy.

Recessively inherited early-onset Parkinsonism (EOPD) has been associated with mutations in the PARKIN, PINK1 AND DJ1 genes. Screening patients cohorts has revealed that more than 50% of patients with mutations in PARKIN or PINK1 have only a single heterozygous mutation. To evaluate the frequency of heterozygous mutations in genes associated with autosomal recessive EOPD, we investigated 134 sporadic cases of EOPD from southern Italy. The genetic screening was performed by direct sequencing of the coding region of PARKIN, DJ1 and PINK1 genes. All exons of PARKIN and DJ1 genes were examined for gene dosage abnormalities in individual with single heterozygous mutations.Moreover in patients carrying of only one mutation in the PARKIN gene, we also investigated rearrangements in the promoter region. Screening identified single heterozygous mutations in 11 EOPD patients. Eight patients (5,9%) carried heterozygous mutations in PARKIN gene (five novel variants: Thr55Ile, Asp18Asn, Lys 32Thr, Asp86Asn, Pro37Pro and three described variants: Arg42Pro, Leu261Leu, Met192Leu). Two patients (1,4%) showed novel heterozygous mutations in DJ1 gene (g159C/G and Asp68Val). One patient (0,7%) carried a novel heterozygous mutation in PINK1 (R207Q). Novel variants were absent in 100 control chromosome. Gene dosage experiment failed to reveal rearrangements within PARKIN and DJ1 genes and in the PARKIN promoter. In our population the frequency of heterozygous mutations in PARKIN and DJ1 genes is similar to that reported by other authors, whereas heterozygous mutations in PINK1 gene are less frequent.The role of single heterozygous mutations in EOPD is difficult to interpret. Haploinsufficiency or a dominant negative effect of the mutant allele may account for the pathogenesis.

Genetic risk estimation in Crohns disease. *C. M. Lewis[1,2], C. G. Mathew[1]* 1) Medical & Molecular Genetics, King's College London, UK; 2) MRC SGDP Centre, Institute of Psychiatry, King's College London, UK.

Genome-wide association studies have enabled researchers to identify disease-gene associations, detecting many novel susceptibility genes for common, complex disorders. However, most variants confer only a small increase in risk and are of questionable value for prediction studies, identifying individuals who are at increased risk of disease. To explore the potential for population screening in Crohns disease (CD) we analyzed six confirmed susceptibility loci for CD, including NOD2. Risks were extracted from UK replication studies. Most SNP effects fitted a multiplicative model, with allele-specific relative risks (RR) ranging from 1.10 (ATG16L1; T300A) to 1.45 (IL23R; rs10889677). For NOD2, individuals were classified by the number of mutations carried, and showed a gene dosage effect (RR for 1 mutation: 2.2, for 2 mutations: 9.2). Assuming no gene-gene interaction, we estimated the relative risk of CD for each genotype combination across SNPs. The RR of CD in the highest risk genotype compared to the lowest risk genotype is >150. This commonly used comparison is inappropriate (although commonly used) as each of these genotypes is extremely rare. Using a baseline genotype whose prior, population risk (assumed to be 0.001) is equal to its posterior risk provides more appropriate (if less striking) relative risks. Then, individuals with genotypes in the top 10% of the risk distribution have relative risks of 1.7 - 45.0, and account for 26% of the CD cases in the population. Only 1% of the population has a RR > 4. Individuals with genotypes in the lowest risk decile are protected against CD, with relative risks of >0.28, and account for only 4.5% of CD cases. NOD2 provides the largest contribution to risk estimation, with other genes having a limited modifying effect. These results suggest that genetic risk profiles for CD will currently be of limited value for population screening, as only a small proportion of the population has substantially increased risk. Focusing tests on those with positive family history or presence of environmental risk factors will be more useful, and can be included in the risk modeling.

FBN1 gene screening in 586 probands reveals the minimal combination of clinical features to predict efficacy of mutation identification. *C. Stheneur[1,2], G. Collod-Beroud[3], L. Faivre[4], L. Gouya[2,5,6], B. Grandchamp[2], B. Chevallier[1,2,6], G. Jondeau[2], C. Boileau[2,5,6,7]* 1) Service de pédiatrie, APHP-Hôpital A.Pare, Boulogne, France; 2) Consultation multidisciplinaire Marfan, APHP-Hôpital Bichat, Paris, France; 3) INSERM U827 Montpellier, France; 4) CHRU Dijon Centre de genetique Dijon, France; 5) Laboratoire central de biochimie d'hormonologie et de genetique moleculaire, Boulogne, France; 6) Universite Versailles-SQY, Versailles, France; 7) INSERM U781, Paris France.

Mutations identified in the FBN1 gene have been associated with Marfan syndrome (MFS) and a wide range of overlapping disorders. Molecular analysis of the gene is performed in probands with classical MFS, to offer diagnosis for at-risk relatives and in children highly suspected of MFS. We screened the FBN1 gene in 586 probands who had been addressed for molecular diagnosis. We identified 354 mutations representing 196 missense mutations, 48 splice site alterations, 55 nonsense mutations, 14 insertions/duplications and 41 deletions. We found that the efficacy of FBN1 gene screening was high in classical MFS probands (75.4 %,); lower (62.9%) in those referred for incomplete MFS and only slight (14.3%) for patients referred as possible MFS but with no major diagnostic criterion (as described in the Ghent nosology). Recursive partitioning was used to build a regression tree to identify combinations of clinical features related to mutation detection rate. We found that the best predictor of the identification of a mutation in the FBN1 gene for incomplete MFS was the presence of features in at least three organ systems, combining one major and various minor criteria. Finally our data also show that our original recommendation (two systems involved with at least one with major criterion), represent the minimal criteria since, in probands not meeting these criteria the yield of mutation identification drastically falls. This recommendation should help clinicians and biologists in identifying probands with a high probability of carrying a FBN1 gene mutation, and thus optimize biological resources.

Family history of hepatoblastoma or hepatocellular carcinoma in children with liver disease in a genetic isolate: a clue for a recessive trait. *M. Girard[1,2], F. Lacaille[2], F. Sauvat[3], F. Jaubert[4], L. Brugières[5], I. Aerts[6], J.-L. Michel[7], V. Verkarre[4], L. Galmiche[4], M. Fabre[8], S. Lyonnet[1], A. Henrion Caude[1]* 1) Dept Genetics, Inserm U781, University Paris Descartes, Necker Hospital, Paris, France; 2) Dept Pediatric Gastoenterology, Necker Hospital, Paris, France; 3) Dept Pediatric surgery, Necker Hospital, Paris, France; 4) Dept Anatomopathology, Necker Hospital, Paris, France; 5) Dept Pediatric Oncology, Gustave Roussy Institute, Villejuif, France; 6) Dept Pediatric Oncology, Curie Institute, Paris, France; 7) Dept Surgery, Felix Guyon Hospital, Reunion Island, France; 8) Dept Pathology, Kremlin-Bicêtre Hospital, University Paris Sud-11, Le Kremlin-Bicêtre, France.

Here we report on the occurrence of either hepatoblastoma or hepatocellular carcinoma, together with chronic liver disease, in three patients, with onset between the neonatal period and 9 years of age. The liver disease was characterized by fibrosis and cholestasis. Extensive questioning of the family revealed no known cases of adenomatous polyposis. Along these lines, all known causes for chronic liver disease were ruled out for each of the three patients. Two of the children with hepatoblastoma and hepatocellular carcinoma were siblings, while the third hepatoblastoma patient was a second cousin. All patients originate from the Reunion Island, a population prone to founder effects. To the best of our knowledge, this is a first description of the occurrence of both hepatoblastoma and hepatocellular carcinoma in a single extended family. The common genetic background as well as the existence of a primitive liver disease in these related cases raise the possibility of a unique recessive trait predisposing to liver tumors in childhood. The results of a genome-wide linkage analysis currently performed will be presented, using the affected-only approach and considering several alternative underlying genetic models.

Adapting the Logical Basis of Tests for Hardy Weinberg Equilibrium. *K. Goddard[1], A. Ziegler[2], S. Wellek[3]* 1) Ctr Health Res, Kaiser Permanente Northwest, Portland, OR; 2) Institute of Medical Biometry and Statistics, University at Lübeck, Germany; 3) Division of Biostatistics, CIMH Mannheim/University of Heidelberg, Germany.

The standard goodness-of-fit (GOF) test to assess HWE is fundamentally flawed with respect to its logical basis, because it is tailored to establish departure from HWE. However, in the majority of applications, we aim to exclude the existence of gross violations of the equilibrium condition. We present a logically unflawed solution to this problem using equivalence testing, and show that the new method provides exact control of the type I error risk. The test is available in one- and two-sided versions, and we provide tools for exact power calculation. The power is 80% for a wide range of allele frequencies when the sample size exceeds 200. We illustrate the method using genotype distributions from 43 candidate gene studies and 2 genome-wide association studies. The conclusions of the GOF and equivalence tests are the same for 70% of the samples. There are two explanations for the discrepancies. First, when the sample size is small, the default behavior of the two tests leads to discordant conclusions in circumstances of low power. For the GOF test, tests with low power fail to reject HWE, and tend to be classified with tests indicating compatibility with HWE. For the equivalence test, tests with low power fail to demonstrate equivalence with HWE, and tend to be classified as indicating a lack of fit to HWE. In the observed studies with this type of discrepancy, the average sample size is 142 (84) for the discordant studies, and 212 (192) for the concordant studies. Second, when the sample size is large, statistically significant, but small, deviations from HWE are detected in the GOF test. We conclude equivalence with HWE using the equivalence test, because these small deviations are unimportant. The magnitude of the deviation from HWE for the discordant studies is about half of the deviation from HWE for the concordant studies (.11 .023 versus .19 .14, respectively). The new test provides more satisfactory assessment of HWE, especially for genome-wide association studies.

The Melatonin Receptor 1A Gene (MTNR1A) Is Associated With Kidney Stones. *R. Chimienti[1], A. Aloia[1], D. Rendina[2], A. Ciccodicola[1], P. Strazzullo[2], F. Gianfrancesco[1], G. Mossetti[2], T. Esposito[1]* 1) Institute of Genetics & Biophysics, Italian National Research Council, Naples, Italy; 2) Department of Clinical and Experimental Medicine, Federico II University Medical School, Naples, Italy.

Several lines of evidence indicate that melatonin regulates renal tubular function in addition to any postulated role for this hormone in CNS physiology. There is also recent hypothesis that melatonin plays a significant role in renal physiology, this is supported by the demonstration of specific, high-affinity melatonin receptors in the kidney of several mammalian and avian species, including humans. We hypothesized that MTNR1A genetic polymorphisms might influence the risk of kidney stones. To validate this hypothesis we resequenced the human genomic MTNR1A gene in 20 unrelated nephrolithiasis patients and in 20 healthy individuals, and performed a systematic genetic analysis. We found 5 SNPs including: two synonymous (R308R and T315T), a non synonymous change (G166E), an intronic polymorphism, and an additional SNP in the regulative region at 5 of the gene. The two synonymous changes showed a minor allele frequency of less than 5% and were removed from further statistical analysis. The remaining 3 polymorphisms with a minor allele frequency of 5% were genotyped in 150 kidney stone cases and 150 controls and used to test allele frequency differences and calculate the degree of linkage disequilibrium between these loci. The SNP -368A/G in promoter region revealed a significant difference in the genotype frequency between cases and controls (OR 0.49, 95% CI 0.26-0.92, p=0.02). The A/T SNP in intron 1, showed a strong association with kidney stone risk (alleles: OR 2.09, 95% CI 1.36-3.20, p=0.00065; genotypes: OR 5.50, 95% CI 2.00-15.09, p=0.00055). TT genotype carriers were at 5.5-fold increased kidney stone risk compared with AA genotype carriers. In conclusion, we have conducted the first mutational screen of the melatonin receptor 1A gene (MTNR1A) in relation to kidney stone formation. We have demonstrated a strong association between genetic variants in regulative region of MTNR1 gene and kidney stone formation. Of course, these results should provoke studies in other populations.

Partial *XNP* duplication causes ATRX syndrome. *D. M. Cohn[1], R. A. Pagon[2], L. Hudgins[3], C. E. Schwartz[1], R. E. Stevenson[1], M. J. Friez[1]* 1) Greenwood Genetic Center, Greenwood, SC; 2) Division of Genetics and Development, Childrens Hospital and Regional Medical Center, Seattle, WA; 3) Division of Medical Genetics, Stanford University, Stanford, CA.

Multiplex ligation-dependent probe amplification (MLPA) has become a useful methodology to identify changes in gene dosage in both research and diagnostic settings. Many commercially available MLPA kits exist for specific gene and clinical indications. Laboratories have the option of developing custom synthetic MLPA kits for applications that are not commercially available. We have taken advantage of the synthetic kit option to query cohorts of males with a suspected X-linked mental retardation (XLMR) syndrome, but are negative on sequence analysis of the associated XLMR gene. Five XLMR genes (*XNP, L1CAM, CDKL5, FGD1* and *NEMO*) were selected along with other autosomal control genes in our custom kit. Males with a specific diagnosis associated with the genes selected along with other males with mental retardation and hypotonia were analyzed for the presence of duplications. Microduplications for these XLMR genes appear to be rare as only one family was found from the screening of 1152 probands. A single microduplication of *XNP* was identified in a male proband with ATRX syndrome. Confirming the segregation, additional family members were tested and each of the affected males and the obligate carrier females were shown to have the same duplication. X chromosome comparative genomic hybridization (CGH) array studies and quantitative real time PCR (qPCR) defined the *XNP* duplication to be partial (exons 2-31) and 248 kb in length. The duplication interferes with the synthesis of full length *XNP* transcript which is apparent on Northern blot analysis and is consistent with the clinical diagnosis of ATRX syndrome. Diagnostic methodologies such as array CGH with adequate coverage in the *XNP* region should be considered in males clinically diagnosed with ATRX syndrome and normal *XNP* sequencing.

A MADA mouse model shows growth retardation, precociuous hair loss and bones anomalies. *M. Bertoli, A. Vielle, F. Lombardi, A. Botta, M. R. D'apice, A. Orlacchio, M. Federici, G. Novelli* Department of Biopathology and Diagnostic Imaging, University of Rome Tor Vergata, Via Montpellier 1, 00133 Rome, Italy.

Laminopathies are an heterogeneous group of genetic disorders, that manifest varied clinical features affecting skeletal and cardiac muscle, adipose tissue, nervous system, cutaneous tissue, and bone. Mutations in the gene encoding lamins A and C (LMNA) cause primary laminopathies, including various types of lipodystrophies, muscular dystrophies and progeroid syndromes, mandibuloacral dysplasia, dilated cardiomyopathies, and restrictive dermopathy. A rare homozygous mutation in LMNA(p.R527H) cause mandibuloacral dysplasia type A (MADA), characterized by postnatal growth retardation, dysmorphic craniofacial and skeletal features, lipodystrophy, metabolic complications and premature ageing features. The pathogenic mechanisms of this mutation in the lamins A and C are still unknown. Variable laminopathic mouse models have been constructed, nevertheless phenotypes were not always as expected.MADA transgenic mouse was generated by the random insertion of the human mutated p.R527H cDNA driven by a strong expression promoter. Transgene copy number was determined by Quantitative Real Time PCR and seemed to correlate with the severity of the phenotype. Mutant mice have slight postnatal growth retardation. Adult MADA mice have sparse and less shiny hair, with nude areas. Radiography of the transgenic mouse, compared to the wild type, showed a reduced bone density, a rounder head with shorter mandibule, and an hypoplasic clavicule. Moreover, we analyzed the behaviour of circulating MMP-9, a bone homeostasis marker altered in MADA disorder, and observed an abnormal activity and pattern in mutant mouse as seen in human patients. An animal model reproducing human phenotype is essential for an in-depth understanding of pathogenic mechanism and for the development of in vivo therapeutic assays. These preliminary results demonstrate that MADA mouse model, showing characteristic bone phenotype, will represent an interesting and useful tool for the up-coming therapeutic studies in laminopathies. This work was supported by EU grant FP6 Euro-laminopathies no. 018690.

A 300 kb terminal deletion of chromosome 4p in patient with autism indicates a possible new autism locus. *M. Velinov[1], N. Dolzhanskaya[1], H. Gu[1], G. Beldia[2], E. C. Jenkins[1], W. T. Brown[1]* 1) Dept Human Genetics, NYS Institute for Basic Research, Staten Island, NY; 2) Jervis Clinic, NYS Institute for Basic Research, Staten Island, NY.

This 16-years-old male patient was born with normal birth weight, after an uncomplicated pregnancy. The newborn period was uncomplicated. He was making consonant sounds at 9 month of age. He walked at 11 months of age and said his first words at 12 months. After his first birthday, as per his parent, his speech development slowed down and he stopped making eye contact. He had diagnosis of autism at the age of 2 that was later confirmed using the Autism diagnostic Observation Scale and the Vineland Adaptive Behavior Scale. His growth and head size were within normal range for his age. This patient was also found to have type 1 diabetes at the age of 6. He receives insulin treatments daily. This patients 10-year-old brother had juvenile diabetes as well, but his cognitive development was normal. No other family members with cognitive impairment were reported. Sub-telomeric analysis (Vysis probe) revealed a terminal 4p deletion in the proband. While enhancing the fluorescence signal of the sub-telomere hybridization, a dim signal of the sub-telomere probe was seen indicating that the breakpoint was most likely within the subtelomere probe locus. This deletion was not present in the patients brother and mother. His father was not available for testing. Further characterization of the deletion was done using 244K microarray of Agilent Inc. and additional FISH clones. The deletion was found to span the most distal 300 kb of 4p. Our patient did not have the characteristic facial features of Wolf-Hirschhorn syndrome, growth delay or microcephaly (associated with larger distal 4p deletions). A limited number of coding genes (namely ZNF595, ZNF718 and MGC26358) are located in the deleted chromosomal area. Although the contribution of these genes in brain development/functioning at this time is unclear, they may be considered as candidate contributors for autism.

Gene expression profiling of normal and pathological testis by microarray analysis. *V. Gatta[1,2], F. Raicu[3], A. P. Scioletti[1,2], A. Ferlin[4], C. Foresta[4], G. Palka[1,2], L. Stuppia[1,2]* 1) Department of Biomedical Science, G. d'Annunzio University Chieti, Italy; 2) Aging Research Center, Ce.S.I. , G. d'Annunzio University Chiet-Italy; 3) Carol Davila University of Medicine and Pharmacy Faculty of Dentistry, Bucharest,Romania; 4) Department of Histology, Microbiology and Medical Biotechnologies,University of Padova, Italy.

Male infertility is a major reproductive health problem, since approximately 15% of couples in western countries seek medical treatment for infertility. In about 10% of cases, male infertility is due to the presence of microdeletions of the Y chromosome, involving three loci on Yq (AZFa, AZFb, AZFc). Despite the large amount of data collected in the last years, the biological mechanisms leading to the disruption of the spermatogenesis in Yq deleted patients are still largely unknown. In this study we carried out a microarray analysis of the testis expression profiles of 7 patients with idiopathic infertility, 6 AZFc deleted patients and 3 control subjects (patients with obstructive azoospermia) in order to detect the specific gene networks involved in each different pathological condition. Hierarchical clustering of differentially expressed genes in testis with different forms of spermatogenesis failure as compared to testis with normal spermatogenesis evidenced the presence of more than 300 significantly downregulated and about 150 upregulated transcripts in AZFc deleted patients. Analysis of these gene clusters using IPA software revealed an interesting down-regulated gene network directly related with spermatogenesis, centred around the YBX2 gene (Y box binding protein 2), involved in RNA storage during gametogenesis. This alteration is responsible for the downregulation of the protamine1 and 2 genes evidenced in the same network analysis. This suggests that impairment of RNA storage could represent one of the biological mechanisms underlying spermatogenesis failure in patients with Yq microdeletion. In the expression profiles comparative analysis between controls and AZFc deleted patients we also observed an interesting downregulation of the CREM pathway, which is a master controller gene for spermatogenesis.

Linkage study of Ectodermal Dysplasias in Pakistani Inbred Families. *I. Ahmad, M. Rasool, M. Tariq, A. Ali, M. Bakhtiar, S. Nawaz, S. Rehman, S. Mahmood Baig* NIBGE Jhang Road P.O Box 577 Faisalabad Pakistan.

Ectodermal dysplasia (EDs) represents a large and complex group of diseases comprising more than 200 different clinical conditions. They are caused by impaired development of epidermal appendages and characterized by primary defect in at least on of the following tissue: nail, hair, teeth and sweat glands. In this study, six consanguineous families with ectodermal dysplasia were located from different areas of Pakistan having multiple affected members. Pedigrees were analyzed to determine the pattern of inheritance; in all families the disease was inherited in the autosomal recessive pattern. Short Tandem Repeat Markers (STR) were used in the exclusion mapping for the ten most common loci reported. According to results, one family with ED was linked to the EDAR gene at locus 2q13 while other families are excluded from all known loci .The families excluded to all known loci will be subjected to genome wide scan by SNP (Single Nucleotide Polymorphism) analysis using Affymetrix 250K array system to find the homozygous regions to find out the locus having the disease gene. Statistical analysis such as LOD (log of odds) will be used to validate the data obtained.

Identification of 23 TGFBR2 and 6 TGFBR1 gene mutations and genotype-phenotype investigations in 457 patients with Marfan syndrome type I and II, Loeys-Dietz syndrome and related disorders. *G. Jondeau[1,2], G. Collod-Beroud[3], L. Faivre[4], L. Gouya[2,5,6], D. Attias[2,6], B. Chevallier[2,6,7], C. Boileau[2,5,6,8], C. Stheneur[2,7]* 1) Service de cardiologie, APHP-Hôpital Bichat, Paris, France; 2) Consultation multidisciplinaire Marfan, APHP-Hôpital Bichat, Paris, France; 3) INSERM U827, Montpellier F-34000, France; 4) CHRU Dijon, Centre de genetique, Dijon,F-21000, France; 5) Laboratoire central de Biochimie, d'hormonologie et de genetique moleculaire, APHP-Hôpital A.Pare, Boulogne F-92100, France; 6) Universite Versailles-SQY, Versailles F-78000, France; 7) Service de pediatrie, APHP-Hôpital A.Pare; Boulogne F-92100, France; 8) INSERM U781, Hôpital Necker-Enfants-Malades, Paris F-75015 France.

TGFBR1 and TGFBR2 gene mutations have been associated with Marfan syndrome types 1 and 2, Loeys-Dietz syndrome and isolated familial thoracic aortic aneurysms or dissection. In order to investigate the molecular and clinical spectrum of TGFBR2 mutations we screened the gene in 457 probands suspected of being affected with Marfan syndrome or related disorders that had been referred to our laboratory for molecular diagnosis. We identified and report 23 mutations and 20 polymorphisms. Subsequently, we screened the TGFBR1 gene in the first 74 patients for whom no defect had been found, and identified 6 novel mutations and 12 polymorphisms. Mutation-carrying probands displayed at referral a large clinical spectrum ranging from the Loeys-Dietz syndrome and neonatal Marfan syndrome to isolated aortic aneurysm. Furthermore, a TGFBR1 gene mutation was found in a Shprintzen-Goldberg syndrome patient. Finally, we observed that the yield of mutation detection within the two genes was very low : 4.8% for classical MFS, 4.6% for incomplete MFS and 1% for TAAD in the TGFBR2 gene; 6.2%, 6.2% and 7% respectively in the TGFBR1 gene; in contrast to LDS, where the yield was exceptionally high (87.5%).

Fragile X premutation alleles in movement disorders. *D. Civitelli[1], E. V. De Marco[1], F. Annesi[1], P. Tarantino[1-], F. E. Rocca[1-2], G. Provenzano[1-3], V. Scornaienchi[1], V. Greco[1], G. Annesi[1]* 1) Inst Neurological Sci, National Research Council, Mangone Cosenza, Italy; 2) Institute of Neurology, University of Magna Graecia, Catanzaro, Italy; 3) Department of Neuroscience, Psychiatry and Anesthesiology, University of Messina, Policlinico Universitario, Italy.

The fragile X-associated tremor/ ataxia syndrome (FXTAS) predominantly occurs in man carrying FMR1 gene premutation alleles (55- 200 CGG rep) over age 50. Associated phenotype includes tremors, balance problems and sometimes dementia, progressively worsening over time. This picture overlaps with those of both Parkinson's disease (PD) and essential tremor (ET). We selected 203 PD patients, 30 ET patients and 370 healthy subjects. We also included two individuals (exhibiting parkinsonian symptoms) from a fragile X mental retardation pedigree, and two cases with intention tremor and postprandial hypotension. All participants had the same ethnic background and gave informed consent. The length variation within the CGG repeat was assessed by a PCR-based test. We did not found FMR1 premutation genotype in any patients with PD and ET or in any healthy controls. There were 17 distinct alleles, ranging from 19 to 37 CGG repeats. On the contrary, the two subjects with parkinsonian symptoms and family history of fragile X syndrome carried, respectively, 57 and 90 CGG repeats. Concerning the two subjects with intention tremor and postprandial hypotension, one of them had 73 CGG repeats and the second one was an uncommon mosaic for a premutation (90 CGG rep) and a normal-size allele. There is no clear biochemical link between FXTAS, PD and ET; they are thought to occur through very different disease mechanisms. However, the wide and variable FXTAS phenotype overlaps the clinical features of many neurological diseases, making diagnosis of this disorder difficult without molecular analysis. Our data show that premutated alleles are rare in PD as well as in ET. Thus the presence of postprandial hypotension or a positive family history of fragile X syndrome, beside the peculiar T2-hyperintense signal in middle cerebellar peduncles, can be considered an important indication for FMR1 expansion genetic testing.

A computational evolution system for the genetic analysis of epistasis. *J. Moore, P. Andrews, C. Greene*
Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Common human diseases are complex and likely the result of nonlinear interactions between multiple different DNA sequence variations. One goal of human genetics is to use data mining and machine learning methods to identify sets of discrete genetic attributes that are predictive of discrete measures of health in human population data. A variety of different computational intelligence methods based on artificial evolution have been developed and applied in this domain. While artificial evolution approaches such as genetic programming show promise, they are only loosely based on real biological and evolutionary processes. It has recently been suggested that a new paradigm is needed where artificial evolution is transformed to computational evolution by incorporating more biological and evolutionary complexity into existing algorithms. Computational evolution systems have been proposed as more likely to solve problems of interest to biologists and biomedical researchers. To test this hypothesis, we developed a prototype computational evolution system for the analysis of human genetics data capable of evolving operators of arbitrary complexity. Preliminary results suggest that more complex operators result in better solutions. Here we introduce modifications including a simpler stack-based solution representation, the ability to maintain and use an archive of solution building blocks, and a simpler set of solution operator building blocks capable of learning to use pre-processed expert knowledge. A parameter sweep suggests that operators that can use expert knowledge or archival information outperform those that cannot. This study supports the idea that complexity matters and thus the consideration of computational evolution for bioinformatics problem-solving in the domain of human genetics.

Findings from a UK National and International Service for Germline TP53 mutational analysis that have implications for genetic testing and counselling. *N. Sodha[1], S. Furnell[1], R. Eeles[2,1]* 1) Cancer Genetics, Royal Marsden NHS Hospital Foundation Trust, Sutton, Surrey, United Kingdom; 2) Section of Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, SM2 5NG, United Kingdom.

Around 75% of families with classical Li-Fraumeni syndrome (LFS) have a germline mutation in TP53 identifiable by direct sequencing of the coding region and splice sites. We have used Multiplex Ligation dependent Probe Amplification (MLPA) to screen affected individuals from 24 classical LFS families, 62 Li-Fraumeni Like (LFL) families (Birch Definition), 13 affected cases from families with very early onset breast cancer at<30yr with or without some family history (FH) and 31 cases with multiple tumours with or without some FH, that were negative for a germline TP53 mutation identifiable by sequencing. 6 cases from classical LFS families 25%) and one case with multiple tumors with some FH of cancer were found to have a large deletion. These findings demonstrate that a substantial fraction of LFS families have a large deletion in TP53 indicating that this type of analysis should be included for a comprehensive analysis of the gene in LFS families. a low penetrance TP53 mutation, R337H, initially reported to be associated with cases with adrenocortical cancer without a family history of cancer in the brazilian population and subsequently in cases with a LFL family structure in the same population, was identified in individuals from four different UK families in out laboratory. Two of the families have cases with adrenocortical tumors and there are individuals with other early onset cncer in all four of these families. These findings have implications for genetic counselling.

Distinct effects of an HLA-C associated SNP on HIV pathogenesis. *R. Thomas[1], Y. Qi[1], D. Ge[2], J. Fellay[2], J. Phair[3], J. Goedert[4], S. Buchbinder[5], G. Kirk[6], A. Telenti[7], B. Walker[8], S. Deeks[9], D. Goldstein[2], M. Carrington[1]* 1) Cancer and Inflammation Program, SAIC-Frederick, NCI-Frederick, Frederick, MD; 2) Center for Population Genomics & Pharmacogenetics, Duke University, Durham, NC; 3) Department of Medicine, Northwestern University Medical School, Chicago, IL; 4) Viral Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 5) San Francisco Department of Public Health, HIV Research Section, San Francisco, CA; 6) Department of Epidemiology, Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD; 7) Institute of Microbiology, University of Lausanne, Lausanne, Switzerland; 8) Partners AIDS Research Center and Infectious Disease Division, Harvard Medical School, Boston, MA; 9) San Francisco General Hospital, San Francisco, CA.

Killer immunoglobulin-like receptors (KIR) are receptors on Natural Killer (NK) cells and bind to specific HLA class I ligands. Interactions between KIR and their HLA ligands have been implicated in NK cell mediated control of HIV-1 replication. A variant located 35kb upstream of the HLA-C gene(-35C/T) was previously shown to associate with high HLA-C mRNA expression and low viraemia. Analysis of this SNP in over 1500 HIV^+ individuals of Caucasian ancestry revealed a significant effect of the -35CC vs TT on mean viral load and a weaker protective effect with progression to late AIDS outcomes. HLA-C alleles are ligands for certain KIRs, including the activating KIR2DS receptors, which are present in some, but not all individuals. We observed that in the absence of KIR2DS, high HLA-C expression (as defined by -35C/T SNP) associated with slow progression to late outcomes of HIV infection, including death (CC/CT no KIR2DS was protective compared to TT no KIR2DS). However, in presence of KIR2DS, HLA-C levels had no effect on progression. Also, KIR2DS did not modulate the effect of -35C/T SNP on viral load. Thus, activating KIR does not influence the protective effect of -35C (high HLA-C levels) on early control of HIV-1, but has a significant effect on AIDS progression in late chronic disease. Funded by NCI Contract N01-C0-12400.

Genotype Frequencies in the MPS I Registry. *G. Cox[1], J. E. Wraith[2], C. Whitley[3], F. Wijburg[4], N. Guffon[5]* 1) Genzyme Corp, Cambridge, MA; 2) Royal Manchester Children's Hospital, Manchester, UK; 3) University of Minnesota, Minneapolis, MN; 4) Academic Medical Center, Amsterdam, The Netherlands; 5) Hôpital Edouard-Herriot, Lyon, France.

Background: The MPS I Registry includes over 700 patients and offers a unique resource to study mutation frequencies and genotype-phenotype correlations. MPS I patients are historically grouped into three phenotypes based on subjective assessment of disease severity: Hurler (severe), Hurler-Scheie (intermediate), and Scheie (attenuated). Although several mutations correlate with disease severity, most patients have at least one private mutation. **Methods:** Reported patient mutations were revised according to standardized nomenclature. Mutations were summarized by frequency, and genotype frequencies were assessed by phenotype. **Results:** IDUA gene mutations were reported for 46% of Hurler, 44% of Hurler-Scheie, and 41% of Scheie patients. Of 107 unique mutations reported in 293 patients, the 10 most common were: W402X (39%), Q70X (13%), P533R (7%), L490P (5%), A327P (3%), L218P and Q380R (2%); and T388R, S633L, and R628X (1%). Of patients with 2 reported mutations (87% of total), 64% were Hurler, 26% Hurler-Scheie, 8% Scheie, and 2% undetermined. Three genotypes were present in 44% of 184 Hurler patients: W402X/W402X (25%), W402X/Q70X (15%), and Q70X/Q70X (4%). Of 71 Hurler-Scheie patients, the 2 most common genotypes were L490P/L490P (18%) and P533R/P533R (7%). Scheie patients had no common genotypes. Patients with 2 nonsense mutations almost invariably had Hurler syndrome. One Hurler-Scheie and 2 Scheie patients had a mild R89Q mutation. Three Hurler, 5 Hurler-Scheie, and 1 undetermined patient were homozygous for the variable P533R mutation, which was combined with W402X in 3 Hurler, 3 Hurler-Scheie, and 1 Scheie patient. **Conclusions:** Mutation frequencies and genotypes reported in the MPS I Registry reflect those in the literature. The probability of a mutation being severe or mild may be estimated by pair-wise matching of mutations with known phenotypes. Genotyping may help in treatment decisions for affected infants and presymptomatic newborns identified by newborn screening.

Mothers genome or maternally-inherited genes acting in the fetus influence gestational age in familial preterm birth. *J. Plunkett, M. Feitosa, M. Trusgnich, T. Rice, I. Borecki, L. Muglia* Washington Univ, St Louis, MO.

Infants born before term (<37 weeks) have an increased risk of neonatal mortality as well as other health problems. The increasing rate of preterm birth in recent decades, despite improvements in health care, creates an impetus to better understand and prevent this disorder. While multiple lines of evidence suggest the importance of genetic contributors to risk of preterm birth, the nature of the genetic component has not been identified. In this study, we perform segregation analyses to identify the best fitting genetic model for gestational age, a quantitative proxy for preterm birth. Because either mother or infant can be considered the proband from a preterm delivery and there is evidence to suggest that genetic factors in either one or both may influence the trait, we performed segregation analysis for gestational age either attributed to the infant (infants gestational age, n=1130), or the mother (by averaging the gestational ages at which her children were delivered, n=191), using 96 multiplex preterm families. Using the Pedigree Analysis Program, likelihood ratio tests identified the parent of origin and mixed free (non-Mendelian) transmission models as the most parsimonious models for infant and mother analysis, respectively. These data lend further support to a genetic component contributing to birth timing since sporadic (ie. no familial resemblance) and nontransmission models, in which gestational age is attributed to environmental factors alone, are strongly rejected ($p<0.001$). Heritability estimates corroborate the general importance of genetics in birth timing (infant 0.33 (95% CI: 0.24, 0.42); mother 0.44 (95% CI: 0.11, 0.77)). Infant-based analyses support a model in which mothers genome and/or maternally-inherited genes acting in the fetus are largely responsible for birth timing, with a smaller contribution from the paternally-inherited alleles in the fetal genome. In stratified analyses, evidence for heterogeneity among black and white races was observed for both traits ($p<0.001$). Overall, our findings suggest that genetic influences on birth timing are important and likely complex.

Glycosylation Defects in Muscular Dystrophy. *S. Sparks[1,2], A. Kesari[2], E. Hoffman[2]* 1) Division of Genetics & Metabolism, CNMC, Washington, DC; 2) Research Center for Genetic Medicine, CNMC, Washington, DC.

Abnormal glycosylation of -dystroglycan (-DG) underlies the pathology of dystroglycanopathies. The clinical phenotype ranges from congenital onset of muscular dystrophy (CMD) with CNS and eye involvement, to a later onset form of limb girdle muscular dystrophy (LGMD). To date, 6 genes have been identified which alter the glycosylation pattern of -DG, all of which are known or putative glycosyltransferases. However, with the anticipated 10-15 steps in the glycosylation of -DG, there are more to be identified.

Methods: The muscle biopsy database of Dr. Eric Hoffman contains over 5000 samples that were referred for diagnostic testing of muscular dystrophy. Standard testing for dystrophin, merosin, dysferlin, and -sarcoglycan were completed. This database was screened for patients without a diagnosis for those potentially with a dystroglycanopathy. Identification of samples with a dystroglycanopathy was done using a combination of immunohistochemisty and sequencing.

Results: Screening the muscle biopsy database yielded 113 samples with unknown muscular dystrophy and clinical features and muscle histology consistent with CMD. These samples were screened for a glycosylation defect using immunohistochemistry, followed by molecular and biochemical characterization. A separate molecular screen for *FKRP* mutations was performed on 1088 patients with unknown LGMD. The c.826C>A (p.L276I) mutation was found in 26 patients, of which 10 were homozygous. A second mutation was identified in an additional 6 patients. In those with two mutations, glycosylation status of -DG has been analyzed.

Conclusion: Screening patients with unknown CMD using immunohistochemistry for abnormally glycosylated -DG on muscle tissue yields a positive result in 25% of patients. In contrast, patients with confirmed molecular defects in *FKRP* may have nearly normal glycosylation of -DG by immunohistochemistry. Therefore, screening LGMD patients for mutations in *FKRP* is a reasonable first step to evaluate LGMD patients for a dystroglycanopathy.

Miglustat in Niemann-Pick disease Type C (NPC): long-term data from a clinical trial. *M. C. Patterson[1], D. Vecchio[2], E. Jacklin[3], J. E. Wraith[3]* 1) Mayo Clinic, Rochester, USA; 2) Columbia University, New York, USA; 3) Royal Manchester Childrens Hospital, UK.

Previous clinical trial findings indicated that miglustat slows disease progression in NPC patients up to 24 months of treatment.[1,2] Here we report the long-term data in adult and juvenile patients who received up to 48 months of treatment with miglustat. Patients aged 12 years who completed an initial 12-month, open-label, randomized phase (either on miglustat 200 mg t.i.d. or standard care) and a further 12-month open-label extension period were offered continued miglustat treatment. Of 19 patients fulfilling these criteria, 16 (84%) continued with further treatment (mean SD [range] age: 22.6 9.4 [12-42] years; 44% female). The number of patients completing the Month 36, 42 and 48 visits were 15 (94%), 11 (69%) and 9 (56%), respectively. Median (range) treatment duration was 48.2 (27.1-67.5) months. Swallowing capacity (among 14 evaluable patients) was improved or stable in 11 (79%) patients (with water), 12 (86%) patients (with puree), and 13 (93%) patients (with both soft lumps and cookies) at last assessment. Ambulation Index (among 12 evaluable patients) remained stable in 8 (67%) patients at last assessment (mean change [95%CI] +0.6 [-0.2, +1.4]). The most frequent adverse events were diarrhea and weight decrease, each observed in 50% of patients, in contrast to 89% experiencing diarrhea and 68% with weight decrease during the first 24 months. Mean SD (range) weight change from baseline to last value was +0.56 8.10 kg (-9.3 to +21.0 kg). Three patients discontinued; none because of adverse events. Four patients did not complete the end of study visit. These data indicate a favourable clinical response with miglustat in adult and juvenile NPC patients, with stabilization of key parameters of disease progression seen over a median exposure of 48 months. Safety and tolerability with miglustat 200 mg t.i.d. in NPC were consistent with previous findings with miglustat 100 mg t.i.d. in type 1 Gaucher disease. [1]Patterson et al. Lancet Neurol 2007;6:765-72. [2]Patterson et al. Presented at the 57th annual conference of the ASHG, 2007, abstract 2253.

Harnessing the power of human perception for exploration of analytical results from genome-wide association studies. *R. Cowper, J. Moore* Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Interpretation of data analysis results from genome-wide associations studies (GWAS) is a daunting challenge. In most cases, the geneticist or epidemiologist relies only on his or her minds eye to envision the vastness and complexity of the human system. This process of analysis and exploration can be greatly enhanced if the power of visualization technologies and information design are used to harness the innate pattern recognition capabilities of human perception. Increasing the synergy between the geneticist and the computer will doubtlessly aid in making novel discoveries. However, information visualization faces several challenges in the field of human genetics due to the large volume, high dimensionality and interconnectedness of the data. In the present study we address some of these challenges and present a conceptual and software framework with which to tackle further challenges. We hypothesize that by representing each SNP in a GWAS as a tree or some other object in a natural landscape we will improve our ability to quickly identify interesting results by relying on our innate pattern recognition capabilities. To test this hypothesis we developed a system for visualizing statistical results as a natural landscape using Java-3D. Here, we represented each SNP as a tree with features like height, shape and color dependent on values of different statistical results such as a chi-square test of independence and ReliefF. We show that visually interesting patterns emerge when trees are drawn using the result of multiple different statistical measures of association. We further show how information from chromosomal location, Gene Ontology and biochemical pathway can be incorporated into these landscapes thus providing a biological context to the visualization. This study represents the first step towards a platform that harnesses the power of human perception for interpreting statistical results from GWAS.

Identification of a mutation in the *UFM1-specific peptidase 2* gene, *UFSP2*, that is linked to Beukes Hip Dysplasia. *C. M. Watson[1], P. Beighton[2], R. Ramesar[2], J. B. J. van Meurs[3], R. Donn[1], G. Wallis[1]* 1) The School of Translational Medicine, The University of Manchester, Oxford Road, Manchester, M13 9PT, United Kingdom; 2) Division of Human Genetics, University of Cape Town, Faculty of Health Sciences, South Africa; 3) Department of Internal Medicine, Erasmus MC, Rotterdam, The Netherlands.

Beukes hip dysplasia (BHD) is a rare, autosomal dominant disorder that leads to severe premature osteoarthritis of the hip that was originally identified in an extended South African family of Dutch origin. Previous studies have linked the disorder to a 2.79 Mb region on chromosome 4q35.

Linkage analysis refined the linked allele to a 1.33 Mb region encompassing 18 genes. Sequence analysis of the exons of these genes identified a heterozygous T to C transition within exon 8 of the *UFM1-specific peptidase 2* (*UFSP2*) gene that predicted a Y290H amino acid substitution in the encoded protein. Segregation of the C allele with the BHD phenotype gave a LOD score of 10.4. Sequence alignments demonstrated that this tyrosine was highly conserved across multicellular organisms. Further, the T/C sequence change was not identified following screening of a control population of 360 Dutch individuals.

UFSP2 has been demonstrated previously to cleave the C-terminal end of a member of the family of ubiquitin-like molecules, ubiquitin-fold modifier 1 (UFM1). We found that introduction of the histidine mutation abolishes UFSP2 cleavage of UFM1 *in vitro*. Preliminary studies in the chondrogenic ATDC5 cell line suggest a correlation of UFSP2 expression and chondrogenesis.

Genetic and preliminary functional studies indicate a role for the UFSP2 Y290H mutation in the aetiology of BHD. Additional studies are underway to investigate this possibility further.

Microcephalia Vera : Neuropsychologic and neuroradiologic findings of 9 children with ASPM gene mutations.

S. Passemard[1,2], M. Schaer[3], L. Titomanlio[1], K. Hernandez[1], T. Billette de Villemeur[4], S. Odent[5], B. Isidor[6], O. Boesflug Tanguy[7], A. Megarbane[8], JL. Alessandri[9], M. Verloes[1,2] 1) Genetic Department, Robert Debré Hospital, Paris, France; 2) INSERM U676, Robert Debré Hospital, Paris, France; 3) Department of Psychiatry, University of Geneva School of Medecine, Geneva, Switzerland; 4) Child Neurology Department, Trousseau Hospital, Paris, France; 5) Genetic Department, Rennes Hospital, France; 6) Genetic Department, Nantes Hospital, France; 7) Genetic Department, Clermont Ferrand Hospital, France; 8) Saint Joseph University, Beyrouth, Liban; 9) Pediatric Department, Saint Denis de la Réunion Hospital, France; 10) Genetic Department, Université Libre, Bruxelles, Belgien; 11) Radiology Department, Robert Debré Hospital, Paris, France.

Primary Human Microcephaly (MCPH previously refered to as Microcephalia Vera) is the autosomal recessive form of primary microcephaly. Affected individuals have a reduced brain size. Cerebral cortex is most severly affected by this reduction. Despite this marked reduction in size, the gyral pattern is relatively well preserved, with no major abnormality in the cortical cytoarchitecture. Individuals have mild to severe mental retardation. Six autosomal recessive loci and four genes have been identified (MCPH1, 3, 5 or ASPM, and 6). We report on the neurological and radiological phenotype of 9 European MCPH patients with ASPM gene mutations. Their intellectual quotien is between 35 and 70. Of all patients, 7 have gyral simplification and one child has a large unilateral polymicrogyria, the latter has not been described in this disease entity. Mental retardation is more severe when the head circumference is smaller, when the gyral pattern is simplified, and when a disorder of neuronal migration is apparent. Despite their mental retardation, the memory capacities of affected children is remarkably preserved. The results of our study suggest a phenotypic continuum between MCPH and microcephaly with simplified gyral pattern. There is a correlation between mental retardation severity and head circunference and gyral pattern simplification.

Regulatory SNPs in double strand break repair genes and their impact in childhood leukemia susceptibility. *M. Bourgey, N. N'Diaye, V. Weth, J. Healy, K. Benhamza, D. Sinnett* Hemotologie-Oncologie, Centre de recherche CHU Sainte-Justine, Universite de Montreal, Montreal, Quebec, Canada.

Acute lymphoblastic leukemia (ALL), the commonest form of childhood cancer, accounts for approximately 25% of all pediatric tumors. Considering that genetic instability is a hallmark of leukemia, that interindividual variation in DNA repair capacity is observed in the general population and that variation in DNA repair capacity is probably genetically determined, we propose that sequence variations in DNA repair genes might constitute a cancer risk factor. In this report, we studied the impact of regulatory SNPs (rSNPs) in genes encoding components of the double strand break (DSB) repair system hypothesizing that variation in regulatory sequences of such finely regulated genes will indeed play significant roles in cancer risk. In a case control study we genotyped 12 rSNPs in 6 genes for a sample of 330 cases and 320 controls all of French-Canadian origin. For each gene, the combination test was used to select the most significantly associated subset of rSNPs. Their haplotypic and genotypic effects on the childhood ALL were then modeled using the Marker Association Segregation Chi-square (MASC) method. Using a logistic regression analysis we also tested for the presence of interactions between selected subsets. We observed an associated combination of rSNPs in two genes, BRCA2 and KU80 ($p = 0.005$ and $p = 0.024$ respectively). The modeling of BRCA2 rSNPs suggested the role of three genotypic groups (GRR = 1 ; 1.52 [1.10 ; 2.04]; 2.27 [1.52 ; 3.28]). For KU80, we showed a dose effect of the rSNP -297T allele (GRR = 1; 1.31 [1.21; 1.86]; 2.02 [1.75 ; 2.88]). There was no evidence of a significant interaction between the two genes ($p = 0,73$). The lack of interaction between these two genes and the fact they belong to two distinct repair mechanisms suggest that quantitative changes in at least one DSB repair component is required to modify individuals risk of childhood ALL. We are now performing functional validation assays of the rSNPs and the related promoter constructs in order to gain knowledge about the biological significance of the observed associations.

Fetal Ventriculomegaly secondary to large choroid plexus cysts: Prenatal findings and postnatal outcome. *T. Friedberg[1,2], K. Chong[1,2,4], A. Toi[3], K. Fong[3], D. Chitayat[1,2,4]* 1) Prenatal Diagnosis and Medical Genetics, Mount Sinai Hospital, Toronto, ON, Canada; 2) Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, ON, Canada; 3) Department of Diagnostic Imaging, Mount Sinai Hospital, Toronto, ON, Canada; 4) Clinical and Metabolic Genetics, The Hosptial for Sick Children, Toronto, ON, Canada.

Choroid plexus cysts (CPCs) are sonographically detectable folds of the epithelial lining of the choroid plexus. In most cases, fetal CPCs are normal variants with a natural history of regression during the third trimester of pregnancy or after delivery. Outcome studies of isolated CPCs have reported no associated developmental delay or other related problems. However, when detected prenatally, CPCs have been associated with an increased risk for fetal trisomy 18. Enlargement of the fetal cerebral lateral ventricles caused by large CPCs, to the best of our knowledge, has not been reported. We report on six cases detected prenatally with a large isolated CPCs that resulted in ventriculomegaly (lateral ventricular width greater than 10 mm). All cases had normal first or second trimester screening for trisomy 18 and all detailed fetal ultrasounds subsequently showed multiple CPCs measuring 10 mm or more. Four patients had amniocentesis with normal karyotypes and the other two patients declined invasive testing. All cases had negative screen for intrauterine infection. Serial ultrasounds were performed during the pregnancy for surveillance of the ventriculomegaly. All cases resulted in healthy newborns delivered at term. Two of the cases have had postnatal follow-up to almost 2 years of age and have not developed any medical or neurological problems. To the best of our knowledge, this is the first report of ventriculomegaly caused by large CPCs. It shows that ventriculomegaly secondary to large CPCs is a different category of mild ventriculomegaly and is associated with normal outcome. This information is important for counselling couples with similar prenatal findings.

FAM-MDR: A flexible method of multifactor dimensionality reduction for high-order genetic interaction detection in related individuals. *K. Van Steen[1,2], M. Calle[3], V. Urrea[3], N. Malats[4]* 1) Department of Electrical Engineering and Computer Science, University of Liège, Liège, Belgium; 2) Department of Human Genetics, University of Leuven, Leuven, Belgium; 3) Department of Systems Biology, Universtiat de Vic, Vic, Spain; 4) Centro Nacional de Investigaciones Oncológicas, Madrid, Spain.

In the search for high-order genetic interactions parametric approaches have severe limitations when there are too many independent variables in relation to the number of observed outcome events. The nonparametric Multifactor Dimensionality Reduction method, MDR (Ritchie et al. 2001), has achieved a great popularity in genetic association screening. It tackles the dimensionality problem of interaction detection by reducing the dimension to one, after pooling multi-locus genotypes into two groups of risk: high and low. However, when analyzing gene interactions in case-control studies more flexible approaches which allow adjustment for confounding variables and for main effects would be preferred. This is the case of the Model-Based Multifactor Dimensionality Reduction Method, MB-MDR (Calle et al. 2007), which is a (potentially) model-based version of MDR that can deal with continuous measurements. Martin et al. (2006) combined the MDR method with the genotype-Pedigree Disequilibrium Test (MDR-PDT) to allow identification of single-locus effects or joint effects of multiple loci in nuclear families. We propose a novel multifactor dimensionality reduction strategy for genetic interaction association analysis in families of any structure. First the individual environmental residuals are estimated using an additive polygenic model, similar to the first step in the GRAMMAR approach of Aulchenko et al. (2007). Second, MB-MDR is applied to these residuals. The approach is evaluated and validated using simulated and real-life data.

Main Reference: Calle ML, Urrea V, Malats N, Van Steen K. (2007) MB-MDR: Model-Based Multifactor Dimensionality Reduction for detecting interactions in high-dimensional genomic data. Technical Report n.24. Department of Systems Biology. Universitat de Vic.

The pharmacogenetics of Nevirapine hepatotoxicity: a retrospective study in a Mozambique population. *C. Ciccacci[1], P. Borgiani[1], S. Ceffa[2], E. Sirianni[1], M. C. Marazzi[3], G. Novelli[1], L. Palombi[4]* 1) 1Department of Biopathology and Diagnostic Imaging, Section of Genetics, School of Medicine, Tor Vergata University, Rome, Italy; 2) DREAM Program, Rome, Italy; 3) LUMSA University, Rome, Italy; 4) Department of Public Health, Tor Vergata University, Rome, Italy.

NNRTIs (nonnucleoside reverse transcriptase inhibitors) nevirapine and efavirenz are widely used to treat HIV-1 infection, but adverse reactions are common (2-10 per cent), in particular the risk of nevirapine associated hepatotoxicity. Previous studies have reported associations between nevirapine-induced hepatotoxicity and some genetic variants of these genes, even if results are not always concordant. We have conducted a pharmacogenetic retrospective study on a cohort of 161 pregnant women initiating antiretroviral treatment in 3 DREAM (Drug Resource Enhancement against AIDS and Malnutrition) clinical centers in Mozambique. In particular we have compared 73 women who presented nevirapine-induced hepatotoxicity (cases) and 88 with no hepatotoxicity (controls). We considered the following 6 polymorphisms (SNPs): MDR1 T3421A, MDR1 C3435T, CYP2B6 G516T, CYP2B6 T983C, CYP3A4 G392A, CYP3A5 A6986G. We also performed haplotypes analysis for the SNPs in the same gene. The MDR1 C3435T SNP presents a significant association with epatotoxicity (p=0.03) with the variant T allele showing a protective effect (O.R. 2.27). The other SNPs are not associated or present a border line P value. The association does not increase condidering haplotypes rather than single SNPs. Analyzing by ANOVA the differences in AST and ALT maximum value among the different genotypes of each locus, it is evident an interesting dose-allele dependent trend for most of the studied SNPs, in particular for CYP2B6 G516T, even if these differences are not statistically significant maybe due to the small sample size. These preliminary results confirm the important contribution of MDR1 C3435T SNP to predict nevirapine-induced hepatotoxicity risk and, in the same time, suggest the necessity of further studies to identify new genes/variants involved in nevirapine adverse reaction.

Ethnicity-Confirmed Genetic Structure in New Hampshire. *C. Sloan, A. Andrew, E. Duell, M. Karagas, J. Moore*
Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Genetic population structure is known to result from shared ancestry. Though there have been several studies of genetic structure within and among different geographic regions and ethnic groups, little is known of the genetic structure of highly admixed US populations or whether the structure is concordant with self-reported ancestry. In this study, 1529 single nucleotide polymorphisms (SNPs) from 864 healthy control individuals from New Hampshire were measured as part of a bladder cancer epidemiology study. The SNPs were from approximately 500 cancer susceptibility genes scattered throughout the genome. Of these, 960 Tag SNPs were used to cluster individuals using the Structure algorithm for between 2 and 5 subpopulations. Subtle genetic structure was found, suggesting the appropriate number of subpopulations to be either 4 or 5 (FSTs 4 populations: 0.0377, 0.0399, 0.0363, 0.0340; 5 populations: 0.0452, 0.0536, 0.0585, 0.0534, 0.0521). We coded the individuals self-reported ancestries in a genotype fashion (i.e. 0= not reporting that ancestry, 1= reporting part that ancestry, 2= reporting only that ancestry) and conducted a Spearmans rank correlation between each ancestry and the structure q value, which represents the proportion of an individual that originated from a certain genetic subpopulation. Those of Russian, Polish and Lithuanian ancestry most consistently clustered together. The ancestry results support either 4 or 5 subpopulations. In order to investigate linkage disequilibrium (LD), the complete set of SNPs from the 7 most densely genotyped genes were used to make haploview plots between the different groups. The results vary by gene, though for one gene in particular, GHR, the results are very different for 4 subpopulations. These results suggest that despite New Hampshires admixture and presumed homogeneity, there are 4 or 5 distinct genetic subgroups within the population that can be linked to self-reported ancestry and display differences in patterns of LD.

Association of Paternal Age and Risk for Congenital Anomalies from the National Birth Defect Prevention Study, 1997-2004. *R.Fisk Green[1], K. S. Crider[1], R. S. Olney[1], O. Devine[1], N. Archer[2], A. Olshan[3], S. K. Shapira[1], National Birth Defect Prevention Study* 1) National Center on Birth Defects and Developmental Disabilities; CDC; Atlanta, GA; 2) Texas Dept. of State Health Services; Austin, TX; 3) Dept. of Epidemiology; University of North Carolina; Chapel Hill, NC.

Previous studies have found associations between advanced paternal age and increased risk for dominant single gene disorders in offspring. The relationship between paternal age and the risk of birth defects not caused by recognized single gene disorders or chromosomal abnormalities remains unclear. We used 1997-2004 data from the National Birth Defects Prevention Study (NBDPS), a case-control study, to look for associations between paternal age and birth defects of unknown etiologies for birth defect categories with 100 case children. We performed logistic regression analyses, including paternal age, paternal age^2, maternal age, and maternal age^2 as continuous variables, while controlling for gravidity, periconceptional folic acid use, maternal body mass index, paternal birthplace, paternal education, paternal race and ethnicity, singleton/multiple birth, maternal smoking, maternal alcohol use, paternal drug use, use of assisted reproductive technology, and previous stillbirth or miscarriage. Preliminary analyses showed associations with paternal age for encephalocele (odds ratio (OR) = 1.26 per year increase in paternal age, 95% confidence interval (CI) 1.03-1.53), cataracts (OR = 1.19 per year, 95% CI 1.02-1.39), esophageal atresia (OR 1.11 per year, 95% CI 1.00-1.23), cleft palate (OR = 1.02 per year, 95% CI 1.00-1.04), and diaphragmatic hernia (OR = 1.04 per year, 95% CI 1.01-1.06). We assessed the need to include the interaction of maternal and paternal age in the models and an interaction term was required in models of the association of paternal age with gastroschisis, omphalocele, and spina bifida. In general, younger paternal age showed an association with gastroschisis, while advanced paternal age was associated with omphalocele and spina bifida. Our findings suggest that paternal age may be a risk factor for some birth defects with complex etiologies.

Chromosomal anomalies and Dandy-Walker syndrome. *M. Martin[1], A. Wagner[2], E. Knudtson[2], H. Zhang[1], J. Lee[1], J. Mulvihill[1], S. Li[1]* 1) Dept. of Pediatrics. University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Dept. of Ob./Gyn. University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Although there is variation in the diagnosis of Dandy-Walker syndrome, it is clinically defined by a triad of malformations: (1) agenesis of the cerebellar vermis (partial or complete), (2) an enlarged posterior fossa with displacement of the tentorium and the torcular and lateral sinus, and (3) cystic dilation of the fourth ventricle. The patients with Dandy-Walker syndrome have a wide range of clinical features; from severe mental retardation and physical handicaps to normal behavior and function. The etiology of Dandy-Walker syndrome in the majority of cases is unknown. There are sporadic case reports of Dandy-Walker syndrome associated with chromosomal anomalies, including whole chromosomal trisomies, partial trisomies/duplications, and deletion of various chromosomal regions of various sizes. In this report, we have searched PubMed and have identified all the reported Dandy-Walker cases up to this date with chromosomal anomalies. We have also made a map of all the identified chromosomal anomalies; this information provides valuable data for our future array CGH analysis in those patients with Dandy-Walker syndrome.

DNA repair genotypes and associated phenotypes in breast cancer. *L. J. Ricks-Santi[1,2], Y. Yang[2], F. Seillier-Moiseiwitsch[2], J. Freudenheim[3], C. Isaacs[2], M. Schwartz[2], R. Dumitrescu[2], C. Marian[2], J. Nie[3], D. Vito[3], M. Trevisan[3], S. Edge[3], P. Shields[2]* 1) National Human Genome Center, Howard University Cancer Center, Washington, DC; 2) Lombardi Comprehensive Cancer Center, Georgetown University Medical Cancer, Washington, DC 20016; 3) Department of Social and Preventive Medicine, University at Buffalo, Buffalo, NY 14214.

This study investigated women from high-risk breast cancer families and a sporadic breast cancer case-control study for associations with specific BRCA1 SNPs and haplotypes, Rad51 SNPs, and deficient DNA repair. The mutagen sensitivity assay, used to measure heritable DNA repair capacity, was applied to EBV-immortalized cell lines from 138 women from high-risk breast cancer families with known BRCA1 mutations. The assay was studied in relation to associations with genotypes and haplotypes for BRCA1 and Rad51. Positive associations were then tested as predictors of breast cancer risk in a population-based case-control study (n= 1165 cases and 2170 controls). It was found that high-risk women with breast cancer had more mean breaks per cell than those without breast cancer. The Rad51 5UTR 135 variant genotype was also associated with high MBPC. In this sample, there also was an increased risk for MBPC with the BRCA1 D693N variant genotype, but this was not statistically significant. There was no association with MBPC for the BRCA1 Q356R and E1038G genotypes or BRCA1 haplotypes. In this sample set, the Rad51 5UTR 135C variant allele and D693N allele were also examined in a population-based case-control study of breast cancer, but no association was found even after stratifying by menopausal status and adjusting for confounding variables. The results indicate that the Rad51 5UTR 135C allele and D693N allele may be modifying genotypes for the penetrance of BRCA1 mutation carriers by affecting DNA repair efficiency. This study provides data to justify a well-designed epidemiology study of the MSA as a predictive phenotype in women from high-risk breast cancer families and breast cancer risk where genetic modifiers could have implications for the clinical management of BRCA1 mutation carriers.

Theory and Methods for Association Testing using Case Trios and Unrelated Controls. *M. Lee[1], Y. Lin[1,2], E. Feingold[1,3]* 1) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 2) School of Medicine, University of Pittsburgh, Pittsburgh, PA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

The case-control study design and the transmission disequilibrium test (TDT) design are commonly used in genetic association studies. When population stratification exists, simple case-control statistics are biased, but the TDT has robust type I error. Many studies, however, have both case trios and unrelated controls (and/or unrelated cases) available, and it is not always clear how to optimally analyze this combination design. Epstein et al.(2005) proposed a likelihood-based method for combining case-control and TDT data. They demonstrated that their method is more powerful than a TDT test alone, but did not make a comparison to a case-control test, We discuss the theory of the combination design and the likelihood test, and then use simulation studies to examine how much power is gained by the likelihood approach under different genetic models and stratification scenarios.

Epistasis in Digital Organisms. *A. Tyler, J. Moore* Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Many of the genes that contribute to complex diseases do so not through independent effects, but through epistatic interactions with other genes. Increasing numbers of studies are acknowledging the importance of epistasis in human genetic architecture and are beginning to discover novel gene-gene interactions associated with complex diseases. It is thought that there may be tens, hundreds, or even thousands of genes interacting to contribute to risk of complex disease. Finding these interactions among the thousands of genes in a genome-wide dataset is a non-trivial task. There are several major barriers that need to be overcome before the complexity of epistasis can be effectively addressed in practice. One of these barriers is that there is a lack of general understanding as to how epistatic interactions fit into the larger picture of genetic architecture. We know that epistatic interactions are a system-wide feature of biological genomes, but what are the patterns in which these interactions arise? How much do they contribute to complex phenotypes? Here we address these questions through the lens of complex systems and digital biology. Digital organisms are computer programs that evolve over time through a process of natural selection that includes mutation, replication, and selection of the most fit organisms. Over many generations digital organisms evolve a complex genetic architecture that in many aspects resembles the genetic architecture of biological genomes. Here we introduce a prototype platform for evolving digital organisms with a complex genetic architecture. We also present preliminary results from genetic knockout experiments demonstrating that these organisms have evolved complex patterns of epistasis similar to those seen in biological organisms. We propose that digital evolution can recapitulate complex features of biological genomes in a system that is much more tractable than the biological alternatives. We hypothesize that digital organisms can help elucidate principles of the genetic architecture of complex traits and will be useful for understanding the general principles of genotype to phenotype mapping relationships.

Effect of borax on lymphocyte proliferation and sister chromatid exchange in human chromosome. *M. Pongsavee*
Department of Medical Technology, Faculty of Allied Health Sciences, Thammasat University, Pathumthani 12121, Thailand.

Borax is used as a food additive. It becomes toxic when accumulated in the body. It causes vomiting, fatigue and renal failure. The heparinized blood samples from 40 healthy Thai men were studied for the impact of borax toxicity on lymphocyte proliferation and sister chromatid exchange. The MTT assay and Sister Chromatid Exchange (SCE) technique were used in this experiment with the borax concentrations of 0.1, 0.15, 0.2, 0.3 and 0.6 mg/ml. The results showed that the numbers of cells and metaphase chromosomes were decreased when the concentrations of borax increased. The borax concentrations of 0.15, 0.2, 0.3 and 0.6 mg/ml significantly induced sister chromatid exchange in human chromosome ($P<0.05$). The borax concentration of 0.6 mg/ml had the most effectiveness to the lymphocyte proliferation and had the highest cytotoxicity index (CI). It can be concluded that borax had effects on lymphocyte proliferation and induced sister chromatid exchange in human chromosome. Toxicity of borax may lead to genetic defect in human.

Teaching genetics courses for the general public: challenges and perspectives. *M. Davis*[1,2] 1) Bryn Mawr College, Bryn Mawr, PA; 2) Wagner Free Institute of Science, Phila., PA.

The Wagner Free Institute of Science in Philadelphia has been dedicated to the mission of providing free education in the sciences for more than 150 years. The adult lecture courses in life and natural sciences are offered on an introductory college level and are open to the general public. This poster will describe the genetics education series that started in 2000.

The objectives of the genetics series are to foster understanding of basic genetics, biotechnology, and the process of scientific research. Each seven week course consists of weekly 90 minute lectures held in public libraries. Individual courses on topics including genomics, genetics in popular culture, bioterrorism, and genetics of dogs have been employed to appeal to a wide audience. College credit is not available; however optional homework assignments may be completed to earn an Institute certificate.

These community based genetics courses have presented many pedagogical challenges and rewards. Class attendees are from a diversity of socio-economic, educational, and cultural backgrounds, and they range in age from home-schooled high school students to retirees. Resources are very limited, which restricts available instructional tools and reference materials. Depth of content coverage is constantly adjusted to accommodate the different expectations of the attendees. Participation in class discussion is encouraged, resulting in a cooperative learning experience. Informal discussions are also held outside of class to enable interested attendees to pursue topics in greater detail. At the end of each course attendees complete evaluations and suggest future topics.

Surveys of attendees indicate strong interest in genetics and biotechnology. The low-key community setting promotes a collegial environment for people to ask questions about genetics. Moreover attendees interact to stimulate excitement about learning science and they seek advice on resources for self-directed learning. The Institute is always seeking new ways to fulfill its goal of making science education available to all.

Identification of essential elements and time points for mouse limb bud development. *S. Schlaubitz[1], B. C. Dawson[2], T. K. Bertin[1], E. Munivez[1], C. A. Shaw[1], B. U. Zabel[3], B. Lee[1,2]* 1) Dept. Human & Molecular Genetics, Baylor College of Medicine, Houston, TX; 2) Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX; 3) Center for Pediatrics and Adolescent Medicine, University of Freiburg, Freiburg/ Germany.

To identify genes differentially expressed in limb bud development at time points critical for limb chondrogenesis and the commencement of osteogenesis, we performed Affimetrix microarray experiments with total RNA from E11.5, E12.5, and E13.5 C57Bl/6 forelimb buds hybridized on Mouse 430 2.0 arrays. Four sets of biological replicates were normalized using RMA (Robust Multi-Array) and analysis of differential expression was performed using the software package LIMMA within the R computing environment. Differentially expressed genes of statistical relevance were grouped according their expression pattern. 707 probes were seen to be up-regulated over time with a fold change of at least 2 (p 0.01), while 768 probes were down-regulated over time (0.5 fold cutoff, p 0.01). Furthermore, we identified genes with expression profile changes over time and found 55 probes up-regulated at E12.5 in comparison to E11.5, but down-regulated at E13.5, while 293 probes showed lowest expression at E12.5 (0.5 fold and a p 0.01). Identical samples from each time point are currently being validated by quantitative real time PCR; probes with yet unknown function in mesenchymal condensation and following patterns will be further investigated. Pilot experiments revealed correlations between microarray data and validation in vitro of more than 90%. We therefore believe that our data robustly identify important genes in forelimb bud development at or near the critical time point of mesenchymal condensation.

An inherited mitochondrial DNA disruptive mutation shifts to homoplasmy in oncocytic tumor cells. *M. Lang[1], G. Gasparre[1], L. Iommarini[2], A. M. Porcelli[3], G. G. Ferri[4], I. Kurelac[1], E. Mariani[3], L. F. Pennisi[1], A. Ghelli[3], E. Bonora[1], C. Ceccarelli[5], M. Rugolo[3], N. Salfi[5], G. Romeo[1], V. Carelli[2]* 1) Unità di Genetica Medica, Policlinico Universitario S. Orsola-Malpighi, Bologna; 2) Dipartimento di Scienze Neurologiche, University of Bologna; 3) Dipartimento di Biologia Evoluzionistica Sperimentale, University of Bologna; 4) Dipartimento di Scienze Chirurgiche Specialistiche ed Anestesiologiche, Sezione di Otorinolaringoiatria, Policlinico Universitario S.Orsola-Malpighi, Bologna; 5) Unità Operativa di Anatomia e Istologia Patologica, Policlinico Universitario S. Orsola-Malpighi, Bologna.

Aim: Oncocytic tumors are characterized by cells with aberrant mitochondrial hyperplasia. Somatic mutations in mitochondrial genome (mtDNA) affecting respiratory chain complex I (CI) subunits have been previously reported in this type of neoplasia. We report the first case of inherited frameshift CI mutation in the ND5 gene associated with a specific tumor phenotype. Methods: The mtDNA was sequenced in microdissected areas from an oncocytic nasopharynx tumor and in different non-neoplastic tissues from the patient and two of his siblings in order to confirm inheritance of the mutation. Immunohistochemical analysis and western blot for CI subunits was performed on tumor tissue to study protein expression. Mutation load in mitochondria and mtDNA copy number were analyzed in all tissues. Results: The oncocytoma harbors a frameshift homoplasmic ND5 mutation which correlated with lack of expression of another mitochondrially coded CI subunit (ND6). Conversely, oncocytic cells expressing ND6 show heteroplasmy for the ND5 mutation and a *de novo* homoplasmic pathogenic ND1 mutation. Such cells also present a lower degree of mitochondrial hyperplasia as shown by mtDNA copy number. The ND5 mutation is heteroplasmic in all normal tissues of the patient and his siblings indicating a shift to homoplasmy only in the tumor. Conclusions: We conclude that complex I mutations may have a selective advantage and induce oncocytic transformation in spite of their unequivocal pathogenic effect.

A Matched Cohort from the Age Related Eye Disease Study Confirms Previous Genetic Associations with Age Related Macular Degeneration. *J. Bergeron-Sawitzke[1], B. Gold[1], S. Schlotterbeck[1], K. Visvanathan[2], R. Allikmets[3], M. Dean[1]* 1) Lab. Experimental Immunology, NCI-Frederick, Frederick, MD; 2) Bloomberg School of Public Heath, Johns Hopkins U, Dept Epi, Baltimore, MD; 3) Dept. of Ophthalmology, Columbia University, NY, NY.

Age-related macular degeneration (AMD) is a heritable late onset vision disorder. Several recent genotyping studies have established that alterations in genes in the complement cascade are associated with AMD. Complement factor H (CFH) variations have been specifically implicated as being responsible for a significant fraction of the disease. In addition, a locus at 10q26 has also contributed a genetic association with AMD. Our matched case control study confirms and extends several reported associations in and near complement related genes; it also explores the reported gene associations on chromosome 10 and with Apolipoprotein E (APOE) haplotype. Subjects were genotyped for a number of single nucleotide polymorphisms (SNPs) from CFH, Complement Component 2 (C2), Complement Component 3 (C3), Complement Factor B (CFB), ARMS2, HTRA1, and APOE. Individual SNPs, and haplotypes within proximal chromosome regions were examined for association with disease. This AREDS sample showed risk trends consistent with those seen in other population studies for allele and haplotype frequencies of CFH, C3, C2, and CFB. SNP rs10490924 on Chr. 10 in exon 1 of the ARMS2 gene showed a highly significant association with an odds ratio (OR) of 3.16 (95% CI 2.37-4.21) for the risk allele, and rs11200638 located in the proximal promoter region of HTRA1 showed a somewhat higher significant association with an OR of 3.37 (95% CI 2.50-4.57) with our AMD cases. We found that APOE haplotypes were not significantly associated with case status. Adjustments for other clinical risk factors also did not significantly alter the observed associations. This study validates the complement pathways involvement in AMD pathology and suggests that unfavorable allelic variants in complement genes have a direct role in AMD disease. These results also support previous findings that variants in the region of 10q26 exert an independent risk for AMD.

Folate pathway genes and the risk of conotruncal heart malformations. *E. Goldmuntz[1], D. Renstrom[1], S. Woyciechowski[1], P. J. Lupo[2], L. E. Mitchell[2]* 1) Division of Cardiology, Department of Pediatrics, The Childrens Hospital of Philadelphia, PA; 2) Institute of Biosciences and Technology, Texas A&M University System Health Science Center, Houston TX.

Conotruncal heart malformations (CTHM) account for 16% of all congenital heart defects (CHD), which are the most common group of major birth defects. Although CHD are prevalent and clinically significant, little is known about their etiology. Recent studies suggest that maternal folic acid supplementation may reduce the risk of CHD, and that variation in folate pathway genes may also be associated with disease risk. Studies suggest some CTHM share a common genetic basis with ventricular septal defects (VSD) and isolated aortic arch anomalies (AAA), such that these lesions were grouped together for this analysis. CTHM, VSD and AAA case-parent triads (N=727) were prospectively ascertained from the Cardiac Center at The Childrens Hospital of Philadelphia. DNA samples were genotyped for ten functional variants in nine genes involved in the folate pathway. Log-linear modeling was used to examine the associations between CTHM and both maternal and case genotype. The following case genotypes were significantly associated with disease risk: CBS 844ins68 (OR[II/IN vs. NN]=1.40 , 95% CI 1.00-1.95; p=0.05) and MTHFR A1298C (OR[AC vs. AA]=0.67, 95% CI 0.53-0.84; OR[CC vs. AA]=0.74 , 95% CI 0.50-1.12; p=0.002). In addition, maternal genotype for MTR A2756G was significantly associated with disease risk (OR[AG vs. AA]=1.40, 95% CI 1.07-1.83; OR[GG vs. AA]=1.26, 95% CI 0.69-2.29; p=0.04). This is the largest study to date on the association between genetic variation within the folate pathway and CTHM. Furthermore, this study employed a design that is robust to confounding due to population structure and allows for the evaluation of both maternal and case genotypes. The results provide additional evidence that the risk of CTHM and related cardiac defects is influenced by variation within folate pathway genes, and indicate that studies to explore these relationships further are warranted.

Ethical, legal, and economic issues arising from the application of human genome epidemiologic evidence as the basis of "personalized" patient care. *N. Markward* Pennington Biomedical Research Center, Baton Rouge, LA.

Human genome epidemiology (HuGE) is the analytical arm of public health that seeks 1) to isolate risk and protective variants that influence the distributions of diseases in populations and 2) to determine the extent to which knowledge of these relationships can be used to enhance existing disease prevention programs. In contrast, the emerging paradigm of genomic medicine (GM) is patient-centered and emphasizes the use of genomic information to personalize health care delivery and resource allocation. In concept, realization of the GM model will be achieved when patient treatment and counseling can be tailored to the specific needs of each individual based on his or her unique genomic profile. The broad objectives of HuGE and GM, as implied by these elementary descriptions, are harmonious insofar as they revolve around the altruistic notion of maximizing the health and societal benefits that can be derived from genomic exploration. However, despite this common ground, the inferential problems of population and individual risk assessment are, in fact, distinct endeavors that are guided by competing philosophical principles (utilitarianism vs. individualism) and systems of logic (deductive vs. inductive reasoning). This project examines the theoretical differences between population and individual risk; reviews the key limitations and appropriate interpretation of sample-level measures of association; and highlights important ethical, legal, and economic issues that may arise if population-based predictive tools become the *sine qua non* of GM decision-making.

Combined effects of *MC4R* and *FTO* common genetic variants on obesity in European general populations. *S. CAUCHI[1], F. STUTZMANN[1], C. PROENÇA[1], E. DURAND[1], A. POUTA[2], A. L. HARTIKAINEN[3], M. MARRE[4], S. VOL[5], T. TAMMELIN[6], J. LAITINEN[6], A. GONZALEZ-IZQUIERDO[2], A. BLAKEMORE[7], P. ELLIOTT[2], D. MEYRE[1], B. BALKAU[8], M. R. JÄRVELIN[2], P. FROGUEL[7]* 1) Genomics and Molecular Physiology, CNRS UMR8090, LILLE, France; 2) Epidemiology and Public Health, Imperial College, London, UK; 3) Obstetrics and Gynecology, University of Oulu, Finland; 4) INSERM U695, Paris, France; 5) Regional Institute for Health, La Riche, France; 6) Finnish Institute of Occupational Health, Finland; 7) Genomic Medicine, Hammersmith Hospital, Imperial College London, United Kingdom; 8) INSERM U780-IFR69, Villejuif, France.

Genome-wide association scans identified common polymorphisms in the *FTO* and *MC4R* loci that modulate body mass index (BMI) and associate with increased risk of obesity. We analyzed independent and combined effects of the *FTO* rs1421085 and the *MC4R* rs17782313 risk alleles on BMI, prevalence and incidence of obesity, fat mass, and their interactions with physical activity levels and gender in two European prospective population-based cohorts of 4,802 Finnish adolescents (NFBC 1986) and 3,167 French adults (DESIR). Compared to participants carrying neither *FTO* nor *MC4R* risk allele (20-24% of the populations), subjects with 3 or 4 risk alleles (7-10% of the populations) had a 3-fold increased susceptibility of developing obesity during childhood. In adults, their combined effects were more modest (~1.8-fold increased risk) and associated with a 1.3% increase in fat mass (P=0.001). Prospectively, we demonstrated that each *FTO* and *MC4R* risk allele was a predictive factor of obesity development, associated with a 24% increased incidence (P=0.02). The Z-BMI and ponderal index of newborns homozygous for the rs1421085 C allele were 0.1 units (P=0.02) and 0.3g/cm^3 (P=0.005) higher, respectively, than in those without *FTO* risk allele. The *MC4R* rs17782313 C allele was more associated with obesity and fat mass deposition in males than in females (P=0.003 and P=0.03, respectively) and low physical activity was found to accentuate the effect of the *FTO* polymorphism on BMI increase and obesity prevalence (P=0.008 and P=0.01, respectively).

Mutational spectrum of the Oral-facial-digital type I syndrome: a study on a large collection of patients. *B. Franco[1,2], C. Prattichizzo[1], M. Macca[1,2], V. Novelli[1], R. Tammaro[1], G. Giorgio[1], A. Barra[1], The OFDI collaborative group* 1) Telethon Institute of Genetics and Medicine (TIGEM), Fondazione Telethon, Naples, Italy; 2) Medical Genetics Services, Department of Pediatrics, Federico II, University of Naples.

Oral-facial-digital type I (OFDI; MIM 311200) syndrome is a male-lethal X-linked dominant developmental disorder belonging to the heterogeneous group of Oral-facial-digital syndromes (OFDS). OFD type I is characterized by malformations of the face, oral cavity and digits. CNS abnormalities and cystic kidney disease can also be part of this condition. This rare genetic disorder is due to mutations in the OFD1 gene (MIM# 300170) that encodes a centrosome/basal body protein necessary for primary cilium assembly and for left-right axis determination, thus ascribing OFDI to the growing number of disorders associated to ciliary dysfunction. We now report a mutation analysis study in a cohort of 109 unrelated affected individuals collected worldwide. Putative disease-causing mutations were identified in about 80% of patients. We describe 67 different mutations, 64 of which represent novel mutations, including 36 frameshift, 9 missense, 11 splice-site and 11 nonsense mutations. Most of them concentrate in exons 3, 8, 9, 12, 13 and 16, suggesting that these exons may represent mutational hotspots. Phenotypic characterization of the patients collected provided a better definition of the clinical features of OFD type I syndrome. Differently to what previously observed, our results indicate that renal cystic disease is present in 60% of cases with over 18 years of age. Genotype-phenotype correlation did not reveal significant associations apart for the high-arched/cleft palate most frequently associated to missense and splice-site mutations. Our results contribute to further expand our knowledge on the molecular basis of OFD type I syndrome. In addition these results will help in further defining the clinical spectrum and recognition of Oral-facial-digital syndromes.

Periventricular heterotopia, mental retardation and epilepsy associated with 5q14.3-q15 deletion. *C. Cardoso[1], A. Boys[2], E. Parrini[3], A. Carabalona[1], S. Khantane[1], C. Mignon-Ravix[4], J. M. McMahon[5], E. Bertini[6], F. Novara[8], O. Zuffardi[8], L. Villard[4], S. Giglio[3], B. Chabrol[7], H. R. Slater[2], A. Moncla[7], Y. Ben-Ari[1], I. E. Scheffer[5], A. Represa[1], R. Guerrini[3]* 1) INMED, INSERM U901, Université de la Méditerranée, Marseille, France; 2) Victorian Clinical Genetics Services, Melbourne, Australia; 3) Children's Hospital A. Meyer, University of Florence, Italy; 4) INSERM U910, Faculté de Medecine La Timone, Marseille, France; 5) Austin Health and Royal Childrens Hospital, Melbourne, Australia; 6) Bambino Gesù Hospital, Rome, Italy; 7) Timone Childrens Hospital, Marseille, France; 8) Genetica Medica, Università di Pavia, Italy.

Periventricular heterotopia (PH) is an etiologically heterogeneous disorder characterized by nodules of neurons ectopically placed along the lateral ventricles. Most affected patients have seizures and their cognitive level varies from normal to severely impaired. To date, two genes have been identified to cause PH. Mutations in FLNA (Xq28) and ARFGEF2 (20q13) are responsible for X-linked bilateral PH and a rare autosomal recessive form of PH with microcephaly. Eleven additional distinct anatomoclinical PH syndromes, including chromosomal rearrangements involving the 1p36, 5p15 and 7q11 regions, have also been reported but the genes implicated remain unknown. Here, we report the clinical and imaging features of three unrelated patients with epilepsy, mental retardation and bilateral PH in the walls of the temporal horns of the lateral ventricles, associated with a de novo deletion of the 5q14.3-q15 region. Using CGH arrays and FISH analysis, we defined the boundaries of the deletions. The three patients shared a common deleted region spanning 5.8 Mb and containing 14 candidate genes. To identify the PH-associated gene, we are currently screening these genes for mutations in sporadic cases with PH. We are also using the in utero RNA interference approach to identify if one of these candidate genes contributes to neuronal migration. This combined strategy should allow us to identify the gene that is implicated in the temporal PH and provide new insights into the genetic and developmental basis of this cortical malformation.

Identification of a risk haplotype within PSORS4 locus. *C. Sinibaldi[1], V. Foti Cuzzola[1,2], C. Peconi[1], A. M. Mazzotta[3], P. Amerio[4], S. Chimenti[3], P. Bramanti[2], J. Fischer[5], E. Giardina[1,6], G. Novelli[1,7,8]* 1) Department of Biopathology and Centre of Excellence for Genomic Risk Assessment in Multifactorial and Complex Diseases School of Medicine, Tor Vergata University of Rome, Italy; 2) IRCCS Neurolesi Center Bonino-Pulejo, University of Messina, Italy; 3) Department of Dermatology, Tor Vergata University, Rome, Italy; 4) Department of Dermatology, University of Chieti, Italy; 5) Centre National de Génotypage, EVRY, France; 6) Univerisy Carlo BOof Urbino, Italy; 7) San Peter Hospital, Fatebenefratelli, Rome, Italy; 8) Department of Cardiovascular Medicine, University of Arkansas for Medical Sciences, Little Rock, AR,USA.

Psoriasis (PS) is a chronic inflammatory skin disorders triggered by both genetic and environmental factors. A susceptibility locus mapped on chromosome 1q21 have been identified for the disease (PSORS4). We refined the PSORS4 susceptibility locus using a LD approach in a preliminary cohort of 128 PS trios. Within the redefined region is a single gene (*LOR*) encoding for loricrin, the major component of the epidermal cornified envelope comprising about 70-85% of the total protein mass of the cornified. Although *LOR* was a good positional and functional candidate gene we failed to reveal evidence of association for intragenic SNPs. To disclose the identity the susceptibly variants we performed an association study by typing a dense panel of SNPs within PSORS4. By typing both familial (128 trios) and sporadic samples (400 psoriatic patients and 400 healthy controls) we identified a conserved LD block (38kb long) upstream LOR gene on risk chromosomes. Thus we performed a re-sequencing of the entire LD block in our patients to identify recombinant haplotypes and refine the locus. Our preliminary results suggested a putative role of specific SNPs for the control of expression of psoriasis misregulated genes within EDC such *LOR, S100A8, S100A9, LELP1* and some SPRRs. Acknowledgements This work was supported by A.DI.PSO.

Knock-In Mouse Model of Dilated Cardiomyopathy Caused by Titin Mutation. *B. Gerull[1], M. Gramlich[1], B. Michely[1], C. Krohne[2], I. Morano[1], H. Granzier[3], S. Labeit[2], L. Thierfelder[1]* 1) Max-Delbrueck-Center for Molecular Medicine, Berlin, Germany; 2) Anesthesiology and Intensive Operative Medicine, University Hospital, Mannheim, Germany; 3) VCAPP, Washington State University, Pullmann, USA.

Dilated cardiomyopathy (DCM) is the most common form of primary myocardial diseases and the third most common cause of heart failure. Familial occurrence, mostly as an autosomal dominant trait, is responsible for 20-30% of all DCM cases. We have previously shown that mutations in the giant muscle filament titin (TTN) cause dilated cardiomyopathy. In a large DCM kindred (A1) with autosomal dominant inherited DCM, we could identify a 2 bp insertion mutation in exon 326 of TTN. This heterozygous nonsense mutation leads to a framshift generating a premature stop codon. We have recently evaluated a cardiac biopsy sample from an affected family member of kindred A1 showing that no truncated protein is observed in western blot analysis. To further investigate the functional consequences of the identified human TTN mutation, we generated a mouse model that includes the 2bp insertion mutation at the corresponding site in the mouse genome. Heterozygous mice are viable and fertile. As in the human situation, the truncated titin is not detectable in western blot analysis of cardiac tissue indicating haploinsufficiency. The ventricles of the heterozygous animals show a decrease in ventricular stiffness as seen in isolated working heart pressure measurements and transmitral Doppler echocardiography (E:A 1.34 vs. 1.075, $p<0.01$; IVRT 13.57ms vs. 17.01ms, $p<0.05$). When exposed to angiotensin II (1.4 mg/kg/d for 14d) as a cardiac stressor, heterozygous animals develop dilatation of the left ventricles (4.45mm vs. 3.77mm, $p<0.05$) with impaired fractional shortening (25.12% vs. 32.86%, $p<0.01$) and a diffuse myocardial fibrosis recapitulating features of patients with DCM. Homozygous mutant embryos die before E9.5 as a result of unformed sarcomeres observed in electronmicroscopy. Our mouse model shows that a mutation in TTN leads to impaired biomechanical properties of the heart, resulting in left ventricular dilatation and decreased systolic function, thereby recapitulating the human phenotype.

Multiple Displacement Amplification (MDA) in forensic samples: time for reconsideration. *I. Pietrangeli[1], C. Martone[1], E. Giardina[1], S. Zampatti[1], P. Marsala[2], L. Gabriele[2], C. Pipolo[2], O. Ricci[2], G. Solla[2], A. Spinella[2], G. Novelli[1,3]* 1) Centre of Excellence for Genomic Risk Assessment in Multifactorial and Complex Diseases, School of Medicine, Tor Vergata University of Rome, Italy; 2) Direzione Centrale Anticrimine, Servizio di Polizia Scientifica, Rome, Italy; 3) Division of Cardiovascular Medicine, Department of Medicine, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Whole genome amplification (WGA) is a technique developed for genetic analysis to obtain sufficient amount of DNA from small pools of cells or even single cells. Presently, the usefulness of WGA in STR-based forensic analysis is limited because of allelic dropout (ADO) and bias in peak area ratios observed in low copy number (LCN) templates. Typing of SNPs is more effective than STRs in LCN templates and less prone to ADO when WGA is applied. We recently validated a panel of 26 TaqMan SNP assays selected to show an high sensibility in LCN templates. In this work we evaluated the performance of multiple displacement amplification (MDA) applied to our optimized SNP assays for typing 300 LCN (1 ng, 0.1 ng and 0.01 ng) and 10 severely degraded DNA samples. We observed an higher positive typing rate in amplified DNA respect to genomic DNA and 100% of concordance rate between amplified vs control DNA for 1 ng and 0.1 ng dilutions. Samples of 0.01 ng revealed a lower concordance rate (99.34%) due to the failure of amplification of one allele in heterozygous samples (ADO). In order to improve the concordance rate in 0.01 ng dilution we applied an optimized TaqMan Genotyping Master Mix to our SNPs panel. ADO occurrence was significantly reduced by using the optimized protocol resulting in better concordance rate even in 0.01 ng samples (99.93%). Significant results have been also observed in artificially degraded DNA and single cell samples. Finally, we successfully typed challenging DNA samples for current STR forensic protocols. These results showed that MDA should be considered as a suitable option for specifically designed SNP assays in challenging forensic caseworks. Work supported by EU FP6 projects NACBO (contract no. NMP4-CT-2004-500804).

Phenotypic consequences of gene CNV: uncoupling gene dosage from positional effect. Clues from the Smith-Magenis (SMS) and Potocki-Lupski (PTLS) syndromes mouse models. *K. Walz[1], J. Molina[1], J. R. Lupski[2]* 1) Region de los Rios, Centro de Estudios Cientificos, Valdivia, Chile; 2) Human Molecular Genetics Department, Baylor College of Medicine, Houston, Tx, USA.

Genomic disorders result from recurrent DNA rearrangements involving unstable genomic regions, and are frequent diseases (~1 per 1,000 births). DNA rearrangements such as deletions, duplications or inversions, can cause genomic disorders. In a subset of such conditions the rearrangements comprise multiple unrelated contiguous genes that are physically linked and thus have been referred to as contiguous gene syndromes (CGS). Smith Magenis syndrome (SMS; MIM182290) is a CGS associated with a microdeletion within chromosome 17 band p11.2. Human chromosome 17p11.2 is syntenic to the 32-34 cM region of murine chromosome 11. The number and order of the genes are highly conserved. By chromosome engineering we have generated mouse models for SMS (Df(11)17/+) and Potocki-Lupski syndrome (PTLS; MIM610883) (Dp(11)17/+). Both mouse models recapitulate several aspects of the patients clinical presentation. To analyze the relationship between genome structural changes and phenotypes we study these mouse models.This is a unique opportunity to uncouple the phenotypes that are due to gene copy number variation versus potential positional effect of the rearrangement. In order to do so we studied the phenotypic consequences of restoring the correct gene copy number within the interval, albeit in a uniallelic fashion, Df(11)/17/Dp(11)17 mice. Viability, weight differences, craniofacial abnormalities, activity levels, anxiety behaviors, memory and learning, and social behaviors were studied among others in mice that carried a deletion (Df(11)17/+), a duplication (Dp(11)17/+) or were compound heterozygous (Df(11)/17/Dp(11)17) in a C57BL/6-Tyrc-Brd inbred genetic background to minimize the effect of genetic background in the analysis. We found that gene copy number restoration was not able to rescue all phenotypic manifestations, highlighting the delicacy of genomic control mechanisms, and uncoupling, for the first time, the effects of gene CNV and genomic structural changes.

Detection of known and novel mutations involved in Retinitis Pigmentosa in a cohort of Northern Irish patients using resequencing genechip technology. *G. R. Clark, D. Muszynska, P. Crowe, G. J. McKay, S. Alexander, J. O'Neill, G. Silvestri, D. A. Simpson* Centre for Vision Science, Queens University Belfast, UK.

The inherited retinal degenerative disease Retinitis Pigmentosa (RP) is extremely genetically heterogeneous. With over 20 genes implicated in non-syndromic recessive RP to date, it is very difficult to identify which gene is mutated in a specific patient. We have therefore developed a microarray capable of resequencing reported mutations and the exons within which they are found. A database of all reported mutations which cause recessive or X-linked RP was compiled and an Affymetrix customseq resequencing array designed to screen these and adjacent sequences. In total 30 kb from 22 genes were tiled on the array. Approximately 100 amplicons spanning the regions of interest were amplified from each patient DNA sample. An average call rate of 91% was achieved for all the sequences analysed in a cohort of 30 recessive and 35 sporadic RP patients. A total of 16 previously reported SNPs and 10 known mutations in CRB1, RGR, RPGR, RPE65 & USH2A were identified. Seventeen novel sequence variants were screened in 350 ethnically matched population controls, using the Sequenom MassARRAY genotyping method. Of these, 8 are likely to be novel SNPs whilst 9 were not observed in the controls and therefore represent likely novel mutations. The segregation of the known and putative novel mutations was assessed in additional family members using direct DNA sequencing. This study has demonstrated that this resequencing platform can provide a rapid and effective screen for RP mutations and provides a new tool to include in screening strategies. Technological improvements will facilitate fuller coverage of recently discovered genes in subsequent genechip designs, although PCR amplification remains a limiting factor. It is anticipated that the improved detection of RP mutations will facilitate genotype:phenotype correlations, better prognosis and application of therapeutic interventions such as gene therapy.

High resolution array comparative genome hybridization reveals de novo and rare inherited changes in patients with congenital diaphragmatic hernia. *M. J. Wat[1], A. M. Holder[1], C. J. Fernandes[2], A. Johnson[3], K. P. Lally[4], D. Tibboel[6], A. de Klein[5], B. Lee[1,7], D. A. Scott[1]* 1) Molecular & Human Genetics; 2) Pediatrics; 3) Ob & Gyn, Baylor College of Medicine, Houston, TX; 4) Ped Surgery, U of Texas Medical School, Houston, TX; 5) Clinical Genetics; 6) Paediatric Surgery, Erasmus Medical Center, Rotterdam, The Netherlands; 7) Howard Hughes Medical Institute.

Congenital diaphragmatic hernia (CDH) is a relatively common sporadic birth defect, with an incidence of ~1:3,000 live births. We are using a positional candidate strategy based on chromosomal data to localize and identify genes that cause or predispose to the development of CDH. By reviewing published reports, we identified 19 chromosomal regions that are recurrently deleted or duplicated in CDH. We hypothesize that each of these regions harbors one or more CDH-related genes. To identify additional CDH-related regionsand refine those previously describedwe screened a cohort of CDH patients using a combination of high density genome-wide array comparative genome hybridization and quantitative PCR. Using this combined approach we identified over 45 rare genomic variants. These included a ~700kb *de novo* deletion of 16p11, a region which has not been previously associated with CDH. Other *de novo* changes identified in our cohort offer insight into the spectrum of diaphragmatic defects and related anomalies associated with deletions of *FOG2* and other genes on chromosome 8q22 and provide further evidence that up-regulation of genes on chromosome 11q23-24 and 13q12 predispose to the development of CDH. Rare inherited changes identified in this cohort involved several signaling pathway genes that regulate cell proliferation, differentiation, and/or migration. One of the most intriguing changes is a 500kb paternally-inherited deletion involving *MAP2K5*. *MAP2K5* is essential for normal embryonic development but homozygous *Map2k5* null mice die before its role in diaphragm development can be determined. It is possible that a reduction in *MAP2K5* expression, in combination with other genetic/environmental stressors, led to the development of right-sided CDH in this child.

Expression profiling of subcutaneous and visceral adipose tissue in lean vs. obese humans. *M. Hubal[1], E. Hoffman[1], H. Barakat[2]* 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) The Diabetes and Obesity Center, Brody School of Medicine, East Carolina University, Greenville NC.

Evidence shows altered metabolism in adipose tissue of obese subjects that are matched for age and sex to lean controls. The molecular mechanisms driving these differences have not been defined. Furthermore, it is not yet known whether different adipose tissue compartments exhibit similar obesity-driven changes at the molecular level. Our aim was to use expression profiling to identify differences in transcription in two distinct adipose tissue depots from lean (L) and obese (Ob) humans. Visceral (VF) and subcutaneous (SF) adipose samples were collected from female morbidly obese (N=4) and lean controls (N=5). RNA was hybridized to Affymetrix microarrays. A repeated measure ANOVA (group * tissue; $p<0.01$) was used for analysis. Obesity up- or down-regulated the expression of 1687 genes in SF and 937 genes in VF samples. Of these genes, 93 genes were similarly affected by obesity in both depots, including defects in several energy metabolism enzymes including dihydrolipoamide branched chain transacylase E2 (DBT; Ob/L ratio of -1.6 in both SF and VF) and succinate dehydrogenase complex, subunit D (SDHD; Ob/L ratio of -2.6 in SF and -1.3 in VF). Lean individuals demonstrated more genes with differential expression between depots (4811 vs. 267) than the obese group, many of which map to the NF-B canonical pathway. In the L group, expression of NF-B pathway components was generally higher in VF than SF (11 genes higher in VF including IL1, TNFR and AKT3), while these genes were similarly expressed in SF and VF in the obese group. These findings suggest obese individuals have impaired expression of enzymes related to energy metabolism in both subcutaneous and visceral adipose. A high degree of tissue-specificity in the lean group was seen in the NF-B pathway with higher expression in VF, an effect that was absent in the obese group, suggesting a loss in normal expression in obese subcutaneous adipose tissue, which could exacerbate inflammatory and cell proliferation signals in obese individuals.

Resequencing of FLG gene in atopic dermatitis. *R. Cascella[1], C. Sinibaldi[1], C. Peconi[1], N. Paolillo[1,2], E. Galli[3], L. Chini[4], V. Moschese[4], P. Rossi[4,5], E. Giardina[1,6], G. Novelli[1,3,7]* 1) Department of Biopathology and Centre of Excellence for Genomic Risk Assessment in Multifactorial and Complex Diseases, School of Medicine, Tor Vergata University of Rome, Italy; 2) Neuropharmacology "Mondino Center" -Tor Vergata University of Rome, Italy; 3) San Pietro Hospital, Fatebenefratelli, Rome, Italy; 4) Department of Pediatrics, Tor Vergata University, Rome, Italy; 5) Division of Immunology and Infectious Disease, Department of Pediatrics, Childrens Hospital Bambino Gesù, Rome, Italy; 6) University Carlo Bo of Urbino, Italy; 7) Department of Cardiovascular Medicine, University of Ankansas for Medical Sciences, Little Rock, AR, USA.

Atopic dermatitis (ATOD) is a frequent chronic inflammatory skin disease associated with immunologic and epidermal abnormalities triggered by both genetic and environmental factors. Linkage and association analysis revealed a susceptibility locus on chromosome 1q21 (ATOD2) and we refined the susceptibility locus within a region of 42 kb upstream the *LOR* gene. Recently, it has been reported that common mutations (R501X and 2282del4) within the filaggrin (*FLG*) gene, located 959 kb from *LOR*, are associated with ATOD in a number of populations. We recently failed to confirm the association of these mutations in italian population suggesting the existence of population-specific mutations or else a negative selection of *FLG* mutations. To verify the presence of unknown mutations here we report a mutational analysis of *FLG* based on the full re-sequencing of the entire gene in an independent cohort of 100 Italian ATOD patients. Although several unknown SNPs have been identified, preliminary data confirmed the low frequency of common *FLG* mutations and excluded the presence of other mutations. Taken together these results may suggest that *FLG* is not the ATOD2 gene in Italian population. Acknowledgements Work funded by the Italian Ministry of Health.

Phenotypically homogeneous autism families yields evidence for epistasis between engrailed 2 and loci on 13q13 and 13q14. *C. W. Bartlett[1], P. Garavito[2], N. Gharani[2], M. A. Azaro[2], J. F. Flax[2], O. Stein[1], R. Goedken[1], E. Di-Cicco Bloom[3], J. H. Millonig[3], V. J. Vieland[1], L. M. Brzustowicz[2]* 1) Battelle Ctr Mathematical Med, The Research Institute at Nationwide Children's, Columbus, OH; 2) Department of Genetics, Rutgers University, Piscataway, NJ; 3) Center for Advanced Biotechnology and Medicine; Department of Neuroscience and Cell Biology, University of Medicine and Dentistry of New Jersey, Piscataway, NJ.

Autism, a genetically complex developmental disorder, has been extensively studied by genome-wide linkage analysis and candidate gene association studies. Results from initial studies were difficult to replicate/interpret across research groups, and neither increased sample size alone nor GWAS has proved to be a panacea. Here we describe a complementary approach based on careful selection of a clinically homogeneous set of families. Using families from the Autism Genetic Resource Exchange, we performed extensive clinical filtering of families based on diagnostic, medical and medical genetic criteria. When the study began, a total of 102 families meeting our strict inclusion criteria had Affymetrix 10k SNP data available (posted to the AGRE website by the Autism Genome Project). Genome-wide linkage analysis using the posterior probability of linkage (PPL) framework yielded evidence for 13q14 (PPL=36%) and 15q13 (PPL=25%). We then conducted two-locus epistasis analysis using the known risk haplotype in engrailed 2 as bait, producing an additional locus of interest on 13q13 (PPL=50%) and further strengthened the evidence for 13q14 (PPL=47% up from 36%). Subsequently Affymetrix 500k data on 215 additional families meeting our criteria became available; we sequentially updated our results to accumulate linkage evidence across the two datasets. Evidence for 13q14 increased to 64% with additional epistasis analysis ongoing. While our follow-up association analysis using htSNPs genotyped by our group did not yield compelling evidence for LD (using PPLD), other groups have implicated all 3 of our loci. In summary, based on a small group of very carefully selected families, we have obtained compelling evidence of linkage to 3 loci as well as evidence of epistasis.

Interpretation of genetic association studies: Markers with widely replicated highly significant odds ratio may be poor classifiers. *J. Jakobsdottir[1], M. B. Gorin[2], Y. P. Conley[3,4], R. E. Ferrell[4], D. E. Weeks[1,4]* 1) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, PA, USA; 2) Department of Ophthalmology and Jules Stein Eye Institute, The David Geffen School of Medicine, UCLA, CA, USA; 3) Department of Health Promotion and Development, School of Nursing, University of Pittsburgh, PA, USA; 4) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA, USA.

Recent successes in the discoveries of potentially causal SNPs for complex diseases hold great promise and commercialization of genomics in personalized medicine has already begun. The hope is that genetic testing will benefit patients and their families and encourage positive life-style changes and guide clinical decisions. However, for many complex diseases, such as age-related maculopathy (ARM), it is arguable whether the era of genomics in personalized medicine is here yet. We discuss and explore some of the issues geneticists and physicians face when presenting the individual-level risk calculations. Our focus will be the clinical validity and utility of genetic testing with additional emphasis on two popular statistical methods for evaluating markers. The majority of genetic association studies are etiological studies aimed at finding variants strongly correlated with disease risk. We then hope to use these variants in individual-level risk estimation, classification, and clinical decision-making. Using our ARM data, we examine the validity of the three strongest risk SNPs discovered so far. For example by using an additive model of the *CFH*, *LOC387715*, and *C2* variants, with odds ratios (ORs) 2.9, 3.4, 0.4, and P-values 10^{-13}, 10^{-13}, 10^{-3}, respectively, the area under the receiver operating characteristic curve is 0.79 but the positive predictive values (PPVs) assuming prevalence of 15%, 5.5%, and 1.5% (which are realistic for age groups 80, 65, and 40 years and older) are only 30%, 12%, and 3%, respectively. PPV is the probability of disease given genotypes and therefore a more relevant risk estimator than the OR.

Mapping of the *blind sterile 2 (bs2)* locus in mice. *R. P. Liegel[1], B. Chang[2], D. J. Sidjanin[1,3]* 1) Cell Biology, Medical College of Wisconsin, Milwaukee, WI; 2) The Jackson Laboratories, Bar Harbor, ME; 3) The Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI.

Blind sterile locus 2 (bs2) is a novel autosomal recessive mouse mutation that arose spontaneously on C57BL/6 background. *bs2* mice exhibit a phenotype of congenital cataracts as well as male-specific sterility. The goal of this study is to identify the gene containing the mutation responsible for the *bs2* phenotype, as well as to investigate the human ortholog of the *bs2* locus. In order to map the *bs2* locus, *bs2* homozygote females were outcrossed to the Cast/Ei strain followed by F1 *(bs2 X Cast/Ei)* intercross to generate F2 progeny. At three weeks of age, progeny were phenotyped and then euthanized. Eye and testis tissues were collected for genetic and histological analysis. Clinically, *bs2* homozygote mice exhibit bilateral nuclear cataracts and micropthalmia. Histological evaluation of eye sections shows that *bs2* mice have severely disrupted lens epithelial and fibroblast cells resulting in mature cataracts. Histological evaluation of testes show that *bs2* testes are smaller than WT controls, do not contain mature sperm, and contain large multinucleate cells in the seminiforous tubules. Linkage analysis mapped *bs2* to mouse chromosome 2, approximately 45cM from the centromere. Evaluation of the Mouse and Human Genome databases did not yield any obvious candidate genes responsible for both cataract and spermatogenesis phenotypes. Our current hypothesis is that the *bs2* mouse phenotype results from a mutation in a novel gene essential for lens transparency and male fertility. However, a possibility exists that *bs2* allele is due to a large deletion encompassing two independent genes responsible for the eye and testis phenotype. Further studies are needed to establish the onset and progression of both the eye and testis phenotypes in *bs2* mice; immunohistochemical staining is currently underway to characterize lens fiber maturation defects. In addition, we are currently focusing our efforts to narrow the critical region containing the mutation via microsatellite and SNP mapping to facilitate identification and sequencing of the gene(s) responsible for the *bs2* phenotype.

Genotype imputation accuracy across worldwide human populations. *L. Huang[1], L. Yun[1], A. B. Singleton[2], J. A. Hardy[3], G. Abecasis[1], N. A. Rosenberg[1,4], P. Scheet[1]* 1) Department of Biostatistics, University of Michigan; 2) Laboratory of Neurogenetics, National Institute on Aging; 3) Institute of Neurology, University College London; 4) Department of Human Genetics, University of Michigan.

A current approach to mapping complex disease susceptibility loci in genome-wide association (GWA) studies is to leverage the information in a reference database of dense genotype data. By modeling the patterns of linkage disequilibrium (LD) in a reference panel, such as HapMap, and by applying the fitted model to genotypes obtained from study samples (such as those from a case-control study), genotypes that are not directly measured in the samples can be imputed and tested for association. This strategy has been successful for GWA studies involving populations that are well-represented by existing high-density reference panels. We used genotypes at 512,762 autosomal SNP loci in 443 unrelated individuals from 29 populations worldwide from the Human Genome Diversity Project (HGDP) to evaluate the "portability" of the HapMap reference panels for imputation in studies of diverse populations. When leveraging a single HapMap panel to impute randomly masked genotypes, European populations had the highest imputation accuracy, followed by populations from East Asia, Central/South Asia, the Americas, Oceania, the Middle East, and Africa. For each population, we also interrogated optimal mixtures of reference panels that produced the maximal imputation accuracy. From an independent survey of the same samples, in which additional 1008 SNPs were typed, we evaluated the imputation accuracy in a scenario in which all the genotypes at a given SNP position were unobserved and were imputed based on SNP data available from a commercial "SNP chip." In this setting, we obtained similar results to those produced when masking genotypes randomly. Our results can serve as a guide for selecting appropriate reference panels for analysis of GWA data. In addition, this study helps characterize genetic distances among human groups in terms of a highly practical metric -- imputation accuracy.

Two novel EBP mutations in Conradi-Hünermann-Happle syndrome. *S. Ausavarat[1], P. Tanpaiboon[2], S. Tongkobpetch[1], K. Suphapeetiporn[1], V. Shotelersuk[1]* 1) Division of Medical Genetics and Metabolism, Department of Pediatrics, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; 2) Department of Pediatrics, Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand.

Conradi-Hünermann-Happle syndrome, also known as chondrodysplasia punctata type 2 (CDPX2), is an X-linked dominant disorder characterized by skin defects, skeletal and ocular abnormalities. CDPX2 was shown to be caused by mutations in the gene encoding emopamil binding protein (EBP). At least 58 different mutations have been described. Here we present clinical and molecular findings in two unrelated Thai girls with CDPX2. Mutation analysis by PCR-sequencing the entire coding region of EBP successfully revealed two potentially pathogenic, novel mutations, c.616G>T and c.382delC. This study has expanded the spectrum of the EBP gene mutations causing CDPX2.

The role of geography and drift in human adaptation. *G. Coop[1,2], J. K. Pickrell[1], S. Kudaravalli[1], J. Novembre[1,3], R. M. Myers[4], M. W. Feldman[5], J. K. Pritchard[1]* 1) Dept Human Genetics, University of Chicago, Chicago, IL; 2) Evolution and Ecology Section, University of California Davis. CA; 3) Ecology and Evolution Department, UCLA. CA; 4) Department of Genetics, Stanford University. CA; 5) Department of Biological Sciences, Stanford University. CA.

Several types of observations argue for a role of adaptation in recent human evolution, including selection signals at candidate genes and genome-wide selection scans. Nonetheless, using genome-wide SNP data from the HapMap, Perlegen, and Human Genome Diversity Panel studies, we find evidence that strong sustained selection is extremely rare in recent human evolution (the last ~70,000 years). There are very few fixed, or nearly fixed differences between human populations, and most fixation events have occurred in the populations that show the most drift at neutral loci. Moreover, the geographic distribution of putatively selected alleles almost invariably conforms to population clusters identified using randomly chosen genetic markers; this indicates that selected alleles have rarely spread across barriers to neutral gene flow. In summary, we propose that the geographic distribution of favored alleles is largely determined by population history and migration, and that the geographic distribution of SNPs with extreme Fst is best described by a model of relatively weak selection with genetic drift. When humans adapt to new environments it may often be via modest allele frequency changes in multiple genes simultaneously.

Amplification and elevated expression/activity of AKT3 frequently occurs in hepatocellular carcinomas and is implicated in the molecular pathogenesis of liver cancer. *J. Xu[1], J. Pei[1], D. Koumbi[1], A. N. Zekri[2], J. R. Testa[1]* 1) Human Genetics Program, Fox Chase Cancer Center, Philadelphia, PA; 2) National Cancer Institute, Cairo University, Cairo, Egypt.

Overexpression and activation of AKT have been reported as important events in the promotion, recurrence, prognosis, and metastasis of hepatocellular carcinoma. The AKT3 gene locus at 1q44 has been shown to be amplified in a majority of clinical samples of human hepatocullular carcinoma. Here we report that the AKT3 locus was amplified in both clinical samples and cell lines of hepatocellular carcinoma by using Affymetrix single nucleotide polymorphism (SNP) mapping arrays. Amplification was verified by real-time PCR analysis of genomic DNA by using primers specific for AKT3. Copy number for the AKT3 gene ranged from 2.5 to 5. Further analysis found that AKT3 protein was also highly expressed and activated in samples exhibiting the gene amplification. Knockdown of AKT3 in hepatocellular carcinoma cells resulted in diminished cell viability. These findings suggest that the amplification of AKT3 may contribute to elevated expression and activity of the AKT3 protein, which may play a significant role in the molecular pathogenesis of hepatocellular carcinoma.

Detection and Control of Bias in Genome-wide Association Studies: A Systematic Review. *T. Pearson*[1, 2], *T. Manolio*[2] 1) Community and Preventive Medicine, University of Rochester Medical Center, Rochester, NY; 2) Office of Population Genomics, NHGRI, NIH, Bethesda, MD.

The heterogeneity of results from gene association studies has several possible explanations, one of which is bias in subject selection and in collection of data on genotype and phenotype. To study the potential for bias and its control in genome-wide association studies (GWAS), we performed a systematic review of the first 109 GWAS entered into the NHGRI Online Catalog of GWAS (http://www.genome.gov/gwastudies). These studies examined 91 discrete disease traits and 40 quantitative traits; 71% had a case-control design. Assessment and control of potential genotyping errors included genotyping completion rates in 75% of studies; 80% performed tests to estimate genotyping error; 56% assayed multiple samples for quality control; and 76% used methods to control for population stratification. Information on phenotype definition and the selection of study subjects was less frequent, however. The method of definition of phenotype was provided in 67% by primary reports, 28% by online supplements, and not at all in 5%. Only 36% of discovery studies used population-based cases or controls. A minority of reports (33%) presented tables comparing cases and controls for potential confounding, and 3.7% tested differences for statistical significance. Only 21% of results were adjusted for baseline differences between cases and controls; analyses stratified by potential confounders in 24% of studies. Nonresponse rates could be assessed only in the 9.2% of reports which published participation rates; only one report compared characteristics of study participants and nonparticipants. In conclusion, the literature pertaining to GWAS has emphasized quality control of genomic analysis and genotyping. The design, conduct, and presentation of GWAS has been less consistent in quality control of phenotype description and in the avoidance and control of potential biases of selection and description of study subjects.

Expression profile of DNA damage signaling and repair responsive genes in Alzheimers disease patients. *D. V. N. P. Oliveira[1,3], D. J. Xavier[1], J. C. Moriguti[2], E. T. Sakamoto-Hojo[1], Oliveira* 1) Genetics Department, Faculty of Medicine of Ribeirão Preto, São Paulo University; 2) Geriatrics Department, Medical Clinic HCFMRP/USP; 3) Radiation Biology Center, Kyoto University, Kyoto, Japan.

Alzheimer's disease (AD) is a chronic neurodegenerative disorder with an impact on public health. The identification of risk factors (genetic and protective factors) related to AD has become of great importance. Among them, there is evidence that the development of AD is strictly related to oxidative damage. Therefore, this work laid in two main lines: (1) evaluating some gene expression levels, by Real Time PCR, associated to oxidative DNA damage responsive system, such as other DNA damage responsive genes, and also those that there might be potentially related to the disease; and (2) a general gene expression screening, by cDNA microarrays. Both experiments using AD patients and healthy donors lymphocytes. Curiously, it was found that all genes analyzed by Real Time PCR, with exception of APOE (FC=+1.43), were downregulated, compared to healthy donors, as well as those genes that do not have yet been reported to be linked with the disease, including *PRKDC*, *FEN1*, *ATM* and *ATR*. Additionally, it was also found 43 differently modulated genes by cDNA microarrays (FDR0.06). Such data showed that, not only oxidative damage responsive system might play a role in the development of AD, but also other DNA damage signalling and repair systems might as well, whether they are a cause or a consequence of that. Besides, the modulation of genes associated to the -amyloid anabolic pathway also indicated its relationship with the pathology. Concluding, those results pointed out that the transcriptional profiles observed among AD patients indicate a multiple and complex signalling pathway involved in the course of the diasease. Although it should be considered that the expression level of those genes in lymphocytes and in neurons are different from each other, they still differ on lymphocytes between AD patients and healthy groups, which bring us new information about it. [Financial support: FAPESP (Proc. 06/01947-8), CNPq, CAPES, RBC].

Multilocus gene-gene interaction analysis of osteoporosis in Chinese population. *X. Hong[1], H. Tsai[1], H. Dong[3], Z. Li[3], X. Liu[3], X. Xu[2], X. Wang[1]* 1) Mary Ann and J. Milburn Smith Child Health Research Program, Childrens Memorial Hospital and Childrens Memorial Research Center, Chicago, IL; 2) Center for Population Genetics, School of Public Health, University of Illinois at Chicago, Chicago, IL; 3) Institute of Biomedicine, Anhui Medical University, Hefei, Anhui, China.

Abstract: A number of osteoporosis candidate genes have been reported previously, but with inconsistent results. This study aimed to validate associations of eight reported genes with osteoporosis in a population-based Chinese cohort and to examine potential gene-gene interactions. A total of 1190 extreme low femoral neck bone mass density (fnBMD) cases and 1192 extreme high fnBMD controls were selected. We tested associations of 16 single nucleotide polymorphisms (SNP) in the 8 genes with extreme low fnBMD and osteoporosis using multiple logistic regression, with adjustment of important covariates. We also tested gene-gene interactions using multifactor-dimensionality reduction and conditional logistic regression. SNP rs1800872 in the IL10 gene and SNP rs1126667 in the ALOX12 gene were associated with an increased risk of extreme low fnBMD and osteoporosis in males only. SNP rs3778082 in the ESR1 gene was associated with osteoporosis in postmenopausal females only. However, none of those remained statistically significant after correcting for multiple testing. Importantly, we identified and validated a two-locus gene-gene interaction between rs12594287 in the CYP19A1 gene and rs2234693 in the ESR1 gene in males. Males with the AA/AG genotype in SNP rs12594187 in the CYP19A1 gene and CC/CT genotype in SNP rs2234693 in the ESR1 gene had a significantly lower risk of extreme low fnBMD (OR=0.47, 95%CI=0.32-0.68, p=0.00005) and osteoporosis (OR=0.25, 95%CI=0.13-0.51, p=0.0001). No gene-gene interaction was found in females. In conclusion: our results demonstrated gender specific genetic association and gene-gene interaction in osteoporosis.

VEGF 936C>T is predictive of retinopathy of prematurity in Japanese infants with gestational age of 30 weeks or less. *M. Yagi[1,2], M. Yamamori[3], I. Morioka[2], N. Yokoyama[2], N. Okamura[4], T. Nakamura[1], T. Sakaeda[5], M. Matsuo[2]* 1) Clin Evaluation of Pharmacotherapy, Kobe Univ Graduate Sch Med, Kobe, Japan; 2) Pediatrics, Kobe Univ Graduate Sch Med, Kobe, Japan; 3) Hospital Pharmacy, Kobe Univ Hospital, Kobe, Japan; 4) Clinical Pharmacy, Sch of Pharmaceutical Science, Mukogawa Womens Univ, Hyogo, Japan; 5) Frontier Education Center, Graduate Sch Pharmaceutical Sciences, Kyoto Univ, Kyoto, Japan.

Background: Retinopathy of prematurity (ROP) is a major problem among premature infants. ROP is characterized by abnormal neovascularization of the retina. It is known that vascular endothelial growth factor (VEGF), a major mediator of vascular permeability and angiogenesis, plays an important role in the pathogenesis of ROP. **Purpose:** To assess the association of ROP with *VEGF* genetic polymorphisms and clinical (maternal, perinatal, neonatal) parameters in the Japanese population. **Methods:** Sixty-seven infants with a gestational age of 30 weeks or less were enrolled and divided into two groups: threshold ROP group included patients who progressed in stage 3 and were treated (n=30); non-threshold ROP group included patients without ROP or with ROP stage 1or 2 (n=37). Genomic DNA was extracted from buccal mucosa or umbilical cord. Six polymorphisms in the *VEGF* gene were evaluated. **Results:** Genotypes distribution of *VEGF* 936C>T, but not -1498T>C, -1154G>A, -634C>G, -7C>T, or 1612G>A were significantly different between threshold and non-threshold ROP groups. Eleven of the tested clinical parameters were also significantly different between the two groups in the univariate analysis. Logistic regression analysis with adjustment for gestational age and birth-weight showed that the heterozygous or homozygous for the T-alleles of *VEGF* 936C>T (OR:4.41; 95%CI:1.05-18.61; P=0.043) and chronic lung disease (CLD) (OR:7.37; 95%CI:1.20-45.47; P=0.031) were independent risk factors of threshold ROP. **Conclusions:** This study showed that *VEGF* 936C>T and CLD as independent risk factors in the development of threshold ROP. *VEGF* 936C>T may be a predictor of ROP in Japanese infants with gestational age of 30 weeks or less.

A synonymous CT substitution in exon 15 of *UBE1* causes reduced expression in patients and carrier females from XL-SMA families. *A. Meindl[1], J. Ramser[1], C. Lenski[1], M. E. Ahearn[2], K. Yariz[2], M. von Rhein[3], B. Wirth[4], L. L. Baumbach[2]* 1) Dept OB/GYN, Klinikum Rechts der Isar, Munich, Germany; 2) University of Miami, Miami, FL, USA; 3) University Children's Hospital Mainz, Mainz, Germany; 4) Insititute of Human Genetics, University of Cologne, Cologne, Germany.

Recently, we have associated two missense mutations and one synonymous CT substitution (c.1731CT, p.Asn577Asn), all located in exon 15 of the *UBE1* gene, with X-linked infantile spinal-muscular atrophy (XL-SMA; MIM301830) (Ramser et al; AJHG 2008). XL-SMA is an X-linked motor neuron disorder that presents with the clinical features of hypotonia, areflexia and multiple congenital contractures associated with anterior horn cell loss and infantile death. *UBE1* codes for Ubiquitin-Activating Enzyme E1 that catalyzes the first step in the ubiquitin-proteasome system (UPS) which is responsible for intracellular degradation of proteins. While the consequences of the two missense mutations for the ubiquitin-proteasome pathway and the SMN complex stability are described in another abstract (Baumbach et al., this meeting), this abstract focuses on the investigation of the pathomechanism of the synonymous CT substitution. In a first step we have performed expression analysis applying quantitative RT-PCR in white blood cells of a still living XL-SMA patient displaying the synonymous substitution and revealed a significant reduction of *UBE1*-expression to one fifth as compared to three male healthy controls. Further expression studies on RNA from white blood cells of eight carrier females of three unrelated XL-SMA families carrying the synonymous substitution revealed a 50% reduction of the *UBE1* expression compared to eight female healthy controls. Since it has been shown that *UBE1* escapes X-inactivation, these results confirm that the synonymous CT substitution, which was shown to be absent in 7914 control X-chromosomes, leads to a significant reduction of *UBE1*-mRNA expression. Whether this reduction is caused by a possible modification of an exonic splice modulator element or by the alteration of the methylation pattern of a putative regulatory element present in exon 15 of *UBE1* is currently under investigation.

Recombination hotspots and haplotype blocks in three isolated Chinese Muslim communities. *M. S. Song[1], W. Wang[1,2], X. M. Lu[3], Y. X. Wang[1]* 1) Department of Epidemiology & Health Statistics, Capital Medical University, Beijing, China; 2) College of Life Sciences, Graduate University of Chinese Academy of Sciences, Beijing, China; 3) Medical Research Center, 1st Teaching Hospital, Xinjiang Medical University, Urumqi, Xinjiang Uygur Autonomous Region, China.

Detection of the patterns of recombination hotspots and haplotype blocks in the human genome is important both for understanding the nature of recombination and for applications such as association studies. The Chinese Muslim minorities are specific resources for such genetic analysis due to their unique culture and marriage practices. The study on the patterns of recombination hotspots and haplotype blocks in the isolated Chinese Muslim communities should aid in exploring the genetic resources of China. Three isolated Muslim communities, i.e. Salar, Boan and Dongxiang, which were resident in Jishishan Minority Autonomous County, Gansu province, northwest China, with a custom of endogamy and preferential consanguineous marriage, were taken as subjects of this study. The recombination hotspots within the human PGM1 gene were estimated by the analysis of SNP genotyping data using a population genetic approach (i.e. the HotspotFisher method). The analysis of haplotype structure of PGM1 was performed by a Haploview version 3.32 software package. The presence of both community-specific and common recombination hotspots with variable recombination rates and Log-likelihood ratio (LLR) were observed among the Salar, Boan and Dongxiang Communities. Different numbers of common haplotype blocks were detected in the three communities, i.e. nine in Salar, six in Baoan and eight in Dongxiang, respectively. The spatial arrangement of haplotype blocks within PGM1 of the three samples was mapped preferentially to the regions where LD collapses, corresponding with the location of hotspots and demonstrating that hotspot is a major factor determining the pattern of haplotype blocks. Our study suggests that investigation of the recombination hotspot patterns of various population isolates, would highlight genetic background of population samples involved in the association study of complex traits.

Genome-wide transcription profiling identifies genes influencing susceptibility to lipotoxicity and type 2 diabetes (T2DM). *S. Das[1,2], W. Chu[1,2], A. Mondal[1,2], N. Sharma[1,2], S. Elbein[1,2]* 1) Internal Medicine/Endocrinology, University of Arkansas for Medical Sciences; 2) CAVHS, Little Rock, AR.

Elevation in plasma free fatty acid (FFA) levels has been implicated in the development of T2DM by the effects on insulin resistance in peripheral tissues and -cell dysfunction. Human transformed lymphocytes (TLs) respond to FFA with increased markers of ER stress, hence making this a viable system to examine genetic influences of lipotoxicity. We hypothesized that T2DM individuals were genetically more susceptible to lipotoxicity, and that polymorphisms responsible for T2DM susceptibility would alter the expression of genes induced by FFA treatment. We selected 4 sib pairs from Caucasians selected to be discordant for T2DM, and exposed TLs to 0.5 mM palmitate or control for 6 hours. Genome-wide transcription profiling was performed using an Agilent 44K array. We detected 22,268 transcripts in all cells under both conditions. Palmitate treated cells showed up and down regulation (1.5 fold) of 123 and 17 genes respectively. The most up-regulated genes included DDIT3, STC2, ATF3 and CEBP, whereas the most down-regulated genes included CXCR3, XCL2, CMKLR1 and FUT7. Expression of DDIT3 was significantly correlated ($r^2$0.5; p0.05) with 2148 genes, but most strongly with MLLT10 (r=0.98) and LRP8 (r=-0.98). Differential expression of 32 and 29 transcripts between T2DM and normal cells was observed under control and palmitate treated conditions, respectively, and included significant differences in ARHGAP22, IFNG, IL18BP, PPAP2C, TNFSF11, CHDH, SLC12A7 and SLC6A6. Genes involved in ER stress response showed marked induction with palmitate. We thus examined ER stress genes in the same TLs under chronic stress condition (0.1mM palmitate for 2 passages followed by 0.5mM for 6hr). Neither T2DM nor normal TLs showed any evidence of adaptation to ER stress induced by palmitate, in contrast to HepG2 treated similarly. Our results indicate that genes involved in FFA metabolism and homeostasis differ between T2DM and nondiabetic siblings, and should be prioritized for analysis as functional candidate genes for T2DM.

Autosomal recessive transmission of male infertility due to Aurora Kinase C mutations is common in North Africa. *P. F. Ray[1,2], S. Hennebicq[1,2,3], R. Zouari[4], F. Vialard[5], R. Harbuz[1,2], K. Dieterich[1,2], H. Bellayou[6], I. Koscinski[7], M. R. Guichaoua[8], A. Zoghmar[9], M. Noruzinia[10], A. Sefiani[11], J. Lunardi[1,2]* 1) Genetique et Procreation, CHU Grenoble, France; 2) Faculté de Médecine-Pharmacie, Université Joseph Fourrier, France; 3) Inserm U823, Institut Albert Bonniot, Grenoble, France; 4) Centre de FIV les jasmins, Tunis, Tunisia; 5) Laboratoire de Cytogénétique, CHI Poissy-Saint Germain, France; 6) Laboratoire de Génétique. Faculté de Médecine et Pharmacie. Casablanca, Maroc; 7) CECOS d'Alsace, CMCO, Schiltigheim, France; 8) Biologie de la reproduction, Hôpital de la Conception, Marseille, France; 9) Médecine de la Reproduction, Cité Boussouf, Constantine, Algérie; 10) Sarem hospital, Ekbatan, Tehrran, Iran; 11) Génétique médicale, Institut National d'Hygiène, Rabat, Maroc.

Patients with primary infertility caused by 100% teratozoospermia with a majority of large-headed spermatozoa with up to four flagella were described 30 years ago (OMIM 24306). Several FISH studies demonstrated that all spermatozoa had gross chromosomal abnormalities, most of them being polyploid. We performed a genome-wide microsatellite scan and could localise a candidate region and identify the same homozygous mutation (c.144delC) in the Aurora Kinase C gene of all the tested men. All the patients had an identical haplotype indicating a founders effect(1). We have now genotyped a total of 37 patients with a typical large headed phenotype. All were mutated: thirty one were homozygous for c.144delC and we identified three novel mutations in 6 patients. No mutations were identified in any of the 7 AURKC exons of 32 patients with lower rates of macrocephalic (<30%) and multiflagelar (<10%) spermatozoa. Genotypes obtained from individuals from the North African general population (n=500) indicate a carrier frequency of 1/70-100. Although rare, the c.144delC mutation is thus probably responsible for the infertility of thousands of Maghrebian men. To our knowledge, AURKC is the first gene in which a recurrent mutation has been shown to cause male infertility by impairing spermatogenesis. 1. Dieterich et al.(2007) Nat Genet 39, 661-665.

A GWAS identifies common variations in the BARD1 tumor suppressor gene predisposing to high-risk neuroblastoma. *M. Capasso[1,2], M. Devoto[1,3], C. Hou[1], S. Asgharzadeh[4], E. Attiyeh[1], Y. Mosse[1,3], J. Bradfield[1], R. Scott[5], S. Diskin[1], J. Jagannathan[1], J. Glessner[1], C. Kim[1], W. London[6], R. Seeger[4], S. Grant[1,3], H. Li[3], N. Rahman[5], H. Hakonarson[1,3], J. Maris[1,3]* 1) The Childrens Hospital of Philadelphia, Philadelphia, PA, USA; 2) University Federico II, CEINGE - Biotecnologie Avanzate, Naples, Italy; 3) University of Pennsylvania School of Medicine, Philadelphia, PA, USA; 4) University of Southern California, Los Angeles, CA, USA; 5) Institute of Cancer Research, Sutton, Surrey SM2 5NG, UK; 6) University of Florida Gainesville, FL, USA.

Neuroblastoma (NB) is characterized by a high degree of clinical heterogeneity. Over half of all patients present with "high-risk" disease features including metastases at diagnosis and survival probabilities <40%. We recently discovered a significant association of common 6p22 SNPs with NB (Maris et al, NEJM 2008). Because this signal was enriched in the high-risk population, we performed a second analysis restricted to the high-risk subset by comparing SNP allele frequencies in 397 cases and 2,043 controls of European descent genotyped with the Illumina HH550 array. In addition to the 6p22 signal, we observed genome-wide significant association with 6 common intronic SNPs of the BARD1 tumor suppressor gene at 2q35 (allelic OR=1.56-1.64, P<10-7). Analysis using HapMap data showed that 4 of the associated SNPs are in strong LD with known BARD1 non-synonymous SNPs (r2>0.5). Association with the 6 BARD1 SNPs was replicated in an independent group of 189 high-risk cases and 1178 controls (allelic OR=1.52-1.80, P<10-3). The two most significant SNPs (rs6435862, rs3768716) were further replicated in two additional groups of high-risk patients from the UK (86 cases and 782 controls) and the US-based Children's Cancer Group (96 cases and 162 controls) using real-time PCR. The total combined allelic ORs and P-values were 1.66 and 8x10-19 for rs6435862 and 1.88 and 9x10-27 for rs3768716. These findings demonstrate that apart from its reported role in breast cancer, BARD1 is a susceptibility gene for NB, suggesting that the molecular mechanisms underlying these disorders may share common biological pathways.

Penetrance of Familial Pulmonary Arterial Hypertension is modulated by the expression of wild-type *BMPR2* transcript levels. *R. Hamid[1], J. Cogan[1], l. Hedges[1], J. Phillips[1], J. Newman[2], J. Loyd[2]* 1) Dept Pediatrics, Div Med Gen, Vanderbilt Univ Sch Med, Nashville, TN; 2) Dept. Medicine, Vanderbilt Univ Sch Med, Nashville, TN.

Rationale: Familial pulmonary arterial hypertension (FPAH) is a progressive, fatal disease caused by mutations in the *bone morphogenetic protein receptor type 2 (BMPR2)* gene. FPAH is inherited as an autosomal dominant trait and shows incomplete penetrance in that many with BMPR2 mutations do not develop FPAH, suggesting a role for, as yet unidentified, modifier genes in disease penetrance. Objectives: We hypothesized that variable levels of expression of the wild type (WT) *BMPR2* allele could act as a modifier and influence penetrance of FPAH. Methods: WT *BMPR2* levels were determined by real-time PCR analysis in lymphoblastoid (LB) cell lines derived from normal controls and individuals with sporadic PAH or FPAH. The FPAH kindreds analyzed carried mutations that result in the activation of nonsense mediated decay (NMD) pathway, which leads to the degradation of the mutant RNA thus ensuring that only the WT *BMPR2* transcripts will be detected in the real-time assay. Results: Our data show that WT and mutant *BMPR2* levels can be reproducibly measured in patient derived LB cell lines and that unaffected mutation carrier derived LB cell lines have higher levels of WT *BMPR2* transcripts than FPAH patient derived LB cell lines ($p<0.005$). Conclusions: Our findings suggest that the levels of expression of WT *BMPR2* allele transcripts is important in the pathogenesis of FPAH caused by NMD+ mutations. Furthermore, our study illustrates a novel application of lymphoblastoid cell lines in the study of PAH, especially important because the affected site, i.e. lung is not available for unaffected mutation carriers.

SURF and TuRF: Computationally efficient algorithms for detecting epistasis in genome-wide association studies. *J. Kiralis, C. Greene, N. Penrod, J. Moore* Computational Genetics Laboratory, Deparment of Genetics, Dartmouth College, Lebanon, NH.

Genome-wide association studies (GWAS) are becoming the de facto standard in the genetic analysis of common complex human disease. Given the complexity and robustness of biological networks, such diseases are unlikely to be the result of single points of failure but instead the joint failure of two or more interacting components. The promise of GWAS is that many of these points of failure can be traced to informative single nucleotide polymorphisms (SNPs). Detecting interacting variants that lead to disease in the absence of single-gene effects is difficult however, and methods to characterize these interactions are of exponential time complexity. In order to successfully model interactions in genome-wide data a heuristic which can detect such interactions is needed. The Relief algorithm was developed in 1992 as a machine learning algorithm that uses a nearest neighbor approach to assign weights to independent variables in a dataset that reflect their importance with respect to a dependent variable. We have previously introduced the novel Tuned ReliefF (TuRF) algorithm and have shown that it can effectively assign weights to SNPs in genome-wide association studies that reflect their role in epistatic interactions. Here, we introduce the Spatially Uniform ReliefF (SURF) algorithm that greatly improves the weights assigned to SNPs by assessing nearest neighbors within a given distance epsilon. To assess these novel algorithms we designed an artificial GWAS with cases and controls simulated using a wide variety of different epistasis models with heritabilities ranging from 0.025 to 0.4 and sample sizes ranging from 400 to 3200. We show here that the combined use of SURF and TuRF dramatically improves the power to highly rank functional interacting SNPs in the context of a GWAS. These results challenge the commonly held assumption that 10 nearest neighbors are sufficient for Relief algorithms. We anticipate SURF and TuRF will play a very important role in prioritizing SNPs for interactions analysis in GWAS of complex human diseases.

LONG-TERM (2-3 YEARS), OPEN-LABEL EXTENSION STUDY OF IDURSULFASE IN THE TREATMENT OF HUNTER SYNDROME. *J. Muenzer[1], E. Wraith[2], M. Beck[3], E. Wraith[4], P. Harmatz[5], C. M. Eng[6], A. Vellodi[7], R. Martin[8], U. Ramaswami[9], M. Calikoglu[1], S. Vijayaraghavan[2], A. C. Puga[4], B. Ulbrich[9], M. Shinawi[6], M. Cleary[7], S. Wendt[3]* 1) Univ North Carolina, Chapel Hill, NC; 2) Royal Manchester Children's Hospital, Manchester, UK; 3) Univ. of Mainz, Mainz, Germany; 4) Medical Genetics Service, HCPA/UFRGS, Brazil; 5) Children's Hospital, Oakland, CA; 6) Baylor College of Medicine, Houston, TX; 7) Great Ormond Street Hospital, London, UK; 8) St. Louis Children's Hospital, St. Louis, MO; 9) Cambridge Univ. Teaching Hospitals, Cambridge, UK.

Hunter syndrome (MPS II) is caused by a deficiency in iduronate-2-sulfatase. In the pivotal 1-year, double-blind, placebo-controlled clinical trial of enzyme replacement therapy with idursulfase (Elaprase, Shire HGT, Cambridge, MA), weekly dosing (0.5 mg/kg) significantly improved the primary endpoint (a composite comprising sum of the ranks of changes in percent predicted forced vital capacity (%FVC) and distance walked in 6 minutes (6MWT) compared to placebo). All patients who completed the double-blind study (n=94) enrolled in the open-label extension study and were treated with idursulfase at 0.5 mg/kg weekly for 2 years. The primary objective of this study was to collect long-term safety and clinical efficacy data from MPS II patients treated with idursulfase. All evaluations made during the double-blind study, including absolute and % predicted FVC, 6MWT, and organ size, were monitored throughout the open-label extension study. Safety was assessed continuously during the study by monitoring treatment emergent adverse events and by periodic determination of anti-idursulfase antibodies in blood samples. In an interim 1-yr analysis, patients in the original placebo group who transitioned to weekly idursulfase therapy (n=28) demonstrated an increase in absolute FVC (+6.8%, P=.005) and decreases in liver (-23%, P<.0001) and spleen volume (-17%, P=.0007) and urine GAG excretion (-66%, P<.0001). In these patients, no new safety issues emerged, and these results continued to support a positive risk-benefit ratio of weekly idursulfase use. The 2-year safety and efficacy results will be presented.

Molecular Characterization and Postmortem Review of Holoprosencephaly (HPE) Cases. *F. Lacbawan[1,2], A. Igbokwe[2], D. Pineda[1], M. Muenke[1]* 1) Med Gen Branch, NHGRI/NIH, Bethesda, MD; 2) SUNY Downstate Medical Center, Brooklyn NY.

HPE is the most common structural forebrain malformation in humans with genetic and environmental causes. Besides chromosomal abnormalities & submicroscopic *dels*, recurring mutations were found in *ZIC2, SHH, SIX3, TGIF1, GLI2*, & *FOXH1*. In our studies, there is variable expressivity and reduced penetrance in SIX3 mutation(+) cases and gonodal mosaicism in ZIC2 mutation(+) cases. A multiple hit hypothesis that predicts that several genetic &/or environmental insults are required to produce HPE in humans was proposed. In our continued efforts to characterize the clinical spectrum, we reviewed 48 cases with postmortem reports. DNA samples were screened for mutations in *ZIC2, SHH, SIX3* and *TGIF* by PCR of exons followed by sequencing. The age ranged from GA 15 wks to 8 yrs & F:M ratio was 2:1. 21 were diagnosed on prenatal USS. Maternal history was significant in only 3 (alcohol, smoking, diabetes & cocaine). 17(35%) had more than 1 clinically affected family member with known karyotype (KT) abnormalities in 4. There were also 4 of 31 sporadic cases with abnormal KT. In 1/2 of the cases with normal KT, we found 2 SHH mut(+) and 1 ZIC2 mut(+). Most cases reviewed were severe forms with 44% alobar, 25% semilobar and 13% lobar. Common craniofacial features were microcephaly, proboscis, olfactory bulb/tract agenesis, hypotelorism, CL/P, ear anomalies and cyclopia/anophthalmia. Other brain findings include corpus callosum a/dysgenesis(23%), cortical/cerebellar malformations(17%), hydrocephalus(15%) and migration defects(6%). 27% also had significant cardiac defects including ASD, VSD, PFO, and hypoplastic left heart. Associated findings included limb anomalies(27%) and GU anomalies like renal, uterine, anterior perineal anomalies and hypospadias(27%). Our review highlights the need for clinicians and pathologists to know the broad spectrum of anatomic features of HPE so that appropriate clinical diagnostic work-up like radiology and use of the algorithm of molecular and chromosomal studies are optimized. A better understanding of HPE pathogenesis will translate to a more comprehensive clinical management of patients and proper counseling of families.

Hypomorphic Mutations in Meckelin (MKS3/TMEM67) Cause Nephronophthisis with Liver Fibrosis. *E. Otto[1], K. Tory[2], M. Attanasio[1], Y. Paruchuri[1], E. Wise[1], B. Utsch[1], M. Wolf[1], C. Becker[3], G. Nuernberg[3], P. Nuernberg[3], A. Nayir[4], S. Saunier[2], C. Antignac[2], F. Hildebrandt[1]* 1) Dept Ped, Univ Michigan, Ann Arbor, MI; 2) Inserm, U574, Univ Paris Descartes, Paris, France; 3) Center for Genomics, Univ Cologne, Germany; 4) Dept Ped Nephrology, Univ Istanbul, Turkey.

Nephronophthisis (NPHP), a rare recessive cystic kidney disease, is the most frequent genetic cause of chronic renal failure in children and young adults. Mutations in 9 genes (*NPHP1-9*) have been identified, accounting for approximately 30% of all cases. NPHP can be associated with retinal degeneration (Senior-Loken syndrome), brainstem and cerebellar anomalies (Joubert syndrome), or liver fibrosis. Its molecular basis relates to functional defects of primary cilia. To identify a causative gene for the subset of patients with NPHP and associated liver fibrosis, we performed a genome-wide linkage search in a family with 5^{th} degree consanguinity and 3 affected children using homozygosity mapping and 50K Affimetrix SNP microarrays. We obtained a significant maximum parametric lod score of Z_{max} =3.72 on chromosome 8q22 and identified a homozygous missense mutation in the gene *MKS3/TMEM67*. When examining a world wide cohort of 62 independent patients with NPHP and associated liver fibrosis we identified altogether 4 novel mutations (p.W290L, p.C615R, p.G821S, and p.G821R) in 5 of them. Mutations of *MKS3/TMEM67*, found recently in Meckel-Gruber syndrome (MKS) type 3 are in 71% truncating mutations. In contrast, the mutations detected here in patients with NPHP and associated liver fibrosis were exclusively missense mutations. This suggests that they may represent hypomorphic alleles, leading to a milder phenotype compared with the more severe MKS phenotype. Additionally, mutation analysis for *MKS3/TMEM67* in 120 patients with Joubert syndrome (JBTS) with associated kidney disease yielded 7 different (6 novel) mutations in 5 patients, 4 of which presented with congenital liver fibrosis. In 105 patients with NPHP without liver or brain involvement no mutations were found. We conclude that hypomorphic MKS3 mutations can cause NPHP (type 11) with liver fibrosis. Thus, NPHP11, MKS3 and JBTS6 are allelic disorders.

The effects of functional DNA elements in cognition-related genes on delay discounting and adolescent cigarette smoking behaviors. *P. J. Weaver[1], T. R. Simmons[1], T. Andrews-Bryant[1], B. Reynolds[2, 3], C. W. Bartlett[1, 3]* 1) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Center for Biobehavioral Health, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 3) Department of Pediatrics, College of Medicine, The Ohio State University, Columbus, OH.

Given that most adult smokers begin smoking during adolescence, understanding smoking behaviors among adolescents is crucial to the development of strong public health policies. Approximately 4,000 adolescents between the ages of 12 and 17 initiate cigarette smoking every day, and of those an estimated 1,140 become daily smokers. Identification of genetic factors related to smoking has significant implications, though genetic variants directly associated with smoking are limited. Using alternative, smoking-related phenotypes such as impulsivity, the present study examines the relationship between these phenotypes through a unique cognitive panel titled CP1. Adolescents who were designated as smokers, non-smokers, or as having tried smoking were rated for impulsivity using measures of delay discounting. DNA was then collected and analyzed using CP1, which is comprised of 29 SNPs, all of which have shown evidence of regulatory effects on gene expression in genes associated with cognition. This panel utilizes 29 DNA primer sets in a single PCR, which is then followed by a ligase detection reaction (LDR). The LDR is performed on the amplicons to interrogate the specific alleles; each coupled to a single fluorescently dyed microsphere. Finally, we use the Luminex 200 to visualize all members of the panel and quantify the signal intensity of each individual allele. To validate the CP1 SNPs, we genotyped a series of 4 extended pedigrees from the anonymous, publicly available CEPH collection. This comparison allowed for error checking (via missegregation of alleles in the pedigrees) as a measure of which assays could be successfully multiplexed together. The goal of this study then, is to identify the main effects of these SNPs, thereby studying the genetic relationship with delay discounting and smoking related behaviors.

Additional high-risk melanoma susceptibility genes. *A. M. Goldstein, Melanoma Genetics Consortium (GenoMEL)*
Genetic Epidemiology Br, DCEG, National Cancer Inst, NIH, DHHS, Bethesda, MD.

CDKN2A/ARF and CDK4 are the high-risk melanoma susceptibility genes identified to date. CDKN2A/ARF encodes two distinct proteins translated, in alternate reading frames (ARF), from alternatively spliced transcripts. Although several recent linkage analyses and candidate gene searches have been conducted, no additional high-risk melanoma susceptibility genes have yet been identified. Using data from GenoMEL, we illustrate why finding additional high-risk melanoma susceptibility genes has been so challenging. GenoMEL created the largest familial melanoma data set yet assembled; it included 466 families with 3 melanoma patients from 17 GenoMEL centers from Europe, Australia, the Middle East, and North America. Germline CDKN2A mutations were detected in 38% of families. Mutations in CDK4 and ARF were much rarer and occurred at similar frequencies, 2-3%. No obvious melanoma or pigmentation-related clinical characteristics distinguished families with CDKN2A mutations from those with CDK4 or ARF mutations. The number of melanoma patients in a family was also strongly and directly associated with mutation detection and showed substantial variation by continent. Using the observed distribution of CDKN2A, CDK4, and ARF mutations by continent and number of melanoma patients per family (3, 4-5, 6), we estimated the number of additional high-risk melanoma susceptibility genes that would be expected in this study sample. Assuming additional high-risk susceptibility genes showed distributions similar to CDK4 and ARF we would expect about seven rare high-risk melanoma susceptibility genes to be detected in about 40 of the 276 mutation negative families. In contrast, a high-risk melanoma susceptibility gene similar to CDKN2A would result in approximately 89 mutation positive families. The results suggest that if additional high-risk melanoma susceptibility genes are similar to CDK4 and ARF, both in frequency and distribution of melanoma patients, traditional methods such as linkage analysis may be very challenging for finding these genes and other detection approaches will be needed.

Copy Number Analysis in Patients with Congenital Heart Disease and Multiple Congenital Anomalies. *P. Paluru[1], J. Garbarini[1], X. Gai[2], J. Glessner[3], J. Biegel[4], H. Hakonarson[3], P. S. White[2,5], T. Shaikh[4], E. Goldmuntz[1]* 1) Division of Cardiology, Children's Hosp Philadelphia, Philadelphia, PA; 2) Center for Bioinformatics, Children's Hosp Philadelphia, Philadelphia, PA; 3) Center for Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 4) Division of Human Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 5) Division of Oncology, Children's Hosp Philadelphia, Philadelphia, PA.

Congenital heart defects (CHD) are among the most common birth defects and are the leading cause of birth defect-related deaths. About 25% of CHD occur in conjunction with other congenital defects and are often part of a specific malformation pattern or genetic syndrome. Large chromosomal alterations, submicroscopic deletions and single gene defects have been identified in a subset of genetic syndromes characterized in part by CHD. We hypothesized that subjects with CHD and additional dysmorphic features or congenital anomalies would be a likely cohort to harbor previously undetected copy number alterations (CNAs). We evaluated 58 subjects with a range of CHD and other dysmorphia and/or congenital anomalies, who did not have a recognized genetic syndrome or chromosomal abnormality. The cohort included patients with left sided lesions (n=16), conotruncal defects (n=20), septal defects (n=18), and other abnormalities (n=4). Subjects were assessed for CNAs using Affymetrix 100k SNP array technology and analytical approaches. We identified 13 unique CNAs including 9 deletions and 4 duplications, that were not present in the Database of Genomic Variants or in over 2,000 control subjects genotyped at our institution. Each of the 13 CNAs were confirmed by alternative methods. The CNAs range from 0.05-9.6Mb in size and are predicted to contain either single or many genes with variable functions. Eight of the CNAs were confirmed to be inherited; some represent unique regions of relative copy number gain or loss. These data may identify new disease loci and/or candidate genes that warrant further evaluation in similarly syndromic and non-syndromic cardiac cohorts. We present the first study of CNAs to focus specifically on subjects with congenital heart disease.

Revisiting sum statistics for detecting epistasis in genome-wide association studies. *C. Greene, J. Moore*
Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Picking a group of SNPs that predict an individual's disease risk is a crucial step in genome-wide association studies (GWAS). However, this is not a trivial exercise when the SNPs in question are involved in nonlinear interactions. Sum statistic methods have been explored in conjunction with chi-square statistics to find a set of SNPs significantly associated with the clinical endpoint being studied. This is a promising approach because it considers sets of SNPs rather than individual SNPs. However, sums of chi-square statistics may fail to identify certain types of gene-gene interactions. Here we introduce a novel combination of sum statistics and ReliefF as a method for picking a significant set of SNPs from a GWAS. The Relief algorithm was developed in 1992 as a machine learning algorithm that uses a nearest neighbor approach to assign weights to independent variables in a dataset that reflect their importance with respect to a dependent variable. We have previously introduced the novel Tuned ReliefF (TuRF) algorithm and have shown that it can efficiently assign weights to SNPs in GWAS that reflect their role in epistatic interactions. Our goal was to compare the power of sum statistics using chi-square values with sum statistics using TuRF scores for detecting interacting SNPs in a GWAS. To accomplish this goal we designed a simulated GWAS with cases and controls simulated using a wide variety of different epistasis models with heritabilities ranging from 0.025 to 0.4 and sample sizes ranging from 400 to 3200. We show that sum statistics that use TuRF scores significantly outperform sum statistics using chi-square values across a wide range of different epistasis models ($P<0.05$). These results support the idea that sum statistics will be useful for detecting epistasis in GWAS when a powerful measure of SNP quality such as ReliefF is used.

Failure to replicate a genetic association may provide important clues about genetic architecture. *N. Penrod, C. Greene, J. Moore* Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Replication has become the gold standard for assessing statistical results from genome-wide association studies. Unfortunately, a real result can fail to replicate for a number of reasons including inadequate sample size or variability in phenotype definitions across independent samples. We hypothesize that some statistically significant independent genetic effects may fail to replicate in a second dataset when the underlying genetic architecture is complex and the functional polymorphism interacts with one or more other functional polymorphisms. This hypothesis is based on the idea that a functional polymorphism with an interaction effect may fail to replicate a significant independent effect due to allele frequency differences between the detection sample and the replication sample. To test this hypothesis we designed a simulation study in which case-control status is determined by two interacting polymorphisms with heritabilities ranging from 0.025 to 0.4 and replication sample sizes ranging from 400 to 1600. Our results across this wide range of epistasis models with differing heritabilities and sample sizes show that the power to replicate a statistically significant independent effect of a polymorphism can drop from 1.0 to 0.05 with a change of allele frequency of less than 0.1 for the interacting partner. These results support our hypothesis and suggest that failure to replicate an independent genetic effect may provide some clues about an underlying genetic architecture that may include gene-gene interactions or epistasis. We recommend that polymorphisms that fail to replicate be checked for interactions with other polymorphisms, especially when there are allele frequency differences between the detection and replication samples for multiple polymorphisms.

Pericentrin molecular analysis in 21 Seckel/MOPDII patients. *M. Willems[1], D. Geneviève[1], G. Borck[1], G. Baujat[1], M. Gérard[2], D. Héron[3], B. Leheup[4], M. Le Merrer[1], A. Verloes[2], L. Colleaux[1], A. Munnich[1], V. Cormier-Daire[1]* 1) Dept of Genetics, INSERM U 781, Hôpital Necker, Paris, France; 2) Dept of Genetics, Hôpital Robert Debré, Paris, France; 3) Dept of Genetics, Hôpital de la Pitié-Salpêtrière, Paris, France; 4) Dept of Genetics, CHU Nancy, Hôpitaux de Brabois, Nancy, France.

Among the primordial dwarfisms, microcephalic osteodysplastic primordial dwarfism type II (MOPD II, MIM 210720) and Seckel syndrome (SCKL, MIM 210600), are both characterized by intrauterine growth retardation, severe proportionate short stature and microcephaly. MOPDII is distinct from SCKL by more severe growth retardation, radiological abnormalities and milder mental retardation. SCKL is associated with defective ATR-dependent DNA damage signalling, but only a single hypomorphic mutation of ATR (Sckl1, 3q22.1-q24) has been yet identified in this genetically heterogeneous condition. In 2008, mutations in the gene encoding pericentrin (PCNT) have been identified in 28 patients, including 3 SCKL (Griffith et al, Nat Genet) and 25 MOPDII (Rauch et al, Science). This gene encodes a centrosomal protein, with key functions, anchoring both structural and regulatory proteins. We performed the direct sequencing of PCNT in 21 cases, including 15 consanguineous families (12 SCKL and 3 MOPDII) and 6 sporadic cases (4 SCKL and 2 MOPD II). We identified nine distinct mutations in 4/16 SCKL and 5/5 MOPDII, namely four stop mutation in exons 11, 15, 28 and 34, three frameshift mutations in exons 16, 30 and 30, one splice site mutation in intron 18, and one missense mutation in exon 19 (c.3840G>C, p.Q1280H). This mutation was absent in 200 controls and was presumably associated with an abnormal splicing resulting in pericentrin loss-of-function. The clinical analysis of the 4 SCKL cases with PCNT mutations showed that they finally all presented minor skeletal changes and a severe growth retardation more suggestive of MOPDII. We therefore conclude that, despite variable clinical severity, MOPDII is a genetically homogeneous condition due to loss-of function of pericentrin.

Multifactor Dimensionality Reduction 2.0: Open Source Software for Genome-Wide Analysis of Epistasis. *P. Andrews, J. Moore* Computational Genetics Laboratory, Department of Genetics, Dartmouth College, Lebanon, NH.

Multifactor dimensionality reduction (MDR) was designed as a nonparametric and genetic model-free approach to identifying, characterizing and interpreting gene-gene interactions in genetic and epidemiologic studies of common human diseases. The kernel of the MDR algorithm uses constructive induction to combine two or more polymorphisms into a single predictor that captures interaction effects. This general approach has been validated in numerous simulation studies and has been applied to a wide-range of different human diseases including asthma and allergy, autoimmune diseases, cancer, cardiovascular diseases, diabetes and metabolic syndrome, Mendelian diseases, pharmacogenetics and psychiatric diseases, for example. We describe here version 2.0 of the open-source MDR software package that has been made freely available to the genetic epidemiology and bioinformatics communities since February of 2005. This new version includes an estimation of distribution algorithm (EDA) for carrying out a stochastic search for the optimal combination of interacting polymorphisms. The new EDA algorithm provides an alternative to exhaustive search that may not be computationally feasible when the number of polymorphisms is large as in a genome-wide association study (GWAS). The key feature of this new algorithm is the ability to use expert knowledge in the form of prior statistical evidence (e.g. LOD scores, ReliefF) or biological evidence (e.g. chromosomal location, KEGG pathway, Gene Ontology) to probabilistically select polymorphisms for consideration in an MDR model. Previous studies have shown that detecting interactions in the absence of statistically significant independent effects in GWAS is not computationally feasible without expert knowledge. We anticipate this new version of MDR will open the door to the routine modeling of nonlinear interactions when the number of measured polymorphisms is large.

The Database of Genomic Variants (DGV) - Annotating structural variation in the human genome. *L. Feuk[1, 2], B. Thiruvahindrapduram[1, 2], J. R. Macdonald[1, 2], J. Zhang[1, 2], S. W. Scherer[1, 2]* 1) Program in Genetics & Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada.

The Database of Genomic Variants (DGV) is a comprehensive and curated catalogue of structural variation in the human genome (http://projects.tcag.ca/variation/). DGV facilitates the interpretation of structural variation data in relation to previously published work. The content is focused on variants described in control samples, thus providing a valuable resource for both clinical and research labs producing structural variation data using array or next-generation sequencing approaches. The current content of the database is based on results from 48 peer reviewed research articles, representing a total of 25,383 variants. These structural variation entries are composed of 15,466 copy number variants (CNVs; defined as gains and losses of DNA segments over 1kb in size), 9,735 InDels (insertions and deletions of 100bp-1kb in size) and 182 inversions. Merging of overlapping CNVs results in a dataset contains 5,083 non-redundant CNV regions. The data are represented in table format, genome browser format, and text files available for download. The genome browser, which is based on the widely used GMOD software (GBrowse), is ideal for viewing structural variation in relation to other genomic features, such as genes, clones and segmental duplications. The database has been designed to be easily navigated and suitable for all users, independent of bioinformatics experience. The data in DGV has been produced with different technologies and analysis methods, which creates challenges with presentation and comparison between datasets. Current work in progress includes separating BAC array data from higher resolution platforms, a new track of known deletion/duplication syndromes to facilitate interpretation, and adding a new section to the database with CNV information for the mouse genome. Here we present an overview of DGV along with future plans for its expanded content and improved presentation.

Genome-wide association scan for the five major dimensions of personality. *A. Terracciano[1], S. Sanna[2], M. Uda[2], B. Deiana[2], EP. Slagboom[4], DI. Boomsma[5], S. Villafuerte[6], M. Burmeister[6], AC. Janssens[7], CM. van Duijn[7], WM. Chen[3], D. Schlessinger[1], GR. Abecasis[3], PTJr. Costa[1]* 1) National Institute on Aging, NIH, Baltimore, MD; 2) Istituto di Neurogenetica e Neurofarmacologia, CNR, Cagliari, Italy; 3) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI; 4) Leiden University Medical Centre, Molecular Epidemiology Section, Leiden, The Netherlands; 5) Department of Biological Psychology, VU university, Amsterdam, The Netherlands; 6) Molecular & Behavioral Neuroscience Institute, Department of Psychiatry and Human Genetics, University of Michigan, Ann Arbor, MI; 7) Erasmus University Medical Center Rotterdam, The Netherlands.

Personality traits are summarized by five broad dimensions with pervasive influences on major life outcomes, strong links to psychiatric disorders, and clear heritable components. To identify genetic variants associated with each of the five major dimensions of personality we performed a genome wide association (GWA) scan of 3,972 individuals from a genetically isolated population within Sardinia. Based on analyses of 362,129 single nucleotide polymorphisms (SNPs) we found several strong signals within or near genes previously implicated in psychiatric disorders. They include the association of Neuroticism with SNAP25 (P = 5 X 10-5), Extraversion with BDNF and two cadherin genes (CDH13 and CDH23; Ps 5 X 10-5), Openness with CNTNAP2 (P = 3 X 10-5), Agreeableness with CLOCK (P = 9 X 10-6), and Conscientiousness with DYRK1A (P = 3 X 10-5). Effect sizes were small (less than 1% of variance explained), and most failed to replicate in the follow-up independent samples (N up to 3903), though the association between Agreeableness and CLOCK was supported in two of three replication samples (overall P = 2 X 10-5). We infer that a large number of loci may influence personality traits and disorders, requiring larger sample sizes for the GWA approach to identify significant genetic variants.

Simultaneous scan of genome-wide association data allowing for epistasis prioritizes multiple interacting loci in type 2 diabetes. *J. T. Bell[1,2], N. J. Timpson[1,3], N. W. Rayner[1], A. P. Morris[1], E. Zeggini[1], M. I. McCarthy[1], UK Type 2 Diabetes Consortium* 1) Univ Oxford, UK; 2) Univ Chicago, USA; 3) MRC CAiTE, UK.

Large-scale genome-wide association (GWA) data allow for systematic scans including epistasis, but at present such analyses are computationally and methodologically challenging. We undertook interaction analyses within data from the Wellcome Trust Case Control Consortium (WTCCC) GWA scan containing 1924 type 2 diabetes (T2D) cases and 2938 controls, with the aim of prioritizing pairs of markers for follow-up study. We performed a two-dimensional genome-wide scan using a joint two-locus test of association including main and epistatic effects in a subset of 70,236 markers tagging common SNP variation at $r^2>0.2$ and MAF0.05. The markers were derived from the tagging of 393,242 genotyped SNPs from the WTCCC Affymetrix chip data which passed stringent quality control. We examined 2.34×10^9 comparisons involving pairs of inter-chromosomal SNPs, and found that 79 pairs showed evidence for two-locus association at a Bonferroni-corrected P-value 0.05 (uncorrected P-value 2.14×10^{-11}). All of the 79 pairs involved loci that showed evidence for joint effects on T2D in cooperation with *TCF7L2*, which has strong single-locus effects. The pair-wise results included confirmed variants in *FTO* and *CDKAL1*, which exhibited significant main-effects and no evidence for epistasis with *TCF7L2*. However, the majority (>85%) of the 79 tag-SNPs did not have compelling single-locus evidence for association (P-value 1×10^{-4}). Epistatic analyses revealed 5 pairs of SNPs with significant additive-by-additive epistasis both in the case/control analyses and in analyses restricted to the T2D cases alone. The 5 loci included tag-SNPs located near *SLC9A9* (rs17635531), and regions on chromosomes 4 (rs1450140), 6 (rs1122637; rs1935683) and 11 (rs12803308). Our findings allow us to prioritize pairs of regions for follow up study in the extended data set. These analyses reveal that systematic genome-wide scans including epistasis are computationally feasible in GWA data, but the appropriate correction for multiple testing will affect the power to detect interactions and requires further study.

Extensions of Conditional Likelihood Bias Adjustment for Disease Association Risk Estimates in Whole-Genome Scans. *F. Zou, A. Ghosh, F. A. Wright* Department of Biostatistics, University of North Carolina, Chapel Hill, NC.

It is widely recognized that genome-wide association studies suffer from inflation of the risk estimates for genetic variants (usually SNPs) identified as significant in the genome scan, a so called "winner's curse". To handle such significance bias, we have developed an approximate conditional likelihood approach that can be applied using odds ratio estimates provided by standard statistical software. We have also developed a principled method to construct confidence intervals for the genetic effect that acknowledges the conditioning on statistical significance. We discuss extensions to the situation where risk estimation is performed for multiple correlated phenotypes in the genome scan. Our approach is widely applicable, is far easier to implement than competing approaches. The results have considerable importance for the proper design of follow-up studies and risk characterization.

Combined Intracerebroventricular/Intraperitoneal Enzyme Replacement Therapy Improves Survival and Reduces Brain Psychosine in a Mouse Model of Krabbe Disease. *L. Sturk[1], W. C. Lee[2], J. Pan[1], A. Herdt[2], G. S. Robinson[1], M. Concino[1], M. Heartlein[1], A. O. Tzianabos[1], C. B. Eckman[2]* 1) Shire Human Genetic Therapies, Cambridge, MA; 2) Department of Neuroscience, Mayo Clinic College of Medicine, Jacksonville, FL.

Globoid cell Leukodystrophy (GLD) or Krabbe disease is an autosomal recessive lysosomal storage disorder that occurs at an incidence of 1:100,000 births. A progressive peripheral (PNS) and central nervous system (CNS) disorder, GLD is the result of genetic mutations causing a deficiency in the enzyme galactocerebrosidase (GALC). We have used the twitcher mouse model to examine the effects of enzyme replacement therapy (ERT) on key endpoints including survival, psychosine levels, and sciatic nerve myelination status. Initial studies suggest that weekly intraperitoneal (i.p.) delivery of murine GALC (mGALC) extends survival and improves myelination of the sciatic nerve. A single intracerebroventricular (ICV) direct injection improved survival (51 1.6 days) compared to vehicle-treated animals (36 0.4 days) in a dose-responsive manner (40 g ICV = 42 1.7 days; 120 g ICV = 49 1.3 days). Brain psychosine levels were reduced following a single ICV injection at both low (39% reduction) and high (63% reduction) dose levels, to a greater degree than observed after i.p. administration. However, the sciatic nerve myelination was unimproved in ICV-treated mice as the vast majority of enzyme may be trapped within brain tissue after ICV administration. Twitcher mice treated with weekly i.p. mGALC combined with a single ICV injection at post-natal day (PND) 20 lived significantly longer (51 1.6 days) with normalized sciatic nerve myelination and dramatically reduced brain psychosine levels. Data from these studies suggest that optimal efficacy in the twitcher mouse model of Krabbe disease may require therapy that targets the PNS and CNS.

BiDil: Media Repersentations of an Emerging "Pharmacogenomic" Medication. *S. Harry* Health Law Inst, Edmonton, AB, Canada.

The print media occupies a pivotal role in informing the lay public of advances in medical treatments. Indeed, studies have shown the type of information disseminated or withheld by medical reporters, influences the attitudes of laypersons toward emerging pharmacogenetic technologies. As such we were particularly intrigued by the medias treatment of BiDil, a combination heart failure medication patented and characterized as the first race-based drug specifically for African Americans. The A-HeFT clinical trials on which the drug gained Food and Drug Administration (FDA) approval have been a source of controversy in the scientific community. The debate played out in a number of scientific journals between supporters of the drug who hail it as the first step towards decreasing health disparities experienced by African Americans as well as the first step towards pharmacogenomic medicine. Critics, meanwhile vocally oppose the drug, calling into question the methodology of the clinical trials, and interpretation of the results. In this charged situation, it is essential to understand the position of the print media and how they portrayed the BiDil story thereby shaping the perceptions of the potential consumers of this medication. This study examines popular representations of BiDil in major North America newspapers, using a coding frame successfully implemented in other media studies. The results indicate the media representation of BiDil was more complex than we first suspected. In some respects it supported the findings of previous studies on pharmaceuticals in the media in that the majority of articles emphasized the benefits of the drug while virtually excluding information on the side effects and contra-indications. Further, there was more emphasis on the strengths of the clinical trials than weaknesses. However, in other respects, the articles diverged from our expectations by portraying BiDil in a critical light by placing heavy emphasis on the potential problems with race-based pharmaceuticals such as the potential for racism. :.

Delineation of the breakpoints of pure duplication 3q due to a de novo duplication event using SOMA. *O. Nahum[1], B. Levy[1], A. Shanske[2]* 1) Department of Pathology, Columbia University. New York, NY; 2) Center for Craniofacial Disorders, Children's Hosp at Montefiore, Albert Einstein Coll of Med, Bronx, NY.

Partial duplication of distal 3q is a well-described condition of multiple congenital anomalies that resemble the Cornelia de Lange syndrome (CDLS). Most cases of dup(3q) syndrome result from an unbalanced translocation or inversion. Pure duplication of 3q is very rare and only a handful of cases have been reported. EC was a FT 3160g baby born to a 26 yr old primip by NSVD. He remained in the NICU for 10 days because of feeding difficulties. He was admitted to our hospital at 5 wks because of apnea and bradycardia. His physical examination at 4½ months revealed a stigmatized youngster. His weight was 5.42 kg, length 58.5 cm and HC 39 cm all below the 2%. He had bushy eyebrows, long eyelashes, synophrys and a nevus flammeus of the forehead. The pinna were crumpled, the nasal bridge was depressed, the philtrum long and the jaw micrognathic. He had bilateral syndactyly of toes 2 and 3 and a remnant of a right-handed post-axial polydactyly and bilateral 5th digit clinobrachydactyly. His psychomotor development was severely delayed and he was hypotonic. A sleep study revealed central apnea. A CT scan revealed craniosynostosis, absence of the corpus callosum & decreased white matter. Cytogenetic analysis revealed 46, XY .ish dup(3)(q21q29)(wcp3+,D3S4560+). Additional SOMA studies using the Affymetrix GenomeWide Human SNP Array 6.0 indicated the duplication to be 61.07 Mb with proximal and distal breakpoints at 3q22.2 & 3q29 respectively. The etiology of CDLS is heterogenous and about half the cases are due to mutations in the NIPBL gene on 5p13. Other causes include mutation in the X-linked SMC1L1 gene and mutation in the SMC3 gene on 10q25. The significant phenotypic overlap of CDLS with the duplication 3q syndrome indicates that an additional gene causing CDLS is located on distal 3q and recent studies have narrowed the region to 3q26.3. Our case confirms the association of duplication 3q with the CDLS and the precise delineation of the duplicated region by SOMA will help us to identify genes that contribute to the clinical features observed in the CDLS and the dup 3q syndrome.

Interaction between hemochromatosis and transferrin receptor genes with breast cancer in Sao Miguel population (Azores, Portugal). *P. R. Pacheco[1,2], M. J. Brilhante[1], T. Eloi[3], C. C. Branco[1,2], R. Cabral[1,2], V. Santos[3], V. Carneiro[4], L. Mota-Vieira[1,2]* 1) Molec Genetics, Pathol Unit, Hosp Divino Espirito Santo EPE, Azores, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Chirurgic Department, Hosp Divino Espirito Santo EPE, Azores, Portugal; 4) Anatomic Pathology Department, Hosp Divino Espirito Santo EPE, Azores, Portugal.

Two different *HFE* mutations (C282Y and H63D) have been found to increase cellular iron uptake and, due to the pro-oxidant properties of iron, altered iron metabolism in hemochromatosis patients might be a potential risk for breast cancer (BC). Some studies concluded that BC risk increase is also dependent on *HFE*-interacting genes, such as the transferrin receptor (*TFR*) and the combination between *HFE-TFR* genotypes. To assess if *HFE* mutations, *TFR*-S142G polymorphism and *HFE-TFR* genotypes are related to BC risk, we compared C282Y, H63D and S142G frequencies in 86 BC women and in 183 gender/age matched healthy controls. Samples were obtained after written informed consent. The C282Y allele frequency in the BC group was 4.07%, higher than in control group, 3.28%; while H63D mutation showed a similar frequency in BC, 21.51%, and controls, 21.04%. Although both groups were stratified according to menopausal status, odds ratio (OR) analysis for cancer risk associated with *HFE* mutations was not statistically significant. Regarding S142G polymorphism, the frequency of S142S, S142G and G142G genotypes were equivalent in both groups. In order to extend the search for a supposed BC susceptibility for *HFE-TFR* genotypes, we analysed BC and controls according to compound genotypes. Again, OR for all *HFE-TFR* genotype combinations revealed no increased risk for BC. In conclusion, the results suggest that *HFE* mutations are not associated with an increased risk for BC. *TFR* polymorphism was not an independent risk factor and did not modify the disease risk. Furthermore, variants of the *HFE-TFR* have, apparently, no direct effect on the incidence of breast cancer in the Azorean female population. (paularpacheco@hdes.pt). Azorean Government funded.

Analysis of DNA methylation in human placentae using the Illumina GoldenGate Methylation Panel I. *W. P. Robinson, L. Avila, M. Peñaherrera, P. von Dadelszen, M. S. Kobor* Univ British Columbia, Vancouver, BC, Canada.

Repetitive elements and X-linked gene promoters have been reported to have less DNA methylation in human placenta as compared to embryonic tissues, and instability of epigenetic programming has been suggested to contribute to placental insufficiency. However, patterns of DNA methylation have not been well-studied in an unbiased and genome-wide fashion. To investigate this, the Illumina GoldenGate Methylation Cancer Panel I (1,505 CpG loci from 807 genes) was used to interogate DNA extracted from placental villi (N=20) and whole blood (N=7). The distribution of beta values (% methylation) was similar, with the majority (59% in blood, 53% in placenta) of CpG-island associated CpGs (N=1044) being hypomethylated (beta value <10%), while most non-island associated CpGs (N=461) were highly methylated (beta value>75%) in both tissues. While no difference was observed in sample methylation averaged across all non-CpG island sites, placental samples had a higher mean methylation for CpG sites located in islands (22.2% vs. 17.7% in blood, P<0.0001). Variability was greater in the placenta, with a mean sd across autosomal sites of 0.079 compared to 0.052 for blood. Hierarchechal clustering showed that the epigenetic profile of placenta was distinct from blood: intra-placental correlations (based on 5 placentae with 2 villous samples each) ranged from 0.94-0.98, inter-placental sample correlations ranged from 0.91-0.96 but the average blood-placenta correlation was only 0.71. A number of sites showed completely discordant (hyper/hypo) patterns of methylation in placenta compared to blood. DNA methylation profiles from placentas associated with IUGR (N=10), preeclampsia (N=14), and CPM16 (N=6) were also analyzed with multiple significant differences compared to controls identified. These findings are being confirmed and extended using a locus specific approach (pyrosequencing). Identification of epigenetic differences between complicated and uncomplicated pregnancies are providing insight into the underlying placental abnormalities and may provide tools for non-invasive prenatal screens for the future.

New tool (mtPHYL) proposed for phylogenetic analysis of human complete mitochondrial genomes. *N. Eltsov, N. Volodko, E. Starikovskaya, R. Sukernik* Laboratory of Human Molecular Genetics, Institute of Cytology and Genetics SB RAS, Novosibirsk, Russian Federation.

The mitochondrial genome is widely used system to study evolutionary history of our species. With the advent of human population genomics (Hedges, 2000, Nature 408:652-653) and rapid accumulation of complete mtDNA sequences available through GenBank, it has become important to expedite the estimation process of increasingly accumulating mtDNA data sets. The central idea behind maximum parsimony is to fit character data to a semi-labeled tree so as to minimize the number of reverse and convergent transitions. The computational effort of standard methods grows exponentially so they are practically inapplicable with large data sets. To solve this problem we have elaborated a novel multistage algorithm. Preliminary analysis reduces an amount of the enumerations and, hence, allowing to reconstruct phylogenetic tree of large datasets at a minimum time-period. The algorithm which we created was implemented in the mtPHYL. This program reconstructs the phylogenetic trees and calculates the respective ages for the clusters within the tree. It can be used to glean a bulk of entire mitochondrial sequences from GenBank database instantly. In addition, it automatically categorizes the mutations and identifies affected genes along with their conservation indices and amino acid replacements. Our software may be easily modified to analyze any non-recombining DNA regions. mtPHYL is available from authors upon request (eltsovnp@bionet.nsc.ru) and at www.bionet.nsc.ru/labs/mtgenome/programs.html.

A *de novo* constitutive, balanced t(3;14) translocation in a patient with primary pulmonary lymphangiectasia. *D. N. Finegold[1,2], A. Smith[2], M. Sathanoori[1,2], M. C. Seleme[1,2], S. Li[2], U. Surti[1,2], M. Kimak[1], S. Bertera[1,2], R. E. Ferrell[1], R. D. Nicholls[1,2]* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of Pittsburgh Medical Center, Pittsburgh, PA.

Primary pulmonary lymphangiectasia (PPL) is a rare disorder of infancy and childhood caused by an abnormal dilatation of the lymphatics of the lung. The cause of PPL is unknown. A child came to our attention that failed to initiate breathing at birth, was resuscitated, and was subsequently diagnosed with PPL without other anomalies. A karyotype revealed a balanced translocation 46,XY,t(3;14)(q27;q11.2), not present in either parent. We developed a novel methodology termed hybrid SNPing to resolve the breakpoints, by applying high density single nucleotide polymorphism (SNP) genotyping to human-mouse somatic cell hybrids retaining each translocation chromosome. Hybrid SNPing takes advantage of the differential hybridization and detection of human and mouse DNA to the SNP probes on the chip. The human SNPs on both recombinant chromosomes are identified within close proximity to the breakpoint while the rodent DNA typically results in no calls. This technique allowed us to rapidly resolve the breakpoints to within 4-5 kb and then easily fully identify the sequence across both breakpoints with PCR and DNA sequence analysis. Although the t(3;14) translocation did not directly interrupt any gene, the breakpoints localize to conserved non-coding sequences between *SALL2* (a putative oncogene) and *METTL3* in chromosome 14q11.2 and 5 of *BCL6* (a known oncogene in diffuse large B-cell lymphoma) in 3q27.3. Balanced translocations within intron 1 of *BCL6* and 5 of the gene are described as causal major and alternative breakpoints, respectively, in B-cell lymphoma. SNP genotype analysis, FISH, and quantitative dosage genomic PCR also identified genome-wide copy number variation (CNV) in this patient with duplication CNV in chromosome 9p24.1 and 16p11.2, and deletion CNV in 1q31.3. These CNV may be incidental or contribute to the PPL phenotype of this patient. Due to the *de novo* origin of the translocation, we suggest that genes flanking one or both breakpoints may be deregulated and potentially causal in PPL.

Integrated Analysis of Genetic and Proteomic Data Identifies Biomarkers Associated with Adverse Events Following Smallpox Vaccination. *D. Reif[1], A. Motsinger-Reif[2], B. McKinney[3], M. Rock[4], J. Crowe[4], J. Moore[5]* 1) Environmental Protection Agency, NC; 2) North Carolina State University, NC; 3) University of Alabama Birmingham, AL; 4) Vanderbilt University, Nashville, TN; 5) Dartmouth College, NH.

Complex clinical outcomes, such as adverse reaction to vaccination, arise from the concerted interactions among the myriad components of a biological system. Therefore, comprehensive etiological models can be developed only through the integrated study of multiple types of experimental data. In this study, we apply this paradigm to high-dimensional genetic and proteomic data collected to elucidate the mechanisms underlying development of adverse events (AEs) in patients following smallpox vaccination. Since vaccination was successful in all of the patients under study, the AE outcomes reported likely represent the result of interactions among immune system components that result in excessive or prolonged immune stimulation. In the current study, we examined 1442 genetic variables (SNPs) and 108 proteomic variables (serum cytokine concentrations) to model AE risk. To accomplish this daunting analytical task, we employed the Random Forests (RF) method to filter out the most important attributes, then we used the selected attributes to build a final decision tree model. Importantly, RF is a natural approach for studying the type of gene-gene, gene-protein, and protein-protein interactions we hypothesize to be involved in development of clinical AEs. Combining information from previous studies on AEs with the genetic and proteomic attributes identified by RF, we built a comprehensive model of AE development that includes the cytokines ICAM-1 (CD54), IL-10, and CSF-3 (G-CSF), and a genetic polymorphism in the cytokine gene IL4. The biological factors included in the model support our hypothesized mechanism for the development of AEs involving prolonged stimulation of inflammatory pathways and an imbalance of normal tissue damage repair pathways. This study enhances and reinforces our working model of AE development following smallpox vaccination.

Synapsis and recombination in a 69,XXX fetus: implications for normal female meiosis. *A. Kashevarova[1], T. Hansen[1], T. Hassold[1], T. Naluai-Cecchini[2], E. Cheng[2]* 1) School of Molecular Biosciences, Washington State Univ, Pullman, WA; 2) Dept of OB/GYN, Univ of Washington, Seattle, WA.

Triploidy is a common chromosome abnormality, accounting for nearly 10% of miscarriages. The extra haploid set makes it useful for studying the consequences of dosage imbalance on synapsis and recombination (events occurring in utero in females) but surprisingly, nothing is known of this process in human triploids. We recently examined meiosis in a 20 week 69,XXX fetus, using antibodies against synaptonemal complex (SC) proteins SYCP1 and SYCP3 and the cross-over associated protein MLH1, CREST antiserum and chromosome 8 and 21 FISH probes, to investigate genome wide and chromosome-specific patterns of synapsis and crossing-over. In analyses of over 200 cells, we identified oocytes at each sub-stage of meiotic prophase. Those that reached pachytene were clearly abnormal, as no cells exhibited 23 fully synapsed trivalents. Nevertheless, some cells were able to proceed through the pachytene checkpoint controls, as evidenced by the presence of diplotene images. Thus, unlike mammalian males, where synaptic errors trigger meiotic arrest, human females appear less responsive to checkpoints monitoring meiotic synapsis. In analyses of genome-wide recombination levels,we found a surprising increase in the triploid fetus: the mean number of MLH1 foci/cell was 109, 1.5 fold that of the normal female value of 75. This suggests that recombination levels respond in a dosage dependent manner to the availability of other meiotic reagents; e.g. to the level of SC proteins binding the three homologs. This was reinforced by analyses of individual chromosomes; e.g., chromosome 21. We identified cells with one of three chromosome 21 synaptic configurations - a bivalent and a univalent, a partially synapsed trivalent, or a completely synapsed trivalent. The first of these (bivalent/univalent) was associated with a normal level of MLH1 foci, while the latter two had significantly increased (1.5 fold) levels. Thus, the presence of even partial synapsis of all three chromosomes was associated with an increase in crossing-over, demonstrating a direct relationship between synapsis and recombination.

Electronic Medical Records Linked to DNA: A Valuable Resource for Large-Scale Genetic Association Studies.

D. Crawford[1,5], M. D. Ritchie[1,5], J. C. Denny[2], A. Havens[3], J. Weiner[3], J. M. Pulley[6], M. A. Basford[6], D. R. Masys[2], D. M. Roden[3,4,6], J. L. Haines[1,5] 1) Ctr Human Genetics Res, Vanderbilt Univ, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 3) Department of Medicine, Vanderbilt University, Nashville, TN; 4) Department of Pharmacology, Vanderbilt University, Nashville, TN; 5) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 6) Office of Personalized Medicine, Vanderbilt University, Nashville, TN.

Large scale DNA databanks linked to electronic medical records (EMR) have been proposed as an approach to generating large, diverse cohorts, given their potential for rapid sample collection and availability of richly detailed longitudinal data. However, it is unknown whether the phenotypes can be reliably extracted with adequate precision, and whether the associated DNA can be analyzed to establish associations. The Vanderbilt DNA Databank approaches these challenges by (1) using DNA collected from discarded blood in an opt-out model, (2) linking to a de-identified derivative of the EMR. The DNA Databank accrues ~700 new samples/week (38,103 as of 6/12/08). As an initial test of the methodology, we used natural language processing techniques and billing code queries on the first 10,000 records to extract European-American cases and controls for rheumatoid arthritis (RA; n=170 cases /701 controls), multiple sclerosis (MS; n=66/1857), Crohns disease (n=116/2643), and atrial fibrillation (AF; n=168/1695). 13 disease-associated, replicated SNPs were extracted from genome-wide association studies (GWAS) and tested for association in these samples. At least one associated SNP for each disease was replicated in our population [RA (rs6457617, $p<0.0001$, OR=1.95); MS (rs3135388, $p<0.0001$, OR=3.3); Crohns (rs17234657, $p<0.001$, OR=1.78; rs1000113, $p=0.028$, OR=1.63; rs17221417, $p=0.02$, OR=1.4); atrial fibrillation (rs2200733, $p=0.04$, OR=1.4)]. These data suggest that the DNA and the data extracted from an EMR system are of sufficient quality and validity for genomic research, providing support for such resources as invaluable for genotype-phenotype hypothesis generation and confirmation.

Association Studies of Positional Candidate Genes to Total Cholesterol Levels on Chromosome 5q31. *B. S. Sutton[1], S. G. Gregory[1], C. Haynes[1], D. R. Crosslin[1], S. C. Nelson[1], J. J. Connelly[1], K. Dehghanpisheh[1], S. G. Watson[1], D. Seo[3], J. M. Vance[3], C. J. H. Jones[4], D. C. Crossman[5], V. Mooser[6], C. B. Granger[2], P. J. Goldschmidt-Clermont[3], W. E. Kraus[2], E. R. Hauser[1], S. H. Shah[1,2]* 1) Center for Human Genomics, Duke University, Durham, NC; 2) Department of Medicine, Duke University, Durham, NC; 3) Miller School of Medicine, University of Miami, Miami, FL; 4) University of Wales, Cardiff, UK; 5) University of Sheffield, Sheffield, UK; 6) GlaxoSmithKline, Philadelphia, PA.

Coronary artery disease (CAD) and its associated phenotypes are widely accepted to be driven by environmental and genetic influences. We have previously shown linkage to total and low density lipoprotein (LDL)-cholesterol to chromosome 5q31 in early-onset CAD families (GENECARD). Fine-mapping was performed using 1409 SNPs covering a 50 Mb region (117 Mb to 167 Mb). Genotyping was performed on two CAD datasets including 272 GENECARD families (N=741) and 1975 case/control samples from an independent CAD cohort (CATHGEN). Lipoprotein measurement was performed on all individuals using NMR spectroscopy and used for quantitative trait analysis. Our trait of interest was very small LDL particle size (VSP) given its high correlation with LDL cholesterol. Human aortas (N=164) were used for association with atherosclerosis as determined by Sudan IV staining and raised lesion assessment. Logistic regression was used for case/control association and APL (Association in the Presence of Linkage) was used for family based association. Sixteen genes were significantly associated ($P<0.05$) with VSP in both GENECARD families and CATHGEN case/control datasets. Of these, 10 genes were also significantly associated ($P<0.05$) with CAD in GENECARD, CATHGEN, and with atherosclerosis in the aortas. Furthermore, four of these genes (TRPC7, CSS3, SPOCK and FSTL4) contained SNPs with evidence of linkage (highest LOD=2.0, 1.8, 1.9, and 1.7 respectively). Thus, based on the convergence of multiple datasets and independent statistical analyses, we have maximized the identification of true associations and are currently evaluating the genetic contributions of the identified genes.

The Duke Personal Variome Project: Analysis of Psychosocial Implications Associated with Whole-Genome Scans. *S. B. Haga, J. M. O'Daniel* Inst Genome Sci & Policy, Duke Univ, Durham, NC.

Whole-genome scans have moved from a solely research technology to a commercial laboratory service offered directly to consumers, revealing information about disease risks and genetic ancestry. However, the related psychosocial implications have not yet been studied. We conducted a pilot study, the Duke Personal Variome Project (PVP), to begin to explore the psychosocial and health behavioral impact associated with testing and disclosure of individual variomes (an assembled catalogue of genetic variations). One million SNPs were tested utilizing the Illumina Infinium whole-genome BeadChip array. SNPs highly associated with a disease were assessed for independence on the basis of linkage disequilibrium. This resulted in a list of variants significantly associated with 31 unique conditions for which individual reports were compiled for each participant. Fourteen subjects with advanced training in genetics were recruited; the median age was 41y and 71% have biological children. A stratified consent was used which required an initial consent to study participation prior to testing and a second consent prior to results disclosure. Participants could indicate their preference for non-disclosure of data associated with particular conditions (e.g., breast cancer) as well as indicate the level with which their data could be further analyzed and reported for study publications. To explore the expected and actual impact of testing, participants underwent semi-structured interviews at pre- and post-test and 3-months follow-up. In addition, they completed a brief survey at 1-week and 3-months post-disclosure. Personal curiosity was a primary motivation (93%) and expectations were guarded. Predictions for testing to reveal a personal disease risk ranged from 10 to 100% (median = 85%). Only 14% believed they would most likely change current health behaviors based on the data; 50% reported they may change behaviors and 36% reported they would not based on several factors. Participants will be followed up to one year post-disclosure. The PVP is one of the first studies to explore psychosocial and behavioral implications that may arise from whole-genome scans.

Characterization of BBS3 (ARL6) isoforms and identification of a distinct role in vision for BBS3 long in mouse and zebrafish. *P. R. Pretorius[1,7], L. M. Baye[2,7], R. F. Mullins[3,7], C. C. Searby[4,7], D. Y. Nishimura[4,7], K. Bugge[4,7], B. Yang[5,7], E. M. Stone[3,4,7], D. C. Slusarski[2,7], V. C. Sheffield[4,6,7]* 1) Genetics Program; 2) Dept Biology; 3) Dept Ophthalmology; 4) HHMI; 5) Dept Obstetrics and Gynecology; 6) Dept Pediatrics; 7) Univ Iowa, Iowa City, IA.

Hundreds of individually rare, but collectively common Mendelian disorders cause blindness. One of these disorders is a heterogeneous syndromic form of retinal degeneration, Bardet-Biedl Syndrome (BBS). Typically, individuals with BBS experience central vision loss during childhood or early adolescence and are blind by the third decade of life. Our lab utilizes both the mouse and zebrafish to unravel the mechanism underlying retinal degeneration seen in BBS. We identified two transcripts of BBS3, a member of the Ras family of small GTP-binding proteins. *Bbs3S*, the common Bbs3 transcript is expressed in all mouse tissues examined, while *Bbs3L* was predominantly expressed in the eye. In the zebrafish, *bbs3S* is ubiquitously expressed at all stages of development, while *bbs3L* expression coincides with photoreceptor development. Moreover, immunohistochemical analysis of BBS3 reveals protein localization to both ganglion cells and photoreceptor cells of human, mouse and zebrafish retinas. The eye-specific expression of the BBS3L isoform will facilitate the dissection of BBS function in the retina, independent of alterations to other tissues. To this end, a Bbs3L knockout mouse has been generated and histological analysis is underway to evaluate retina structure. Interestingly, using an antisense morpholino to transiently knockdown bbs3 function in the zebrafish, different morphological phenotypes arise when *bbs3S* is targeted compared to *bbs3L*. A morpholino that targets both isoforms results in defects to the ciliated Kupffers Vesicle, melanosome transport delays and cone vision impairment. Defects to the Kupffers Vesicle, as well as a delay in retrograde transport are both cardinal features of BBS phenotypes (*bbs1-12*) in zebrafish. Consistent with an eye specific function *bbs3L* morphant embryos have normal Kupffers Vesicle formation and melanosome transport, but show cone vision defects.

Early Siberian Maternal Lineages in the Tubalar of Northeastern Altai Inferred from High-Resolution Mitochondrial DNA Analysis. *R. Sukernik, I. Mazunin, E. Starikovskaya, N. Volodko, N. Eltsov* Laboratory of Human Molecular Genetics, Institute of Cytology and Genetics SB RAS, Novosibirsk, Russian Federation.

At the hight of the last glaciation (~18 kya) Siberians were confined to the southern strongholds, which were areas of continuous occupation, and where immediate ancestors of the Uralic, Kettic and Altaian language groups differentiated. To better understand the evolutionary relationships between the earlier and contemporary Siberians, we focused on the northern Altaic prehistory preserved in the mtDNA diversity of the Tubalar, until recently representing a typical hunting-gathering population. The present study includes 139 Tubalar. All mtDNAs were subjected to high-resolution SNP analysis, followed by complete sequencing of selected mtDNA samples. We showed that the core of the Tubalar genetic makeup proved to be a mixture of west (H8, U4b, U5a1, and X2e) and east Eurasian (A and B1) haplogroups derived from macrohaplogroup N, and Siberian derivatives of the macrohaplogroup M identifiable by subhaplogroup-specific mutations. For example, among the 36 Tubalar mtDNA samples that belong to haplogroup D, 10 (28%) harbored diagnostic markers of the subhaplogroup D3a2a shared with the Chukchi and Eskimos. This finding verified at the complete sequence level we attributed to ancient link between early Siberians, who underwent pronounced differentiation in the Altai-Sayan region, and some of the Eskimo tribes. A comparison of the mtDNA data generated through the course of this study with published complete sequences has contributed essentially to parsimonious phylogenetic structure of mtDNA evolution in west Siberia. Specifically, northeastern Altai appears to be a good candidate for the ancestral homeland of the haplogroup U4b, which is apparently ancient European. For some haplogroups, such as X2e, the relatively recent arrival to the Altai region is more likely.

Analysis of fat mass and obesity associated (FTO) gene variants with measures of obesity and glucose homeostasis in the IRAS Family Study. *M. R. Wing[1], J. Ziegler[1], C. D. Langefeld[1], S. M. Haffner[2], J. M. Norris[3], M. O. Goodarzi[4], D. W. Bowden[1]* 1) Wake Forest University School of Medicine, Winston Salem, NC; 2) University of Texas Health Sciences Center at San Antonio, San Antonio, TX; 3) University of Colorado Health Sciences Center, Denver, CO; 4) Cedars-Sinai Medical Center, Los Angeles, CA.

Studies focusing on European-derived populations have provided evidence that FTO variants are associated with adiposity measures such as body mass index (BMI). Replication studies in other ethnicities have had mixed success. The goal of this study was to evaluate whether FTO SNPs were associated with adiposity measures, including computed-tomography derived measures of visceral and subcutaneous adipose tissue (VAT; SAT), and glucose homeostasis (frequently sampled glucose tolerance test derived measures of insulin sensitivity and acute insulin response, and fasting glucose and insulin) in the Insulin Resistance Atherosclerosis Family Study cohorts. SNPs covering FTO intron 1, including those prominent in the literature (rs9939609, rs8050136, rs1121980, rs17817449, rs1421085, rs3751812), were genotyped in 1,424 Hispanics and 604 African Americans and analyzed using the variance component method implemented in SOLAR. In Hispanics, multiple SNPs were associated with BMI and SAT (p-values ranging from 0.001 to 0.033), and trending or associated with waist circumference (p-values ranging from 0.008 to 0.099). For glucose homeostasis measures, SNPs were associated with fasting insulin but consistent with other studies, after BMI adjustment no association was observed. In the African Americans, only rs8050136 and rs9939609 were trending or associated with BMI, waist, and SAT (p-values ranging from 0.011 to 0.058). This genetic analysis adds to the growing evidence that FTO SNPs predispose individuals to obesity by increasing overall fat mass. In this study FTO does not contribute to differential fat deposition in a specific site and does not influence glucose homeostasis when adjusted for the contribution of BMI. Evidence of association in Hispanic Americans with measures of adiposity is fairly consistent, but more marginal in African Americans.

Fertility and Fitness Among the Deaf. *S. Blanton[1], A. Burt[1], W. Nance[2], A. Pandya[2], K. Welch[3], V. Norris[3], K. Arnos[3]*
1) Univ Miami, FL; 2) VA Commonwealth Univ, Richmond; 3) Gallaudet Univ, Washington DC.

The acquisition of sign language is perhaps the most important factor that can improve the genetic fitness of the deaf. Although their fitness was generally quite low in Europe prior to the introduction of sign language and the establishment of schools for the deaf nearly 400 years ago, there are several recent examples of population isolates in which indigenous sign languages are used within extended families to allow deaf and hearing family members to communicate with one another. This integration into the community diminishes the effect of deafness on fitness. In order to obtain contemporary estimates of the genetic fitness of the deaf in the US, we collected pedigree data as part of a larger epidemiologic study of deaf probands who are alumni of Gallaudet University. Information on the mating type and number and hearing status of children of both probands and their hearing and deaf siblings was collected. Data was obtained on a total of 686 deaf individuals and 602 hearing siblings; all individuals were at least 35 years old. Data was further subdivided into four groups based on marital status and gender. The average age of the four groups of adults ranged from a low of 50 (single deaf males) to 58 (married hearing males). The proportion of deaf adults who marry is similar to hearing adults (.83 vs .85). Among married individuals, the fertility of deaf individuals is less than their hearing siblings (p=.005), with a greater difference between females (p=.006). Genetic fitness has classically been measured as the ratio of the overall fertility of affected subjects to their unaffected siblings. While the fitness of deaf individuals in our study is significantly reduced (p=.002), it is not substantial. Our fitness estimates are substantially higher than contemporary values obtained from Sichuan (0.6) and Shanghai (0.78) China. We have also stratified fertility rates among deaf individuals and their hearing siblings by mating type; while HxH matings have the highest average number of children (2.24), DxD matings produced more children (2.11) than DxH matings (1.85), suggesting that fertility among the deaf is influenced by multiple factors.

Genetic variation in tribes of Eastern and North-Eastern India: inference from distribution of Y-chromosomal polymorphisms. *M. Borkar, F. Ahmed, F. Khan, S. Agrawal* Medical Genetics, SGPGIMS, Lucknow, India.

Background: The Eastern and North-Eastern region of Indian subcontinent is mainly inhabited by tribes belonging to Austro-Asiatic and Sino-Tibetan linguistic family. The different migratory episodes influenced their genetic structure. **Objectives**: To investigate the paternal population history of total 607 individuals from nine populations of Eastern and North-Eastern tribes from India. **Methods**: 34 binary markers and 17 short-tandem-repeat loci from the non-recombining part of the human Y chromosome were analyzed by RFLP, Sequencing and Genescanning. **Results**: The tribal populations were characterized by a diverse set of 15 haplogroups. A single haplogroup (O-M175) accounts for ~70% of North-East Indian Y chromosomes. The Neighbour joining tree drawn to analyze the phylogenetic relationship of tribal populations with different world populations revealed a strong genetic affinity of Austro-Asiatic and Sino-Tibetan populations with Orientals inhabiting in East-Asia. The results were compared with different castes and tribal populations of India to draw the complete phylogeny picture of studied tribes. The results support the hypothesis that the upper castes from North India are descendant of European populations. On the basis of Y-chromosomal STR haplotypes the Tibeto-Burman tribals can be differentiated from Austro-Asiatic tribals but both group showed considerable genetic similarity suggesting that they may have shared a common habitat in East-Asia. AMOVA analysis suggests that the Indian lower castes are genetically more similar to the tribal populations, than to the higher castes. Our results support that there was mostly male-mediated migration of the population to India, where they admixed with local females. The overall haplotype diversity for the 17 Y-STR loci was 0.9998, and the discrimination capacity was 0.9695. These results are compared with those observed in worldwide populations at both the locus and the haplotype level. **Conclusion**: The phylogeographic profile demonstrated different clinal patterns that may indicate source, direction, and relative timing of different waves of dispersals and expansions involving these nine populations.

Linear clinical progression independent of age of onset in Niemann-Pick Disease, type C. *N. M. Yanjanin[1], J. I. Vélez[1], A. Gropman[2], K. King[1], C. C. Brewer[1], B. Solomon[1], W. Pavan[1], M. Arcos-Burgos[1], M. C. Patterson[3], F. D. Porter[1]* 1) NICHD, NHGRI, NIDCD or CC of NIH, DHHS, Bethesda, MD; 2) CNMC, Washington, DC; 3) Mayo Clinic, Rochester, MN.

Niemann-Pick Disease, type C (NPC) is a neurodegenerative storage disorder characterized by ataxia, dystonia, dementia, and vertical ophthalmoplegia. The heterogeneous clinical nature and variable age of onset confounds the characterization of potential biomarkers, and the absence of an accepted biomarker is an impediment to the development of therapeutic trials. Thus, we developed a clinical severity scale to correlate with potential biomarkers, and monitor disease progression. Clinical data were collected from 18 current patients and retrospective data were extracted from the records of 19 patients. Symptoms in 9 major (scored 0-5: ambulation, cognition, eye movement, fine motor, hearing, memory, speech, seizures, swallowing) and 8 minor domains (scored 0-3: ABR, behavior, gelastic cataplexy, hyperreflexia, incontinence, narcolepsy, psychiatric, respiratory) typically noted in a medical history were scored. Interestingly, both cohorts showed a linear increase in severity. Cross-sectional analysis of 18 current patients showed a linear increase (r^2=0.64, p<0.0001) with a mean progression of 1.40.3 points per year. Longitudinal chart review of 19 patients showed that although age of onset varied significantly, the rate of progression (mean=1.90.2 points per year) was independent of age of onset and similar in 18/19 patients. Combining the data from both cohorts, progression could be mathematically modeled: $Åœt_0+x=Åœt_0+1.87x$; where $Åœt_0$ is the initial score and $Åœt_0+x$ is the predicted score after x years. The standard error and the 95% CI for the slope were 0.18 and 1.6-2.3 respectively, allowing for power estimates to be obtained. Our observation that disease progression is similar in patients and independent of age of onset is consistent with a biphasic pathological model for NPC and does not support a model of slower progression in later onset cases. In addition, this scale may prove useful in the characterization of potential biomarkers, and as an outcome measure to monitor disease progression.

Long-term Rescue of a Lethal Murine Model of Methylmalonic Acidemia using AAV 8 Mediated Gene Therapy.
R. J. Chandler, C. P. Venditti Genetic Disease Research Branch, NHGRI/NIH, Bethesda, MD.

Methymalonic acidemia (MMA), a severe organic acidemia, is caused by deficient activity of the ubiquitous mitochondrial enzyme methylmalonyl-CoA mutase (MUT). MMA patients exhibit increased methylmalonic acid levels in the plasma, urine and CSF and display a clinical phenotype of lethal metabolic decompensation, growth retardation, renal failure and metabolic strokes. To assess the potential of genetic therapy for MUT MMA, we employed a mouse model of MMA that produces no detectable Mut transcript or protein. AAV 8 CBA-Mut was injected directly into the liver of newborn Mut-/- pups. Currently, 28 out of the 29 Mut-/- mice injected with 1 or 2x1011GC of AAV 8 CBA-Mut are alive beyond DOL 90 with some treated Mut-/- mice older than 200 days. All the untreated mutants (n=21) perished before DOL 72. The treated Mut-/- mice are thriving and indistinguishable from their wild-type (WT) littermates. AAV 8 CBA-Mut treated Mut-/- mice achieved body weights comparable to controls while untreated mutants experienced post-natal growth retardation and reached only 40% of the weight of the WT. Plasma methylmalonic acid levels in the treated mutant mice on an unrestricted diet were significantly reduced compared to uncorrected animals, indicating that substantial Mut enzymatic activity was restored after AAV therapy. At DOL 90 the liver from a treated Mut-/- mouse had WT levels of Mut protein by Western blot analysis. These experiments provide the first evidence that gene therapy has clinical utility in treatment of MMA and support the development of gene therapy for other organic acidemias.

Isolated autosomal recessive nail dysplasia with pachonycia and onycholysis in a consanguineous Pakistani family. A novel form of nail dysplasia that maps to chromosome 8. *A. Fröjmark[1], M. Entesarian[1], S. Nawaz[2], J. Schuster[1], J. Klar[1], M. Rasool[2], M. Tariq[2], I. Ahmad[2], S. Baig[2], N. Dahl[1]* 1) Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Health Biotechnology Division, National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan.

Developmental nail abnormalities are clinically and genetically heterogeneous, being small and rare subgroups. We have investigated a consanguineous Pakistani family with four members affected by autosomal recessive nail dysplasia. Affected individuals present with claw-like pachonychia, nail clubbing and onycholysis of both finger- and toenails but no other ectodermal symptoms. Hair, skin and teeth were found normal and affected individuals reported normal sweating. We performed a genetic analysis on the family using a 250K SNP array (Affymetrix) as well as microsatellite markers. One genomic region spanning more than 90 homozygous SNPs on chromosome 8 was found to be shared by affected individuals. Linkage analysis with chromosome 8 microsatellite markers revealed a maximum LOD score of 2.96 (= 0). Recombination events restricted the candidate region to 18 Mb which spans approximately 100 genes. We are now in the process of sequencing candidate genes in search for mutations.

A homozygous deletion of 8q24.3 including the NIBP gene associated with severe delay, agenesis of corpus callosum and facial dysmorphism. *A. Koifman[1,4], A. Feigenbaum[1], B. Weimin[2], LG. Shaffer[3], D. Chitayat[1,4]* 1) The Hospital for Sick Children, Division of Clinical and Metabolic Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Departments of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA; 3) Signature Genomic Laboratories, Spokane, Washington, USA; 4) Mount Sinai Hospital, The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynecology, University of Toronto, Toronto, Ontario, Canada.

We have identified by microarray-based comparative genomic hybridization analysis (aCGH), a homozygous deletion of 8q24.3 in a patient with clinical manifestations of severe global developmental delay, agenesis of corpus callosum and facial dysmorphism. The deletion was inherited from asymptomatic, consanguineous parents, each of them being heterozygous for the same deletion. The only gene known to map to this segment is the NIBP gene and so far no clinical manifestation have been found in association with this gene mutation in homozygous or heterozygous state in humans. Our findings suggest that a mutation in the NIBP gene results in an autosomal recessive condition with multiple abnormalities including agenesis of the corpus callosum, severe developmental delay and specific facial dysmorphism . In addition, the child inherited a 781 Kb deletion on 4q32.2 from the mother that contains the SPOCK3 gene. We present evidence that this heterozygous deletion is likely to be noncontributory to the phenotype.

11q Terminal Deletion in a Patient with Jacobsen Syndrome: Molecular Characterization. *L. D. Kulikowski, T. B. De Maio, J. F. S. Franco, F. T. S. Bellucco, S. I. Nogueira, D. M. Christofolini, A. N. X. Pacanaro, R. S. Guilherme, A. B. A. Perez, M. I. Melaragno* Universidade Federal de Sao Paulo, Sao Paulo Brazil, Sao Paulo, Brazil.

Jacobsen syndrome is a contiguous gene disorder caused by a deletion in the long arm of chromosome 11. Common clinical findings include developmental delay, short stature, congenital heart defects, thrombocytopenia, genitourinary anomalies, pyloric stenosis and facial dysmorphology. We report on a male patient with the 11q terminal deletion with many of the features of Jacobsen syndrome. The karyotype of the patient is 46,XY,der(11)t(8;11)(q24.3;q23)pat. The deletion terminal was confirmed using a set of BAC-FISH probes for distal 11q including the subtelomeric RP11-345O3 probe, corresponding to position 134.2 Mb from 11p, that was absent in the der(11). Previous molecular analyses of 11q deletions have been performed on a small number of cases and have demonstrated that the deletions range in size from 7 Mb to greater than 20 Mb. All cases analyzed using molecular techniques demonstrated the presence of a terminal deletion with retention only of telomeric sequences at the end of 11q. The present case differs from the reported cases since there was no FISH signal for the specific 11q subtelomeric probe. The molecular characterization of the segment deleted in patients with terminal 11q deletion is important to localize disease-causing genes in this region. The deletion present in our patient includes JAM-3 gene, a candidate gene for causing several heart defects in Jacobsen syndrome, although he has only a heart murmur. Most of patients with del(11q) had a history of thrombocytopenia and/or abnormal platelet morphology indicative of Paris-Trousseau syndrome. There is strong evidence that the FLI-1 gene, a transcription factor that plays a role in megakaryopoiesis, is implicated in this syndrome. Interestingly our patient did not have giant platelets, suggesting that a second gene may contribute to this aspect of Paris-Trousseau phenotype. Apparently, the clinical picture of the Jacobsen syndrome is related to the molecular architecture, size and location of the deleted chromosome segments.

Linkage analysis of nonsyndromic cleft lip with or without cleft palate in a consanguineous Pakistani family. *E. Richards[1], S. Malik[2,3], B. Egbert[1], A. Ferguson[1], D. Wilcox[1], A. Lalwani[4], S. Naz[2], E. Wilcox[1]* 1) Dept Biol, Brigham Young Univ, Provo, UT; 2) School of Biological Sciences, Univ of the Punjab, Quaid-e-Azam Campus, Lahore, Pakistan; 3) Dept of Microbiology and Molecular Genetics, Univ of the Punjab, Lahore, Pakistan; 4) Dept of Otolaryngology, NYU School of Medicine, New York, NY.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is a heritable disease with a complex etiology. NSCLP is highly heterogeneous and loci identified so far only account for a small percentage of cases. To identify additional loci for NSCLP, we are studying large consanguineous families segregating NSCLP, an approach that has been shown to be effective in other gene-mapping studies. So far, we have performed linkage analysis on one Pakistani family segregating unilateral cleft lip (25 total samples with 7 affected individuals and 7 instances of consanguinity [4 documented and 3 undocumented]).

To find alleles segregating among the affected members of this family, SNP alleles for a portion of the samples were determined using Affymetrix GeneChip Human mapping 250K Nsp arrays. The resulting SNP data was screened in Alohomora [Bioinformatics 21(9): 2123] to remove problematic or uninformative genotypes. Data was formatted further by Mega2 [Bioinformatics 17(12): 1244-5] and parametric and nonparametric linkage (NPL) analyses were performed by Simwalk2 [Hum Hered 52:121-131]. These analyses yielded 17 regions with LOD and NPL scores >3.0. We then typed two additional highly heterogeneous STRs in each of these regions using fragment analysis. The STR alleles were added to the SNP data, and the 17 regions were reanalyzed. Linkage analysis with the additional markers eliminated 11 regions (reducing both LOD and NPL scores to <3.0) and further enhanced 4 regions (increasing LOD and NPL scores to as high as 3.9 and 3.4 respectively). No single allele exhibits simple dominant or recessive inheritance across all affected and unaffected individuals, suggesting that several loci work in concert to express the phenotype.

Potential Role of BRD2 Splicing in Juvenile Myoclonic Epilepsy. *H. M. Sanders[1,2], E. Shang[2,3], D. J. Wolgemuth[3,4,5,6], D. A. Greenberg[1,2,7]* 1) Psychiatry Department, Columbia University, New York, NY; 2) Division of Statistical Genetics, Columbia University, New York, NY; 3) Institute of Human Nutrition, Columbia University, New York, NY; 4) Department of Genetics and Development, Columbia University, New York, NY; 5) Department of Obstetrics and Gynecology, Columbia University, New York, NY; 6) Herbert Irving Comprehensive Cancer Center, Columbia University, New York, NY; 7) New York Psychiatric Institute, Columbia University, New York, NY.
